Alopecia areata (AA) is a highly prevalent and poorly understood autoimmune disease which targets the hair follicle causing disfiguring hair loss. There is an enormous unmet medical need for the 5.3 million patients in the US who suffer from AA, arising primarily from a lack of understanding of disease pathogenesis. Our initial GWAS in AA revealed the first disease association to ULBP3/6 genes in any human disease. These genes are ligands for the NKG2D activating receptors for a repertoire of leukocytes. We biologically validated our statistical evidence by showing a marked upregulation of ULBP3/6 in lesional hair follicles and the presence of CD8+NKG2D+ T cells within the immune infiltrate. These findings, together with the previous demonstration of MICA overexpression in AA hair follicles, placed the NKG2D axis squarely at the center of AA pathogenesis, and invited a functional genomics approach to uncover causal variants predisposing to disease. In order to better understand the genetic variation driving the tagSNP associations identified in our GWAS at the ULBP locus, we selected a subset of 124 cases from our GWAS cohort for targeted deep resequencing with RainDance technology, amplifying 72Kb of sequence encompassing the entire region of association. As preliminary analysis of this dataset, we looked at the distribution of rare variants (p<0.01 in EVS and 1000G) across this region. We identified two rare missense variants, one of which is highly overrepresented in our cohort (p=0.005) and is located within ULBP6. Of the 127 rare or novel variants located within intergenic regions we identified 34 that fall within transcription factor binding sites, 7 of which are overrepresented in our cases, which cluster into two regions. One of these regions is a CTCF binding site, which is known to influence chromosome structure providing a mechanism for the regulation of gene expression. We have begun to assess the biological consequences of the ULBP6 protein coding variant, by developing a battery of functional assays aimed specifically at examining mRNA expression levels, protein levels, effects on cell surface display, receptor binding affinity and killing efficiency. We are additionally developing cellular assays to determine the effects of the regulatory variants. This work will clarify how GWAS identified genetic variation influences NKG2D-mediated cytotoxicity in the pathogenesis of autoimmune disease.

Exploring the genome for the secrets of human longevity. *E.B. van den Akker[1,2], S.J. Pitts[3], M.H. Moed[1], S. Potluri[3], J. Deelen[1,4], J.J. Houwing-Duistermaat[5], D.R. Cox[3,6], M.J.T. Reinders[2], M. Beekman[1,4,7], P.E. Slagboom[1,4,7], Genome of The Netherlands Consortium.* 1) Molecular Epidemiology, Leiden University Medical Center, Leiden, Zuid Holland, The Netherlands; 2) The Delft Bioinformatics Lab, Delft University of Technology, Delft, Zuid Holland, The Netherlands; 3) Rinat-Pfizer Inc, South San Francisco, CA 94080, USA; 4) Netherlands Consortium for Healthy Ageing, Leiden, The Netherlands; 5) Leiden University Medical Center, Medical Statistics and Bioinformatics, Leiden, The Netherlands; 6) In Memoriam; 7) These authors contributed equally to this work.

The clustering of longevity in families is being studied worldwide and the genetic contribution to longevity in the population at large is estimated at 25%. This is illustrated by the fact that first-degree family members of nonagenarians and centenarians also have a life-long survival advantage that can be attributed to a lower risk of coronary artery disease, cancer and type-2 diabetes. The survival advantage in 420 Dutch long-lived families from the Leiden Longevity Study (LLS), which have been selected on the basis of living nonagenarian siblings (≥2), could not be explained by the absence of risk alleles at known disease susceptibility loci. To investigate whether rare private genetic variants contribute to their longevity, we explored the whole-genome sequence of 220 unrelated Dutch nonagenarians (mean age 94 years) in comparison with 95 younger controls from the general Dutch population. The nonagenarians were selected from the LLS study population on the basis of having the best family history of survival and the controls were randomly selected from Dutch biobanks included in the BBMRI-NL consortium consisting of healthy individuals. High quality whole-genome sequences of DNA from leukocytes were generated by Complete Genomics (USA) at >30x coverage. The mean numbers of SNPs, deletions, insertion and substitutions per individual are remarkably similar between controls and the nonagenarians, which may be regarded as supercontrols. The mean numbers of variants observed in the exome of controls were 3,344,320.57 SNPs, 224,143 deletions, 217,134 insertions and 81,475 substitutions and in nonagenarians 3,357,346.38 SNPs, 225,241 deletions, 213,847 insertions and 80,436 substitutions, respectively. Further, we investigated differences between the groups in the presence of longevity alleles at known loci (a.o. *TOMM40/APOE* and *FOXO3A*). Next, we explored all genes in a burden analysis and paid special attention to IIS and mTOR pathway related genes. For this analysis we selected all detected genetic variants with an impact on protein function according to ANNOVAR. Our preliminary data analysis indicated a tendency that for many exonic annotations the nonagenarians carry fewer variants than controls.

Simulation of Finnish population history, guided by empirical genetic data, to assess power of rare variant tests in Finland.
R. Wang[1,2,3], V. Agarwala[2,4,5], J. Flannick[2,3,6], D. Altshuler[2,3,6], J.N. Hirschhorn[1,2,3]. 1) Division of Endocrinology, Boston Children's Hospital; 2) Program in Medical and Population Genetics, Broad Institute; 3) Department of Genetics, Harvard Medical School; 4) Harvard-MIT Division of Health Sciences and Technology, MIT; 5) Program in Biophysics, Graduate School of Arts and Sciences, Harvard University; 6) Department of Molecular Biology, Massachusetts General Hospital.

The Finnish population has been extensively utilized in genetic studies. It is considered to be a relatively homogenous founder population, and hence well suited for gene mapping, especially for variants of lower frequency. However, without realistic population demographic and phenotypic models, it is difficult to assess the implications of the founder effect for association studies of rare variants in exome genotype or sequence data. In this study, we developed a population genetic framework to address these issues. We first confirmed the Finnish founder effect in deep resequencing data by showing that allele frequency spectra are shifted towards higher end in the Finns compared to non-Finnish Europeans (NFEs). Next, building on recent simulations that generate representative sequence data for European populations, we used empirical sequence data to develop a simultaneous forward simulation of sequence variation in the NFE population and the Finnish population. We then simulated phenotypes in these populations under different disease models characterized by different correlation between phenotypic effects of variants and their effects on fitness. With simulated genotype and phenotype data, we conducted rare variant statistical tests (single variant, burden tests), and assessed their performance by calculating power. Our results showed that founder populations such as the Finns could provide additional power especially when phenotypic effects of variants correlate well with effects on fitness. The single variant test shows good performance in a founder population under different disease models, and it is particularly powerful if rare variants play a big role in explaining phenotypic variance. Finally, we compared the efficiency of genotype data (exome chip) and sequence data (exome sequencing) under different scenarios. Our results suggest that exome chip is currently much more cost-efficient than exome sequencing, especially in a founder population. Our study has highlighted the usefulness of understanding the population-genetic properties of a study population and exploring a range of genetic models for recognizing the features and limitations of association studies in that population. As the field of human genetics moves forward to explore new and expanded sources of variation, such models offer a context with which to interpret the data and to plan future studies for gene discovery.

De novo and inherited retrotransposon insertions associated with autism revealed by whole genome sequencing.
X. Jin[1,2], A. Ewing[3], J. Ju[1], R. Yuen[4], J. Wu[5], Y. Jiang[6], M. Wang[1], A. Shih[7], Y. Li[1], J. Wang[1], S. Scherer[4], Z. Sun[5], H. Yang[1], H. Kazazian[8], J. Wang[1]. 1) BGI, Shenzhen, Guangdong, China; 2) School of Bioscience and Bioengineering, South China University of Technology, Guangzhou, China; 3) Center for Biomolecular Science and Engineering, University of California at Santa Cruz, Santa Cruz, California, USA; 4) The Hospital for Sick Children, Toronto, ON Canada; 5) The Institute of Genomic Medicine, Wenzhou Medical College, Wenzhou, China; 6) Department of Paediatrics and Neurobiology, Duke University School of Medicine, Durham, NC, USA; 7) Autism Speaks, New York, NY, USA; 8) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.

Retrotransposons are genetic elements that are capable of moving by a 'copy-and-paste' mechanism to spread throughout genome. Around 45% of the human genome is composed of retrotransposons. Recent studies have revealed that somatic mosaicism driven by retrotransposition may reshape the genetic circuitry that underpins normal and abnormal neurobiological processes. Autism spectrum disorder (ASD) is a lifelong developmental condition that affects about 1 in 88 individuals. Multiple researches have confirmed the contribution of de novo and rare inherited mutation to the risk for ASD. Here we sequenced the whole genome of 232 individuals from 74 families with ASD collected in China and the US. We developed a novel method to identify both de novo and inherited retrotransposon insertions from paired-end whole-genome sequencing data. We indentified 2 high-confidence de novo retrotransposon insertions in genes MARK2 and RIMS2, both of which have been reported to contain de novo functional mutations in recent large-scale exome studies of autism. We also detected 1281 to 1725 (average 1530) inherited retrotransposon insertions in each family. Several inherited retrotransposition insertions were located in known autism related genes such as CTNNA3, AUTS2 and TCF4. Our findings suggest that de novo and inherited retrotransopon insertions may play an important role in autism genetics.

1151F

Exome sequencing of 55 multiply affected coeliac families and large scale resequencing follow up.
V. Mistry[1], N.A. Bockett[1], M. Muddassar[2], K.A. Hunt[1], S.L. Neuhausen[3], P.J. Ciclitira[4], V. Plagnol[5], D.A. van Heel[1]. 1) Centre for Digestive Diseases, Barts and The London School Of Medicine and Dentistry, Blizard Institute, 4 Newark Street, Whitechapel, London E1 2AT, United Kingdom; 2) Division of Genetics and Molecular Medicine, Kings College London School of Medicine, 8th Floor Tower Wing, Guy's Hospital, London SE1 9RY, United Kingdom; 3) Department of Population Sciences, City of Hope, Duarte, California 91010, USA; 4) King's College London, Division of Diabetes and Nutritional Sciences, Gastroenterology, The Rayne Institute, St Thomas' Hospital, Westminster Bridge Road, London SE1 7EH, United Kingdom; 5) University College London Genetics Institute, Gower Street, London WC1E 6BT, United Kingdom.

Coeliac disease is a highly heritable common autoimmune disease involving chronic small intestinal inflammation in response to dietary wheat. The HLA region, and 40 newer regions identified by GWAS and dense fine mapping (many immune genes), account for ≈ 40% of heritability. We hypothesized that rare mutations of larger effect size (OR ≈ 2 - 5) might exist, especially in multiply affected pedigrees. We exome sequenced 75 subjects from 55 multiply affected families. We selected interesting variants/genes for further follow up using a combination of: linkage, shared variants between multiple related subjects and gene burden tests for multiple potentially causal variants. We next performed highly multiplexed amplicon sequencing (Fluidigm) of all RefSeq exons from 24 candidate genes in 2,304 coeliac cases and 2,304 controls. High coverage data enabled direct genotyping (99.98% of all sample genotype calls had a read depth >40) and extensive quality control. 1,335 unique variants with a 99.98% genotyping call rate were observed in 4,478 (post quality control) samples, of which 939 were present in coding regions of 24 genes (Ti/Tv 2.99). 91.7% of coding variants were rare (MAF in 2,230 controls, <0.5%) and 60% were novel. No common or low frequency variants were seen at novel sites. Gene burden tests (C-Alpha, SKAT) performed with rare functional variants identified no rare significant associations ($P<1\times10^{-3}$) at the resequenced candidate genes. Our strategy of sequencing multiply affected families, and deep follow up of candidate genes, has not identified new disease risk mutations. Common variants (and other factors, e.g. environmental) may instead account for familial clustering in this common autoimmune disease.

1152W

Pathway analysis using whole exome sequencing in Parkinson disease.
K. Nuytemans[1], V. Inchausti[1], L. Maldonado[1], W. Perry[1], E.R. Martin[1,2], G.W. Beecham[1,2], L. Wang[1,2], W.K. Scott[1,2], J.M. Vance[1,2]. 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL, USA.

Previously, we reported several biological pathways (KEGG) to be associated with Parkinson Disease (PD) using gene expression and GWAS data (Edwards 2011). The top 3 pathways included 'axon guidance', 'focal adhesion' and 'calcium signaling pathway'. These analyses are based on common, often intergenic or intronic genomic variants with low risk effects and downstream differences in transcript level. In contrast, variants identified in whole exome sequencing (WES) are enriched for 'rare risk variants'; variants with a low frequency but possible higher risk effect on disease. We set out to determine whether the combination of exome variants in the same pathways also provides evidence for association with increased PD risk. We performed WES in 315 PD patients and 344 controls (all unrelated). Association of sets of variants in pathways/gene groups with increased risk for PD was assessed using the Cochran-Armitage sum and max test implemented in the RVASSOC program and the Sequence Kernel Association test (SKAT). Analyzed pathways included 13 top KEGG pathways identified in the previously reported pathway study as well as candidate gene groups 'axonal transport', 'mitochondrial' (MitoCarta) and 'lysosomal' genes (Human Lysosome Gene Database). On average, ~85% and ~73% of exome variants in these pathways have a frequency <5% and <1% respectively. Only minimal significant results (0.05>p>0.01) were obtained for 5 out of 13 tested KEGG pathways when analyzing all exome variants. However, we observed evidence for association with PD risk for the 'mitochondrial' and 'lysosomal' gene groups (p<0.001). Permutation tests (N=500) on random sets of the same number of genes or variants as the original groups showed that the original groups are not significantly more associated than the random gene sets. Interestingly, when filtering on variant frequency (<5% or <1%) we obtained similar results for all but the 'lysosomal' gene group. A significant p-value for this group was observed in both rare variant analyses (p<0.001; $p_{perm}<0.02$). No strong evidence for association of previously reported pathways with PD risk could be identified when analyzing all exome variants. Further filtering on frequency indicated that rare variants in the 'lysosomal' gene group are significantly contributing to disease. Additional analyses on smaller candidate gene groups and pathways with variants filtered on function will be performed to elucidate the observed signal in this analysis.

1153T

Whole-genome Sequencing in a Multiplex Nuclear Family of Schizophrenia to Identify Its Rare Susceptibility Variants. *S.C. Yu[1], H.Y. Chen[2], S.L. Yu[3], C.M. Liu[4,5], H.G. Hwu[1,4,5], W.J. Chen[1,4,5,6].* 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, Nat, Taipei, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan 115, R.O.C; 3) Department of Clinical Laboratory Sciences and Medical Biotechnology, National Taiwan University College of Medicine, 1 Chang-Te Street, Taipei, 100, Taiwan; 4) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University; 5) Graduate Institute of Brain and Mind, College of Medicine, National Taiwan University Hospital, National Taiwan University; 6) Genetic Epidemiology Core, Center of Genomic Medicine, National Taiwan University.

Background: Genome-wide association study (GWAS) has limitations for exploring rare genetic variants. With the advent of next-generation sequencing (NGS), it becomes feasible to search the whole genome for rare genetic variants specific to schizophrenia patients. A previous study among a large number of families of sib-pair co-affected with schizophrenia in Taiwan has revealed several linkage signals by incorporating several endophenotypes. This implies existence of genetic heterogeneity in schizophrenia. We hence postulated that high density nuclear families of schizophrenia may help identify certain inherited rare variants that can be used for replication in other multiplex families of schizophrenia. **Method:** We selected one high density schizophrenia family from Taiwan Schizophrenia Linkage Study (TSLS), which recruited schizophrenia patients and their first-degree relatives throughout Taiwan from 1998 to 2002. NGS was performed to sequence the whole genomes of a 5-member nuclear family, in which the mother and 2 children affected with schizophrenia, and the father and another child unaffected. Both dominant and recessive inheritance models were used to explore schizophrenia related genomic variations. **Results:** The results showed that total 384 variants (2 exonic single nucleotide variants; SNVs) selected under recessive inheritance model, i.e., with schizophrenia patients having homozygous variants and health persons having heterozygous variants. In dominant inheritance model, there were 13715 variants (70 exonic SNVs) selected, i.e., with schizophrenia patients having the variant and health persons having wild-type allele only. In addition, 10 non-synonymous exonic SNVs that exhibited inheritance in the family but not seen in 1000 genomes project were identified for those in accordance with dominant inheritance model. **Discussion:** Our findings demonstrated the utility of NGS in identifying inherited rare genetic variants that are potentially associated with multiplex schizophrenia. Our use of a multiplex family can help exclude those variants due to typing error, or de novo mutations, and hence select those with high-penetrating susceptibility genetic variants for schizophrenia. In particular, the 10 non-synonymous exonic SNVs warrant future replication in other multiplex families from TSLS. This may lead to discovery if rare but inheritable susceptibility variants for schizophrenia and their underlying pathophysiology.

Contribution of rare variants in the development of gout in Japanese males. *A. Taniguchi, C. Sekita, H. Kaneko, W. Urano, N. Ichikawa, H. Yamanaka.* Institute of Rheumatology, Tokyo Women's Medical Univ, Shinjuku-ku, Tokyo, Japan.

Background: Genome-wide association studies (GWAS) have identified multiple loci associated with serum levels of uric acid (SUA) and gout. Especially, *SLC22A12, SLC2A9, ABCG2, SLC17A1*, and *SLC17A3* have been reported to be associated with SUA or gout in multiple ethnicities including Japanese. However, these polymorphisms explain about 10% of variation. Contribution of rare variants in the development of gout has not extensively been studied especially in Japanese. Objective: The aim of the present study was to identify low frequency variants associated with gout in Japanese males. Methods: Genomic DNA was extracted from 325 Japanese male patients with gout and 597 Japanese male controls. Rare variants were defined as minor allele frequencies less than 0.01 in controls. Resequencing of *SLC22A12, SLC2A9, ABCG2, SLC17A1*, and *SLC17A3* was preformed using genomic DNA samples from a hundred of gout and a hundred of controls. Every exon and exon/intron boundaries were amplified by PCR and the PCR products were sequenced using the Big Dye Terminator cycle sequencing kit and the ABI PRISM 3100xl Genetic Analyzer (Life Technologies). Based on the results of resequencing, genotyping of each variant was performed by TaqMan methods (Life Technologies) using all samples. Results: We identified seven rare variants in *SLC17A1, SLC17A3*, and *ABCG2* that are responsible for uric acid secretion in the renal proximal tubules. Of those, two were nonsense and five were missense mutations. A significant accumulation of rare variants was identified in gout patients compared to controls ($p=2.461\times10^{-6}$). Six rare variants were identified in *SLC2A9* and *SLC22A12* that are responsible for uric acid reabsorption in the renal proximal tubules. One mutation was nonsense and the rest of the mutations were missense. We found a significant accumulation of those variants in controls (p=0.037). Conclusion: It is suggested that rare variants in *SLC17A1, SLC17A3*, and ABCG2 promote gout and those in *SLC2A9* and *SLC22A12* are protective for gout. The present study indicated that two types of rare variants that were protective for gout or promote it were associated in the development of gout in Japanese males.

1155W

Targeted sequencing of the pericentromeric region of chromosome 2 in Finnish constitutional delay of growth and puberty families. *D. Cousminer[1], L. Dunkel[2], A. Palotie[1,3], E. Widén[1].* 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 2) Department of Pediatrics, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

Constitutional delay of growth and puberty (CDGP) is the most common cause of pubertal delay, representing about 65% of boys and 30% of girls with late puberty. CDGP is defined as the absence of pubertal development at an age 2 standard deviations above the population mean, an extreme variant of normal pubertal timing. While both environmental and genetic factors contribute to variability of pubertal timing and tempo, high heritability estimates of up to 80% predict a strong influence from genetic factors. At the tail ends of the population distribution, one or several genes with large effect sizes are predicted to have a strong influence on the phenotype. Recent studies showed that the majority of Finnish families segregated CDGP in an autosomal dominant manner, and a subsequent linkage study identified a susceptibility locus in the pericentromeric region of chromosome 2. We followed up on this linkage signal by performing targeted sequencing of over 60 Mb under the linkage peak in the proband and affected parent of the 13 best-linked families. Poorly sequenced regions were imputed against Finnish 1000 Genomes reference samples. Following sequencing and imputation, transmitted coding variants and non-coding regulatory variants will be compared among the probands to create a list of potentially causative candidate variants. These candidate variants will be assessed for association with pubertal delay by genotyping independent cases and controls. Preliminary results show that the 13 probands are not more closely related to one another than expected, nor is there a high probability of consanguinity among their recent ancestors. Furthermore, principal component and multidimensional scaling analyses indicate that the probands fit against a background of population controls and do not cluster more closely together than the population in general. Prior to imputation, there were no shared transmitted variants or indels among all 13 probands at a known 1000 Genomes allele frequency of <10%. There were also no shared 3'UTR, noncoding transcript, or nonsynonymous transmitted variants with unknown 1000 Genomes frequency that did not appear in reference genomes in the ensemble genome browser. Predicted regulatory regions remain to be analyzed, and it is possible that only a subset of probands share a causative mutation. We hope the results of this study may elucidate part of the as-yet poorly known genetic landscape underlying delayed puberty.

1156T

Population genetics of rare variants and complex diseases. *R. Hernandez[1], M. Maher[1], L. Uricchio[1], D. Torgerson[2].* 1) Bioeng. & Therapeutic Sci, UCSF, San Francisco, CA; 2) Department of Medicine, UCSF, San Francisco, CA.

Identifying drivers of complex traits from the noisy signals of genetic variation obtained from high throughput genome sequencing technologies is a central challenge faced by human geneticists today. We hypothesize that the variants involved in complex diseases are likely to exhibit non-neutral evolutionary signatures. Uncovering the evolutionary history of all variants is therefore of intrinsic interest for complex disease research. However, doing so necessitates the simultaneous elucidation of the targets of natural selection and population-specific demographic history. Here we characterize the action of natural selection operating across complex disease categories, and use population genetic simulations to evaluate the expected patterns of genetic variation in large samples (n=10,000). We focus on populations that have experienced historical bottlenecks followed by explosive growth (consistent with many human populations), and describe the differences between evolutionarily deleterious mutations and those that are neutral. We find that the genes associated with several complex disease categories exhibit stronger signatures of purifying selection than non-disease genes. In addition, loci identified through genome-wide association studies of complex traits also exhibit signatures consistent with being in regions recurrently targeted by purifying selection. Through simulations, we show that population bottlenecks and rapid growth enables deleterious rare variants to persist at low frequencies just as long as neutral variants, but low frequency and common variants tend to be much younger than neutral variants. This has resulted in a large proportion of modern-day rare alleles that have a deleterious effect on function, and that potentially contribute to disease susceptibility. The key question for sequencing-based association studies of complex traits is how to distinguish between deleterious and benign genetic variation. We used population genetic simulations to uncover patterns of genetic variation that distinguish these two categories, especially derived allele age, thereby providing inroads into novel methods for characterizing rare genetic variation driving complex diseases.

1157F

Exome sequencing of extended families with autism reveals genes shared across neurodevelopmental and neuropsychiatric disorders.
H.N. Cukier[1], N.D. Dueker[1], S.H. Slifer[1], J.M. Lee[1], P.L. Whitehead[1], E. Lalanne[1], N. Leyva[1], I. Konidari[1], R.C. Gentry[1], W.F. Hulme[1], D. Van Booven[1], V. Mayo[1], N.K. Hofmann[1], M.A. Schmidt[1,2], E.R. Martin[1,2], J.L. Haines[3], M.L. Cuccaro[1,2], J.R. Gilbert[1,2], M.A. Pericak-Vance[1,2]. 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Autism spectrum disorders (ASDs) encompass a constellation of neurodevelopmental conditions and studies to date demonstrate that the underlying etiology is extremely heterogeneous. To help unravel this genetic complexity, we performed whole exome sequencing in 40 ASD families with multiple, distantly related, ASD affected individuals. In contrast to previous autism exome studies which have primarily focused either on simplex families to discover de novo alterations or consanguineous families that carry recessive mutations, our study required that each family contain at minimum one pair of affected cousins. A total of 164 individuals were captured with the Agilent SureSelect Human All Exon kit, sequenced on the Illumina HiSeq 2000, and the resulting data processed and annotated with BWA, GATK, and SeattleSeq. Each family had approximately 90,000 changes. Variants were filtered to those in identity by descent (IBD) regions delineated by SNP genotyping data. Initial analyses focused on novel and rare (MAF < 0.05) variants predicted to be detrimental, either by altering amino acids or splicing patterns. In accordance with a dominant model of inheritance, exome sequencing identified 742 heterozygous changes, 499 of which were validated either by Sanger sequencing or genotyping on the Infinium HumanExome BeadChip. We identified numerous potentially damaging, ASD associated risk variants in genes previously unrelated to autism. A subset of these genes has been implicated in other neurological disorders including depression (*SLIT3*), epilepsy (*CLCN2*, *PRICKLE1*), mental retardation (*AP4M1*, *CEP290*), schizophrenia (*WDR60*), and Tourette syndrome (*OFCC1*). This reinforces the theory that there are shared genetic components across distinct neurological disorders. Additional alterations were found in previously reported autism candidate genes, including three genes with alterations in multiple families (*CSMD1*, *FAT1*, and *STXBP5*). Compiling a list of ASD candidate genes from the literature, we determined that variants occurred in ASD candidate genes 1.65 times more frequently than in random genes captured by exome sequencing ($p=8.55\times10^{-5}$). By studying these unique pedigrees, we have identified novel DNA variations related to ASDs, demonstrated that exome sequencing in extended families is a powerful tool for ASD candidate gene discovery, and provided further evidence of an underlying genetic component to a wide range of neurodevelopmental and neuropsychiatric diseases.

Nextgen RNA sequencing of monocytes coupled with association data identifies several genes in Systemic Lupus Erytrhematosus susceptibility.
AK. Maiti[1], C. Sun[1], P. Motghare[1], M. Arango[2], J-M. Anaya[2], SK. Nath[1]. 1) Gen Epidemiology Unit, A & CI, OMRF, Oklahoma City, OK; 2) Universidad del Rosario-Corporación para Investigaciones Biológicas, Bogotá, Colombia.

Systemic Lupus Erythematosus (SLE) is a devastating autoimmune disease. While there is no cure, disease progression may be delayed by proper treatment early in the disease process. Thus, identification of distinct target for drug development could have immense impact in developing disease specific therapy. Along with lymphocytes and other blood cells, monocytes play a critical role in SLE pathogenesis. Although several large scale genomic studies such as microarray gene expression have reported results for peripheral blood mononuclear cells (PBMC) or lymphocytes, no studies have been performed using only monocytes from SLE patients. Since the ratio of the monocytes to lymphocytes is very low in PBMC, major changes in gene expression observed in microarray studies could come from only lymphocytes, thus monocyte biology in SLE has not been studied in detail. To understand the monocyte biology in SLE, we performed Nextgen RNA sequencing from monocytes of SLE patients and healthy controls and identified several differentially expressed genes (e.g. IL9R, LTBP3, DTX3, MAVS, FGF4 and ARHGEF40 that are not studied extensively for their role in the pathogenesis of SLE. We also identified several novel structural variations, such as deletions, insertions and splice variations in several genes and nongenic regions that could be potentially associated with SLE. When these novel variations are correlated (LD>80%) with known SLE associated variants from our SLE GWAS data we observed that nearest SNP of some of these novel variants carrying genes/regions are strongly or suggestively associated with SLE, such as, HIP1 ($p=6.7 \times 10$ (-16), DTX3 ($P= 3 \times 10$(-3)), LTBP3 (6.78×10 (-6), PTPN3 (9×10 (-4). Among genes, some of them (e.g DTX3, LTBP3) are both identified as differentially expressed genes in monocytes and suggestively associated with SLE. Also, several similar variations are identified in multiple cases although no information could be obtained from previous studies since SNPs from these regions are not present in GWAS CHIPs but could be potentially associated with lupus. Association studies with these newly identified variations with a large number of samples are in progress to identify novel SLE associated variants. Taken together, RNA sequencing of monocytes not only identified differentially expressed genes, but also identified novel variants that could be pathogenic to SLE and implicate their roles in genotype-phenotype correlation.

1159T

Multiplexed targeted capture of *FBN1* and *FBN2* reveals association with adolescent idiopathic scoliosis.
J.G. Buchan[1], D.M. Alvarado[3], P. Yang[3], C. Cruchaga[4], M.B. Harms[2], K. Ha[3], T. Zhang[1], M.C. Willing[5], D.K. Grange[5], T.E. Druley[1,5], A.C. Braverman[6], M. Lovett[1], M.B. Dobbs[3,7], C.A. Gurnett[2,3,5]. 1) Genetics, Washington University, Saint Louis, MO; 2) Neurology, Washington University, Saint Louis, MO; 3) Orthopedic Surgery, Washington University, Saint Louis, MO; 4) Psychiary, Washington University, Saint Louis, MO; 5) Pediatrics, Washington University, Saint Louis, MO; 6) Medicine, Washington University, Saint Louis, MO; 7) St. Louis Shriners Hospital for Children.

Adolescent idiopathic scoliosis (AIS) is a common pediatric spine deformity that affects up to 3% of the population. Despite a strong genetic component, few genes have been associated with AIS and the pathogenesis remains poorly understood. Marfan syndrome and congenital contractual arachnodactyly are Mendelian disorders that are highly associated with scoliosis and are caused by mutations in the large fibrillin genes, *FBN1* and *FBN2*. To determine whether rare genetic variants in fibrillin contribute to the pathogenesis of AIS, we sequenced *FBN1* and *FBN2* using a novel and cost-effective method of targeted capture called multiplex direct genomic selection (MDiGS) in combination with exome sequencing. In individuals of European ancestry, an increased frequency of private *FBN1* and *FBN2* variants was identified in AIS cases (8.2%; n=233) compared to controls (2.0%; n= 393) (OR=4.27; $p=2.7\times10^{-4}$). Private *FBN1* and *FBN2* variants were associated with more severe spinal deformity ($p=3.2\times10^{-4}$), but were not associated with systemic features of Marfan syndrome or congenital contractural arachnodactyly. Activation of the TGF-β signaling pathway was demonstrated by elevated pSMAD2 in muscle of AIS patients with private *FBN1* variants. Our findings underscore the functional importance of rare fibrillin variants in AIS pathogenesis and provide the possibility of novel therapeutic strategies for treating AIS.

ImmunoSeq: Discovery of novel rare variants implicated in autoimmune and inflammatory diseases by targeting regulatory regions in immune cells. *A. Morin[1,2], T. Kwan[1,2], K. Tandre[3], M.L Eloranta[3], V. Arsenault[2], M. Caron[1,2], L. Létourneau[2], C. Wang[5], G. Bourque[1,2], C. Laprise[4], A. Montpetit[2], A.C. Syvänen[5], L. Rönnblom[3], M. Lathrop[1,2], T. Pastinen[1,2].* 1) Department of Human Genetics, McGill University, Montréal, Quebec, Canada; 2) McGill University and Genome Québec Innovation Centre, Montréal, Quebec, Canada; 3) Department of Medical Sciences, Section of Rheumatology, Uppsala University, Uppsala, Sweden; 4) Département des sciences fondamentales, Université du Québec à Chicoutimi Saguenay, Quebec, Canada; 5) Department of Medical Sciences, Molecular Medicine and Science for Life Laboratory, Uppsala University, Uppsala, Sweden.

Genome-wide association studies (GWAS) have identified many common SNPs associated to complex traits, yet they only partially explain their genetic component. Whole-exome sequencing has been used in the discovery of rare variants associated to complex traits, but its potential success is limited, since GWAS have shown that the associated SNPs are predominantly located in noncoding regions. A recent study showed that rare coding variants have limited impact on the development of autoimmune diseases. Comprehensive DNase I hypersensitive site (DHS) mapping by the ENCODE project identified all classes of cis-regulatory elements, and recent studies showed enrichment of GWAS noncoding variants in DHS. The discovery of rare variants located in regulatory regions specific to immune cells should explain part of the heritability of autoimmune complex traits. Our approach combines selective DNA capture of relevant regulatory regions coupled to next-generation sequencing. Genome-wide DHS mapping data from the ENCODE and NIH Roadmap Epigenomics Projects were used to select regulatory regions of immune cells. We designed a custom DNA capture panel (Roche SeqCap EZ developer) to target these selected regions, as well as exonic and HLA regions. Captured DNA (163Mb) is indexed (5-fold per lane) for sequencing on Illumina HiSeq2000 system, yielding average coverage of ~28x. We first applied the 'Immunoseq.' assay to 30 healthy individuals from Swedish (Uppsala BioResource), where we have existing transcriptome, methylome and ChIP-seq data from three primary immune-cell subsets (monocytes, B-cells and T-cells). The capture panel was also applied to 40 trios from the SaguenayLac-Saint-Jean asthma familial collection. Rare variants were defined as novel if absent in genotyping data, dbSNP137, or from 1000 Genomes imputation data. We observe a large proportion (15080/21626=70%) of rare variants falling into regulatory regions. A subset of these rare variants (8%, n=1747) are highly conserved (GERP ≥ 4), and of these, 69 are proximal to 52 genes identified by autoimmune disease GWAS. This highlights the 1) potential impact of non-coding variation in the development of autoimmune and chronic inflammatory diseases, and 2) power of our targeted capture approach to identify novel rare variants in regulatory regions. On-going work focuses on correlating these rare, non-coding variants to gene expression and regulatory element activity as well as risk of inflammatory disease.

1161W

Novel candidate genes putatively involved in stress fracture predisposition detected by whole Exome sequencing. *E. Friedman[1,2], D.S. Moran[3], D. Ben- Avraham[4], R. Yanovich[3], G. Atzmon[4].* 1) Oncogenetics Unit, Inst Gen, Chaim Sheba Med Ctr, Tel Hashomer, Israel; 2) The Sackler School of Medicine, Tel-Aviv University, Ramat Aviv; 3) The Military Physiology Unit, Heller Institute, Sheba Medical center, Israel; 4) Departments of Medicine and Genetics, Albert Einstein College of Medicine, Bronx, NY 10463.

While clearly genetic factors are involved in stress fracture (SF) pathogenesis, few studies that focused on candidate genes reported on the contribution of sequence variants in these genes to this common overuse injury. We employed an unbiased screening approach by using exome sequence capture arrays followed by next generation sequencing (HiSeq2000) of two pooled DNA samples from Israeli soldiers: cases with high grade SF (n= 34) and ethnically and age matched controls with no evidence of SF (n= 60). Of the 144,217 and 202,406 sequence variants (control and case pools, respectively) 67,408 variants passed the various QC filtering stages with 3-20,000 reads/variant. Of 1900 variants with more than 600 reads/variant in both DNA pools, 145 sequence variants (in 127 genes) displayed statistically significant ($p<0.05$) differences in rates between cases and controls. Subsequent validation of these 145 sequence variants individually for the 55 controls and 32 SF soldiers who formed the pooled samples using the Sequenom platform, validated 11/145 SNPs. A second, independent, individually genotyped validation cohort with 72 controls and 104 SF soldiers using the Sequenom platform to query the same 145 SNPs, validated only 1 SNP: a missense mutation in the BTN3A1 gene. Combined analysis the two datasets for all cases and controls with adjustment for inter-batch variability resulted in 8/145 SNPs that were statistically different between cases and controls, 5 of which were in the originally detected and validated 11 SNPs. Of these, three SNPs were Synonymous SNPs located within the SEC24D, PAWR, LRRC55 genes. SEC24D and PAWR encode for proteins involved in carbohydrate and lipid post translational modifications and Ubiquitin C network. The LRRC55 protein acts in the calcium-activated potassium channel. In conclusion, exome sequencing of DNA pools provided novel candidate genes seemingly involved in SF pathogenesis and predisposition.

1162T

A possible role of Transposable Elements in dysregulating the genomic architecture of Schizophrenia. *F. Macciardi[1], G. Guffanti[2], S.G. Potkin[1], M. Pato[3], I. Guella[1], M. Vawter[1], J.A. Knowles[3], T. VanErp[1], C. Pato[3], S. Gaudi[4].* 1) Dept. of Psychiatry & Human Behavior, University of California Irvine (UCI), Irvine, CA; 2) Department of Psychiatry Division of Epidemiology & Division of Child and Adolescent Psychiatry Columbia University/ NYSPI, New York, NY; 3) Department of Psychiatry and the Behavioral Sciences - Keck School of Medicine at USC, Los Angeles, CA; 4) Department of Infectious, Parasitic and Immune-Mediated Diseases, Italian National Institute of Health, Rome, Italy.

Background. Between half and two-third of our genome is composed of repetitive, low-complexity Transposable Elements (TEs, e.g., LINEs, SINEs, SVAs and HERVs). Since their discovery TEs were thought to act as 'controlling elements' of nearby genes. While the notion that DNA could be mobile was accepted, the idea of control was not. The role of TEs as regulatory elements is now more recognized. TEs create variability by retro-transpositions and by SNVs in fixed TEs. By retrotransposing to new insertional sites, TEs create structural variants and provide novel promoters, splice sites, exons or polyadenylation signals. **Methods.** We identified and annotated SNVs and Retrotrasposition Insertion Polymorphisms (RIPs) for various classes of TEs (LINEs, SINE, HERVs and SVAs) from whole-genome sequence data in post-mortem brains of 10 cases and 10 controls. We examined TE sequence differences (including RIPs) between SZ patients and controls, using re-alignment and de novo assembly and characterized the genomic context of RIPs (exon, introns, 5' and 3' UTRs, non-coding regions). **Results**. We found that RIPs are largely underrepresented in SZ patients compared to controls for all TE classes. The number of RIPs in controls ranges from 3,000 to at least 4,500, within the boundaries calculated from the 1,000 Genome Project for dbRIP-reference and RIP non-reference TEs, a larger estimate than from previous studies. In cases RIPs are 1/10 to 1/20 than in controls. **Discussion.** The low number of RIPs in SZ subjects suggests a neuro-developmental defect affecting embryonic brain development. Recent stem cell models show that a high number of RIPs for L1s and Alus is a key factor for somatic neuronal development, although the precise mechanisms are not yet clear. It is thus possible that a reduction of RIPs in SZ at the early embryonic level may be less relevant than the somatic retrotransposition that occurs in neurons at later developmental stages and results in an increased transcriptome heterogeneity among neurons. Our preliminary results reveal a new, unexpected dimension of the regulatory genome that may play a pivotal role in the etiology of schizophrenia. Since their identification, TEs represent a controversial concept due to their biology and mechanisms of action that challenge genetic dogma. Our findings, however, suggest that TEs can represent an important new genomic risk factor in schizophrenia.

1163F

AMD risk and association with variation in 202 drug target genes. *P.L. St Jean[1], W.H. Cade[2], F. Grassmann[3], M. Schu[4], S. Slifer[2], Z. Ye[5], M.H. Brilliant[5], M.M. DeAngelis[6], L.A. Farrer[4], J.L. Haines[7], T.E. Kitchner[5], M.A. Pericak-Vance[2], B.H.F. Weber[3], L. McCarthy[1], C.-F. Xu[1], M.G. Ehm[1].* 1) Quantitative Sciences, GlaxoSmithKline, RTP NC, USA; Stevenage UK; 2) University of Miami Miller School of Medicine, Miami, FL, USA; 3) Institute of Human Genetics, University of Regensburg, Regensburg, Germany; 4) Boston University Schools of Medicine and Public Health, Boston, MA, USA; 5) Marshfield Clinic Research Foundation, Marshfield, WI, USA; 6) Department of Ophthalmology and Visual Sciences , Moran Eye Center, University of Utah, Salt Lake City, UT USA; 7) Center for Human Genetics Research, Vanderbilt University Medical School, Nashville, TN, USA.

Age-related macular degeneration (AMD) is a common cause of blindness and visual impairment in older adults occurring in ~12% of people over age 80. Advanced forms of AMD are geographic atrophy (GA) involving retinal pigment epithelial atrophy, and neovascular (NV) complications characterized by abnormal blood vessel growth and leakage of blood and protein. Approved treatments of AMD, focused on the neovascular forms, include ranibizumab and aflibercept which are both administered by injection. Developing drugs effectively treating GA, as well as non-injectable treatments for neovascular forms, would have a substantial, positive impact for people with advanced AMD. Our objective is to identify genetic variants in drug targets gene that are associated with AMD risk with the hope that some of these genes may prove to be effective targets for developing therapeutics for AMD. Exons and flanking regions of 202 genes encoding current or prospective GSK drug targets were sequenced in 14,000 European subjects. Illumina 500K or Affymetrix 500K data were available on 6900 of these subjects and were used to create reference haplotype sets allowing us to impute into several AMD collections of European origin. Association between AMD risk and dosage was conducted on a total of 2,696 cases and 3,335 controls for variants with an R2 quality metric threshold of $\geq$0.5. A meta-analysis of effect estimates was performed using the inverse variance method in METAL while testing for heterogeneity across studies. A predefined statistical threshold of $p \leq 3.65E-5$, accounting for the effective number of variants, was used to identify significant results while a less stringent threshold of $p<0.005$ was used to identify suggestive results. Across the collections, 46,957 variants with an R2 quality$\geq$0.5 were analyzed. Thirteen variants were associated at $p \leq 3.65E-5$ and these reside in regions flanking, but not within the 202 target genes. Ten of these variants are on chromosome 6 and map to reported AMD risk genes C2, CFB, SKIV2L; however, they are 400-800 kb from the closest GSK target gene. Several variants within GSK target genes were associated at $p<0.005$ and many of these genes are implicated in AMD disease mechanisms such as inflammation and lipo-protein processing. Further support of the involvement of these target genes in AMD risk will be assessed in independent replication studies.

1164W

Matrix metalloproteinase 2, 3, 9, 10, 13 gene polymorphisms and risk for polycythemia and essential thrombocytosis patients. *E. Uctepe[1], S. Maral[2], O. Bender[1], T. Yasar[1], E. Gunduz[1], M. Gunduz[1,3].* 1) Medical Genetics Department, Turgut Ozal University, Ankara, Turkey; 2) Internal Medicine Depertmant,Fatih University, Ankara, Turkey; 3) Departments of Otolaryngology Head and Neck Surgery,Turgut Ozal University, Ankara, Turkey.

Chronic myeloid disorders such as polycythemia vera (PV), essential thrombocytosis (ET) and idiopathic myelofibrosis arises from clonal proliferation of neoplastic stem cells in the bone marrow. Matrix metalloproteinases (MMPs) are a family of zinc-dependent endopeptidases that have potential to degrade all types of extracellular matrix (ECM) and also play a role in remodeling of the ECM. It is known that MMPs play a role in bone marrow fibrosis. The primary goal of our study is to determine the relationship between chronic myeloproliferative diseases and MMP gene polymorphisms. The demonstration of a relationship will determine whether polymorphisms lead to susceptibility to disease and with future work may aid in the development of new therapeutic modalities. Patients were selected from outpatient clinics of the Turgut Ozal Medical University Hospital between December 2010 and May 2011. Twenty-eight patients which previously diagnosed and follow-up with a diagnosis of polycythemia vera, seventeen with secondary polycythemia, and twelve with essential thrombocytosis were enrolled in the study, along with a control group of 22 healthy patients. DNA isolation from peripheral blood, DNA amplification with polymerase chain reaction (PCR) and agarose gel electrophoresis was performed. Using PCR-RFLP, MMP-2, -3, -9, -10, and MMP-13 gene polymorphisms were analyzed. There was a statistically significant difference between the groups in terms of Gln279Arg polymorphisms rates of MMP 9 . ($\psi2 = 22.975$, $p = 0.001$). The highest MMP 9 Gln279Arg polymorphism rate was observed in the ET group. It were determined that MMP 13 gene 77A> G polymorphism had significantly higher prevalence rates in the ET group. ($\psi2 = 12.605$, $p = 0.05$). There was nostatistically significant difference between the groups in terms of MMP-2 -735 C> T, MMP -3-1612 5A/6A, and MMP-10 180G> A polymorphism rates. (respectively: $\psi2 = 6.447$, $p = 0.375$, $\psi2 = 10.870$, $p = 0.092$). In conclusion, Gln279Arg MMP-9 and 77A> G MMP-13 gene polymorphisms were associated with ET and PSV diseases. Hence, it is thought that these gene polymorphisms may play a role in the mechanism of bone marrow fibrosis and may be a factor that increases the risk of thrombosis. Illumination of the molecular basis of the relationship between MMP-thrombosis and MMP-fibrosis provides a better understanding of the pathophysiology of PSV and ET diseases and will allow new approaches to diagnosis and treatment.

1165T

Race and sex effects on the relationship between sarcopenia and BMD.
H. He[1], Y.J. Liu[1], J. Li[1], H. Shen[1], Q. Tian[1], H.W. Deng[1,2]. 1) Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, New Orleans, LA; 2) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China.

The relationship between reduced muscle mass (sarcopenia) and bone mineral density remained unclear. The main purpose of this study was to determine this relationship and examine effects of fat mass (FM), lean mass (LM), and muscle strength on regional and whole body BMD in different race cohorts and to determine if these relationships are altered by sex and/ or race. The study population was collected from different clinical centers and consisted of 17,891 individuals from three ethnic populations, including 8604 Caucasians, 5013 Chinese and 4274 African-Americans. Partial correlation analyses, controlling for race, study site, gender, regular exercise, smoke and alcohol use were conducted to investigate the relationships between BMD and body composition variables. Multiple regression analysis was used to examine the independent effects of FM, LM and grip strength on regional and whole body BMD. Regression models were stratified by race and sex and adjusted for age, height, city, menopause status, current smoking, alcohol use and regular exercise. Men had a greater lean mass, lower fat mass and lower fat percentage than women. Whole body and regional BMDs were significantly greater in men than in women. African-Americans had the highest mean bone density, follows by Caucasians and then Chinese. As expect, grip strength was higher in men than in women and highest in Caucasians. Age was negatively associated with height, grip strength, lean mass, whole body and regional BMDs, and positively associated with fat mass and fat percentage. LM and FM were positively associated with BMD at all sites ($r = 0.14$-0.37, $p < 0.001$). The partial correlation was stronger for LM and BMDs than for FM and BMDs. LM was a significant independent (Std β= 0.11- 0.34, $p < 0.001$) contributor to BMDs across race and sex and had greater effects on BMDs than FM. FM was also a significant ($p < 0.001$) determinant of BMD, except in African-American and Caucasian men. Compared to LM, Grip strength contributed less effect to whole body BMD and wrist ultradistal radius BMD. Non-significant race×FM and race×LM interaction terms were found. Sarcopenia was associated with a 3-fold higher risk of osteoporosis(OR=3.02; 95%CI= 2.622, 3.473). LM is the strongest predictor of BMD for all race and sex group. Sarcopenia is associated with low BMD and osteoporosis. Further studies may assess whether maintaining lean mass contributes to prevent osteoporosis.

1166F

Unexpected pleiotropy: Do asthma and dental caries share a genetic basis? *J.R. Shaffer[1], R.J. Weyant[2], R. Crout[3], D.W. McNeil[4], M.L. Marazita[1,5,6]*. 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Dental Public Health and Information Management, University of Pittsburgh, Pittsburgh, PA; 3) Periodontics, West Virginia University, Morgantown, WV; 4) Dental Practice and Rural Health, West Virginia University, Morgantown, WV; 5) Oral Biology, University of Pittsburgh, Pittsburgh, PA; 6) Clinical and Translational Science, University of Pittsburgh, Pittsburgh, PA.

The surprising association between asthma and dental caries (i.e., tooth decay) has been repeatedly observed in epidemiological studies. However, at present, the cause of this relationship is largely speculative. As part of an initiative by the Center for Oral Health Research in Appalachia (COHRA), we explored the relationship between dental caries scores (assessed by intra-oral examination) and parent-reported asthma in a cohort of 940 rural children <10 years of age. These children comprise part of a larger sample of 2- and 3-generation families, all of which were genotyped on an Illumina whole-genome SNPchip. Approximately 14% of children reported asthma, which was significantly associated with both whether or not a child experienced dental caries ($p=0.04$; ψ^2 test) and the number of carious (i.e., decayed or restored) tooth surfaces ($p=0.001$; Wilcoxon test). Using a variance components approach, we determined that both asthma and dental caries showed high heritability (90% for asthma, 40-60% for dental caries; both consistent with other studies). Moreover, estimates of genetic correlation (ρ_G) indicated that asthma and dental caries may partly share a common genetic basis ($\rho_G=0.36$ for asthma and number of carious surfaces, $p = 0.006$; $\rho_G=0.35$ for asthma and yes/no caries, $p=0.03$). In other words, the suites of genes affecting susceptibility to these two complex diseases may partly overlap. Next, we explored whether the ORMDL3-GSDMB locus on chromosome 17, which has been repeatedly implicated in childhood asthma in large-scale association studies, was associated with dental caries. The SNP rs8082130 in this region was associated with number of carious tooth surfaces ($p=0.0004$). Other loci implicated in asthma (e.g., HLA-DQA1/A2, RORA, SMAD3, and IL2RB) showed nominal associations with dental caries. These results support the hypothesis that asthma and dental caries are linked, and suggest that a shared genetic basis may partly explain this relationship. However, the exact nature of this relationship remains speculative: do asthma and dental caries share a root etiology, or are asthma-liability genes influencing dental caries through a mechanistic artifact, such as exposure to antiasthma medications? While additional work is needed to tease out the causality of this association, this study illustrates that pleiotropic actions of the genetic determinants of complex diseases may yet to be fully appreciated. R01-DE014899; U01-DE018903.

1167W

A pilot T1D risk prediction study using custom panel and advanced multivariate predictive models. *C. Kim[1], Z. Wei[1], J. Glessner[1], K. Thomas[1], H.K. Åkerblom[2], M. Knip[2], H. Hakonarson[1,3,4], I. Ilonen[4,5].* 1) The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Children's Hospital University of Helsinki, Finland; 3) The Department of Pediatrics, The Perelman School of Medicine, Philadelphia, PA; 4) Turku Immunogenetics Laboratory, University of Turku, Turku, Finland; 5) equal contribution.

Recent progress in genetic research has expanded our knowledge of the genes affecting risk of Type 1 Diabetes (T1D). Up to 50 gene loci outside the HLA region have been identified at the moment. However, the effect of each of these genes is relatively small and their combined effect has been estimated to be only around 10-15 percent. Given the relatively modest individual contributions of T1D loci, towards genetic risk, the simple univariate methods for prediction of T1D are not optimal. We have designed and validated a better multivariate non-linear genetic test that can be used to determine which infants are most at risk of T1D in the future. By scoring approximately 400 to 500 of the most strongly associated SNPs ($P \leq 10\text{-}5$) from GWAS with a support vector machine (SVM), we can achieve a negative predictive value (NPV) of virtually 100 percent in siblings of affected patients. These 'SVM SNPs' comprise approximately 300 informative markers that map to the major histocompatibility complex (MHC) with the remaining being distributed throughout the genome. Given these promising performance, we hypothesize that T1D can essentially be ruled out in children with a strong family history. As a proof-of-concept, here we conduct a risk prediction study for children enrolled in the full TRIGR study and early pilots. We designed a custom chip that covers 384 most relevant T1D SNPs. We genotyped 198 Finnish samples with unknown disease status using this chip for prediction. To evaluate and optimize model performance, we also genotyped 185 samples (132 controls and 53 cases) collected at the Children's Hospital of Philadelphia (CHOP). The WTCCC T1D dataset (2938 controls and 1963 T1D cases) was used to train predictive models. We employ SVM and L1 penalized logistic regression (LR) for risk prediction. The SVM model achieved AUC of 0.796 (95 percent CI=[0.715, 0.868]), and the LR model, AUC of 0.797 (95 percent CI=[0.717, 0.867]), when testing on the CHOP samples. The predicted risk status for the Finnish samples demonstrates significant correlation with autoantibodies, suggesting that in addition to HLA typing and family history, the T1D disease status could be predicted with greater accuracy when coupled with the predictive score from the 384 markers than by the HLA status and family history measures alone. Whole exome sequencing is underway to further improve the predictive accuracy of the algorithm and to better understand the pathogenesis of the disease.

1168T

Prediction of complex phenotypes, such as skin, eyes and hair color based on the analysis of polymorphisms of pigmentation genes for forensic purposes. *F.T. Goncalves, F.A. Lima, R.S. Gonzales, C. Fridman.* Legal Medicine, Ethics and Occupational Health, Medical School, University of São Paulo, Sao Paulo, Sao Paulo, Brazil.

Human pigmentation traits, including color variation in skin, eye, and hair, belong to the most visible and differentiating human traits. The genetic basis underlying variation in human pigmentation traits has been the subject of intensive research by investigators in a variety of life science communities, including forensic purposes, in which the use of these trials can help identifying missing person or guide some police investigations. The variations in skin pigmentation are dependent on geographic location and population ethnicity. The two types of melanin synthesized in well defined chemical reactions are the protective dark colored eumelanin and the sulphur containing light red-yellow pheomelanin. The events leading to the synthesis of melanin are controlled by signaling cascades that involve a host of genes encoding ligands, receptors, transcription factors, channel transporters and many other crucial molecules. The aim of this study was evaluate polymorphisms in MC1R, TYR, ASIP, SLC24A5 and SLC45A2 genes in a sample of 132 individuals of admixed population from Brazil, intending to use the data in forensic genetics casework in several situations. No significant differences were detect in all polymorphisms and eye, hair and skin color association, except the SNP rs1426654 of the SLC24A5 gene. The polymorphic homozygous genotype (GG) for gene SLC24A5 was associated with dark skin (OR, 0.07; CI, 0.009-0.49) compared with light skin, while the heterozygous genotype (AG) showed association with black hair (OR 0.22, CI 0.07-0.66 p = 0.008) when compared with brown hair. The SLC24A5 gene encodes the protein NCKX5, which involves a cellular transport complex of ions sodium/calcium. It is postulated that this gene participates in the control of calcium in melanosomes. As the production of melanin is dependent on the amount of calcium in these cells, we infer that the polymorphism in the SLC24A5 gene would result in a transmembrane protein with increased permeability to calcium in the cell, which would lead to a higher concentration of this ion in melanosome, that increases the production of melanin resulting in dark skin and hair color, as described in homogenous population of Africa and Europe. We are increasing our sample to confirm these results.

Common dysfunctional variants of urate exporter gene ABCG2/BCRP are a major cause of early-onset gout. *H. Matsuo[1], K. Ichida[2], T. Takada[3], A. Nakayama[1], H. Nakashima[4], T. Nakamura[5], Y. Kawamura[1], Y. Takada[6], K. Yamamoto[7], S. Shimizu[1], M. Sakiyama[1], T. Chiba[1], N. Hamajima[8], Y. Sakurai[4], T. Shimizu[9], N. Shinomiya[1].* 1) Dept. Integrative Physiol. Bio-Nano Med., Natl Defense Med Col, Tokorozawa, Japan; 2) Dept. Pathophysiol., Tokyo Univ. Pharm Life Sci, Tokyo, Japan; 3) Dept. Pharm., Univ. Tokyo Hospital, Tokyo, Japan; 4) Dept. Prev. Med. Public Health, Natl Defense Med Col, Tokorozawa, Japan; 5) Lab. Math., Natl Defense Med. Col., Tokorozawa, Japan; 6) Central Res. Inst., Natl Defense Med Col, Tokorozawa, Japan; 7) Med. Inst. Bioregulation, Kyushu Univ., Fukuoka, Japan; 8) Dept. Healthcare Admin., Nagoya Univ., Nagoya, Japan; 9) Midorigaoka Hosp., Takatsuki, Japan.

Background and objectives Gout is a common disease which mostly occurs after middle age, but more people nowadays develop it before the age of thirty. The major genetic causes of early-onset gout are still unclear, but some genetic predisposition has been supposed. ATP-binding cassette (ABC) transporter, subfamily G, member 2 (ABCG2/BCRP) is a high-capacity urate exporter which regulates serum uric acid levels. We conducted a study to determine whether common variants of ABCG2 cause early-onset gout. **Design, setting, participants & measurements** 705 Japanese male gout cases with onset age data and 1,887 male controls were genotyped, and the ABCG2 functions which are estimated by its genotype combination were determined. We then conducted a logistic regression analysis among them to investigate the involvement of ABCG2 dysfunction in early-onset gout. **Results** The onset age was 6.5 years earlier with severe ABCG2 dysfunction than with normal ABCG2 function ($P = 6.14\times10^{-3}$). Patients with mild to severe ABCG2 dysfunction accounted for 88.2% of early-onset cases (twenties or younger). Severe ABCG2 dysfunction particularly increased the risk of early-onset gout, conferring an adjusted odds ratio [OR] of 22.2 (95% confidence interval [CI] 5.89-83.7, $P = 4.66\times10^{-6}$). Moderate (1/2 function) and mild (3/4 function) dysfunction of ABCG2 also increased the risk of early-onset gout, conferring ORs of 15.3 (95% CI 7.53-30.9, $P = 4.08\times10^{-14}$) and 6.47 (95% CI 3.31-12.7, $P = 4.89\times10^{-8}$), respectively. **Conclusions** Common dysfunction of ABCG2 proved to be a major cause of early-onset gout. Early screening of ABCG2 dysfunction and appropriate interventions will greatly benefit high-risk individuals.

Quantitative genetic analysis of preterm birth in a sample of 2 million births yields precise heritability estimates. *W. Wu[1], A. Fraser[2], E. Clark[3], A. Rogers[4], G. Stoddard[5], D. Witherspoon[1], T. Manuck[3], K. Chen[6], S. Esplin[3], K. Smith[2], M. Varner[3], L. Jorde[1].* 1) Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 2) Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, UT; 3) Department of Obstetrics and Gynecology, University of Utah School of Medicine, Salt Lake City, UT; 4) Department of Anthropology, University of Utah, Salt Lake City, UT; 5) Study Design and Biostatistics Center, University of Utah School of Medicine, Salt Lake City, UT; 6) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Preterm birth (PTB), defined as birth prior to 37 completed weeks' gestation, occurs in more than 10% of all births in the United States. PTB is the leading cause of neonatal mortality, and it causes a broad spectrum of lifelong morbidity in survivors. The etiology of spontaneous PTB (SPTB), PTB not due to obstetric or medical indication, is complex and has an important genetic component. Previous studies have shown that the heritability of SPTB is approximately 30%. However, these studies defined SPTB as a maternal phenotype, were assessed within selected families, were based on twin pairs, or were based on a dichotomous binary case/control design. Using the Utah Population Database (UPDB), we assessed SPTB in more than 2 million post-1945 births in Utah. We analyzed SPTB using the newborn's gestational age as a quantitative trait. Our estimate of SPTB heritability is 13.33% (95% confidence interval 10.96% - 15.69%), and the broad-sense heritability is 24.4%. These figures are lower than those of previous studies. In addition to estimating heritability, we partitioned other genetic and environmental components contributing to gestational age variance: dominance variance = 11.12%, common maternal environmental variance = 15.23%, and individual environmental variance =60.33%. Our results suggest that the environmental component of SPTB may be larger than previously realized, providing guidance for future studies. In particular, high-risk pedigrees with multiple affected cases, rather than samples of unrelated cases, have a greater likelihood of revealing genes that underlie this multifactorial condition.

Visceral adiposity linked to chromosome 9p24.2 in adults from the Fels Longitudinal Study. *B. Towne[1], J. Blangero[2], A.C. Choh[1], J.E. Curran[2], C. Bellis[2], T.D. Dyer[2], E.W. Demerath[3], M. Lee[1], S.A. Czerwinski[1].* 1) Wright State University School of Medicine, Dayton, OH; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) University of Minnesota, Minneapolis, MN.

Elucidating the genetic underpinnings of overweight and obesity continues to be a challenge. Part of the problem has been an over-reliance on crude measures such as weight or BMI. Using more direct and delineated phenotypic measures, however, especially of metabolically active fat depots, can provide new insights into the genetics of body composition and associated disorders. We present here results from genome-wide linkage analysis of visceral adipose tissue (VAT) volume in the entire trunk in 739 healthy adults (329 males; 410 females) aged 18 to 96 years (mean 46.1 years) in the Fels Longitudinal Study. VAT data were obtained using a multi-slice MRI protocol. Mean VAT was 3611 cc in males and 1735 cc in females. Subjects were all SNP genotyped using the Illumina Human 610-Quad BeadChip, and a subset of 17,583 SNPs identified as being in linkage equilibrium in our study population were used in whole-genome multipoint linkage analysis conducted using SOLAR (Almasy and Blangero, 1998). Significant linkage (LOD = 3.53) of VAT to markers on chromosome 9p24.2 was found, with the linkage peak being between SNPs rs7870248 and rs10758400. The 1-LOD support interval around this linkage peak contains several plausible positional candidate genes potentially relevant to visceral adiposity and cardiometabolic dysregulation, including *VLDLR* (very low density lipoprotein receptor), *GLIS3* (GLIS family zinc finger 3), and *RCL1* (RNA terminal phosphate cyclase-like 1). Of particular interest is *GLIS3* which is involved in the regulation of pancreatic beta cell development and insulin gene transcription. Recent GWA studies have found SNPs in *GLIS3* to be associated with increased risk of T1DM and T2DM. Those findings, and the results presented here, suggest that there may be a genetically mediated relationship between visceral adiposity and diabetes mellitus risk that warrants further investigation. Supported by NIH grants R01HD012252, R01DK064391, R01DK064870, R01AR052147, and R37MH59490.

Leveraging Genetic Information to Assess the Effect of Diabetes on Memory Scores in the Health and Retirement Study. *S. Walter[1], J. Daniel[1], L. Kubzansky[1], S.C. Chang[1], M.C. Cornelis[1], D.H. Rehkopf[2], M.M. Glymour[1,3].* 1) Department of Social and Behavioral Sciences, Harvard School of Public Health, Boston, MA, USA; 2) Department of Medicine, Stanford University, Stanford, CA, USA; 3) Department of Epidemiology & Biostatistics, University of California, San Francisco, San Francisco, CA, USA.

Background: Extensive observational analyses suggest that type II diabetes increases risk of dementia and memory impairment, but this association may be spurious and reflect unmeasured common prior causes of diabetes and dementia. The research question is not easily amenable to experimental approaches, but natural experiments based on genetic instrumental variables (IV) can lend insight into whether lifelong elevations in diabetes risk are associated with differences in late life memory functioning. Methods: Data are from 6555 non-diabetic and 1947 diabetic white participants in the nationally representative Health and Retirement Study with complete information on genetics, self-reported diabetes status, and memory functioning. Based on 40 Single Nucleotide Polymorphisms (SNPs) shown in previous research to predict type II diabetes, we calculated a genetic risk score (GRS) as the sum of the number of risk alleles multiplied by the per allele effect size on type II diabetes (based on prior publications). Self-reported type II diabetes was used to confirm the GRS predicts diabetes within HRS. Memory score was based on a composite of immediate and delayed word recall plus a proxy report for extremely impaired respondents. Memory score was regressed on the GRS plus age, sex, and population stratification eigenvectors to test whether genetic variations in diabetes risk predict memory functioning. Results: Mean GRS was 4.07 (standard deviation [SD]= 0.44) in non-diabetics and 4.22 (SD=0.45) among diabetics. Each one unit change in the GRS was associated with a 13.0 percentage point (95% CI: 11.1, 15.0) increase in the probability of diabetes ($p=3.7\times10^{-38}$). The GRS was not associated with memory functioning (beta=0.003; 95% CI: -0.006, 0.013; p=0.5136). These associations provide no evidence of an effect of diabetes on memory but are consistent with an upper bound estimate of the effect of approximately a tenth of a standard deviation in memory score. Conclusions: A genetic risk score associated with a large increase in lifetime risk of developing diabetes was unassociated with memory functioning in this sample of older adults.

1173W

Employing a phenome-wide association study approach to investigate the pleiotropic nature of mitochondrial DNA variation. *S.L. Mitchell[1], S.A. Pendergrass[2], R. Goodloe[1], K. Brown-Gentry[1], R. McClellan[1], J. Boston[1], M. Allen[1], P. Mayo[1], N. Schnetz-Boutaud[1], D.G. Murdock[1], D.C. Crawford[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA.

Hematologic abnormalities, including sideroblastic anemia, have been observed comorbid with mitochondrial disorders. Rare mitochondrial (mt) DNA point mutations in COX1 and MT-TL2 have been reported in patients with anemia. Data also support a role for common mitochondrial variation in human disease, such as type 2 diabetes & Alzheimer's, highlighting the potential pleiotropic nature of the mitochondrial genome. Thus far, phenome-wide association studies (PheWAS) to identify pleiotropy have focused predominantly on the nuclear genome. To characterize the pleiotropic effects of mtDNA variation, we, as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study accessed the National Health and Nutrition Examination Surveys (NHANES), epidemiologic surveys conducted by the Centers for Disease Control and Prevention, which collect demographic, lifestyle, and health data from participants using questionnaires, medical exams, and laboratory measures; DNA is collected for a subset of participants. We selected and genotyped 63 mtSNPs to tag ancestral mitochondrial haplogroups for the major NHANES populations: non-Hispanic whites (NHW; n=8856), non-Hispanic blacks (NHB; n=4325), and Mexican Americans (MA; n=4766). A simplified mitochondrial phylogenetic tree rooted at the most recent common ancestor was constructed using these SNPs and a custom algorithm was developed to automate haplogroup classification. Preliminary tests of association were performed in NHW using linear or logistic regression to identify associations between European haplogroups and a range of phenotypes (n=132). Preliminary results revealed an association between mean cell hemoglobin and haplogroups U ($p=9.0\times10^{-4}$, $\beta=0.19$) and H ($p=3.6\times10^{-3}$, $\beta=-0.12$). The correlated phenotype mean cell volume was also associated with both haplogroup U ($p=3.2\times10^{-3}$, $\beta=0.42$) and haplogroup H ($p=1.5\times10^{-4}$, $\beta=-0.41$). The association of mitochondrial haplogroups with hemoglobin and mean cell volume is consistent with evidence that mitochondria are essential for heme synthesis. Notably, the haplogroup H-defining SNP mt7028 and the haplogroup U-defining SNP mt12308 are located in COX1 and MT-TL2, respectively. These preliminary results suggest that PheWAS is a valid approach for identifying novel mitochondrial genotype-phenotype correlations relevant to human health.

1174T

RNA-sequencing identifies novel differentially expressed coding and non-coding transcripts in Sjögren's syndrome. *C.J. Lessard[1,2], I. Adrianto[1], M.G. Dozmorov[1], G.B. Wiley[1], J.A. Ice[1], H. Li[1,2], J.A. Kelly[1], A. Rasmussen[1], S.B. Glenn[1], K.S. Hefner[3], D.U. Stone[2], G.D. Houston[2], D.M. Lewis[2], J.A. Lessard[4], J.M. Anaya[5], B.M. Segal[6], N.L. Rhodus[7], L. Radfar[2], J.B. Harley[8], J.A. James[1,2], C.G. Montgomery[1], R.H. Scofield[1,2], P.M. Gaffney[1], J.D. Wren[1,2], K.L. Sivils[1,2].* 1) Arthritis & Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Hefner Eye Care and Optical Center, Oklahoma City, OK; 4) Valley Bone and Joint Clinic, Grand Forks, ND; 5) Universidad del Rosario, Bogota, Colombia; 6) Hennepin County Medical Center, Minneapolis, MN; 7) University of Minnesota, Minneapolis, MN; 8) Cincinnati Children's Hospital Medical Center and the Department of Veterans Affairs Medical Center, Cincinnati, OH.

Sjögren's syndrome (SS) is a common, clinically heterogeneous autoimmune disease characterized by exocrine gland dysfunction that involves both innate and adaptive immune responses. SS etiology is complex, with environmental, genetic, and genomic factors contributing. Of the many genetic associations reported in complex diseases, >80% map to non-protein coding DNA sequences; however, many reside in regions shown to be transcriptionally active. We used RNA-seq to identify differentially expressed (DE) protein-coding (~3% of the genome) and non-coding transcripts in 57 SS cases and 37 healthy controls. RNA samples were isolated from whole blood and prepared for sequencing using the NuGEN Encore kit and sequenced on the Illumina HiSeq 2000. Raw FASTQ files were aligned to the human genome (hg19) using TOPHAT. DE transcripts were determined using DESeq with a false discovery rate (FDR) q-value of 0.05 and a fold change of >2. After alignment, the reads were summarized for 55,076 transcripts across the human genome annotated by Ensembl. A total of 2614 DE transcripts were identified. Of the protein-coding regions, SRP14 was the most statistically DE locus in the case-control analysis (q=2.03×10E-20, fold change (FC)=2.32). Two other DE protein-coding transcripts of interest were identified: UQCRB (q=1.94×10E-19, FC=2.86) and ATP5I (q=1.88×10E-18, FC=2.34). Among the 408 DE non-protein coding transcripts, we observed DE of a long non-coding RNA (lncRNA) at 2p25.1 (q=3.69×10E-5, FC=2.55). lncRNAs are important regulators of the human genome with diverse functions; however, most have yet to be characterized. Bioinformatics evaluation in the 2p25.1 region showed transcription factor binding sites and transcription of lncRNA sequences using immunologically relevant cell lines. To formulate functional hypotheses for the lncRNA at 2p25.1, we evaluated co-expression patterns with protein coding sequences and identified T cell activation and development as the most likely pathways influenced. In this SS RNA-seq study, we identified multiple candidate loci and, for the first time, DE lncRNA regions in SS. Although the function of the lncRNAs identified in this study are unknown, many others have been described to function as scaffolds, decoys, signals, and guides for various proteins by conferring nucleotide sequence specificity not possible by motifs alone. Future studies in SS are warranted to elucidate the functional consequences of these lncRNA.

1175F

Genetically distinct subtypes of Rheumatoid Arthritis. *B. Brynedal[1], L. Klareskog[2], L. Padyukov[2], L. Alfredsson[1], H. Källberg[1].* 1) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Medicine, Karolinska Institutet, Stockholm, Sweden.

Complex diseases are heterogeneous in both their presentation and etiology. The identification of subgroups might therefore reveal more homogeneous populations with a smaller and distinct set of pathways. Earlier studies have demonstrated major heterogeneity regarding risk alleles in the HLA-DRB1 gene and immunologically defined (presence (ACPA+) or absence (ACPA-) of antibodies toward citrullinated peptides) subsets of Rheumatoid Arthritis (RA). We set out to characterize how the genotypic profile differs between subsets of RA patients and whether their genetic distinction is restricted to the HLA region. We focused our analysis on the combination of established risk factors of RA using two measures; genetic distance (GD) and genetic risk score (GRS). We used data from the Swedish Epidemiological Investigation of Rheumatoid Arthritis (EIRA) case-control study encompassing 2747 cases (1856 ACPA+ and 891 ACPA-) and 1590 controls. The GRS was compared between groups (ACPA+, ACPA- and controls) including and excluding variants in the extended HLA region. We similarly calculated the GD between pairs of groups with and without HLA variants, and derived the empirical significance using permutation of group labels. ACPA+ and ACPA- RA were expectedly found to genetically distinct with a significant GD, and significantly different GRS. The exclusion of HLA variants removed much of this distinction, illustrating that RA subsets share a substantial part of their etiology. The GD between both groups of RA patients and controls is significant both including and excluding HLA variants. ACPA-RA patients and controls do not have a significantly different GRS, but excluding the variants close to the HLA region increases the GRS of ACPA-RA patients more than controls rendering the difference significant. This also illustrates that ACPA- RA patients carries proportionally more 'RA protective' HLA variants than controls. We conclude that previous published genetic risk factors show that there are both differences and similarities between subsets of RA defined by the absence or presence of ACPA. The major difference related to presence of ACPA is associated with alleles in the HLA region. Omitting the alleles in chromosome six makes ACPA+ RA and ACPA-RA more similar but different from controls. This exemplifies the importance of defining clear subsets of disease.

Assessing human craniofacial morphology as complex phenotype in genetic association studies. *F.I. Martinez[1, 2].* 1) Anthropology Program and ICIIS, Pontificia Universidad Catolica de Chile, Santiago, Chile; 2) Leverhulme Centre for Human Evolutionary Studies, University of Cambridge, UK.

The availability of current genotyping and sequencing technologies combined with high-resolution medical imaging (such as MRIs and CT Scans) has led to a renewed interest in identifying genetic variants responsible for the genetic components of human craniofacial morphology. Recent GWAS have revealed, for the first time, genetic variants correlated with normal variation in human craniofacial phenotype. Some of these loci map to genes with previously known role in craniofacial development, thus implying strong support to the findings and suggesting an unambiguous link between genotype and phenotype. There is general agreement that many genes with small effect (hundreds or thousands) should influence complex phenotypes such as body height or face morphology. Therefore, it is relevant to note that linear measurements are the sole proxy for facial phenotype currently used in GWAS. If many genes with small effect influence complex phenotypes, then the reliability of linear measurements as proxies seems an unrealistic assumption. Is it feasible to assume that linear distances account for the effect of few loci between many genes implicated in craniofacial developmental pathways? Or, is it more likely that observed variability captured by linear measurements reflects mainly the effect of non-genetic patterns of morphological variation in the population such as age or sexual dimorphism? In order to explore these questions, a small sample of 100 virtually reconstructed medical CT scans was analyzed by means of geometric morphometrics and linear measurements. In addition, single nucleotide polymorphism rs6180 (I526L) in the exon 10 of the growth hormone receptor gene (GHR) was chosen as independent variable to run correlation analysis with craniofacial morphology. This polymorphism was selected due its previous link to cranial morphology, human height and the role of GHR in the GH/IGF-1 axis, that promotes bone growth. A significant statistical association was found between rs6180 and craniofacial morphology. Permutation of the data was performed in order to explore the influence of sample structure in the results. Although the findings suggest a putative effect of the rs6180 polymorphism in craniofacial morphology, the correlation is actually driven by the pattern of craniofacial growth in the population. Results show that linear measurements should be regarded with more caution when used as proxy for craniofacial morphology in association studies.

SNPs and smoking: What can the aggregate of genome-wide SNPs tell us about genetic liability to smoking initiation and quantity smoked?
A.G. Wills, M.C. Keller. Institute for Behavioral Genetics, University of Colorado, Boulder, CO. Department of Psychology, University of Colorado, Boulder, CO.

Twin studies have established the genetic contribution to cigarette smoking initiation and progression and have suggested that the dimensions underlying liability to each of these stages of the smoking trajectory may be correlated. Using whole-genome SNP data from a combined sample of 10,162 European Americans that had participated in the Atherosclerosis Risk in Communities Study (ARIC) and the Multi-Ethnic Study of Atherosclerosis (MESA), we examined the degree to which the aggregate of genome-wide SNPs contributed to trait variation, or 'SNP heritability', for smoking initiation and quantity (cigarettes/day multiplied by years smoked). We then estimated the genetic correlation, defined as the additive genetic correlation tagged by the aggregate of SNPs, between initiation and quantity. Using the entire sample, common SNPs explained 11% (p=.0001) of the variance in smoking initiation and, among smokers (n = 5967), only 4% (p=.2) of the variance in quantity smoked. However, when the quantity measure was analyzed separately for each sex, common genome-wide SNPs could not explain variation in quantity smoked for female smokers but explained 15% of the variance in quantity smoked among male smokers. Given that the standard error (.12) in our female analysis of smoking quantity was large, we continued analysis on the sexes combined for the bivariate analysis of initiation and quantity. In the bivariate analysis, we re-coded initiation as an ordinal variable that included both early and late onset users in addition to those that did not initiate to allow for the estimation of the genetic correlation between initiation and quantity. The correlation between the set of SNPs that explained variance in initiation and those that impacted quantity smoked was high (rg = .83) and not significantly different from 1 (p = .30). Thus, common genetic variation, as indexed by genome-wide SNPs, contributed to cigarette smoking liability, and the genetic factors that influenced smoking initiation were largely shared with those that impacted quantity smoked. Grant support: NICHD, 2T32HD007289, Stallings; NIMH, 1R01MH100141, Keller.

Endometrial expression profiling in women with recurrent early pregnancy loss.
G. Kosova[1], C. Billstrand[1], V.J. Lynch[1], M.D. Stephenson[2,3], C. Ober[1,2]. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Obstetrics and Gynecology, University of Chicago, Chicago, IL; 3) Current address: Department of Obstetrics and Gynecology, University of Illinois College of Medicine at Chicago, Chicago, IL.

Recurrent early pregnancy loss (REPL), defined as at least two documented intrauterine miscarriages of less than 10 weeks of gestation, affects up to 5% of couples trying to conceive. The endometrium's ability to acquire a receptive state during the mid-secretory phase is a crucial component of successful implantation and, therefore, has been the focus of many studies that aim to identify predictive markers of early pregnancy. In order to better understand the molecular mechanisms that are perturbed in REPL, we examined the gene expression profiles of mid-secretory phase endometrium in patients with different diagnoses of endometrial dysfunction. Using the Illumina HumanHT-12v4 BeadChip arrays, gene expression levels were compared between women with 1) abnormally elevated cyclin E levels (n= 9) vs normal cyclin E levels (n=23), and 2) out-of-phase histological dating (n=10) vs normal histology (n=22). Differentially expressed (DE) genes were identified using a likelihood ratio test within a fixed-effects linear model framework. Overall, 81 genes were DE in the first comparison and 56 in the second at $P<0.001$. The two genes with the largest differential expression were *S100P* (3.5-fold up-regulation in women with high cyclin E), and *LEFTY2* (4.6-fold up-regulation in out-of-phase endometria). *S100P* expression peaks in the endometrium during the window of implantation (Tong et al. Fertil Steril 94:1510). *LEFTY2* levels normally decrease during that phase, and aberrantly high expression levels were observed in patients with implantation failure and infertility (Tabibzadeh et al. JCEM 85:2526). Gene enrichment analyses of the DE genes (at $P<0.01$) for each comparison revealed over-representation of biological processes including immune response, signal transduction, leukocyte activation and cell adhesion among down-regulated genes in women with elevated cyclin E; and cell adhesion, cell motility and TGF-β signaling among up-regulated genes in women with out-of-phase histology. Lastly, when the analyses were limited to genes that evolved function in the endometrium of Eutherian mammals, significant enrichments of DE genes were observed in both groups ($P=0.005$ in cyclin E, $P=0.003$ in histology). Taken together, the results of this study suggest that this is a promising approach for identifying genes and pathways whose tight regulation during the endometrial secretory phase is necessary for optimal implantation and successful pregnancy outcome.

Association study of ERCC3 genetic variations with nasal polyposis in asthmathics.
J.H. Kim[1], B.L. Park[2], C.S. Park[3], H.D. Shin[1]. 1) Research Institute for Basic Science, Sogang University, Seoul, South Korea; 2) Department of Genetic Epidemiology, SNP Genetics, Inc., Seoul, Republic of Korea; 3) Division of Allergy and Respiratory Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea.

Nasal polyps, as an inflammatory condition and one of the clinical symptoms of aspirin exacerbated respiratory disease (AERD), are edematous protrusions arising mainly from the mucous membranes of the nasal sinuses. Despite the well-defined triggers, the exact mechanisms involved in the development of asthma with nasal polyps still need to be clarified. The ERCC3, one of nucleotide excision repair family genes, has been considered to play roles in the inflammation mechanisms and cancers. To investigate the associations of ERCC3 polymorphisms with nasal polyposis in asthmatics, single nucleotide polymorphisms (SNPs) were genotyped in a total of 475 asthmatics including 161 nasal polyp-positive and 314 polyp-negative subjects. Results of logistic analysis revealed that SNPs and haplotypes were significantly associated with nasal polyp development in the overall asthma group. Despite the need for further replications and functional evaluations, our preliminary findings suggest that ERCC3 may contribute to nasal polyposis susceptibility in asthmatics.

1180T

Examining ocular SNPs for regulatory enhancer potential: What does a non-coding GWAS hit really mean?
C.N. Simonti[1], J.A. Capra[1,2]. 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) have enabled the discovery of genes and functional non-coding regions underlying many complex ocular diseases, such as age-related macular degeneration (AMD) and glaucoma. However, the mechanisms behind the vast majority of these associations remain to be elucidated. There are strong indications that many SNPs associated with ocular diseases may affect enhancer or regulatory regions. For example, two of AMD-associated SNPs in high linkage disequilibrium (LD; calculated from 1000 Genomes; $r^2 \geq 0.8$) have been shown to alter a transcription factor (TF) binding site in a manner that changes gene expression. As anticipated, most ocular diseases have associated non-coding SNPs near eye developmental genes. To assess the regulatory potential of all known ocular trait-associated SNPs,we intersected them with a genome-wide set of predicted regulatory enhancers identified from analysis of histone marks, evolutionary conservation, and sequence motifs in variety of cellular contexts. Ten percent of SNPs associated with ocular traits from the NHGRI GWAS catalog fall into predicted enhancers, a slightly higher fraction than the 8.5% of all trait-associated SNPs that overlap predicted enhancers. The majority of ocular disease SNPs in predicted enhancers did not have a gene within its LD region suggesting a regulatory function. Most of the remaining predicted enhancer SNPs were in sizable introns or known TF binding sites. Comparing the genomic context of SNPs associated with different ocular traits revealed several trait-specific patterns. For example, AMD is distinct from other ocular diseases in its immunologic and cholesterol-related contributing factors. Reflecting its uniqueness, AMD was the only ocular phenotype associated with SNPs nearby complement or cholesterol genes, several of which were in predicted enhancers. GWAS hits for glaucoma are enriched in predicted enhancers when compared to other ocular diseases like AMD, pathological myopia, and corneal astigmatism. SNPs associated with glaucoma demonstrating a distinct profile suggests new functional information may in fact be gleaned from such comparative analyses. Our analysis of the regulatory potential of ocular SNPs highlights contexts and variants relevant to the associations and suggests follow-up studies. For example, profiling the expression driven by the identified enhancer variants in ocular tissues would be a useful focus for future inquiries.

AutDB: A modular database for accelerating ASD genetic research. *E. Larsen, U. Kuppuswamy, S. Banerjee-Basu*. MindSpec Inc., McLean, VA.

A major focus of research in the post-genomic era is to decipher the heterogeneous genetic landscape underlying the pathogenesis of complex human diseases such as Autism Spectrum Disorders (ASD). A number of genes in which rare and/or common genetic variants thought to potentially play a role in ASD onset and pathogenesis have been identified. The advent of new techniques such as next generation sequencing (NGS) has resulted in a significant increase in the number of ASD genes with rare genetic variants. With the accelerated growth of genetic data obtained from ASD individuals adding to the already complex genetic landscape of this disease, there is a critical need for databases specialized in the storage and assessment of this data. The autism genetic database AutDB (http://autism.-mindspec.org/autdb/Welcome.do) was developed to serve as a publically available web-based modular database for the on-going curation and visualization of ASD candidate genes. Since its release in 2007, AutDB has been become widely used by individual laboratories in the ASD research community, as well as by consortiums such as the Simons Foundation, which licenses it as SFARI Gene. AutDB has been designed using a systems biology approach, integrating genetic information within the original Human Gene module to corresponding data in subsequent Animal Model, Protein Interaction (PIN) and Copy Number Variant (CNV) modules. The number of ASD susceptibility genes in the Human Gene Module of AutDB has increased from 304 genes in December 2011 to 546 genes in June 2013, which demonstrates both the continued discovery of ASD candidate genes and the ongoing curation of these genes into AutDB. In addition, the usage of NGS techniques has contributed to a dramatic increase in the number of rare variants identified in ASD candidate genes (from 1202 in Dec 2011 to 3061 in June 2013) compared to common variants (from 534 to 791 over the same period). Functional profiling of ASD genes with rare variants provides insight into the enriched molecular functions of these genes, including ionotropic glutamate receptor binding, serotonin receptor activity, beta-tubulin binding, and voltage-gated sodium channel activity. AutDB serves as a valuable resource for understanding the ever-evolving genetic landscape of ASD and provides researchers with information useful in bioinformatics analyses such as those described above that will aid in unraveling the molecular mechanisms underlying the disease.

1182T

General financial risk factors for risk and ambiguity associated respectively with dopamine D4 receptor (*DRD4*) and serotonin transporter (5-HTTLPR). *R.P. Ebstein[1], M. Monakhov[2], S.H. Chew[2]*. 1) Psychology Dept, National Univ Singapore, Singapore; 2) Economics Dept. National Univ Singapore, Singapore.

Only a handful of investigations have focused on the neurogenetic underpinnings underlying financial decisions that are risky (uncertain outcomes with certain probabilities) or ambiguous (uncertain outcomes with uncertain probabilities) despite the fact that such attitudes are heritable and stable traits. Little is known regarding specific genes that correlate with the propensity to take financial risk especially under ambiguity. Two widely studied common polymorphisms in human behavioral genetics, the *DRD4* exon III VNTR and the serotonin transporter gene (*SLC6A4*) 5-HTTLPR promoter repeat, are biologically plausible candidates for contributing to risk attitude. A large number of Han Chinese university students (N=2,351) completed a battery of incentivized economic tasks and a risk preference phenotype (gR) was extracted from 12 moderate gain gambles using principal component analysis (PCA). Overall, risk proneness was significantly associated with the long 5HTTLPR *SLC6A4* repeat whereas carriers of the *DRD4* 4R/4R genotype showed less risk taking compared to all other exon III genotypes (mainly 2R). Notably, when moderate gain tasks are further informed by comparing gambles with known and unknown probabilities, 5HTTLPR is associated with risk only for ambiguous gambles whereas the *DRD4* is associated with risky gambles only with the known deck. Altogether these results suggest a general risk factor for moderate gain domain, fine-tuning the analysis shows that there are two general risk factors for risky and ambiguous gambles. The neurogenetic approach distinguishes between these two preferences and identifies distinct genes, indexing dopamine and serotonin neural pathways that respectively underpin risky and ambiguous decision-making. Overall, these neurogenetic findings strengthen the notion that risk attitude towards gambles with known probabilities and uncertain probabilities not only have a different anatomical architecture but also differ at the neurochemical and DNA level.

1183F

A molecular genetic study of amyotrophic lateral sclerosis/parkinsonism-dementia complex (ALS/PDC) in Kii peninsula of Japan. *H. Ishiura[1], Y. Fukuda[1], B. Ahsan[1], J. Mitsui[1], Y. Kokubo[2], S. Kuzuhara[3], S. Yoshida[4], T. Kihira[4], J. Yoshimura[5], K. Doi[5], K. Higasa[5], S. Morishita[5], A. Toyoda[6], A. Fujiyama[6], R. Kuwano[7], K. Hara[7], M. Nishizawa[7], J. Goto[1], S. Tsuji[1]*. 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Department of Neurology, Mie University, Mie, Japan; 3) Department of Medical Welfare, Suzuka University of Medical Science, Mie, Japan; 4) Department of Neurology, Kansai University of Health Science, Osaka, Japan; 5) Department of Computational Biology, Univ Tokyo, Tokyo, Japan; 6) Comparative Genomic Laboratory, National Institute of Genetics, Shizuoka, Japan; 7) Brain Research Institute, Niigata University, Niigata, Japan.

[Background] ALS/PDC is a neurodegenerative disorder characterized clinically by a combination of upper and lower motor neuron involvement, parkinsonism, and dementia, and neuropathologically by wide-spread neurofibrillary tangles in the central nervous system. ALS/PDC has been described to be prevalent in the island of Guam, southern West New Guinea, and Kii peninsula of Japan. In Kii peninsula of Japan, there are two major disease foci (southernmost and north eastern parts of the peninsula). Presence of multiplex families has been observed, in particular, in the north eastern region, suggesting involvement of genetic component to the disease. [Method] Twenty six patients and 66 unaffected family members from 12 multiplex families, 15 apparently sporadic patients and 24 unaffected family members, and 27 regional control subjects from the north eastern region and 1 familial patient and 14 apparently sporadic patients in the southernmost region were included in the study. Extensive mutational analyses were conducted employing whole genome resequencing of 7 patients with pathological diagnosis of ALS/PDC. In addition, recently identified repeat expansions in *C9ORF72* was analyzed by repeat-primed PCR analysis. [Results] Whole genome resequencing analysis of 7 patients with the pathological diagnosis of ALS/PDC showed coverages of 35X - 73X. Of 3.5 - 3.7 million SNVs called in each patient, no shared novel nonsynonymous substitution was revealed. Repeat-primed PCR analysis revealed three patients with expansion of hexanucleotide repeats in *C9ORF72*. These patients are from the southernmost region of Kii peninsula. Haplotype analysis revealed an extended shared haplotype spanning 3.3 - 63 Mb, suggesting a fonder effect in this region. [Conclusion] Although *C9ORF72* mutations can explain in part a high prevalence of ALS in the region, the majority of the patients in these two regions cannot be accounted for by the *C9ORF72* mutations. Furthermore, whole genome sequence analysis did not reveal novel nonsynonymous mutations shared among the seven patients, raising various possibilities including genetic heterogeneity, structural variation, and repeat expansion mutation.

1184W

HLA-DQB1*03:02 is associated with narcolepsy in the Japanese population. *T. Miyagawa[1], H. Toyoda[1], A. Hirataka[1], SS. Khor[1], M. Yamasaki[1], Y. Honda[2], M. Honda[2,3], K. Tokunaga[1]*. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Somnology, Tokyo Medical University, Tokyo, Japan; 3) Sleep Research Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan.

Narcolepsy, a sleep disorder characterized by excessive daytime sleepiness, cataplexy, and rapid eye movement (REM) sleep abnormalities, is tightly associated with human leucocyte antigen (HLA)-DQB1*06:02. Almost all the patients carry HLA-DQB1*06:02. Since HLA-DQB1*06:02 allele is common in the general populations (10-30%), it has been suggested that it is almost necessary but not sufficient for the development of narcolepsy. To investigate the influence that additional HLA-DQB1 alleles have on susceptibility or resistance to narcolepsy, We examined HLA-DQB1 in 625 Japanese narcoleptic subjects and 1,418 Japanese control subjects The strongest association was with HLA-DQB1*06:01 ($P = 2.2\times10^{-10}$, OR = 0.37) as reported in previous studies. We also found additional predisposing effects of HLA-DQB1*03:02 ($P = 2.7\times10^{-7}$, OR = 1.93) as the second hit in this study. A conditional analysis controlling for the effect of HLA-DQB1 revealed an independent association with HLA-DPB1*05:01 in narcolepsy ($P = 1.8\times10^{-3}$, OR = 1.44). We also performed case-control analyses of HLA-DQB1 for narcolepsy without cataplexy (n = 110) and idiopathic hypersomnia without long sleep time (n = 82). Predisposing effects of HLA-DQB1*06:02 ($P = 7.3\times10^{-9}$, OR = 2.81) and protective effects of HLA-DQB1*06:01 ($P = 2.2\times10^{-3}$, OR = 0.50) were observed in narcolepsy without cataplexy, as with narcolepsy. No significant association was seen between idiopathic hypersomnia without long sleep time and HLA-DQB1 alleles. These results indicate complex HLA associations contribute to the genetic predisposition to narcolepsy and narcolepsy without cataplexy.

1185T

Association between the dopamine D4 receptor (*DRD4*) and political ideology in a large Singapore Han Chinese sample. *M. Monakhov[1], S.H. Chew[1], R.P. Ebstein[2].* 1) Economics Dep't., National University of Singapore, Singapore; 2) Psychology Dep't., National University of Singapore.

The liberalism - conservatism ideological divide has become pervasive in American politics viz., red and blue states, and understanding the determinants of this continuing conflict is of keen interest not only to political scientists and psychologists, but also to the media and the public at large. Importantly, there are marked individual differences in political ideology that have been attributed to both dispositional and situational factors. In addition to situational factors contributing to political orientation, accumulating evidence shows that social attitudes are partially heritable suggesting that genes may contribute to individual differences in liberalism - conservatism. A specific gene polymorphism, the dopamine D4 receptor (*DRD4*) exon III VNTR was recently identified by Fowler and his group as provisionally contributing to individual differences in political ideology, but contingent on the subject's number of friends. By leveraging our ongoing investigation of economic decision-making, we had the opportunity to undertake an independent replication of the association between *DRD4* and political ideology in a large sample of ~1,800 Han Chinese university-students in Singapore. We employed the same self-report question, as did Fowler's group, to measure political ideology and demonstrate an association between the *DRD4* exon III repeat region and ideology for students who grew up in a singular Singaporean political culture and are characterized by a distinctive allele distribution compared to their American counterparts. In the combined male and female sample, carriers of *DRD4* exon III VNTR genotype 4R/4R reported more conservative political orientation, compared to all other genotypes (ordered logit coeff. = -0.18, p = 0.04, N = 1803). The association was evident also in an additive genetic model (regression of political attitude on number of 4R alleles in the genotype, coef = -0.15, p=0.027). The association was observed only in females (coeff.=-0.385, p=0.002, N=901) and not in male subjects. Cliff's delta (effect size measure for ordinal data) was 0.057 in combined sample and 0.11 in females subsample. Similar to the first study by Fowler's group, we also observed some evidence that the gene association depends on subject's number of friends. Finally, we have evidence that the main effect of DRD4 on political ideology in women is mediated in part by the NEO-PI-R personality trait of Neuroticism (Sobel test: p=0.035).

An approach to complex disease modifier genes and mouse-to-human translation: transcriptome analysis of mouse strains reveals Alzheimer disease modifier gene. *T. Morihara[1], N. Hayashi[1], H. Akatsu[2], M. Silverman[4], M. Yokokoji[1], N. Kimura[5], M. Sato[1], K. Kamino[3], Y. Yamagichi[6], T. Tsunoda[7], T. Tanaka[1], M. Takeda[1].* 1) Psychiatry, Osaka University, Suita, Osaka, Japan; 2) Choju Medical Institute, Fukushimura Hospital, Toyohashi-shi, Aichi, Japan; 3) National Hospital Organaization Yamato Mental Medical Center, Nara, Japan; 4) Simon Fraser University Vancouver Cabada; 5) Laboratory of Disease Control, Tsukuba Primate Research Center, National Institute of Biomedical Innovation Tsukuba, Japan; 6) Tohoku University, Sendai, Japan; 7) Riken, Yokohama, Japan.

Background: Alzheimer's disease (AD) is a common complex disease and characterized by the accumulation of Abeta in brain. To identify Abeta modifier gene(s) efficiently, we postulated that combining distinct mouse strains and model mice with transcriptomics would have a synergistic effect and minimize the drawbacks encountered in approaches like genome-wide association studies (GWAS), human transcriptome studies and mouse quantitative trait locus (QTL) analysis. Methods: To avoid detecting secondarily affected genes by Abeta, we used non-Tg mice in the absence of Abeta pathology and selected candidate genes differently expressed in the certain strain. We also prepared AD model (APP-Tg) mice with mixed genetic backgrounds. APP Tg mice were crossed onto three different strains, C57BL6 (B6), SJL and DBA/2 (DBA). The levels of Abeta in the cortex were measured by ELISA. The levels of mRNA in the hippocampus were measured using Illumina Mouse-Ref-8 (40 arrays) and QPCR. SNPs in mice with mixed genetic background were analyzed by TaqMan assay. We also measured the total and splice variant E levels of KLC1 in human brain (14 control and 10 AD) and lymphocyte (17 control and 47 AD). The functional analysis of the identified gene is performed using transfected neuroblastoma cells. Results: Abeta accumulation levels in mice with DBA rich genetic backgrounds were drastically lower, less than one third of those in SJL or B6 rich genetic background (e.g. APP Tg mice whose 75% genetic background came from DBA had only 15% Abeta40 and 32% Abeta42 of those with 69% SJL and 31% B6 genetic background.) To identify the gene(s) which control Abeta accumulation, we performed transcriptomics in the mouse brains. QPCR analysis confirmed the correlation between the levels of identified gene and Abeta (Pearson's product-moment correlation R2=0.33, p<0.0001). Genomic analysis in identified gene also supported these findings. Because the transcriptome of brain is considerably conserved between species, we continued with our transcript analysis approach to examine whether the findings in mice can be translated to humans. We observed that the mRNA levels of identified gene were elevated in AD brain (+30.7%, p=0.0096).

Expression of neurotransmitter receptors and regulators genes in peripheral blood of a drug-naïve first-episode psychosis sample before and after antipsychotic treatment. *M.L. Santoro, V.K. Ota, C.S. Noto, A. Gadelha, P.N. Silva, M.I. Melaragno, M.A.C. Smith, Q. Cordeiro, R.A. Bressan, S.I. Belangero.* Federal University of Sao Paulo, Sao Paulo, Brazil.

The psychotic symptoms in Schizophrenia usually manifest in the late adolescence and early adulthood. The investigation of patients during their first episode of psychosis (FEP), particularly before they take any antipsychotic medication, could be especially helpful to disentangle the biological underpinnings of disease onset, progression and the antipsychotic effects. In this way, our aim was to carry out an expression profiling study comparing: 1) drug-naïve FEP patients (n=10) and healthy subjects (n=9); and 2) drug-naïve FEP patients before and after (n=10) 8 weeks of risperidone treatment. Blood samples were collected and RNA was isolated and reverse-transcribed to cDNA. To verify gene expression we used PCRarray technology, which assesses expression of 84 neurotransmitter receptor and regulatory genes plus five housekeeping genes. We considered as a detectable level of expression those genes with ΔCt < 35 - HKG (housekeeping genes) geometric mean of each group sample. We were able to identify three groups of genes: A, genes not expressed in any group (14 genes); B, genes not expressed in some groups group (10 genes); and C, genes expressed in all groups (55 genes). For group C, we performed Mann-Whitney U test (FEP×Control) or the Wilcoxon test (FEP before × after treatment) and Bonferroni correction for multiple comparisons, and for group B we used Fisher exact test, in order to find genes that are expressed only under a specific condition. After Bonferroni correction, none of the associations remained for the group C of genes (p > 0.009). Concerning group B, we found that PROKR1 expressed preferentially in drug-naïve FEP patients compared to the FEP patients after treatment (p=0.02), and with a tendency between FEP and controls (p=0.07). Our results suggest that treatment with risperidone may decrease expression levels of PROKR1, returning to undetectable expression in FEP patients after treatment such as the control group. However, this gene has not been investigated in psychiatric disorders, and further studies are needed to investigate the role of the prokineticins in antipsychotic treatment. These present data are relevant in terms of cost and effectiveness to studies of gene expression. PROKR1 was expressed only in FEP group, but not in others, indicating that its expression could be regulated by the psychosis condition or risperidone treatment.

1188T

The cerebral glucose transporter SLC45A1 is mutated in individuals with non-syndromic intellectual disability and epilepsy. *M. Srour[1,2], N. Shimokawa[3], F.F. Hamdan[1], S. Dobrzeniecka[4], G.A. Rouleau[5], C. Poulin[2], J.L. Michaud[1].* 1) Sainte-Justine Hospital Research Center, Montréal, H3T 1C5, Canada; 2) Division of Pediatric Neurology, Montreal Children's Hospital-McGill University Health Center, Montreal, H3H 1P3, Canada; 3) Department of Integrative Physiology, Gunma University Graduate School of Medicine, Gunma 371-8511, Japan; 4) CHUM Notre-Dame Hospital Research Center, Montreal, H2L 2W5, Canada; 5) Montreal Neurological Institute, McGill University, Montreal, H3A 2B4, Canada.

We have identified a consanguineous Lebanese family with two sisters affected with moderate non-syndromic intellectual disability and epilepsy of unknown etiology. SNP genotyping was performed in the two affected sisters as well as in their unaffected sibling. We identified 7 regions larger than 1Mb that were homozygous in the two affecteds but not in the unaffected sister. Whole exome sequencing was performed in one affected individual. The exome dataset was analyzed by looking for homozygous rare (<0.5% minor allele frequency) coding and splicing variants found in the candidate homozygous regions. We excluded variants that did not segregate with the phenotype in the family or that were found in 95 ethnically-matched controls. Of the remaining variants, only one missense variant in *SLC45A1* (c.C629T/ p.A210V) was predicted damaging by Polyphen-2 and mutation taster. *SLC45A1* encodes a glucose transporter that has only recently been characterized. Slc45a1 is highly expressed in the brain of mice, is induced after hypercapnia and mediates glucose uptake along the pH gradient. We show that *Slc45a1*-transfected COS-7 cells carrying the same c.C629T (p.A210V) mutation exhibited a 40-50% decrease in intracellular glucose uptake, suggesting that the mutation affects the function of the Slc45a1 transporter. Mutations in another cerebral glucose transporter, *GLUT1*, are implicated in neurologic disease and are well known to result in epilepsy with variable degrees of intellectual disability, or movement disorders. Our results suggest the possibility of specific treatment in the form of a ketogenic diet for the family, and implicate for the first time *SLC45A1* in human disease. Identification of additional similarly affected families will be necessary to establish *SLC45A1* as a neurodevelopmental disease gene. Collaborations towards this effort are welcome.

1189F

Adducin function is essential for sustained changes in neuronal activity upon learning. *V. Vukojevic[1,2], F. Peter[1,2], P. Demougin[1,2], N. Hadziselimovic[1,2], J.-F de Quervain[2,3,4], A. Papassotiropoulos[1,3,4], A. Stetak[1,3,4].* 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 2) University of Basel, Department Biozentrum, Life Sciences Training Facility, Klingelbergstrasse 50/70, 4056 Basel, Switzerland; 3) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 4) University of Basel, University Psychiatric Clinics, Wilhelm Klein-Strasse 27, 4055 Basel, Switzerland.

Identifying molecular mechanisms that underlie learning and memory is one of the major challenges in neuroscience. Previously, we have reported that genetic variability of the human ADD1 gene is significantly associated with episodic memory performance in healthy young subjects. Taken the advantages of the nematode Caenorhabditis elegans, we have shown that α-adducin is required for consolidation of synaptic plasticity, for sustained synaptic increase of AMPA-type glutamate receptor (GLR-1) content and altered GLR-1 turnover dynamics. ADD-1, in a splice- form- and tissue-specific manner, controlled the storage of memories presumably through actin-capping activity (Vukojevic et al, 2012). In the present work, we further investigated the effects of adducin dependent changes on neuronal activity during synaptic transmission. With the help of genetically encoded calcium indicators (GECIs) we visualized the neuronal activity in vivo in defined neuronal populations. Specifically, we monitored calcium currents in neurons crucial for avoidance behavior, especially in AVA and RIM neurons that controll activation and inhibition of reversals. Taken together, the method implemented enabled us to get the insight of function and integration at the level of a single neuron. Moreover, we were able to caught in vivo, a single neuronal cell in learning and memory formation. Remarkably, in add(lf) mutants the learning phase induced changes in AVA and RIM neuronal activity fail to be consolidated after 30 minutes. Therefore we were also capable to investigate in vivo the role of neurons in memory storage. These findings further support the role of ADD-1 in the stabilization of synapses, changes in GLR-1 dynamics and finally modulations of neuronal activity patterns. All together, our results suggest that the lack of adducin in AVA interneuron has consequences on synapse remodelling and changes of neuronal activity that are functionally reflected also in other members of the motor network.

1190W

Influence of Alzheimer's disease genes on cognitive decline: the Guangzhou Biobank Cohort Study. *S.S. Cherny[1], H.S. Gui[1], L. Xu[2], P.C. Sham[1], C.Q. Jiang[3], T.H. Lam[2], B. Liu[3], Y.L. Jin[3], T. Zhu[3], W.S. Zhang[3], G.N. Thomas[4], K.K. Cheng[4].* 1) Psychiatry & Centre for Genomic Sciences, Univ Hong Kong, Pokfulam, Hong Kong; 2) Department of Community Medicine, School of Public Health, University of Hong Kong, Hong Kong; 3) Guangzhou No. 12 Hospital, Guangzhou, China; 4) Public Health, Epidemiology, and Biostatistics, University of Birmingham, Birmingham, UK.

Mild cogntive impairment is a reliable predictor of the future onset of clinical dementia. In Hong Kong, the prevalences of very mild dementia and mild dementia in people aged 70 years and older were estimated to be 8.5% and 8.9%, respectively, in a population-based sample. For those subjects with a clinical diagnosis of dementia, Alzheimer's disease (AD) was the most common likely cause (73.5%), with 22.4% having vascular dementia (VaD), and 3.9% dementia with symptoms of Parkinson's disease. In addition to the impact on the patient and their family members, the economic cost of AD has been estimated to range from around $48,000 to $585,000 per patient per year around the world. To identify risk factors involved in cognitive decline, we selected 1325 extreme cognitive decline subjects and 1083 matched controls from Guangzhou Biobank Cohort Study (GBCS) for DNA genotyping at 30 known AD associated SNPs. Full information maximum likelihood (FIML) regression was adopted to analyse quantitative cognitive change scores, while multiple logistic regression was used to investigate the genetic effect of those variants on dichotomous phenotype. No allelic association was found by individual variant analysis. At the level of genotypic association, not only did we confirm that the APOE $\varepsilon 4$ homozygote can significantly predict cognitive decline ($p < 0.05$), but also revealed carriers of the ACE rs1800764_C allele are more likely suffer decline than non-carriers, especially in the samples without college education. However, these effects together only explain 1.3% of the phenotypic variance, and suggest that AD risk variants/genes are only minor predictors of cognitive decline in these Chinese samples.

1191T

Fine Mapping and Association Analysis of Candidate Genes for Autism Spectrum Disorder and Language Impairment in the NJLAGS Sample. *A. Hare[1], A. Seto[1], J. Flax[1], M. Azaro[1], S. Buyske[2], C. Bartlett[3], L. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Statistics, Rutgers University, Piscataway, NJ; 3) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and The Ohio State University, Columbus, OH.

Over the past decade, the New Jersey Language and Autism Study (NJLAGS) has collected families that contain one individual with autism and another individual with Specific Language Impairment (SLI) but not autism. This is the first study of its kind to investigate the share genetics between autism and SLI. Using a comprehensive neuropsychological testing battery, three categorical phenotypes: language impairment (LI), reading impairment (RI), and social impairment (SRS-DT), and two quantitative phenotypes: social impairment (SRS-QT) and obsessive-compulsive behaviors (YBOCS) were developed. Autism proband scores were included in the quantitative phenotypes and all categorical phenotypes included autism diagnosis as impaired for language, reading, or social skills, respectively. A previous study identified linkage in these families to 13q21.2 (YBOCS), 14q32.31 (SRS-QT), 15q25.1 (LI), 15q26.2 (SRS-DT), and 16p12.3 (RI). As genome-wide association did not reveal strong evidence for association, Ingenuity Pathway Analysis (IPA) was used to select candidate genes for fine mapping analysis. Four groups were analyzed in IPA: communication impairment (LI + RI), social impairment (SRS-DT + SRS-QT), restricted/repetitive behaviors (YBOCS), and an overall autism model (LI + RI + SRS-DT + SRS-QT + YBOCS). Genes in each analysis group were given a score that corresponded to the number of relevant functions identified by IPA. Seven of the highest-ranking genes were selected for association analysis from the LI, RI, and SRS-DT linkage regions: AKT1, JAG2, PTPN9A, SEMA7A, NTRK3, FES, and SCCN1B. Each gene was fine mapped using an oligonucleotide ligation assay and was analyzed for association using the KELVIN framework. Each gene was analyzed for association to its respective phenotype with and without the inclusion of autism diagnosis and for autism diagnosis only. JAG2 yielded the strongest evidence for association (PPLD|L = 5%) when autism diagnosis was included. When autism diagnosis was excluded, NTRK3 yielded the strongest evidence for association (PPLD|L =7%). For autism diagnosis only, no evidence for association was detected. The lack of strong evidence for association provides support for a role of rare variants in autism susceptibility and their role in the shared genetics between autism and SLI.

1192F

***TRPM8* variants that protect from migraine make individuals less susceptible to cold pain.** *M.A. Kaunisto[1,2], E.J. Holmström[2], V. Anttila[1,3,4,5], M. Kallela[6], E. Hämäläinen[1,5], A. Stubhaug[7], M. Wessman[2,1], C.S. Nielsen[8], E. Kalso[9,10], A. Palotie[1,4,5].* 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 2) Folkhälsan Research Center, Helsinki, Finland; 3) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 5) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom; 6) Department of Neurology, Helsinki University Central Hospital, Helsinki, Finland; 7) Division of Emergencies and Critical Care, Oslo University Hospital, Rikshospitalet, Oslo, Norway; 8) Division of Mental Health, Norwegian Institute of Public Health, Oslo, Norway; 9) Institute of Clinical Medicine, University of Helsinki, Finland; 10) Pain Clinic, Department of Anaesthesia and Intensive Care Medicine, Helsinki University Central Hospital, Finland.

Several common variants predisposing to migraine have recently been identified. The most consistently associating variants lie within or around *TRPM8*. TRPM8 is a ligand-gated cation channel that plays a key role in sensing cold pain. Although the function of this channel has been intensively studied, no evidence of *TRPM8* variants affecting cold pain sensitivity exists.

To elucidate the putative role of *TRPM8* in cold pain, we genotyped two migraine-associated SNPs, rs10166942 and rs17862920, in two study cohorts. First of these, the BrePainGen study cohort consists of 1,000 Finnish patients undergoing breast cancer surgery and tested for experimental pain before surgery. From the second cohort, the population-based Tromsø Study, 2,369 Norwegian individuals tested for experimental cold pain were studied. Cold pain was measured in both cohorts by immersing the hand to circulating +3ºC water for the maximum time tolerated by the study subjects. Pain intensity was assessed at regular intervals with a 0 to 10 Numerical Rating Scale (NRS). Association between *TRPM8* SNPs and NRS values as well as time to withdrawal was examined with linear regression analysis. Sex, age, BMI and anxiety status were included as covariates. The primary phenotype was the NRS value reported soon after the beginning of the test (at 15 s or 13 s, depending on the cohort).

Meta-analysis combining the results of these two cohorts showed that both of the SNPs were associated with cold pain sensitivity at the specified time-point (p=0.001, beta=-0.24 for rs10166942 and p=0.004, beta=-0.3 for rs17862920, assuming an additive model). The carriers of the minor alleles reported less intense cold pain than the non-carriers which is in line with the fact that the minor alleles of these SNPs are known to protect from migraine. The mean NRS of the homozygous rs17862920 T-allele carriers was 1.2 scores lower, compared to the rest of the subjects.

When the later time-points were examined, it became evident that the effect was only seen in the beginning of the test. Furthermore, there was no evidence of association between the SNPs and cold pain tolerance. This suggests that the difference is in the early sensory processing of cold pain. Based on these results it seems possible that rather than being migraine specific susceptibility variants these SNPs may have a role in more general pain sensitivity mechanisms.

1193W

The Role of CNTNAP2 in a Developmental Language Disorder and Potential Mechanisms. *N. Li[1], S.L. Wolock[1], S.A. Petrill[2], J.F. Flax[3], A.S. Bassett[4], L.M. Brzustowicz[3], C.W. Bartlett[1].* 1) The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 2) Department of Psychology, The Ohio State University, Columbus, OH; 3) Genetics, Rutgers University, Piscataway, NJ; 4) Department of Psychiatry, University of Toronto, Toronto CA.

Background: The purpose of this study was to assess CNTNAP2 in a sample of extended pedigrees ascertained for specific language impairment (SLI). SLI is a developmental failure to learn vocabulary and grammar at the expected rate despite normal cognition, speech patterns and hearing. CNTNAP2 is associated with different behavioral disorders including SLI and autism, as well as with normal language development. However, studies to date have focused on SNPs across the gene without regard to functional potential. Here, we performed three studies to examine the potential function of CNTNAP2 in language development. Methods: STUDY 1: We used dense SNPs in 21 nuclear and extended SLI families from the U.S. and Canada. Nine language and reading phenotypes were tested for linkage/association. STUDY 2: We conducted a meta-analysis of 798 subjects from five published human brain expression Quantitative Trait Loci (eQTL) studies with SNPs imputed to the 1000 Genomes reference haplotypes. STUDY 3: We performed follow-up analysis of SNPs in 106 human brain samples (frontal lobe) from our lab. Results: STUDY 1: Using the quantitative trait analysis of a standardized language assessment, we observed a multipoint posterior probability of linkage (PPL) of 85% (MOD=4.7). Analysis of a categorical written language impairment diagnosis yielded a PPL of 40%, and similar results occurred with the quantitative trait underlying the categorical written language impairment trait. There was no linkage with intelligence in this sample. STUDY 2: Two SNPs directly underneath the multi-point linkage peak were also found to be eQTLs for CNTNAP2 expression in frontal cortex with posterior probability of linkage disequilibrium (PPLD) values from 10%-39%. STUDY 3: Follow-up analysis using qPCR on an in-house collection of brain samples also indicated three SNPs that were potentially eQTLs for CNTNAP2. Conclusions: While CNTNAP2 is associated with multiple neurocognitive phenotypes, we observed no evidence that CNTNAP2 influences general intelligence. Furthermore, the linkage peak in our samples appears to be driven by one or more eQTLs within CNTNAP2 that influence expression in a genotype dependent way. Studies to isolate the causal SNP(s) that actually influence expression levels are warranted.

1194T

Association of Language Impairment with Language, Reading, and ADHD candidate genes. *S. Smith[1], J. Gayan[2], M. Rice[3].* 1) Dept Pediatrics, Univ Nebraska Med Ctr, Omaha, NE; 2) Bioinfosol, Sevilla Area, Spain; 3) Dept. Speech, Language, Hearing, Univ Kansas, Lawrence, KS.

Specific language impairment is a significant developmental disorder in language acquisition occurring in about 7% of 6-year-olds in the US. Estimates of heritability vary based on the severity, with heritabilities greater than 0.5 for children who had been seen by a speech pathologist. We previously reported association of LI with SNPs in a Reading Disability candidate gene, KIAA0319, and with a language candidate gene, FOXP2. The current study expands the coverage of these and additional genes, with concentration on SNPs in regulatory regions. We genotyped 422 SNPs in 23 candidate genes in 293 people from 62 nuclear families with a proband with SLI. Probands were between 3 and 12 years old and were ascertained through school-based speech pathologists, with diagnosis confirmed with standardized testing appropriate for the child's age. Their siblings between ages 2 and 17 were also recruited and tested. All children were given an additional battery of 9 tests covering reading and language abilities. Quantitative association analysis was done with the PBAT program implemented by SVS (Golden Helix) testing the hypothesis of association in the presence of linkage since these were candidate genes with some previous evidence for relationship with LI or a related disorder. Several genes and phenotypes showed association with multiple SNPs. The greatest evidence for association was in the expected genes FOXP2, CNTNAP2, and KIAA0319, but additional evidence was found with DRD2, BDNF, and DBH. The strongest results were with FOXP2. The most significant SNPs were concentrated at the 5' end of the gene, with the haplotype rs923875.rs7785744.rs73716355 (C:T:G) at a nominal p=0.000074 for the Gray Oral Reading phenotype. For CNTNAP2, the haplotype rs12703865.rs9640492.rs10952672 (A:G:A) showed a nominal p=0.0013 for a measure of vocabulary growth. For KIAA0319, the strongest haplotype was not in the same region that is generally associated with reading: rs807533.rs2760179.rs807509 (G:G:C) p=0.00098 for a reading phenotype; however, another haplotype was located within the putative reading disability region: rs3087943.rs2294689.rs2143340 (G:C:T) with the Gray Oral reading phenotype, p=0.0037. We also replicated association with PCDH9 on chromosome 13 with 3 SNPs, all with the TEGI grammar phenotype: rs2324908 (p=0.0084), rs4883774 (p=0.0094), and rs9564308 (p=0.0094). An additional 21 families has been genotyped on the same platform and will provide additional data.

1195F

Molecular delineation of the 1p36.3 locus and candidate gene resequencing in 363 patients with polymicrogyria. *S. Beijnsberger[1], G.L. Carvill[1], S.F. Berkovic[2], I.E. Scheffer[2], W.B. Dobyns[3], H.C. Mefford[1].* 1) Department of Pediatrics, Division of Genetic Medicine, University of Washington, Seattle, WA 98195, USA; 2) Epilepsy Research Center and Department of Medicine, University of Melbourne, Austin Health, Australia; 3) Pediatrics and Neurology, University of Washington, Seattle, WA, 98195, USA.

Polymicrogyria (PMG) is characterized by an abnormal folding pattern of the cortex, which results in an excessive number of gyri and abnormal cortical lamination. PMG occurs in several forms and causes a wide spectrum of phenotypes, ranging from minimal neurologic manifestations to severe intellectual disability and refractory epilepsy. Mutations in a small number of genes have been shown to cause PMG, including *TUBA1A*, *TUBB5*, *TUBB2B*, *TUBB3* and *WDR62*. Furthermore, copy number variants (CNVs) at several genomic loci have been consistently linked to PMG, including the 1p36.3 locus. The 1p36.3 critical interval for PMG was previously localized to the terminal 4.8Mb of 1p. Using genome-wide array-CGH we recently detected an interstitial 4Mb *de novo* 1p36.3 deletion in a patient with bilateral perisylvian PMG. Importantly, this deletion partially overlaps with the known 1p36.3 critical interval and allowed us to refine this PMG locus to a 2.3Mb region (chr1: 2.5-4.8Mb) encompassing 12 genes. We selected six candidate genes from this region for targeted resequencing, based on gene function and expression in the brain: *ACTRT2*, *AJAP1*, *ARHGEF16*, *TP73*, *TPRG1L* and *WRAP73*. Using molecular inversion probes for targeted capture followed by multiplexed next generation sequencing we are screening 363 patients with PMG, for mutations in these genes. To date we have sequenced 118/363 probands with 90% of the target base pairs sequenced at >25X required for reliable variant calling. We have identified eight non-synonymous variants in four candidate genes (*TP73*, *WRAP73*, *ARHGEF16* and *AJAP1*) that are not present in 6500 control exomes. Segregation analysis of these variants to determine whether these variants arose *de novo* and are therefore likely causative for PMG is underway. This targeted resequencing approach and segregation analysis will be performed for the remaining 245 probands to identify *de novo* mutations in our candidate genes. Furthermore, we are expanding our targeted resequencing approach to include candidate genes from additional CNV loci and exome sequencing studies. In conclusion, we have reduced the size of the 1p36.3 PMG region more than twofold, and present both candidate genes and variants for identification of the causative PMG gene at this locus.

1196W

Application of customized CGH-array for mGluR genes in Attention Deficit/Hyperactivity Disorder (ADHD). *R. Pellegrino, C. Kao, L. Vazquez, D. Hadley, A. Kini, J. Glessner, H. Hakonarson.* CAG, Children s Hospital of Philadelphia, Philadelphia, PA.

The purpose of the project is to perform higher-resolution genotyping by aCGH on subjects with autism and ADHD to determine the prevalence of CNVs in genes within the metabotropic glutamate receptor (mGluR) network. Recently,Center for Applied Genomics(CAG)has found genes in this network were enriched for CNVs in patients with ADHD and autism (data not published). The analysis was based on genotyping on Illumina SNP arrays(550–610K). The CNV analyses revealed that ~10% of individuals with ADHD and ~2–3% of individuals with autism have CNVs within genes in the mGluR network. However, the resolution of the analyses was limited by the spacing of the probes in these SNP arrays (~4–6kb between probes)and potentially important CNVs that were missed due to lack of sensitivity of the arrays. Therefore, we designed a custom array for comparative genomic hybridization (CGH) with dense coverage (~300–400bp between probes) within genes in the mGluR network as well other genes implicated in ADHD and other mental disorders. The ADHD and autism cohort within CHOP that were used in the previous analyses will be systematically screened again with the custom CGH array for mGluR network mutations. Importantly, those subjects with these mGluR network mutations could represent a distinct subset where the etiology of their disorder arises from mGluR dysfunction. This potential discovery could lead to responsive therapeutic with mGluR modulators.

1197T

***FOXG1* is implicated in abnormal brain development in two unrelated cases with 14q aberrations.** *G. Macintyre[1], K. Schlade-Bartusiak[1], M.L. Martínez-Fernández[2], M.L. Martinez-Frías[2], R. Arteaga[3], P. O'Brien[4], M.A. Ferguson-Smith[4], D.W. Cox[1].* 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Research Centre for Congenital Anomalies (CIAC), CIBER de Enfermedades Raras (CIBERER), Instituto de Salud Carlos III, Madrid, Spain; 3) Neuropediatrics service, Hospital Universitario Marques de Valdecilla, Santander, Spain; 4) Centre for Veterinary Science, University of Cambridge, Cambridge, UK.

We have characterized two cases of *de novo* 14q rearrangements on the proximal long arm of chromosome 14, each associated with abnormal brain development. The first is a *de novo* inversion in a male, who presented at 6 months with microcephaly, hypotonia, epilepsy, developmental and psychomotor delays, and partial agenesis of the corpus callosum. Weight and length were normal. At 11 months, the patient exhibited partial, generalized seizures. At 20 months, developmental delay was evident, weight 10.5Kg (25th centile), length 81cm (25th centile) and occipital frontal circumference (OFC) = 43cm (<3rd centile). Karyotype and FISH analyses revealed a *de novo* paracentric inversion: 46,XY,inv(14)(q12q21.3). The proximal break lies between genes, while the distal break is in a gene-rich area and may cause a gene disruption. Candidate genes for disruption include *KLHDC1*, *KLHDC2*, *SOCCAG1* and *ARF6*. However, lymphoblast gene expression analyses indicated altered expression of several other genes compared to controls, including genes adjacent to the proximal breakpoint at 14q12: *FOXG1*, position unchanged, is upstream of the proximal breakpoint and is up-regulated in patient lymphoblasts, while *ARHGAP5* is displaced to a more distal location on chromosome 14 as a result of the inversion, and is down-regulated. FOXG1, originally known as Brain Factor 1 (BF1), is essential to normal mammalian brain development and *FOXG1* gene deficits have been associated with corpus callosum defects, as well as an atypical Rett syndrome. Of additional interest, is the altered regulation of *ARHGAP5*, encoding RhoGAP5/p190B, as p190B deficits have previously been associated with altered neuronal migration, as well as major forebrain and corpus callosum defects in mice. The second case involves the posthumous CGH characterization of a 4.2Mb deletion within 14q12 (46,XY,del(14)(q12q12)). The patient exhibited cyanosis and hypotonia, with agenesis of the corpus callosum. Several genes were found to be deleted including *NOVA1*, *FOXG1*, and *PRKD1*. Our data from two unrelated cases support published findings from various authors that identify the transcription factor, FOXG1, as a protein essential for the normal development and function of the brain.

1198F

Uncovering Obsessive-Compulsive Disorder risk genes using a high-resolution genome-wide CNV approach. *M.J. Gazzellone[1,2], S.M. Shaheen[3], B. Li[3], R.J. Schachar[3], A.C. Lionel[1,2], B. Thiruvahindrapduram[1], M. Uddin[1], K.D. Fitzgerald[4], C.R. Marshall[1,2], D.R. Rosenberg[5,6], N. Soreni[7], G.L. Hanna[4], P.D. Arnold[3,8], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics and Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 3) Department of Psychiatry and Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Psychiatry, University of Michigan Medical School, Ann Arbor, MI, United States; 5) Department of Psychiatry and Behavioral Neurosciences, Wayne State University, Detroit, MI, United States; 6) The Children's Hospital of Michigan, Detroit, MI, United States; 7) Department of Psychiatry and Behavioural Neurosciences, Faculty of Health Sciences, McMaster University, St. Joseph's Healthcare, Hamilton, Ontario, Canada; 8) Department of Psychiatry and Institute of Medical Science, Toronto, Ontario, Canada.

Background: Obsessive-Compulsive Disorder (OCD) is a neuropsychiatric condition characterized by persistent unwanted thoughts (obsessions), ritualized actions and repetitive behaviors (compulsions), and excessive anxiety. It is common (2% lifetime prevalence) and often presents during childhood. Family and twin studies suggest that genetic factors underlie the pathology of OCD, particularly when the symptoms begin in childhood. To date, genetic investigations have focused primarily on candidate gene, genetic linkage, and genome-wide association approaches, but there have been no published copy number variation (CNV) studies. Findings reported to date explain only a fraction of the genetic architecture of OCD. Our approach seeks to build upon the foundation established in studies of other neuropsychiatric conditions which posit that rare inherited and *de novo* CNVs may elevate disorder risk. We aimed to establish whether this type of variation contributes to the pathogenesis of OCD. **Methods:** We undertook a genome-wide CNV scan using two high-resolution microarrays: the Affymetrix CytoScan HD array and the Illumina OMNI 2.5M Quad array (both featuring around 2.5 million probes). In stage one of the project, DNA was obtained from 100 affected children and their parents and run on the CytoScan HD array. We then conducted a second scan of unrelated probands on either the CytoScan HD array (50 probands) or the OMNI 2.5M Quad array (112 probands). We identified high-confidence CNVs by requiring their identification by two or more CNV detection algorithms. Rare variants were identified by comparing the stringent CNV calls from our case cohorts to stringent calls obtained from population-based controls genotyped on the same array (873 CytoScan HD controls and 2,988 OMNI 2.5M Quad controls). **Results:** Rare CNVs overlapping genes previously implicated in neuropsychiatric disorders, and absent in the controls, were uncovered in the OCD probands. These include exonic deletions or duplications of genes involved in neuronal migration (i.e. *ASTN2*), synaptic function and signal transmission (i.e. *NLGN1* and *NLGN4X*), and postsynaptic scaffolding in glutamatergic synapses (i.e. *DLGAP1* and *DLGAP2*). In addition, we identified new candidate OCD genes involved in synaptic function or plasticity (i.e. *BTBD9*). Our findings suggest that rare copy number changes contribute to OCD risk and that genes expressed at the synapse may play a role in the onset of OCD when perturbed.

1199W

Family structure is predictive of genetic architecture in autism spectrum disorders. *K. Schmitz-Abe[1,2,4,5,6], M. Chahrour[1,2,3,4,5,6], T. Yu[1,2,3,4,5,6,7], S. Hill[1,2,3,4,5,6], G. Sanchez-Schmitz[8,9], J. Partlow[1,2,3,4,5], B. Barry[1,2,3,4,5], B. Mehta[1], S. Servattalab[1], A. Ngoc Lam[1], C. Walsh[1,2,3,4,5,6], K. Markianos[1,2,5].* 1) Division of Genetics, Department of Medicine, Children's Hospital Boston, Boston, Massachusetts, USA; 2) Manton Center for Orphan Disease Research, Children's Hospital Boston, Boston, Massachusetts, USA; 3) Howard Hughes Medical Institute, Children's Hospital Boston, Boston, Massachusetts, USA; 4) The Autism Consortium, Boston, Massachusetts, USA; 5) Departments of Pediatrics and Neurology, Harvard Medical School, Boston, Massachusetts, USA; 6) Broad Institute of Massachusetts Institute of Technology and Harvard University, Cambridge, Massachusetts, USA; 7) Department of Neurology, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, USA; 8) The Division of Infectious Diseases, Boston Children's Hospital; 9) Harvard Medical School, Harvard University Boston, MA 02115, USA.

Analyses of large autism datasets have provided statistical and functional evidence for the role of rare point mutations and transmitted and de novo copy number variants (CNVs), and offer crucial insights into the diverse genetic mechanisms that can lead to Autism Spectrum Disorders (ASDs). Here we present CNV analysis for a cohort of 183 consanguineous families with one or more children affected with ASD. We provide new insights into the genetic architecture of ASDs as our cohort is uniquely enriched for recessive loss of function variants. We follow up findings and draw comparisons with additional large ASD and control datasets: the Simons Simplex and the Autism Genetic Resource Exchange (AGRE) collections (2,670 affected individuals; 9681 total individuals). Comparing across these cohorts, we demonstrate that ascertainment can lead to selection of different underlying genetic mechanisms causing ASDs. These differences are reflected in metrics such as the affected male:female ratio and the relative contribution of de novo CNVs versus inherited homozygous deletions. Specifically, we find that de novo CNVs play a significant role in non-consanguineous families with a single affected child ($p=0.04$), but a lesser role in multiplex families, and they are no more common in ASD cases than controls in multiplex consanguineous families. In contrast, we present the strongest statistical evidence ($p=0.013$) to date that homozygous deletions, are a major contributor to ASD disease burden in consanguineous families, contributing to as much as 5–10% of cases.

Susceptibility Loci for Pigmentation and Melanoma In Relation to Parkinson's Disease. *J. Dong[1], J. Gao[1], M. Nalls[2], X. Gao[3], X. Huang[4], J. Han[5], A. Singleton[2], IPDGC. IPDGC[6], H. Chen[1].* 1) NIEHS, durham, NC; 2) National Institute on Aging, Bethesda, Maryland; 3) Harvard School of Public Health, Boston, Massachusetts; 4) Pennsylvania State University-Milton S. Hershey Medical Center, Hershey, Pennsylvania; 5) Channing Laboratory, Harvard Medical School, Boston, Massachusetts; 6) International Parkinson's Disease Genomics Consortium (IPDGC).

Objective: To examine potential associations between genetic susceptibility loci for pigmentation or melanoma and the risk for Parkinson's disease (PD). Methods: We examined 13 SNPs from previous GWAS studies on pigmentation or melanoma in relation to PD risk among 808 PD cases and 1,623 controls in the Parkinson's Genes and Environment (PAGE) Study and then a broader selection of 360 SNPs among 5,333 cases and 12,019 controls from the International Parkinson's disease Genomic Consortium (IPDGC). In the PAGE study, we also examined the colors of hair, eye, or skin and melanoma in relation to PD risk. All participants were self-reported Caucasians. Results: As expected, many of these SNPs were associated with pigmentation phenotypes among PAGE participants. However, neither these SNPs nor pigmentation phenotypes were associated with PD risk after adjusting for multiple comparisons. In PAGE, 18 PD cases (2.2%) and 26 (1.6%) controls also had melanoma, resulting in an odds ratio of 1.3 (95% confidence interval: 0.7-2.4). The IPDGC analysis confirmed that none of the pigmentation or melanoma SNPs was associated with PD risk. Conclusions: Our study did not show any association between pigmentation or melanoma related SNPs and the risk for PD.

1201F

Genetic Risk Factors in Utah Pedigrees at High Risk for Suicide. *H. Coon[1], R. Pimentel[2], K.R. Smith[2,3], C. Huff[4], H. Hu[4], L. Jerominski[1], J. Hansen[1], M. Klein[5], W.B. Callor[6], J. Byrd[6], A. Bakian[1], S. Crowell[1,7], W.M. McMahon[1], E. McGlade[1], D. Yurgelun-Todd[1], P. Renshaw[1], T. Grey[6], D. Gray[1].* 1) Dept Psychiatry, Univ Utah, Salt Lake City, UT; 2) Pedigree & Population Resource, Huntsman Cancer Inst., Univ Utah, Salt Lake City, UT; 3) Dept Family Consumer Studies, College Soc Behav Sci, Univ Utah, Salt Lake City, UT; 4) Dept Epidemiol MD Anderson Cancer Center, Univ Texas, Houston, TX; 5) Core Research Facilities, Health Sci Center, Univ Utah, Salt Lake City, UT; 6) UT State Office Medical Examiner, UT Dept Health, Salt Lake City, UT; 7) Dept Psychology, Univ UT, Sale Lake City, UT.

We used unique population-based data resources to identify 22 high-risk extended pedigrees that show clustering of suicide twice to three times that expected from age-sex-cohort adjusted incidence rates that also incorporate pedigree structure. We have studied genetic risk factors in 5 of these large pedigrees each with 17–51 related suicide decedents, 5-9 of which have previously-collected DNA. These decedents were genotyped with the Illumina HumanExome BeadChip. Genotypes were analyzed using the Variant Annotation, Analysis, and Search (VAAST) program package that computes likelihoods of risk variants using the functional impact of the DNA variation, aggregative scoring of multiple variants across each gene, and pedigree structure. We prioritized variants that were: 1) shared across pedigree members, 2) rare in publicly-available sequence data from 1,358 controls, and 3) screened against 258 other Utah suicides not in the pedigrees to eliminate potential false positives. Sequence variants were prioritized statistically and then implicated genes were screened for previous disease associations and functional relevance. Findings included membrane protein genes and several genes with neuronal involvement and/or known associations with psychiatric conditions. Genes implicated in particular pedigrees may be associated with significant co-morbid psychiatric or medical conditions and/or demographic attributes unique to that pedigree. While the study is limited to variants included on the HumanExome BeadChip, these findings warrant further exploration, and demonstrate the utility of this high-risk pedigree resource.

1202W

Association study of BDNF with completed suicide in the Japanese population. *A. Hishimoto[1,2], W. Ratta-apha[1], K. Shiroiwa[1], I. Sora[1].* 1) Dept. of Psychiatry, Kobe Univ Grad Sch Med, Kobe, Japan; 2) Dept. of Psychiatry and Behavioral Science Albert Einstein College of Medicine, Bronx, NY. USA.

Brain-derived neurotrophic factor (BDNF) is involved in neuronal survival, brain plasticity, and neuronal development. Impairment of BDNF has been implicated in the pathophysiology of psychiatric disorders and suicide. Previous reports have provided evidence for an association between a Val66Met single nucleotide polymorphism (SNP) in BDNF and suicidal behavior among various psychiatric disorders. The present study was conducted to investigate the association between BDNF and subjects who completed suicide. The allelic and genotypic distributions of eight SNPs found in BDNF were determined in 307 subjects who completed suicide and 380 normal subjects using a Taqman probe assay. The genotypic and allelic distributions of the selected SNPs did not differ between the completed suicide and normal subjects. In addition, we performed a meta-analysis of the BDNF Val66Met SNP in suicidal behavior and completed suicide using data from the present study as well as seven previously published studies. These results showed that the Met allele of the BDNF Val66Met SNP tended to associate with suicidal behaviors in the Asian population but not with the completed suicide subjects.

1203T

Rare and common variants near CHRNB3-CHRNA6 are associated with cocaine dependence. *B. Sadler[1, 2], G. Haller[1], N. Saccone[1], L. Bierut[1], A. Goate[1], Study of Addiction, Genetics and Environment (SAGE) Collaborators.* 1) Washington University School of Medicine Department of Psychiatry 660 S. Euclid Ave. Saint Louis, MO 63110; 2) Arizona State University School of Human Evolution and Social Change 900 S. Cady Mall Tempe, AZ 85281.

In the U.S.A., cocaine is the second most frequently abused illicit drug. Although there have not yet been large-scale GWAS for cocaine dependence, but the CHRNA3-A5-B4 nicotinic receptor gene cluster on chromosome 15, identified by GWAS to be associated with nicotine dependence, also harbors variants associated with decreased risk for cocaine dependence. Variants within the CHRNA6-B3 gene cluster on chromosome 8 were found to affect nicotine consumption in several GWAS and thus represent intriguing candidate genes for the study of drug dependence. Using genotype data from a GWAS of the Study of Addiction: Genetics and Environment (SAGE) dataset including 2714 European Americans (605 subjects with non-zero scores on the DSM-IV cocaine symptom count and 2109 subjects with scores of zero on the DSM-IV cocaine symptom count), we tested for association of CHRNA6-B3 SNPs with DSM-IV cocaine dependence symptom count. The top SNP for symptom count was rs9298626 ($\beta = 0.528$, $p=7.0\times10{-}4$), although multiple SNPs passed the multiple test correction. To determine whether there was evidence for multiple independently associated variants at the locus contributing to risk for this phenotype, the most significant SNP was added as a covariate in a linear regression model. We find evidence for more than one independent signal within this locus in European Americans for cocaine dependence symptom count. Further, when using only exposed but not addicted individuals as controls, the signal remained. This signal appears to be related to the previously observed association with nicotine dependence in the region. These data suggest that the CHRNA6-B3 locus contains multiple independent variants affecting risk for cocaine dependence symptom count and other drug addictions.

1204F

De novo deletion of 1q21.1 and Xq28 duplication in a family with developmental delay. *K. Ha, H. Cho, L. Layman, H. Kim.* Georgia Regents University, Augusta, GA.

Distal 1q21.1 microdeletion syndrome is a rare contiguous gene deletion disorder with de novo or autosomal dominant inheritance patterns. MECP2 duplication syndrome is an X-linked neurodevelopmental disorder characterized by intellectual disability, global developmental delay, and other neurologic complications including seizures later in life. Patients with these syndromes share some phenotypes such as mild dysmorphic features, cardiac abnormalities and mental retardation. Since these two syndromes are genetically unrelated, it has not been reported for these two different genetic syndromes to occur in the same family. Here we describe two siblings carrying a chromosome 1q21.1 microdeletion and chromosome Xq28 duplication. Using a comparative genomic hybridization (CGH) array, we identified a 1.24 Mb distal heterozygous deletion at 1q21.1 from position 146.5-147.78 Mb resulting in the loss of 12 genes and a 68 Kb deletion within intron 2 of AUTS2 gene at 7q11.22 in a girl with hypothyroidism, short stature, sensory integration disorder, and soft dysmorphic features including cupped ears and a unilateral ear pit. Protein kinase, AMP-activated, beta 2 non-catalytic subunit (PRKAB2) regulating cellular energy metabolism, and Gap junction alpha-5 protein (GJA5), a gap channel protein, might have contributed the short stature, chronic constipation and sensory integration disorder in this patient. We also characterized a 508 Kb duplication at Xq28 encompassing MECP2 in the younger brother referred for hypotonia, poor speech, cognitive and motor impairment. In addition to MECP2, this duplication encompassed several other genes including L1CAM and FLNA that previously reported in other patients with a Xq28 duplication. The parental CGH analysis revealed that the 1q21.1 deletion in the elder sister is de novo, but the Xq28 duplication in the younger brother was inherited from the mother with a normal phenotype, suggesting a recessive pattern of genes involved in this region. We have described the candidate genes and phenotype-genotype relationships in two different chromosome regions of these two syndromes.

1205W

The first familial null mutation of an autism susceptibility gene in Autism Spectrum Disorder. *N. Lambert[1,3], V. Wermenbol[2], B. Pichon[1], S. Acosta[3], J. van den Ameele[3,4], C. Perazzolo[3], D. Messina[2], F. Musumeci[2], B. Dessars[1], A. De Leener[1], M. Abramowicz[1], C. Vilain[1].* 1) ULB Center of Human Genetics, Hôpital Erasme, ULB, Brussels, Belgium; 2) Department of Paediatric Neurology, Hôpital Erasme, Université Libre de Bruxelles (ULB), Brussels, Belgium; 3) Institut de Recherche Interdisciplinaire en Biologie Humaine et Moléculaire (IRIBHM), Université Libre de Bruxelles (ULB), Brussels, Belgium; 4) Department of Neurology, Ghent University Hospital, Ghent, Belgium.

The autism spectrum disorder results from interactions of genetic and environmental factors. Many genes have been described as candidate gene for autism susceptibility. The gene we studied is a candidate gene for autism susceptibility and is implicated in neurodevelopment and social brain circuit, but no mutation of this gene has ever been described. Here, we describe the first case of a familial mutation of this gene, consisting of an interstitial genomic deletion removing exons 12 through 15, causing a frameshift and premature stop codon, with evidence of nonsense-mediated mRNA decay. The heterozygous mutation was associated with autism in one patient and language and social impairment in a sibling. Our observations delineate the phenotypic spectrum associated with a clearly defined, very likely complete loss of function mutation of this gene. Incomplete penetrance in this family was consistent with this gene as a partial susceptibility gene for ASD. Implication of this gene in normal and pathological brain development opens new perspectives for understanding the pathophysiology of autism and for eventual therapeutical clues.

1206T

Use of a custom-designed array-CGH to identify small CNVs in nonsyndromic Autism Spectrum Disorders. *C.M. Ribeiro[1], E.S. Moreira[1], A.L.B. Martins[2], A.G. Morales[1], S.G. Ferreira[1], V.N. Takahashi[1], D.P. Moreira[1], K. Griesi-Oliveira[1], A.C.F. Conte[3], C. Rosenberg[1], E. Vadasz[4], M.R. Passos-Bueno[1].* 1) Departamento de Genetica e Biologia Evolutiva, Instituto de Biociencias, University of Sao Paulo, Sao Paulo, Brazil; 2) UNESP, Sao Jose do Rio Preto, Sao Paulo, Brazil; 3) Laboratorio de Genetica, Hospital de Base, Faculdade de Medicina de Sao Jose do Rio Preto, Sao Paulo, Brazil; 4) Instituto de Psiquiatria, Hospital das Clinicas, Faculdade de Medicina, University of Sao Paulo, Sao Paulo, Brazil.

Autism Spectrum Disorders (ASD) are highly heterogeneous and, despite the enormous efforts to identify their underlying genetic causes, at least 70% of the cases are idiopathic. We have hypothesized that a proportion of these cases might be caused by small CNVs not detected through conventional microarray platforms or NGS. To address this hypothesis, we designed an array-CGH with high density of probes targeted to the coding exons and to the UTR of 269 genes involved in biological processes potentially significant to the pathophysiology of ASD. A total of 508 ASD Brazilian patients and 550 Brazilian healthy individuals were included in the study after a signed informed consent. The IB-USP Ethics Committee approved this research. All patients were diagnosed by psychiatrists using DSM-IV, ICD-10 and ASQ, and all were negative for CNVs at 15q11-13, 16p11 and 22q13 through MLPA. Exclusion criteria comprised autism-related syndromes, metabolic disorders, facial dysmorphisms, congenital malformations, or maternal exposition to known teratogenic drugs/ infectious agents during pregnancy. The number of individuals harboring at least one CNV and the number of CNVs per subject were significantly different between 103 cases and 200 controls ($p<0.0001$). These findings also applied to the separate analyses of the microdeletions and microduplications ($p\leq0.0002$), with odds ratios related to the number of alterations per individual between 2.92 and 3.32. Considering the subjects with two or more alterations, the differences between cases and controls were even greater (for microdeletions, $p=0.000005$; OR=28.74 [95% CI 3.7-223.1]). Forty-five out of 103 patients (43.7%) presented at least one CNV smaller than 1 kb which disrupted one of the genes in our customized array, a rate significantly higher than the proportion (21.5%) found in controls ($p=0.00009$). Finally, we detected 10 ASD-specific CNVs (five in the UTR) in 11.6% of the patients. These results are different from those usually obtained through conventional screenings with genome-wide platforms and indicate that the use of this high-resolution custom-designed array can increase the chance of detecting alterations enriched in ASD. This study also suggests that disruption of non-coding DNA may contribute to the risk factors for ASD, corroborates the association of *SHANK2*, *DIAPH3*, *GCH1*, *GRM5* and *MARK1* with nonsyndromic ASD, and reveals *SNAP29*, *SLC17A6*, *PRKC*α, *MBD2* and *GAD2* as new candidates for these disorders.

1207F

Linkage Disequilibrium Mapping of the 13q21 Specific Language Impairment Locus Using Epistasis Analysis Models. *S.L. Wolock[1], N. Li[1], S.A. Petrill[2], J.F. Flax[3], A.S. Bassett[4], L.M. Brzustowicz[3], C.W. Bartlett[1,5].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Psychology, The Ohio State University, Columbus, OH; 3) Department of Genetics, Rutgers University, Piscataway, NJ; 4) Department of Psychiatry, University of Toronto, Toronto, Canada; 5) Department of Pediatrics, The Ohio State University, Columbus, OH.

Background: We present a fine-mapping study of the 13q21 region linked to Specific Language Impairment (SLI), a neurodevelopmental failure to develop normal vocabulary and grammar despite otherwise normal cognition and ability. In previous work, we mapped the SLI3 locus to 13q21 using a written language impairment phenotype using five extended families from Canada. We replicated the locus using nuclear and extended families from the United States. In refining the localization, we found that a coding SNP in BDNF associated with memory greatly increased localization and evidence for the locus when included as part of a gene-gene interaction with the unidentified 13q21 risk alleles. Here, we performed additional mapping of the region to identify the gene responsible for the linkage signals. Methods: We assessed linkage/association of Illumina SNP array genotypes with eight phenotypes using the posterior probability of linkage (PPL) and the posterior probability of linkage disequilibrium (PPLD) metrics. We conducted two analyses: a baseline analysis and an analysis that incorporated BDNF genotypes from a coding SNP associated with memory into a gene-gene (epistatic) interaction model. The posterior probabilities from the two models are on the same scale and can be directly compared to assess the evidence that a SNP has an epistatic interaction. Results: Several SNPs within an LD block showed association with the categorical written language impairment diagnosis used to map this locus in the original genome scans (maximum PPLD = 41%). We also observed weaker association with the quantitative trait underlying the written language impairment trait (maximum PPLD = 17%). In both cases, modeling the coding SNP in BDNF showed an epistatic effect. The implicated region overlaps ATXN8OS, an anti-sense transcript of the KLHL1 gene. ATXN8OS contains a tri-nucleotide repeat that, when expanded, may increase the risk for a form of spinocerebellar ataxia. It has additionally been associated with several neuropsychiatric phenotypes. Conclusion: While additional work to elucidate the role of this antisense transcript is ongoing, the findings suggest a role for BDNF-ATXN8OS interaction in the etiology of SLI.

1208W

Evidence for the involvement of MIR185 and its target genes in the development of schizophrenia. *AJ. Forstner[1,2,19], FB. Basmanav[1,2,19], M. Mattheisen[3,4], AC. Böhmer[1,2], MV. Background: The 22q11.2 deletion syndrome (22q11.2DS) is a phenotypically complex syndrome caused by a hemizygous microdeletion in chromosomal region 22q11.2. It occurs approximately 1 in 2,000 - 4,000 births and about 30% of carriers develop schizophrenia, making this syndrome one of the strongest known genetic risk factors for schizophrenia. Most of the deletions at 22q11.2 are either 1.5 or 3 megabases in size spanning 35 and 60 known genes, respectively. Research has yet to confirm which genes within the deletion region are of importance in terms of this schizophrenia-risk effect. The minimal 1.5 megabase deletion region contains the gene MIR185, which encodes microRNA 185. This has two validated targets (RhoA, Cdc42), both of which have been associated with altered expression levels in schizophrenia. **Methods:** The role of MIR185 in schizophrenia was investigated by: 1) monitoring miR-185 expression in embryonic and adult mouse brains; and 2) investigating the role of common and rare variants at this locus in humans. The latter approach involved three steps. Firstly, gene-based analyses were performed for common variants in MIR185 and its target genes using Schizophrenia Psychiatric Genomics Consortium genome wide association data. Secondly, the MIR185 gene was resequenced in 1,000 schizophrenia patients and 500 controls of German origin to investigate the role of rare variants. Thirdly, promising variants were followed up by genotyping an additional 3,530 patients and 4,018 controls. **Results:** In situ hybridization in mice revealed miR-185 expression in brain regions implicated in schizophrenia and other neuropsychiatric manifestations of 22q11.2DS. Gene-based tests revealed no association between schizophrenia and MIR185 at either the gene-level or the level of individual SNPs. However, three target genes were associated with schizophrenia after correction for multiple testing. Resequencing identified two rare patient-specific novel variants directly flanking MIR185. However, follow-up genotyping provided no further evidence for their involvement in schizophrenia. **Conclusions:** The miR-185 expression patterns in mice and the genetic association results for the three miR-185 target genes suggest that miR-185 and its down-stream pathways may be implicated in the development of schizophrenia in both 22q11.2DS patients and idiopathic cases. MicroRNA-mediated dysregulation is therefore a possible etiological mechanism in schizophrenia.

1209T

Identification of novel mutations in *SLC20A2* and *PDGFRB* in a Brain Bank series of IBGC. *M. Sanchez-Contreras[1], M. Baker[1], N. Finch[1], A. Nicholson[1], A. Wojtas[1], A.J. Strongosky[2], D.B. Calne[3], S. Calne[3], A. Jon Stoessl[3], J.E. Allanson[4], D.F. Broderick[5], M. Hutton[1], D.W. Dickson[1], O.A. Ross[1], Z.K. Wszolek[2], R. Rademakers[1].* 1) Department of Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Department of Neurology, Mayo Clinic, Jacksonville, FL; 3) Pacific Parkinson's Research Center and National Parkinson Foundation Center of Excellence, Neurology, University of British Columbia, Vancouver, B.C., Canada; 4) Eastern Ontario Regional Genetics Program, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 5) Department of Radiology, Mayo Clinic, Jacksonville, FL.

Idiopathic Basal Ganglia Calcification (IBGC) is characterized by bilateral calcification of the basal ganglia and presents clinically with a spectrum of neuropsychiatric and motor syndromes including dystonia, parkinsonism, tremor and chorea. Mutations in 2 genes, *SLC20A2* and *PDGFRB*, have recently been shown to cause familial forms of IBGC. We set out to identify and study mutations in *SLC20A2* and *PDGFRB* in a series of pathologically confirmed IBGC cases from the Mayo Clinic Florida Brain Bank. Methods: 27 cases were included based on the presence of significant basal ganglia calcification upon pathological examination. All coding regions of *SLC20A2* and *PDGFRB* were sequenced. For *SLC20A2*, copy number analysis was also performed using real-time quantitative PCR. Confirmatory assays for a genomic deletion in *SLC20A2* were performed by PCR based on the coordinates obtained from whole-genome sequencing (WGS) in one patient. For *PDGRFB*, we generated wild type and mutant forms and performed transient expression in HeLa cells to evaluate its tyrosine kinase function. Upon stimulation with PDGF-BB, the autophosphorylation of wild-type and mutant PDGFRB at multiple tyrosine residues was assessed by western blot. Results: In our IBGC brain bank series, we identified two novel coding variants in *SLC20A2*. One novel variant was predicted to induce a nonsense mutation in exon 3 (p.S113X) and the second mutation consisted of a 563,256 bp genomic deletion with precise breakpoints defined by WGS. This deletion co-segregated with the disease in a large Canadian family and affected multiple genes. The combined deletion of *SLC20A2* and *THAP1* in this family likely contributed to the early onset and predominant dystonia. Additionally, we identified one novel coding variant in exon 15 of *PDGFRB* predicted to induce a missense mutation in the kinase domain (p.R695C). Our functional studies indicate that *PDGRFB* mutations disrupt the autophosphorylation of PDGFRB. Conclusion: Genetic mutations in *SLC20A2* and *PDGFRB* were found in 3 cases of our IBGC series. The identification of a novel mutation and a complete deletion of *SLC20A2* confirm an important role for *SLC20A2* haploinsufficiency in IBGC. Our work further supports a pathogenic role for PDGFRB in IBGC. Moreover, abnormal signaling through PDGFRB and deficient phosphate transport through SLC20A2 may be involved in the same pathogenic pathway leading to calcification in IBGC.

Autism spectrum disorders (ASD) are a group of complex neurodevelopmental disorders characterized by impairment in social interaction, language and communication deficits and repetitive behavior. The etiology for ASD has only been identified in 10-20% of cases screened so far. The aim of this study is to identify copy number variants (CNVs) with a high pathological potential for ASD and to clarify the complex genetic heterogeneity of the disorder in a well-characterized ASD cohort. A cohort of 716 German patients with ASD and their relatives (in a total of 2114 subjects) were assessed using the ADI-R and ADOS diagnostic tools. The control group is composed of 1320 German subjects ascertained through the Heinz Nixdorf Recall Study. Both cohorts have been genotyped on the Illumina Human OmniExpress 730K-SNP-array. For copy number variation (CNVs) analysis, we used 4 calling algorithms: PennCNV, QuantiSNP, GNOSIS, CNVPartition. A total of 1967 ASD-samples passed stringent quality control, 673 being probands (572 males and 101 females). Of these, 394 were from trios, 42 from quads and 20 from large families. Using also data from an additional 5000 European controls, priority was given for rare CNVs (*de novo* or inherited). A variety of *de novo* CNVs was detected in cases, from large aberrations (e.g. a novel 13q14.2 5Mb-deletion) to rare pathogenic CNVs (e.g. a Potocki-Lupski 17q12-duplication-syndrome). Interestingly, inherited CNVs along with second genomic hits were seen in four subjects (e.g. a maternal *NRXN1* intragenic deletion and *de novo* 22q11.2-duplication), giving support to a multiple-hit hypothesis. Also, we found CNVs that are often related to a remarkably variable neurobehavioral phenotype such as the 3q29-deletion syndrome, which can present as intellectual disability, ASD, psychosis, anxiety, hyperactivity and/or aggressiveness. Further experimental validation and network modelling of genes intersected or disrupted by CNVs are ongoing.

1211W

Different homozygous mutations in *Italic Text*PARKIN*Italic Text* gene are responsible for early onset Parkinson's disease in Arab-Israeli families that live in close vicinity. *S. Ben-Shachar[1], Z. Afawi[2], R. Masalha[3], S. Badarny[4,5], T. Neiman[1], A. Bar-Shira[1], A. Orr Urtreger[1,6].* 1) Genetic Institute, Tel Aviv Sourasky Med Ctr, Tel-Aviv, Israel; 2) Center for Neuroscience, Ben-Gurion University of the Negev, Be'er Sheva, Israel; 3) Department of Neurology, Soroka Medical Center, Ben Gurion University of the Negev, Be'er Sheva, Israel; 4) 4.Department of Neurology, Carmel Medical Center, Haifa, Israel affiliated to Rappaport Faculty of Medicine -Technion, Haifa, Israel; 5) Rappaport Faculty of Medicine -Technion, Haifa, Israel; 6) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Bold Text Introduction:**Bold Text** Parkinson's disease (PD) affects about 2% of the population older than 65 years. Multiple genetic, environmental and age-related factors influence the risk for PD. Mutations in the *Italic Text*PARKIN, PINK1, DJ1*Italic Text*, and *Italic Text*ATP13A2*Italic Text* genes cause many of the less common autosomal recessive PD (ARPD). A founder mutation in *Italic Text*PARKIN*Italic Text* gene, c.101delA, has been previously detected in Arab-Israeli families with ARPD. We aimed to detect the genetic etiology for this disease in consanguineous families from this origin. **Bold Text**Methods:**Bold Text** Six consanguineous families, with a positive family history of PD and at least two affected members, concordant with ARPD, were recruited. The known *Italic Text*PARKIN*Italic Text* founder mutation was screened, followed by homozygous mapping using SNP based array. Analysis was completed by Sanger sequencing of *Italic Text*PARKIN*Italic Text* coding region. **Bold Text**Results:**Bold Text** In only one family, the known *Italic Text*PARKIN*Italic Text* c.101delA founder mutation was detected in an homozygous state. In two of the other five families, loss of heterozygocity (LOH) was detected at the *Italic Text*PARKIN*Italic Text* locus. A novel homozygous mutation, c.C996G>A (p.C332X), was detected in one family, segregating with the phenotype. In another family a homozygous deletion of exon 4 was detected. Interestingly, this homozygous deletion was previously described in a few families with early onset ARPD in Japan. Full sequence of *Italic Text*PARKIN*Italic Text* coding region in the families that did not demonstrate LOH at this locus did not detect homozygous/compound heterozygote mutations. We also detected LOH of *Italic Text*PINK1*Italic Text* gene in two families: in the family that carry the *Italic Text*PARKIN*Italic Text* exon 4 deletion, and in another family that demonstrated additional LOH in the *Italic Text*ATP13A2*Italic Text* gene locus. None of the six families showed LOH in the *Italic Text*DJ1 locus. **Bold Text**Conclusions:-**Bold Text** Three different homozygous mutations in *Italic Text*PARKIN*Italic Text* were detected in 3/6 of consanguineous Arab-Israeli families with PD. Of note that the different homozygous alleles were found in families that are living in a same geographic region. These results further demonstrate the high mutation rate in the *Italic Text*PARKIN*Italic Text* gene. Other, yet unknown, genes likely to be associated with ARPD in this population.

1212T

Transcriptome outlier analysis implicates schizophrenia candidate genes as harboring rare functional variants of large effects. *J. Duan[1], W. Moy[1], J. Freda[1], E.I. Drigalenko[2], H.H.H. Göring[2], A.R. Sanders[1], P.V. Gejman[1], Molecular Genetics of Schizophrenia (MGS) Collaboration.* 1) Dept Psychiatry, Northshore Univ Healthsystem/Univ of Chicago, Evanston, IL; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

Multiple rare and large copy number variants (CNVs) are associated with high risk for schizophrenia (SZ), and some common risk variants have been uncovered by GWAS. However, a substantial part of the genetic risk still remains unexplained and disease mechanisms are largely unknown. To uncover additional loci of large effect, we propose to sequence targets derived from transcriptome analyses. Most gene expression studies rely on the study of average abundances in case-control samples. Although useful, this approach assumes substantial etiologic homogeneity, and may miss rarer genetic effects. We have employed an alternative approach to identify expression outliers (i.e., expression distribution extremes) where the tails of the distribution are enriched for cases. We hypothesize that such case-enriched expression outliers are caused by rare coding variants (e.g., nonsense or splice site mutations) or regulatory mutations of large effect on gene expression. We analyzed an RNAseq dataset comprised of lymphoblastoid cell lines from 312 SZ cases and 322 controls, none of which carry a known SZ-associated CNV. We calculated the Z-scores of the expression for each gene for the whole sample. Expression outliers were defined as genes with abundances beyond a predefined standard deviation cutoff (2SD or 3SD). We identified 828 expression outlier genes with 2SD-tails (401 lower and 427 upper) enriched for SZ cases. In these genes we observed enrichment of brain-expressed genes, SZ-risk CNV-spanned genes, and genes within CNVs associated with neurodevelopmental disorders. Noteworthy outlier genes: *KCTD13* that drives the 16p11.2 CNV phenotype, *DGCR8* at 22q11.21 deletion region, and *TCF3* belonging to the same gene family as the SZ-associated *TCF4*. We did not find global outlier burden differences in SZ cases and controls (i.e., total number of outlier genes/individual). However, SZ cases showed higher outlier burden for genes spanned by the above SZ-risk CNVs and a trend towards higher outlier burden for genes within CNVs associated with neurodevelopmental disorders. These results suggest that genes identified by outlier expression analyses are relevant to SZ pathogenesis. However, given the moderate sample size and multiple statistical tests, we consider our results exploratory. We are currently sequencing exons and regulatory sequences of top ranking outlier genes and will report the functional variants contributing to aberrant mRNA expression in SZ cases.

Molecular genetic study on a Japanese family with amyotrophic lateral sclerosis. *Y. Ichikawa[1], H. Ishiura[1], J. Mitsui[1], S. Endo[1], Y. Takahashi[2], A. Ishii[3], M. Watanabe[3], A. Tamaoka[3], M. Murata[2], K. Doi[4], J. Yoshimura[4], S. Morishita[4], J. Goto[1], S. Tsuji[1].* 1) Dept Neurology, Univ of Tokyo, Tokyo, Japan; 2) Dept Neurology, National Center of Neurology and Psychiatry, Tokyo, Japan; 3) Dept Neurology, Univ of Tsukuba, Ibaraki, Japan; 4) Dept Computational Biology, Univ of Tokyo, Tokyo, Japan.

Background: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder characterized by degeneration of motor neurons in the brain and spinal cord. Although the majority of ALS patients are sporadic, approximately 10% of ALS cases are familial (FALS). In the Japanese population, mutations of *SOD1*, *FUS*, *TARDBP*, and *C9orf72* account for approximately 60% of the cases of FALS, and the causative genes remain to be elucidated in 40 % of the cases of FALS. **Objective:** This study is aimed to search for a causative gene for a Japanese autosomal dominant FALS family. **Subjects and Methods:** Three patients were affected in this family. The age of onset of one patient was around 60 and those of the other two patients were in their 70s. Concerning the clinical presentations, one was progressive bulbar palsy; the others were Aran-Duchenne type. Genomic DNAs were extracted from nine individuals including two affected patients. Genotyping was carried out using Affymetrix SNP Array 6.0 and linkage analysis was performed using allegro and SNP HiTLink. To explore the causative mutations, we conducted an exome analysis of the index patient. **Results:** The linkage analysis revealed the highest multipoint parametric LOD score of 1.8 in 13 regions on chromosomes 1, 4, 5, 6, 8, 9, 10, 11, 12, and 14 spanning 189.5Mb in total. Although, the loci of the causative genes for dominant FALS including *SETX*, *ANG*, and *TARDBP* were included in the candidate region, the mutations of these genes were not detected by the exome analysis. **Conclusion:** The results of the analyses suggest that ALS in the present family is caused by a mutation of a novel gene.

1214W

Association between serotonin transporter variant, 5-HTTLPR, and hoarding traits in a population-based pediatric sample. *V. Sinopoli[1], A. Dupuis[2], C. Burton[1,2], J. Crosbie[1,2], J. Shan[2], R. Schachar[1,2], P. Arnold[1,2].* 1) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada.

Obsessive-compulsive disorder (OCD) is an anxiety disorder characterized by recurring, intrusive obsessions, and compulsive behaviors aimed at alleviating the resulting anxiety. It is a heterogeneous disorder that is both genetically and phenotypically complex, which complicates our ability to identify the heritable components of OCD and the genes that are responsible. At the phenotypic level, studies consistently reveal specific symptom dimensions within the disorder. At the genetic level, the promoter region of the serotonin transporter gene, 5-HTTLPR, has been implicated in OCD, but findings have been inconsistent. Statement of Purpose: The aim of this study is to examine a functionally triallelic variant in 5-HTTLPR and its genetic association with obsessive-compulsive (OC) traits, as a whole, and specific subgroups of OC traits in a population-based sample of children. Methods: We have identified OC traits in 7,500 Caucasian children, from the Ontario Science Centre in Toronto, and have selected the top and bottom 10% of our sample for comparison. Following collection and extraction of DNA, we directly genotyped the 5-HTTLPR polymorphism and classified variants based on functionality. We examined the association between 1) genetic presentation of the variant and high versus low OC traits and 2) genetic presentation of the variant and high versus low OC traits within each factor-based subgroup we have identified. Results: No significant difference is seen between the high OC trait group and the low OC trait group, as a whole. A significant difference in allelic and genotypic distribution is seen between individuals with high and low OC trait extremes specifically in the hoarding factor group. The LA/LA genotype occurs more often with low extreme hoarding traits (P-value 0.004). Likewise, the LA allele occurs more often with low extreme hoarding traits, compared to any other allele (P-value 0.005). Conclusion: Our findings reveal a significant difference in genotypic and allelic distribution only between individuals with high versus low extreme hoarding scores. This illustrates a need to consider specific symptom dimensions within OCD, when examining serotonergic and other genetic variants. By reducing phenotypic heterogeneity, our approach promises to more accurately facilitate identification of genetic risk factors in OCD.

1215T

Disruption of a large intergenic noncoding RNA, *FLJ42709*, is associated with developmental delay and language disorder. *S. Fan[1], L. Dukes-Rimsky[1], S. Ladd[1], B.R. DuPont[1], C. Skinner[1], L. Wang[2], K.B. Clarkson[1], A.K. Srivastava[1, 2].* 1) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, SC.

Large intergenic noncoding (linc) RNAs are emerging as key regulators of diverse cellular processes including neurodevelopment. However, the function of the majority of these lincRNAs remains uncharacterized. We identified a paternally inherited balanced translocation t(5;12)(q15;q15) in a 2 year and 7-month-old male patient with developmental delay, speech delay, significant expressive language delay, and congenital infantile left eye esotropia. Fluorescence *in situ* hybridization and whole genome sequencing defined the chromosomal breakpoints and revealed the disruption of a previously uncharacterized lincRNA gene, *FLJ42709* at 5q15. The breakpoint at 12q15 disrupted no gene. Further studies by PCR amplification and sequencing of the breakpoint junctions revealed the identical breakpoints in the patient's father who had dyslexia and stutters. We analyzed quantitative expression of several genes flanking each chromosomal breakpoint and found no change in their expression levels than control individuals. In addition, we looked for disease causing variants other than the translocation breaks using the Ingenuity Variant Analysis tool (Ingenuity Systems Inc, CA). No potential disease causing variant was found. Thus, we further characterized *FLJ42709* and confirmed expression of at least three major transcribed isoforms of *FLJ42709*. We further determined that all three isoforms were expressed abundantly in human fetal brain and in most other tissues tested. To infer the physiological function of *FLJ42709*, we looked for genes that are co-expressed with *FLJ42709*. On the basis of probe-to-probe correlation coefficient calculated from an integrated set of 2,968 microarray expression profiles of healthy human tissue samples, we found that the expression of *FLJ42709* was largely correlated with genes enriched with Gene Ontology terms including synaptic transmission, cell-cell signaling, neuron projection, and synapse. Recently, several genomic deletions at 5q15 encompassing *FLJ42709*, *NR2F1*, *FAM172A*, *POU5F2*, and *MIR2277* genes have been reported in patients with developmental delay, hypotonia, strabismus/estropia, deafness and significant delay in gross motor skills, cognitive and communication skills. All together, our findings raised the possibility of a likely role for the lincRNA gene *FLJ42709* in neurodevelopmental disorders.

1216F

Gene-based association analysis of Alzheimer's disease risk gene CD33 with brain amyloid-β burden and microglial activity measured by PET. *K.T. Nho[1,2], S. Shanker[1], S. Kim[1,2,3], S.L. Risacher[1,3], V.K. Ramanan[1,10], L. Shen[1,2,3], K.K. Yoder[1,3], P.S. Aisen[4], R.C. Petersen[5], M.W. Weiner[6,7], B.C. McDonald[1,3,8], E.F. Tallman[1,3], G.D. Hutchins[1,3], J.W. Fletcher[1], M.R. Farlow[3,8], B. Ghetti[2,3,9], A.J. Saykin[1,2,8,10] for the Alzheimer's Disease Neuroimaging Initiative (ADNI).* 1) Radiology and Imaging Sciences, Indiana University, Indianapolis, IN; 2) Center for Computational Biology and Bioinformatics, Indiana University School of Medicine, Indianapolis, IN; 3) Indiana Alzheimer Disease Center, Indianapolis, IN; 4) Department of Neurosciences, University of California, San Diego, San Diego, CA; 5) Mayo Clinic, Rochester, MN; 6) Departments of Radiology, Medicine and Psychiatry, University of California, San Francisco, San Francisco, CA; 7) Department of Veterans Affairs Medical Center, San Francisco, CA; 8) Department of Neurology, Indiana University School of Medicine, Indianapolis, IN; 9) Department of Pathology and Laboratory Medicine, Indiana University School of Medicine, Indianapolis, IN; 10) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN.

Background: Large-scale GWAS have identified and confirmed *CD33* significantly associated with late onset Alzheimer's disease (LOAD) (Naj et al., 2011). A recent study showed *CD33* is expressed in microglial cells in the human brain and inhibits microglial uptake of amyloid-β (Griciuc et al., 2013). Our aim was to perform gene-based association analyses to investigate the relationship of *CD33* variants with amyloid-β (Aβ) burden measured using florbetapir positron emission tomography (PET) imaging (Ramanan et al., 2013) (Analysis 1) and microglial activity measured using [^{11}C]PBR28 PET imaging (Yoder et al., in press) (Analysis 2). **Methods:** 550 participants in the ADNI (Alzheimer's Disease Neuroimaging Initiative) cohort with florbetapir PET scans were used in Analysis 1, and 26 participants in the IMAS (Indiana Memory and Aging Study) cohort with [^{11}C]PBR28 PET scans were used in Analysis 2. The endophenotypes used in Analysis 1 were mean regional standardized uptake value ratio (SUVR) values from 5 regions adjusted for age, gender, diagnosis, *APOE* ε4 status, and *BCHE* genotypes (Ramanan, et al. 2013) and in Analysis 2 were mean PBR SUV from 8 regions adjusted for *TSPO* genotype. SNPs within ±10 kb of the *CD33* gene after imputation using MACH were included. Gene-based association analyses were performed using a dominant genetic model and SNPs were considered significant if they had a $p<0.05$ on linear regression analyses and independent if $r^2 \leq 0.5$. Permutation was used to correct for multiple SNPs. **Results:** From our analyses, we found that the *CD33* gene was significantly associated with Aβ SUVR ($p<0.0044$) and marginally PBR SUV ($p<0.072$) in many regions. In Analysis 1, rs12971800 located at the 3' end of the gene was identified with the minor allele associated with higher Aβ SUVR and accounted for ~2% of the phenotypic variation. In Analysis 2, another SNP (rs273645) located at the 3' end of the gene was identified with the minor allele associated with lower PBR SUV. **Conclusions:** *CD33* was associated with PET imaging measures associated with AD, suggesting *CD33* apprears to contribute to known neuropathologic features of AD such as amyloid burden and inflammation. This is relevant in light of the previous findings and warrants further investigation in independent and larger samples.

1217W

Association of ADH and ALDH variants with alcohol-related phenotypes in a Native American community sample. *Q. Peng[1], I.R. Gizer[2], O. Libiger[1], C. Bizon[3], K.C. Wilhelmsen[4], N.J. Schork[1,5], C.L. Ehlers[6].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) Department of Psychological Sciences, University of Missouri, Columbia, MO; 3) RENCI, University of North Carolina, Chapel Hill, NC; 4) Department of Neurology and Genetics, University of North Carolina, Chapel Hill, CA; 5) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 6) Department of Molecular and Integrative Neurosciences, The Scripps Research Institute, La Jolla, CA.

Previous studies have shown that alcohol dehydrogenase (ADH) genes and aldehyde dehydrogenase (ALDH) genes may affect the risk of development of alcohol dependence, and that polymorphisms within these genes may differentially affect risk depending on the ethnic group evaluated. We considered variations in the ADH and ALDH genes in a large study investigating risk factors for substance use in a Native American (NA) population. We ultimately tested for associations between alcohol dependence, severe alcohol use and alcohol withdrawal symptoms in the genomic regions around the ADH and ALDH genes. Seven hundred and eight (708) NAs, from extended pedigrees, participated in the study. Blood derived DNA was sequenced using Illumina low-coverage whole genome sequencing (WGS), as well as genotyped using an Affymetrix Exome1A chip. All subjects were assessed using the Semi-Structured Assessment for the Genetics of Alcoholism (SSAGA) in order to make DSM-IV diagnoses. To control for admixture and familial relatedness a variance component approach that incorporated ancestry admixture estimates was used in the association tests. In additional analyses we examined the ancestral backgrounds of the genomic regions under investigation and their influence on the phenotypes. False discovery rates were used to set significant p values. Seventy-seven (77) ADH variants showed significant evidence of association with a severe alcohol use phenotype. These significant variants spanned across the entire 7 ADH gene cluster region on chromosome 4q, however, the majority of them resided in ADH4-ADH6-ADH1A-ADH1B, in both genic and inter-genic regions. Four significant associations (three in ADH and one in ALDH2) were also observed with alcohol dependence symptoms for variants. These studies suggest that WGS combined with ancestry and admixture analyses can identify significant variants associated with alcohol dependence phenotypes in the regions of the major alcohol metabolizing enzymes. (Supported by AA10201, DA030976...).

Characterization and Replication of Chromosome 15q25 Nicotine Dependence Signals in an Old Order Amish population. *J.D. Backman[1], A.D. Million-Mrkva[1], L.E. Hong[3], M.A. Ehringer[4], B.D. Mitchell[2], A.R. Shuldiner[2], K.A. Ryan[2], K.L. Nugent[3], S.H. Stephens[2].* 1) Epidemiology and Human Genetics, University of Maryland at Baltimore, Baltimore, MD; 2) Endocrinology, Diabetes, and Nutrition; University of Maryland School of Medicine, Baltimore, MD; 3) Psychiatry, University of Maryland School of Medicine, Baltimore, MD; 4) Institute for Behavioral Genetics, University of Colorado, Boulder, CO.

The *CHRNA5/CHRNA3/CHRNB4* locus on chromosome 15q25 encoding neuronal nicotinic acetylcholine receptor genes has been associated with nicotine dependence and smoking behaviors in multiple populations. This region includes three statistically distinct loci that have been associated with various smoking-related phenotypes tagged by three SNPs: rs16969968, rs578776, and rs588765. This analysis focuses on a replication of previous studies in a unique population, namely the Old Order Amish (OOA) of Lancaster County. The OOA is a closed founder population with exceptional genetic and environmental characteristics lending themselves to the study of complex diseases. As virtually no Amish women reportedly smoke, we restricted analysis to the 896 OOA males, who ranged in age from 18 to 96 years. Smoking behaviors, obtained by questionnaire, included regular tobacco use (yes/no), quantity used, and age of initiation. Smoking rates are low in Amish men (20%), and among smokers the intensity of smoking is low; between 1 to 3 cigarettes per day for those who reported quantity. Direct genotypes were not available for the three SNPs of interest and so we substituted highly correlated ($r^2>0.8$) SNP proxies that captured the genetic information at each locus. A fourth SNP in this cluster (rs1948) was also evaluated that had previously been associated with age of smoking initiation. SNP associations were tested using a regression approach under an additive genetic model that adjusted for age and family structure. Regular smoking was significantly associated, and in the expected direction, for all loci (odd ratios ranging from 1.16 - 1.34, all $p < 0.003$). Interestingly, frequency of the 'risk' allele (A) for rs16969968, normally 0.39 in Caucasian populations (CEU), is 0.56 in the OOA population. Neither age of initiation nor quantity smoked was significantly associated with any of these 4 SNPs. We observed that the highly replicated, statistically distinct loci in the *CHRNA5/CHRNA3/CHRNB4* gene cluster were associated with smoking behaviors in the Amish, with similar effect sizes. It is striking that these loci stand out given the low smoking rates and low intensity of smoking in this population.

1219F

Phospholipid Flippase ATP8A2 is essential for Normal Visual and Auditory Function and Photoreceptor and Spiral Ganglion Cell Survival. *X. Zhu[1,2], Y. Zhou[1,2], X. Zhu[1,2].* 1) The Sichuan Provincial Key Laboratory for Human Disease Gene Study and The Institute of Laboratory Medicine, Sichuan Academy of Medical Sciences & Sichuan Provincial People's Hospital, Chengdu, Sichuan, China; 2) Sichuan Translational Medicine Hospital, Chinese Academy of Sciences, Chengdu, Sichuan, China.

ATP8A2 is an important P4-ATPase phosphatidylserine flippase, which is required for proper maintenance of neuron and axon function. Atp8a2 is highly expressed in the brain, spinal cord, testes and retina. In the retina, ATP8A2 is primarily expressed in the light-sensitive photoreceptor cells and localized in the outer segment compartment. Although mutations in ATP8A2 have been reported to cause mental retardation in humans and spinal motor neuronal degeneration in the wabbler-lethal (wl) mouse, the physiological and cellular role of ATP8A2 in sensory systems have not been investigated. In this study we have analyzed the retina and cochlea of Atp8a2 mutant wl mice in order to determine the role of ATP8A2 in visual and auditory systems. ATP8A2-deficient mice had shortened photoreceptor outer segments, a significant reduction in rod and cone photoresponses, and decreased photoreceptor viability. The ultrastructural organization of photoreceptor outer segments appeared normal. The auditory brainstem response threshold was significantly higher in the ATP8A2-deficient mouse. The inner and outer hair cells appeared normal, but a significant degeneration of spiral ganglion cells was apparent. Our studies indicate that ATP8A2 plays a crucial role in photoreceptor and spiral ganglion cell function and survival by maintaining phospholipid composition and asymmetry and contributing to vesicle trafficking in these neurons.

1220W

Mutations in Secretin receptor may be related to autism spectrum disorder. *K. Kojima, T. Yamagata, A. Matsumoto, Z. Yang, S. Nakamura, E. F. Jimbo, M. Y. Momoi.* Pediatrics, Jichi Medial University, Shimotsuke-shi, Tochigi, Japan.

Secretin is a peptide hormone released from duodenum to stimulate exocrine secretion from pancreas. It is also produced in the brain and functions as a neuropeptide hormone in the central nervous system. Secretin receptor (SCTR) is a member of the type G-protein coupled receptor family, and expressed in the brain. In the rat brain during the early postnatal period, an active synaptogenesis period, expression levels of secretin and SCTR mRNA are higher than in the adult brain. (Tay, et al. Neuroscience letters. 2004) Since SCTR-deficient mice show abnormal social and cognitive behaviors, furthermore, synaptic plasticity in the hippocampus is impaired (Nishijima, et al.HMG.2006), the involvement of secretin to the pathogenesis of autism spectrum disorder (ASD) is suggested. To investigate the contribution of secretin and its pathway to ASD, we screened the SCTR gene for mutations in ASD patients. (Subjects and methods) We analyzed 197 DNA samples from Japanese ASD patients with the parent's informed consent and Caucasian patients from the Autism Genetic Resource Exchange (AGRE). Each exon and adjacent intron of SCTR was amplified by PCR and subjected to direct sequencing. Base changes detected in ASD samples were screened in 126 Japanese and Caucasian control samples. (Results) We detected three missense mutations in the SCTR gene that were not detected in controls, the R2C in one Caucasian male patient, the P90L in one Japanese male patient and the A245T in one Caucasian male patient. We also found another base substitution in the SCTR gene, the F411S in two Caucasian patients, but also in one control. (Discussion) These mutations are conserved regions. The R2C mutation in the SCTR is located in signal peptide domain and the P90L mutation is located in hormone binding domain. These mutations can have effect to alter the secretin binding to the receptor and its function. These findings suggested that secretin pathway play an important role in the pathogenesis of ASD.

1221T

Hypermethylation of the enolase gene (ENO2) in autism: A candidate biomarker for screening. *N. Zhong[1, 2, 3], Y. Wang[2].* 1) Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilties, Staten Island, NY; 2) Institute of Children Health Care, Shanghai Children's Hospital, Shanghai Jiao Tong University, Shanghai, China; 3) Peking University Center of Medical Genetics, Beijing, China.

It has been hypothesized that dysregulation of brain-expressed genes is the major predisposing underlying mechanism for autism. This dysregulation may be mediated by differential methylation of CpG sites within gene promoters, resulting in the unbalanced production of certain proteins, which could be candidate biomarkers and which could be used for early clinical screening of autism. Peripheral blood from autistic and control children were analyzed by methylated-DNA immunoprecipitation (MeDIP) chips to discover differential methylation. One neuron-specific gene, ENO2, was found to be hypermethylated in the autistic samples. This difference was validated by bisulfite sequencing PCR (BSP). The differential expression of ENO2 gene was further analyzed with real-time quantitative polymerase chain reaction (RT-qPCR) and by ELISA. We obtained blood samples from 101 age and sex matched autistic and control subjects. Five pairs were randomly selected for MeDIP chip analysis. A total 475 genes were found to be differentially methylated comparing the five pairs. This included 228 different in promoter regions and 247 different in CpG islands. The hypermethylation of ENO2 within the promoter region was confirmed by BSP to be present in 15.8% (16/101) of the autistic samples. The mean ENO2 RNA levels in these 16 autistic samples was reduced by about 70% relative to that in controls. The average level of ENO2 protein expression in the 16 autistic samples (15.15±3.52 μg/L) was about half of that in the controls (33.78±8.18 μg/L). These findings suggest that reduced ENO2 expression may be a biomarker for a subset of autistic children.

1222F

Application of causal inference methods to investigate APOE variation and cognitive impairment in multiple sclerosis. *E. Elboudwarej[1], P. Yousefi[2], L. Shen[3], M.F. George[1], H. Quach[1], F.B.S. Briggs[1], A. Bernstein[4], C. Schaefer[3], L.F. Barcellos[1,3].* 1) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, UC Berkeley, Berkeley, CA; 2) Division of Environmental Health Sciences, School of Public Health, UC Berkeley, Berkeley, CA; 3) Division of Research, Kaiser Permanente, Oakland, CA; 4) Palm Drive Hospital, Petaluma, CA, USA.

Previous studies have shown that apolipoprotein E (APOE) variation, particularly the ε4 allele, is not associated with overall risk of developing multiple sclerosis (MS) or disease severity measured by the MS Severity Score (MSSS). Cognitive deficits affect ~70% of MS cases and greatly impact daily activities, employment and relationships. However, cognitive issues vary among MS cases and do not strongly correlate with physical disability or disease course. APOE is a widely studied gene in relation to cognition, and recent studies suggest a possible link between ε4 and greater cognitive dysfunction in MS. Here, a causal framework was used to assess the effect of APOE ε4 genotype on cognitive impairment. Subjects were recruited from the Kaiser Permanente Medical Care Plan, Northern California Region (877 MS cases and 576 controls). Cognitive status was determined using a 37 point scale validated telephone interview cognitive status (TICS-M) assessment tool, and accounted for level of education. As expected, when compared to control individuals, MS case cognitive scores were lower ($p=4\times10$-4). The G-computational formula simple substitution estimator (SS) and target maximum likelihood estimation (TMLE) were used to estimate the effect of APOE ε4 carrier status on cognitive score in MS cases. Non-parametric models were adjusted for the following covariates to help identify the true causal relationship between genotype and outcome: gender, depression, genetic ancestry, family history of MS, MSSS, age of onset, age at cognitive assessment, and previous use of disease modifying therapies. The machine learning algorithm, SuperLearner in R, was used to select the prediction model with the lowest cross-validated risk, for implementation of SS and TMLE. Results were also compared to those obtained from traditional parametric linear regression modeling. Using the G-computational formula SS, MS cases carrying at least one ε4 allele scored higher on the cognitive test, though this difference was very modest (β =0.27; 95%CI: 0.12, 0.76). Results based on TMLE showed no evidence for an APOE ε4 effect on cognitive impairment in MS cases (β =0.30; 95%CI: -2.40, 3.77) and were consistent with linear regression analyses (β =0.24, 95%CI: -0.49, 0.97). Overall, our results based on causal inference methods do not support a role for APOE ε4 in cognitive impairment observed in MS.

Social skills impairments in girls with Turner syndrome. *M. Inbar-Feigenberg[1,2], D. Grafodatskaya[2], S. Choufani[2], BHY. Chung[1,3], LJ. Roberts[2], C. Russell[4], W. Roberts[4], J. Hamilton[5,6], R. Weksberg[1,2,6].* 1) Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Genetics and Genome Biology Program, Hospital for Sick Children, Toronto, ON, Canada; 3) Centre of Reproduction, Growth & Development, Department of Pediatrics & Adolescent Medicine, The University of Hong Kong, Hong Kong; 4) Autism Research Unit, Hospital for Sick Children, Toronto, ON, Canada; 5) Division of Endocrinology, Department of Pediatrics, Hospital for Sick Children, Toronto, ON, Canada; 6) Department of Pediatrics, University of Toronto, Toronto, ON, Canada.

Introduction: Turner syndrome (TS) is one of the most common sex chromosome abnormalities caused by complete or partial monosomy of the X chromosome, with a prevalence of ~1/2000 female live births. Individuals with TS present with short stature, gonadal dysfunction and other systemic malformations. A specific neuro-cognitive profile has been reported, sometimes including impaired social cognition. Autism and autism spectrum disorders (ASD) are reported in 5% and 25% of TS patients respectively. Skuse et al, 1997 reported that females who inherit their single X-chromosome from their father have better social skills than females who inherit it from their mother. The authors hypothesized that an imprinted locus on the X-chromosome is relevant to social functioning. Hypothesis: Females with TS demonstrate parent of origin- specific differences in social cognition. Methods and Results: We recruited 28 individuals with TS (age 3–18 years) and their parents at the Pediatric Endocrinology Clinic. We collected buccal samples from the proband and both parents. In addition, parents completed two social skills questionnaires for their daughters, one used originally by Skuse et al and the Social Responsiveness Scale (SRS) that assesses social awareness, social cognition, social communication, social motivation, and autistic mannerisms. SRS total scores fall into three categories: normal (T score ≤59); mild to moderate, consistent with mild ASD (T score=60–75); and severe, consistent with autism (≥76). We compared the scores for groups of girls with TS carrying a single maternal vs paternal X chromosome, as well as a group with karyotypes other then XO. In 14/28 patients (50%) scores were> 60. In 7/28 (25%), scores were in the mild/moderate ASD range and in 7/28 (25%), scores were in the severe autism range. Score differences for the sub-scales of SRS showed higher scores for autistic mannerisms. A good correlation between Skuze et al and the currently SRS was found ($R^2 = 0.80$). We did not find any correlation in social skill measures with parent of origin of the X chromosome in our small TS cohort. Conclusions: We found the rate of autistic features in TS to be significantly higher than previously reported. These data have significant implications for genetic counseling. We suggest that individuals with TS be routinely screened for ASD for early identification and initiation of behavioral interventions.

1224T

Examining the role of the 1q deletion critical region gene *SCCPDH* in early brain development in zebrafish. *E.A. Burke[1,2], W.A. Gahl[2], C.F. Boerkoel[1].* 1) NIH Undiagnosed Diseases Program Translational Laboratory, Bethesda, MD; 2) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Submicroscopic terminal 1q deletion results in a syndrome consisting of severe psychomotor delays, aphasia, hypotonia, microcephaly, corpus callosum abnormalities, and facial dysmorphism. Though previous studies have narrowed the critical region for this phenotype to 1q43-1q44, the deleted genes responsible for the syndrome remain unknown. We hypothesized that a potential contributor to this syndrome is *SCCPDH*, which lies within the 1q44 critical region and is expressed in the developing human and zebrafish brain. Knockdown of the zebrafish homologue using morpholinos caused a dose-dependent loss of brain tissue at the midbrain-hindbrain boundary, decreased eye size, and hydrocephalus. Each phenotype was rescued by co-injection of wild type *SCCPDH* mRNA in over 80 percent of embryos. Overexpression of wild type mRNA in zebrafish resulted in an increased incidence of cyclopia and abnormal forebrain development. Through *in situ* hybridization, *SCCPDH* morphants were found to widely overexpress *pax2* in the optic primordia in a manner similar to embryos injected with *shh* (sonic hedgehog) mRNA. These results, along with gene expression analyses, suggest a potential link between SCCPDH and Shh-related signaling. Therefore, we conclude that SCCPDH expression is highly regulated during brain development and that one mechanism by which it may affect brain development is through modulation of Shh signaling.

1225F

Investigation of the role of serotonin pathway in the etiology of Tourette's syndrome. *N. Sun[1,2], Z. Pang[5], L. Deng[1,2], RA. King[6], M. Sheldon[1,2,3], JC. Moore[1,3], RP. Hart[3,4], M. Konsolaki[1,2], GA. Heiman[1,2], JA. Tischfield[1,2,3].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Human Genetics Institute of New Jersey, Piscataway, NJ; 3) RUCDR Infinite Biologics NIMH Stem Cell Resource, Piscataway, NJ; 4) Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ; 5) Child Health Institute of New Jersey, New Brunswick, NJ; 6) Yale Child Study Center, Yale University School of Medicine, New Haven, CT.

Tourette's syndrome (TS) is a childhood onset neurodevelopmental and genetic disorder characterized by chronic motor and phonic tics. Previous studies suggest the etiology of TS is the result of interactions between multiple genetic and environmental factors, but specific genetic factors contributing to TS causation are poorly understood. A recent publication documented that an I425V mutation in the serotonin transporter gene (SLC6A4) is found in certain subsets of TS patients, suggesting the involvement of the serotonin pathway in the etiology of TS. It is unclear how this mutation leads to altered expression of genes in neurotransmitter pathway(s). We collected blood samples from all five family members of a two-generation pedigree from the New Jersey Center for Tourette Syndrome Sharing Repository. Four individuals from this family, diagnosed with TS or/and Obsessive-Compulsive Disorder (OCD), carry the I425V mutation. We established induced pluripotent stem cell (iPSC) lines from each individual in this family. In order to develop a neuron-based TS model in vitro, we induced iPSC lines into neural stem cells (NSCs) and further differentiated the NSCs into electrophysiologically functional neurons. By performing whole cell patch clamp analysis on these neurons, we are assessing whether or not the I425V mutation leads to electrophysiological changes. In addition, we are conducting gene expression analyses of NSCs and neurons to identify any differentially expressed genes in neurogenesis pathways involving serotonin which may lead to the discovery of epigenetically-modified genes involved in disease causation and development.

1226W

Distinguishing Autism Spectrum Disorders From Other Developmental Delays Using Blood RNASeq. *S. LETOVSKY[1], M. Causey[1], M. Aryee[2], J. Skoletsky[1], C. Proulx[1], F.R. Sharp[3], I.N. Pessah[3], R. Hansen[3], J. Gregg[3], I. Hertz-Picciotto[3].* 1) SYNAPDX, Woburn, MA; 2) Massachusetts General Hospital, Boston, MA; 3) MIND Institute, University of California, Davis, CA.

There is an unmet need for objective biomarkers to assist clinicians in the early diagnosis of childhood neurodevelopmental disorders. The aim of this study was to assess whether blood gene expression measured using next generation RNA sequencing (RNASeq) could provide a biomarker to distinguish children on the autism spectrum from children with other conditions that might present in the same clinical setting. The CHARGE (CHildhood Autism Risks from Genetics and the Environment) study recruited children between the ages of 2 and 5, some of whom were diagnosed on the autism spectrum, and others with other developmental delays. Subjects were grouped based on thresholds of the ADOS, ADI-R, Vineland and Mullens test into autism spectrum disorder (ASD) and other developmental delay (DD) groups to approximate the clinical use case of a secondary screen for autism in children suspected of neurodevelopmental disorders. RNASeq was performed on RNA from blood samples acquired in PAXgene tubes. 174 ASD and 96 DD samples passed final QC, for a total of 270 samples. Sequence data were processed through the Tuxedo RNASeq pipeline. Samples were divided into a training set (n= 153) and a holdout set (N=117), each of which was repeatedly subsampled to achieve gender and age balance between the ASD and DD groups. On each iteration, informative features were selected by t-test and a support vector machine classifier was trained on a balanced subsample of the training set and tested on a balanced subsample of the holdout set; AUC's (area under the ROC curve) were averaged across iterations. The mean AUC for the holdout set was 65.6 +/– 2.9%. When a 90% sensitivity threshold was selected on the classifier risk score, the mean specificity was 25.3, with 95% CI [13.6, 40.6%]. Gene categories found significant by ranksum test on the t-statistic include RNA processing, cell cycle, immune and inflammation-related GO categories. To our knowledge this represents the first report of a classification signature for ASD vs. DD using blood RNASeq. A gene expression signature with moderate AUC has potential clinical utility as a sensitive assay for identifying children at risk for ASDs within a population that is already suspected of neurodevelopmental disorders. Planned followup studies include a multicenter clinical study to further refine and validate a blood-based assay.

1227T

A 3.1 Mb deletion at 2q22.1-q22.3 including NXPH2 gene in a boy with intellectual disability. *N. Yoshihara[1], K. Kurosawa[1], I. Oohashi[1], Y. Kuroda[1], H. Osaka[2], S. Yamashita[2], M. Iai[2], K. Takano[2], M. Okuda[2], M. Takagi[2], R. Anzai[2], T. Wada[3].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Division of Pediatric Neurology, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Division of Medical Genetics, Kyoto University, Kyoto, Japan.

[Introduction] The synapses play a crucial role in neural transmission and complicated brain function. NXPH2 gene, expressed in brain and kidney, encodes Neurexophilin 2, which is a glycoprotein, working as signaling molecules with Neurexin 1, cell surface receptors at synapses. [Case] The patient is 4-year-old boy, without any familial history nor abnormal birth history. He was referred to our medical center for investigation of his intellectual disability (IQ 63). He did not show autistic signs or symptoms. He had a distinctive facial appearance with full cheeks and widely spaced eyes, low-set-ears and narrow mouth. MRI and EEG were normal. Array-comparative genomic hybridization revealed a 3.1Mb deletion at 2q22.1-q22.3 including NXPH2 and a part of LRP1B gene, which is known as a tumor suppressor gene. [Discussion] Recently, more reports are published suggesting the link between genes coding synaptic proteins, including the Neurexin family and autism, intellectual disability or schizophrenia. Previously, only 3 cases of the deletion including NXPH2 were reported. All of those regions include other several genes and all of those patients presented with external malformation and severe autism or intellectual disability. The present case had a minimum deletion including NXPH2. These results indicated that intellectual disability of this patient results from haploinsufficiency of NXPH2.

1228F

Mutation spectrum in the dystrophin gene disclosed by MLPA in 181 Vietnamese Duchenne/Becker muscular dystrophy patients. *K.V. Tran[1], H.N. Do[1], T.H. Tran[1], M.H. Ta[1], A.T.P. Le[1], D.C. Vu[2], V.T. Ta[1], M. Matsuo[3].* 1) Center for Gene and Protein Research, Hanoi Medical University, Hanoi, Viet Nam; 2) Department of Medical Genetics, Metabolism & Endocrinology, National Hospital of Pediatrics, Hanoi, Vietnam; 3) Department of Medical Rehabilitation, Faculty of Rehabilitation, Kobegakuin University, Kobe, Japan.

Duchenne/Becker muscular dystrophy (DMD/BMD) the most common X-linked muscular dystrophy is caused by mutation in dystrophin gene. Deletion and duplication in the dystrophin gene account for 60-70% of mutation. Multiplex ligation-dependent probe amplification (MLPA) is the most powerful and convenient method to identify exon deletions or duplications in the dystrophin gene because of its overall gene coverage. The present investigation was designed to detect mutation in the dystrophin gene in 181 unrelated Vietnamese Becker/Duchenne patients using MLPA analysis. Among the 181 cases, deletions and duplications encompassing one or more exons were identified in 105 (58%) or 12 (6.6%) cases, respectively. Deletions were found to cluster in the proximal (14.3%) and central hotspot regions (72.4%); 14% were observed to have gross deletions and 1.2% had deletion out of hotspot regions (exon 61-67). The deletion patterns were categorized into 48 patterns. Deletion of exon 48-50 or 45-50 where the most common pattern was deletion of exon 48-50,which was found in 11 cases (10%). Single-exon deletion was found in 14 cases (13%) by MLPA. Further examination disclosed that one of them was not an exon deletion but a single-nucleotide change (c.2227C>T) leading to a nonsense mutation. Outliers from the reading frame rule were 11 DMD (10.4 %). Remarkably, 25 and 14 cases were found treatable by exon 51 and 53 skipping, respectively. From these findings, the largest mutation database of Vietnam dystrophinopathy was established.

Underlying Genetic Etiologies in Epilepsy Patients:A retrospective large single centre study. *A. Guerin[1], E. Imhof[1], M. Zak[2], S. Mercimek-Mahmutoglu[1].* 1) Division of Clinical and Metabolic Genetics, Departmant of Pediatrics, The Hospital for Sick Children, Toronto, Canada; 2) Division of Neurology, Department of Pediatrics,The Hospital for Sick Children, Toronto, Canada.

Background: Epilepsy is abnormal neuronal electrical activity in the brain causing recurrent seizures. About 0.5-1% of the general population are affected by epilepsy. 25-30% are classified as intractable. Despite extensive investigations and neuroimaging studies, an underlying etiology is not determined in more than 50% of patients. Methods: All epilepsy patients were included into this retrospective review followed in the Neurology and Clinical and Metabolic Genetics Clinics at The Hospital for Sick Children between 2004-2013. Electronic patient charts were reviewed. Information was entered into an excel database. Genetic etiologies were subdivided into chromosomal, defined genetic syndromes, inherited metabolic disorders and neurogenetic syndromes. Results: There were 1298 epilepsy patients. There was no identifiable underlying cause in 688 patients (53%). In 610 patients (47%) there was an identifiable cause. In the latter group, chromosomal disorders, detected by karyotype and microarray, comprised 43/610 patients (7%). Identifiable genetic syndromes, e.g. Marfan syndrome, Down syndrome, Williams syndrome, represented 67/610 patients (11%). Neurogenetic causes, e.g. Dravet syndrome and Tuberous sclerosis complex were found in 74/610 patients (12.1%). Inherited metabolic disorders were represented by 45/610 cases (7.4%) the two most common causes being lysosomal storage disorders and mitochondrial encephalopathy. Conclusion: Collectively, genetic etiology was the most common underlying cause in 37.5% epilepsy patients. It is very likely that there is an underlying genetic cause in the 53% epilepsy patients with no known etiology. Prospective studies using whole genome sequencing will help us to unravel genes causing epilepsy, which will guide us to find new treatment for intractable epilepsies.

1230T

A useful approach for the genetic diagnosis of infectious agents using next-generation sequencing. *Y. Sakiyama[1], Y. Higuchi[1], H. Tanabe[1], J. Yuan[1], S. Nozuma[1], A. Yoshimura[1], A. Hashiguchi[1], Y. Okamoto[1], R. Hirano[1], E. Matsuura[1], R. Okubo[1], T. Iwasaki[2], F. Matsuda[3], S. Izumo[4], H. Takashima[1].* 1) Department of Neurology and Geriatrics, Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan; 2) Department of Dermatology, Graduate School, Tokyo Medical and Dental University, Tokyo, Japan; 3) Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto Japan; 4) Center for Chronic Viral Diseases, Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan.

Background: We found four patients with slowly progressive encephalomyelitis with cognitive dysfunction in the same geographical area. Histopathologic analysis of biopsied brain tissue revealed aggregation of periodic acid-Schiff-positive macrophages, and an agent with distinctive features was observed around the vessels in all patients. However, culture polymerase chain reaction (PCR) and serologic assays for a wide range of infectious agents were uninformative. **Methods:** Transcriptome analysis was performed using a next-generation sequencer (MiSeq®, Illumina) on cDNA extracted from the biopsied brain samples of two patients using a paired-end sequencing approach. To identify nonhuman cDNA, the Burrows-Wheeler Aligner (BWA) was first used against a human genome (UCSC: hg19) and human RefSeq (release 54, mRNA) to roughly remove most human sequences. The remaining unmapped reads were subsequently analyzed by BLASTN against the nucleotide database from NCBI. To detect DNA fragments of the pathogen more efficiently, the PAS-stained pathogens located in the perivascular spaces of the brain of the two patients were separately isolated from the section by laser microdissection (LMD). **Findings:** Among the cDNA sequences obtained from the affected brain tissue of two patients, a few reads displayed striking homology to a gene present in a microorganism, which we considered the infectious agent causing the present disease according to morphological observation. Furthermore, additional DNA sequences from the LMD-isolated tissue of the two patients were extremely homologous to the genome of the same microorganism. **Interpretation:** We consider that unbiased high-throughput sequencing using LMD-isolated tissue can be a useful tool for the detection of infectious agents if the morphological features are already revealed by microscopic observations.

Decreased tryptophan metabolism: the biochemical fingerprint of Autism Spectrum Disorders. *L. Boccuto[1], C.F. Chen[1], A.R. Pittman[1], C.D. Skinner[1], H.J. McCartney[1], K. Jones[1], B.R. Bochner[2], R.E. Stevenson[1], C.E. Schwartz[1].* 1) Greenwood Genetic Center, Greenwood, SC; 2) Biolog, Hayward, CA.

Autism spectrum disorders (ASDs) are common neurodevelopmental conditions whose biological basis has been largely undetermined. Although the ASD prevalence has risen to 2% of the school-aged US population and the conditions have a tremendous impact on society and families, the current diagnosis is solely based on the analysis of the complex behavioral phenotype and is typically not performed before the age of 3 years. We analyzed the metabolic profile of lymphoblastoid cell lines from 87 patients with ASDs, 50 with non-ASD neurodevelopmental disorders, and 78 normal individuals, using Biolog Phenotype MicroArrays (PMs). This assay is designed to evaluate the production of energy (NADH) in cells via diverse metabolic pathways. The ASD cohort showed reduced energy production when tryptophan was the sole energy source. The abnormality in tryptophan metabolism correlated with both syndromal and non-syndromal ASD, independent of the genetic background of the individual. This metabolic alteration was not observed in lymphoblastoid cell lines from the 78 normal patients or from the 50 patients with non-ASD intellectual disability, schizophrenia or conditions similar to syndromal ASD except for the behavioral traits. Additionally, analysis of data from a previous gene expression study of 10 patients with ASDs found abnormal levels for some genes involved in tryptophan metabolic pathways. Preliminary results indicate that the decreased tryptophan metabolism is detectable even in fresh blood leukocytes from patients with ASDs, suggesting that the assay might be further simplified and optimized into a quick and reliable screening tool, applicable at any age. Tryptophan is an essential amino acid and a precursor of serotonin, quinolinic acid, and kynurenic acid which are involved in neurodevelopment and synaptogenesis. Quinolinic acid is the structural precursor of NAD+, a critical energy carrier in mitochondria and the serotonin branch of the tryptophan metabolic pathway generates NADH. Additionally, the levels of quinolinic and kynurenic acid are strongly influenced by the activity of the immune system. Therefore, decreased tryptophan metabolism may alter brain development, neuroimmune activity and mitochondrial function. Our finding of decreased tryptophan metabolism appears to provide a unifying biochemical basis for ASDs and an initial step in the development of treatment or prevention protocols.

Genetic evaluation of hereditary spastic paraplegia. *S. Schirmer[1], Z. Kohl[2], T. Rödl[1], M. Becher[1], J. Winkler[2], U. Hehr[1,3].* 1) Center for Human Genetics , Regensburg, Germany; 2) Division of Molecular Neurology, University Hospital Erlangen, Erlangen, Germany; 3) Department of Human Genetics, University of Regensburg, Regensburg, Germany.

Hereditary spastic paraplegias (HSPs) comprise a clinically and genetically heterogeneous group of neurodegenerative disorders with progressive degeneration of the corticospinal tract. Patients with complicated forms show additional clinical findings, e.g. thin corpus callosum, cognitive impairment or peripheral neuropathy overlapping with a wide spectrum of other underlying genetic conditions. Currently 56 HSP loci have been assigned with causal mutations identified in 37 genes. Genetic testing by conventional Sanger sequencing in the diagnostic setting usually is restricted to the genes, most frequently affected. We here report the results of genetic testing for HSP by linkage analysis, Sanger sequencing and MLPA over the last 10 years. A subgroup of 20 patients received extensive neurologic workup in our outpatient clinic for movement disorders (cohort 1). In the overall cohort of 176 patients with suspected pure and complicated HSP causal mutations were identified in SPG4 (n=39), SPG3a (n=8), SPG7 (n=2), SPG11 (n=2), SPG20 (n=2) and SPG31 (n=2). To further increase the diagnostic yield we now evaluated a virtual gene panel for massive parallel sequencing of currently 30 HSP genes (step 1) based on the Illumina TruSight™Exome assay, which for further diagnostic workup of mutation negative patients allows subsequent evaluation of additional candidate genes (step 2) associated with other monogenic forms of spastic movement disorders. We validated step 1 on a cohort of 12 HSP patients with known mutations. Sample preparation was processed with the TruSight™Exome Enrichment kit, the Library was sequenced as a 150bp paired-end run with the MiSeq Reagent Kit v2. Reads were aligned to the human reference genome (UCSC hg19, NCBI build 37.1) and evaluated with an in house workup including the DNASTAR Lasergene®SeqMan Pro™ and DNASTAR ArrayStar® software. With our step 1 protocol we reached an average coverage of 58x with a minimal coverage of more than 20x for 91% of all 460 analyzed targets. All 12 expected HSP causing mutations were reliable detected including nonsense (n=2), missense (n=7) and frameshift (n=1) mutations, one 5bp deletion and one 9bp duplication. Clinically selected families of cohort 1 with suspected complicated HSP and more than one affected patient are currently evaluated with the step 1 and step 2 panel in order to further delineate the genetic spectrum of rare autosomal recessive complicated HSP.

1233T

Functional Analysis of the Autism and Intellectual Disability Gene PTCHD1 Reveals interactions in Synapses and Involvement in the Hedgehog Pathway. *K. Mittal, K. Sritharan, B. Degagne, J. Vincent.* Molecular Neuropsychiatry and Development Laboratory, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

This study is focused on investigating the functional aspects of a recently identified gene, PTCHD1, and how its disruption leads to Autism Spectrum Disorder and/or Intellectual Disability. Firstly, we sought to identify PTCHD1 splice variants contributing different coding sequences that might have higher or more specific expression in brain. We identified a new transcript skipping exon 2. This new transcript is predicted to encode a 542 amino acid protein in comparison to the 888 amino acid protein encoded by the PTCHD1 long isoform. It has just 4 transmembrane domains, and encodes a 62 kDa protein as compared to 12-transmembrane domains in the long isoform and a 101 kDa protein. We also found the presence of an additional exon upstream of exon 1. The quantitative expression analysis demonstrates that expression of the two new PTCHD1 transcripts is highest in human cerebellum as compared to the brain sub-regions and other tissues. The biological relevance of the new isoforms remains to be investigated. Initial expression data, indicates that these additional PTCHD1 transcripts are expressed chiefly in the brain, thus, these transcripts and encoded isoforms may be more relevant to autism and ID. PTCHD1 is structurally similar to the Hedgehog (Hh) signaling pathway receptors PTCH1 and PTCH2. The Hh pathway plays an important role in embryonic development and adult stem cell functioning. To establish the involvement of PTCHD1 in Hh pathway, expression analysis was done with Hh pathway genes and putative PTCHD1 partners. The quantitative expression analysis with over expression of PTCHD1 revealed increased levels of neuroligin and neurexin transcripts, which indicates either interaction with proteins at the synapse or a regulatory effect on these genes. Immunoprecipitation studies indicate interactions between PTCHD1 and Postsynaptic Density protein 95 (PSD-95). PSD-95 determines the size and strength of synapses in the postsynaptic density of neuronal excitatory synapses, and this putative interaction could be important to elucidate disease etiology. Preliminary results suggest sub-cellular localization of PTCHD1 in cilia, suggesting similar function as other Patched-related proteins. We hypothesize that PTCHD1 localization to primary cilia could inhibit the Hh pathway by excluding Smoothened and also allows cilia to function as chemo sensors for the detection of extracellular Shh, similar to PTCH1, during neuronal development and synapse formation.

1234F

GABRB2 in Schizophrenia. *H. Xue.* Division of Life Science, Hong Kong University of Science and Technology, Hong Kong, China.

Deciphering the molecular basis of schizophrenia is essential to effective management of this devastating mental disorder. Over the past decade, my research group has focused on the basic research on schizophrenia etiology through the discovery and characterization of a schizophrenia-associated gene - GABRB2, coding for GABAA receptor β2 subunit. The association between schizophrenia and single nucleotide polymorphisms (SNPs) in introns 9 and 10 of GABRB2, first reported by my group, has been cross-validated for multiple ethnic groups. Functional impacts of the schizophrenia associated non-coding SNPs in GABRB2 have been demonstrated at both mRNA and protein levels, viz. genotype-dependent alterations in mRNA expression and splicing, and effects of genotypes on isoform ratios and electrophysiological attenuation of GABAA receptors. Through extensive molecular genetics, population genetics and evolutionary genetics characterizations, GABRB2 has been shown by us to be under strong positive selection, active recombination as well as genomic imprinting, likely contributed to by a human lineage-specific insertion of an AluY transposable element. Their work on epigenetic regulation of GABRB2 revealed its developmental control and disruption in schizophrenia. Most recently, they have also extended GABRB2 association from psychotic disorders to social cognitions. Our work has thus improved current understanding of schizophrenia at molecular level centered at GABRB2, which represents at present one of the best characterized schizophrenia candidate genes.

1235W

Association between emotional memory and genetic polymorphisms on histone deacetylase 5. *F.R. Hartmann[1], D.J.-F. de Quervain[2,3], A. Papassotiropoulos[1,2,4], A. Heck[1].* 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Basel, Switzerland; 2) University of Basel, Psychiatric University Clinics, Basel, Switzerland; 3) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Basel, Switzerland; 4) University of Basel, Department Biozentrum, Life Sciences Training Facility, Basel, Switzerland.

Histone acetylation is a key epigenetic mechanism that enhances gene transcription by adding acetyl groups to the histone tail. Histone deacetylases (HDACs) remove acetyl groups, thus leading to a less accessible chromatin structure and a supressed gene expression. Several studies have shown that inhibition of HDACs enhances synaptic plasticity and memory formation. For example, HDAC inhibition modulates memory in the hippocampus via CREB (cyclic-AMP response element binding) binding protein. In mice, HDAC inhibition during memory consolidation of an object recognition task enhances formation of long-term memory. Histone deacetylase 5 (HDAC5) is a member of class II HDACs, which are characterized by shuttling between the nucleus and the cytoplasm and play an important role in transcription regulation, cell cycle progression and developmental events. HDAC5 has been associated with behavioural adaptations to emotional stimuli (cocaine addiction and chronic stress) in mice. However, the role of HDAC5 in learning and memory formation in humans is still unclear. We therefore investigated the role of the HDAC5 gene for episodic memory in two samples of healthy young participants (n=1'293 and n=983), who performed the identical picture-based episodic memory task using stimuli from the International Affective Picture System (IAPS). The phenotype of interest was episodic memory performance, measured by the number of correctly recalled pictures after 10 minutes delay. Genotype data were available for five single nucleotide polymorphisms (SNPs) mapping on HDAC5 (Affymetrix chip 6.0). We observed significant associations between two SNPs and memory performance particular for emotional stimuli in both samples, with carriers of the minor-allele showing worse memory performance (p(combined sample) = $7.2*10^{-5}$ and $7.8*10^{-5}$; respectively). Our results suggest a role for HDAC5 in emotional memory formation.

***CMYA5*, a candidate gene for schizophrenia: Expression in the brain and the effect of a functional variant on binding.** *A. Hsiung, R. Shiang, X. Chen.* Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA.

Schizophrenia is a devastating psychiatric disorder with a prevalence of approximately 1% and is characterized by delusions, hallucinations and deficits of cognition and emotion. Although many DNA variants are identified to associate with schizophrenia, the functional consequences of such variants that result in increased risk are unknown. In collaboration with a large group of investigators, we have found strong evidence that the *CMYA5* gene is associated with schizophrenia in a two-stage study using more than 33,000 subjects (Chen et al., 2010). The non-synonymous single nucleotide polymorphism (SNP), rs10043986, is a functional variant that changes the highly conserved proline residue 4063 to leucine in the *CMYA5* protein, myospryn. Current studies of *CMYA5* focus on its role in skeletal and cardiac muscles, and no studies of *CMYA5* in the brain and neuronal cells have been reported, the tissue most likely to be affected in patients with schizophrenia. We hypothesize that myospryn is expressed in the brain and this SNP affects the binding properties of myospryn to its binding partner, desmin intermediate filament. Using reverse transcription PCR, myospryn and desmin transcripts are shown to express in mouse brain regions. Western blotting analysis also confirms the protein expression of myospryn and desmin in the same brain regions. Next, we investigated whether the two variants of rs10043986 would change myospryn binding to desmin using a yeast two-hybrid assay (Y2H) and validating with surface plasmon resonance (SPR). The results show that both alleles of myospryn bind to desmin. A quantitative Y2H assay shows that the Pro allele has significantly weaker binding compared to the Leu allele, providing evidence that rs10043986 results in a functional change of myospryn's binding to desmin. The SPR result shows that the Pro allele has higher equilibrium dissociation constant than the Leu allele in the steady-state analysis, confirming the differential binding. In conclusion, expression of *CMYA5* in the brain provides evidence that it has function in the brain and is important for the schizophrenia pathophysiology, and rs10043986 affects the binding properties of myospryn to desmin and is a potential causal variant.

1237F

Association of NTRK2 and emotional processing in healthy young subjects. *K. Spalek[1], A. Heck[2], D. Coynel[1], D.J.-F. de Quervain[1, 4], A. Papassotiropoulos[2, 3, 4].* 1) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Basel, Switzerland; 2) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Basel, Switzerland; 3) University of Basel, Department Biozentrum, Life Sciences Training Facility, Basel, Switzerland; 4) University of Basel, Psychiatric University Clinics, Basel, Switzerland.

The neurotrophin tyrosine kinase receptor 2 (NTRK2), also known as 'tropomyosin-related kinase' receptor B (TrkB), is one of two receptor types binding neurotrophins with high affinity. Its activation plays a central role in cell survival, differentiation and synaptic plasticity as well as neurotransmitter release. Several studies provide support for a relationship of NTRK2 and psychiatric disorders, e.g. depression, schizophrenia, addiction, eating and anxiety disorders. Expression studies in patients with psychiatric disorders and animal models of psychiatric diseases report reductions of TrkB expression in the brain. Furthermore, injection of TrkB agonist in mice' hippocampus induced long-term activation of TrkB and antidepressant effects whereas the injection of TrkB antagonist decreased TrkB activity and increased anxiety- and depression-like behaviours. In general, emotional dysregulation is a common denominator of many psychiatric disorders, and it can be assumed that NTRK2 is involved in this process. Based on the evidence for an influence of NTRK2 on emotional processing in psychopathology and the lack of studies investigating the role of NTRK2 in healthy young subjects, we investigated genetic associations between NTRK2 single nucleotide polymorphisms (SNPs) and emotional processing, measured by arousal ratings of emotional (negative and positive) and neutral pictures from the International Affective Picture System (IAPS) in a sample of 1'161 healthy young subjects. Our results show a significant association between two NTRK2 SNPs and emotional processing of positive pictures. Specifically, major allele carriers rated positive pictures as more arousing compared to non-carriers. We were able to replicate this association result in an independent sample of 822 healthy young subjects who performed the identical picture rating task. Our findings suggest a role of NTRK2 in emotional processing in healthy young subjects and might add useful information for the understanding of its role in psychopathology.

1238W

PRICKLE1 interaction with SYNAPSIN I reveals a role in Autism Spectrum Disorders. *L. Paemka[1], V.B. Mahajan[1], J.M. Skeie[1], L.P. Sowers[1], S.N. Ehaideb[1], P. Gonzalez-Alegre[1], T. Sasaoka[2], H. Tao[3], A. Miyagi[4], N. Ueno[4], S. Wu[1], B.W. Darbro[1], P.J. Ferguson[1], A.A. Pieper[1], J.K. Britt[1], J.A. Wemmie[1], D.S. Rudd[1], T. Wassink[1], H. El-Shanti[5], H.C. Mefford[6], G.L. Carvill[6], J.R. Manak[1], A.G. Bassuk[1].* 1) University of Iowa, Iowa City, IA; 2) Kitasato University School of Medicine, Japan; 3) Hospital for Sick Kids, Toronto, Canada; 4) National Institute for Basic Biology, Japan; 5) Shaffalah Medical Genetics Center, Doha, Qatar; 6) University of Washington, Seattle, Washington.

The frequent comorbidity of Autism Spectrum Disorders (ASDs) with epilepsy suggests a shared underlying genetic susceptibility; and several genes, when mutated, can contribute to both disorders. Recently, PRICKLE1 missense mutations were found to segregate with ASD, however the mechanism by which mutations in this gene might contribute to ASD is unknown. To elucidate the role of PRICKLE1 in ASDs, we carried out studies in Prickle1+/- mice and Drosophila, yeast, and neuronal cell lines. We show that mice with Prickle1 mutations exhibit ASD-like behaviors. To find proteins that interact with PRICKLE1 in the central nervous system, we performed a yeast two-hybrid screen with a human brain cDNA library and isolated a peptide with homology to SYNAPSIN I (SYN1), a protein involved in synaptogenesis, synaptic vesicle formation, and regulation of neurotransmitter release. Endogenous Prickle1 and Syn1 co-localize in neurons and physically interact via the SYN1 region mutated in ASD and epilepsy. Finally, a mutation in PRICKLE1 disrupts its ability to increase the size of dense-core vesicles in PC12 cells. Taken together, these findings suggest PRICKLE1 mutations contribute to ASD by disrupting the interaction with SYN1 and regulation of synaptic vesicles.

1239T

Altered dose-response relationships in addiction genetics. *G.R. Uhl[1,2], J. Drgonova[1], F.S. Hall[1].* 1) Molecular Neurobiology, NIDA IRP NIH, Baltimore, MD; 2) .Depts of Neurology, Neuroscience and Mental Health, Johns Hopkins Medical Institutions.

Classical genetic studies document substantial heritable influences on DSM substance dependence. Linkage and genome wide association studies identify only modest-sized effects at any locus. Clusters of nearby SNPs within selected genes, including those that encode the cell adhesion molecules PTPRD, CDH13 and NrCAM, do display 10-2 > p > 10-8 associations with dependence in many more independent samples than expected by chance. For each of these genes, 5' SNPs display nominally-significant associations with levels of mRNA expression in postmortem brain samples. A validated model for abuse liability, conditioned place preference, can provide dose-response information about the rewarding (and aversive) properties of abused substances in mouse models, providing typical inverted U dose-response relationships. Unexpectedly, in mice with altered expression of each of these genes, we have identified altered dose-response relationships for cocaine-conditioned place preferences. Reduced expression of either CDH13 or PTPRD provides a leftward shift in dose response relationships for the ascending limb of the 'inverted U' dose response relationship that is characteristic of cocaine reward. Conversely, reduced expression of NrCAM appears to depress the descending limb of the dose response relationship for cocaine conditioned place preference. Control behavioral tests fail to provide evidence for confounding explanations for these results. Each of these observations receives significant additional support from human datasets that include association with altered dose response relationships from stimulant doses administered in laboratory settings, association with doses of self administered coffee or cigarette consumption, and association with self reported doses of alcohol required to exert subjective effects. It is important to consider dose-response relationships for both rewarding and aversive features of abused substances in genetic, nosologic and therapeutic approaches to addictions. (Financial support: NIDA-IRP/NIH/DHHS).

Alzheimer's disease risk gene CD33 inhibits microglial uptake of amyloid beta. *A. Griciuc[1], A.R. Parrado[1], A. Serrano-Pozo[2], A.N. Lesinski[1], C.N. Asselin[1], K. Mullin[1], B. Hooli[1], S.H. Choi[1], L. Bertram[3], B.T. Hyman[2], R.E. Tanzi[1].* 1) Genetics and Aging Research Unit, Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Charlestown, MA; 2) Alzheimer's Disease Research Laboratory, Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Charlestown, MA; 3) Neuropsychiatric Genetics Group, Max-Planck Institute for Molecular Genetics, Berlin, Germany.

Preservation of cognitive abilities is one of the major medical challenges of the 21st century. Here, we describe a novel pathway that regulates the clearance of amyloid beta (Aβ) in the aging brain, and might play a pivotal role in the pathogenesis of Alzheimer's disease (AD) [1]. We have previously shown that mutations in the CD33 gene confer increased risk for AD. CD33 is a sialic acid-binding immunoglobulin-like lectin that regulates innate immunity but has no known roles in the brain. Our extensive pathological analyses uncovered a prominent microglial expression of CD33 in the aging human brain; moreover, the number of CD33-positive microglia is markedly increased in AD relative to age-matched control brains. The minor (T) allele of the CD33 single nucleotide polymorphism (SNP) rs3865444, which confers protection against AD, is associated with marked reductions in CD33 protein levels, CD33 microglial expression and levels of insoluble Aβ42 in AD brain. Furthermore, the numbers of CD33-immunoreactive microglia closely correlate with the levels of insoluble Aβ42 levels and plaque burden in AD brain. Experiments using microglial cell cultures indicate that CD33 inhibits the uptake of Aβ42 by microglia, and requires its sialic acid-binding domain to mediate this effect. Mouse genetics experiments further indicate that CD33 deletion markedly decreases the levels of insoluble Aβ42 and the amyloid plaque burden in APP/PS1 transgenic mice. To gain further insight into the regulation of CD33 expression in the aging human brain, we are currently characterizing 5 additional CD33 mutations (including both protective and risk variants) that we have recently identified. Collectively, our results suggest that CD33 activity in microglial cells promotes Aβ pathology and inhibition of CD33 function could represent a novel therapy for AD.
[1] Griciuc et al. (2013), Alzheimer s Disease Risk Gene CD33 Inhibits Microglial Uptake of Amyloid Beta. Neuron, 78(4):631-43.

Involvement of non-Hsa21 genes and MicroRNAs provide etiological basis for abnormal phenotypes in pathogenesis of Down syndrome. *A. Pathak, S.R. Phadke.* Department of Medical Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, Uttar Pradesh , India.

Down syndrome (DS), the most frequent genetic disorder leading to mental retardation is caused by partial or complete triplication of human chromosome 21 (Hsa21). The differential expression of genes located on extra chromosome 21 is generally assumed responsible for phenotypic abnormalities but this gene dosage hypothesis has not been fully assessed on genome-wide basis. The expression patterns of genes related to phenotypic abnormalities may provide insights into their roles in pathogenesis of DS. To analyze the differential gene expression and understand the molecular mechanism underlying pathogenesis of DS, we performed global gene expression profiling in blood samples of 14 DS and 4 normal subjects using human whole transcriptome microarray. The microarray analysis revealed total of 624 genes (195 upregulated and 429 down regulated) were differentially expressed in DS patients as compared to control. Out of the genes present on chromosome-21, a total of 210 genes were differentially expressed ranging from 1.5 to 5 fold compared to normal individuals. Genes involved in physiological pathways such as apoptosis regulation, cell cycle regulation, signal transduction, cell maturation, and immunity showed dysregulation. Several genes localized on chromosome-21 such as APP, SOD1, DYRK1A, COL6A1 showed differential expression and the levels were conserved across all DS subjects. Interestingly, several non chromosome-21 genes such as RCAN3 (chromosome 1), ANK3 (chromosome 10), CDK17 (chromosome 12) etc., having roles in cardiogenesis, signal transduction and differentiation of neurons showed conserved levels of expression across the DS subjects. Further to investigate the role of microRNAs (miRNAs) in regulation of gene expression, global miRNA profiling was performed in 4 Down syndrome patients and 1 control using Affymetrix miRNA 3.0 array. Several Hsa21 miRNAs like miR-99a, let-7c, miR-125b-2, miR155, miR-802 showed overexpression effecting the regulation of genes involved in DS pathogenesis. The gene dosage hypothesis on chromosome-21 may partially explain the neurological and other symptoms but our results substantiate the involvement of genes localized across different chromosomes in pathogenesis of DS. Further, identification of miRNAs involved in DS pathogenesis may lead to identification of new therapeutic targets for DS. Our data lead to more systematic and improved understanding of molecular mechanism underlying the pathogenesis of the disease.

1242T

Induced pluripotent stem cell derived neural cells and Parkinson's Disease-associated rare variants. *K. Belle, J.M. Van Baaren, A. Liu, J.A. Vance, D.M. Dykxhoorn.* Human Genetics and Genomics, Univeristy of Miami, Miami, FL.

Parkinson's disease (PD) is a neurodegenerative disorder of the central nervous system. Late in life PD patients experience motor-dysfunction and cognitive impairments such as dementia, progressing in severity with age. PD has been linked to genetic mutations (familial, idiopathic) as well as environmental exposure, though the causal reasons are different, the end phenotype is the same. While many of these genes have basic roles in many different cell types and throughout the life cycle, the disease manifests itself specifically in pars compacta of the substantia nigra. Symptoms are first noticed late in life and progress until death. The advent of iPSC technology provides researchers with a safe and relevant way to investigate and treat genetic disorders in a patient specific manner; a small tissue sample from an affected patient is used to produce appropriate cell type for study. To date, animal models have been used as models for PD. These animal models have been very useful, but it is difficult to use them to accurately recreate a complex disease, as their genetic backgrounds differ so greatly from that of humans. The study of PD in affected human cells will lead to better understanding of the genes and pathways involved in PD. Our research centers around modeling PD in vitro, with symptomatic cell types derived from actual patient disease cells, and age-matched controls, (to differentiate between effects related solely to age versus those related to PD). The goal of this research is to provide cellular models for PD in vitro. To further investigate PD-related gene expression and morphologies, we have devised a system using shRNA-mediated silencing of PD-associated genes, and expression of rare variants, in aging neural cells derived from controls and affected patient. Gene expression and morphological changes are collected with respect to patient disease status, as well as sample age (days in culture and passage number). This system of co-knockdown/expression, allows us to further study the effects of rare variants on different genetics backgrounds (familial affected, idiopathic affected, and control). It is believed that this system will exacerbate cellular phenotypes related to the disease. These types of experimentation will help us obtain insight into the pathways involved in the disease. Further, successful iPSC models of PD could be useful in testing potential therapeutic interventions.

More than ER stress: molecular mechanism for misfolded PLP1 that impacts subcellular dynamics and clinical severity of Pelizaeus-Merzbacher disease. *Y. Numata[1, 2], T. Morimura[3], S. Nakamura[1], E. Hirano[1], S. Kure[2], Y. Goto[1], K. Inoue[1].* 1) Mental Retardation and Birth Defect Research, NCNP, Kodaira, Tokyo, Japan; 2) Dept. Pediatrics, Tohoku Univ. School of Med, Sendai, Japan; 3) Unit for Neurobiology & Therapeutics, MNRC, Shiga Univ. of Medical Science, Otsu, Japan.

Involvement of endoplasmic reticulum (ER) stress and the subsequent unfolded protein response (UPR) has been implicated in pathogenesis of multiple human inherited diseases, including Charcot-Marie-Tooth disease (CMT) and Pelizaeus-Merzbacher disease (PMD). PMD-causing mutant PLP1 accumulates in the ER and induces ER stress. However, the link between the wide clinical severity of PMD and the cellular response induced by mutant PLP1 remains largely unknown. Here we identified that misfolded mutant proteins also impact global subcellular dynamics and cellular environment. We found that expression of mutant PLP1 in HeLa cells, MO3.13 oligodendrocytic cells, and primary oligodendrocytes depletes major ER chaperones with a KDEL (Lys-Asp-Glu-Leu) motif from the ER. This can be detrimental to cells because accumulation of misfolded proteins in the ER generally up-regulate ER chaperones to alleviate ER stress. The PLP1 mutants also induce fragmentation of the Golgi apparatus (GA). These organelle changes are more prominent in cells expressing severer mutant, potentially associated with disease phenotype. Similar changes are also observed in CMT-causing MPZ mutant that triggers ER stress, suggesting a common molecular mechanism among these disease genes. Moreover, PLP1 mutants inhibited global trafficking of secretary and membrane proteins, possibly leading to deleterious cellular environment. Notably, we found that KDEL receptor, which is critical in retrotransport of ER chaperons, was also dislocated in the ER, possibly causing the depletion of ER chaperons. The fact that inhibition of GA to ER trafficking by brefeldin A induced similar cellular phenotypes supported this hypothesis. Altogether, we propose that misfolded disease-causing mutant proteins not only induce ER stress and trigger UPR, but also cause depletion of ER chaperones, GA fragmentation and protein trafficking deficit, further contributing to the pathogenesis of inherited ER stress-related diseases and their disease severity.

1244W

Potential regulatory functions of late-onset Alzheimer's disease associated variants. *S.L. Rosenthal[1], M.M Barmada[1], X. Wang[1], F.Y. Demirci[1], O.L. Lopez[2,3], M.I. Kamboh[1,3].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA, USA; 3) Alzheimer's Disease Research Center, University of Pittsburgh, Pittsburgh, PA, USA.

Late-onset Alzheimer's disease (LOAD) is a multifactorial neurodegenerative disorder resulting in loss of cognitive and executive function and ultimately death. It currently affects over 5 million individuals in the United States alone. To date, ten loci (*APOE, BIN1, CLU, EPHA1, PICALM, CD2AP, CD33, ABCA7, MS4A4A/MS4A6E*, and *CR1*) have been implicated as risk loci for LOAD. Despite a number of associated variants located in these loci, the identified associations show only modest effect sizes, with *APOE* as the sole producer of a considerable odds ratio. Given its complex nature, LOAD is a disease about which we stand to gain substantial insight by examining how these variants may alter transcription and subsequently, pathology and phenotype. This study aims to effectively utilize the newly developed RegulomeDB (http://regulomedb.org) to achieve a better understanding of the potential regulatory function of previously published genome-wide significant SNPs in these nine loci (excluding *APOE*), as well as other suggestive GWAS loci (total 31 top SNPs). We used Broad Institute's SNP Annotation and Proxy search (SNAP - http://www.broadinstitute.org/mpg/snap/) tool to identify 140 SNPs in linkage disequilibrium ($r^2 \geq 0.8$) with the 31 previously published LOAD-associated SNPs. We then examined all 171 SNPs for potential regulatory function using RegulomeDB and found 14 with scores of 2b or lower, indicating a high likelihood of affecting gene expression. Half of these SNPs were located in the *MS4A* region, including the SNP with most evidence for regulatory function (rs667897, RegulomeDB score=1b). Data included in RegulomeDB indicates that this intergenic SNP serves as an eQTL for *MS4A4A* and mediates binding of transcription factors through TCF11:MafG and NFE2L2 motifs. Variants in the regions of *CD2AP, CLU, ABCA7*, and *PICALM* showed low RegulomeDB scores (2a or 2b), suggesting good evidence for affecting gene expression. *SLC28A1* (Regulome DB score=1f) and *HRK/RNFT2* (Regulome DB score=2a), two suggestive LOAD loci, were also among the top 14 SNPs with strong evidence for regulatory function. Notably, all 14 SNPs with suggested regulatory function fall in intronic or intergenic regions. Our results indicate further possibilities for explaining the associations between replicated SNPs and LOAD risk, especially for non-coding variants.

1245T

A functional variation in the *CHRNB3* promoter affects Parkinson's disease risk and smoking. *A. Bar-Shira[1], M. Gana-Weisz[1], Z. Gan-Or[1], E. Giladi[1], N. Giladi[2,3], A. Orr-Urtreger[1,3].* 1) Genetic Institute, Tel Aviv Sourasky Medical center, Tel Aviv, Israel; 2) Movement Disorders Unit, Parkinson Center, Department of Neurology, Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel; 3) Sackler Faculty of Medicine, Tel-Aviv University, Tel Aviv, Israel.

Introduction: Parkinson's disease (PD) is affected by various genetic alterations, environmental factors and aging. Interestingly, cigarette smoking is being considered as a protective factor, and it was suggested that nicotine and nicotinic-acetylcholine receptors (nAChRs) may play a role. Since the β3 nAChR subunit is depleted in the striatum of PD patients, we aimed to test the possibility that variations in the *CHRNB3* gene, which encodes this subunit, are involved in PD. **Methods:** *CHRNB3* was sequenced in 100 PD patients. The alteration that was found in the putative promoter of this gene was further analyzed in a cohort of 596 PD patients and 369 controls. Its effect on promoter binding and activity was studied in cellular models using Chromatin immunoprecipitation and Luciferase assays. **Results:** The minor G allele frequency was 0.31 and 0.26 among patients and controls, respectively (p=0.02), and carriers had an OR of 1.33 (95% CI=1.03-1.73) for PD. In addition, the minor allele was strongly associated with smoking in patients, as 48.4% of carriers reported smoking history compared to 32.6% of non-carriers (p<0.0001). The transcription factor Oct-1 binding was almost eliminated in lymphoblasts homozygous for the minor G allele, to only 6.5% percent of the binding in cells with the major A allele. Furthermore, the *CHRNB3* promoter activity was reduced by 70%-96% in cells homozygous for the minor allele. **Conclusions:** The association between the *CHRNB3* variation and smoking in PD patients and its functional role in the promoter may suggest a molecular link between PD, smoking and nAChRs. These findings may also raise the possibility that nicotine treatment in PD should involve genotyping and personal adjustment.

Identification of microRNA expression quantitative trait loci in the nucleus accumbens of human postmortem brains from alcohol dependent subjects and matched controls. *M. Mamdani, V. Williamson, G. McMichael, B. Riley, K. Kendler, V. Vladimirov.* Virginia Institute for Psychiatric and Behavioral Genetics, VCU, Richmond, VA.

Alcohol dependence (AD) is a chronic addiction disorder with heritable factors accounting for 60% of the risk. While genetic studies have identified numerous AD loci, the mechanisms underlying neuroadaptations to excessive alcohol consumption are unclear. MicroRNAs (miRNAs), a species of non-coding RNA, are abundantly expressed in the brain and predominantly function by down-regulating gene expression. Involved in normal brain development and function, miRNAs are also implicated in several neuropsychiatric disorders; however, only one study has assessed miRNA expression in human AD subjects and in the prefrontal cortex only. Here, we evaluate miRNA expression and function in the nucleus accumbens (NAc), a major addiction-related brain region within the mesocorticolimbic pathway that is involved in drug-seeking motivation and reward. Expression quantitative trait loci (eQTL) are genomic loci that can regulate miRNA and/or mRNA expression; however, no such studies have been conducted in postmortem AD brains. We hypothesize that genetic risk loci for AD will also impact the expression of those miRNAs and mRNAs differentially expressed in the NAc of AD subjects and controls. In our preliminary results we detected 240 differentially expressed miRNAs at p<0.05; after multiple testing correction at a false discovery rate (FDR) <10%, 29 miRNAs remained significant. Within this list were miRNAs reported to be involved in aging/neurodegeneration (hsa-miR-1538, -516, -34c, -487a) and neurodevelopment/function (hsa-miR-371, -154, -1247). Interestingly, hsa-miR-154 is also reported to be associated with mesocorticolimbic pathway modulation in opiate addiction. To better understand the mechanisms contributing to the miRNA expression we identified AD-associated eQTLs affecting miRNA expression. We detected 275 cis-eQTLs (within 1 megabase) for all 29 miRNAs (FDR <10%). Several of these cis-eQTLs are located in functionally relevant sites including transcription factor binding sites, splicing enhancers/silencers, and putative miRNA target sites. To further explore the specific mechanisms driving AD, mRNA expression data derived from the same sample will be integrated with the genetic and miRNA data to **1)** identify miRNA/mRNA AD-specific interactions and **2)** detect eQTLs mediating these interactions. Subsequently, weighted gene co-expression network analyses (WGCNA) will be performed to identify specific gene network modules under the control of AD-implicated miRNAs.

1247W

Behavioral and neurochemical characterization of mutant mice lacking Lphn3, a gene implicated in ADHD and addiction. *D. Wallis[1], C.A. Orsini[2], B. Setlow[2].* 1) Biochemistry and Biophysics, Texas A&M University, College Station, TX; 2) Department of Psychiatry McKnight Brain Institute University of Florida College of Medicine Gainesville, FL 32610.

The latrophilin 3 (Lphn3) gene has been linked to susceptibility to attention deficit hyperactivity disorder (ADHD) and vulnerability to development of addiction. This suggests that this gene may be a genetic biomarker of these disorders and may lead to more selective therapeutic targets for treating them. However, little is known about the function of this gene. To characterize the function of the Lphn3 gene, we generated mutant mice. We then performed neurochemical, pharmacological, and behavioral assays to assess Lphn3 function. Four to 6 week old male Lphn3 mutant mice had significantly higher dopamine and serotonin levels in the dorsal striatum than their wild type (WT) counterparts. Given that elevated striatal dopamine is associated with locomotor hyperactivity in other mouse mutant lines, we evaluated locomotor activity in an open field arena. As expected, Lphn3 mutant mice displayed significantly more horizontal activity than both WT and heterozygous mice. Additionally, when Lphn3 mutant mice were administered acute i.p. injections of cocaine (20 mg/kg), they showed a significant elevation in locomotor activity relative to WT mice. In a separate cohort of male and female mice, we explored the contribution of the Lphn3 gene to reward-seeking behavior by assessing instrumental responding (lever pressing) for food pellet rewards under various fixed ratio (FR) schedules of reinforcement. Mice were first trained on a FR1 schedule for five 30 min sessions, after which they were tested on FR3, FR10, FR20 and FR40 schedules (one schedule/session). Lphn3 mutant mice displayed significantly greater instrumental responding for food than WT mice, particularly under high response ratios. Finally, we evaluated performance on rotarod assays and found a statistically significant difference between WT and null Lphn3 females with mutants having decreased latency to fall. Further, the WT mice were more likely to do a passive rotation on the rod, and the mutants were more likely to fall off. Together, these findings are consistent with a role for Lphn3 in regulating behavior, and show that a loss of gene function results in increased reward-seeking, possibly via enhanced striatal monoamine signaling. Current work is focused on characterizing Lphn3 mutant mice in additional behaviors, such as impulsivity and learning, and investigating the neurobiological consequences of the Lphn3 mutation.

1248T

Induced Pluripotent Stem Cells to Model Tourette's Syndrome. *L. Deng[1,2], N. Sun[1,2], Z. Pang[5], RA. King[6], M. Sheldon[1,2,3], JC. Moore[1,3], RP. Hart[3,4], M. Konsolaki[1,2], M. State[7], GA. Heiman[1,2], JA. Tischfield[1,2,3].* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Human Genetics Institute of New Jersey, Piscataway, NJ; 3) RUCDR Infinite Biologics NIMH Stem Cell Resource, Piscataway, NJ; 4) Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ; 5) Child Health Institute of New Jersey, New Brunswick, NJ; 6) Yale Child Study Center, Yale University School of Medicine, New Haven, CT; 7) Department of Psychiatry , UCSF, San Francisco, CA.

Much of our current knowledge about the central nervous system (CNS) and neural function in patients with neuropsychiatric disorders has been obtained from relatively degraded postmortem brain. The inability to sample live CNS tissues impedes our progress to understand possible alterations in gene function and neuropathological abnormalities that develop during the course of the disorder. The rapid growth of iPSC technology has turned somatic cells into multipurpose basic and clinical research tools and opened new windows for modeling human diseases. Tourette syndrome (TS) is a childhood onset neurodevelopmental and genetic disorder characterized by chronic motor and phonic tics. Recent studies have indicated that the histaminergic neurotransmission pathway plays a role in the etiology of TS (Fernandez TV et al., Biol Psychiatry 2012). A previous study of a densely affected two-generation TS pedigree identified a rare segregating nonsense mutation, Hdc W317X, in the l-histidine decarboxylase (Hdc) gene (Ercan-Sencicek et al., NEJM 2010). The causal connection between a reduction in HDC activity and the symptoms of TS remains unclear. We collected whole blood samples from three members of this family and established induced pluripotent stem cell (iPSC) lines from each individual's T cells. Further differentiation of HDC mutant family's iPSCs into histaminergic neurons will enable us to model TS with regard to the histamine and other brain pathways. We will determine if partial loss of HDC function affects the expression of other genes and the metabolism/phenotype of these neurons. Comparison studies of the neurons from TS patients to the unaffected members within this family may lead to a better understanding of the TS phenotype.

1249F

Forgetting in *C. elegans* is regulated via Musashi (*msi-1*) mediated translational control of the Arp2/3 complex. *N.O. Hadziselimovic[1,2], F. Peter[1,2], P. Hieber[1,2], V. Vukojevic[1,2], P. Demougin[1,2], D.J.F. de Quervain[1,3], A. Papassotiropoulos[1,2,4], A. Stetak[1,2,4].* 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 2) University of Basel, Biozentrum, Life Sciences Training Facility, Klingelbergstrasse 50/70, 4056 Basel, Switzerland; 3) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 4) University of Basel, University Psychiatric Clinics, Wilhelm Klein-Strasse 27, 4055 Basel, Switzerland.

In order to maintain a highly flexible nervous system, not only learning and generation of memory but forgetting is also essential to eliminate unnecessary memories to allow adaptation to a constantly changing environment.

Using *C. elegans* as a model organism, we recently performed a targeted candidate-gene based screen and found that the highly conserved RNA-binding protein musashi (*msi-1*) mediates forgetting. MSI-1 is expressed in neurons and tissue specific rescue in *C. elegans* demonstrates that the MSI-1 function is exclusively necessary in the AVA command interneuron. Among the previously identified MSI mRNA binding partners in vertebrate cells, ACTR2 is one subunit of the Arp2/3 protein complex serving as a nucleation core for the branching of the actin cytoskeleton. Using immunoprecipitation and subsequent RT-qPCR, we found that mRNAs of the *arx-1, -2* and *-3* subunits of the Arp2/3 complex associate with MSI-1 *in vivo*. We also show that the protein levels of ARX-1, ARX-2 and ARX-3 are downregulated upon associative learning, that is mediated by the translational inhibitory activity of MSI-1. Using genetic epistasis, we establish a link between MSI-1 and the levels and activity of the Arp2/3 protein complex. We show that activation of the Arp2/3 protein complex through expression of a constitutive active form of *wsp-1* in the AVA interneuron can block forgetting similar to deletion of the *msi-1* gene. The role of *msi-1* on forgetting is also reflected in *msi-1* mutants by the strong and persistent consolidation of GLR-1 containing synaptic size increase induced by associative learning. Finally, we demonstrate that GLR-1 signaling regulates both actin capping through the activation of adducin (*add-1*) and inhibition of the Arp2/3 complex mediated actin branching by *msi-1* regulated translational repression and both mechanisms act in concert to establish the proper memory. Thus, our results demonstrate that MSI-1 induces forgetting and represent a novel mechanism of memory regulation linking translational repression to regulation of the structure and complexity of the actin cytoskeleton in neurons.

1250W

Transcriptional impact of *POLR3A* and *POLR3B* mutations in Pol III-related hypomyelinating leukodystrophies. *K. Choquet[1], S. Durrieu[2], G. Boldina[2], M-J. Dicaire[1], D. Forget[3], K. Guerrero[4], B. Coulombe[3], M. Teichmann[2], G. Bernard[4], B. Brais[1].* 1) Neurogenetics of Motion Laboratory, Montreal Neurological Institute, McGill University, Montreal, Canada; 2) INSERM U869, Institut Européen de Chimie et Biologie, Université Bordeaux Segalen, Bordeaux, France; 3) Institut de Recherches Cliniques de Montréal (IRCM), Montreal, Canada; 4) Pediatric Neurodegenerative Laboratory, Department of Pediatrics, Neurology and Neurosurgery, Division of Pediatric Neurology, Montreal Children's Hospital, McGill University Health Center, Montreal, Canada.

Leukodystrophies are a heterogeneous group of neurodegenerative diseases characterized by abnormal white matter in the central nervous system (CNS). It has been established that mutations in *POLR3A* and *POLR3B* are an important cause of five clinically overlapping hypomyelinating leukodystrophies (HML). *POLR3A* and *POLR3B* encode the two catalytic subunits of RNA Polymerase III (Pol III), which synthesizes over 200 non-coding RNAs including transfer RNAs (tRNAs). We hypothesized that mutations in *POLR3A* and *POLR3B* alter Pol III's transcription efficiency, leading to a decrease in the expression of key transcripts for the development and maintenance of CNS white matter. We designed a custom microarray with probes for all known Pol III transcripts to compare expression levels between fibroblasts of four *POLR3A*-confirmed cases and four controls. A relatively small group of transcripts were found to be downregulated (n=21), of which an even smaller number (n=5) were found to be more expressed in brain compared to other tissues. We further validated their downregulation by performing quantitative RT-PCR and Northern Blots in a larger cohort composed of *POLR3A*- and *POLR3B*-confirmed cases as well as healthy controls. We also isolated Pol III from patients and controls fibroblasts' nuclei and performed in vitro transcription assays to evaluate Pol III's transcriptional efficiency. Deregulated Pol III targets are being further investigated to determine whether impairment of Pol III transcription is indeed central to the pathophysiology of Pol III-related HML. Elucidating the molecular mechanisms responsible for this disease is essential to develop potential therapeutic approaches.

The NINDS Repository: A unique resource of patient-derived, highly characterized primary fibroblasts and induced pluripotent stem cells for neurodegenerative disease research. *C.A. Pérez[1,4], S. Heil[1,4], S. Gandre-Babbe[2,4], C. Rhoda[2,4], K. Panckeri[2,4], M. Self[1,4], K. Hodges[3,4], M. Shutherland[5], R.A. Corriveau[5], C. Tarn[1,4].* 1) NINDS Repository; 2) Stem Cell Biobank; 3) Cell Culture Laboratory; 4) Coriell Institute for Medical Research, Camden, NJ; 5) National Institute of Neurological Disorders and Stroke (NINDS), Bethesda, MD.

Induced pluripotent stem cells (iPSCs) reprogrammed from patient-derived primary fibroblasts have become an increasingly utilized resource for the study of human disease and have proven especially valuable in studying neurodegenerative disorders for which disease models are difficult to establish. The National Institute of Neurological Disorders and Stroke (NINDS) Repository is a public resource established in 2002 aiming to provide a centralized and open collection of biological samples (DNA, lymphoblastoid cell lines, fibroblasts, iPSCs, biofluids such as plasma, serum, cerebrospinal fluids, and urine) and associated de-identified clinical data from a diverse population of affected patients and normal controls. Since 2011, the NINDS Repository has added to its web-based catalog (http://ccr.coriell.org/NINDS) more than 40 iPSC and 130 fibroblast lines. Most iPSC lines are contributed by investigators from a Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS) and Huntington's disease (HD) NINDS-sponsored consortia funded by the American Reinvestment and Recovery Act (ARRA). Additional iPSC lines have been also submitted by other investigators. To ensure the quality of these valuable resources, all iPSCs and fibroblasts submitted to the NINDS Repository by iPSC Consortia and other investigators undergo rigorous quality assessments (viability, pluripotency, karyotyping, differentiation status, gene expression analysis, sterility) prior to distribution by the NINDS repository. The results are summarized in a Certificate of Analysis displayed on the web-based catalog along with the recommended culturing protocol. The NINDS Repository fibroblast and iPSC collections include mostly cell lines bearing specific genetic mutations associated with PD, ALS, HD, frontotemporal degeneration, or Alzheimer's disease, as well as samples derived from neurologically normal controls. For certain affected individuals, the parental fibroblast, corresponding iPSC line, and whole blood DNA are available. It is important that all related biospecimens from the same individual, and their specific characterization details describing publicly available iPSCs and fibroblasts be documented and clearly presented to potential requestors. The NINDS Repository serves as a unique and effective centralized resource for these iPSCs and fibroblasts and their critical phenotypic data, to basic and applied research investigators worldwide.

1252F

Understanding the Risk Pathway from *GABRA2* to Alcoholism: Effects of Personality, Brain, Development and Gene x Environment Interactions. *M. Burmeister[1,2], S. Villafuerte[1,2], E.M. Trucco[2], M. Heitzeg[2], R.A. Zucker[2].* 1) Molecular & Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI; 2) Department of Psychiatry, University of Michigan, Ann Arbor, MI.

SNPs within *GABRA2* have long been known to be associated with alcoholism. To understand the path from a genetic variant to complex behavior, alcohol abuse, we used the Michigan Longitudinal Study (MLS), consisting of ~463 families who were recruited >20 years ago with a 3-5 year old boy, his siblings and parents. ~70% of fathers met criteria for alcoholism, plus neighborhood controls. Assessments were every 3 years, teenagers every year. Measures considered here include impulsiveness in adults (NEO-PI-R), fMRI during a modified incentive monetary delay task, life-time alcohol problems, youth externalizing behavior (Young Self Report) and parental monitoring. *GABRA2* genotypes were tested for association by regression analysis. Mediation was tested using bootstrapping procedures in AMOS. Growth mixture modeling (GMM) was used to identify externalizing trajectory classes. Class labels were regressed on GABRA2, parental monitoring, and their interaction using multinomial linear regression via GMM. Most *GABRA2* SNPs were in strong LD and formed two major haplotypes. The G (minor) allele of rs279827 represents the risk haplotype with regard to alcoholism. We identified three trajectory classes of externalizing behavior across adolescence, a low, a developmentally limited, and a high risk class. Parental monitoring but not genotype predicted lower levels of externalizing behavior. We observed a significant *GABRA2* x parental monitoring interaction effect on trajectory class membership: While A-carriers' trajectory class membership was largely unaffected by parental monitoring, those with the risk (G) genotype were affected by parental monitoring, both positively and negatively. These and our previously published results demonstrate that subjects who carry the risk haplotypes of *GABRA2* 1) are more impulsive, which mediates the association of *GABRA2* SNPs with alcohol problems, 2) their brains (especially the insula) react stronger when anticipating a reward, and, 3) when not monitored by parents, are more likely to engage in problem behaviors ('act out') during adolescence, and later become more likely to have alcohol problems. Our study demonstrates how understanding of the path from SNP to final phenotypic outcome can be achieved in smaller, well characterized longitudinal samples, and how genetic findings can be pulled into the existing psychosocial literature, merging studies of nature with nurture to explain some aspects of human behavior.

1253W

Investigation of maternal stress among women who carry the FMR1 premutation who are mothers of a child with fragile X syndrome: involvement of the corticotrophin-releasing hormone receptor 1 gene to impact maternal well-being. *J.E. Hunter[1], A. Lori[1,3], D. Hamilton[1], L. Shubeck[1], A. Abramowitz[2], J.F. Cubells[1,3], S.L. Sherman[1].* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept Clinical Psychology, Emory Univ, Atlanta, GA; 3) Dept Psychiatry and Behavioral Sciences, Emory Univ, Atlanta, GA.

The FMR1 contains a polymorphic CGG repeat which, once unstable, is capable of expansion across generations with maternal transmission. Women who carry a premutation allele of FMR1, defined as an allele with 55-199 repeats, are at risk of passing on a full mutation allele, defined as an allele with >200 methylated repeats, to their offspring. Methylated full mutation alleles result in the intellectual disability disorder, fragile X syndrome (FXS). We recently published a study among mothers of children with FXS who carry a premutation showing evidence that polymorphisms within the corticotrophin releasing hormone receptor 1 gene (CRHR1), a major regulator in the endogenous cortisol response to stress, moderated the impact of maternal stress on the severity of distress experience in social situations as measured by the Social Phobia and Anxiety Inventory (SPAI). The goal of the current study is to follow up on these results to determine the severity and sources of maternal stress associated with raising a child with FXS involved in this interaction. Preliminary results for 25 mothers indicate that the interaction between maternal stress and CRHR1 polymorphisms is associated with both child characteristics (Aberrant Behavior Checklist: Irritability subscale, $p=0.04$; Social Avoidance subscale, $p=0.02$) and the impact of having a child with an intellectual and developmental disability on the family (Questionnaire on Resources and Stress: Parent and Family Problems subscale, $p=0.01$). The results of this study will provide potential targets for maternal interventions to alleviate stress and maternal well-being.

1254T

Advanced paternal age is associated with earlier onset of schizophrenia in the affected siblings of multiplex families. *W.J. Chen[1,2,3,4], S.H. Wang[1,2], C.K. Hsiao[1,2], C.M. Liu[3,4], H.G. Hwu[1,3,4].* 1) Institute of Epidemiology & Preventive Medicine, National Taiwan Univ, Taipei, Taiwan; 2) Genetic Epidemiology Core Laboratory, Center of Genomic Medicine, National Taiwan University; 3) Institute of Brain and Mind Sciences, College of medicine, National Taiwan University; 4) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University.

Introduction: Advanced paternal age has been reported to increase the risk of schizophrenia. Early onset, an important component phenotype for schizophrenia, may disrupt the normal processes of maturation of the brain and cause neurodevelopmental deviance. This study aimed to explore if advanced paternal age is associated with not only increased risk of schizophrenia but also earlier onset of schizophrenia in multiplex families. Methods: A total of 1359 affected siblings with schizophrenia and 308 healthy siblings from 694 multiplex families recruited throughout Taiwan were included for this study. Probands and their first-degree relatives were interviewed using the Diagnostic Interview for Genetic Studies. Offspring's paternal age was calculated as its father's age minus the offspring's age at the time of recruitment. We compared the paternal age of affected siblings with their counterparts of healthy sibling within each family using random-effect models to control for familial dependence. Then we compared the distribution of onset age of schizophrenia for eight paternal age groups (<20, 20–25, 25–30, 30–35, 35–40, 40–45, 45–50, and ≥ 50). Results: Increasing 1 year in paternal age was associated with an increased risk of schizophrenia, with an adjusted odds ratio of 1.12 (95% confidence interval 1.03-1.22). Using paternal age of 20–25 as the reference, advancing paternal age was associated with younger age at onset of schizophrenia in the affected siblings. On average, the onset age was lowered for 1.5 years for the paternal age of 25–30 and 5.5 years for the paternal age of ≥ 50, with a P value of 0.04 for the trend test. Conclusion: Advanced paternal age was associated with an increased risk of schizophrenia in the offspring as well as earlier onset of schizophrenia in the affected siblings. These findings derived from multiplex families of schizophrenia imply that the influence of advanced paternal age may be due to that fathers bequeath more mutations as they age.

1255F

Parents and teachers report on different aspect of children's and adolescent's conduct disorder and hyperactivity/inattention behavior.
X.W. Zhang[1,2], P.C. Sham[2,3], S.S. Cherny[2,3], H.Q. Meng[4], Y.X. Fu[4], Y. Huang[1], T. Li[1]. 1) Psychiatry, West China Hospital, Sichuan University, China; 2) Psychiatry, Hong Kong University, Hong Kong; 3) Genome Research Centre, Hong Kong University, Hong Kong; 4) Mental Health Center, First Affiliated Hospital, Chongqing Medical University, China.

Background: Either conduct disorder or hyperactivity/inattention problem poses considerable burden on health care and education, the co-occurrence bring more pressure and impairments for the children and their family. However, the etiology of overlapping is still unclear, and one of the reasons is assessment inconsistent in different cultural background. Method: Subjects were 433 twin pairs aged between 6 and 16 years from Prospective Twin Registry in Southwestern China, whose parent and teacher completed the Strengths and Difficulties Questionnaires. It both contained estimation on twins' conduct disorder and hyperactivity problem from different point of views. And then used the structure equation model to explore the relationship between conduct disorder or hyperactivity/inattention problem in children and adolescent. Results: Both in the bi-traits twin model and bi-raters twin model, biometric model was the best fitting one. According to this model, conduct disorder and hyperactivity behavior were correlated with phenotypic correlation 0.45-0.65, and genetics factors contributed majority (around 70%) to the covariance both for boys and girls on parent's view, whereas environmental also played important (around 55%) in teacher's view. Meanwhile, the results between parent's and teacher's information were not that consistence. The phenotypic correlation between two informants was less than 0.2. In bi-raters twin model fitting, rater bias model was rejected. in the best fitting model, the common environmental effect always contributed more on variance from teacher's point of view than from parent's point of view, so I alluded that they maybe observe the children in different occasions, or evaluate them without fixed reference group. Conclusion: conduct disorder and hyperactivity behavior are correlated with each other, substantially contributed by genetic factors, but not governed by the common specific underlying phenotype. The information from parents and teacher are disparity, and it suggests us to collect data from more than one informant when using questionnaire to evaluate conduct disorder or hyperactivity/inattention problem in China.

1256W

Association of *APOE* Polymorphism and Stressful Life Events with Dementia in the Pakistani Population.
M. Chaudhry[1], S. Hasnain[1], B. Snitz[2], X. Wang[3], D. Winger[4], L. Wang[4], S. Rosenthal[3], F.Y. Demirci[3], M.I. Kamboh[3]. 1) Department of Microbiology and Molecular Genetics, University of the Punjab, Lahore, Pakistan; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA, USA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA, USA; 4) Clinical and Translational Science Institute, University of Pittsburgh, Pittsburgh, PA, USA.

Dementia is a major public health problem worldwide. Alzheimer's disease (AD) is a major form of dementia and the *APOE*4* allele is an established genetic risk factor for AD. Similarly, stressful life events (SLE) are also associated with dementia. The objective of this study was to examine the association of *APOE*4* and SLE with dementia in a Pakistani population, which to our knowledge has not been reported previously. We also tested for an interaction between SLE and *APOE*4* and the risk for dementia in this sample. A total of 176 subjects (61 cases and 115 controls) were recruited for this study. All pre-diagnosed cases and healthy controls were then interviewed to assess cognition, co-morbidities, history of SLE and possible differences in demographics. Blood samples were also drawn and genotyping for the *APOE* polymorphism (E2/E3/E4) was performed. The *APOE*4* and stressful life events were each independently significantly associated with the risk of dementia. The odds ratios (ORs) for *APOE*4* carriers and SLE were 2.81 (95%CI: 1.26-6.21; P=0.011) and 1.008 (95% CI: 1.004-1.012; P=1.15E-05), respectively. The gender stratified analysis revealed that *APOE*4* and SLE were independently associated with dementia in males but not in females. However, we did not find a significant interaction between *APOE*4* carrier status and stressful life events in affecting the risk of dementia (P=0.677). Although the sample size of this study was small, the established association of *APOE*4* with dementia was confirmed the first time in the Pakistani population. Furthermore, SLE was also found to be a significant predictor for dementia in this population. Our study also emphasizes the need to improve mental health facilities for older people in Pakistan and to facilitate future dementia research.

1257T

Association between MAOA and aggressive behavior in adolescents receiving the pharmaceutical treatment lisdexamfetamine dimesylate for ADHD symptoms.
K.A. Nelson, M.S.[1], A. Stoker[2], P. Huizenga, H.T.(ASCP), rLAT[1], S. Weaver, R.N.[1], T. Jung[1], E.A. Ehli, R.N., M.S.[1, 3], T.J. Soundy, M.D.[3], K. Bohlen, PharmD[1, 3], Y. Hu, Ph.D.[1, 3], G.E. Davies, Ph.D.[1, 3]. 1) Avera Institutue for Human Genetics, Avera McKennan Hospital and University Health Center, Sioux Falls, SD; 2) University of South Dakota, Sanford School of Medicine, Sioux Falls, South Dakota; 3) Department of Psychiatry, University of South Dakota, Sanford School of Medicine, Sioux Falls, South Dakota.

Attention deficit hyperactivity disorder (ADHD) is one of the most common childhood neuropsychiatric disorders, affecting 5.29% of children worldwide. ADHD symptoms manifest as severely disruptive behaviors of inattention, hyperactivity, and/or impulsiveness. The pharmaceutical lisdexamfetamine dimesylate (LDX [Vyvanse®]), a prodrug stimulant prescribed for ADHD, is thought to alleviate symptoms by inhibiting the dopamine and norepinephrine reuptake pathways. Monoamine oxidase A (MAOA) is an X-chromosome linked gene that catalyzes the degradation of dopamine and norepinephrine. The number of 30-bp repeats located in the polymorphic MAOA promoter region has been shown to alter the enzymatic degradation of dopamine and norepinephrine. Wildtype alleles consist of 3.5 or 4 repeats (high enzymatic activity alleles). The genotypes of 2, 3, or 5 repeats (low enzymatic activity alleles) have been associated with increased aggression in males. This study looked at adolescents being treated for ADHD symptoms with LDX. Nearly half of the study individuals discontinued the medication due to aggressive behavior. Here, we hypothesized that individuals with the low enzymatic activity MAOA alleles would be the individuals more likely to discontinue the drug due to aggressive behavior than individuals with the higher MAOA enzymatic activity genotypes. The study sample included 73 adolescents averaged 12 (6–18) years in age. The final study sample was 85% male and 90% Caucasian. All individuals were being treated within a behavioral health outpatient facility by licensed child psychiatrists for ADHD symptoms. After the ADHD diagnosis, each individual at one time during their treatment, received LDX medication. Each child's buccal cell DNA was used to perform the genotyping of the MAOA 30-bp polymorphism. We found that individuals with high MAOA enzymatic activity alleles were significantly more likely to discontinue LDX due to aggression than individuals with the low enzymatic activity MAOA alleles (OR=0.3083 [95% CI: 0.11, 0.86] p=0.02). Stimulant medications are the first-line pharmacological treatment for children with ADHD. Although these treatments are very effective for the majority of its users, there are patients who can experience considerable adverse side effects. This study has shown a significant association between the discontinuation of LDX due to aggressive behaviors in adolescents with the high MAOA enzymatic activity alleles (3.5 and 4).

1258F

Psychosocial factors are correlated with gender-sensitive differences in relative telomere length (RTL) in Han Chinese university undergraduates.

O. Yim[1], M. Monakhov[2], X. Zhang[3], P.S. Lai[1], S.H. Chew[2], R.P. Ebstein[4]. 1) Pediatrics, National University Singapore, Singapore; 2) Dep't. Economics, National University Singapore, Singapore; 3) Business School, National University of Singapore, Singapore; 4) Psychology Dep't., National University of Singapore.

Telomeres (TTAGGG repeats) cap the ends of chromosomes and numerous studies suggest that telomere length (TL) is a reliable index of cellular and tissue aging. More recently social stress has been shown to predict decreased TL but much remains unknown about the psychosocial factors, especially in early adulthood, that modulate TL. To provide a better understanding of factors that influence TL and by implication aging and health, leukocyte DNA from 991 NUS Chinese undergraduates (52.4% Female) were measured for Relative TL (RTL) and compared to house-keeping β-Hemoglobin gene using the method of Cawthon (2009). A significant difference (T-Test P = 0.0001 ; 989 d.f) in RTL by gender was observed and women, as previously reported, show greater RTL than male students. For women only, increased risk proneness over moderate gain, measured by incentivized behavioral economic tasks, was associated with shorter RTL (coeff. =-0.0102; P = 0.040). Delay discounting was also associated in women only with reduced RTL (coefficient =-0.0089; P = 0.010). Impatient women have shorter telomeres. We also observed a relationship in women between RTL and scores on the NEO-PI-3 Neuroticism-Anxiety facet (coeff.= 0.0072, p=0.045). Higher anxiety scores predict greater RTL in women. Intriguingly, for males and not females, students from families with incomes below the unofficial poverty line are characterized by reduced RTL (T-test P = 0.022). Again in males only, NEO-PI-3 Agreeableness scores are associated with greater RTL (coeff.=0.0208, p=0.017). Agreeableness is a personality trait suggesting the individual is kind, sympathetic, cooperative, warm and considerate. The current study examined the role of risk attitude, personality and socio-economic status on aging at the cellular level indexed by RTL. These psychosocial and behavioral characteristics appear to affect RTL but differently in men and women. Such gender-sensitive responsiveness in RTL to psychological and social environmental cues, that are already present in early adulthood in a non-clinical population, are suggested to have important implications for differential ageing in men and women over the course of the lifespan.

A Translational Approach for Cocaine Abuse: From Man to Mouse to Man.

R.F. Clark, E. Solano, M.J. Edlund, N.R. Garge, E.O. Johnson. RTI International, Research Triangle Park, NC.

Three categories of factors contribute to the development of cocaine addiction: 1) environmental factors, including cues, conditioning, and external stressors, 2) drug-induced factors, which lead to neurobiological changes resulting in altered behaviors, and 3) genetic factors, accounting for approximately half the risk of developing an addiction. Drug addiction cannot be adequately addressed solely within a single discipline and instead requires a more transdisciplinary approach.

In our methodology, we first used mouse system genetics to identify genes, gene networks and pathways associated with cocaine dependence. We used in silico systems genetics tools on previously identified candidate genes for cocaine abuse phenotypes in humans to initiate these mouse systems genetics studies. Using homologous mouse genes to these human candidate genes, we identified several mouse genes that were strong candidates for expression-QTL mapping of gene regulation in the hippocampus and nucleus accumbens, including Arrb2, Chrna5, Comt, and Oprm1. Global mapping revealed several networks of genes whose expression was correlated with these genes associated with cocaine addiction. In addition, we identified gene networks associated with multiple cocaine abuse phenotypes in mice, such as differential cocaine response to locomotion in an open field. We were able to assemble several pertinent genetic pathways linked to these genes associated with cocaine addiction.

To build a model of cocaine abuse and addiction, the gene networks and pathways were added to an ontology-based network model of cocaine addiction. This network model was built from the integrated expertise from our team members in diverse domains of knowledge that are suspected to be causally related to cocaine addiction, including known environmental factors, such as drug availability, social stressors, peer support, and environmental exposures. This model can be utilized to provide a framework for future cocaine-addiction studies by supporting interdisciplinary research with graphical representation of complex scientific theories, highlighting potential interactions, facilitating meta-analyses across studies, and supporting statistical analysis and predictive modeling, as well as to translate these findings into the clinical setting for improvement of treatment of cocaine addiction.

1260T

The impact of the metabotropic glutamate receptor and other gene family interaction networks on the autism spectrum disorders.

D. Hadley, Z. Wu, C. Kao, A. Kini, A. Mohamed-Hadley, K. Thomas, L. Vazquez, H. Qiu, F. Mentch, R. Pellegrino, C. Kim, J. Glessner, H. Hakonarson, Autism Genome Project Consortium. The Children's Hospital of Philadelphia, Center for Applied Genomics, 3615 Civic Center Boulevard, Philadelphia, PA 19104.

As multiple defective duplicated genes have been discovered to contribute to the etiology of the autism spectrum disorders (ASDs), we prioritized pathways robustly enriched for structural defects of duplicated genes and their gene family interaction networks (GFINs) using a novel network permutation test. Across 6,742 patients with ASDs relative to 12,544 neurologically normal controls, the metabotropic glutamate receptor (GRM) GFIN was significantly enriched for structural defects (P <= 2.40E-09, 1.8-fold enrichment) in ASDs and previously observed to impact attention deficit hyperactivity disorder (ADHD) and schizophrenia. The MAX dimerization protein (MXD) GFIN was also significantly enriched (P <= 3.83E-23, 2.5-fold enrichment) and known to interact with the MXD-MYC-MAX network of genes and transcription factors that is dysregulated in various types of cancer. Furthermore, the calmodulin 1 (CALM1) gene interaction network was strongly enriched (P <= 4.16E-04, 14.4-fold enrichment) and known to regulate voltage independent calcium-activated action potentials at the neuronal synapse. Taken together, our genome-wide focus on GFINs illustrates the respective contributions of many different biological pathways in the etiology of ASDs.

1261F

The potential use of uncommon variants in GWAS data sets of pedigrees with autism spectrum disorders.

H.Z. Wang[1], H. Qin[1], K. Ahn[2], W. Guo[1], Y.Y. Shugart[1]. 1) Division of Intramural Research Program, National Institute of Mental Health, Bethesda, MD; 2) Childhood Psychiatry Branch, National Institute of Mental Health, Bethesda, MD.

GWAS data sets are often overlooked in rare-variant analysis, for the simple reason that DNA chips only sample a small subset of the genome. However with collapsing methods, rare-variants are linearly combined and analyzed as a group rather than individually, and rare variant analysis can further be enhanced using pedigree based methods, since variants rare in the population are enriched within families. We therefore explored the possibility of analyzing rare variants in GWAS data sets using such methods. To test this hypothesis we used FBAT-Rare, a pedigree-based collapsing method, and collapsed rare variants in genes using a frequency based weighing scheme. We applied this method to the Autism Genome Project (AGP) data set consisting of 2665 trios with autism spectrum disorder (ASD) afflicted offspring. We focused our efforts on CNTNAP2, a gene that encodes a member of the neurexin family which functions in the vertebrate nervous system as cell adhesion molecules and receptors. It is positively identified by multiple research teams, including Anney et al. (2012), the authors of the AGP data itself, to be strongly associated with ASD as well as other neurological development disorders. Using FBAT-Rare, we are currently able to detect an association of $p=6.37*10^{-5}$ for the European-only, high IQ male population for ASD, and $p=2.77*10^{-3}$ for strict autism. We realize the presented results do not meet the standard GWAS-wide significance level. However, our results appear to support the previous findings on CNTNAP2 reported by other investigators. More research work will focus on using several other analytical tools to re-analyze the AGP data set obtained from dbGap.

1262W

Genome-wide scan identifies candidate loci for gene-gene interactions affecting relationships between Aβ42, p-tau, and disease status. *M.T.W. Ebbert[1,2], P.G Ridge[1], K. Boehme[1], M. Bailey[1], C. Cruchaga[3], A. Goate[3], S. Bertelsen[3], C.D. Corcoran[4,5], T. Maxwell[6], J.S.K. Kauwe[1], Alzheimer's Disease Genetic Consortium.* 1) Department of Biology, Brigham Young University, Provo, UT; 2) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 3) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 4) Department of Mathematics and Statistics, Utah State University, Logan, Utah; 5) Center for Epidemiologic Studies, Utah State University, Logan, Utah; 6) Human Genetics Center, University of Texas, Houston, Texas.

Alzheimer's disease (AD) is complex and affects 35.6 million people worldwide. Aβ42 and p-tau levels in cerebrospinal fluid are key biomarkers for the presence of pathological features of AD, Aβ plaques and neurofibrillary tangles, respectively. Like any complex disease, however, there are individuals that exhibit brain pathology indicative of AD but never develop clinical symptoms. In fact, more than 25% of individuals exhibit such pathology but show no cognitive decline. Likewise, there is considerable variation in the rate of decline in AD patients. These remarkable observations and other poorly understood attributes of AD are likely the result of undiscovered complex gene-gene interactions. To discover candidate loci for gene-gene interactions driving AD we used genotype data from 2,726 subjects for whom CSF biomarker levels have been measured to test for relationship quantitative trait loci (rQTL) that modify the relationships between (1) Aβ42 and p-tau; and (2) Aβ42 and disease case-control status. These rQTL are likely involved in gene-gene interactions but may be overlooked in typical association studies because they often do not have marginal effects on the individual traits whose relationship they modify. Specifically, we hypothesize that genetic modifications that modify these well-characterized relationships exist and explain, at least in part, variation in disease progression and the numerous individuals exhibiting known AD brain pathology without exhibiting clinical symptoms. We hypothesize that genetic factors that modify these relationships are likely to alter disease risk or age of onset. Scanning for rQTL in genome-wide SNP data we identified 3 genome-wide significant SNPs that may modify the relationship between Aβ42 and p-tau, and 2 genome-wide significant SNPs that may modify the relationship between Aβ42 and case-control status. rs8027714 (intergenic between NPAP1 and SNRPN, $p < 1.7e-09$), rs1036819 (intron of ZFAT and ZFAT-AS1, $p < 4.2e{-}08$), and rs7844573 (intron of PSD3 and exon of RPL35P6 pseudogene, 9.7e–08) may modify the relationship between Aβ42 and p-tau while rs57216348 and rs59251601 (both in intron of CPLX2, $p < 2.881e{-}08$) may modify the relationship between Aβ42 and case-control status. We concluded that the reported SNPs affect the relationships between (1) Aβ42 and p-tau; and (2) Aβ42 and disease case-control status, and that they may play an important role in AD etiology.

1263T

Family-based Genome-wide Association Study of resting EEG identifies UROC1 and neurotransmitter biosynthetic process. *S. Kang, M. Rangaswamy, D. Chorlian, N. Manz, B. Porjesz, COGA collaborators.* State University of New York, Downstate Medical Center, Brooklyn, NY.

Electroencephalography (EEG) measures are highly heritable neuroelectrical correlates of resting brain state, and contribute several markers of risk for alcoholism and related disorders. Increased beta power has been found to be a hallmark of alcoholism and related disorders and also a marker of those at risk, and is an index of neural hyperexcitability. To identify genetic variants associated with EEG, we performed a family-based genome-wide association study using extended multiplex families densely affected by alcohol dependence. The advantage of the design of this study is robustness against population substructure. High beta power (20-28 Hz) of the frontal-central bipolar electrode pairs (F3-C3, Fz-Cz, F4-C4) were calculated using standard Fourier transform methods. Samples from the Collaborative Study on the Genetics of Alcoholism (COGA) were genotyped using the Illumina Human OmniExpress array on 118 families, densely affected by alcohol use disorder. Phenotype data was derived from multivariate linear regression models which were constructed from log transformed high beta power EEGs, controlling for log-transformed age and stratified by gender. After quality control procedures, association testing was done on 1,564 samples assuming an additive model using the generalized disequilibrium test. Pathway analysis was performed using ALIGATOR (Association List Go Annotator) to study groups of genes by testing for overrepresentation of members of those groups within lists of genes containing significantly associated SNPs from the GWAS. We found that a SNP in *UROC1* (rs1687482) was significantly associated with F3-C3 high beta power EEG at a genome-wide significant level ($p = 4.8 \times 10^{-8}$). The most significant individual GO category from the pathway analysis is a neurotransmitter biosynthetic process with significantly associated SNPs in *PAH* ($p = 1.2 \times 10^{-5}$). These results suggest *PAH* accounts for some of the variations in high beta power EEG. *PAH* catalyzes the conversion of phenylalanine to tyrosine, shares physical, structural and catalytic properties with tyrosine hydroxylase and tryptophan hydroxylase that catalyze the rate-limiting steps in the biosynthesis of the neurotransmitters dopamine, noradrenaline and serotonin. These findings underscore the utility of using EEG phenotypes to identify meaningful genetic correlates of resting brain state with pathophysiology of neuropsychiatric conditions.

1264F

Association between rs10520400 and Caudate Nucleus Asymmetry in Alzheimer's Disease and Mild Cognitive Impairment. *M.E. Renteria[1,2], P. Rajagopalan[3], S.E. Medland[1], S.K. Madsen[3], J.L. Stein[3], D.P. Hibar[3], N.G. Martin[1], M.J. Wright[1], P.M. Thompson[3], Alzheimer's Disease Neuroimaging Initiative (ADNI).* 1) Queensland Inst Medical Research, Herston, Queensland, Australia; 2) The University of Queensland, School of Psychology, St Lucia QLD 4072, Australia; 3) Imaging Genetics Center, Department of Neurology, Laboratory of Neuro Imaging, UCLA School of Medicine, Los Angeles, CA, USA.

In Alzheimer's disease (AD) and mild cognitive impairment (MCI), atrophy of the caudate nucleus appears in MR brain scans as reduction in volume and loss of normal asymmetry in patients compared to healthy controls. In the present study, we extracted caudate nuclei volumes of 731 individuals from the Alzheimer's disease Neuroimaging Initiative (ADNI) cohort. Using caudate asymmetry as a disease-associated quantitative trait, we asked whether genetic factors contribute to such inter-hemispheric differences in rates of neurodegeneration. We conducted a genome-wide association analysis of caudate asymmetry across >500,000 directly genotyped single nucleotide polymorphisms (SNPs) in two groups of patients diagnosed with either MCI (N=354) or AD (N=172), and a group of healthy elderly controls (N=204). SNP rs10520400, located in chromosome 4q34.3, was significantly associated in both patient cohorts ($P=6.26 \times 10{-}05$ in MCI, and $P= 1.77 \times 10{-}05$ in AD; combined $P= 4.51 \times 10{-}09$), but not in healthy elderly controls (P=0.13). Interestingly, rs10520400 had previously been reported as a cis expression QTL (eQTL) for the AGA gene, which participates in glycoprotein metabolism. Deficiencies in the AGA enzyme lead to aspartylglucosaminuria, a Mendelian condition that causes progressive decline in mental functioning. Moreover, AD-related neurodegeneration that leads to loss of normal caudate asymmetry may explain why SNP rs10520400 is specifically associated with AD and MCI patients, but not normal aging.

1265W

Scan for rare copy-number variation in 11,850 Swedish schizophrenia samples suggests novel susceptibility loci and provides evidence for convergence with regions of common variant association.
C. O'Dushlaine[1], J. Szatkiewicz[2], J. Moran[1], K. Chambert[1], A. Kähler[3], C. Hultman[3], P. Sklar[4], S. Purcell[1,4], S. McCarroll[1,5], P. Sullivan[2]. 1) Broad Institute, Boston, MA, USA; 2) UNC, USA; 3) Karolinska Institutet, Sweden; 4) Mount Sinai School of Medicine, USA; 5) Harvard Medical School, USA.

Background: Schizophrenia (SCZ) is a heritable disorder with substantial public health impact. Several rare copy number variants (CNVs) have been implicated in this disorder. However, prior studies indicate that larger samples are necessary for new discoveries to be made.

Methods: We conducted a genome-wide association study for schizophrenia with a Swedish national sample (4,719 cases with SCZ and 5,917 controls post-QC). All subjects from the Swedish Schizophrenia Study were born in Sweden and the schizophrenia (SCZ) cases were identified via the Swedish Hospital Discharge Register. DNA was extracted from whole blood and was genotyped at the Broad Institute using Affymetrix (5.0 and 6.0) and Illumina OmniExpress arrays. We used Birdseye to generate rare CNV calls from GWAS arrays. In addition, this Swedish sample has been well characterized for common SNPs (Ripke, O'Dushlaine, et al), enabling an examination of potential overlap in loci and pathways implicated by both sources of variation.

Results: Our results are consistent with literature reports of an increased burden of CNVs in SCZ cases. Our data confirm several known associations, including 16p11.2 duplications and 22q11.2 deletions, and also suggest a number of novel associations. Intriguingly, pathway analysis implicates several biological pathways that have also been implicated by common SNP polymorphisms, including calcium signaling and FMRP target sets. For events of >100kb, we note modest enrichment in cases for deletions in the post-synaptic density (human core) gene set, and also modest association for duplication and deletion in the NMDAR complex, known to modulate synaptic plasticity. We find evidence for modest enrichment of larger deletions in regions of SNP association.

Discussion: Together, these finding suggest both direct (loci) and indirect (pathway) convergence between these disparate sources of variation, shedding further light on core molecular components driving the etiology of this disorder.

1266T

Genome-Wide Association Study for Domain-Specific Cognitive Function.
H. Milo Rasouly[1], J. Chung[1], R. Au[4], L.A. Farrer[1,2,3,4,5], G. Jun[1,2,3]. 1) Department of Medicine (Biomedical Genetics), Boston University School of Medicine, Boston, MA, USA; 2) Department of Ophthalmology, Boston University School of Medicine, Boston, MA, USA; 3) Department of Biostatistics, Boston University School of Medicine, Boston, MA, USA; 4) Department of Neurology, Boston University School of Medicine, Boston, MA, USA; 5) Department of Epidemiology, Boston University School of Public Health, Boston, MA, USA.

Neuropsychological (NP) tests are commonly used to assess cognitive function and impairment in clinical settings. Recently, several genome-wide association (GWA) studies for general cognitive ability have combined tests representing domain-specific cognitive functions and failed to uncover genome-wide significant associations. We performed heritability and GWAS for performance on several NP test 2,700 individuals from 1,790 families in the Framingham Heart Study (FHS). The three most heritable NP tests were the Boston naming test with no cues (BNT), the Wide range achievement test (WRAT) and the Trails B test (TRB) (0.30 to 0.72, p <10−4) after adjusting for age and sex. Family-based GWA analyses using 346,497 genotyped SNPs were conducted separately for each test after adjustment and normalization from the FHS sample. The most significant associations were discovered with two genotyped SNPs in the *PRDM10* gene (PR domain containing 10) for BNT (best SNP: rs6590429, p =1.81×10-7) and four genotyped SNPs in the *PDE11A* gene (Phosphodiesterase 11A) for WRAT (best SNP: rs1880916, p =3.64 ×10−6). No SNP met the initial cutoff for the significant association level p<10−5 with TRB. The association of 17 SNPs (p<10-5) from the discovery GWA analyses were further evaluated with five additional NP tests. The four *PDE11A* SNPs were significantly associated (p<10-3) with two more tests (best SNP: rs4335982 with Wechsler Adult Intelligence Scale- Similarities p=5.0×10-7), while the association of the *PRDM10* SNPs was limited to the BNT test (other tests: p>10-3). We attempted to replicate our top findings in a family-based cohort, the NIA-LOAD Study 3,828 subjects (1,840 Alzheimer disease cases and 1,988 controls from 2,265 families) using the HapMap 2 imputed data. A family-base approach revealed that the *PDE11A* gene contained 17 SNPs significantly associated (p<10−3) with animals category fluency test (best SNP: rs7605091, p=6.4×10-5), while the top discovery SNP rs1880916 was nominally significant (p=0.05). Rs7605091 was also associated with the episodic memory of immediate and delayed logical memory tests (p<0.01). However, none of *PRDM10* SNPs were strongly associated with these tests (p>0.01). Our results suggest that the *PDE11A* gene is involved in a general cognitive function.

1267F

Williams syndrome: Ribosomal profiling reveals genome-wide alterations in protein synthesis.
R. Weiss[1], L. Dai[2], J.R. Korenberg[2]. 1) Human Genetics, Univ. of Utah, Salt Lake City, UT; 2) Center for Integrated Neuroscience and Human Behavior, Brain Institute, Department of Pediatrics, Univ. of Utah, Salt Lake City, UT.

Williams syndrome (WS) is a copy-number variation (CNV) disease caused by a recurrent 1.5 million base pair hemizygous deletion of 28 genes. The WS phenotype includes a specific cognitive profile and unique personality characteristics. Central to interpreting the genetic and neural contributions phenotype induced by these genomic changes is to go beyond the transcriptional level to elucidate how the CNV-alterations play out at levels closer to cellular functions, ie., to determine abundance of the WS encoded protein(s) and their downstream effects on the abundance and networks of proteins expressed from other regions of the genome. Our prior work showed striking, biologically meaningful perturbations of the transcriptome response to the deletion in WS patient-derived lymphoblastoid cell lines (LCLs) using exon microarrays and RNA-Seq. We have shown that the WS deletion initiates a transcript level cis-effect that perturbs both WS region mRNAs, and mRNAs forming a network of interacting proteins and their associated pathways, including MAPK signaling and in actin cytoskeletal regulation. However, to help close the gap to brain circuitry and cellular function, protein consequences of transcriptional hints must be elucidated both in WS and in emerging data on Autism and Schizophrenia. To do this, we examined the level of protein synthesis in WS-derived LCLs by using ribosome profiling, a quantitative measure of translation that utilizes deep sequencing of ribosome-protected fragments. We analyzed the WS region transcripts by RNA-Seq and confirmed the expected 2-fold decrease in mRNA levels caused by gene dosage. We observed that the ribosome profile data supports a similar decrease at the level of actively translating ribosomes on these mRNAs, indicating that there is no compensation for the gene dosage effect at the level of translation for these mRNAs. However, perturbations in the translational efficiency of mRNAs from genes outside the WS region were observed, and in one case, we observed increased translation of LIMK2, a paralog of the WS-region Lim domain kinase 1 (LIMK1) gene. A profile of protein changes at the synapse is in progress. These data suggest a role for altered translational efficiency of mRNAs in interpreting how CNVs alter the abundance of their encoded protein(s) and their secondary effects on the abundance of proteins expressed from other regions of the genome.

1268W

A genome wide association study of epilepsy in a multi-ethnic cohort.
J.P. Bradfield[1], Z. Wei[2], C. Kim[1], R. Chiavacci[1], F. Mentch[1], W. Lo[3], M.R. Sperling[4], D.J. Dlugos[5], T.N. Ferraro[6], R.J. Buono[6], H. Hakonarson[1,7,8]. 1) Center For Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 3) Department of Pediatrics, The Ohio State University; Nationwide Children's Hospital, Columbus,OH; 4) Department of Neurology, Thomas Jefferson University, Philadelphia, PA; 5) Departments of Neurology and Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 6) Department of Biomedical Sciences, Cooper Medical School of Rowan University, Camden, NJ; 7) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 8) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Epilepsy is a common complex disorder characterized by recurrent seizures. To search for common variants associated with this disorder, we performed a genome wide association study in Caucasians (1364 cases/ 6419 controls) and African Americans (271 cases/ 2843 controls). Along with an analysis of all epilepsies combined together, we analyzed two different subtypes of the disorder. Genetic generalized epilepsies (GGE) accounted for 770 (656 Caucasian/ 114 African American) of the cases, while non-symptomatic/cryptogenic focal epilepsy (Focal) accounted for 865 (708 Caucasian/ 157 African American) of the cases. Samples were genotyped on a combination of the Illumina HumanHap 550v1, 550v3, 610 Quad, and OmniExpress BeadChip platforms. All samples were imputed to ~38 million variants using imputev2 and the 1KG phase 1 interim reference haplotypes. A logistic regression was used to access significance of each variant and the results from both ethnicities were meta-analyzed together. There was one SNP (rs34018214, p=4.97×10-8) that reached genome wide significance in the GGE Caucasian cohort. This SNP resides in the PADI6 gene on chromosome 1p36.13. Loci with suggestive association (p < 1.0×10-6) were found at 20q12(PTPRT), 2q32.2(GLS) and 13q22.3(EDNRB) for all epilepsies; Focal epilepsy showed suggestive association at 9q31.2(ZFN462), 7p21.1(ITGB8), 19q13.11(NUDT19) and 2p16.1(RTN4); GGE showed suggestive association at 6q22.1-q22.31(SLC35F1), 4q22.1-q22.2(GRID2), 16p12.3(XYLT1) and 1q42.12(CNIH3). The validity of these associations will be dependent on replication in a larger independent cohort but nonetheless there are some interesting potential genes at these loci with association supported by multiple SNPs. Glutaminase (GLS) catalyzes the hydrolysis of glutamine to glutamate and ammonia, GRID2 is an ionotropic glutamate receptor, and CNIH3 regulates the trafficking and gating properties of AMPA-selective glutamate receptors. XYLT1 also lies in an area of chromosome 16 which has been shown to contain copy number variants associated with epilepsy, autism, and schizophrenia.

1269T

Analysis of onset age in Late-onset Alzheimer Disease genome-wide association data identifies novel onset age loci and confirms the predominance of *APOE*. *A.C. Naj[1], G. Jun[2,3,4], C. Reitz[5,6,7], B. Kunkle[8,9], W. Perry[8], Y.S. Park[8,9], G.W. Beecham[8,9], R. Rajbhandary[8], K.L. Hamilton-Nelson[8], L.S. Wang[10], J.S.K. Kauwe[11], E.R. Martin[8,9], J.L. Haines[12,13], R. Mayeux[5,6,7], L.A. Farrer[2,3,4,14,15], G.D. Schellenberg[10], M.A. Pericak-Vance[8,9], Alzheimer's Disease Genetics Consortium.* 1) Department of Biostatistics & Epidemiology, University of Pennsylvania, Philadelphia, PA; 2) Department of Medicine (Genetics Program), Boston University, Boston, MA; 3) Department of Biostatistics, Boston University, Boston, MA; 4) Department of Ophthalmology, Boston University, Boston, MA; 5) Taub Institute on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 6) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 7) Department of Neurology, Columbia University, New York, NY; 8) The John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 9) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 10) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 11) Department of Biology, Brigham Young University, Provo, UT; 12) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 13) Vanderbilit Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 14) Department of Epidemiology, Boston University, Boston, MA; 15) Department of Neurology, Boston University, Boston, MA.

Late-onset Alzheimer disease (LOAD) risk loci may also contribute to variation in LOAD age at onset (AAO), as do the allelic variants in *APOE*. However, roles in AAO for the confirmed risk loci outside of *APOE* have not been explored. Daw et al. (2000) estimated 4 additional loci with effects as great or greater than *APOE* contribute to AAO variation. We examined variants at ten confirmed LOAD risk loci (*APOE*, *CLU*, *PICALM*, *CR1*, *BIN1*, *CD2AP*, *EPHA1*, *ARID5B*, the *MS4A* region, *ABCA7*, and *CD33*) to determine if they contribute to variation in AAO among 9,160 LOAD cases in 14 datasets from the Alzheimer's disease Genetics Consortium (ADGC). Examining the variants most significantly associated with LOAD risk at each locus, we tested association with AAO using linear modeling assuming additive effects, adjusted for population substructure, and performed a random-effects meta-analysis across datasets. We also examined genetic burden using genotype scores weighted by risk effect sizes to examine the aggregate contribution of these loci to variation in AAO. Preliminary analyses confirmed association of *APOE* regional variation with AAO (rs6857, $P=3.30\times10^{-96}$). Variants at several other LOAD risk loci also demonstrated statistically significant associations with AAO ($P<0.005$), including rs6701713 in CR1 ($P=0.00717$), rs7561528 in BIN1 ($P=0.00478$), rs561655 in *PICALM* ($P=0.00223$). Burden analyses demonstrated that *APOE* contributes to 3.1% of variation in AAO ($R^2=0.220$) whereas the other nine genes contribute to 1.1% of variation ($R^2=0.200$) over baseline ($R^2=0.189$), after excluding study-specific effects. Secondary analyses of genomewide association with AAO performed among 10 ADGC case-control datasets (excluding cohort and family studies due to ascertainment differences) identified several regions with multiple SNPs showing suggestive associations ($P<10^{-5}$). These included chromosome 18q21.33 (rs12956834, $P=1.62\times10^{-6}$) and 9p13.3 (rs17356611, $P=2.49\times10^{-6}$), with one set of signals nearing genome-wide statistical significance in a chromosome 13q33.3 biological candidate gene *MYO16* (rs9521011, $P=7.62\times10^{-8}$). We confirmed the association of *APOE* variants with AAO among LOAD cases, and observe associations with AAO in *CR1*, *BIN1*, and *PICALM*. In contrast to earlier hypothetical modeling, we show that the combined effects of other loci do not exceed the effect of *APOE* on AAO, and if additional genetic contributions to AAO exist, they are likely very small individually.

Mapping Autism Spectrum Disorder Susceptibility Loci in Hispanic or Latino Populations. *Y.S. Park[1,2], N. Dueker[1], J. Jaworski[1], I. Konidari[1], P.L. Whitehead[1], C.D. Bustamante[3], J.L. Haines[4], M.A. Pericak-Vance[1,2], M.L. Cuccaro[1,2], E.R. Martin[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, USA; 2) Dr. John T. Macdonald Dept. of Human Genetics and Genomics, University of Miami Miller Schools of Medicine, Miami, fl, USA; 3) Department of Genetics, Stanford University School of Medicine, Stanford, CA, USA; 4) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN, USA.

Individuals of Hispanic or Latino origin (Hispanics), currently the largest minority group in the US and projected to be nearly 30% of the US population by the year 2050, present a unique challenge in complex disease genetic studies due to their admixed genomic background. Autism spectrum disorder (ASD) is highly heritable disorder with strong evidence for genetic influence. Current epidemiologic evidence suggests that ASD may occur as often as 1 in 88 children. Most ASD studies have primarily focused on individuals of European ancestry, making it difficult to generalize results in other populations. Our study interrogated a total of 253,682 SNPs genotyped in 2,033 individuals in over 550 families from three independent cohorts: HIHG (University of Miami and Vanderbilt University), AGRE (Autism Genetic Resource Exchange) and SSC (Simons Simplex Collection). Families with either the proband or at least one parent defined as self-reported Hispanics were included in the analysis. To our knowledge, this is the largest GWAS targeted to study ASD in Hispanics. These individuals have not been studied collectively in any other GWAS. Genomic ancestry was investigated with EIGENSTRAT principal component analysis (PCA) using HapMap 3 and GOAL (Latinos from South Florida) projects as reference populations. Association with ASD was assessed by PDT for nuclear families. The most significant SNP resided in *Low Density Lipoprotein Receptor-Related Protein 1B (LRP1B)* gene (PDT $p=2.62\times10^{-5}$). A deletion involving the region has been noted in a case report for severe intellectual disability, omphalocele, hypospadias and high blood pressure. Also notable among SNPs with nominal significance was a missense exonic SNP in *Thyroglobulin (TG)* gene (PDT $p=1.67\times10^{-4}$) and an intronic SNP in the same gene (PDT $p=5.20\times10^{-5}$). Interestingly, several genes previously implicated in ASD susceptibility also remained nominally significant in our Hispanic ASD individuals, such as: *CDH7* (PDT $p=1.11\times10^{-3}$), *CNTNAP2* (PDT $p=8.76\times10^{-3}$) and *RBFOX1* (PDT $p=4.23\times10^{-2}$). In conclusion, our study shows that common variants may contribute to the genetic complexity of ASD in Hispanics.

1271W

Genome-wide association study of age at onset of alcohol dependence in large COGA families. *M. Kapoor[1], JC. WANG[1], L. Wetherill[2], S. Bertelsen[1], J. Budde[1], L. Nhung[1], A. Agrawal[1], V. Hesselbrock[3], J. Rice[1], J. Nurnberger[2], L. Bierut[1], T. Foroud[2], A. Goate[1].* 1) Psychiatry, Washington University in St Louis, Saint Louis, MO, USA; 2) Indiana University School of Medicine, Indianapolis, USA; 3) University of Connecticut Health Center, Farmington, USA.

The age at onset of alcohol dependence (AD) is a critical moderator of genetic associations for alcohol dependence. The present study evaluated whether genetic variants can predict the occurrence of AD in large high-risk families from the Collaborative Study on the Genetics of Alcoholism (COGA). The primary analysis was performed in 2312 subjects from 118 of the largest and most densely affected families. Analyses were limited to the subjects who were regular drinkers. We tested for association between age at onset of AD and variants on the Illumina Omniexpress array using a Cox proportional hazards regression model after adjusting for the effects of birth cohort, gender and family structure. Non-dependent subjects were right censored at the age at last interview. A Schoenfeld residual test was also performed to test the proportionality for the strongest signal. This family-based analysis identified a SNP, rs9847462 near micro RNA on chromosome 3, that is strongly associated (P = 1.03 × 10-11) with the age at onset of AD among regular drinkers. rs9847462 and other tagged SNPs were located under the region of linkage peak identified in our previous analysis. The results indicated that with each year of increase in age, carriers of the minor allele of rs9847462 were 1.5 times more likely to become AD than those homozygous for the wild-type genotype. By the age of 20 years, nearly 60% of subjects homozygous for the minor allele of rs9847462 variant were alcohol dependent in comparison to 20% of subjects homozygous for the major allele. This SNP was also associated with AD symptom count (P = 8.53 × 10-7) and DSM4 AD (P = 3.04 × 10–8) in COGA families, but time to onset analysis significantly improved the power to identify these genetic variants. The present study also identified several other novel variants with suggestive evidence of association with age at onset of AD. These results indicate that there is a moderating effect of age on the risk of AD and time to onset analysis can increase the power to identify novel signals for AD.

1272T

Genetic determinants of the natural history of Alzheimer's. *X. WANG[1], O.L. Lopez[2,3], R.A. Sweet[2,4], M.M. Barmada[1], F.Y. Demirci[1], M.I. Kamboh[1,3].* 1) HUMAN GENETICS, University of Pittsburgh, PITTSBURGH, PA; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA,; 3) Alzheimer's Disease Research Center, University of Pittsburgh, Pittsburgh, PA; 4) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Alzheimer's disease (AD) is a devastating neurodegenerative disease and is characterized by a gradual cognitive and functional decline. Alzheimer's disease is a significant public health problem worldwide and the cost associated with AD is staggering. In order to effectively plan for the future care and treatment of AD patients, it is important to understand the factors that influence the natural history of AD. Although multiple factors have been identified that may affect the natural history of AD, including time to admission to nursing home (NH) and time to death, no studies have been conducted on the genetic determinants of the natural history of AD. In the present study, we have performed a genome-wide association study (GWAS) on 1,187 European American AD patients in order to identify genetic factors that may affect the time to NH admission and time to death. All patients were examined at the University of Pittsburgh Alzheimer's Disease Research Center who had at least one follow-up evaluation (mean follow-up time 4.3 + 2.7 years, range 0.8–18 years). Genotyping was performed using the Illumina Human Omni 1-Quad BeadChip and the analysis was conducted using Cox proportional hazards regression under an additive genetic model with adjustment for age, sex, education, baseline MMSE score, medication, psychosis and the first four principal components. The established genetic risk factor, APOE*4, was not strongly associated with NH admission (P= 0.05) and death (P=0.15). However, we found multiple top significant signals for time to admission to NH on chromosome 6 (P<1E–06) in three adjacent genes: ZUFSP (P=1.08E–07), RSPH4A (P=4.15E–07), and KPNA5 (P= 6.45E–07). We also observed multiple suggestive loci for time to death of AD, including the top signal between the KDR and SRD5A3 genes on chromosome 4 (P=1.82E-07), ARTNL1 on chromosome 10 (P=1.38E–06), SYNPO on chromosome 5 (P=2.36E–06), PPP1R36 on chromosome 14 (P=3.76E-06) and NEUROD4 on chromosome 12 (P=4.288E-06).Our data s suggest that natural history of AD has genetic basis and this novel finding needs to be confirmed in independent studies.

1273F

A genome-wide association study of the response to cognitive behavioral therapy in children with anxiety disorders. *J.R.I. Coleman[1], K. Lester[1], C. Curtis[1], J.L. Hudson[2], C. Creswell[3], G. Breen[1], T.C. Eley[1].* 1) MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, King's College London, UK; 2) Centre for Emotional Health, Department of Psychology, Macquarie University, Sydney, Australia; 3) Winnicott Research Unit, School of Psychology and Clinical Language Sciences, University of Reading, Reading, UK.

Anxiety disorders are the most common psychiatric disorders, with a prevalence in adults of approximately 30%. Psychosocial treatments, including cognitive behavioral therapy (CBT), are the primary treatment modality for anxiety disorders in the United Kingdom. Response (at 6-12 month follow-up) for CBT is estimated at 65%, demonstrating heterogeneity. Evidence suggests individual differences in treatment response have a genetic basis. Preliminary evidence exists for beneficial effects of the 5HTTLPR SS genotype, and for the T allele of rs6330 (NGF gene), on CBT response at 3-12 month follow-up in a cohort of children with a variety of anxiety disorders (Eley et al., 2012, Lester et al., 2012). Such therapygenetic candidate gene studies motivated our current genome-wide association study (GWAS).

Genetic samples were gathered from 1272 children (aged 7–13) diagnosed with anxiety disorders, undergoing CBT. The sample originated from ten different sites in the UK, USA, Australia and Western Europe. Clinical Severity Ratings were established at baseline, upon completion of treatment, and at follow-up. DNA was extracted using a standard protocol, concentrated by filtration, and genotyped using the recently released Illumina HumanCore-Exome array, which assays roughly 250000 SNPs and 250000 exomic variants. The initial outcome variable was primary disorder presence at follow-up. The SNPs most strongly associated with this outcome are presented. Additional measures include genome-wide complex trait analysis (GCTA) and quantitative trait heritability analyses. Further analyses will explore the association between SNPs and changes in Clinical Severity Ratings, and investigate response immediately post-treatment. This is, to our knowledge, the first GWAS of response to psychosocial treatment, and the first treatment response GWAS to be performed in anxiety disorder. Past analyses in related phenotypes such as antidepressant response suggest that the effect sizes of variants underlying treatment response are likely to be small. As the sample size of this study is relatively small, it is probably underpowered to detect such variants. However, GCTA could yield valuable insight; one study that found no SNPs at genome-wide significant levels for antidepressant response gave a SNP-heritability estimate of 42% from GCTA.

1274W

Genome-Wide Association Study of Shared Components of Reading Disability and Language Impairment. *J.D. Eicher[1], N.R. Powers[1], L.L. Miller[2], S.M. Ring[2], J.R. Gruen[1,3], Pediatric Imaging, Neurocognition, and Genetics Study.* 1) Genetics, Yale University, New Haven, CT; 2) School of Social and Community Medicine, University of Bristol, Bristol, UK; 3) Pediatrics and Investigative Medicine, Yale University School of Medicine, New Haven, CT.

Written and verbal language are inherently intertwined neurobehavioral traits vital to the development of communication skills. Unfortunately, disorders involving these traits~specifically reading disability (RD) and language impairment (LI)~are common and prevent affected individuals from developing adequate communications skills, leaving them at risk for adverse academic, socioeconomic, and psychiatric outcomes. Both RD and LI are complex traits that frequently co-occur, leading us to hypothesize that these disorders share genetic etiologies. To test this, we performed a genome wide association study on individuals affected with both RD and LI in the Avon Longitudinal Study of Parents and Children. The strongest associations were seen with markers in ZNF385D (OR=1.81, minimum p=5.45 × 10–7). These associations were strengthened when examining LI cases (OR=1.62, minimum p=6.96 × 10–8). We replicated association of ZNF385D using receptive vocabulary measures in the Pediatric Imaging Neurocognitive Genetics study (minimum p=0.00245). We then used diffusion tensor imaging fiber tract volume data on 16 fiber tracts to examine the implications of replicated markers. ZNF385D was a predictor of overall bilateral fiber tract volumes, specifically in the inferior longitudinal, inferior fronto-occipital, and temporal superior longitudinal fasculi. Here, we present evidence for ZNF385D as a candidate gene for individuals with both RD and LI. The implication of the transcription factor ZNF385D in RD and LI underscores the importance of transcriptional regulation in reading and language. Further study is necessary to discern the target genes of ZNF385D and how it functions within neural development, particularly in fiber tracts vital to fluent language.

A genome wide association between migraine in bipolar disorder and Neurobeachin. *K.K. Jacobsen[1, 2, 3], S. Johansson[1, 2, 3], C.M. Nievergelt[4], T. Zayats[1, 2, 3], T.A. Greenwood[4], H.S. Akiskal[4, 5], J. Haavik[1, 3, 6], O.B. Fasmer[3, 6, 7], J.R. Kelsoe[4, 5], K.J. Oedegaard[3, 6], BiGS Consortium.* 1) Department of Biomedicine, University of Bergen, Bergen, Norway; 2) Center for Medical Genetics and Molecular Medicine, Haukeland Universtiy Hospital, Bergen, Norway; 3) K. G. Jebsen Center for Research on Neuropsychiatric Disorders, University of Bergen, Bergen, Norway; 4) Department of Psychiatry, University of California San Diego, San Diego, USA; 5) Department of Psychiatry, VA hospital, San Diego, USA; 6) Division of Psychiatry, Haukeland University Hospital, Bergen, Norway; 7) Section for Psychiatry, Department of Clinical Medicine, University of Bergen, Bergen, Norway.

Background: Migraine is a common headache disorder, with a prevalence of approximately 12%. It is characterized by unilateral attacks, and in some patients accompanied by visual aura symptoms (1). Bipolar disorder is a mood disorder ranging from severe depression to mania, with migraine as a common comorbidity seen in 25–45% (2,3). Bipolar disorder patients with migraine are more likely to have a worse outcome than those without migraine(4). Methods: We performed a genome wide association analysis on 460 bipolar patients with self-reported migraine and 914 bipolar patients without migraine. The individuals are from the TGEN sample, a part of the Bipolar Genetics Study (BiGS). Replication was attempted in the GAIN sample, a separate part of BiGS. Results: We found a genome wide significant association between migraine in bipolar disorder and rs1160720, an intronic single nucleotide polymorphism (SNP) in NBEA (P-value 2.97×10–8, OR: 1.82, 95% CI: 1.47-2.25). The SNP resides in a linkage disequilibrium block with several other associated SNPs, spanning several exons. We were not able to replicate our finding in the GAIN sample. Discussion: NBEA encodes the protein neurobeachin, which is involved in the transport of neurotransmitter receptors, among them glutamatergic receptors (5). This receptor system is implicated in both bipolar disorder and migraine (6). Our study provides putatively new clues to the cause of migraine in bipolar disorder, though further studies are needed to verify this association.

Genome-wide association study of HLA-DQB1*06:02 negative essential hypersomnia. *SS. Khor[1], T. Miyagawa[1], H. Toyoda[1], M. Yamasaki[1], Y. Kawamura[2], H. Tanii[3], Y. Okazaki[4], T. Sasaki[5], L. Lin[6], J. Faraco[6], T. Rico[6], Y. Honda[7], M. Honda[7,8], E. Mignot[6], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo 113-0033, Japan; 2) Yokohama Clinic, Warakukai Medical Corporation, Yokohama 221-0835 Japan; 3) Department of Psychiatry, Mie University School of Medicine, Mie 514-8507 Japan; 4) Metropolitan Matsuzawa Hospital, Tokyo 156-0057, Japan; 5) Graduate School of Education, The University of Tokyo, Tokyo 113-0033 Japan; 6) Stanford Center for Sleep Sciences and Medicine, Stanford University School of Medicine, 1050A Arastradero Rd., Palo Alto, CA 94304, USA; 7) Department of Somnology, Tokyo Medical University, Tokyo 160-0023, Japan; 8) Sleep Research Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo 156-8506, Japan.

Essential hypersomnia (EHS), a sleep disorder characterized by excessive daytime sleepiness, can be divided into two broad classes based on the presence or absence of the HLA-DQB1*06:02 allele. HLA-DQB1*06:02-positive EHS and narcolepsy with cataplexy are associated with the same susceptibility genes. In contrast, there are fewer studies of HLA-DQB1*06:02 negative EHS which, we hypothesized, involves a different pathophysiological pathway than does narcolepsy with cataplexy. In order to identify susceptibility genes associated with HLA-DQB1*06:02 negative EHS, we conducted a genome-wide association study (GWAS) of 125 unrelated Japanese EHS patients lacking the HLA-DQB1*06:02 allele and 562 Japanese healthy controls. A comparative study was also performed on 268 HLA-DQB1*06:02 negative Caucasian hypersomnia patients and 1761 HLA-DQB1*06:02 negative Caucasian healthy controls. We identified three SNPs that each represented a unique locus~ rs16826005 (P = 1.02E-07; NCKAP5), rs11854769 (P = 6.69E-07; SPRED1), and rs10988217 (P = 3.43E-06; CRAT) that were associated with an increased risk of EHS in this Japanese population. Interestingly, rs10988217 showed a similar tendency in its association with both HLA-DQB1*06:02 negative EHS and narcolepsy with cataplexy in both Japanese and Caucasian populations. This is the first GWAS of HLA-DQB1*06:02 negative EHS, and the identification of these three new susceptibility loci should provide additional insights to the pathophysiological pathway of this condition.

1277W

Genome-wide Association Study and Admixture Mapping of Age-related Cognitive Decline in African Americans. *T. Raj[1,2,3], L.B. Chibnik[1,2,3], C. McCabe[1], B. Stranger[4], H. Hendrie[5], L. Barnes[6], T. Foroud[7], J.M. Murrell[8], D.A Bennett[6], K.S. Hall[9], D.A. Evans[10], P.L. De Jager[1,2,3].* 1) Department of Neurology, Brigham and Women's Hospital, Boston MA; 2) The Broad Institute, Cambridge MA; 3) Harvard Medical School, Boston MA; 4) Section of Genetic Medicine, University of Chicago, Chicago IL; 5) Department of Medicine, Indiana University, Indianapolis IN; 6) Rush Alzheimer Disease Center, Rush University Medical Center, Chicago, IL; 7) Department of Medical and Molecular Genetics, Indiana University, Indianapolis IN; 8) Department of Pathology and Laboratory Medicine and Indiana Alzheimer Disease Center, Indianapolis IN; 9) Department of Psychiatry, School of Medicine, Indiana University, Indianapolis, IN; 10) Department of Internal Medicine, Rush Institute for Healthy Aging, Rush University Medical Center, Chicago, IL.

Objective: To leverage genome-wide data from several cohorts so as to identify genomic determinants of age-related cognitive decline among older African Americans.

Data and Methods: We examined genome-wide genotyping data for 3,964 unrelated older African American (AA) subjects who had at least two repeated measures of cognition from five (CHAP, IIDP, ROS, MAP, and MARS) prospective community-based studies. We compared them to 2,703 unrelated non-Hispanic European Americans (EAs) from the ROS, MAP and CHAP studies. Within each cohort, individual cognitive tests were combined to form an aggregate measure of global cognition. We used linear mixed effects models to characterize individual paths of change in cognition, controlling for age, sex and education as fixed effects. After quality control, imputation was performed using the 1000 Genomes Project Phase I combined reference panels of EA and AA ancestry. Common variants were meta-analyzed across cohorts using weighted fixed-effect models. HAPMIX and MIXSCORE programs were used to estimate ancestry at each locus, and to test for association of cognitive decline with locus-specific proportion of ancestry.

Results and Conclusion: *APOE* ε4 haplotype was strongly associated with rate of cognitive decline in AAs ($P= 1.92 \times 10^{-14}$) but the magnitude of the effect was significantly weaker in AAs ($\beta= -0.01$) compared to EAs ($\beta= -0.05$). In AAs we replicated previously known loci in EAs including *ABCA7* ($P= 4.13 \times 10^{-4}$), *PICALM* (7.35 × 10–4), and *EPHA1* ($P=8.06 \times 10^{-4}$). We discovered one genome-wide significant association at the *TRPS1* locus (chr 8q23), and replicated that association in EAs ($P(DISC) = 2.52 \times 10^{-7}$; $P(REP) = 9.79 \times 10^{-3}$; $P(JOINT) = 1.37 \times 10^{-8}$). The top variant in the region is significantly associated with cis gene expression of *TRPS1* in primary monocytes. We also found another variant at the *TEK* locus (chr 9p21) with suggestive evidence of association ($P(DISC) = 4.10 \times 10^{-7}$). Using genome-wide admixture mapping, we did not detect any significant admixture peak, suggesting that genetic factors alone may not explain the differences in age-related cognitive decline between AAs and EAs.

1278T

Genome-wide association study of growth rate and energy status in lymphoblastoid cell lines. *A.R. Sanders[1,2], W. Moy[1], H.H.H. Göring[3], J. Freda[1], D. He[1], S.L. Fuentes[1], J. Duan[1,2], P.V. Gejman[1,2], Molecular Genetics of Schizophrenia (MGS) Collaboration.* 1) Department of Psychiatry and Behavioral Sciences, NorthShore University HealthSystem, Evanston, IL; 2) Department of Psychiatry and Behavioral Sciences, University of Chicago, Evanston, IL; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

The determinants of growth rate and energy status in LCLs, whether genetic, environmental, or both, remain largely unknown, though growth rate and energy status vary across LCLs and strongly influence many cellular phenotypes. We performed a GWAS using 2,060 samples from the European ancestry (EA) portion of the MGS case-control collection with transformation site, age, EBV load, sex, caseness, and ancestry PCs as covariates. For the top 500 most associated SNPs for each trait, we extracted their genes (or if intergenic, the genes closest on each side), resulting in 429 genes (growth rate) and 383 genes (energy status). The genomic inflation factors for the growth rate (1.000) and the energy status (1.014) GWAS indicated little cryptic population substructure. We found some associations for growth rate with age (p=0.018), sex (p=1.7×10^{-6}), and EBV load (p=8.3×10^{-5}), and for energy status with sex (p=1.8×10^{-4}), caseness (p=0.0076), transformation site (p=0.024), and EBV load (p=0.0090), suggesting the utility of including such covariates in the analysis. We found no genome-wide significant association. For growth rate, the strongest association with additional support was with rs7750067 (p=5.9×10^{-7}), with supportive findings (six SNPs with $5\times10^{-6}<p<10^{-4}$) over this intergenic region, which contains a predicted microRNA (miRNA), ENSG00000266073. The nearest RefSeq genes are *SLC25A51P1*, *EYS*, and *BAI3*. *EYS* contains multiple epidermal growth factor (EGF)-like and LamG domains and is implicated in retinitis pigmentosa. *BAI3* encodes a brain-specific angiogenesis inhibitor, which is an adhesion-G protein-coupled receptor and has been shown to control dendritic arborization growth and branching in cultured neurons. Both *EYS* and *BAI3* are expressed in various tissues, including brain and blood. Pathway analyses revealed the most enriched GO-term for growth rate to be neuron projection (FDR=0.08), and for energy status two were significant: regulation of cell proliferation (FDR=0.0067) and neuron differentiation (FDR=0.042). We describe the effect of epidemiological variables and of specific genomic loci on growth rate and energy status in LCLs. Our results have potential to lead to a better understanding of these important cellular traits. We will present data on the expanded sample of LCLs at the meeting, projecting to reach ~2,500 EA subjects, along with ~1,000 African American subjects.

1279F

Distinct genetic contributions to Tourette Syndrome and Obsessive Compulsive Disorder as revealed by cross-disorder genome-wide studies. *D. Yu[1, 2] on behalf of TS GWAS Consortium, TSAICG, and IOCDFGC.* 1) CHGR, Massachusetts General Hospital, Boston, MA; 2) Stanley Center, Broad Institute, Boston, MA.

Investigation of the genetic relationship of phenotypically-related heritable diseases is important for identifying both shared and distinct genetic risk factors and ultimately for providing molecular insights into diagnosis and treatment. Polygenic score analysis of genome-wide association study (GWAS) data is a powerful tool to examine aggregate cross-disorder genetic effects. Likewise, enrichment analysis of top GWAS signals using expression quantitative loci (eQTLs) from specific tissues is emerging as a complementary approach to assess shared, putatively functional variants between disorders. Here we applied both methods to investigate the genetic relationship between Tourette syndrome (TS) and obsessive-compulsive disorder (OCD), two developmental neuropsychiatric disorders with overlapping clinical symptoms and high rates of comorbidity. In a combined GWAS of TS and OCD in 2,723 cases, 5,667 ancestry-matched controls, and 290 OCD parent-child trios, no markers achieved genome-wide significance (p= 5×10^{-8}) after imputation to the data from the 1000 Genomes Projects. Among 9,099 single nucleotide polymorphisms (SNPs) with p<1×10^{-3}, we found significant enrichment for eQTLs in several brain regions (empirical p<0.001 for frontal cortex and cerebellum, p=0.005 for parietal cortex). While top loci from the individual TS and OCD GWAS studies both demonstrated brain eQTL enrichment, the specific brain regions differed between the two disorders, with TS enriched strongly with cerebellar eQTLs (p<0.001) and OCD with eQTLs from frontal cortex (p<0.001). Within-disorder polygenic score analyses identified a significant polygenic component for OCD (p= 2×10^{-4}) and a smaller polygenic component for TS (p=0.06), explaining 3% and 0.6% of the phenotypic variance, respectively. Reducing the sample size of OCD to that of TS resulted in a decreased, but still significant OCD polygenic signal (p=0.01), explaining 1.4% of OCD phenotypic variance. Intriguingly, no shared polygenic signal was detected in cross-disorder polygenic analysis; furthermore, the OCD polygenic signal was attenuated when TS cases with co-morbid OCD were included. Together, these data suggest that TS and OCD both have a polygenic component, but may have distinct genetic risk loci. In addition, OCD in the presence of TS/CT may have different underlying genetic susceptibility compared to OCD alone.

1280W

Coding variations and the risk of adult ADHD. An exome-chip association study in adult ADHD from the IMpACT. *T. Zayats, S. Johansson, J. Haavik, IMPACT Consortium.* Biomedicine, University of Bergen, Bergen, Bergen, Norway.

Introduction: Attention deficit hyperactivity disorder (ADHD) is a highly heritable childhood onset neuropsychiatric condition that often persists into adulthood. Still, genetics of ADHD, and particularly ADHD in adults is largely unknown. The main purpose of this study was to perform a genome-wide scan of adult ADHD using the newly available Illumina HumanExome12v1 chip, and to evaluate the performance of this technology for genotyping common and rare variants. Materials and Methods: The analyses were carried out using DNA samples collected by the International Multicenter persistent ADHD Consortium (IMpACT). The evaluation of HumanExome12v1 chip was implemented on 2215 individuals, 25 of which were also whole exome sequenced using Roche-NimbleGen Sequence Capture EZ Exome v2 kit and paired-end 100nt sequencing on the Illumina HiSeq. All participants were genotyped on Illumina HumanExome12v1 chip. Genotypes were called in Illumina GenomeStudio V2011.1 software, with additional genotype assignments in zCall software. Performance of HumanExome12v1 chip as well as GenomeStudio V2011.1 software was assessed by direct comparison of data obtained from different DNA sources (blood and saliva), duplicate samples and sequenced genotypes. Mendelian consistency testing was also utilized. Sanger sequencing was used to validate rare variants with minor allele frequency <1%. Association testing was carried out as single marker logistic regression correcting for population substructure and gender in PLINK software. Results: We developed a quality control analysis pipeline for the variants of HumanExome12v1 chip using series of steps implemented in PLINK, GenomeStudio V2011.1 and zCall softwares. Overall, the performance of HumanExome12v1 chip was comparable to that of next generation sequencing. However, it is worth mentioning that mismatch rates were notably higher for rare variants with minor allele frequency < 1% compared to the rest of the chip; the exact specifics will be discussed in details. Association testing in a total of 2600 adult ADHD cases and 7000 controls are currently being performed and will be presented. Conclusion: This study provides insight into the performance of the newly available Illumina HumanExome12v1 chip, serving practical guidance to its quality control with special emphasis on rare variants. Being the largest systematic adult ADHD study to date, this study expected to shed new light on our understanding of adult ADHD genetics.

Genome-Wide Association Study of Rate of Cognitive Decline in Six Alzheimer's Disease Cohorts. *R. Sherva[1], AL. Gross[2], S. Mukherjee[3], S. Newhouse[4,12], J. Kauwe[5], L. Munsie[6], AJ. Saykin[7], DA. Bennett[8], LB. Chibnik[9,13,14], P. Kraft[10], PK. Crane[3], RC. Green[11,15], Alzheimer's Disease Neuroimaging Initiative and GENAROAD Consortium.* 1) Department of Biomedical Genetics, Boston University School of Medicine, Boston, MA; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Medicine, University of Washington, Seattle, WA; 4) King's College London, Institute of Psychiatry, London, UK; 5) Departments of Biology and Neuroscience, Brigham Young University, Provo, UT; 6) Tailored Therapeutics, Eli Lilly and Company, Indianapolis, IN 46285; 7) Indiana University School of Medicine, Indianapolis, IN; 8) Rush Alzheimer's Disease Center, Department of Neurological Sciences, Rush University Medical Center, Chicago, IL, USA; 9) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology & Psychiatry, Brigham and Women's Hospital Boston, MA, USA; 10) Departments of Epidemiology and Biostatistics, Harvard School of Public Health, Boston, MA; 11) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 12) NIHR Biomedical Research Centre for Mental Health at South London and Maudsley NHS Foundation; 13) Department of Neurology, Harvard Medical School, Cambridge, MA, USA; 14) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 15) Partners Healthcare Center for Personalized Genetic Medicine, Boston, MA.

Background: Variability in cognitive decline in Alzheimer's disease (AD) cannot be entirely explained by demographic, health, or clinical features and genetics are likely to play a role. Determining genetic factors contributing to the variability in the rate of cognitive decline in AD might help reveal previously unidentified biological pathways responsible for disease progression. **Methods:** We developed composite measures of global cognition in seven studies of persons with AD: Alzheimer's Disease Neuroimaging Initiative, National Alzheimer's Coordinating Center, Religious Orders Study, Rush Memory and Aging Project, clinical trial of the drug Tarenflurbil, the Cache County Study on Memory, Health, and Aging, and the AddNeuroMed study (N=3,128). We performed a pre-statistical harmonization to identify tests in common across studies, then used factor analysis consistent with item response theory to estimate cognitive ability scores for each observation at all time points in all studies. Heritability (h^2) of rate of decline was estimated using the Genome-wide Complex Trait Analysis (GCTA; J Yang *et al*. 2010) package to estimate the proportion of variance of slopes calculated within each individual based on their cognitive ability scores at each time point that can be explained by the genome-wide SNP data (SNP-based h^2). Association tests were performed on the cognitive ability scores using generalized estimating equations regressions with an interaction between months with AD and SNP genotype. Results were combined in a meta-analysis. **Results:** The median follow-up time was 1.5 years (range 0–19 years). The composite had interval-level properties, was internally consistent (Cronbach's α=0.96), and demonstrated reliable measurement precision over a broad range of cognitive ability. Rate of decline in our pooled sample was heritable (h^2=0.38, P=0.06). We identified several variants strongly associated with rate of decline with evidence from multiple samples, including SNPs in intergenic regions on chromosomes 18 (P_{meta}=1.23E-08) and 19 (P_{meta}=2.33E-08). APOE ε-4 allele counts were not associated with rate of decline in any cohort where it was available (ADNI, NACC, and the Tarenflurbil trial, P>0.05). **Conclusions:** Genetics influence rate of decline, although there is little evidence that AD risk genes have a strong influence.

1282F

Rare Variant Discovery in Late-Onset Alzheimer's Disease using Exome Arrays. *L.-S. Wang[1], A.C. Naj[2], C. Cruchaga[3], S. Mukherjee[4], R. Graham[5], B. Kunkle[5], A. Partch[1], L. Cantwell[1], P. Two genome-wide association (GWA) studies in 2012 increased the number of susceptibility genes for LOAD to 9. Last year the rare APP A673T variant as well as several rare variants in the TREM2 genes were also reported by three studies. Exome chips use proven chip-based genotyping technology to genotype nearly 250,000 rare functional variants identified in whole-exome sequencing studies of more than 12,000 subjects, and represent a powerful tool for identifying rare functional variants involved in complex diseases like LOAD. The Alzheimer's Disease Genetics Consortium (ADGC) has generated or collected genotype data of 16,525 samples from four cohorts using Illumina HumanExome BeadChips (version 1), which consisted of 247,870 exonic SNPs, indels, known GWAS hits, and other relevant markers selected from a consortium of more than 12,000 whole exome sequencing samples. Genotype calls were done using clustering profiles generated from GenenTech (>35,000 samples). 14,355 samples (8,221 AD cases, 6,134 controls) passed QC and were divided into discovery and replication cohorts. Our preliminary analysis led to the following discoveries. We applied several quality control steps including (a) removing mismatched samples using GWA SNP array data genotype concordance, (b), removing subjects and variants with low call-rate (>5% missingness), and (c) excluding monomorphic variants, after which we retained 5,801 subjects and 145,681 markers. We found that the APP A673T variant is extremely rare in the American Caucasian population (2 heterozygotes in 14,355 samples). We performed analyses with SKAT (Optimized Sequence Kernel Association Test) on rare SNPs (MAF<2%), adjusting for age-at-onset (cases)/age-at-exam (controls), number of APOE ε4 alleles, and population principal components. No genome-wide significance was found. We found that the rare signal from TREM2 is replicated in the SKAT analysis (P=6.97e–5). SKAT analysis on known AD genes detected rare variants SORL1 (P= 0.0236) and PICALM (P=8.45e–5), showing that sophisticated association tests are needed to tease out rare variant signal. These findings suggest that other rare exonic variants may contribute to LOAD risk. PCR validation of genotype calls is being performed. We will report on the replication of these preliminary findings in this presentation.

1283W

A Noise-Reduction GWAS in Multiple Sclerosis. *J.P. Hussman[1,2], A.H. Beecham[1], M. Schmidt[1], J.L. McCauley[1], J.L. Haines[3], M.A. Pericak-Vance[1], International Multiple Sclerosis Genetics Consortium.* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Hussman Foundation, Ellicott City, MD, USA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Genome-wide association studies (GWAS) have proven useful in identifying disease susceptibility genes in multiple sclerosis. However, GWAS have focused on the testing of each single nucleotide polymorphism (SNP) independently. Given it is likely that the disease variants have not been directly genotyped, tests that account for multiple flanking SNPs in linkage disequilibrium (LD) with the disease variants may increase the power to detect association. We have used the GWAS noise reduction (GWAS-NR) approach to identify LD blocks which are significantly associated with multiple sclerosis. As GWAS-NR uses a linear filter to identify genomic regions demonstrating correlation among association signals in multiple data sets, we have divided the genotype data from a previously published GWAS in a total sample of 9722 cases and 17376 controls into seven population specific strata from Australia, Central Europe, the Mediterranean, Finland, Scandinavia, United Kingdom, and the United States. Within each stratum, we adjusted for the first five principal components from Eigenstrat. Of the 87838 LD blocks in the GWAS data, defined by the confidence intervals algorithm, we have identified 1434 blocks with p-value < 5.0E−02. A total of 226 of the 1434 blocks show p-value < 5.0E-08 using a modified version of the Truncated Product Method, 138 being within the Major Histocompatibility Complex (MHC) on chromosome 6 (28-34 MB). Of the remaining 88, 24 contain SNPs previously identified in GWAS at a genome-wide level and 47 lie within 2 MB of previously identified SNPs. The remaining 17 are in regions novel to previous GWAS efforts. In particular, four of the 17 blocks are on chromosome 1 in the region of FCRL2, FCRL3, and FCRL4. Previous studies have found that the Fc receptor-like (FCRL) molecule may contribute to the autoimmune disease process. Other noteworthy findings include blocks within JAK1 and COL11A2. Like TYK2, which has been shown to be associated with multiple sclerosis, JAK1 is a non-receptor tyrosine kinase. Three blocks in COL11A2, located within the MHC at ~33 MB, show significance (p-values < 5.0E-08). This is of interest as our recent analysis of sequence data in multiplex families also pointed to this gene, with one of the identified variants being located within one of the LD blocks. These data support the use of this approach to identify additional genetic factors contributing to multiple sclerosis risk.

1284T

Genome-Wide Association Study of Alcohol Consumption in the Kaiser Permanente/UCSF Genetic Epidemiology Research on Adult Health and Aging Cohort. *E. Jorgenson[1], L. Shen[1], T. Hoffmann[2,3], M. Kvale[3], Y. Banda[2,3], D. Ranatunga[1], N. Risch[2,3], C. Schaefer[1], C. Weisner[1,4], J. Mertens[1].* 1) Kaiser Permanente Division of Research, Oakland, CA; 2) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA; 3) Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 4) Department of Psychiatry, University of California San Francisco, San Francisco, CA.

Alcohol consumption is a common trait with a complex etiology. There is strong evidence that both genetic and environmental factors play a role in determining an individual's alcohol use, including patterns of alcohol consumption and the risk of alcohol dependence. A number of genome-wide association studies of alcohol dependence and alcohol consumption, utilizing samples of several thousand subjects, have identified association signals that require further confirmation in independent samples. Here, we report the results of a genome-wide association study of alcohol consumption in the Kaiser Permanente/UCSF Genetic Epidemiology Research on Adult Health and Aging Cohort (n=110,266), the largest study to date. We identified genome-wide significant associations between SNPs in the ethanol metabolism pathway and measures of alcohol consumption. Among non-Hispanic white subjects who report drinking alcohol, we observed an association between rs1229984, which encodes an arginine to histidine change in the amino acid sequence of alcohol dehydrogenase 1B (ADH1B), the major metabolizing enzyme of ethanol, and a reduction of 1.29 drinks per week per copy ($p=1.2*10^{-26}$). We also observed a similar effect, a reduction of 1.47 drinks per week ($p=6.9*10^{-5}$), in Latino subjects, and a more modest reduction of 0.38 drinks per week (p=0.05) in East Asian subjects. The smaller effect of rs1229984 on the number of drinks consumed per week in East Asian subjects is due to the presence in East Asian populations of rs671, a polymorphism that encodes an amino acid substitution from glutamine to lysine in aldehyde dehydrogenase 2 (ALDH2), the major metabolizing enzyme of acetaldehyde, the intermediate product in the ethanol metabolism pathway. In East Asian subjects, rs77768175, which is in strong linkage disequilibrium with rs671, was associated with a reduction of 0.80 drinks per week (p=0.008). More strikingly, subjects who carry the rs77768175 G allele are considerably less likely to report any alcohol consumption (OR = 0.32, $p=3.6*10^{-58}$).

1285F

Transethnic genome-wide meta-analysis of Alzheimer disease in Alzheimer's Disease Genetics Consortium. *G. Jun[1,2,3], J. Chung[1], J. Kozubek[1], C. Reitz[6], B.N. Vardarajan[6], K.L. Lunetta[2], J.L. Haines[7], M.A. Pericak-Vance[8], R. Kuwano[9], R. Mayeux[6], G.D. Schellenberg[10], L.A. Farrer[1,2,3,4,5], Alzheimer's Disease Genetics Consortium.* 1) Medicine (Biomedical Genetics), Boston University, Boston, MA; 2) Biostatistics, Boston University, Boston, MA; 3) Ophthalmology, Boston University, Boston, MA; 4) Neurology, Boston University, Boston, MA; 5) Epidemiology, Boston University, Boston, MA; 6) Neurology, Columbia University, New York, NY; 7) Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 8) The John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 9) Molecular Genetics, Niigata University, Niigata, Japan; 10) Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA.

The Alzheimer Disease Genetics Consortium (ADGC) has performed genome-wide association (GWA) studies for late-onset Alzheimer's disease (LOAD) in European American (EA), African American (AA), and Japanese (JPN) populations. GWA analyses were conducted separately in samples containing 22,289 EA (11,641 cases, 11,341 controls), 5,028 AA (1,489 cases, 3,539 controls), and 1,845 JPN (951 cases, 894 controls) subjects using imputed genotypes for 7,911,420 SNPs in a logistic regression model adjusting for age and sex. Results from the three groups for the total sample (ALL) and subgroups of APOE ε4-positive(58% of cases and 27% of controls) and ε4-negative (38% cases and 69% controls) subjects were combined using meta-analysis. Top-ranked SNPs in transethnic meta-analysis were further examined for ethnic-specific or transethnic signals by evaluating results within each ethnic group. Significant associations (transethnic meta P-value $<10^{-6}$) were identified with SNPs in novel LOAD loci in the ALL (*MTOR*, *HBEGF*, *CASS4*, and near *ODZ2*) and in ε4-positive (*METTL19*, *GRIK2*, *GJC1*, *TRMT44*, *SH2D4B*, and near *EOMES*) groups. We observed a novel genome-wide significant (GWS) association ($P<5\times10^{-8}$) with a *GJC1* SNP in the ε4-positive group, but this finding was evident in Caucasians only (rs11871429: $P_{EA}=9.1\times10^{-9}$, $P_{AA}=0.83$, $P_{JPN}=0.17$, and $P_{EA\text{-}AA\text{-}JPN}=6.1\times10^{-8}$). Associations for other novel loci were most significant in the transethnic meta-analysis (top result: *SH2D4B* SNP rs12772279 in ε4-positive subjects; $P_{EA}=4.0\times10^{-5}$, $P_{AA}=0.015$, $P_{JPN}=0.16$, $P_{EA\text{-}AA\text{-}JPN}=2.8\times10^{-7}$). Top-ranked transethnic signals showed the same direction of the effect but the minor allele frequency varied substantially across the ethnic groups. In addition to genes in the *APOE* region, GWS results for previously established LOAD loci were observed with SNPs in *BIN1*, *PICALM*, *CR1*, *MS4A6E*, and *PTK2B* in ALL subjects (best SNP: rs586274 in *PICALM*; $P_{EA}=5.8\times10^{-11}$, $P_{AA}=0.633$, $P_{JPN}=3.0\times10^{-4}$, $P_{EA\text{-}AA\text{-}JPN}=1.1\times10^{-12}$). Among other established LOAD loci in EA, different SNPs showed the smallest P values in the AA or JPN samples, whereas top-ranked SNPs were not significant (P>0.1). An attempt to replicate and extend the top findings in independent Caucasian (N~9,000) and Hispanic (N~5000) samples is underway. This study suggests that the transethnic approach can detect novel LOAD susceptibility genes whose effects are either independent of or influenced by APOE genotype.

1286W

Pathway-based polygenic scores and variation explained by functional SNPs in schizophrenia. *K.K. Nicodemus[1], G. Donohoe[1], D. Tropea[1], D. Morris[1], K. Kendler[2], F. O'Neill[3], D. Walsh[4], B. Riley[2], M. Gill[1], A. Corvin[1], Wellcome Trust Case Control Consortium 2.* 1) Department of Psychiatry, Trinity College Dublin, Dublin, Ireland; 2) Virginia Commonwealth University, Virginia, USA; 3) Queen's University Belfast, Belfast, UK; 4) Health Research Board, Dublin, Ireland.

Schizophrenia (SZ) is a complex disorder with aetiology due to multiple genetic effects, which are likely to be enriched in specific pathways. Using experimentally-derived pathways from SZ-associated genes in the cellular adhesion molecule (CAM), DISC1, miR-137, NRXN1, TCF4 and ZNF804A pathways, we assessed the polygenic score contribution to variation explained in case status in the WTCCC2 schizophrenia case (N = 1378)-control (N = 1086) GWAS. Further, we assessed the contribution of functional SNPs (fSNPs) versus intronic SNPs not in LD with fSNPs in amount of variation explained.

We created polygenic scores based on p-value thresholds and weighted by the log10(odds ratio) from the PGC1 SZ GWAS. The number of genes/SNPs included were: CAM (125/6332), DISC1 (130/5384), mir-137 (474/21368), NRXN1 (131/5931), TCF4 (566/9424) and ZNF804A (138/3080). Restricting to fSNPs produced (% total): CAM 4.8, DISC1 5.8, miR-137 5.0, NRXN1 5.3, TCF4 8.9 and ZNF804A 8.5. Nagelkerke's R2 was estimated using logistic regression. P-values were obtained using a LRT. We compared the R2 from the set of functional SNPs to that obtained using 1000 same-size sets of randomly-selected intronic SNPs not in LD ($r2 < 0.2$) with the fSNPs.

The amount of variation explained (R2, LRT p) was: CAM (0.25%, 0.031), DISC1 (0.95%, 2.9e-05), TCF4 (0.76%, 0.00018), ZNF804A (0.91%, 4.3e-05), NRXN1 (0.27%, 0.026) and miR-137 (2.7%, 1.1e–12). The use of fSNPs explained a significant proportion of variation estimated (% R2 attributable to functional SNPs): CAM 84, DISC1 54, TCF4 34, ZNF804A 32, miR-137 5.2 and NRXN1 1.2. Further, the % of LE intronic SNP sets exceeding the R2 for the fSNPs was: CAM 1.9%, DISC1 8.2%, TCF4 29%, ZNF804A 0% miR-137 56.0% and NRXN1 92%, indicating fSNPs may explain more variation.

The polygenic score based on fSNPs explained a significant proportion of the total variation explained and was larger than that able to be explained using intronic SNPs in LE with fSNPs. Assuming equal variation explained by each SNP, the fSNP polygenic score should explain 4-9% of the total; in all but 2 pathways the percent variation explained by fSNPs was > 30%. The use of fSNPs may improve interpretability of the polygenic score by restricting to SNPs with known function and by reducing the number of SNPs to examine in follow-up studies.

1287T

Meta analysis identifies TSNARE1 as novel Schizophrenia / Bipolar susceptibility locus. *P. Sleiman[1], D. Wang[2], J. Glessner[1], D. Hadley[1], R.E. Gur[3], N. Cohen[2], Q. Li[2], H. Hakonarson[1], Janssen-CHOP Neuropsychiatric Genomics Working Group.* 1) Center Applied Genomics, CHOP, Philadelphia, PA; 2) 4Janssen Research & Development, LLC, Raritan, NJ; 3) Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia PA 19104, USA.

We carried out a meta-analysis of combined schizophrenia, schizoaffective, and bipolar cohorts that resulted in the identification of six genome-wide significant loci, including one novel locus at chr8q24.3, encompassing TSNARE1 ($P=1.28\times10^{-9}$). The study included 13,394 schizophrenia and bipolar cases and 34,676 controls. Of these: 3,182 schizophrenia (of which 377 were classified as schizoaffective) cases and 1,032 bipolar I cases were collected from 28 clinical trials conducted by Janssen Research & Development, LLC. These samples were matched to 15,277 and 8,000 controls, respectively, from the biorepository at the Center for Applied Genomics (CAG) of the Children's Hospital of Philadelphia (CHOP). In addition, 1,157 cases meeting DSM-IV-TR criteria for schizophrenia or schizoaffective disorder from the Center for Applied Genomics (CAG) at The Children's Hospital of Philadelphia and the Department of Psychiatry at the University of Pennsylvania, School of Medicine and 2,107 controls from the biorepository at CAG were also included in the analysis. The remaining 8,023 schizophrenia cases and 9,292 controls were part of the Schizophrenia Psychiatric Genome-Wide Association Study Consortium (PGC), as previously described, and were obtained from the NIMH as schizophrenia distribution 9 (https://www.nimhgenetics.org/). The function of the TSNARE1 gene remains unknown. A recent publication suggests it may have evolved within the vertebrate lineage from the harbinger transposon superfamily. Bioinformatic predictions based on phylogenetic ancestry indicate it may bind SNARE (soluble N-ethylmaleimide-sensitive factor attached protein receptor) proteins and have SNAP receptor activity. TSNARE1 may therefore have a vertebrate-specific function in intracellular protein transport and synaptic vesicle exocytosis.

1288F

Psychiatric Genomics Consortium quadruples schizophrenia GWAS sample-size to 35,000 cases and 47,000 controls. *S. Ripke, Schizophrenia Group of the Psychiatric Genomics Consortium.* ATGU, Mass Gen Hosp, Boston, MA.

The PGC (Psychiatric Genomics Consortium) is an international group of researchers whose major aim is to maximize the utility of extant psychiatric GWAS through mega-analysis. In a previous study, our first wave of genome-wide schizophrenia association analysis identified multiple loci involved in this genetically complex and clinically heterogeneous disorder (Nature Genetics, 2011). While around 20,000 individuals were necessary to achieve this result, detailed analysis of the data suggested that there are many more genes to discover, and that this should be possible by further increase of sample size.

Here we present an update of this international endeavor, which now comprises 35,476 schizophrenia cases and 46,839 controls coming from 52 substudies. The presented data is imputed into 1000 Genomes (Aug, 2012) and analyzed using standard logistic regression with ancestry components as covariates. All index SNPs with a p-value smaller than 1×10^{-6} were used for replication lookup in an independent GWAS analysis with 1,500 cases and 66,000 controls.

The number of independent genome-wide significant regions in this newest round of meta-analysis increased to 108 ($P < 5\times10^{-8}$). These results increase the number of loci strongly implicated in schizophrenia by more than 80. The loci implicated include prior targets (MIR137, CACNA1C, ZNF804A) along with a host of new targets many of which are now implicated by multiple lines of genomic evidence (DRD2, KCTD13).

These results are in line with prior predictions and developments in other complex disease GWAS with sufficiently large samples like Crohn's disease. They provide new insights into the biology of schizophrenia.

1289W

Polymorphisms in the CACNA1C gene region and amygdala activation during encoding of negative emotional stimuli. *L. Gschwind[1], C. Vogler[3], D. Coynel[2], A. Milnik[1], V. Freytag[1], K. Spalek[2], D. de Quervain[2,3], A. Papassotiropoulos[1,3,4].* 1) Molecular Neurosciences, University of Basel, Basel, Basel, Switzerland; 2) Cognitive Neuroscience, University of Basel, Basel, Basel City, Switzerland; 3) Psychiatric University Clinic, University of Basel, Basel, Basel City, Switzerland; 4) Department Biozentrum, Life Sciences Training Facility, University of Basel, Basel, Switzerland.

Background: Imaging genetics links brain imaging data (e.g. functional Magnetic Resonance Imaging (fMRI)) to genetic variation. Narrowing down the neuronal correlates of psychopathology, i.e. identifying patterns of alternated brain activation could serve as valuable endophenotype in genetic research. Differences in amygdala activation, a brain region that is involved in processing of emotional content, have frequently been reported comparing psychiatric patients to healthy controls. Recent studies reported genotype dependent activation differences of the amygdala for the intragenic SNP rs1006737 in CACNA1C (Wessa et al., 2010 and Tisli et al, 2013), a gene implicated in psychiatric disorders. We hypothesized that intragenic variation of CACNA1C might affect amygdala activation also in healthy individuals. Therefore we tested variants in the CACNA1C gene for association with mean amygdala activation in response to emotional stimulus material during an fMRI session in a large sample of healthy individuals. Methods: A sample of N=917 healthy young Swiss individuals encoded a set of 24 negative emotional pictures taken from the International Affective Picture System in a 3 Tesla fMRI scanner. Genotyping of the CANA1C gene was done using the Affymetrix Human SNP Array 6.0. A total of 183 SNPs fulfilled genotype quality criteria (MAF > 5 %, Deviation from HWE p>0.01). Automated segmentation procedures of structural Magnetic Resonance images were used to create individual masks for the accurate extraction of individual brain activation. Subsequently, amygdala activation was calculated contrasting negative emotional pictures vs. scrambled pictures. Genetic associations were tested under the assumption of an additive model using the Plink software package. Results: The lowest p-value out of the 183 SNPs assessed was found for SNP rs7139329 (p=0.00052), which did not survive conservative multiple testing (Bonferroni corr. p = 0.09). Further studies are warranted to elucidate the role of genetic variation of CACNA1C for amygdala activation in healthy individuals.

1290T

Genetic variation underlying amygdala-volume is highly enriched with schizophrenia susceptibility variants in healthy young individuals.
P. Lee[1,2,3], A. Holmes[1,4], P. Gallagher[1], L. Germine[1], M. Hollinshead[1], J. Roffman[1], R. Buckner[1,4], J. Smoller[1,2,3]. 1) Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Stanley Center for Psychiatric Research, Broad Institute, Cambridge, MA; 4) Harvard University, Cambridge, MA.

Background: Variations in amygdala volume have been implicated in the pathophysiology of schizophrenia, bipolar disorder, and autism, but the genetic basis of these volumetric differences remains undefined. Here we report genome-wide association analysis of amygdala volume in a cohort of 1,426 healthy individuals and the genetic relationship between this brain structure and major neuropsychiatric disorders. **Methods:** Our study is based on the Harvard/MGH Brain Genomics Superstruct Project (GSP), a neuroimaging and genetics study of brain and behavioral phenotypes comprising more than 3,500 healthy subjects. Structural MRI images of amygdala volume were assessed for all GSP subjects using a standardized imaging protocol (3T, 12-channel coil, T1). Genome-wide genotyping was performed on 1870 subjects of European ancestry, yielding the discovery GWAS data of 1,140,419 SNPs. All study subjects were young adults with no history of psychiatric illnesses or major health problems ($18 \leq age \leq 35$). Imputation using the 1000 Genomes produced the allele dosages of 8,839,342 SNPs ($R2>0.3$; $MAF>0.01$), for which single-variant association was assessed using linear-regression. Covariates included age, gender, handedness, intracranial volume, scanner, console, and MDS factors to control for potential population sub-stratification. Genetic relationships of amygdala-volume-associated SNPs to major neuropsychiatric disorders were examined using multivariate enrichment analyses of genomic inflation factor, λ, as previously described by Stein et al. **Results:** Single-SNP-based linear-regression identified four genomic regions that show significant association with amygdala volume at $P < 1e\text{-}06$. While the top association locus on chromosome 3q24 (highest $P=4.8e\text{-}08$; $\beta=-81.33$mm3; SE= 14.90mm3) resides on a non-genic region, nearby brain-expressed genes of potential interest include PLOD2 and PLSCR4. Furthermore, enrichment analyses revealed inflated association of schizophrenia susceptibility variants [9] with amygdala volume differences ($\lambda=3.931$; $P<5e\text{-}05$). **Conclusions:** Using a neuroimaging GWAS analysis of healthy young adults, we identified genetic variants influencing individual differences in amygdala volume. We also found a potential role for schizophrenia susceptibility variants in modulating normal variation of amygdala volume, suggesting an etiologic link between amygdala structural changes and emotional/cognitive abnormalities present in this serious brain disorder.

1291F

Brain N-acetylaspartate is Increased in mouse models of Pelizaeus-Merzbacher disease: implication for human imaging findings.
K. Inoue[1], Y. Itoh[1], S. Saito[2], I. Aoki[2], J. Barkovich[3], J. Takanashi[2,4]. 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Japan; 2) Molecular Imaging Center, National Institute of Radiological Sciences,Chiba, Japan; 3) Dept. Radiology & Biomedical Imaging, Univ. California San Francisco, CA , USA; 4) Dept. Pediatrics, Kameda Medical Center, Kamogawa, Japan.

In order to evaluate a hypothesis that hypomyelinating process may affect N-acetylaspartate (NAA) and N-acetylaspartylglutamate (NAAG) biochemical pathways, we examined brains of mouse models of Pelizaeus-Merzbacher disease. Two distinct lines, myelin synthesis-deficient (msd) and Plp1-transgenic (Tg) mice, each modeling point mutation and overexpression respectively, were subjected to study. We performed magnetic resonance imaging and proton magnetic resonance spectroscopy (1H-MRS) of the thalamus for msd and wild-type mice with a 7.0 tesla magnet. NAA and NAAG were independently measured by high performance liquid chromatography (HPLC). Immunohistochemical analysis using anti-Mbp, Gfap, Ng2, and NeuN antibodies were also performed. We also performed HPLC on Tg mice.In msd mice, 1H-MRS revealed increased tNAA, creatine, glutamine, and glutamate, and decreased choline (Cho). HPLC analysis revealed increases of both NAA and NAAG in the msd brains. Histologically, the msd brains revealed hypomyelination and astrogliosis. Oligodendrocyte progenitor cells and neurons were normal in number in the thalamus wherein 1H-MRS was obtained. In Tg mice, HPLC analysis also revealed increases of both NAA and NAAG. Despite of distinct molecular and cellular pathology between point mutation and overexpression, we observed similarly increased NAA and NAAG in both mouse lines, suggesting a presence of common downstream biochemical pathway. We hypothesized that a primary increase of NAA resulting from the lack of mature oligodendrocytes may lead to a secondary increase of NAAG. Such neurochemical derangement observed in the PMD mice may provide critical information in understanding MRS finding in human PMD patients with unique increase in total NAA. In conclusion, increased total NAA with decreased Cho detectable on 1H-MRS may be an important marker for PMD, which can be distinguished from more common neurological disorders that have decreased tNAA.

Epileptic encephalopathies are severe developmental disorders characterized by early onset epilepsy and poor neurological outcome. The genetic origins and underlying molecular processes of early onset epileptic encephalopathies have been described in only a few well defined syndromes. The objective of this study was to identify the disease-related gene in two unrelated patients with a distinctive phenotype characterized by refractory epilepsy, absent developmental milestones, thick corpus callosum and cavum septum pellucidum on brain MRI. In order to identify the disease-associated gene, we performed whole exome sequencing of the DNA of two probands, a 10 year-old girl of Iraqi Jewish origin and a 9 year-old Spanish boy who both presented with an infantile encephalopathy with refractory epilepsy. In both patients, we identified biallelic mutations of the Seizure Threshold 2 (SZT2) gene. The causative mutations include a homozygous nonsense mutation in the girl patient and compound heterozygosity for a nonsense mutation and an exonic splice site mutation in the boy. The latter mutation leads to exon skipping and premature termination of translation. Thus, all three mutations are predicted to result in nonsense-mediated mRNA decay and/or an N-terminal protein truncation and thereby loss of SZT2 function. SZT2 contains a putative superoxide dismutase motif and is presumably localized to the peroxisome where it has been suggested that it protects from oxidative stress and glutamate toxicity. Thus, glutamate-mediated excitotoxicity is a plausible mechanism underlying epileptogenesis caused by SZT2 mutations. We conclude that mutations in SZT2 are a novel cause of a severe type of autosomal recessive infantile encephalopathy with intractable epilepsy, thick corpus callosum and cavum septum pellucidum. While the cellular function of SZT2 is unknown and no diseases caused by SZT2 mutations have been reported in humans, Szt2 is known to influence seizure threshold and epileptogenesis in mice. Truncating mutations of Szt2 can confer low seizure thresholds and embryonic lethality in mice, phenotypes that are well consistent with the severe seizures and developmental arrest in our patients.

1293T

Association between Alzheimer's genetic risk scores and hippocampal and amygdala volume.
M.K. Lupton[1], W. Wen[2], K. Mather[2], H. Brodaty[2], D. Ames[2], J.N. Trollor[2], N.J. Armstrong[3], A. Simmons[4], S. Lovestone[4], J.F. Powell[4], P.S. Sachdev[2], M.J. Wright[1], GERAD1 Consortium, Addneuromed Consortium, Alzheimer's Disease Neuroimaging Initiative. 1) Neuroimaging Genetics, Queensland Institute of Medical Research, Herston, QLD, Australia; 2) Brain and Ageing Research Program, School of Psychiatry, University of New South Wales, Sydney, Australia; 3) Garvan Institute of Medical Research, Darlington, NSW 2010, Australia; 4) Institute of Psychiatry, King's College London, London. SE5 8AF, UK.

Alzheimer's disease (AD) is the most common form of dementia with an estimated 35.6 million sufferers worldwide . Recent GWAS findings have identified twenty one common genetic risk alleles, in addition to APOE ε4, which effect risk for late onset AD. However, there is limited understanding of how these genetic risk factors affect the magnetic resonance imaging phenotypes of hippocampal and amygdala volumes, which are the first to be affected in AD pathogenesis. Evidence of an early influence would increase our understanding of how these genetic variants work to affect risk. In addition, the identification of robust biomarkers would allow both screening and targeting of interventions to subpopulations of those most at risk. Here we test the hypothesis that there is an association between AD genetic risk variants and hippocampal and amygdala volumes in a large sample (N=2729). We included two AD case control cohorts from the Alzheimer's disease Neuroimaging Initiative (ADNI, N=743) and Addneuromed Consortium (N=356), two elderly (Memory and Ageing Study (MAS, N=542), Older Australian Twins Study (OATS, N=199) and one young (Queensland Twin Imaging (QTIM N=632) population cohorts. We tested for an effect in each cohort, and using Meta analysis, in AD and mild cognitive impairment (MCI) groups, as well as a healthy older group (with sample sizes of 271, 614 and 711 respectively). We found a significant association of the AD risk score with reduced hippocampal and amygdala volumes in both AD case control cohorts as well as reduced hippocampal volumes in the AD and MCI groups. The addition of the AD risk variants outside the APOE genotype did significantly strengthen association within these cohorts and disease groups. Importantly, we found no association between the AD risk score and the subcortical volumes in either the healthy older (N=704) or young (N=465) adult groups, and no association with the APOE ε4 genotype, which is in contrast to some previous underpowered studies. Although there is an effect of AD genetic risk scores on hippocampal and amygdala volume overall in case control cohorts, and in separate MCI and AD groups, there is no association in healthy older people. The lack of association, especially with APOE genotype calls into question the usefulness of these MRI measures in the prediction of future decline to MCI and AD. Alternatively the genetic and MRI measures presented here may be valid but independent predictors.

1294F

Genome-wide linkage analysis suggests oligogenic regulation of the human parieto-occipital 10-Hz rhythmic activity.
E. Salmela[1], H. Renvall[2], M. Vihla[2], J. Kujala[2], R. Salmelin[2], J. Kere[1, 3]. 1) Research Programs Unit, Molecular Neurology, University of Helsinki, Helsinki, Finland; 2) Brain Research Unit, O.V. Lounasmaa Laboratory, Aalto University, School of Science, Espoo, Finland; 3) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden.

The human cerebral cortex shows several intrinsic oscillations (rhythms) that can be characterized with non-invasive neuroimaging methods such as magnetoencephalography (MEG). The most prominent of them is the 10-Hz rhythm recorded over the parieto-occipital cortices. This rhythm is strongly attenuated for example by opening the eyes, and its reactivity is widely used to probe cortical functions in both healthy and clinical populations. However, little is known about its underlying molecular mechanisms. To study the possible genetic determinants of the parieto-occipital 10-Hz rhythm in a normal population, we measured spontaneous brain activity with MEG in 98 pairs of healthy siblings while the subjects had their eyes closed and open (3 minutes each). The cortical activity was recorded with a 306-channel Elekta Neuromag neuromagnetometer, and amplitude spectra at each channel were calculated using Fast Fourier Transformation (FFT). The subjects were genotyped on Affymetrix 250K StyI SNP arrays, yielding genotypes for more than 28,000 single-nucleotide polymorphisms (SNPs) after filtering for genotyping quality and linkage disequilibrium.

The brain activity was quantified from the difference spectra between "eyes closed" and "eyes open" conditions. Width of the main spectral peak at ~10Hz, its peak frequency and peak strength were measured at the maximum channels in three regions over the parieto-occipital cortices. The peak strengths of the rhythm were highly heritable ($h^2 > 0.75$), and a variance component-based analysis revealed linkage for both the strength and the width of the spectral peak. The highest linkage peak was seen for the width of the spectral peak over the left parieto-occipital cortex on chromosome 10q23.2 (LOD = 2.814, $p < 0.03$ based on 1001 permutations with Merlin). This genomic region contains several functionally plausible genes, including *GRID1* which encodes a subunit of glutamate receptor channels that mediate the fast excitatory synaptic transmission in the central nervous system. Altogether, 12 suggestive or significant linkage peaks were seen across the 9 phenotypes tested; in 1001 permutations, the probability of observing 12 equally high peaks by chance was 0.046. Overall, the results demonstrate the potential of genetic analysis in linking macroscopic cortical phenotypes with molecular-level processes controlled by specific genes.

1295W

Genetic resilience to neurodegeneration in the presence of tau pathology.
T. Hohman, M. Koran, T. Thornton-Wells. Molecular Physiology and Biophysics, Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

The disease cascade in Alzheimer's Disease (AD) involves tauopathies, β-amyloid plaques, progressive neurodegeneration, and cognitive impairment. Certain individuals present with pathologic protein biomarkers but no clinical manifestation of AD. The current project sought to identify genetic variants that modify the relationship between biomarkers of pathology and ventricular volume (neurodegeneration). We also investigated whether the observed protein-gene interactions had an effect on levels of neuroinflammatory markers in plasma. We used ventricular volume from Magnetic Resonance Imaging (MRI) images quantified in Freesurfer as our outcome measure. Our statistical model controlled for age, education, diagnosis, and gender. Our term of interest was a gene x Phosphorylated Tau (Ptau) interaction. Ptau was quantified from protein levels in cerebrospinal fluid (CSF). Genes were identified using a Genome-wide Association Study (GWAS) approach to look for significant single nucleotide polymorphism (SNP) x Ptau interactions. We corrected for multiple comparisons using a False Discovery Rate threshold of $p < 0.05$. In addition, we tested for consistency across two subsets of the ADNI study. We identified one SNP x Ptau interaction that was consistent across both the ADNI-1 and ADNI-2/GO data sources: POT1 (rs4728029; t = 5.269, p =1.82x 10-7). The POT1 x Ptau interaction explained two percent of the variance in ventricular volume even when including APOE and the other covariates previously mentioned in the model. POT1 expression has been related to telomere length in previous research (Kondo et al., 2004), and telomere length has been associated with a neuroinflammatory response in Alzheimer's disease (Panossian et al., 2003). Therefore, in posthoc analyses we tested the Ptau x rs4728029 interaction in relation to neuroinflammatory markers measured in plasma. Indeed, this interaction was related to levels of interleukin 6 receptor (IL6R), providing additional support for a possible neuroinflammatory mechanism that explains the observed genetic interaction. These results suggest that genetic variation may modulate the neuroinflammatory response to Alzheimer's tau pathology and ultimately modify risk for the neurodegenerative cascade. Future work will use a more focused pathway approach to further investigate genetic resilience related to a beneficial neuroinflammatory response.

1296T

Genetic interactions found between calcium channel genes modulate amyloid load measured by positron emission tomography. *M. Koran, T. Hohman, T. Thornton-Wells, Alzheimer's Disease Neuroimaging Initiative.* Vanderbilt University, Nashville, TN.

Late-onset Alzheimer's disease (LOAD) is known to have a complex, oligogenic etiology, with considerable genetic heterogeneity. We investigated the influence of genetic interactions between genes in the Alzheimer's disease (AD) pathway on amyloid-beta (Aβ) deposition as measured by AV-45 ligand positron emission tomography (PET) to aid in understanding this disease's genetic etiology. The Alzheimer's Disease Neuroimaging Initiative (ADNI) cohorts were used for discovery and replication. We discovered and validated a significant genetic interaction between the genes *RYR3* and *CACNA1C*, both of which encode calcium channels expressed in the brain. The results shown here support previous animal studies implicating interactions between these calcium channels in amyloidigenesis and suggest that the pathological cascade of this disease may be modified by interactions in the amyloid-calcium axis. Future work focusing on the mechanisms of such relationships may inform targets for clinical intervention. .

1297F

Genetic interactions within inositol-related pathways are associated with longitudinal changes in ventricle size. *T. Thornton-Wells[1], T. Hohman[1], S. Meda[2], M. Koran[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Olin Neuropsychiatry Research Center, Harford Hospital, Hartford, CT.

The genetic etiology of late onset Alzheimer disease (LOAD) has proven complex, involving clinical and genetic heterogeneity and gene-gene interactions. Recent genome wide association studies (GWAS) in LOAD have led to the discovery of novel genetic risk factors; however, the investigation of gene-gene interactions has been limited. Conventional genetic studies often use binary disease status as the primary phenotype, but for complex brain-based diseases, neuroimaging data can serve as quantitative endophenotypes that correlate with disease status and more closely reflect pathological changes. In the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort, we tested for association of genetic interactions with longitudinal MRI measurements of the inferior lateral ventricles (ILVs), which have repeatedly shown a relationship to LOAD status and progression. We performed linear regression to evaluate the ability of pathway-derived SNP-SNP pairs to predict the slope of change in volume of the ILVs. After Bonferoni correction, we identified four significant SNP-SNP interactions in the right ILV (RILV) corresponding to gene-gene pairs *SYNJ2-PI4KA, PARD3-MYH2, PDE3A-ABHD12B* and *OR2L13-PRKG1* and one significant interaction in the left ILV (LILV) corresponding to *SYNJ2-PI4KA*. The SNP-SNP interaction corresponding to *SYNJ2-PI4KA* was the same in both the RILV and LILV and was the most significant interaction in each (RILV: $p=9.13\times10^{-12}$; LILV: $p=8.17\times10^{-13}$). Both genes belong to the inositol phosphate signaling pathway which has been previously associated with neurodegeneration in AD.

1298W

Associations of the rs4818 polymorphism in the COMT gene with demyelination of the inferior longitudinal fasciculus in the white matter of the brain and cognition in schizophrenia patients. *Z. Kikinis[1], K. Green[1], M. Giwerc[1], S. Bouix[1], N. Makris[1], N. Schreiber[2], G. Corfas[1], R. Kucherlapati[1], R. Kikinis[1], M. Kubicki[1, 2], M.E. Shenton[1, 2].* 1) Harvard Medical School, Boston, MA; 2) Harvard Medical School, Brockton, MA.

A single nucleotide polymorphism (SNP), rs4818, located at the 4th intron of the Catechol-O-methyltransferase (COMT) gene, has been observed to cause changes in expression of the COMT protein. COMT is a schizophrenia susceptibility gene and variants of rs4818 have been reported to be associated with variations in cognitive performance in schizophrenia. However, the impact of rs4818 polymorphism on the white matter of the brain has yet to be investigated. Here, we compared CC, CG and GG carriers of the rs4818 SNP for changes in the inferior longitudinal fasciculus (ILF). The ILF is a long association fiber tract connecting occipital and temporal lobes in the white matter of the brain. We used MR-Diffusion Tensor Imaging (MR-DTI), to analyze white matter microstructure of this tract and we applied neuropsychological tests to assess cognitive performance. Methods: MR-DTI images were acquired on 30 patients with chronic schizophrenia and 26 matched healthy controls and tractography of ILF was performed. Changes in MR-DTI output measures, such as Fractional Anisotropy (FA), trace, Axial Diffusivity (AD) and Radial Diffusivity (RD), were analyzed as they might reveal microstructural changes of axons, such as changes in myelination. DNA was extracted from saliva. The effect of the rs4818 polymorphism on cognition was tested using scores of Wisconsin Card Sorting test (WCST). Results: Schizophrenia patients with the CC genotype (N=10) at rs4818 exhibited higher values in RD, higher values in trace and lower values in FA in the ILF in the right hemisphere, which were all statistically significant (p=0.008, p=0.02, p=0.05). Increases in RD, while no changes in AD and decreases in FA have been reported previously in animal studies as consequence of demyelination in brain white matter. Schizophrenia patients with CG/GG and the control groups with either genotype did not differ in the DTI values. Further, RD significantly and positively correlated to the scores of several subtests of the WCST (p<0.02) in the group of schizophrenia patients with the CC genotype at rs4818. This suggests that demyelination of the axon is associated with poorer performance on the test. Conclusion: Our results suggest that the CC genotype at rs4818 of the COMT gene is associated with demyelination of the white matter tract ILF in schizophrenia patients. These changes in myelination might affect working memory and cognition in schizophrenia patients with this particular genetic make up.

1299T

Identification of robust biomarkers of neuronal and glial metabolic changes in spinocerebellar ataxia type 1,2,3 and 7. *F. Mochel[1], I. Mawusi[1], T.M. Nguyen[1], D. Rinaldi[1], C. Jauffret[1], R. Valabregue[2], P.G. Henry[3], A. Brice[1], A. Durr[1].* 1) Department of Genetics, Hôpital de La Salpêtrière, Paris, France; 2) CENIR, Institut du Cerveau et de la Moelle, Paris, France; 3) University of Minnesota, Center for Magnetic Resonance Research, Minneapolis, Minnesota, USA.

Background: Spinocerebellar ataxias (SCAs) belong to the group of polyglutamine repeat disorders and lead primarily to neurodegeneration in the cerebellum and the pons. We recently demonstrated that even the most sensitive clinical scores would require large number of patients to assess any therapeutic benefit. Therefore, the identification of robust biomarkers is critical to assess disease progression for therapeutic development. Methods: 1H-NMR spectroscopy was performed at 3T to determine the neurochemical profile of 24 metabolite concentrations in the vermis and pons of a unique cohort of 66 SCA patients - SCA1 (N=18), SCA2 (N=13), SCA3 (N=22) and SCA7 (N=13) - as well as in healthy controls with similar median age (N=34). Results/Interpretation: Compared to controls, SCAs patients displayed a significant decrease of neuronal metabolites, N-acetylaspartate and glutamate, but increased glia-related metabolites, glutamine and myoinositol. The neuronal loss in both affected regions was associated with a significant increase in creatine and phosphocreatine suggesting compensatory energetic mechanisms. Of note, there was a strong negative correlation between ataxia rating score (SARA) and total N-acetylaspartate in the pons of SCA2 (r = -0.7942, p = 0.0186), SCA3 (r = –0.7868, p= 0.0008) and SCA7 (r = -0.7614, p = 0.0105). In the vermis, SARA score correlated with total creatine in SCA1 (r = 0.7573, p = 0.0007), SCA2 (r = 0.6310, p = 0.0278) and SCA3 (0.5679, p = 0.0072). A correlation with myoinositol was also found in SCA2 (r = 0.6142, p = 0.0336) and SCA3 (r = 0.5831, p =0.0055). The PCA confirm that neuronal metabolites (N-acetylaspartate and glutamate) in the vermis and the pons vary inversely to glia-related metabolites (myoinositol) and energy-related metabolites (creatine and phosphocreatine), suggesting compensatory mechanisms to the neuronal loss.

1300F

Analysis of Structural Variants in the DISC1 gene: Association Test with P300 ERP and Brain Volumes. *V. De Luca[1], G. Spalletta[2].* 1) Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada; 2) Neuropsychiatry, IRCCS Santa Lucia Foundation, Italy.

In a large Scottish family with a (1;11)(q42;q14.3) translocation, the carriers of this balanced translocation were significantly associated to reduction in the amplitude of the P300 event-related potential (ERP). In healthy controls, we tested the association between two non-synonymous SNPs in DISC1 gene with P300 amplitude and the volumes of the brain structures that are the putative P300 generators. We have investigated the measurement of the visual P300 event-related potential (ERP) during a modified Stroop task. For this study, 32 healthy subjects (drug free) were recruited for the ERP arm and 100 subjects were recruited for the structural MRI arm. The mean age in the ERP was 34.53+/−8.5. There were 18 males and 14 females. The analysis of the SNP rs 821616 (Cys704Ser) was performed using the ABI7000. For the neutral word condition, there was no difference between the subjects who were carrying the variant 704Ser and those who did not carry this variant [F (1/ 26) = 1.732, p=0.200]. In the structural MRI arm, we did not find association with the SNP rs821616. Although our results did not show an association between Cys704Ser in DISC1 and P300 amplitude, this pilot study suggests a new methodology to combine multiple samples with related endophenotypes to test the pleiotropic effect of specific functional variants.

1301W

Clinical and Molecular Investigation of Spinocerebellar Ataxia with Hypogonadism: Not So Far, Not So Close. *C. Lourenco[1], C. Sobreira[1], P. Frassinete de Medeiros[2], M. Gonzalez[3], F. Speziani[3], S. Zuchner[3], W. Marques Jr[1].* 1) Neurology, Univ Sao Paulo, Ribeirao Preto, SAO PAULO, Brazil; 2) Genetics Service , Federal University of Campina Grande, Campina Grande, Brazil; 3) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

BACKGROUND: The association between cerebellar ataxia and hypogonadism was first described in four sibs by Holmes in the beginning of the XX century, and has since become known as Holmes type ataxia. Several syndromes with hypo/hypergonadotrophic hypogonadism and ataxia have been published, however there is a remarkable clinical heterogeneity among them. Here, we present the clinical data and molecular/biochemical studies of nineteen Brazilian patients with cerebellar ataxia and hypogonadism. MATERIAL AND METHODS: All patients were evaluated in the neurogenetics clinics by geneticists, neurologists and endocrinologists. Brain MRI, ophtalmological exam, EMG/NCV, hormone and biochemical tests, screening for CDG disorders (IEF and MS analysis), karyotype, muscle biopsy with chain respiratory enzyme assays and measuremente of coenzyme Q10, molecular tests for Friedreich ataxia and for SCAs (types 1, 2, 3, 6 and 7) were performed in the course of the investigation.Exome sequencing as performed in selected patients with a consistent phenotype. RESULTS: All patients had cerebellar ataxia, but the age of the onset was variable; it was worthy to note that ten patients had early onset ataxia (in the first decade of life). Consanguinity of parents was noted in three families; seven patients had hypergonadotropic hypogononadism. Mental retardation was seen in five patients with hypergonadotropic hypogonadism. None of the patients had chromosomal anomalies. Molecular tests for Friedreich and SCAs 1, 2 ,3 , 6 and 7 were all negative. Optic atrophy and retinochoroidal degeneration were found in five patients; axonal neuropathy was present in four patients. Cerebellar atrophy with pons or prominent vermis involvement was a constant feature. In two patients with ataxia and hypergonadotropic hypogonadism, coenzyme Q10 deficiency was confirmed in muscle biopsy.Two unrelated adult patients with hypergonadotropic hypogonadism had biochemical features of CDG Ia. One family - with four affected sibs - have features consistent with a rare neurological disorder , Boucher-Neuhauser syndrome. CONCLUSIONS: The association between cerebellar ataxia and hypogonadism comprise hetereogenous entities whose clinical investigation can elighten the pathological basis of these fascinating neuroendocrinological syndromes. Screening for CDG and Coq10 deficiency should be done in such patients as a part of the work-up investigation.

1302T

Novel ATM mutation in late-onset autosomal recessive cerebellar ataxia with neuropathy. *H. Shimazaki[1], R. Sugaya[1], J. Honda[1], A. Meguro[2], I. Nakano[3].* 1) Neurology, Jichi Medical University, Shimotsuke, Tochigi, Japan; 2) Hematology, Jichi Medical University, Shimotsuke, Tochigi, Japan; 3) Neurology, Tokyo Metropolitan Neurological Hospital, Fuchu, Tokyo, Japan.

Backgrounds: Autosomal recessive spinocerebellar ataxias (ARSCA) comprise many types of diseases. Most frequent ARSCA is Friedreich ataxia, but other types are relatively rare. We encountered a consanguineous family with two patients of late-onset cerebellar ataxia with neuropathy. We attempt to identify the causative gene mutation of this family with ARSCA. Methods: We investigated the proband with detailed neurological examination, blood examination, brain MRI, electrophysiological study, nerve biopsy and gene analyses. Results: The neurological examination revealed cerebellar ataxia, hand tremor, distal muscle wasting and diminished tendon reflexes. Patients had no conjunctival telangiectasias and showed immunodeficiency. Blood examination showed slightly elevated AFP. Brain MRI demonstrated marked cerebellar atrophy. Electrophysiologic study and nerve biopsy showed axonal neuropathy. We could not detect GAA repeat expansions of FXN gene, and sequencing analyses could not reveal pathologic substitutions in the APTX, SETX, and TDP1 genes. Whole-exome sequencing (WES) could identify the novel homozygous missense mutation in the ATM gene. This homozygous mutation was found in another patient, co-segregated within the family members and not found in 200 Japanese control DNAs. Subsequently, the patients suffered and died from bile duct cancer and chronic lymphocytic leukemia. Conclusion: We could identify ATM mutations in adult, late-onset ARSCA family. Ataxia-Telangiectasia (AT) is usually early-onset and show immunodeficiency and telangiectasia. We should consider AT even in late-onset ARSCA without telangiectasia and immunodeficiency. WES is one of the useful methods for identify the causative mutation in atypical adult-onset autosomal recessive cerebellar ataxias.

1303F

Modelling collybistin deletion neuropathology in induced pluripotent stem cells (iPSC)-derived neurons. *A. Sertie[1,2], K.G. Oliveira[1], C.O.F. Machado[1,2], C. Rosemberg[1], F. Kok[1,3], M.R. Passos-Bueno[1].* 1) Genetics and Evolutionary Biology Department, Institute of Biosciences, University of São Paulo, Brazil; 2) Experimental Research Center, Albert Einstein Jewish Hospital, Sao Paulo, Brazil; 3) Clinics Hospital, School of Medicine, University of São Paulo, Brazil.

Collybistin (CB) is a neuron-specific guanine nucleotide exchange factor implicated in inhibitory synapse development and plasticity that cluster and localize gephyrin and inhibitory neurotransmitter receptors to the postsynaptic membrane. We have identified a Brazilian patient with a deletion of the entire collybistin gene (ARHGEF9, Xq11.2) who shows severe mental retardation, epilepsy, and autistic behavior. In order to gain further insight into the underlying cellular neuropathology, we generated iPSC-derived neural progenitor cells (NPCs) and neurons from this patient and two unaffected individuals. iPSC were generated from skin fibroblasts using standard retroviral reprogramming technology. iPSC differentiation into NPCs and neurons was performed under conditions that favor the generation of either excitatory or inhibitory neurons. Expression of pluripotency-, NPC- and neuron-specific markers was determined by immunocytochemistry and/or western blotting. mTOR signaling pathway analysis was performed in NPCs treated nor not with rapamycin by western blotting. We observed that all control and patient iPSC clones express pluripotent markers such as Nanog, Oct4, Sox2 and Lin28. NPCs were positive for early neural precursor markers, such as Nestin and Musashi1. Mature neurons were positive for neural markers β-III Tubulin and Map2; in addition, these cells also express PSD-95 and GABARγ2 proteins, markers for excitatory and inhibitory synapses respectively. Interestingly, collybistin expression, which is not detected in normal fibroblasts, was reactivated in control IPSC, NPCs and mature neurons. We did not detect any significant differences between patient and control cells with respect to the reprogramming and differentiation capacities. However, iPSC and NPCs derived from the patient showed increased proliferation rate. Because mTOR signaling has been linked to cell proliferation and the CB partner gephyrin interacts with mTOR, we investigated the mTOR signaling pathway in patient-derived NPCs. Compared to control NPCs, our preliminary results suggested altered mTOR signaling in patient NPCs. Together, our results suggest that iPSC-derived NPCs and neurons from the patient carrying a deletion of the CB gene provide very promising model systems to explore the roles of CB in human neural development and physiology, as well as the mechanisms underlying the cognitive impairment in CB-deficient patients. Support: FAPESP, CNPq, Autismo & Realidade.

1304W

Genetic basis of Math genetic difficulty. *M.R.S. Carvalho[1, 3], M.de Miranda[1, 3], G. Pena[6], A. Julio-Costa[4], P. Pinheiro-Chagas[4, 7], L. Salvador[2], M. Andreata[1], V.G. Haase[2, 4, 5].* 1) Departamento de Biol Geral, Univ Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 2) Departamento de Psicologia, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 3) Pós-Graduação em Genética, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 4) Pós-Graduação em Neurociências, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 5) Pós-Graduação em Saude da Criança e do Adolescente, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 6) Pós-Graduação em Enfermagem, Escola de Enfermagem, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 7) Inserm-CEA Cognitive Neuroimaging unit NeuroSpin Center.

Math learning difficulty (MD) is a common cognitive condition affecting from 3 to 6% of the school-age population. Impacts of MD are low scholar achievement, low self-esteem, low employability, and low income. Social and economical factors and low educational standards may contribute to MD. However, a primary, genetic predisposition was also proposed. Familial aggregation has been reported for MD, but there is only two reports in the literature analyzing family history. Heritability and relative risks were never estimated. This project was approved by the Ethics in Research Committee of the Universidade Federal de Minas Gerais. It is part of a population based case-control study, in which a random sample of the school age population of Belo Horizonte city, Brazil, was collected. In order to ascertain individuals with MD, a two phase strategy was adopted. In the first phase, a Math achievement test (TDE) was responded by 1564 children. Students with results below the percentile 25 in TDE were further evaluated with a battery of tests covering intelligence, attention, mental state, memory, working memory, fine motor coordination, language, somato-sensorial function. Students with IQ<85 were excluded. A family history was collected with an specifically developed, structured questionary composed by simple questions such as 'can he/she add?', 'can he/she subtract?', 'can he/she multiply?', 'can he/she divide?', 'can he/she exchange money', 'can he/she discriminate left and right', 'can he/she tell the time on the clock?', 'can he/she go around by himself/herself', 'can he/she write?', 'can he/she read?'. Besides, data were collected on health conditions, consanguinity, scholarship, profession, and familial income. Fifty-eight family histories were collected (34 cases and 24 controls). Information was obtained on 1778 relatives, 981 biological ones. MD frequency among the 1564 students that took part in the first phase was estimated in 7%. No significative differences in sexual proportion were observed among MD index cases. Familial recurrence was reported in 32/34 families of the affected children. MD was reported in 27% of the mothers, 16% of the fathers, and 40% of the brothers and sisters of the affected children. These results are similar to those found in the two previous reports. Heritability was estimated in 70% for MD. Both autosomal dominant and X-linked recessive inheritance were detected among the MD families. Support: CNPq, FAPEMIG.

Whole Transcriptome Analysis of Fetal and Adult Ts1Cje Brains Provides New Perspectives for Prenatal and Postnatal Treatment of Neurocognition in Down Syndrome. *F. Guedj[1], J.LA Pennings[2], L.C Graham[1], E.L Newman[3], K.A Miczek[3], D.W Bianchi[1].* 1) Mother Inftant Research Institute, Tufts Medical Center, Boston, MA, USA; 2) Laboratory for Health Protection Research (GBO), National Institute for Public Health and the Environment (RIVM), Bilthoven, The Netherlands; 3) Department of Psychology, Tufts University, Bacon Hall, 530 Boston Ave, Medford, MA, USA.

Background: Learning deficits in Down syndrome (DS) emerge in early childhood and are associated with microcephaly and reduced neurogenesis. Although these anomalies originate during fetal life, pre-clinical trials are mainly focused on adults. We have proposed using non-invasive prenatal testing (NIPT) as an opportunity for prenatal treatment to improve cognition in DS (PrenatDiagn 2013;33:614). We hypothesize that prenatal treatment of brain and cognitive anomalies can be achieved using a systems biology approach. As baseline information, we analyzed whole transcriptome changes in embryonic and adult brains of the Ts1Cje mouse model of DS, as well as neonatal behavior via the ultrasonic vocalization (USV). **Methods:** For gene expression studies, total RNA was prepared from adult cortex and hippocampus (Ts1Cje=6/WT=5) and E15 whole brains (Ts1Cje=5/WT=5) for hybridization to Affymetrix mouse gene 1.0ST arrays. Data were analyzed to identify genes that are differentially regulated. Functional analyses were performed using GSEA and DAVID to identify altered signaling pathways in Ts1Cje brains. For behavioral studies, P7 pups were separated from their dams and the number of USVs was recorded. Motor activity was assessed by estimating the number of grid crossings and rollings on the testing platform. **Results:** More genes were significantly differentially regulated in the Ts1Cje vs. WT E15 brains (n=71) compared to the hippocampus (n=30) and cortex (n=7) at FDR-BH < 20%. Interestingly, similar regulation patterns are observed at both stages. Functional analyses highlighted imbalances of several cellular pathways (inflammation, oxidative stress, apoptosis and G-protein signaling) at both stages. Importantly, cell cycle genes (28 genes) and amino acid transporters (7 genes) are exclusively affected in fetal brain. Ts1Cje neonates produced more ultrasonic vocalizations (sum of ranks= 274.50) than WT pups (sum of ranks=221.50) (p<0.01,Mann-Whitney test). They also display abnormal motor activity indicated by reduced number of grid crossings (Sum of ranks=141.50) versus WT (Sum of ranks=141.50) (p<0.01). **Conclusions:** Data acquired from analysis of the brain transcriptome and early neonatal behavioural screening in Ts1Cje mice suggest novel pathway differences and behavioral abnormalities that are already present during fetal and neonatal life in DS. These differences provide baseline information on which to evaluate the effect of in utero treatment strategies.

Monoamine Oxidase Deficiency: The clinical relevance of personal genomics in a new developmental brain dysfunction disorder. *D. Moreno-De-Luca*[1], *E.R. Riggs*[2], *D.H. Ledbetter*[2], *C.L. Martin*[2], *J.F. Cubells*[3]. 1) Department of Psychiatry Yale University 300 George Street, Suite 901 New Haven, CT 06511; 2) Geisinger Health System 100 North Academy Avenue Danville, PA 17822; 3) Department of Human Genetics Emory Autism Center Department of Psychiatry and Behavioral Sciences Emory University School of Medicine Woodruff Memorial Building, Suite 7213 1638 Pierce Drive Atlanta, GA 30322.

Now considered the standard of care for developmental disabilities, chromosomal microarray testing has opened the door for detailed phenotypic delineation of new neurodevelopmental syndromes, defined by specific molecular criteria. Here we describe the phenotypic, familial, and genetic characterization of a male patient with a deletion involving the X-linked MAOA and MAOB genes, essential for amine-neurotransmitter homeostasis. The male proband presented at the age of 27 for psychiatric care. Facial dysmorphology, autism and ID, plus a family history remarkable for four maternal uncles with ID and premature deaths due to stroke, prompted evaluation by array comparative genomic hybridization (aCGH). We used the International Collaboration for Clinical Genomics (ICCG, formerly ISCA) consensus microarray design, containing 180K oligonucleotide probes across the whole genome. To fine-map initial results, we used a custom-designed high-density exon targeted microarray based on the same platform. aCGH revealed a 897 kb deletion on the X chromosome (chrX:42,625,499-43,523,142) that entirely removes MAOA and disrupts the coding region of MAOB. The patient's phenotype including ID, complete lack of productive language and very limited receptive language, complex wringing limb and body movements, constant motor restlessness, severe constipation with radiographic evidence of a flaccid large bowel, self-injurious behavior (hand-biting), and frequent brief syncopal episodes, is remarkably similar to other individuals with deletions involving MAOA and MAOB, but strikingly different from Brunner syndrome, arising from a point mutation in MAOA alone. The family was advised to refrain from giving the patient foods containing tryamine, and they were provided a list of sympathomimetic medications to avoid. The clear genotype-phenotype correlation in this individual, and the dramatic family history of premature death, is similar to the presentations of other males with deletions disrupting both MAO-encoding genes. Our observations and prior reports establish MAO deficiency as a new developmental brain dysfunction disorder with explicit clinical implications, namely the need for a low tyramine diet and clear contraindication of sympathomimetic agents. Knowledge of the genetic etiology of the phenotype in these patients allows for a tailored clinical management targeting directly the deficient pathway and serves as an example of personalized medicine.

VRK1 mutations associated with complex motor and sensory axonal neuropathy plus microcephaly. *W. Wiszniewski*[1], *C. Gonzaga-Jauregui*[1], *T. Lotze*[2], *L. Jamal*[3], *S. Penney*[1], *I. Campbell*[1], *D. Pehlivan*[1], *J. Hunter*[2], *S. Woodbury*[2], *G. Raymond*[4], *A. Adesina*[2], *S. Jhangiani*[5], *J. Reid*[5], *D. Muzny*[5], *E. Boerwinkle*[6], *R. Gibbs*[5], *J. Lupski*[1], *Centers for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Texas Children's Hospital, Houston, TX; 3) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD; 4) Department of Neurology, University of Minnesota, Minneapolis, MN; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 6) Human Genetics Center and Institute of Molecular Medicine, University of Texas-Houston Health Science Center, Houston, TX.

Here, we report three children from two unrelated families with a previously uncharacterized complex axonal motor and sensory neuropathy accompanied by severe non-progressive microcephaly and cerebral dysgenesis. We performed whole-genome and targeted whole-exome sequencing in these three affected subjects. Using genome-wide sequence analysis, we identified compound heterozygous mutations in two affected siblings from one family and a homozygous nonsense mutation in the third unrelated patient in the vaccinia-related kinase 1 (VRK1) gene. VRK1 encodes a serine/threonine kinase that is crucial for cell cycle progression and cell division and is proposed to be involved in nervous system development and maintenance. It is an early response gene that directly phosphorylates and regulates p53 and has crucial roles throughout the cell cycle. It has been proposed that VRK1 acts downstream of CLP1, and the disruption of the latter was shown recently to result in abnormal neuronal apoptosis leading to a similar neurodegenerative phenotype defined by microcephaly, brain dysgenesis and axonal neuropathy in mice. We hypothesize that a similar mechanism of abnormal neural apoptosis may explain the neurologic phenotype observed in patients with VRK1 mutations. Patients with rare diseases and complex clinical presentations represent a challenge for clinical diagnostics. Genomic approaches are allowing the identification of novel variants in genes for very rare disorders enabling a molecular diagnosis. Genomics is also revealing a phenotypic expansion whereby the full spectrum of clinical expression conveyed by mutant alleles at a locus can be better appreciated.

Evidence for phenotypically-linked bounds on the role of *de novo* loss of function variation in autism spectrum disorders. *E.B. Robinson*[1, 2, 3, 4], *K.E. Samocha*[1, 2, 3, 4], *J. Kosmicki*[1, 3, 5], *L.M. McGrath*[6], *B.M. Neale*[1, 2, 3, 4], *M.J. Daly*[1, 2, 3, 4]. 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Medical and Population Genetics Program, Broad Institute of Harvard and MIT, Cambridge, MA; 4) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, MA; 5) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 6) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA.

Background The distribution of cognitive ability in individuals with autism spectrum disorders (ASDs) ranges from severe impairment to high intelligence. While ASD with intellectual disability has been associated with a greater frequency of deleterious genetic events than ASD alone (e.g. Girirajan et al. 2012), the extent to which cognitive variation can be used to delineate bounds on the influence of *de novo* variation in ASDs has not been well characterized. The goal of this study was to determine whether *de novo* loss of function (LOF) mutations were associated with ASDs across the range of cognitive ability in 955 sequenced trios from the Autism Consortium and Simons Simplex Collection. Method Participants were included if they attempted any one of the 8 IQ tests used across the consortia that offered a comparable estimate of full scale IQ (e.g. the Differential Ability Scales, the WISC; n=801). To maintain adequately powered subsets, we divided the sample into three groups: 1) measured IQ at or above average (≥100; n=229), 2) measured IQ below average IQ (<100; n=457), and 3) IQ test attempted but not successfully completed (n=115). We compared the observed rate of *de novo* LOF mutations per exome in each group against the expected rate in the general population as estimated in the Exome Sequencing Project (0.09 per exome). Results The ASD sample as a whole featured an excess of *de novo* LOF mutations (observed rate= 0.13, p=2.05e−7). However, there was no *de novo* LOF excess in the group with IQ≥100 (observed rate=0.08, p=0.59). The association between ASDs and *de novo* LOF variants became stronger when evaluated separately within the groups with measured IQ<100 (observed rate=0.16, p=2.37e-7) and IQ attempted by not successfully completed (observed rate=0.21, p= 9.72e-5). The difference in *de novo* LOF rate between the IQ≥100 and other groups was also statistically significant (p=0.001). Discussion These findings suggest that *de novo* LOF variation does not play a role in ASDs when intelligence exceeds the general population average. Further, they suggest that ASDs include etiologic subtypes that can be distinguished through phenotypic variation. We discuss these findings in terms of their relevance to study design in ASD genetics.

Phenotypic categorization of putative pathogenic Copy Number Variants (CNVs) in a population of Autism Spectrum Disorder (ASD) patients. *I.C. Conceição[1,2,3], B. Oliveira[1,2,3], C. Correia[1,2,3], M. Rama[1], J. Coelho[1], C. Café[4], J. Almeida[4], S. Mouga[4,5], F. Duque[4,5], G. Oliveira[4,5,6], A.M. Vicente[1,2,3].* 1) Instituto Nacional de Saúde Dr Ricardo Jorge, Lisbon, Portugal; 2) Center for Biodiversity, Functional & Integrative Genomics, Lisboa, Portugal; 3) Instituto Gulbenkian de Ciência, Oeiras, Portugal;; 4) Unidade Neurodesenvolvimento e Autismo, Centro de Desenvolvimento, Hospital Pediátrico (HP) , Centro Hospitalar e Universitário de Coimbra (CHUC), Coimbra, Portugal; 5) Instituto Biomédico de Investigação em Luz e Imagem, Faculdade de Medicina da Universidade de Coimbra, Portugal; 6) Faculdade de Medicina da Universidade de Coimbra, Portugal ;.

The in depth characterization of CNVs in patients with ASD is fundamental to improve the distinction between benign and disease-causing structural variants, defining the clinical and genomic attributes with better predictive power for the development of CNV categorization methods for diagnostic purposes. In this study we characterize and categorize CNVs of clinical significance present in a population of 342 ASD patients, genotyped by the Autism Genome Project using SNP arrays. We selected all high confidence genic CNVs that did not overlap more than 20% in sequence with benign CNVs identified in public databases control populations (N=5459), and included CNVs containing syndromic genes/gene regions associated with ASD. A total of 180 genic CNVs were identified, ranging from 5 kb to 3 Mb, 62% of which were deletions. Genic CNVs included between one (73% of all genic CNVs) to 25 genes in a single CNV. Most CNVs (86%) were present in a single individual, but 23 common CNVs with a frequency of 1% or higher, distributed in 6 genomic regions, were identified in 26 individuals. Each of these common CNVs were present in 3 to 6 individuals, and encompassed candidate gene/gene regions for ASD, such as 16p13.11, *DPYD*, *PARK2* and *VPS13B*. Network analysis of the 314 genes encompassed by these CNVs yielded a network including 85 genes, enriched in central nervous system development and regulation of cellular catabolic processes. 23.5% of genic CNVs were *de novo*. CNV inheritance was further explored using parental information on autistic traits assessed using the Social Responsiveness Scale (SRS) and the Broad Autism Phenotype Questionnaire (BAPQ). A significant excess of BAPQs positive for autistic traits was observed in CNV-transmitting fathers, mainly in the 'aloof' personality. Familial correlations assessed for all pairs using the SRS for parents and probands showed a significant correlation between parents, suggestive of assortative mating in ASD. CNVs were further categorized according to various phenotypic attributes. We observe a trend towards individuals with intelectual disability, dysmorphisms and family history of neuropsychiatric disorder having a higher CNV burden, larger average CNVs sizes and a higher number of genes *per* CNV and *per* individual. Data mining algorithms are being employed for additional detailed categorization of specific CNVs according to clinical data, including ASD severity, social communication, language, regression and epilepsy.

1310W

Fragile X, intermediate, and premutation alleles in the Autism Genetic Resource Exchange (AGRE). *W. Brown, A. Glicksman, X. Ding, N. Ersalesi, C. Dobkin, S. Nolin.* Dept Human Gen, NYS Inst Basic Res, Staten Island, NY.

AGRE is an autism family registry and resource that includes primarily multiplex families, having two or more children affected by autism spectrum disorders. Family pedigree, phenotypic and genotypic data, and genetic material is available. They represent a relatively unbiased sample. ~35% of the first 480 families were noted to have had some genetic testing prior to entering the registry. The individuals receive ADI-R and ADOS. We have screened the FMR1 locus in one proband from each of 1742 families. We found 8 families that had the fragile X mutation present. Among these, 6 were found among the first set of 480 families. The prevalence of fragile X among the ~312 AGRE families that had had no prior genetic screening was ~ 1.9%. An estimate of the IQ score of the autistic subjects was 98±23 by Raven and 90±21 byStanford-Binet testing with 10-14% <70. Thus, the AGRE sample has a higher IQ distribution than typical for fragile X subjects (mean ~40±25). Previous prevalence studies of fragile X in autistic samples range from 0 to 16%; with a mean of ~4%; (Feinstein 98). Our initial 1.9% is similar to a report of 1.6% among 123 unrelated autistic individuals (Bailey 93), but lower than the 13% we found on an earlier multicenter study of 183 individuals (Brown 86). A growing awareness of fragile X syndrome has decreased the probability of fragile X in these multiplex autism families due to screening and exclusion from AGRE, and due to higher shifts in the IQ distribution for more recent autism cohorts. The overall observed frequency was was 8/1742 or ~ 0.5%. This finding still confirms an association of fragile X and autism exists. We tested to see if there is an association of autism with premutations or intermediate alleles. Among the 1535 male probands tested, there were 2 with premutation (59 & 64 CGGs) and 12 with intermediate (45-54 CGGs) alleles for an intermediate prevalence of 0.78%. Among the 206 female probands tested there were 2 with premutations (55, 59) and 7 with intermediate alleles. Since females have two alleles, dividing by 2 gives an intermediate allele prevalence of 1.7% in female alleles or an overall intermediate allele prevalence of 0.98%. Our control value was 1.15%. Thus, there was no excess of intermediate or premutation alleles among the AGRE registry autistic probands. This finding indicates autism is NOT associated with intermediate (45-54) or premutation (55-200) alleles in the AGRE probands.

1311T

Genome-wide association study identifies variants for major depression through age at onset stratification. *R.A. Power[1], K. Tansey[1], H. Buttenschøn[2], H. Lee[3], S. Cohen-Woods[4], S. Ripke[5], N.R. Wray[3], P.G.C. MDD Working Group[6], C.M. Lewis[1].* 1) Social Genetic & Developmental Psychiatry Centre, Institute of Psychiatry, London, United Kingdom; 2) Institut for Klinisk Medicin, Aarhus Universitet, Denmark; 3) Queensland Brain Institute, University of Queensland, Australia; 4) University of Adelaide, Australia; 5) Massachusetts General Hospital Simches Research Center, USA; 6) Consortium.

Major depressive disorder (MDD) is a highly prevalent and disabling disease. Despite moderate heritability and the pooling of large GWAS samples, no replicable genetic variants have been established for MDD. Here we used age at onset (AAO) to dissect the considerable heterogeneity within MDD, and better understand the underlying genetic architecture of this disorder. In the Psychiatric Genomics Consortium's sample of 9 studies containing 8,920 MDD cases and 9,521 controls, we split cases into 8 subsets based on AAO percentile within their study (i.e. first 8th of earliest onset cases, second 8th of earliest onset, etc.). These octiles were analysed systematically against controls to look at both early and late-onset specific risk factors. A replication threshold of p=5E−7 was used, with SNPs replicated in a sample of 6 studies containing 4,922 cases and 15,141 controls. GCTA and polygenic profile scoring were used to examine the heritability of early vs. late onset MDD, and how it overlapped with other psychiatric disorders. Ten independent SNPs met our replication threshold with AAO specific MDD sub-groups, of which two were genome-wide significant in the meta-analysis with the replication sample. These were rs7647854 on chromosome 3 (p=1.0E−11, OR=0.81) and rs7950328 chromosome 11 (p= 1.0E-08, OR=1.35). Further analysis showed that the effect of these SNPs was specific to the 50% latest onset cases, and increased in effect size as AAO increased. With a median AAO at age 27 across samples, 'late-onset' here reflects an adult-onset form of MDD rather than one developing in old age. We found no difference in the heritability of early and late-onset MDD, though did find a significantly greater burden of schizophrenia and bipolar risk variants in early-onset cases. In this study we have identified the first genome-wide significant replications for major depression and helped redefine its clinical picture. Our results suggest that adult-onset MDD is a more homogenous disorder with risk variants of larger effect, while adolescent-onset MDD is genetically more similar to both schizophrenia and bipolar disorder. We also highlight how the approach of more homogenous phenotyping can increase power beyond simply increasing sample size.

1312F

Divergent and convergent quantitative dysmorphic phenotypes among neuropsychiatric patients with rare de novo Copy Number Variants.
C.K. Deutsch[1], F. Momen-Heravi[2], R. Francis[1], A.T. Hunt[1], J.M. Stoler[3], L.B. Holmes[4], J. Sebat[5]. 1) Psychobiology Program, Eunice Kennedy Shriver Ctr, Waltham, MA; 2) Harvard Catalyst, Harvard Medical School, Boston, MA; 3) Clinical Genetics, Boston Children's Hospital, Boston, MA; 4) Medical Genetics Unit, MassGeneral Hospital for Children, Boston, MA; 5) Beyster Center for Molecular Genomics of Neuropsychiatric Disease, University of California San Diego, La Jolla, CA.

Over the last 25 years, quantitative dysmorphology methods have found increasing application in clinical and medical genetics. This has been facilitated by the publication of Farkas' atlas Anthropometry of the Head and Face. This craniofacial surface measurement system has become a popular standard reference, providing the most extensive normative database extant for direct craniofacial measurement in North America (N=1312). These anthropometric measurements have been used to render the diagnosis of anomalies both objective and reliable. Until recently geneticists have had to rely on cumbersome hard-copy look-up tables for these norms. Through the support of NIH, we have made the use of these norms more user-friendly by creating a computer-based interactive craniofacial measurement database for them. This software, FaceValue, provides tables of normative measurements conditioned on patient demographics. With these tables, the clinical/ medical geneticist configures operational definitions of anomalies, computes their z-scores as continuously distributed variables, and generates reports based on output measures. Here, we have applied FaceValue to the assessment of dysmorphic features in children with rare de novo Copy Number Variants (CNVs), using an anthropometric protocol to document for the first time clusters of specific, quantitatively-defined anomalies for molecular cytogenetic duplications and deletions. We provide worked examples of craniofacial anomalies among specific CNVs, including cases of 1q21.1 duplication, 15q11.2 deletion, and 22q11.2 deletion and duplication. These cases have also been phenotyped with respect to a spectrum of neuropsychiatric diagnosis, including but not confined to autistic disorders. Further, we present worked examples of dysmorphology observed in cases of teratogenesis in the form of prenatal exposure to anticonvulsants. In addition to distinctive combinations of dysmorphic features among these patients, convergent phenotypes emerged that are shared among multiple cases with autistic disorders. This convergence may signal common underlying forms of maldevelopment contributed by heterogeneous etiologies. Grant support: Simons Foundation SFARI (REACH Study; Sebat J, PI), Interactive Craniofacial Normative Database (R42DE016442; Deutsch CK, PI), Simons Foundation SFARI (Dysmorphology in Autism; Deutsch CK, PI).

Late-onset Alzheimer disease neuropathology genomic screen identifies novel loci for neuritic plaque and other AD neuropathology features.
K.L. Hamilton-Nelson[1], G.W. Beecham[1], A.C. Naj[3], L.-S. Wang[3], E.R. Martin[1], R. Mayeux[4], J.L. Haines[5], L.A. Farrer[6], G.D. Schellenberg[3], M.A. Pericak-Vance[1], T.J. Montine[2], Alzheimer's Disease Genetics Consortium. 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Fl; 2) Department of Pathology, University of Washington, Seattle, WA; 3) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Taub Institute of Research on Alzheimer Disease, Columbia University, New York, NY; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 6) School of Medicine, Boston University, Boston, MA.

Background: Late-onset Alzheimer disease (LOAD) is a highly heritable neurological disease with several known genetic risk loci (APOE, CR1, etc). Most of these loci have small effects on risk (e.g., odds ratios ≈1.1-1.2) and, aside from statistical association, no clear connection to LOAD etiology. To further investigate underlying genetic mechanisms of LOAD, we have performed a genome-wide association study (GWAS) of AD neuropathology and related phenotypes, including a neuropathology-confirmed case-control analysis, and analyses of neuropathology features, including neuritic plaques (NP), lewy bodies (LB), amyloid angiopathy (AA), medial temporal sclerosis (MTS), AD Braak stage, and vascular brain injury (VBI). We used this expanded neuropathology approach to limit the effects of phenotypic heterogeneity, and provide additional insights into AD subphenotypes. Methods: We examined 4,914 samples from 11 datasets in the Alzheimer Disease Genetics Consortium which were genotyped with high-density chips and imputed to a 1,000 Genomes Project reference panel. Primary pathology was assessed on ordinal scales (e.g., none, sparse, moderate, or frequent NP); statistical analyses were performed on either the ordinal or binary (i.e., presence or absence) scales as appropriate. Association was performed using logistic regression for binary traits and polytomous logistic regression for ordinal traits, followed by meta-analysis. Subjects examined included 3,887 neuropathologically-confirmed LOAD cases and 1,027 neuropathologically-confirmed cognitive controls. Results: Associations of APOE and BIN1 with LOAD were confirmed. Additionally, several novel LOAD associations were found, including PHF21B ($P=2.0\times10^{-8}$), and SMOX ($P=9.0\times10^{-7}$). Multiple loci were associated with the presence of neuritic plaques, including APOE ($P=1.8\times10^{-30}$), GALNT7 ($P=6.0\times10^{-9}$), ABCG1 ($P=8.0\times10^{-9}$), and a region near LMX1B ($P=4.3\times10^{-8}$). Additional loci were found to be associated with several ordinal neuropathology traits including LB, AA, MTS, VBI, and AD Braak staging (data to be presented). Conclusion: These results confirm several known AD risk loci and implicate novel loci in the etiology of LOAD neuropathology features, neuritic plaque in particular. Additional analyses including gene-based and pathway-based tests are being performed and will be reported, including thorough investigations of the known LOAD candidate genes.

1314T

Canine Multiple System Degeneration is Associated with Distinct SERAC1 Mutations in Two Different Dog Breeds. *J. Guo[1], R. Zeng[1], G.S. Johnson[1], T. Mhlanga-Mutangadura[1], E. Morava[2], T. Kozicz[2], J.F. Taylor[3], D.P. O'Brien[4], R.D. Schnabel[3].* 1) Department of Veterinary Pathobiology, University of Missouri College of Veterinary Medicine, Columbia, MO; 2) Hayward Genetics Center, Tulane University, LA; 3) Division of Animal Sciences, University of Missouri College of Agriculture, Food and Natural Resources, Columbia, MO, USA; 4) Department of Veterinary Medicine and Surgery, University of Missouri College of Veterinary Medicine, Columbia, MO, USA.

Canine Multiple System Degeneration (CMSD) is an autosomal recessive neurodegenerative disease. The initial cerebellar ataxia appears at 3 to 6 months and progresses to severe parkinsonism requiring euthanasia during the second year of life. Marked degeneration of the cerebellum, caudate nucleus, putamen, and substantia nigra are apparent at necropsy. CMSD has been recognized in two breeds: Kerry Blue Terrier (KBT) and Chinese Crested (CC). Previously, we mated CMSD obligate carriers from the two breeds and produced two normal and two CMSD-affected siblings, indicating that in both breeds CMSD is caused by the same mutation or by allelic mutations. Linkage mapping with samples from both breeds restricted the CMSD locus to a 5.2 Mb segment of CFA1 which contained 83 genes. We used Illumina sequencing technology with paired-end libraries to generate a whole genome sequence (WGS) with a 24-fold average coverage for a CMSD-affected KBT and a WGS with a 21-fold average coverage for a CMSD-affected CC. The reads from each WGS were separately aligned to the canine reference genome sequence (build 3.1) with NextGENe software (SoftGenetics). The detected sequence variants were prioritized according to predicted functionality and were filtered to remove variants also present in 54 other WGSs generated for dogs not affected with CMSD. After filtering, two homozygous sequence variants from the KBT alignment and four homozygous sequence variants from the CC alignment were in genes located within the previously mapped CFA1 region. Among these were a SERAC1 nonsense mutation in exon 15 in the KBT and a 4 bp deletion in a SERAC1 splice donor site sequence in the CC. RT-PCR amplification of RNA from a CMSD-affected CC showed that the SERAC1 splice donor site sequence deletion causes exon 4 skipping and a frame shift. All 6 CMSD-affected KBTs and all 20 CMSD-affected CCs were homozygous for their respective mutations, whereas, none of the 287 genotyped CMSD-free dogs were homozygous for these alleles. Mutations in human SERAC1 have been associated with a rare progressive neurodegenerative disease known as MEGDEL syndrome. MEGDEL syndrome patients exhibit dystonia, deafness, Leigh-like syndrome, impaired oxidative phosphorylation, and 3-methylglutaconic aciduria. The pathologic pathways underlying the neurodegeneration in this disease are poorly understood. Dogs with nullifying mutations in canine SERAC1 may prove useful as models to investigate these pathways.

1315F

Does gene function predict cognition and behaviour in X-linked intellectual disability? *K. Baker[1], G. Scerif[2], D.E. Astle[3], P.C. Fletcher[4], F.L. Raymond[1].* 1) Department of Medical Genetics, University of Cambridge, Cambridge, United Kingdom; 2) Department of Experimental Psychology, University of Oxford, United Kingdom; 3) MRC Cognition and Brain Sciences Unit, Cambridge, United Kingdom; 4) Behavioural and Clinical Neurosciences Institute, University of Cambridge, United Kingdom.

Genetic diagnosis is rapidly becoming a reality for many more individuals and families affected by Intellectual Disability (ID). Post-diagnostic challenges include establishment of a prognostic evidence base for ultra-rare disorders and elucidation of neurodevelopmental mechanisms. To this end, we have collected standardised medical, behavioural and cognitive data on participants with ID in the GOLD (Genetics of Learning Disability) cohort, who carry pathogenic variants in X-linked genes implicated in diverse neuronal functions including receptor dynamics, vesicle trafficking, ubiquitination and palmitoylation. Our aim is to determine which aspects of phenotype may be predicted by gene function. Severity of global impairment (assessed via Vineland Adaptive Behaviour Scales) varies widely within groups. However, beyond global impairment, function-associated characteristics start to emerge. For example, mutations in membrane-associated guanylate kinase genes (e.g. *DLG3*, *PAK3*) are associated with poor cognitive task performance (assessed via WASI-II), and high rates of behavioural problems particularly affecting attention and anxiety (assessed via the Developmental Behavior Checklist). Mutations in pre-synaptic and post-synaptic genes are associated with deficits in accuracy and speed-of-responding on computerised assessments of visual and auditory attention. Lastly, we have identified a previously-unreported association between *ZDHHC9* and childhood-onset nocturnal seizures, highlighting the importance of post-diagnostic medical phenotyping. The specificity of these observations will be tested via investigation of larger post-diagnostic samples and additional functional groups.

1316W

Serotonin Transporter Methylation and Response to Cognitive Behaviour Therapy in Child Anxiety Disorders. *S. Roberts[1], K.J. Lester[1], C.C.Y Wong[1], J.L. Hudson[2], C. Creswell[3], J. Mill[1,4], T.C. Eley[1].* 1) King's College London, MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, London, UK; 2) Centre for Emotional Health, Department of Psychology, Macquarie University, Sydney, NSW, Australia; 3) Winnicott Research Unit, School of Psychology and Clinical Language Sciences, University of Reading, Reading, UK; 4) University of Exeter Medical School, Exeter University, St Luke's Campus, Exeter, UK.

Anxiety disorders are the most common psychiatric disorders in childhood and are associated with a range of social and educational impairments. Cognitive Behaviour Therapy (CBT) is effective for the majority of childhood anxiety cases, although up to 40% of children retain significant impairments after CBT. Recent research in the newly emerging field of 'therapygenetics' indicates that individual differences in treatment response may have a genetic basis. Of particular interest is the Serotonin Transporter gene (SERT), which has been associated with disorders such as anxiety and depression. Furthermore, the short (S) allele of the serotonin promoter polymorphism (5HTTLPR) has been associated with poorer outcomes in high-stress environments but better outcomes in positive environments. A study from our group demonstrated that anxious children with the SS genotype showed an increased response to CBT, suggesting an interaction between genes and environmental influences. Epigenetic mechanisms that influence transcriptional regulation (such as DNA methylation) have been shown to be susceptible to the environment, making them plausible candidates for the biological embedding of experience. We tested whether DNA methylation of CpG sites upstream of the SERT promoter were associated with response to CBT in a subsample of 168 clinically anxious children. Buccal swabs DNA was collected at pre- and post-treatment, and SERT methylation determined using the Sequenom EpiTyper. Treatment response was defined as the presence or absence of all anxiety disorder diagnoses at follow-up. We detected a significant 3-way interaction between clinical response, percentage methylation at pre- and post-treatment and CpG site ($F(5,77)= 2.39$, $p = 0.046$). A significant difference between treatment responders and non-responders was found in percentage methylation change (averaged across all sites) across treatment time ($t(115)= 3.20$, $p = 0.002$), with this effect being particularly strong for CpG site 4 in particular ($t(92)= 3.43$, $p = 0.001$). At this site, non responders displayed a decrease in methylation from pre to post treatment time points at CpG site 4 (mean change = -6.3%), while treatment responders showed an increase in methylation (mean change = 3.5%). These findings imply that responders and non-responders show differences in DNA methylation change across treatment time, most prominently at a CpG site upstream of the serotonin transporter gene.

1317T

Using transcriptomic data to understand the processes involved in antidepressant treatment response. *K. Hodgson[1], K.E. Tansey[1], G. Coppola[2], G. Breen[1], R. Uher[1,3], P. McGuffin[1].* 1) SGDP, Institute of Psychiatry, Kings College London, London, United Kingdom; 2) Department of Psychiatry, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, USA; 3) Department of Psychiatry, Dalhousie University, Halifax, NS, Canada.

Research indicates that antidepressant response is a complex trait, involving interactions between both genetic and environmental factors (Tansey et al 2012). However the mechanisms by which antidepressants have their effects is unclear, and clinicians remain unable to identify who will respond best to which drug. Gene expression levels may capture the molecular changes that occur with antidepressant treatment, and can be influenced by both genetic and environmental factors. By examining the transcriptome and its alteration during treatment, this study aims to understand the biological mechanisms of antidepressant action, and identify if any of these processes are linked to individual variability in treatment response. Blood samples were taken from patients recruited into the Genome-Based Therapeutic Drugs for Depression (GENDEP) study both prior to treatment (week 0) and after receiving an antidepressant for eight weeks. RNA was extracted from whole blood, and processed on the Illumina HumanHT-12 v4 Expression BeadChip. After quality control measures, 123 patients had transcriptomic data available from both time points. Gene probes which varied significantly in expression levels between week 0 and week 8 were identified, and gene probes with expression levels significantly associated with antidepressant response (as measured by percentage change in the Montgomery-Asberg Depression Rating Scale) were identified. Network-level analyses of gene expression changes were undertaken using weighted-gene coexpression network analysis (WGCNA) to examine networks of gene coexpression, for analysis of alterations in gene-connectivity during treatment and links to treatment response. No significant associations were observed when performing the gene probe level analysis, using a threshold of FDR $q<0.1$. Network level analysis undertaken using WGCNA identified modules of coexpressed genes shared between week 0 and week 8 samples. However, the changes in the gene probe levels within each module (module eigengenes) from week 0 and week 8 did not differ significantly over the period of drug treatment. Whilst previous research looking into gene expression changes associated with antidepressant treatment has focused on candidate genes. However, our results indicate that any gene expression changes occurring as a result of antidepressant treatment are not of a large enough magnitude to be detected at transcriptome-wide significance at either the probe or network level.

1318F

MicroRNA-137 is Associated with Epigenetic Variation at the HCG9 Gene in the Amygdala. *A.P.S. Ori[1], K.R. van Eijk[2], M.F. Stokman[3], E. Strengman[2], The. Netherlands Brain Bank[4], M.P.M. Boks[5], S. de Jong[1], R.A. Ophoff[1, 6].* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, Los Angeles, CA; 2) Department of Medical Genetics, University Medical Centre, Utrecht, The Netherlands; 3) Department of Clinical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 4) The Netherlands Institute of Neuroscience, Amsterdam, The Netherlands; 5) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, Utrecht, The Netherlands; 6) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California 90095, USA.

Noncoding RNAs are widely abundant in cells and fulfill critical roles as transcriptional and post-transcriptional regulators. Noncoding RNAs have been implicated in the regulation of the epigenetic mechanisms. MicroRNA-137 (miR-137) is a small non-coding RNA important for neurodevelopment. A large genome-wide association study recently suggested miR-137 mediated dysregulation as an etiologic mechanism in schizophrenia. This study aims to investigate the role of miR-137 function in epigenetic variation across regions of the human brain.

We investigated 249 postmortem brain samples originating from 44 non-demented control, 6 schizophrenia and 11 bipolar disorder individuals. Data was collected on whole genome DNA methylation and microRNA-137 expression. Linear models were used to investigate the relationship between microRNA expression and DNA methylation levels.

MicroRNA-137 expression showed to be regional specific with highest expression in cortical regions, limbic system and basal ganglia and lowest expression in the cerebellum. In addition, miR-137 expression showed a strong correlation with methylation levels at a CpG site of the HLA complex group 9 gene (HCG9) in the amygdala. This correlation was significant ($b = 6.98$, $t = 9.52$, $p=0.0066$) and showed to be independent of disease status.

This study demonstrates a relationship between the schizophrenia associated microRNA miR-137 and DNA methylation at HCG9 in the amygdala. This is a brain region involved in processing emotions and memories and reproducibly implicated in schizophrenia pathology. Interestingly, the HCG9 gene is located within the major histocompatibility complex (MHC) class 1 region, which is also associated to schizophrenia. Future work involves investigating the effect of the miR-137 schizophrenia risk variant and miR-137 target genes on miR-137 expression levels and epigenetic variation at the HCG9 gene. Taken together, this study reveals microRNA-137 expression across the human brain and provides key insights on cross talk between this small RNA molecule and DNA methylation. These findings contribute to understanding etiologic mechanisms in schizophrenia pathology.

1319W

The genetic architecture of white matter integrity: Insights from quantitative genetics and genome-wide associations. *E. Sprooten[1], E.E.M. Knowles[1], D.R. McKay[1], M.A. Carless[2], M.A.A. de Almeida[2], A. Winkler[3], T. Dyer[2], J.E. Curran[2], H. Göring[2], R. Olvera[2], P. Kochunov[4], P. Fox[5], L. Almasy[2], R. Duggirala[2], J. Kent[2], J. Blangero[2], D.C. Glahn[1].* 1) Department of Psychiatry, Yale University, New Haven, CT; 2) Department of Genetics, Texas Biomedical Research Institute, University of Texas Health Science; 3) FMRIB, Oxford University; 4) Maryland Psychiatric Research Center, University of Maryland; 5) Research Imaging Institute, University of Texas Health Science Center San Antonio.

Background: White matter integrity as measured by diffusion tensor imaging (DTI) is heritable and implicated in several complex phenotypes including major depressive disorder, bipolar disorder, schizophrenia and dementia. We investigated the genetic architecture of white matter and its homogeneity across regions using quantitative genetics and genome-wide association (GWAS) of global and regional fractional anisotropy (FA).

Methods: Participants included 776 Mexican-American individuals from extended pedigrees. DTI data were acquired on a Siemens 3T Trio scanner (b=0 and b=700 s/mm2) along 55 non-collinear directions and a spatial resolution of 1.7x1.7x3mm. TBSS was applied to create white matter skeletons representing the centers of white matter within each subject. Heritability estimates of mean FA within this skeleton and within 48 regions of interest, and genetic correlations between them, were calculated using SOLAR. Genome-wide association was conducted utilizing Illumina microarrays under an additive genetic model. Covariates included age, sex, their interactions, and the first 4 principal components to account for population stratification.

Results: FA was significantly heritable (h2=0.52, p=1.09*10−10). Genetic correlations between global FA and each of the tracts were between .28 and .94. A number of genome-wide significant SNPs were found for global FA. The strongest association was on 17q24.1 with the intergenic SNP rs10853057 (p=3.18*10−10) close to the gene GNA13, and the second strongest SNP rs12249377 (p=3.26*10-10) was in the serotonin receptor HTR7 gene on 10q23.31. An additional three significant hits were on chromosomes 12 (p=7.97*10−10), 16 (p=1.94*10−9) and 1 (p=2.00*10−8). The betas of the GWAS of the global FA measure explained on average 44% (15%-70%) of the rankings of the betas of sub-regions of interest.

Conclusions: FA is a heritable trait and a powerful quantitative phenotype to examine in genome-wide association studies. Genetic correlations and comparisons of GWAS results suggest that a substantial portion of genetic influence on white matter structure is uniform across the brain. Our results encourage further research into the biological roles of these genome-wide significant SNPs in health and disease.

1320T

Association of KIBRA With Episodic and Working Memory: A Meta-Analysis. *A. Milnik[1,2], A. Heck[1,3,4], C. Vogler[1,3,4], H.-J. Heinze[2,5,6], D.J.-F. de Quervain[4,7], A. Papassotiropoulos[1,3,4].* 1) Division of Molecular Neuroscience, Department of Psychology, University of Basel, Basel, Switzerland; 2) Department of Neurology, University of Magdeburg, Magdeburg, Germany; 3) Life Sciences Training Facility, Department Biozentrum, University of Basel, Basel, Switzerland; 4) University Psychiatric Clinics, University of Basel, Basel, Switzerland; 5) Leibniz Institute for Neurobiology, Magdeburg, Germany; 6) Helmholtz Center for Neurodegenerative Diseases, Magdeburg, Germany; 7) Division of Cognitive Neuroscience, Department of Psychology, University of Basel, Basel, Switzerland.

WWC1 was first implicated in human cognition through a genome wide association study in 2006 that reported an association of the intronic single nucleotide polymorphism (SNP) rs17070145 with episodic memory performance. WWC1 encodes the protein KIBRA, which is almost ubiquitously expressed. Together with its binding partners, KIBRA is assumed to play a role in synaptic plasticity. T-allele carriers of SNP rs17070145 have been reported to outperform individuals that are homozygous for the C-allele in episodic memory tasks. Here we report two random effects meta-analyses testing the association of rs17070145 with episodic and working memory. All currently available population-based association studies that investigated effects of rs17070145 on episodic or working memory were included in the analyses. Where performance measures for multiple domain-specific tasks were available for a given study population, averaged effect size estimates were calculated. The performed meta-analyses relied on 17 samples that were tested for episodic memory performance (N = 8,909) and 9 samples that had performed working memory tasks (N = 4,696). We report a significant association of rs17070145 with both episodic (r = 0.068, P = 0.001) and working memory (r = 0.035, P = 0.018). In summary, our findings indicate that SNP rs17070145 located within KIBRA explains 0.5% of the variance for episodic memory tasks and 0.1% of the variance for working memory tasks in samples of primarily Caucasian background.

1321F

A Meta-analysis including 9,038 individuals confirms an interaction effect between depression and *FTO* genotype on BMI. *M. Rivera[1,2], T. Corre[3,4], C. Wolf[5], D. Czamara[5], S. Kloiber[5], B. Muller[5], M. Preisig[6], G. Breen[1], I. Craig[1], A. Farmer[1], C. Lewis[1], P. McGuffin[1].* 1) MRC SGDP Centre, Institute of Psychiatry, King's College London, London , London, United Kingdom; 2) CIBERSAM, University of Granada, Spain; 3) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 4) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 5) Max-Planck-Instutite of Psychiatry, Munich, Germany; 6) Department of Psychiatry, CHUV, Lausanne, Switzerland.

Background Depression and obesity are leading causes of disease burden and disability and major public health concerns worldwide. Both conditions are highly prevalent and are major risk factors for chronic (physical) diseases. The association between depression and obesity has repeatedly been reported in many studies. The role of the *FTO* gene in BMI and obesity has been confirmed in many independent studies. Recently, we have reported for the first time that depression amplifies the effect of *FTO* gene variation on BMI. The aim of the present study is to replicate these findings by investigating the *FTO* rs9939609 polymorphism in a meta-analysis including four independent studies consisting of depression cases and controls. **Methods** The sample consists of 5,134 depression cases and 3,904 controls from different studies: Radiant (3,251), PsyCoLaus (2,994), GSK (1,677) and MARS (1,116). As common inclusion criteria were available information on depression phenotypes, BMI and genotype data for rs9939609 *FTO* polymorphism. The distribution of BMI was positively skewed in all studies. We therefore transformed the data to $Log_{10(}$BMI) to achieve a closer approximation to normal distribution. In each individual study, linear regression models for quantitative traits assuming an additive genetic model were performed to test for the interaction between rs9939609 polymorphism and depression for an effect on Log_{10}BMI. All individuals were of white European ancestry. A classical approach meta-analysis with effect size estimates and standard errors was performed using the statistical package METAL. **Results** The results supported a significant interaction between *FTO* rs9939609 genotype and depression in relationship to Log_{10}-BMI (β=0.092, SE=0.033, p=0.0058). There was significant heterogeneity among studies. The sources of heterogeneity are being investigated. The meta-analysis interaction results show that in cases with depression there is an increased of 0.092 units of BMI for each *FTO* rs9939609 risk allele. **Discussion** This is to date the first meta-analysis investigating the relationship between *FTO*, BMI and depression. The results confirm that a history of depression increases the effect of *FTO* gene on BMI. This finding could have implications for predicting which patients with depression are at risk of high-BMI related disorders and potentially highlights how to improve prevention, management and treatment programs.

1322W

The genetic basis of solitude: lower heterozygosity in people with strict definition autism spectrum disorders and their parents. *S. Huang, X. Lu, J. Liang, D. Yuan.* State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China.

Autism Spectrum Disorders (ASDs) are >4 times more common in males and parents of people with ASDs often show mild forms of autistic-like characteristics or broad phenotypes. Strict (STR) and spectrum (SPC) definition ASDs differ mainly in social deficits with STR only slightly lower in IQ. Our recent work reveals a link between nucleotide diversity and complex traits/diseases consistent with stabilizing selection on SNP amounts and a priori truth on entropy and order. Heterozygosity (Het), a measure of random diversity, may be under stabilizing selection. From a priori reasoning, solitude should be linked with more homozygous (Hom) genomes since social deficits and tendency to marry people like oneself favor less admixture. Parents of ASDs are more populated in science and engineering fields demanding both IQ and creativity. While ASDs may be under negative selection, solitude is critical to creativity. An aesthetic hallmark of great creative works is unity in harmony of opposites in a pure and high contrast fashion. A genome ranked high in aesthetics with more Hom parts should make more creative people with all around balanced traits. Remarkably, previous work indeed shows less social but more novelty seeking behavior in inbred versus hybrid mice. We analyzed SNP dataset from dbGAP of 1154 ASD trios of European ancestry and correlated each individual's number of Het SNPs with STR vs SPC status. We found a moderate but significant correlation of low Het to STR cases (Spearman $r = 0.086$, $P < 0.01$) and their fathers ($r = 0.08$, $P < 0.01$). The average Het of STR cases is lower than SPC ($P < 0.05$, t test). STR sons have lower Hom minor allele content or amount (MAC) than their fathers ($P = 0.02$, t test), and the same holds for SPC sons and fathers ($P = 0.006$). (MAF was determined using parents.) Similar results were found for 148 trios of non-European ancestry. Finally, we analyzed relevant control cohorts from dbGAP including the Framingham study. Low Het associates significantly with living alone, never married, lower birth order, and higher education level and income. These results suggest that function and solitude in STR fathers may be at precarious near imbalance under more Hom DNAs. A moderate decrease in their sons in Hom MAC coupled with a slight increase in Het may tilt the balance towards extreme functions at either end without much improvement on solitude. The same may also apply to SPC involving more drop in Hom MAC.

1323T

Shared genetic vulnerability for Attention Deficit Hyperactivity Disorder, Substance Use and Gambling in Australian Adolescents. *P.A. Lind[1], D.A. Hay[2], T.J. Cicero[3], N.G. Martin[4], S.E. Medland[1].* 1) Quantitative Genetics, Queensland Institute of Medical Research, Brisbane, Australia; 2) School of Psychology, Curtin University, Perth, Australia; 3) School of Medicine, Department of Psychiatry, Washington University, USA; 4) Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Australia.

Previous studies have shown that the prevalence of substance use (including legal and illicit drugs) and gambling in children with Attention Deficit Hyperactivity Disorder (ADHD) is higher than in the general population. The aim of this study was to explore whether cigarette smoking, alcohol drinking and gambling in adolescents with ADHD was due to shared genetic risk factors. We analyzed self-report substance use and gambling data in twin participants from the Genetics of Inattention in Australia study (N = 500 individuals) who completed a structured psycho-social interview. Data included age of first use, number of DSM-IV symptoms for substance dependence or pathological gambling, the maximum number of cigarettes smoked in 24 hr (MAXCIG), the maximum number of alcoholic drinks consumed in 24 hr (MAXDR), and the number of different types of gambling used (PGVAR). Using quantitative genetic modelling, we found that genetic risk factors for ADHD also increased DSM-IV dependence symptoms (genetic correlations, r_g, .03-.19), the number of cigarettes consumed ($r_g = .45$) and types of gambling tried ($r_g = .07$), and reduced the age of onset for gambling, smoking and using alcohol (r_g ranges from −.07 to −.48). However, a negative genetic correlation was observed with alcohol consumption ($r_g = -.29$). These results suggest that the variants influencing ADHD behaviours influence substance use and gambling in later life and provide support for the development of an ADHD-substance use cross disorder consortium.

Bennett[3], Alzheimer's Disease Genetics Consortium.* 1) Department of Neurology, Harvard Med Sch/Brigham & Women's Hosp, Boston, MA; 2) Program for Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, IL; 4) Boston University, School of Medicine, Boston, MA; 5) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 6) Neurogenomics Division, Translational Genetics Research Institute and Arizona Alzheimer's Consortium, Phoenix, AZ; 7) Banner Alzheimer's Institute and Department of Psychiatry, University of Arizona, Phoenix, AZ; 8) Department of Psychiatry, University of Arizona, Tucson, AZ; 9) Division of Genetics, Department of Medicine, Brigham & Women's Hospital, Boston, MA; 10) Partners Healthcare Center for Personalized Genetic Medicine, Boston, MA; 11) Department of Medicine, University of Washington, Seattle, WA; 12) Taub Institute on Alzheimer's Disease and the Aging Brain, Department of Neurology, Columbia University, New York, NY; 13) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 14) Departments of Neurology, Epidemiology and Population Health and the Montefiore Headache Center, Albert Einstein College of Medicine, Bronx, NY; 15) Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 16) Rush Institute for Healthy Aging, Department of Internal Medicine, Rush University Medical Center, Chicago, IL.

Background: Cognitive decline, especially decline in episodic memory, is the clinical hallmark of Alzheimer's disease (AD) and known to start long before the onset of clinically diagnosed AD dementia. Thus, it may serve as a useful quantitative phenotype for GWAS and other 'omics' analyses. Methods: We included non-Hispanic White participants from four prospective community-based cohort studies (ROS, MAP, CHAP, EAS) who were non-demented at study entry and have at least two repeated measures of cognition. Within each cohort, individual cognitive tests were combined to form aggregate measures of global cognition and episodic memory. Genotype data from each cohort was quality controlled and imputed using 1000Genomes reference panel. We used linear mixed effects models to characterize individual paths of change in cognition, modeling age, sex and education as fixed effects and intercept and slope as random effects. We extracted individual residual cognitive slope estimates from the models and fit a linear regression model for each single nucleotide polymorphism (SNP), adjusting for population stratification. Results were meta-analyzed across cohorts. Results: A total of 3534 subjects were analyzed. The average age at enrollment in each study ranged from 72 to 81, follow-up ranged from 2–18 years and incidence of clinical diagnosis of AD ranged from 19% and 34%. The most significant loci for decline in both global cognition and episodic memory was APOE ($p=3.1\times10^{-34}$ and $p=2.1\times10^{-24}$, respectively). Although no other non-APOE locus reached genome-wide significance, we found suggestive results at two other regions. First, near the EDAR gene, previously found suggestive in a large AD case/control GWAS, with the top locus in the intergenic region 23kb upstream of EDAR reaching a $p=8.9\times10^{-8}$ for global cognition and $p=1.0\times10^{-4}$ for episodic memory and second, on the RAB3GAP2 gene with the top locus (non-coding intron) reaching a $p=1.3\times10^{-7}$ for global cognition and $p=1.3\times10^{-6}$ for episodic memory. We are currently analyzing data from two other cohort studies for validation. Conclusion: One previously un-described SNP and one possible AD associated SNP are observed to be associated with cognitive decline in a meta-analysis of community-based elders followed longitudinally. Our findings to date suggest that cognitive decline may be a useful phenotype for identifying genomic variation associated with AD or other factors influencing cognitive decline.

1325W

Combining RNA-sequencing and genotyping data to identify genes and pathways associated with major depression. *S. Mostafavi[1], A. Battle[1], X. Zhu[1], J. Potash[2], M. Weissman[3], J. Shin[4], K. Beckman[5], C. Haudenschild[6], C. McCormick[7], R. Mei[8], M. Gameroff[2], H. Glindes[3], P. Adams[2], F. Goes[9], F. Mondimore[9], D. MacKinnon[9], L. Notes[10], B. Schweizer[9], D. Furman[1], S. Montgomery[1], A. Urban[1], D. Koller[1], D. Levinson[1].* 1) Stanford University, Stanford; 2) University of Iowa, Iowa City; 3) Columbia University, NY; 4) National Cancer Institute, Bethesda; 5) University of Minnesota, Minneapolis; 6) Personalis, Menlo Park; 7) Ilumina, La Jolla; 8) Centrillion Biosciences, Palo Alto; 9) Johns Hopkins University, Baltimore; 10) American University, Washington DC.

Altered gene expression levels in disease can reflect the effect of sequence variation, environmental factors and their interaction with genetics, as well as the effects of the disease processes itself. To gain insights into biological mechanisms that are relevant to major depressive disorder (MDD) by identifying genes and pathways with altered expression levels, we compiled genome-wide gene expression, genotype, and physiological data in a case/control cohort of MDD from a large population-based sample. We analyze 463 recurrent MDD cases and 459 controls, that were recruited from a nationally-representative survey research panel. We sequenced RNA from whole-blood, genotyped these individuals for common SNPs, and derived information on psychiatric and medical history. Using these data, we assessed the association of MDD status with each gene and with sets of genes (pathways), while accounting for the influence on expression levels of potentially confounding variables such as environmental factors, and computational estimates of cell type proportions. Our analysis consists of three components: (1) association analysis of single gene expression levels with MDD; (2) analysis of association of MDD with canonical gene pathways, and hypergeometric tests of the enrichment of pathways in subsets of the most strongly-associated genes; and (3) joint analysis of association of gene expression and eQTLs (SNPs associated with expression, or expressed quantitative trait loci) with MDD. In the analysis of association between MDD and expression levels of autosomal genes, a significant excess of low p-values was observed, but no single-gene association was significant after genome-wide correction. Pathway-based analyses of expression data detected a significant association (FDR<0.05) between MDD and the interferon-I signaling pathway, with increased expression levels in MDD cases, where secondary analysis did not identify this result subject to additional confounding factors. Finally, joint evaluation of gene expression and eQTL genotypes identified a significant association with CINP, a gene involved in cell cycle arrest. The results support the hypothesis that altered immune signaling plays a role in the pathogenesis and/or the persistence and progression of MDD, and in particular implicates type I interferon signaling in pathology of MDD.

The PD Brain Map Project: Mapping the Transcriptional Architecture of Dopamine Neurons in Human Brain. *C.R. Scherzer[1,2,6], C. Vanderburg[2], T.G. Beach[3], C.H. Adler[4], J.J. Locascio[1,2], N. Pochet[5,6], A. Regev[5], B. Zheng[1], Z. Liao[1].* 1) The Neurogenomics Laboratory, Harvard Medical School and Brigham & Women's Hospital, Cambridge, MA; 2) Department of Neurology, Massachusetts General Hospital, Boston, MA; 3) Civin Laboratory for Neuropathology, Banner Sun Health Research Institute, Sun City, AZ; 4) Department of Neurology, Arizona Mayo Clinic, Scottsdale, AZ; 5) The Broad Institute of MIT and Harvard, Cambridge, MA; 6) Department of Neurology, Brigham & Women's Hospital, Boston, MA.

While the number of human genes has shrunk to an estimated ~22,000, a hidden universe of an ever-increasing number of tens of thousands of non-coding RNAs and splice variants is revolutionizing our thinking about the complexity of the human brain. We hypothesize that in complex genetic neurodegenerative diseases such as Parkinson's (PD) combinatorial effects of genetic and environmental risks disrupt the ordered flow of genetic information into vulnerable brain cells through cell-type-specific modulation of transcript abundance, transcription start site use, and sequence. The PD Brain Map Project's goal is to chart the flow of information from the entire human genome into a prototype brain cell-type - the dopamine neuron. Genetic variation between more than 100 individuals is examined for correlation with differences in transcribed elements — both protein-coding and non-coding — to identify regions of the genome that influence whether, how, and how much a transcript is expressed in this specific cell type *in situ* in human brains. Transcriptomes of control and diseased brains are probed using laser-capture microdissection, massively parallel sequencing of near ultra-low amounts of RNA, and expression Quantitative Trait Locus analysis. The PD Brain Map will provide a high-resolution encyclopedia of transcribed elements in a prototype cell-type in human brains, help to understand inherited susceptibility to PD, and highlight targets for precision therapies. Pilot phase results indicate that tens of thousands of isoforms of protein-coding genes and of non-coding RNAs are abundantly expressed in dopamine neurons and suggest a more diverse and complex transcriptional architecture than previously imagined. Adult onset painful sensory polyneuropathy caused by a dominant NAGLU mutation. *M. Tetreault[1,2], MJ. Dicaire[1], P. Allard[3], K. Gehring[4], D. Leblanc[3], N. Leclerc[5], J. Mathieu[5], B. Brais[1].* 1) Neurogenetics of motion laboratory, Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, PQ, Canada; 2) Centre of Excellence in Neuroscience of Université de Montreal, CHUM Research Center, Montréal, Québec, Canada; 3) Laboratoire de génétique médicale, CHU-Ste-Justine, Montréal, Québec, Canada; 4) Department of Biochemistry, McGill University, Montréal, Québec, Canada; 5) Cliniques de maladies neuromusculaires, Jonquière, Québec, Canada.

Late-onset painful sensory neuropathies are usually considered to be acquired and most commonly associated with common diseases such as diabetes. Adult presentations of known hereditary forms such as Amyloidosis and Fabry's are accompanied by other organ involvement. We recruited a large French-Canadian family (45 individuals; 21 affected cases) with a dominantly inherited late onset painful sensory neuropathy to uncover the underlying genetic mutation. The main clinical features of this dominant painful sensory polyneuropathy are the appearance of excessive cramps as early as 20 years old, constant painful paresthesias in the feet and later the hands appearing on average around age 55 (30–65) that interfere with sleep and progresses into a mild sensory ataxia. Electrophysiological studies are normal until late in the course of the disease where it documents a sensory polyneuropathy. Four affected individuals were sent for exome sequencing. Analysis of rare variants shared by all affected cases led to a list of four candidate variants. Segregation analysis in all recruited individuals has shown that only the p.Ile403Thr variant in the α-N-acetyl-glucosaminidase (NAGLU) gene is segregating with the disease. Recessive NAGLU mutations cause the severe childhood lysosomal disease Mucopolysaccharidosis IIIB (MPS-IIIB). Family members carrying the mutation showed a significant decrease of the enzymatic function. The late onset and variable severity of the symptoms may have precluded the description of such symptoms in parents MPS IIIB cases since they usually are lost to follow-up. The identification of a dominant phenotype associated with a NAGLU mutation supports that some carriers of lysosomal enzyme mutations may develop later in life much milder phenotypes.

Exome Sequencing of Extended Families Identify Putative Novel Candidate Genes for Autism. *A. Patowary, I. Stanaway, R. Nesbitt, W. Raskind, D. Nickerson, Z. Brkanac.* University of Washington, Seattle, WA.

Autism is a complex neurodevelopmental disorder behaviorally characterized by impairments in social interactions, communication and repetitive and restricted patterns of behavior. Autism has a strong genetic component. Currently more than 100 genetic causes of autism are recognized accounting for approximately 20% of cases and indicating high levels of genetic heterogeneity. Recently additional genes with de-novo mutations with large effects were identified in simplex families, with each gene accounting for a very small fraction of cases. In similar manner to genetics of simplex autism it is likely that for a subset of familial cases rare highly penetrant genetic variants are causal as well. Identification of genes responsible for familial autism is important as genetic architecture of familial autism might have important epidemiological implications. Under assumption that causal mutations are private or very rare, exome sequencing is a powerful tool for identification of highly penetrant variants in families with multiple affected cases. We performed whole exome sequencing in 27 NIMH and University of Washington autism families. We have selected families that include affected cousins and frequently additional affected siblings to minimize variant sharing between affected family members. The exome sequencing using NimbleGen SeqCap v2.0 and Illumina HiSeq2000 was performed at University of Washington Northwest Genomic Center. Sequences were aligned to the reference genome with BWA and variants were called with GATK. Functionally annotations of the variants were performed using ANNOVAR. As candidate variants we consider variants that are private, (not present in dbSNP, 1000 genomes or ESP6500) and functional (coding, missense, stop-gain, stop-loss, splice). The annotation and frequency filtering resulted in identification of 22±12 shared private functional variants in each family. In aggregate our sample has generated 198 private candidate variants. We have compared our candidate gene list with list of 424 genes with single de-novo mutations from recent exome sequencing studies. We have found 7 genes that are present in de-novo cases and in our families as well. As a next step, to confirm association with autism for the genes with mutations in simplex and familial cases, we are using molecular inversion probes and next generation sequencing to perform a large gene based case-control study of 1500 familial autism cases and 500 unscreened controls.

Identification of Rare Variants in Childhood Onset Schizophrenia using Exome Sequencing. *A. Ambalavanan[1], S.L. Girard[2], J. Gauthier[2], L. Xiong[2], A.D. Laporte[2], D. Spiegelman[2], E. Henrione[2], O. Diallo[2], S. Dobrzeniecka[2], P.A Dion[2], R. Joober[1,3], J.L. Rapoport[4], G.A. Rouleau[1,5].* 1) Department of Human Genetics, McGill University, Canada; 2) Centre de Recherche du Centre Hospitalier de Université de Montréal (CRCHUM), and Department of Medicine, Université de Montréal, Montreal, Quebec, Canada; 3) Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 4) Child Psychiatry Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland, USA; 5) Montreal Neurological Institute, McGill University, Canada.

Background: Childhood Onset Schizophrenia (COS) is a rare severe form of schizophrenia for which definitive genetic causes remain elusive even though the disease itself is heritable. The linkage and association studies of COS have been ineffective in attempting to identify explicit risk variants. We now know that de novo mutations play a significant role in the genetic mechanism of Schizophrenia, thus, we hypothesized that rare de novo mutation in different genes account for a portion of COS individuals. **Methods:** Our approach is to identify causative genes by targeted capture of the exome of COS proband and their respective parents followed by massively parallel sequencing of each individual in the family. We prioritized coding variants that are found only in the affected children within the family as well as variants found to be de novo. Each candidate variant is validated by Sanger sequencing in the proband and both parents. **Results:** We found interesting variants, including many de novo mutations and these potential variants are being validated with Sanger sequencing and further sequencing is being conducted to explore the genes and their major biological pathways **Conclusion**: We believe that insights from the identification of COS genes may help to device diagnostic tools which in turn may help to intervene earlier before the onset of symptoms which ultimately lead to the identification of therapeutic avenues for better treatment.

Family Genomics Reveals a Network of Calcium Signaling Genes Underlying Bipolar Disorder. *S.A. Ament[1], G. Glusman[1], H.C. Cox[1], D.E. Mauldin[1], S.Z. Montsaroff[1], N.D. Price[1], S. Szelinger[2], D.W. Craig[2], H.J. Edenberg[3], L. Hood[1], F.J. McMahon[4], J.R. Kelsoe[5], J.C. Roach[1], The Bipolar Genome Study.* 1) Institute for Systems Biology, Seattle, WA; 2) Translational Genomics Institute, Phoenix, AZ; 3) Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN; 4) National Institute of Mental Health, Bethesda, MD; 5) Department of Psychiatry, University of California, San Diego, CA.

We sequenced 200 personal genomes from 43 multiplex families with bipolar disorder to elucidate its genetic causes. Analysis of single pedigrees suggested oligogenic causation, with multiple uncommon, segregating coding and putative regulatory variants in each pedigree but little evidence for highly penetrant monogenic causes of disease. We developed new computational tools to aggregate candidate genomic variants across multiple pedigrees, and gene- and network-level tests for their statistical association with bipolar disorder. Comparison of the 43 sequenced bipolar disorder pedigrees to whole genome sequences from 158 individuals in 34 non-bipolar pedigrees revealed single genes and functionally-related gene networks that harbored segregating candidate variants frequently in bipolar pedigrees but rarely in control pedigrees. Voltage-gated calcium channels, calmodulin-dependent protein kinases, and GABA receptors were among the pathways most strongly associated with bipolar disorder in this analysis. We chose 30 top candidate genes for re-sequencing in 6000 additional bipolar disorder cases and controls. Our results suggest that a network of rare genomic variants in multiple genes with synaptic functions increase risk for bipolar disorder. In addition, our results suggest that -- despite multigenicity - family genomics is a powerful approach to discover genetic causes of common, complex diseases.

Partial deletion of the *RBFOX1* gene in a 16-year-old male patient with autism spectrum disorder, attention deficit hyperactivity disorder and intellectual disability. *O. Bartsch, D. Galetzka, E. Weis, S. Schweiger, J. Winter.* Institute of Human Genetics, Johannes Gutenberg University Mainz, Mainz, Germany.

The RBFOX1 protein is a muscle, heart and brain specific RNA-binding protein that regulates the alternative splicing of various genes in neuronal development and maintenance. Copy number variations within the *RBFOX1* gene (alias *FOX1*, *A2BP1*, OMIM *605104) are increasingly realized as causes of human neurodevelopmental disorders including intellectual disability, autism spectrum disorder (ASD), epilepsy, attention deficit hyperactivity disorder (ADHD), and schizophrenia. Here, we report on a 16-year-old male with ASD, mild intellectual disability (IQ 59, tested at age 13 years) and a heterozygous deletion spanning 100.3 kb in the 5' region of the *RBFOX1* gene. From age 2 years onwards, he showed speech delay and behavioural abnormalities including autoaggression, head banging and teeth grinding. He responded towards touch with beating, frequently cried himself to sleep and had fits of anxiety, e.g. towards noise. He also had frequent fits of laughter and tantrums without obvious cause. Neurological examinations at 5 and 6 years of age indicated mild muscular hypotonia, reduced gross and fine motor skills, clumsiness and ADHD (agitation, inability to concentrate, distractibility, impulse control disorder, and emotional lability). At age 16 years he read fluently with proper intonation and understanding (school grade 3 level) but could not write, perform simple mathematical calculations or hold eye contact. The deletion on chromosome 16p13.2 (chr16:6,751,824-6,852,175, UCSC hg19) included the promoter region and exon 1 of transcript variant 6 of *RBFOX1*. A previous report describes a patient with remarkably similar molecular and clinical findings (Mikhail et al., 2011, AJMG-A 155A:2386-2396). Our study further supports the role of *RBFOX1* gene mutations and in particular, of heterozygous loss-of-function mutations of *RBFOX1* transcript variant 6, in the etiology of ASD, ADHD and intellectual disability.

Genetics and Cellular Neurobiology of Severe Mental Illness. *C.G. Bouwkamp[1], F.M.S. De Vrij[1], N. Gunhanlar[1], S.T. Munshi[1], M.P.H. Coesmans[1], M. Quadri[2], G. Breedveld[2], J.A. Maat-Kievit[2], B. Oostra[2], V. Bonifati[2], S.A. Kushner[1].* 1) Dept of Neurobiological Psychiatry, Erasmus University Medical Center, Rotterdam, The Netherlands; 2) Dept of Clinical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands.

The neurobiological mechanisms of severe psychiatric disorders such as schizophrenia, bipolar disorder, and autism remain elusive. The aim of our project is to uncover the molecular and cellular neurobiology of psychiatric disorders by identifying rare highly-penetrant causative Mendelian genetic variants in severely affected families. A profound problem in studying the neurobiology of psychiatric disorders has always been the wide phenomenological heterogeneity. In fact, there is emerging consensus that the diagnosis of psychiatric disorders reflect a multitude of different syndromes at the biological level. Our study attempts to circumvent the difficulties inherent in studying genetically unrelated patients by using exome and whole-genome sequencing in a family-based design, which has yielded some notable recent successes in the literature. Families are recruited throughout the Netherlands from psychiatric clinics, national patient organizations, and the Erasmus MC department of Clinical Genetics. In particular, we have included families in which there are four or more affected family members who share a similar form of disorder. Affected and unaffected family members undergo structural clinical assessments by clinically-trained staff of our research group and whole-blood DNA is obtained. Exome sequencing or whole-genome sequencing is performed, in combination with linkage and copy number variant analysis using Illumina OmniExpress BeadChips. Called variants are filtered based on linkage regions, inheritance model, coding region, Minor Allele Frequency (MAF) <2 percent; in public databases, and being nonsense, missense or splice-affecting. Remaining variants are Sanger-validated in the family DNA samples and candidate-variants are validated by large case-control cohort screening. Furthermore, we obtain skin biopsies from the family members that are enrolled in our study. Using human induced pluripotent stem cell technology (hiPSC), it is possible to reprogram fibroblasts to pluripotency and subsequently derive neurons under controlled conditions. We are developing standardized methodology for comparing electrophysiological, morphological and molecular biological signatures of affected versus unaffected family members to elucidate the underlying neurobiological mechanisms.

Mapping the schizophrenia brain: Genes harboring damaging de novo mutations in schizophrenia map to a highly interconnected network of transcriptional co-expression and protein interaction in fetal prefrontal cortex. *S. Gulsuner[1], T. Walsh[1], A.C. Watts[1], M.K. Lee[1], A.M. Thornton[1], S. Casadei[1], C. Rippey[1], H. Shahin[1], M.-C. King[1], J.M. McClellan[2], Consortium on the Genetics of Schizophrenia (COGS), PAARTNERS Study Group,.* 1) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA; 2) Department of Psychiatry, University of Washington, Seattle WA.

Schizophrenia is a chronic neuropsychiatric disorder with a prevalence of 1% and requires lifelong treatment. Despite strong evidence of a familial component, genetic causes of the disease remain elusive. Many patients have no family history of mental illness. Genes responsible for schizophrenia can be revealed by de novo mutations in such patients. Participants in our project were 105 quads or trios comprising a proband with schizophrenia, an unaffected sibling if available and their unaffected parents. Families were selected for absence of history of serious mental illness. Exome sequencing of all 399 persons revealed 57 damaging de novo mutations in 47 of 105 schizophrenia probands and 35 such mutations in 25 of 84 unaffected siblings (X2 = 4.45; P = 0.035). The genes harboring de novo damaging mutations yielded networks based on protein-protein interactions (PPI) and transcriptional co-expression in different brain regions at different developmental stages, as revealed by RNASeq analysis from the BrainSpan Atlas of Developing Brain. The network generated by genes harboring de novo damaging mutations in schizophrenia had significantly more physical interactions (P=0.0005) and significantly greater levels of transcriptional co-expression in dorsolateral (P=0.0001) and ventrolateral (P=0.0004) regions of the prefrontal cortex during fetal development, compared to networks derived from genes mutant in unaffected siblings. Overall, 40 genes with de novo damaging mutations in schizophrenia mapped to this highly interconnected network. These genes function in the brain in neuronal migration, synaptic transmission, signaling, transcriptional regulation, and transport. These results support prefrontal cortex as a critical region in the pathogenesis of schizophrenia. The approach also supports the applicability of proteomic and transcriptome analyses in order to map critical genes to shared biological networks for conditions characterized by extreme genetic heterogeneity.

1334W

Targeted re-sequencing of HDC and SLITRK1 in Tourette syndrome using next-generation sequencing. *A. Inai[1], H. Kuwabara[1], Y. Eriguchi[1], T. Shimada[2], M. Furukawa[1], T. Sasaki[3], M. Tochigi[2], C. Kakiuchi[2], K. Kasai[2], Y. Kano[1].* 1) Depaerment of Child Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Japan; 2) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Japan; 3) Department of Health Education, Graduate School of Education, University of Tokyo, Japan.

Introduction; Tourette syndrome (TS) is neurodevelopmental disorder characterized by both motor and vocal tics. Family studies and twin studies provide strong evidence for genetic nature of TS. Although heritability of TS is high, genetic factors remain largely unknown. Association studies revealed that common genetic variants explain a modest fraction of heritable risk for TS, suggesting the important role of rare variants for the unexplained heritability. Histidine decarboxylase gene (HDC) and Slit and Trk-like 1 gene (SLITRK1) were proposed as causative factors for TS, however, subsequent studies showed difficulty in confirming some of these results. The aim of the present study is to examine whether TS is related to the HDC and SLTRK1 in Japanese population. Methods; A total of 95 individuals with TS participated in this study. All the participants provided written informed consent after they were given a complete explanation of the study as required by the ethics committee of the University of Tokyo Hospital. The exon region of HDC and SLITRK1 were amplified on TruSeq Custom Amplicon kit following the manufacturer's protocols. Amplified libraries were sequenced on the Illumina Miseq as pair-end 151-bp reads. Sequence reads were mapped to the reference genome (hg19). Variant calls were filtered to coordinate with at least 10×coverage. Results; There were total of 370 single nucleotide variants (SNVs) called in the 95 TS participants. After filtering for synonymous substitutions and database SNPs (db131), four novel and non-synonymous variants remain. Three participants had distinct SNVs on HDC, and other three participants had identical SNV on SLITRK1. PolyPhen algorithm predicted that all three SNVs on HDC disrupted the conformation of the protein. On the other hand, the SNV on SLITRK1 was predicted to be benign mutation. Conclusions; Present study suggested that HDC gene could play a role in the pathogenesis of TS, whereas SLITRK1 might play few or no role in TS susceptibility in Japanese population.

1335T

Exome sequences of multiplex, multigenerational families reveal schizophrenia risk loci involved in fatty acid oxidation. *M.Z. Kos[1], J. Peralta[1], M.A. Carless[1], M. Almeida[1], R.C. Gur[2], M.F. Pogue-Geile[3], D. Roalf[2], V. Nimgaonkar[4], R.E. Gur[2], L. Almasy[1].* 1) Dept Gen, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA; 3) Department of Psychology, University of Pittsburgh, Pittsburgh, PA; 4) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Schizophrenia is a serious mental illness defined by severe psychosis and disruptions in thought and behavior, with a worldwide prevalence of about 1 percent. Although schizophrenia is highly heritable, with estimates hovering around 0.80, much of the genetic liability is yet to be explained. In this paper, we search for susceptibility loci in multiplex, multigenerational families affected by schizophrenia, by targeting coding regions that are more likely to harbor protein-altering variants with potential risk effects. Exome sequencing was performed on 134 samples from eight European-American families, including 25 individuals with DSM-IV schizophrenia or schizoaffective disorder, using Illumina TruSeq technology. The exome variant calls were filtered based on stringent GATK probabilistic quality scores (LODs ≥ 4.0), as well as functional relevance as computed by the SIFT and PolyPhen algorithms. In total, 11,878 nonsynonymous variants with putative deleterious effects, representing 5,867 genes, were tested for their association with the schizophrenia spectrum disorders. Our top association hit is for a common polymorphism (rs1094111; MAF = 0.40) in the gene AMACR, which has been previously implicated in the risk of schizophrenia, a result that remained highly significant after correcting for multiple-testing (corrected P =0.0043). The enzyme coded by this gene, alpha-methylacyl-CoA racemase, is involved in oxidative metabolism of branched-chain fatty acids. Its deficiency can lead to the accumulation of pristanic acid in neural tissue, which may influence brain function and structure. In addition, the SNP rs10378 in the gene TMEM176A is also significant (corrected P = 0.031). Interestingly, permuted pathway analysis (1,000 runs) of the top association hits (P < 0.01; n = 249 genes) revealed significant enrichment of genes involved in 'fatty acid oxidation' (empirical P = 0.027), which includes the gene AMACR. Rare, nonsynonymous variants were found in two other genes involved in this metabolic pathway: a novel one in the gene ACAA1 (P = 0.0016; MAF = 0.008); and rs2894359 in the gene HSD17B4 (P = 0.0065; MAF = 0.025). In conclusion, our association findings from family-based exome sequence data suggest an important role for genes involved in fatty acid metabolism in the risk of schizophrenia, in particular the gene AMACR, providing key insights into possible strategies for preventative and therapeutic treatments.

1336F

Runs-of-homozygosity are associated with intellectual disability and female gender in simplex autism. *E. Morrow[1,2], E. Gamsiz[1], E. Viscidi[1], A. Frederick[1], M. Schmidt[1], E. Triche[1], S. Nagpal[1].* 1) Molecular Cellular Biology, Brown University, Providence, RI; 2) Simons Simplex Genetics Collaborative.

Background: To date there have been few genome-wide studies designed to examine excess homozygosity in autism, particularly in pedigrees without recent shared ancestry, which could indicate the effect of autosomal recessive loci. Methods: We have investigated a possible role for autosomal recessive loci through the study of autosomal runs-of-homozygosity (ROH) using SNP arrays. We have analyzed the Simons Simplex Collection comprised of 2108 North American simplex ASD families. We test the hypothesis that ROH is associated with affected status in those children with autism and co-occurring ID, or in affected females. We also analyze exome sequencing data for rare, homozygous deleterious variants within relevant ROH intervals for sequence mutations in candidate autism genes. Results: We discovered that affected status is associated with an increased burden of ROH in probands with IQ≤70. As minimum block size was increased, we observed an increased burden of ROH in affected probands with IQ≤70 as compared to unaffected matched siblings but no such excess was seen for IQ>70. For example, at a minimum segment size ≥ 2500kb, the total burden of ROH in probands with IQ≤70 was 1.326 times greater than unaffected siblings (p = 0.012). By contrast, the ratio of the ROH burden in affected versus unaffected siblings in the cohort with proband IQ>70 was 1.012 (p = 0.8935). Girls with autism also revealed a statistically significant burden of ROH as compared to their same sex siblings (p < 0.01), whereas boys with autism relative to their male unaffected siblings did not show this pattern. Within the autism cohort, we noticed a strong statistical association between ROH (minimum segment >2500kb) and measures of intellectual (IQ) and adaptive function (Vineland), but not measures of autism symptoms or severity. ROH segments are widely distributed across the entire genome. There are many regions of the genome wherein there is an excess of ROH in affected probands as compared to controls. We did identify several candidate, homozygous deleterious variants that require further study as candidate disease-associated variants. Discussion: Our study argues that autosomal recessive loci may contribute to an important part of the genetic architecture of autism in low IQ probands at least in simplex autism. In addition, we present among the first data that support a model involving a distinct genetic architecture in girls and patients with low IQ autism.

A Novel Autosomal Dominant Dystonia and Spastic Paraplegia Caused by a Mutation in *ATP5G3*, a gene that encodes for subunit c of mitochondrial ATP Synthase. *D.E. Neilson[1], T. Huang[1], X. Wang[1], N.D. Leslie[1], R.B. Hufnagel[1], D.L. Gilbert[2].* 1) Div. of Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Div. of Neurology, Cincinnati Children's Hosp, Cincinnati, OH.

OBJECTIVE To identify the genetic basis for the neurological phenotype in a large, multigenerational family with a novel, autosomal dominant, highly penetrant neurological disease causing childhood onset dystonia and adulthood onset spasticity.

BACKGROUND: We previously characterized the phenotype of this disease which has highly variable onset between the first year and fifth decade. Clinically it presents with progressive, deep brain stimulation-responsive idiopathic generalized dystonia in childhood and/or spastic paraplegia in adulthood. Linkage to chromosome 2q24-2q31 was identified, in a region in which no prior inherited dystonias or spastic paraplegias had been identified.

DESIGN/METHODS: Forty family members were seen and examined of whom 18 were affected. Exome sequencing was performed on two distantly-related family members. The resulting analysis was constrained to the genetic locus on chromosome 2q. Confirmatory Sanger-based sequencing was performed on the remainder of the affected and unaffected family members. Functional analyses of isolated mitochondrial complexes, derived from patient fibroblast culture, were performed.

RESULTS: A single, novel heterozygous mutation (p.106N>K) in ATP5G3 was identified in a highly conserved region of the c subunit of mitochondrial complex V ATP synthase. This mutation segregated with disease in the family. ATP synthase catalyzes ATP synthesis during oxidative phosphorylation. The c subunits of this complex form the trans-membrane proton pore structure. ATP5G1, ATP5G2 and ATP5G3 provide functional redundancy. Mitochondrial assays demonstrate a statistically significant 20% reduction in complex V activity, whereas complexes I through IV displayed normal activity.

CONCLUSIONS: An amino acid substitution in complex c of mitochondrial ATP synthase causes progressive generalized dystonia and spastic paraplegia. Initial studies suggest that the mutant protein interferes with complex V activity, proportional to its relative expression. Tissue specific or stress-induced increases in expression of this mutant ATP5G3 may produce stronger reductions in activity. This may explain the restricted pattern of neuronal dysfunction. *In vivo* and *in vitro* studies currently in progress may reveal a mechanism for neurological dysfunction in this and other progressive neurological diseases.

1338T

Whole exome sequencing of patients with Rett-like features negative for MECP2 mutations:. *H.E. Olson, O. Khwaja, C. LaCoursiere, E. Martin, W.E. Kaufmann, A. Poduri.* Neurology, Boston Children's Hospital, Boston, MA., USA.

Objective: To identify genetic etiologies in cases with Rett syndrome or with Rett-like features when clinical testing for MECP2 mutations or deletions is negative. Methods: A cohort of eleven patients with Rett syndrome-like features, four meeting criteria for the disorder, and negative clinical testing for mutations or deletions in *MECP2* were recruited by a Rett syndrome specialist to the Core for Neurological Diseases at Boston Children's Hospital. We completed a detailed phenotypic analysis and performed whole exome sequencing. Results: Using 2010 diagnostic criteria, three patients had classical Rett syndrome and mutations in *MECP2* (two frameshift deletions and one pathogenic missense mutation). One patient met criteria for atypical Rett syndrome, with neonatal onset epilepsy including focal seizures and epileptic spasms, and had a frameshift deletion in *STXBP1*. The remaining patients had Rett-like features but did not meet criteria for Rett syndrome, most often due to lack of regression. One patient with Rett-like features without epilepsy had a missense mutation in *FOXG1*, and consistent MRI findings. One had a deletion in *MECP2*. For the remaining five, candidate genes were identified including known epilepsy genes. Conclusions: Whole exome sequencing is high yield for patients with Rett syndrome or Rett-like features negative for mutations in *MECP2*, though targeted gene testing may also provide a diagnosis. Genes associated with atypical Rett syndrome, epilepsy, or intellectual disability should be considered in cases not meeting criteria for Rett syndrome or when *MECP2* testing is negative. Clinical criteria supportive of classical Rett syndrome correlated well with *MECP2* mutations.

1339F

Detecting novel mutations of Alzheimer's disease gene using semiconductor sequencing. *Y. Ryoichi[1,2], M. Ryosuke[1,3], M. Hiroyuki[1], I. Yuishin[3], K. Masahito[1], K. Takashi[4], M. Hirofumi[1], M. Noriyoshi[2], K. Hidemi[2], K. Hideshi[1].* 1) Epidemiology, Research Institute for Radiation Biology and Medicine Hiroshima University, Hiroshimashi, Hiroshimaken, Japan; 2) Department of Periodontal Medicine, Graduate School of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan; 3) Department of Neurology, Tokushima University Hospital, Tokushima, Japan; 4) Department of Anatomical Pathology, Hiroshima University Hospital, Hiroshima, Japan.

Alzheimer's disease (AD) is a progressive neurodegenerative disease, characterized by an impaired ability to remember, poor judgment, impaired visuospatial abilities, language functions or changes in personality. Neuronal loss, senile plaque, and neurofibrillary tangle are pathological hallmarks of AD. To date, several genes have been identified as causative of AD, including PSEN1, PSEN2 and APP. These genes are involved in the amyloid-beta pathway, and are included in the new diagnostic guidelines for AD as 'probable AD dementia carriers of a causative AD genetic mutation'. In addition, APOE also points to an association with late-onset AD, in that APOEε4 allele frequency is high in sufferers. Until recently, we screened these genes using Sanger sequencing. However, it was time consuming and costly if used for routine diagnostic purposes. Over the past few years, high-throughput genome technologies have changed the genetic landscape of AD. Here, we used Ion sequencing technology, which uses an integrated semiconductor device, detects the hydrogen ions at non-optical, high speed. To reveal the causative gene of AD, we investigated 45 Japanese AD patients with positive family histories, and 27 sporadic patients with early-onset (<60 years old). In familial cases, we found 5 heterozygous variations in 4 genes. Two variations were detected in the PSEN1 gene. One is a known heterozygous missense mutation in the PSEN1 gene (c.488 A>G, p.H163R, rs63750590). Another novel heterozygous missense variation in the PSEN1 gene (c.1158C>A, p.F386L,). APOEε4 (c.471T>C, p.C130R, rs429358) was detected. The frequency of patients who had the APOEε4 allele was 31% in the familial group. None of the patients with PSEN1,PSEN2 and APP mutations carried the APOEε4 allele. In the early onset group, only a novel heterozygous missense variation (c.1262C>T, p.T421M) was detected in the PSEN2 gene. We detected mutations of the PSEN1 and PSEN2 that are causes of AD, using Ion sequencing technology. This technology can help to diagnose autosomal dominant AD that has been difficult to investigate with conventional methods, and will help to expand both clinical knowledge of the disease and consultations with patients and their families.

1340W

Exome sequencing of Parkinson's disease in order to identify genetic variants with high disease-risk. *W. Satake[1], Y. Suzuki[2], Y. Ando[1], H. Tomiyama[3], M. Yamamoto[4], M. Murata[5], N. Hattori[3], S. Tsuji[6], S. Sugano[2], T. Toda[1].* 1) Div of Neurol/Mol Bra Sci, Kobe Univ Grad Sch Med, Kobe, Japan; 2) Dept of Med Genome Sci, the Univ of Tokyo, Japan; 3) Dept of Neurol, Juntendo Univ Sch Med, Tokyo, Japan; 4) Takamatsu Neurology Clinic, Takamatsu, Japan; 5) Dept of Neurol, Natl Cent Hosp of Neurology and Psychiatry, Kodaira, Japan; 6) Dept of Neurol, the Univ of Tokyo, Tokyo, Japan.

Parkinson's disease (PD) is one of the most common neurodegenerative diseases worldwide, mainly manifesting motor impairment due to degeneration of dopamigenic neurons. Common form of PD appears following a multi-factorial inheritance pattern; that is, the majority of PD-patients show sporadic onset, and 5-10% of the patients show familial aggregation and an elevated relative risk ratio typical of disorders with complex inheritance. Relatives of an affected individual are more likely to have disease-predisposing alleles in common with the affected person than are unrelated individuals. It is reasonable that more genetic variants with high disease-risks of polygenic PD are thought to exist in patients with family history than in sporadic cases, although there are some cases who will be due to single-gene mutation causing parkinsonism of mendelian inheritance that is masked by small family sizes and incomplete penetrance. Therefore, performing exome sequencing of PD-patients with family history will be effective in order to identify genetic variants with high PD-risk, such as rare variants. We performed exome sequencing using 66 patients from 33 families. We obtained genome of 2 affected individuals from each family. We extracted exome using Agilent SureSelect and performed massive parallel sequencing using HiSeq2000 (average depth ×102). After BWA mapping, GATK calling, and dbSNP132 filtering, we detected an average of 565 nonsynonymous SNVs. Because 2 patients from the same family would share alleles with disease risk, we extracted and detected an average of 244 SNVs (per family) which are sheared between 2 patients from the same family. Among these, 793 SNVs were shared between more than 2 families in total, and 35 SNVs showed variant-frequency <0.25% in data of control samples, which may contain candidates of rare-variants with high risk for Parkinson's disease. We will examine association between these variants and PD by association studies using exome sequencing of sporadic cases.

1341T

Clinical exome sequencing identifies two novel IQSEC2 mutations associated with X-linked intellectual disability with seizures: implications for genetic counseling and clinical diagnosis. *S. Tang[1], S.K. Gandomi[1], K.D. Farwell Gonzalez[1], L. Shahmirzadi[1], J. Mancuso[2], P. Pichurin[2], R. Temme[3], S. Dugan[3], W. Zeng[1].* 1) Clinical Genomics, Ambry Genetics, Aliso Viejo, CA., USA; 2) Mayo Clinic, Department of Medical Genetics, Rochester, MN, USA; 3) Children's Hospital & Clinics of Minnesota, St. Paul, MN.

Intellectual disability (ID) is a heterogeneous disorder with a wide phenotypic spectrum. Over 1,700 OMIM genes have been associated with this condition, many of which reside on the X-chromosome. The IQSEC2 gene is located on chromosome Xp11.22 and is known to play a significant role in the maintenance and homeostasis within the neural environment of the brain. Mutations in IQSEC2 have been historically reported as causing non-syndromic X-linked intellectual disability (XLID) characterized by early onset limited intellectual functioning and limited adaptive behavior. Case reports of affected probands show phenotypic overlap with conditions associated with pathogenic MECP2, FOXG1, CDKL5, and MEF2C gene mutations. Affected individuals, however, have also been identified as presenting with additional clinical features including seizures, autistic-behavior, psychiatric problems, and delayed language skills. Although once thought to be a rare cause of XLID, IQSEC2 mutations are becoming more frequently detected through Next Generation Sequencing technologies utilized in clinical diagnosis. To date, a total of four unrelated families and 32 male probands are reported to carry mutations in this gene. Here we report two novel IQSEC2 de novo truncating mutations (c.2582G>C; p.S861T affecting splicing and c.2052_2053delCG; p.C684X) identified through diagnostic exome sequencing (DES) in two unrelated male probands manifesting developmental delay, seizures, hypotonia, plagiocephaly, and abnormal MRI findings. Both patients also presented with other mild features, not typically seen with IQSEC2 mutations, and neither patient presented with behavioral disturbances as seen in previously reported patients. Our two probands expand on the current understanding of genotype-phenotype correlations that exist for this gene. Our data also suggests that patients with truncating mutations in IQSEC2 are more severely affected compared with previously reported cases known to carry missense alterations. Overall, DES established a molecular diagnosis for two patients in whom traditional testing methods were uninformative while contributing to expanding the mutational and phenotypic spectrum of IQSEC2. In addition, our data clearly supports recently published data suggesting that IQSEC2 plays a more significant role in the development of XLID than previously anticipated. It should also be considered as a candidate gene in cases of male probands presenting with ID plus seizures.

1342F

Homozygosity mapping and exome sequencing in consanguineous Pakistani pedigrees with autism spectrum disorder and intellectual disability. *L. Xiong[1,2,4], S. Li[1,2], C.S. Leblond[2], S. Laurent[2], Q. Jiang[1,2], S. Zhou[2], D. Spiegelman[2], A. Ambalavanan[2], M. Christian[2], C. Caron[3,4], B. Forgeot d'Arc[1,2,4], S. Rasheed[5], Z.A. Nanjiani[6], M.Q. Brohi[7], L. Mottron[1,2,4].* 1) Centre de recherche, Institut universitaire en santé mentale de Montréal, Montreal, Canada; 2) Centre de recherche du CHUM, Montreal, Canada; 3) Centre for Excellent in Pervasive and Developmental Disorders, University of Montreal, Montreal, Canada; 4) Department of Psychiatry, University of Montreal, Montreal, Canada; 5) Autism Institute, Karachi, Pakistan; 6) Ma Ayesha Memorial Centre, University of Karachi, Pakistan; 7) Sir Cowasjee Jehangir Institute of Psychiatry, Pakistan.

Background: Pakistan has the highest rate of consanguineous marriage, due to historical, religious, cultural and social reasons. This population characteristic makes Pakistan an excellent location for collecting large families for genetic studies, particularly for autosomal recessive traits and for severe psychiatric disorders plagued by extreme heterogeneity and reduced reproductive fitness in outbred Western populations. **Methods:** In the past few years, with the cooperation from local geneticists and clinicians, we have identified and characterized 6 consanguineous pedigrees with 3-5 affected siblings/first-cousins per pedigree with variable intellectual disability (ID)and autism spectrum disorder (ASD), which fits with a recessive inheritance pattern. We have thoroughly investigated all the symptomatic individuals, including standard clinical examinations, comprehensive psychological evaluations, routine laboratory tests, MRI and EEG investigations; and have collected blood samples from all the affected individuals, their unaffected parents and siblings. We have carried out homozygosity mapping in these 6 ASD/ID pedigrees using high density DNA microarrays. Due to the extreme genetic heterogeneity of ASD/ID, as well as the efficiency and reduced cost of whole exome sequencing, we also performed whole exome sequencing in 2-3 selected affected individuals/pedigree. **Results:** We have identified extensive runs of homozygosity region in each individual genome, as well as shared identical-by-descent regions among the affected individuals in each or branch of these 6 pedigrees independently. Combined with whole exome sequencing, we have so far identified a novel frameshift nonsense mutation in the VPS13B gene in one family with 3 affected brothers with atypical Cohen syndrome and autism phenotype. We have also identified another frameshift nonsense mutation in the CC2D1A gene in one family with 5 affected brothers with intellectual disability and autism behaviors. Genetic validation of potential disease-causing mutations in other 4 pedigrees is underway. **Discussion:** Our results strongly indicate extensive genetic heterogeneity in these consanguineous pedigrees with ASD/ID phenotypes. Direct whole exome sequencing could be the most useful and efficient approach to identify causative disease mutations and to facilitate clinical diagnosis, as well as for much needed early intervention and genetic counseling.

1343W

Mutations in the mitochondrial chaperone *TRAP1* are associated with the triad of chronic fatigue, pain and gut dysmotility: Crazy, criminal, or just caught in the *TRAP*? *R.G. Boles[1,2,3], L.R. Susswein[1], S.A. Wong[1,2], K.J. McKernan[1], A.S Zare[1], T.R. Foss[1], H.A. Hornung[1], K.M Sheldon[1].* 1) Courtagen Life Sciences, Inc., Woburn, MA; 2) Division of Medical Genetics, Children's Hospital Los Angeles, Los Angeles, CA; 3) Medical School, University of Southern California, Los Angeles, CA.

Functional symptoms, such as chronic fatigue, pain, and gastrointestinal dysmotility, are common and can dramatically impair a person's quality of life, including leading to disability. Patients with these subjective symptoms are often discounted by the medical establishment as being complainers, mentally ill, or even causing the condition (Munchausen, including by proxy). While the etiology of functional symptomatology is largely unknown, these conditions are common in patients with mitochondrial disease, suggesting that genes involved in energy metabolism are good candidates in functional disorder pathogenesis. DNA from 270 patients referred for clinical testing was sequenced using Courtagen Life Science's nucSEEK™ Next Generation sequencing platform. The test sequences 1,195 nuclear-encoded genes for proteins that localize to the mitochondria or are associated with phenotypes which mimic mitochondrial disease. Ten patients were found to harbor mutations in the ATPase domain (I253V x 7 patients, E192K x 2, E216* x 1) of TNF receptor-associated protein 1 (*TRAP1*). Nine of 10 patients have a triad of chronic pain, fatigue, and gastrointestinal (GI) dysmotility (the 10th patient does not report dysmotility), versus only 10 of 95 patients without *TRAP1* mutations referred to us for sequencing (P=3×10-7). Only 1 of 17 patients with *TRAP1* mutations outside the ATPase domain have this triad (P=0.0001 v. in domain mutations); rather, these patients present with varying symptoms and the variants are likely unrelated to their disease. *TRAP1* is a mitochondrial antioxidant chaperone involved in preventing apoptosis under oxidative stress. Antioxidant supplementation is often used in the treatment of functional disorders. Therefore, we hypothesize that mutations in the ATPase domain of *TRAP1* prevent appropriate antioxidant chaperoning, which predisposes towards the development of functional disease symptomatology. Anecdotal clinical reports suggest substantial improvement, at least in fatigue and pain, among the 4 of our 10 patients known to be treated on antioxidants to date. More rigorous treatment with acetylcysteine is underway, with favorable initial responses. We propose the name of *TRAP1*-Related Disease (T1ReD) for this likely-treatable novel condition, and suggest that genes involved in antioxidant defense be investigated more thoroughly as candidates in functional disease pathogenesis.

1344T

GENETIC CAUSES OF INTELLECTUAL DISABILITY IN 22Q11.2 DELETION SYNDROME PATIENTS. *T. Guo[1], T. Wang[2], J. Chung[1], J. Cai[1], D. McDonald-McGinn[3], A. S. Bassett[4,5], E. Chow[4], M. Velo-cardio-facial/DiGeorge/22q11.2 deletion syndrome (22q11DS) is the most common microdeletion disorder, occurring in ~1:4,000 live births. Clinical features are quite variable but can often include conotruncal heart defects (CTDs), palatal, immune, endocrine and behavioral problems and intellectual disabilities (ID). We are investigating genetic risk factors to explain this variable intellectual functioning. This variability could be due to genes on the remaining allele of 22q11.2 or elsewhere in the genome. We obtained single time point Verbal, Performance and Full Scale IQ measurements from 559 subjects with 22q11DS. Average full-scale IQ scores (FSIQ) in 22q11DS subjects (73±14) was significantly lower than the average FSIQ score in the general population (100±15). Within 22q11DS subjects mean verbal IQ (VIQ 77±15) was significantly higher than mean performance IQ (PIQ 73±12). Also relevant is the comparison of IQ score to present or absence of cardiac anomalies. Subjects with CTDs had on average, a lower FSIQ score compared with those with normal heart or just a minor aortic arch anomaly (n = 322 with a CTD and 220 without; 72 vs 75, p=0.03). Although most individuals with the syndrome have a typical 3 Mb deletion, a subset have smaller deletions, thus we further investigated the possible association of deletion size on IQ. Among 559 DNA samples from 22q11DS subjects with IQ scores, 281 have Affymetrix SNP 6.0 array data. From this data, we found 85% had a 3 Mb deletion (LCR A-D), 8% had a 1.5 Mb deletion (LCR A-B) and 0.8% of the patients had a 2 Mb deletion (LCR A-C). Notably, individuals with a 3 Mb deletion have significantly lower FSIQ (72 vs 78; p=0.03) and VIQ (75 vs 84; p=0.009) versus those with the smaller deletion. This suggests that genes in the distal 1.5 Mb region (LCR C-D) may contribute to this difference. Among 14 genes in this region, CRKL and SNAP29 are expressed in brain and could contribute to ID. Analysis is underway for an additional 278 22q11DS DNA samples with IQ and Affymetrix 6.0 array data. In addition, whole exome sequence was performed on DNA samples from 69 22q11DS subjects including 28 samples with ID (IQ<70), 16 with borderline IQ (~75) and 25 with near normal IQ (IQ>80) using the Illumina HiSeq 2000 (NHLBI Resequencing Contract). Analysis of this data is underway. The results will help to identify candidate genes for ID, both on the remaining allele of 22q11.2 and outside of the deleted region.

1345F

Novel dominant associations with PANS, autism, anxiety, pain, fatigue and GI dysmotility identified by NextGen sequencing the 1,100 Mito-Carta genes in 270 probands. *L.R. Susswein[1], K.M. Sheldon[1], T. Foss[1], A. Zare[1], K.J. McKernan[1], S.A. Wong[1], R.R. Trifiletti[2], R.G. Boles[1].* 1) Courtagen Life Sciences, Inc., Woburn, MA; 2) Private practice, Ramsey, NJ.

Often referred to as 'functional', 'psychosomatic' or 'non-organic', disease composed of subjective symptomatology is a frequent cause of disability and poses a major challenge for physicians and researchers. Since these conditions are very common among patients with mitochondrial disorders, mitochondrial genes are good candidates in functional disease pathogenesis. Courtagen has NextGen sequenced all ~ 1100 genes encoding mitochondrial proteins (MitoCarta) in 270 unrelated individuals referred for clinical testing because of a suspicion of possible mitochondrial disease. Herein, we present novel disease associations. To limit type II errors due to multiple comparisons, candidates are identified based on family studies or an increased prevalence of deleterious-predicted variants among our patients in comparison to controls, and candidates are assigned based on the presence of a unique associated phenotype versus in a group representative of all patients referred for our testing. Below are three among many candidates. ***FPGS***: This gene encodes folylpolyglutamate synthetase, an enzyme that has a central role in folate homeostasis. R466C is the only suspicious variant in a mother and three-affected children with Pediatric Autoimmune Neurological Syndrome (PANS), and is found in 8/270 (3%) probands v. 0.5% in 1000 Genomes (p=0.0018). 7/8 probands share a PANS-like phenotype defined by the presence of autism, OCD or tics, v. 24/99 in our referral group (p=0.02). ***ABCB6***: This gene encodes a protein that transports porphyrins across the inner mitochondrial membrane. A deleterious-predicted variant was identified in 13 probands v. in 0/41 negative controls (p=0.2). Ten of the 13 probands (77%) were reported to have a PANS-like phenotype including anxiety, tics, OCD and/or loss of milestones v. 35/100 of our referral control group (p=0.006). The 3 remaining probands have developmental delay, whereas this phenotype may be unrecognized. ***TRAP1***: This gene encodes a mitochondrial chaperone. In 10 probands, three deleterious-predicted variants in the ATPase domain were detected, demonstrating a clinical triad of chronic fatigue, pain and GI dysmotility (P=3×10-7). **Conclusion**: Comprehensive data analysis among MitoCarta genes has revealed multiple candidates in disease pathogenesis for which additional study is ongoing. None of the above genes were previously associated with disease. All are potentially treatable, and anecdotal attempts at treatment have been successful.

1346W

Major Depression Susceptibility Loci Identified Using Whole Genome Sequencing in Extended Pedigrees. *E.E.M. Knowles[1], M.A.A. De Almeida[2], J.W. Kent[2], T.D. Dyer[2], J.E. Curran[2], H.H. Goring[2], M.A. Carless[2], R.L. Overa[3], D.R. McKay[1], E. Sprooten[1], J. Blangero[2], D.C. Glahn[1].* 1) Department of Psychiatry, Yale University, New Haven, CT; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 3) Department of Psychiatry, University of Texas Health Science Center, San Antonio, TX.

Background MDD is a common and costly disorder. While effective treatments exist many patients fail to receive them. Identifying genetic markers for depression may provide a reliable indicator of depression risk, which would substantially improve detection, and in so doing enable earlier more effective treatment. The aim of this study was to identify genes for depression modelled as a continuous trait, using whole genome sequence data. The sample comprised 530 Mexican-American individuals from extended pedigrees. Whole genome sequence (WGS) data with a 60-fold coverage were available for the entire sample amounting to ~3.4M SNPs per individual. Association testing was performed using a unitary factor score derived by applying CFA to all items from the Major Past Depressive Episode section of the Mini-International Neuropsychiatric Interview. Genome wide-significant hits were followed up using gene-specific analyses. WGS analysis revealed two variants on chromosome 3 that were significantly associated with depression, plus a number of variants that reached a suggestive level of significance. The first was located at ~188.0 Mb ($\Psi 2$ = 40.15, p = 2.35 × 10–10) and the other at ~67.0 Mb ($\Psi 2$ = 35.21, p = 2.96 × 10–09). Post-hoc analysis revealed a number of interesting candidate genes. Using a continuous measure of depression combined with WGS data we have identified genetic influences for depression. These genetic influences are located on chromosome 3 and overlap, in part, with identifications from linkage studies and also from the GWAS for depression carried out by the PGC.

1347T

Deletions Between 1 and 30 kb Associate with Risk for Autism. *J.D. Buxbaum, C.S. Poultney, A.P. Goldberg, M. Fromer, E. Drapeau, H. Harony-Nicolas, Y. Kajiwara, S. de Rubeis, S. Durand.* Icahn School of Medicine at Mount Sinai, New York, NY.

Genetic studies have shown a strong association between autism spectrum disorders (ASD) and both inherited and de novo copy number variation (CNV). Studies to date focused on CNV that were >30kb. In the current study, we investigated the role of smaller exome-targeted CNV.

Methods: Whole exome sequencing (WES) was performed on 811 subjects (432 ASD cases, 379 controls) using the Agilent Whole Exome 1.1 capture kit Illumina sequencing to generate 75 bp paired-end reads (Neale et al. 2012, Nature, 485:242–5). XHMM (eXome Hidden Markov Model; Fromer et al. 2012, Am J Hum Genet, 91:597–607) was used to call CNV from exome read depths after removing batch effects.

XHMM calls were filtered to retain CNV with XHMM quality score ≥ 65, number of exons spanned ≥ 3, CNV length ≥ 1 kb, per-sample number of CNV ≤ 55, per-sample total kb CNV ≤ 18 Mb, and MAF ≤ 1%. The filtered set contains 1386 CNV calls in 559 samples. These results were further stratified on type (deletion/duplication) and CNV size (1-10 kb, 10–30 kb, 30+ kb). Burden analyses were performed with PLINK on each subset to assess the CNV called per sample, the proportion of samples with CNV, and the number of genes hit by CNV per sample. After finding increased burden for all three measures in the 1–30 kb deletions, we chose a subset of those to validate using qPCR and/or Sanger sequencing.

Results: Strong enrichment was found in the 1-30 kb deletion subset, as measured by the number of CNV calls per sample (p=0.0037), proportion of samples with CNV (28% in cases vs. 21% in controls, p=0.017), and number of genes hit by CNV per sample (p=0.041). We used qPCR to attempt to validate 66 of the 219 deletions in the 1-30 kb range. Of these, qPCR confirmed 55 deletions overlapping the deletion predicted by XHMM. Further validation of 5 deletions via Sanger sequencing validated three deletions, with two technical failures.

Conclusion: We found a significant (p=0.017) burden of small (1–30 kb) deletions in ASD cases that represents a genetic finding that would be made in 7% of individuals with ASD.

1348F

Contribution of LIN7A to developmental disorder. *A. Matsumoto[1], M. Mizuno[2], N. Hamada[2], E. Jimbo[1], K. Kojima[1], M.Y. Momoi[1], K. Nagata[2], T. Yamagata[1].* 1) Pediatrics, Jichi Medical University, Shimotsukeshi, Tochigi, Japan; 2) Department of Molecular Neurobiology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan.

Disorder of synaptic proteins was a major pathophysiology of autism spectrum disorder (ASD). Among them, deletion, duplication and base substitution of SHANK3, one of the scaffolding protein working in the synapse, were detected as causes of autism. We focused on LIN7A and LIN7B that were another scaffolding proteins, and analyzed their contribution to intellectual disability (ID) and ASD. (Patients) Patient 1 is one-year-old boy with ID, spastic diplegia, facial anomalies and thin corpus callosum. Patient 2 is a boy with Asperger syndrome. Patient 3 was a girl with ASD. (Materials and Methods) Their DNA was extracted from lymphocytes after obtaining informed consent from their parents. Array CGH analysis was performed using Agilent Human genome CGH 180K. On the screening for mutation of LIN7B, each exon and intron nearby was amplified and subjected to direct sequencing. Biochemical fraction followed by Western blotting was performed to determine the subcellular localization. In utero electroporation, LIN7A or LIN7B was suppressed using RNAi on on embryonic day 14.5 and the brain was analyzed afer birth. (Results) On array CGH analysis of patient 1, a 14 Mb deletion on 12q21 was detected, and LIN7A was located on it. Patient 2 had a 73kb duplication on 19q31.33, where LIN7B was included. In patient 3, G to C base substitution on the donor site of exon 5 was detected. This base change induced exon 5 skipping and made the truncated protein missing a part of PDZ domain. Lin7A and Lin7B expressed in all fraction, and Lin7A slightly enriched in crude synaptosomal pellet and synaptosome fraction. Lin7B enriched in synapt, postsynaptic density fraction I(PSD-I), postsynaptic vesicle fraction II(PSD-II). Suppression of LIN7A or LIN7B in the embryonal brain resulted the delayed migration of cortical neurons. (Discussion) LIN7 was reported to bind with CASK that is a gene for ID, or NMDA type 2 receptor. We confirm the localization of LIN7A and LIN7B on the synapse. Our results suggested that LIN7A and LIN7B had an important role on neuronal cells and contributed to ID and ASD.

1349W

Cross-disorder copy number variation analysis of Tourette syndrome and obsessive-compulsive disorder. *J.M. Scharf on behalf of the TSAICG and IOCDFGC.* Psychiatric Neurodevelopmental Genetics Unit, Massachusetts Gen Hosp, Boston, MA.

Background: Tourette syndrome (TS) and Obsessive-compulsive disorder (OCD) are highly heritable neuropsychiatric disorders with evidence for shared genetic risk factors from twin and family studies. TS/OCD segregation patterns also suggest the presence of within-family pleiotropy in the expression of the disorders. In general, genetic pleiotropy has been noted in the copy number variation (CNV) literature, where several large genomic regions have been identified repeatedly to be associated with multiple neurodevelopmental disorders, such as autism, epilepsy, schizophrenia and intellectual disability (ID). This study, which represents the first genome-wide analysis of CNVs in OCD and the largest analysis to date in TS, addressed whether large (>500kb), rare (<1%) CNVs contribute to the genetic architecture of TS and OCD. **Methods:** Given prior evidence favoring a shared genetic relationship between TS and OCD, a cross-disorder design was employed to maximize power to detect rare events. The sample consisted of 2699 cases (1086 TS, 1613 OCD) and 1789 controls, including a subset of 348 OCD cases recruited as parent-proband trios to allow a *de novo* CNV analysis. CNVs were called with two algorithms (PennCNV and iPattern) to ensure reliability. **Results:** There was no increased burden of large, rare CNVs in the cross-disorder analysis or in secondary, disorder-specific analyses. However, a trend (p=.06) was noted for a >3-fold increase in deletion burden in regions previously associated with other neurodevelopmental disorders. Further examination revealed that a single locus, 16p13.11, harbored most of the neurodevelopmental burden (5 case deletions: 0 control deletions, p=0.09 in current study, p=0.025 compared to published control rates). Furthermore, three of these 16p13.11 deletions were confirmed as *de novo*, supporting the etiological significance of this region. **Discussion:** These results demonstrate that TS and OCD are associated with known neurodevelopmental deletions, most notably at 16p13.11 which previously was associated with ID and autism. 4/5 cases with a 16p13.11 deletion had OCD (3 OCD only, 1 OCD + tics) whereas one case had TS only; none had ID or ASD. These data are consistent with pleiotropy at the 16p13.11 locus with TS and OCD as part of the phenotypic spectrum. Further study of large, rare CNVs in OCD and TS will be important to expand the range of phenotypes associated with CNVs implicated across neurodevelopmental disorders.

1350T

Large deletion of the PRRT2 gene frequently involves paroxysmal dyskinesia in Korea. *SJ. Lee[1], MW. Seong[1], HJ. Kim[2], G. Ehm[2], HJ. Yang[2], YE. Kim[2], KT. Choi[1], SS. Park[1], BS. Jeon[2].* 1) Department of Laboratory Medicine, College of Medicine, Seoul National University Hospital, Seoul, Korea; 2) Department of Neurology and Movement Disorder Center, Parkinson study group, and Neuroscience Research Institute, College of Medicine, Seoul National University, Seoul, Korea.

Introduction: Recently, it has been found that mutations of PRRT2 cause paroxysmal kinesigenic dyskinesia (PKD) and other paroxysmal dyskinesias (PxDs). However, detailed clinical features of the patients with PRRT2 mutation in comparison with those without mutation are not well described. Furthermore, 16p11.2 microdeletions including PRRT2 also have been reported in patients with PKD but it is unknown to what extent PRRT2 deletion contributes to development of PKD and other PxDs. Methods: To address these issues, we performed mutation screening in 30 Korean patients with PxDs by sequence analysis and gene dosage analysis of PRRT2, then analyzed their clinical features. Results: Overall, genetic abnormality in PRRT2 was identified in 9 patient (30%), 3 of the 7 familial cases (43%) and 6 of the 23 sporadic cases (26%). The previously reported c.649dupC and c.649delC was found in 5 and 1 patient, respectively, and a novel mutation c.323_324delCA was found in 1 patient. The other two patients were found to have PRRT2 deletion involving at least exon 2 and 3. Compared with mutation-negative cases, age at PxDs onset was earlier in mutation-positive cases. However, there was no difference in other clinical features. Contrary to common belief that patients with PKC show excellent response to carbamazepine, 4 mutation-positive patients taking carbamazepine reported only partial responses. Conclusion: Our result shows that PRRT2 is the common causative gene for PxDs in Korea. The PRRT2 deletion might frequently involve development of PxDs and gene dosage analysis should be included in the genetic test for PxDs. The mutation detection rate in familial cases is lower than expected and compared with those in previous studies. This result suggests that other genetic, epigenetic or environmental factors are related to paroxysmal dyskinesia. Further studies are needed to identify the possible effect of these factors.

1351F

Epileptic encephalopathies of unknown etiology: de novo mutations and pathway analysis. *S. Esmaeeli Nieh[1], G. Da Gente[1], H.C. Mefford[2], I. Scheffer[3], A. Poduri[4], D. Dlugos[5], E.H. Sherr[1], EPGP and Epi4K investigators.* 1) Department of Neurology, University of California San Francisco, San Francisco, CA; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Department of Neurology, Royal Children's Hospital, Victoria, Australia; 4) Department of Neurology, Children's Hospital, Boston, MA; 5) Department of Neurology, Children's Hospital of Philadelphia, PA.

Background, Approximately 40% of all seizures occurring during the first three years of life are epileptic encephalopathies (EE), including Infantile Spasms (IS) and Lennox-Gastaut Syndrome (LGS), a devastating group of childhood disorders for which the cause is often unknown. We report whole exome sequencing data and related pathway / network-based study from 264 IS/LGS trios (patients and biological parents) as part of the Epi4k project, studying the genetics of EE (http://www.epgp.org/epi4k/). **Patients and methods**, Participants with EE were enrolled in the Epilepsy Phenome/Genome Project (EPGP, an NINDS-sponsored multi-center study). Detailed inclusion criteria are found at www.epgp.org. We sequenced exomes of the probands and their parents, and confirmed de novo mutations by Sanger sequencing. To identify potential biological pathways involved in EE, we conducted pathway/network-based analysis of confirmed *de novo* mutations using GenMAPP-CS interface, incorporating different databases (i.e. PathwayCommons, KEGG, Gene Ontology (GO)). To optimize pathway overrepresentation, pathways were statistically evaluated (Z-score, permutation, gene counts). **Results**, We sequenced the exomes of 264 probands and their parents, and confirmed 329 *de novo* mutations. We found nine genes with multiple *de novo* SNV mutations in two or more trios. We rank all sequenced human genes based on their tolerances to putatively damaging polymorphic gene variants in the human population. Interestingly, we observed an excess of *de novo* mutations to intolerant functional genetic variation, of which some already known to be associated with other neurodevelopmental diseases (Epi4k & EPGP Investigators, 2013, Nature). Pathway analysis pointed to a hotspot with more than 35 nodes for pathways involved in mitosis and cell growth, i.e. G2/M transition, Netrin mediated signalling events, MTOR and MAPK/ERK signalling pathways. Further investigation of pathways and networks is ongoing. **Significance**, We have identified *de novo* mutations in novel candidate genes for both IS and LGS. This large cohort of patients shows significant genetic heterogeneity underlying IS and LGS involving both known and novel genes. Despite this genetic heterogeneity, many of these single-hit mutations appear to converge on specific biologic pathways, suggesting pathway-based analyses of information across multiple genes may offer insight both for EE etiology and disease progression.

1352W

Assessing the potential clinical application of *SCN1A* genetic testing in Dravet and Doose epilepsy syndromes. *M.C. Gonsales[1], C.V. Soler[1], R.R. Kieling[2], A. Palmini[2], D.H. Nakanishi[3], M.L. Manreza[3], P. Preto[4], M.A. Montenegro[4], M.M. Guerreiro[4], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas, Campinas, Brazil; 2) Porto Alegre Epilepsy Surgery Program, Hospital São Lucas, PUCRS, Porto Alegre, Brazil; 3) Clinical Hospital of Faculty of Medicine, USP, Sao Paulo, Brazil; 4) Department of Neurology, Faculty of Medical Sciences, University of Campinas, Campinas, Brazil.

Purpose Although several genes have been implicated with increased susceptibility to epilepsy, only a few are considered potentially useful for clinical testing. *SCN1A* mutations are associated with phenotypes within the spectrum of generalized epilepsy with febrile seizures plus (GEFS+), but the prognostic value of these mutations and a possible correlation with the different clinical subtypes remain unclear. Therefore, the aim of this study was to expand the knowledge on the clinical use of genetic testing for the most severe phenotypes within the GEFS+ spectrum, namely Dravet and Doose syndromes. **Methods** *SCN1A* mutation screening was performed in 21 patients with Dravet and 15 with Doose syndrome. Potentially deleterious mutations found were investigated in 100 individuals without epilepsy. In addition, eight algorithms were used to analyze the possible impact of missense mutations in protein function. Furthermore, MLPA analyzes were performed to detect copy number variations within *SCN1A*. **Results** We identified 14 potentially deleterious mutations in 15 patients with Dravet: six missense, four splice-site, two frameshift and two in-frame deletions. None of these were found in controls. Furthermore, all missense mutations are predicted to affect protein function. Two patients are monozygotic twins and presented the same alteration, an 18-basepair deletion, which was detected by both sequencing and MLPA. Interestingly, they also presented a missense mutation, which differently from the six mentioned above, was predicted as benign by five algorithms. In addition, this missense change was also present in their unaffected mother and in a control subject, strongly suggesting that the main cause of epilepsy in these patients is the deletion rather than the missense mutation. In contrast, only one patient referred to us as presenting Doose showed a potentially deleterious mutation, although this patient may have indeed a borderline/atypical phenotype. **Conclusion** Patients with Dravet syndrome showed a high frequency of *SCN1A* mutations (71%). Most mutations are missense (43%) and located in functionally important regions. However, we found that *SCN1A* testing in patients with classic Doose syndrome does not seem to be clinically relevant. In addition, we achieve a good discrimination power for identifying potential deleterious sequence variations in *SCN1A*, including missense changes by incorporating prediction algorithms and sequencing of control individuals.

1353T

Trio sequencing in malformations of cortical development. *E.L. Heinzen[1], A. Poduri[2], Epi4K and EPGP Investigators.* 1) Duke University, Durham, NC; 2) Boston Children's Hospital, Boston, MA.

Malformations of cortical development (MCD) are a heterogeneous group of conditions characterized by structural and cellular abnormalities in the cerebral cortex. These conditions arise from errors in cell proliferation, neuronal migration, or cortical organization during cortical development. MCD are strongly associated with severe, intractable epilepsy and intellectual disability. Germline mutations in a number of genes have been identified as the cause of particular subtypes of MCD; however, the cause of MCD in the majority of patients remains unknown. Given the typically sporadic presentation of MCD, we performed exome sequencing of leukocyte DNA of 125 patients with two common subtypes of MCD, polymicrogyria (PMG; n=68) and periventricular nodular heterotopia (PVNH; n=57), and their unaffected parents, to look for de novo mutations responsible for the disease. We identified disease-causing de novo mutations in two previously reported MCD genes: PIK3R2 (n=2) in PMG patients and in FLNA (n=3) in patients with PVNH. Similar to other neurodevelopmental disorders, we see no increase in the total number of de novo mutations in the MCD patient exomes. Comparing de novo mutations identified in this study to those recently published from another Epi4K study of epileptic encephalopathies, and to what was previously reported by other groups for autism spectrum disorders and intellectual disability, we see fewer MCD cases likely explained by germline or very early somatic mutations in known or novel genes. These data suggest that MCD may have a different genetic architecture than epileptic encephalopathies. One possible explanation is a larger role of post-zygotic somatic mutations in MCD that would be overlooked in leukocyte DNA, as has previously been reported in one severe subtype of MCD (hemimegalencephaly). Here we will discuss the results of this study, and discuss future opportunities for somatic gene discovery in MCD making use of fresh tissue specimens available through therapeutic resections.

1354F

Linkage analysis and exome sequencing in a large highly inbred consanguineous kindred to identify idiopathic generalized epilepsy genes. *F. Tuncer[1], S.A. Ugur Iseri[1], M. Calik[2], A.O. Caglayan[3], A. Iscan[4], M. Gunel[3], U. Ozbek[1].* 1) Genetics, Istanbul University Institute for Experimental Medicine, Istanbul, Turkey; 2) Department of Pediatric Neurology, Harran University, Faculty of Medicine,Sanliurfa, Turkey; 3) Departments of Neurosurgery and Genetics, Yale School of Medicine, New Haven, CT, USA; 4) Department of Pediatric Neurology, Bezmialem Vakif University, Faculty of Medicine, Istanbul, Turkey.

Epilepsy is a complex neurological disorder affecting 1% of the world's population. Among different forms of epilepsies, idiopathic generalized epilepsies (IGEs) are characterized by bilateral and synchronous generalized seizures in the absence of detectable brain lesions or metabolic abnormalities. Thus, the primary etiology for this disorder is believed to be genetic. The proposed study includes a large highly inbred consanguineous kindred with multiple IGE affected individuals and an ultimate aim in identifying novel epilepsy gene(s) to delineate the molecular basis of this disorder. Physical, neurological and electroencephalography (EEG) examinations were performed on the subjects recruited with information on family history, revealing 6 affected family members composed of 4 siblings and 2 cousins presenting varying seizure types. Experimental approaches included SNP genotyping of affected and 4 unaffected family members using Illumina Human HumanCytoSNP-12 BeadChip (300K). Genotype data was utilized using easyLinkage Plus software platform, where Mendelian genotyping errors were determined using PedCheck, multipoint lod scores were calculated under the assumption of autosomal recessive inheritance and haplotypes were constructed through GeneHunter. Linkage analyses were performed utilizing 4 affected sibs with their healthy brother and parents. Linkage peaks obtained were investigated through homozygosity mapping, which revealed partitioned homozygous regions in the affected cousins that were homozygous in the affected sibs. To facilitate in finding epilepsy genes, Illumina HiSeq2000 was used to perform exome sequencing on the affected child described to have drug resistance seizures and mental retardation. This child was chosen as the representative phenotype among the affected family members, due to the severest clinical presentation. Exome data obtained from this child was analyzed utilizing the pipeline developed by Yale University's bioinformatics team. Data was filtered for homozygous variants that either reside under the linkage peaks, within the homozygous regions shared by affected members and/or are novel and not caught by previous analyses. Validation of candidate variants obtained from exome data via Sanger sequencing, followed by familial segregation underline the current experiments. Prospective work includes healthy population screening for the candidate variant that shows familial segregation in line with affection status.

1355W

Mutation screening in the mitochondrial D-loop region in FMR1 premutation carriers. *F. Silva[1,2], L. Rodriguez-Revenga[1,3,4], I. Madrigal[1,3,4], MI. Alvarez-Mora[1,3], DM. Elurbe[1,3], M. Milà[1,2,3,4].* 1) Department of Biochemistry and Molecular Genetics, Hospital clinic Barcelona; 2) Fundació Clínic per a la Recerca Biomèdica, Barcelona, Spain; 3) CIBER de Enfermedades Raras (CIBERER), Barcelona, Spain; 4) IDIBAPS (Institut d'Investigacions Biomèdiques August Pi I Sunyer), Barcelona, Spain.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset neurodegenerative disorder that occurs in FMR1 premutation carriers. Many studies have shown that mitochondrial dysfunction is involved in neurological diseases. The mitochondrial DNA (mtDNA) could be considered as a candidate modifier factor for FXTAS, since mitochondrial oxidative stress caused by mtDNA mutations has been implicated in the neuronal death in neurodegenerative disorders. The main goal of this work was to determine the mutation rate in the D-loop region, since this region has been considered a 'hot spot' for mutations in many diseases. In order to identify mutations, the hypervariable region I (HVR-I) was sequenced in 44 FMR1 premutated carriers, 20 of which presenting with FXTAS disease (11 females and 9 males) and 24 without FXTAS (18 females and 6 males), and 22 control individuals (22 males). Alignment was made with the revised Cambridge reference sequence. All FXTAS present one or more changes in the D-loop region, 22 of the 24 non-FXTAS and 21 of the controls present mutations. The T16519C change was the most prevalent mutation in all groups (55% FXTAS; 37,5% non-FXTAS and 54,5% controls). Our results do not show differences on the rate of D-loop changes between FXTAS, non-FXTAS and controls.

1356T

"Game of Exomes" and Autism Spectrum Disorder. *M. Cuccaro[1], N. Dueker[1], E.R. Martin[1,2], A.J. Griswold[1], H.N. Cukier[1], S. Slifer[1], J. Jaworski[1], I. Konidari[1], P.L. Whitehead[1], M. Schmidt[1], J.R. Gilbert[1,2], J.L. Haines[3], M.A. Pericak-Vance[1,2].* 1) Hussman Institute for Human Genomics, Univ Miami Sch Med, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN.

Autism spectrum disorder (ASD) is a highly prevalent developmental disorder, affecting an estimated 1 in 88 individuals, and is associated with significant morbidity. Despite demonstrating high heritability estimates, only a small proportion of the genetic risk for ASD is explained. While previous research, including genome wide association studies, has focused on the effects of common variants, recent exome sequencing studies suggest that rare variants (RVs) contribute significantly to ASD risk. Therefore, we analyzed RV data to identify loci associated with ASD. Participants were drawn from a large, family-based study of ASD and included 995 unrelated cases and 650 controls that were genotyped using the Illumina HumanExome-12v1 Array (HIHG sample). In addition, whole exome sequencing data on 1,014 cases and 866 controls from the ARRA autism sequencing consortium was utilized for replication and joint analyses (ARRA sample). To identify individual SNPs associated with ASD, we performed Fisher's Exact Test on all SNPs with MAF<5% and Fisher's method for combining p-values to perform meta-analyses. To identify genes associated with ASD we performed gene-based analyses testing autosomal genes genotyped on the Array for association with ASD. The sequence kernel association optimal test (SKAT-O), Cochran-Armitage (CA) Sum and CA Max tests were used for these analyses. A total of 108,045 SNPs were included in single-SNP analyses and none met chip-wide significance in our HIHG analyses or meta-analyses. Of the 12,612 genes analyzed in our HIHG sample, 27 genes were associated with $p<0.001$ in at least one test. A total of 13,064 genes were included in our joint analyses and 17 were associated with $p<0.001$ in at least one test. We also identified 19 ASD candidate genes with $p<0.01$, the most significantly associated being adenylate cyclase 5 (*ADCY5*) (SKAT-O $p=0.002$, CA Sum test $p=1.84\times10^{-4}$, CA Max test $p=3.9\times10^{-4}$). *ADCY5* is an excellent ASD candidate as it plays an important role in G-protein signaling and two separate reports have identified cases with de novo mutations in this gene. While our study failed to identify RVs of large effect size (individual RVs or RVs within genes) to be significantly associated with ASD, we did identify several nominally significant associations providing suggestive evidence for a role of RVs in ASD risk.

1357F

Role of *MAPT* variation in neurodegenerative disorders. *C. Labbe[1], A. Ortolaza[1], S. Rayaprolu[1], R. Uitti[2], D. Dickson[1], Z. Wszolek[2], O. Ross[1].* 1) Department of Neuroscience, Mayo Clinic , Jacksonville, FL; 2) Department of Neurology, Mayo Clinic, Jacksonville, Florida, USA.

Tau inclusions define the neurodegenerative diseases called tauopathies. Rare variants in *MAPT*, the gene encoding protein tau, cause tau dysfunction leading to neurodegeneration. A common non-recombining *MAPT* haplotype (*MAPT* H1) has been associated to several tauopathies including progressive supranuclear palsy, corticobasal degeneration, and Pick's disease; yet *MAPT* H1 has also been implicated in the risk to Parkinson's disease (which is not a traditional tauopathy). Preliminary sub-haplotype analyses suggest that different genetic variants on the *MAPT* H1 haplotype associate with each of these disorders. To date it remains unclear which variant(s) at the *MAPT* locus is(are) responsible for the risk and what is the underlying pathomechanism of disease. The objective of this study is to identify causal variants for Parkinson's disease and progressive supranuclear palsy (and other tauopathies) within the *MAPT* region using next generation sequencing technologies. We captured the entire *MAPT* gene and 10kb on each side, a 154kb genomic region that was sequenced in 300 patients with Parkinson's disease, 300 patients with progressive supranuclear palsy, 20 patients with Pick's disease, 30 patients with corticobasal degeneration and 300 controls using a pooling strategy (10 DNA samples/pool). We used the Haloplex system and designed 4248 amplicons for a total coverage of 96.3%. We selected: (a) common variants tagging each of the *MAPT* sub-haplotypes (frequencies >5%); and (b) rare variants most likely to be functionally relevant. Common and rare genetic variants identified are being genotyped in our independent case-control series (747 progressive supranuclear palsy patients vs 727 controls; Parkinson's disease: 692 clinically diagnosed patients vs 689 controls), with linear regression analyses to study all variants with a minor allele frequency (MAF) ≥1%. A collapsed marker approach will assess joint effects of variants with MAF<1%. We will present results using the latest sequencing and genotyping technologies to comprehensively define the *MAPT* locus associated with Parkinson's disease and progressive supranuclear palsy and thus identify novel targets for both neuroprotective and symptomatic therapies.

1358W

Whole genome sequencing in adults with 22q11.2 deletion syndrome: A pilot study. *N.J. Butcher[1,2], C.R. Marshall[3], A.S. Bassett[1,2,4].* 1) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 3) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

Background: 22q11.2 deletion syndrome (22q11.2DS) is a common multisystem genetic syndrome (~1/4000) associated with a hemizygous 22q11.2 deletion. Major features of 22q11.2DS include congenital and later onset conditions such as birth defects, intellectual disability, schizophrenia and most recently, Parkinson's disease. Despite the similar deletion between patients, the reduced penetrance and variable expressivity suggest mediation of the phenotype by variants on the intact chromosome 22q11.2 region and/or elsewhere in the genome. Methods: We conducted whole genome sequencing (WGS; Complete Genomics) and high-resolution SNP microarray genotyping in a pilot study of nine individuals with 22q11.2DS (aged 22.2 to 58.9 years; 5 male, 4 female) using DNA extracted from blood. Major phenotypes included serious congenital heart defects, n=4; schizophrenia, n=6; and Parkinson's disease, n=3. We examined each case for very rare sequence and copy number variants in the coding regions of the intact 22q11.2 chromosome. Results: Eight subjects had the typical ~2.5 Mb hemizygous 22q11.2 deletion; one had a typical nested proximal 1.5 Mb deletion. After filtering for segmental duplications, the total number of very rare coding sequence variants in the 22q11.2 deleted region ranged from 2 to 10 per case. Three of the nine individuals had a single very rare coding variant predicted to be damaging by SIFT and Polyphen (genes: MED15, TRMT2A, GNB1L). Four subjects, all with schizophrenia, had a very rare coding variant in CLDN5 (n=1 stop mutation; n=3 frameshift). Notably, there were no deleterious mutations in genes previously implicated in 22q11.2DS phenotypes, including COMT, PIK4CA, and SNAP29. Only one subject, without congenital cardiac disease, had a very rare coding variant in TBX1. There were no very rare copy number variations. Conclusions: These pilot findings suggest that expression of specific major conditions associated with 22q11.2DS, including congenital cardiac disease, schizophrenia, and Parkinson's disease, may not often be related to the unmasking of deleterious variants on the intact 22q11.2 chromosome. Replication in larger samples would be needed to confirm these findings. Studies of coding and non-coding variants in the rest of the genome, together with expression studies, may help reveal the genetic underpinnings of the variable 22q11.2DS phenotype and the aetiology of its major developmental, psychiatric, and neurodegenerative features.

1359T

Complete Genome Sequence Based Family Analysis of Monozygotic Twins Discordant For Schizophrenia. *C. Castellani[1], R. O'Reilly[2], S. Singh[1].* 1) Department of Biology, The University of Western Ontario, London, Ontario, Canada; 2) Department of Psychiatry, The University of Western Ontario, London, Ontario, Canada.

The reality of individual genome sequencing now offers a new hope in the search of the cause of complex diseases. When combined with genetic relationships, individual sequences add an unrivaled proficiency. Given the near identical genetic structure of monozygotic twins, any difference between monozygotic twins discordant for a disease will have a high likelihood of being causal. With this in mind we have sequenced the DNA of two pairs of MZ twins discordant for schizophrenia and one set of parents using the Complete Genomics system. The sequences were further assessed for accuracy in relation to Affymetrix SNP Array 6.0 results on the same samples. Genome wide variations including SNPs, indels, and CNVs were assessed. Our approach has allowed us to evaluate the similarities and differences across unrelated individuals, parents and children, as well as between MZ twins and to identify variants unique to affected individuals. Variant comparisons were performed using Golden Helix SNP and Variation Suite. The results show that an individual carries approximately 3.7 million SNPs, 400,000 indels, and 150 CNVs. Also, two unrelated individuals differed for 1.5-1.8 million SNPs (45 percent), a parent and child differed for 0.9-1.0 million SNPs (30 percent) and a pair of MZ twins differed for 100,000 (3 percent) SNPs. In our family analysis, a total of 968 variants were found in the affected twin that were not found in their Mother or Father. Of these variants, 138 were also present in the unaffected co-twin. Of the 830 unique variants to the affected twin, 6 variants were found to be in coding regions. In our pair-wise analysis, 24 and 40 coding variants respectively were found in the affected patient of twin pair 1 and twin pair 2 that were not found in their co-twins. It should be noted however that a number of these differences will be the result of sequencing errors and confirmation of variants of interest will serve as the next step of this analysis. The results support our strategy and identify patient specific genetic changes that may lead to schizophrenia. The novel results re-enforce that individual genomes harbor extensive variability, some inherited and others acquired during parental meiosis and/or mitosis during ontogeny. Even monozygotic twins are not identical and each individual may be a mosaic. This is supported by a high mutation rate and the persistence of genetic diseases with a severely reduced fecundity in all human populations.

1360F

Whole genome DNA sequencing identifies variants showing allelic association with bipolar affective disorder. *A. Fiorentino[1], N. O'Brien[1], A. McQuillin[1], A. Narula[1], A. Anjorin[1], R. Kandaswamy[1], R. Blizard[1], D. Curtis[2], H. Gurling[1].* 1) Molecular Psychiatry Laboratory, UCL, Rockefeller building, London, United Kingdom; 2) Department of Psychological Medicine, Queen Mary University of London, London, UK.

A number of different loci and chromosomal regions have been reported to be implicated in bipolar disorder (BD) through GWAS. These studies have succeeded in identifying specific regions which could be implicated in disease aetiology. It is therefore probable that rare aetiological variants exist in these regions. Variants increasing genetic susceptibility to bipolar disorder may be found in non-protein coding control regions of genes as well as in exons. We have sought to detect these variants using whole genome sequencing data from 99 BD subjects. Two of the best implicated BD susceptibility genes are CACNA1C (L-type voltage gated calcium channel alpha-subunit) and ANK3 (ankyrin 3). The region of CACNA1C that shows the strongest linkage disequilibrium signal from markers showing allelic association with BD is entirely within intron 3. For ANK3 there are two regions that show the strongest evidence for association and these are in intron 2 and intron 26 (isoform NM_001204403). We have selected variants in coding and noncoding cDNA regions, splicing regions, promoter regions and in potentially functional regions of CACNA1C intron 3. Variants with markedly different allele frequencies in the bipolar samples compared to European samples from the 1000 Genome Project were then genotyped in 1,510 bipolar subjects and 1,095 controls. We identified an A to G base pair change in ANK3 (rs139972937) at position 8266 resulting in a missense amino acid change from an asparagine to a serine at protein position 2643. The G allele encoding for serine was associated with BD at p=0.042. A base pair change (rs79398153) in the 3rd intron of CACNA1C likely to affect an ENCODE-defined control region also showed allelic association with BD (p=0.015). SNPs at the ANK3 and CACNA1C loci previously associated with BD in previous GWAS were not found to be in linkage disequilibrium with the two new possible aetiological base pair changes that we have found.

1361W

Whole genome sequencing for bipolar disorder. *A.E. Locke[1], M. Flickinger[1], T. DeAngelis[6], D. Absher[6], S. Vrieze[1], S. Ramdas[1,2], B. Li[2], J. Li[2], M. Burmeister[2,3,4], L. Legrand[10], M. Rivera[8], J.L. Sobell[9], W.G. Iacono[10], M. McGue[10], C.N. Pato[9], M.T. Pato[9], J.A. Knowles[9], G. Breen[8], J.B. Vincent[7], M. McInnis[3,5], G. Abecasis[1], H.M. Kang[1], L.J. Scott[1], S. Levy[6], R.M. Myers[6], M. Boehnke[1] on behalf of the Bipolar Research in Deep Genome and Epigenome Sequencing (BRIDGES) Study.* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Psychiatry, University of Michigan, Ann Arbor, MI; 4) Molecular and Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI; 5) University of MIchigan Depression Center, Ann Arbor, MI; 6) HudsonAlpha Institute for Biotechnology, Hunstville, AL; 7) Center for Addiction and Mental Health, Department of Psychiatry, University of Toronto, ON, Canada; 8) Medical Research Council Social, Genetic and Developmental Psychiatry Centre, Institute for Psychiatry, Kings College London, London, UK; 9) Department of Psychiatry and Behavioral Sciences, University of Southern California, Los Angeles, CA; 10) Department of Psychology, University of Minnesota, Minneapolis, MN.

Bipolar disorder is a psychiatric condition characterized by alternating periods of mania and depression that affects >1% of individuals worldwide. Despite estimated heritability between 45 and 70% and sibling recurrence risk estimates between five and ten, relatively little is understood about the genetics of this debilitating disease. Here we present results from whole genome sequencing at a mean depth of ~10x for 1,583 unrelated individuals (788 clinically diagnosed bipolar I cases and 795 controls with no diagnosed mental illness) of northern European descent, an initial data freeze for a larger study aiming to sequence 4,000 individuals. Using the gotCloud sequence analysis pipeline, we identify >32.3M SNP variants, including 14.3M singletons (44.4% of SNPs) after quality control filtering. 53% of these SNPs and 86% of the singletons are not catalogued in dbSNP build 135. Comparison to existing GWAS array data yielded overall genotype concordance of >99.9%. LD-aware genotype refinement significantly improved heterozygote concordance from 95% to 99.7%. In addition to SNP variants, we are currently calling indels and larger structural variants to generate an integrated map of genetic variation for use in testing association with bipolar disorder. In preliminary case/control association tests no single variant reached genome-wide significance. Low frequency variants upstream of *SLC24A2*, a calcium/potassium/sodium transporter expressed in the brain, had the strongest association signal ($P=7\times10^{-7}$). We replicate the same direction of effect for all five previously published bipolar disorder risk variants (rs12576775 at *ODZ*, rs4765913 at *CACNA1C*, rs9371601 at *SYNE1*, rs10994397 at *ANK3*, and rs736408 at *NEK4*), three at nominal significance ($P\leq0.05$). We will perform aggregate tests using SKAT and variable threshold tests to combine low frequency and rare variants across protein coding genes or annotated non-coding regions, with a particular focus on gene regulatory regions in brain tissues.

1362T

Identifying Functional Variation in Schizophrenia GWAS Loci by Pooled Sequencing. *E.K. Loken[1], S. Bacanu[1], D. Walsh[2], F.A. O'Neill[3], K.S. Kendler[1], B.P. Riley[1].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, VA; 2) Health Research Board, Dublin, Ireland; 3) Department of Psychiatry, Queens University, Belfast, United Kingdom.

Mounting evidence supports excess rare variants in cases in GWAS-identified loci. Rare functional variants in these regions are independent of the common variant signal and provide independent support for the gene as part of the disease pathway. Pooled sequencing allows efficient target capture and library construction of this large sample. A large study of this type has not yet been pursued for the GWAS loci in schizophrenia. We use this method to interrogate 500 kb of schizophrenia GWAS loci exons from the first Psychiatric GWAS Consortium (PGC) schizophrenia analysis and additional evolutionarily constrained regions in our sample of 912 cases from the Irish Case/Control Study of Schizophrenia (ICCSS) sample and 1296 Irish population controls from the Trinity Biobank in Dublin. We sequenced 38 case pools and 54 control pools (total N=912 cases and 1296 controls, 24 per pool). Samples were quantified and normalized twice using PicoGreen followed by equimolar pooling. Pools were prepared for sequencing using the Agilent SureSelect targeted sequencing protocol and sequenced on the Illumina HiSeq platform using 2×100 bp reads. We selected exons and regions with significant mammalian conservation in linkage disequilibrium with the significant SNPs in the PGC analysis. We used Syzygy to call allele frequencies (AFs) from the sample pools. Variants will be validated using Sequenom iPLEX Gold. We compared called variant AFs with imputed AFs for the pool. We considered a correlation above 0.99 to be good evidence for successful equimolar pooling. We use the SNP-set Kernel Association Test (SKAT) to test all functional variants in a gene with MAF < 2%;. We also individually test variants >2%; MAF which are rated by PolyPhen as likely to be damaging. Preliminary sequencing at ~50x coverage per sample per pool for eight pools shows a high correlation (>0.99) between called AFs and 1774 known AFs from imputed genotype array data. We observe low false positive (2%) and false negative rates (<1%). These values should improve in the final ~100x coverage sequencing run. Our goal is to detect and validate causal rare variation in the PGC defined schizophrenia GWAS loci (MIR137, PCGEM1, TRIM26, CSMD1, MMP16, CNNM2, NT5C2, STT3A, CCDC68, TCF4, ITIH3/4, ANK3, and CACNA1C) and establish patterns of biased rare variation between cases and controls in GWAS loci using the region based test SKAT.

Exome sequencing identifies novel rare variants in human T-cell leukemia virus type-1-associated myelopathy/tropical spastic paraparesis. *S. Nozuma[1], E. Matsuura[1], Y. Higuchi[1], J. Yuan[1], Y. Sakiyama[1], A. Hashiguchi[1], Y. Okamoto[1], A. Yoshimura[1], T. Matsuzaki[2], J. Mitsui[3], H. Ishiura[3], Y. Takahashi[3], J. Yoshimura[4], K. Doi[4], R. Kubota[2], S. Morishita[4], S. Tsuji[3], S. Izumo[2], H. Takashima[1].* 1) Neurology and Geriatrics, Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan; 2) Molecular Pathology, Center for Chronic Viral Diseases, Kagoshima University, Kagoshima, Japan; 3) Neurology, The University of Tokyo Graduate School of Medicine, Tokyo, Japan; 4) Computational Biology, Graduate School of Frontier Sciences, the University of Tokyo, Tokyo, Japan.

The majority of human T-cell leukemia virus type-1 (HTLV-1)-infected individuals remain lifelong asymptomatic carriers, but some infected individuals develop HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP). HAM/TSP is a chronic inflammatory disease of the central nervous system that presents as slowly progressive spastic paraparesis with neurogenic bladder. Previous studies revealed that several host genetic factors were associated with the development of HAM/TSP. To identify the genetic factors contributing to HAM/TSP, we analyzed familial HAM/TSP. We performed whole-exome sequencing in 32 patients with familial HAM/TSP, 20 patients with sporadic HAM/TSP, and 20 HTLV-1 carriers. Rare variants with minor allele frequencies of less than 5% in 1000 genomes were considered for analysis. To predict loss-of-function genes, we determined whether missense mutations predicted by PolyPhen2 were damaged or frameshift indels. A total of 28,052 SNPs and 2097 indels were identified among patients with familial HAM/TSP. Rare variants identified in patients with familial HAM/TSP but not in HTLV-1 carriers were analyzed. The maximum number of patients with familial HAM/TSP who commonly shared the variants was 11. The affected rare variants shared by a minimum of 5 patients were investigated, and refining the variants to those associated with a predicted loss of function resulted in the selection of 23 genes. Among these, 5 genes were functionally related to the immune system, 2 genes were related to cell communications, and 1 gene was related to the nervous system. Some variants were detected in patients with sporadic HAM/TSP. These results demonstrate that rare variants are related to the development of HAM/TSP. Exome sequencing is a useful method to identify rare variants in common diseases.

1364W

Discovery and Analysis of Rare Variants for Bipolar Disorder by Exome Sequencing in Multiplex Families. *S. Ramdas[1], A.B. Ozel[2], J. Li[2].*
1) Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Bipolar disorder (BPD) is a severe psychiatric disease marked by alternating manic and depressive episodes. Twin and family studies have shown that BPD is highly heritable; but extensive genetic and phenotypic complexity remains a major barrier to identifying its genetic basis. In this study we focus on multi-generation multiplex BPD families in the NIMH repository. We hypothesize that these families manifest a nearly Mendelian or at least highly penetrant subset of bipolar cases and may transmit one or more high-impact coding variants that alter the function of key neurodevelopmental or neural signaling genes. We genotyped and performed exome sequencing for 82 affected individuals in 29 families representing first cousin pairs or more distant relatives, aiming to detect functionally damaging rare variants in regions shared by affected relatives. Comparison of exome sequencing and HumanExome Beadchip genotype data revealed high levels of concordance: on variant sites that were both genotyped and had a called genotype in the exome data, overall concordance is 0.98 and heterozygote concordance is 0.91. Variant filtering were applied to identify those that are bi-allelic, have a minor allele frequency of <5% in European samples from the Exome Sequencing Project, and are damaging missense, nonsense, or splicing site variants, resulting in a median of 336 variants per family. As Exome chip genotype data allow inference of genomic segments shared among family members identically by descent (IBD), we used Beagle to identify IBD regions shared by BPD cases within each family. This led to a further reduction in the number of candidate variants. In one family, only one gene, FOXD4 (Forkhead box protein D4), was identified after filtering. This gene has previously been implicated in suicidality and Obsessive Compulsive Disorder (OCD). Members in another family carry damaging variants in DRD5 (Dopamine receptor D5) and GRIK3 (Glutamate receptor, ionotropic kainate 3), which were reported in association studies of ADHD and schizophrenia respectively. Additional filtering and validation are underway for the candidate variants across all families. (This study is supported by the IMHRO - Johnson & Johnson Rising Star Translational Research Award.).

We present results for low pass sequencing from the CONVERGE project, a case-control study of major depressive disorder (MDD) using 12,000 Han Chinese women. To date, no genetic loci have been robustly associated with MDD using genome-wide association based on genotypes called from arrays. Low pass sequencing allows novel approaches to genotyping, particularly in accessing low frequency variants. We applied gene enrichment tests on functional SNPs with different levels of filtering and allele frequency cut-offs to test whether cases were enriched with disease causal SNPs than controls in any genes, and if so, where they are on the allele frequency spectrum. The filtering includes base quality, mapping quality, exclusion of non-pair end reads and alternative allele supported by at least two reads. The gene enrichment analysis has given us candidate genes, which can now be verified by targeted re-sequencing. Furthermore we report higher copy number of the mitochondrial genome in cases with MDD. This is the largest GWAS using whole genome low coverage sequencing data. Although we face the challenge of calling and imputing low frequency variants accurately, my pipeline allows different levels of filtering at an individual level, which enables us to examine rare variants aggregately down to a singleton level. The results help to answer an important question about whether rare functional variants are responsible for the genetic susceptibility to MDD.

Exome sequencing identifies de novo missense mutation in *KCND2* in identical twins with autism and seizures that results in slow potassium channel inactivation. *S. Nelson[1,2], H. Lee[2], M. Lin[3], H. Kornblum[4], D. Papazian[3].*
1) Dept Human Genetics, UCLA Medical Ctr, Los Angeles, CA; 2) Dept Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 3) Dept Physiology, UCLA, Los Angeles, CA; 4) Dept Pediatrics, Los Angeles, CA.

There have been numerous studies and case reports showing co-existence of autism and epilepsy suggesting significant overlap between the two phenotypes. However, the relationship between the two on the molecular level remains unclear. Here, we performed whole exome sequencing on a family with identical twins affected with autism and severe, intractable seizures. A de novo variant p.Val404Met was identified in *KCND2* gene that encodes A-type potassium channel Kv4.2 which forms the pore of the somatodendritic subthreshold A-type potassium current (I_{SA}) channels. The p.Val404Met variant is a novel variant and occurs at a highly conserved residue within the C-terminal end of the transmembrane helix S6 region that makes up the ion permeation pathway. In available exome data, the transmembrane domains in Kv4.2 protein have a low frequency of predicted-to-be damaging variants relative to the cytoplasmic domains indicating strong selection against variation in the pore domains. To investigate the functional effect of the heterozygous p.Val404Met mutation on the properties of Kv4.2 channels, reference and mutant proteins were expressed together and individually in Xenopus oocytes and analyzed using a two electrode voltage clamp. The mutant channel demonstrated significantly reduced rate of both the opening and inactivation of the channel. Co-expression of the reference with the mutant channels was mostly indistinguishable from the mutant channel alone demonstrating the autosomal dominant gain of function mutational effect. The effect of the mutation on closed-state inactivation was evident in the presence of the auxiliary subunits that associate with Kv4 subunits to form I_{SA} channels in vivo. Our results taken together with previous reports strongly suggest that the size of the residue at position 404 is a major factor in determining the likelihood of inactivation and given the key role of closed-state inactivation in determining the steady state availability of I_{SA} channels in neurons, the dominant phenotype of p.Val404Met is likely to disrupt the normal physiological functions of I_{SA}. Discovery of a predicted to be damaging, novel de novo variant in *KCND2* at a conserved residue, coupled with physiological evidence of the mutant protein disrupting the potassium current inactivation impose a strong indication that *KCND2* is the causal gene for the epilepsy in this family, and provides suggestive evidence of a role in the autistic features that they exhibit.

1367W

Amish revisited: A next-generation sequencing study of bipolar disorder among the Plain people. *L. Hou[1], N. Akula[1], L. Kassem[1], D. Chen[1], Y. Yao[2], J.L. Haines[3], M. Pericak-Vance[4], T.G. Schulze[1,5], F.J. McMahon[1].* 1) Human Genetics Branch, National Institute of Mental Health Intramural Research Program, Bethesda, MD USA; 2) Unit of Statistical Genomics, National Institute of Mental Health Intramural Research Program, Bethesda, MD, USA; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN USA; 4) Hussman Institute for Human Genomics, University of Miami, Miami, FL USA; 5) University of Goettingen, Goettingen, Germany.

Bipolar disorder (BP) is a common, highly heritable mental illness. A number of risk loci have been identified by GWAS, but the large proportion of unexplained genetic variance suggests that rare variants might contribute to risk of the disorder. Isolated populations with large families, like the Amish, have many advantages for discovering rare genetic susceptibility loci, such as lower allelic and locus heterogeneity, higher environmental and phenotypic homogeneity, and enrichment of rare disease alleles. We are ascertaining distantly related cases of BD and their relatives from Plain (Amish and Mennonite) communities in the US. So far we have 170 study participants, 94 of whom have been assigned a diagnosis of BD with high confidence. Identity-by-descent (IBD) analysis of SNP array (Illumina OmniExpress) genotypes (by use of Beagle v 3.3.2) demonstrates sharing of many long (>5 cM) chromosomal segments, consistent with known pedigree relationships, state of residence, and Amish vs. Mennonite affiliation. To identify IBD segments that were shared more often by case-case pairs than others, we combined the OmniExpress data with SNP array (Affymetrix 6.0) data from 893 Midwestern Amish individuals (collected by JLH & MPV), extracted 154,271 overlapping markers, excluded closely related pairs (pi-hat >0.1), and carried out a shared segment analysis with PLINK (v 1.07). Several highly shared IBD segments were identified on chromosomes 1p34.3, 2q31.1, 7p22, 7q36.3, 9p24.2-p24.1, and 10q22.1 at permutation p-values ranging from 0.01 to 2E-05. Interestingly, SNPs in several of these segments have been reported to be associated with bipolar disorder by previous GWAS. Exome sequencing has so far been carried out on 21 distantly related cases using the Illumina HiSeq system. The BWA/GATK package was applied for single nucleotide and insertion-deletion variant calling, with filtering of common SNVs (MAF > 5% in the Exome Sequencing or 1000 Genomes Project). Five novel, nonfunctional SNVs and 9 potentially functional SNVs, including 8 non-synonymous and 1 frame-shift insertion, were found within the highly shared regions and were each detected in at least 4 cases. While additional shared segment analysis and sequencing in larger samples is needed, these preliminary results suggest that rare variants may contribute to BD in Plain populations.

Genetic etiologies of speech sound disorders. *B. Peter[1], E.M. Wijsman[2,3], M. Matsushita[2], K. Oda[2], K. Chapman[4], U.W. Center Mendelian Genomics[5], I. Stanaway[6], W.H. Raskind[1,7].* 1) Dpt. of Speech & Hearing Sciences, University of Washington, Seattle, WA; 2) Dpt. of Medicine, University of Washington, Seattle, WA; 3) Dpt. of Biostatistics, University of Washington, Seattle, WA; 4) Dpt. of Communication Sciences & Disorders, University of Utah; 5) Dpt. of Genome Sciences, University of Washington; 6) Dpt. of Environmental and Occupational Health, Toxicoloy, University of Washington; 7) Dpt. of Psychiatry and Behavioral Sciences.

Speech sound disorders (SSDs) are disorders of the speech output mechanism, often diagnosed before the age of 4. Children with SSD fail to develop speech that is easily understood by others, due to omitted, distorted, or substituted speech sounds. SSD runs in families and there is evidence of a genetic etiology but the genetic pathways are poorly understood. One proposed SSD subtype is childhood apraxia of speech (CAS), a severe SSD subtype that is thought to result from deficits in motor programming. In some forms of syndromic CAS, the genetic etiology is known, e.g., GALT mutations in galactosemia and FOXP2 mutations in severe speech and language disorder. The genetic etiology of idiopathic CAS has not been delineated. We study multigenerational families with familial idiopathic CAS from phenotypic and genetic perspectives. Our results indicate that motor programming deficits are not limited to the speech production system but can also be observed in hand motor tasks, primarily when the task involved alternating-sequential movements, not repetitive ones. An even more comprehensive deficit in sequential processing emerged from group differences in adults with, and without, a childhood history of CAS in tasks involving sequential processing on linguistic and cognitive levels, for instance nonword reading and spelling. To investigate the genetic etiologies of CAS, we use approaches made possible by our multigenerational family design. A combination of linkage analysis, exome sequencing, and identity-by-descent studies are leading to the identification of new candidate regions and genes for CAS. In one family consisting of 23 individuals in three generations, two new candidate genes, expressed in relevant brain regions, were identified on chromosomes 3 and 5. Similar genetic analyses in other multigenerational families are underway. The long-term goal of this study is to create a catalogue of genetic etiologies in SSD to aid in early identification of infants at genetic risk for SSD and development of effective intervention and prevention approaches to avoid or ameliorate the devastating social, psychological, and educational trauma of unintelligible speech in the preschool and early school years. Sequencing was provided by the University of Washington Center for Mendelian Genomics funded by NIH grant 1U54HG006493 to Drs. D. Nickerson, J. Shendure and M. Bamshad.

Comprehensive annotation and analysis of noncoding autism spectrum disorder risk loci by targeted massively parallel sequencing. *A.J. Griswold[1], D. Van Booven[1,2], J.M. Jaworski[1], S. Slifer[1], M.A. Schmidt[1,2], W. Hulme[1], I. Konidari[1], P.L. Whitehead[1], J.A. Rantus[1], S.M. Williams[3], R. Menon[4], M.L. Cucccaro[1,2], E.R. Martin[1,2], J.L. Haines[5], J.R. Gilbert[1,2], J.P. Hussman[6], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN, USA; 4) Rollins School of Public Health, Emory University, Atlanta, GA, USA; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA; 6) Hussman Foundation, Ellicott City, MD, USA.

Genome-wide association studies (GWAS) of autism spectrum disorder (ASD) show that common variants with small effects do not greatly impact ASD risk. Exome sequencing studies, while implicating rare, *de novo* protein coding variations in a few genes, suggest that many rare variants in hundreds of genes influence ASD. A largely unstudied hypothesis is that rare, functional variants in non-protein coding regions of the genome contribute to ASD. To identify such variants, we sequenced 17Mb of ASD associated genes and genomic loci (Hussman et al, 2011) in 919 cases and 854 controls. We targeted exons, including UTRs, of 681 genes, and conserved regions in their introns, 5kb from the 5' and 3' ends, and ASD associated intergenic regions. This is the first large scale study of noncoding variants in ASD. We identified 427,676 single nucleotide variants (SNVs), of which only 20,293 were in coding exons. We annotated each noncoding SNV with databases including ENCODE (DNaseI sensitivity and transcription factor binding sites), VISTA (noncoding segments with demonstrated gene enhancer activity), and GENCODE (evidence based noncoding transcribed loci). SNVs without predicted functional effects are assessed using predictions for splice enhancing ability, RNA secondary structure effects, and transcriptional regulatory potential. Restricting our analysis to the 358,432 rare, noncoding SNVs (MAF≤0.01 in our dataset), 113,896 are predicted to have a functional role in at least one database. Of these, 11 occur at least once and uniquely in cases and had a score of 2a in the RegulomeDB, suggesting they affect a known transcription factor binding site motif. Two of these are in the potassium channel gene *KCNN3*, in AR and POU2F2 binding sites. We used the sequence kernel association test (SKAT) to detect association between ASD and sets of SNVs in noncoding elements while adjusting for population stratification. SKAT did not identify multiple testing corrected association of ASD with any noncoding feature. However, a promising nominal association was detected in enhancer hs1316 (p=0.03) that enhances expression in the midbrain of mouse embryos. To increase statistical power and identify new variants, sequencing of an additional 1525 cases and 425 controls is underway. This work adds noncoding SNVs to the growing list of ASD risk loci and may implicate biological mechanisms beyond protein coding changes contributing to ASD etiology.

1370W

Genome-wide frequencies of phase-specific functional variant combinations in a large set of families with bipolar disorder. *D.X. Quarless[1,4], K. Bhutani[2,4], V. Bansal[5], A. Torkamani[5], N. Rens[9], S.A. Ament[6], H. Li[6], M.E. Brunkow[6], R. Gelinas[6], J. Nurnberger[7], H. Edenberg[7], E. Gershon[8], G. Glusman[6], J.C. Roach[6], J.R. Kelsoe[3], N.J. Schork[4,5], The Bipolar Genome Study Consortium.* 1) Biomedical Sciences Department, University of California San Diego, La Jolla, CA; 2) Bioinformatics Graduate Program, University of California San Diego, La Jolla, CA; 3) Department of Psychiatry, University of California San Diego, La Jolla, CA; 4) The Scripps Translational Science Institute, The Scripps Research Institute, La Jolla, CA; 5) Department of Molecular and Experimental Medicines, The Scripps Research Institute, La Jolla, CA; 6) Computational Biology Genetics Genomics Immunology, Institute for Systems Biology, Seattle, WA; 7) Department of Psychiatry, Indiana University, Indianapolis, IN; 8) Department of Psychiatry, University of Chicago, Chicago, IL; 9) Johns Hopkins University, Baltimore, MD.

There is growing interest in the identification of complex combinations of inherited variants that influence phenotypic variation. These combinations can implicate any number of genomic functional elements. In addition, many potential phenotypically relevant variant pair combinations can operate either in cis or trans and thus their identification requires phase information. For example, protein coding compound heterozygous variant pair combinations acting in trans and coupled, epistatic regulatory and protein coding variant paired combinations acting in cis could not be identified if the nucleotide content of the two homologous chromosomes an individual possesses has not been differentiated. We characterized the number of phase-specific functional variant combinations in the genomes of 114 individuals within 35 different families using a suite of computational tools for both genome phasing and functional variant annotation. We find that a typical human genome has a large number of likely phase-specific functional variant pairs. We comment on the implications of our findings for sequencing and gene mapping studies focusing on rare and common conditions, as well as clinical studies seeking to identify functional variants for idiopathic diseases.

1371T

Investigation of the role of microRNAs in autism by deep RNA-sequencing. *J.A. Lamb[1], F. Marriage[1], E. Tsitsiou[2], P. Wang[2], L. Zeef[2].* 1) Centre for Integrated Genomic Medical Research, Faculty of Medical and Human Sciences, University of Manchester, Manchester, United Kingdom; 2) Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom.

Background. Numerous heterogeneous rare intragenic variations and copy number variants have been recently identified in autism, with predicted effects on protein function. Non-coding RNA has an important function in genome regulation, and there is evidence for a role of microRNAs in development and in several neuropsychiatric and neurological disorders. MicroRNAs act as pleiotrophic regulators of gene expression, targeting a large number of neuronal genes, suggesting that genetic variation in microRNAs may underlie the clinical heterogeneity of autism. **Objectives**. To identify novel genetic variation in microRNAs and differentially expressed microRNAs in individuals with autism compared to healthy controls. **Methods**. Genomewide microRNA expression profiling was carried out on lymphoblastoid cell line RNA from 60 individuals with autism and 10 healthy controls on the SOLiD 4.0 analyzer. Sequence data was processed and mapped to the human genome reference sequence (SeqTrimMap and Bowtie), and against all known human mature microRNAs (miRBase v19). Differentially expressed microRNAs were identified using DESeq and false discovery rate correction. Dysregulated microRNAs were validated by qRT-PCR. Variant calling was carried out using Samtools and filters including minimal base and map quality. **Results**. Seven differentially expressed microRNAs were identified in samples from individuals with autism compared to healthy controls (6 up-regulated, 1 down-regulated; FDR $P<0.05$). Altered expression profiles were validated by qRT-PCR. Data for hsa-miR-130b are indicative of possible arm switching in individuals with autism. Seven novel sequence variants were identified in the seed region of the mature microRNA in individuals with autism that were not present in control samples or in dbSNP (137). These may alter target mRNA binding and are therefore predicted to be functionally deleterious. Validation of these novel variants and segregation analysis within families of affected individuals is ongoing by Sanger sequencing. The putative mRNA targets of differentially expressed microRNAs and microRNAs containing novel variants are being investigated using *in silico* target prediction programmes (Ingenuity Pathway Analysis). **Conclusion**. A number of differentially expressed microRNAs and novel variants within microRNA genes have been identified in individuals with autism. These may affect target mRNA binding, suggesting a possible pathogenic role in individuals with autism.

Rouleau[2].* 1) McGill university, Montreal, Canada; 2) Montreal Neurological Institute and Hospital, Neurology and Neurosurgery departement, Mc Gill University, Montreal (Qc) Canada; 3) Equipe Génétique des Anomalies du Développement (EA 4271 GAD), Université de Bourgogne, France; 4) Laboratoire de Génétique Moléculaire, Centre Hospitalier Universitaire Dijon, France; 5) Molecular Brain Research Group, Robarts Research Institute, University of Western Ontario, London (On) Canada; 6) Department of Clinical Neurological Sciences, Schulich School of Medicine and Dentistry, University of Western Ontario, London (On) Canada; 7) Tanz Centre for Research in Neurodegenerative Diseases, and Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto (On) Canada; 8) Sunnybrook Health Sciences Centre, Toronto (ON) Canada; 9) Pathology and Cellular Biology department of Montreal University, Montreal (Qc) Canada.

Amyotrophic lateral sclerosis (ALS) is a devastating neurological disease characterized by the degeneration of upper and lower motor neurons of the motor cortex, brainstem and spinal cord. The majority of ALS cases are sporadic (sALS) and only 5-10% have a family history (fALS). SALS cases are clinically and pathologically very similar to FALS cases. Whereas 60-80% of fALS cases are explained by germinal mutations, the genetic etiology of sALS remains unclear. The lack of genetic evidence in sALS suggests that inherited or germinal de novo mutations are very rare events in this disease. Nonetheless it is important to keep in mind that current genetic evidence for sALS comes from genetic examinations made using blood DNA for the most part and to a lesser extent from available post-mortem neuronal tissues. Here, we hypothesize that somatic mutations appear early during the embryogenesis events that underlie the development of the spinal cord. These somatic events could later trigger the development of ALS in sporadic cases, as observed in patients with germline ALS-predisposing gene mutations. Given ALS is a motor neuron disease that essentially affects the corticospinal tract, we are in the process of preparing a total of one thousand sections isolated from flash frozen SALS patient spinal cords. These sections will be individually screened for the presence of mutations in the most commonly observed ALS genes. At first, we will look for repeat expansions in C9ORF72 by repeat-primed PCR (RP-PCR) since repeat mutations have been shown to be unstable during replication and DNA repair. Following this, we will look for point mutations in SOD1, TARDBP and FUS using a targeted deep sequencing method 'single molecule Molecular Inversion Probe (smMIP)' specifically designed to identify rare somatic events. The smMIP method has been shown to be highly accurate and sensitive for the detection of sub-clonal variations based on the tagging of amplified DNA molecules that originated from one of the various inputted DNA molecules from the different cells found in a tissue or sample. Preliminary results showed that our RP-PCR conditions are sensitive enough to detect expansions at a low level of mosaicism (20%). To date, we have examined 499 spinal cord sections that were derived from 13 sALS patients for the presence of expanded C9ORF72 alleles but have thus far detected no expansion.

1373W

Towards the identification of new genes implicated in recessive early-onset forms of Parkinson's disease. *S. Lesage[1], A.S. Cocquel[1], A.L. Leutenegger[2], A. Honoré[1], C. Condroyer[1], A. Dürr[1,3], A. Brice[1,3].* 1) INSERM UMR_S975, ICM, Pitié-Salpêtrière hospital, Paris, France, France; 2) INSERM UMR_S946, Fondation Jean Dausset-CEPH, Paris, France; 3) Département de Génétique et Cytogénétique, Hôpital de la Pitié-Salpêtrière, Paris, France.

BACKGROUND: Parkinson's disease (PD) is a progressive neurodegenerative disorder, probably resulting from the interplay between genetic and environmental factors. To date, more than 15 loci have been identified and 6 genes are now confirmed to be causative for monogenic forms of PD, including 4 genes (Parkin/PARK2, PINK1/PARK6, DJ-1/PARK7 and ATP13A2/PARK9) that account for only ~50% of PD cases with early-onset (EO) autosomal recessive (AR) inheritance. Hence, a significant proportion of inherited PD cases still remain unexplained genetically. AIM: We propose to use an integrative approach combining homozygosity mapping/genomic rearrangement detection and targeted exome sequencing in consanguineous PD families with an early age at disease onset (≤55 years) to identify new causative genes for recessive PD. PATIENTS AND METHODS: Homozygosity mapping was performed in a series of 160 PD consanguineous families or isolated patients originating from Europe (n=38), North Africa (n=57), Turkey (n=61) and other countries (n=4) excluded for PARK2, PINK1, DJ-1, and the common LRRK2 G2019S mutation, using SNP genotyping microarrays (Illumina Infinium HD HumanCytoSNP-12 BeadChip) and an original linkage statistics program that allows the inclusion of individuals for whom genealogical information is lacking. Using the same SNP microarrays, rare large deletions and duplications were searched for. To identify causative genes, whole exome sequencing using the Agilent SureSelect 50 Mb Human Exome target enrichment technology was performed in 60 EO PD families confirmed to be consanguineous by their Genomic inbreeding coefficient F values. RESULTS: Linkage analyses using the Genomically Controlled Homozygosity Mapping Statistic under heterogeneity (HLOD) and stratified according to geographical origin have revealed 5 linked regions (7p, 7q, 10p, 1p, 1q) across the genome with HLOD scores ≥ 2. Using the Illumina cnvPartition module, we did not detect any large rare rearrangements in the series of 160 consanguineous families. First analyses of the whole exomes of index cases have led to the identification of homozygous mutations in ATP13A2, FBX07. CONCLUSION: As a proof of concept, the strategy combining homozygosity mapping/ genomic rearrangement detection and exome sequencing using a unique series of EO PD consanguineous families has led to the identification of homozygous mutations in ATP13A2, FBX07 and probably more novel causative genes for recessive PD.

1374T

Rare variant discovery of progressive supranuclear palsy using whole-exome sequencing. *C-F. Lin[1,2], E.T. Geller[1], O. Valladares[1,2], Y-H. Hwang[2,3], L. Stutzbach[1], L. Cantwell[1], L-S. Wang[1,2], G.D. Schellenberg[1].* 1) Department of Pathology and Laboratory Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 2) Institute for Biomedical Informatics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 3) Genomics and Computational Biology Graduate Group, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

Progressive supranuclear palsy (PSP) is a rare neurodegenerative disorder that causes movement disability and cognitive decline, and hence is often misdiagnosed as Parkinson's disease or Alzheimer's disease. MAPT is a well known genetic factor for PSP with strong effect size. In 2011 a GWAS of 1114 cases and 3247 controls identified SNPs within three genes (STX6, EIF2AK3 and MOBP) with genome-wide significance. However, these common variants do not fully explain the known heritability of PSP. Whole-exome sequencing (WES) technologies provide a cost-effective approach to genotype more than 44Mb human exonic regions of the human genome and represents an exciting direction for rare variant discovery. We performed WES of 278 PSP patients using Illumina Hi-Seq 2000 (100nt pair-end) and Nimblegen SeqCap EZ Human Exome library v2 for target capture. Sequencing data were analyzed using the NIAGADS DRAW workflow, following the best practices suggested by the Broad Institute Genome Analysis Toolkit (GATK) site. All samples have at least 80% of the targeted regions at >20x and 90%; of the regions at >10x coverage. Overall we observed 165,768 exonic variants (including core splice sites), 37,731 (23%) of which were not reported in dbSNP 137; ~95,000 were not synonymous SNVs. On average each sample has 15371 (CI:15202-15541) single nuclear variations (SNVs) and small insertions/deletions. We next examined the variants in a set of 61 genes known to be related to neurodegenerative disorders. We found that a missense SNV in the GAK gene shows significant association: the minor allele is present in five out of 566 alleles (five out of the 278 PSP subjects). Four of the five heterozygotes were confirmed through Sanger sequencing. A fisher exact test with four out of 8598 alleles in the NHLBI GO Exome Sequencing Project (ESP) European American population results in a P-value of $7.7 \times 10{-}4$ (OR=15.6). We also observed an elevated number of loss of function variants in the FIG4 gene. Our initial analysis is encouraging as it suggests that rare variants in the exome may contribute to PSP risk. Our next step is to complete whole-exome sequencing of 750 PSP subjects, perform exome-wide association analysis as well as gene-wise burden tests using additional controls, and validate called rare variants using independent molecular methods such as Sanger sequencing or TaqMan PCR. We will report on the replication analyses of these preliminary findings in this presentation.

1375F

A recurrent microdeletion at 20p13 unmasks a recessive mutation in PLCB1 in a patient with severe infantile epileptic encephalopathy. *I.M. Wentzensen[1], A. Mctague[2], E. Meyer[2], C. Applegate[1], A. Ngoh[2], E. Kossoff[3,4], D. Batista[5,6], T. Wang[1,3].* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Neurosciences Unit, University College of London, Institute of Child Health, London, UK; 3) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Kennedy Krieger Institute, Baltimore, MD.

Phospholipase C beta 1 (PLCB1) is a G protein-coupled phosphodiesterase which catalyzes the formation of second messenger molecules inositol 1,4,5-trisphosphate and diacylglycerol from phosphatidylinositol 4,5-bisphosphate. PLCB1 plays an important role in several intracellular signaling pathways in the central nervous system. A recent report described a homozygous 20p13 microdeletion involving the promoter and first three exons of PLCB1 to cause infantile epilepsy in consanguineous families. We report a 10 month-old African American female with intractable epilepsy, severe global developmental delay, and regression. This infant was born at 37 weeks of gestation after a normal pregnancy and delivery. No significant dysmorphic features or congenital malformations were present on physical exam and imaging studies. Metabolic studies were unremarkable. Brain MRI showed mild cerebral volume reduction, mildly hypoplastic corpus callosum, age-appropriate myelination, and normal neuronal migration patterns. EEGs showed right temporal lobe sharp waves and spikes followed by generalization of epileptiform activities. A SNP microarray identified a heterozygous microdeletion of 476kb (8,094,442-8,580,722; GRCh37/hg19) on chromosome 20p13 involving the promoter region and first three exons of the PLCB1 gene. This deletion was inherited from her mother who has no history of seizures. Long-range PCR was performed to establish the exact breakpoints of the deletion. These are similar to the previously reported first cases of microdeletion at 20p13. Interestingly, these recurrent microdeletions are flanked by two long interspersed (LINE) elements suggesting nonallelic homologous recombination at this location. Sanger sequencing of all exons of PLCB1 identified a single base substitution (c.99+1G>A) which involves the conserved splice site of intron 1 in the proband and her unaffected father. These results support that loss-of-function mutations in PLCB1 cause a rare recessive from of early infantile epileptic encephalopathy and that flanking LINE elements may play a role in recurrent microdeletions in human disease.

A Follow-Up of Whole-Exome Sequencing in Multiplex Families. *A.H. Beecham[1], J.L. McCauley[1], A. Hadjixenofontos[1], P.L. Whitehead[1], W.F. Hulme[1], I. Konidari[1], S.L. Hauser[2], J.R. Oksenberg[2], J.M. Vance[1], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Department of Neurology, School of Medicine, University of California, San Francisco, CA, USA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Multiple sclerosis (MS) is a common neurodegenerative disease, affecting more than 1.3 million individuals worldwide. Given the number of multiplex families found in MS, it is plausible that rare variants may contribute to MS in these families. We have used next-generation sequencing to scan multiplex families for rare variants. Filtering 127 individuals (91 affected and 36 unaffected) from 26 multiplex families, assuming a dominant model with incomplete penetrance, we identified 578 high quality coding (nonsense, missense, or splice), conserved, potentially damaging, and rare (MAF $\leq$ 0.01) variants in 550 genes segregating completely in all affected of at least one family. Three of the 578 variants are in confirmed MS genes including CLEC16A, EOMES, and SLC9A8. Assuming a recessive model, we identified 68 high quality coding, conserved, potentially damaging, and rare (homozygote frequency $\leq$ 0.05) variants in 61 genes segregating completely in at least one family. Using a gene focused approach; we found 20 genes having at least two different filtered variants segregating in at least two different families. Eight of the 20 genes showed significant burden ($p < 0.05$ from Fisher's exact test) in our families when compared to 141 non-diseased controls including: PNPLA6, PLXNA4, DNAH1, PDHA2, SAMD3, COL11A2, SMAD5, and HIVEP2. Lastly, we identified 510 rare (MAF $\leq$ 0.01) and 10 moderately rare (0.01 < MAF $\leq$ 0.05) high quality coding, conserved, potentially damaging variants in known MS genes, including the Major Histocompatibility Complex (chromosome 6 from 26-36 MB) that were present in at least one MS affected individual. We submitted 1,154 unique variants from our three filtering approaches (dominant, recessive, known MS genes) for inclusion in a custom Illumina Infinium HumanExome +BeadChip designed by the International Multiple Sclerosis Genetics Consortium. In total, 1082 of our nominated variants made it onto the chip after manufacturer quality control, including all priority variants from the eight genes demonstrating significant burden. We are currently genotyping 114 affected individuals from 51 additional multiplex families to screen for these variants and other rare variation in these genes included as part of the exome chip content.

1377T

Exome Sequencing for Schizophrenia and Alcohol Dependence in an Irish Cohort Using Low-cost Library Prep and Target Capture. *D.G. Brohawn[1], T. Hendon[1], T. Bigdeli[1], E. Loken[1], D. Walsh[2], F.A O' Neill[3], S. Bacanu[1], K. Kendler[1], B.T Webb[1], B. Riley[1].* 1) Virginia Commonwealth University, Richmond, VA; 2) Health Research Board, Dublin, Ireland; 3) Queens University, Belfast, Ireland.

Common and rare alleles both influence common disorder risk. Identifying specific common alleles and elucidating their function remain difficult due to the small effect sizes. Rare functional variation in relevant genes may have more direct impact on trait risk and may elucidate the role of variation in the gene on risk. However, these variants are relatively rare and large sample sizes are required to detect these effects. Library preparation, target capture, and sequencing remain costly for the sample sizes necessary. We adapted a recently published protocol for reduced cost library preparation and target capture by at least 30%; in order to efficiently collect exome data. DNA is quantified, sheared to a mean size of 170 bp, and indexed partial Illumina adapter sequences are added and target capture using the Agilent 71 Mb exome + UTR kit is performed on equimolar pools of 6 samples. Sequencing is performed on the Illumina HiSeq 2500 platform using 2×100 bp reads. Reads are aligned, base quality scores are generated, and variants are called using STAMPY and GATK, and analyzed using the SNP-set Kernel Association Test (SKAT) for burden and gene-based association. Variants with MAF >2%; will be tested individually. We sequence both cases of alcohol dependence (AD, N=500) and schizophrenia (SCH, N=250) to 50X average depth using this approach. Sample sizes are increased by imputing sequence variants into unsequenced samples with GWAS data. Variants from cases and the UK10K controls (N=2432) will be used to produce a single reference panel for imputing variants into additional unsequenced cases and controls (AD total N=4897, SCH total N=6478). We compared the standard and adapted library preparation, target capture, and sequencing protocols. The standard protocol involved single sample exome capture, while the adapted protocol involved pooled sample exome capture. Our baseline is the standard Truseq Illumina library prep, capture and sequencing of the 71 Mb exome + UTR target sequenced to 50X average cover of unique reads yielding 10x coverage for >93% of target. The baseline protocol had comparable QC metrics to initial runs of the pooled capture protocol for unique reads (87.2% baseline vs. 86.1% pooled) and % of bases on or near bait (89.2% baseline vs 91.5% pooled). We have completed prep for 73 additional samples and we anticipate that >100 exomes will be complete and analyzed by the time of presentation.

Reduced mRNA expression and aberrant intron DNA methylation of EGR2 in female schizophrenia patients. *M. Cheng[1], Y. Chuang[1], S. Hsu[1], C. Chen[2].* 1) Department of Psychiatry, Yuli Veterans Hospital, Hualien, Taiwan; 2) Department of Psychiatry, Chang Gung Memorial Hospital at Linkou and Chang Gung University School of Medicine, Taoyuan, Taiwan.

Background: Abnormal myelination has been considered as part of the pathophysiology of schizophrenia. Early growth response 2 (EGR2) has a specific function in the regulation of hindbrain development, myelination of peripheral nervous system, and the stabilization of long-term potentiation. And it has been considered as a candidate gene for schizophrenia. Methods: We compared the EGR2 mRNA levels in lymphoblastoid cell lines between 119 schizophrenic patients and 114 controls using real-time quantitative PCR. We attempted to detect genetic variants of the EGR2 gene in 500 patients with schizophrenia and 500 non-psychotic controls from Taiwan using direct sequencing and conducted a case-control association study. We measured the EGR2 mRNA in SH-SY5Y cells treated with a DNA methyltransferase inhibitor, 5-azacytidine, for 24 hours. We also compared DNA methylation status of EGR2 gene in the lymphocytes in between 61 patients with schizophrenia and 64 control subjects using pyrosequencing. Results: Female but not male schizophrenic patients had significantly reduced EGR2 mRNA levels compared to controls (p=0.024). We identified 6 known single nucleotide polymorphisms (SNPs) in this sample. However, SNP-based analysis showed no association of these SNPs with schizophrenia. We also detected 24 rare mutations in this sample. Notably, a c.518-519insTCC variant which causes a proline insertion was found in 2 unrelated patients, but not detected in 500 controls. EGR2 expression was up-regulated in human SH-SY5Y after being treated with 5-azacytidine. One CpG site of EGR2 intron region had significantly increased DNA methylation in peripheral blood cells of female schizophrenia compared to female controls. Conclusions: Our results suggest that rare variants of the EGR2 gene might contribute to the pathogenesis of schizophrenia in some patients, but further functional assays are needed to verify their relevance to the pathogenesis of schizophrenia. The increased DNA methylation in the EGR2 gene in female schizophrenia patients may partly account for the reduced EGR2 gene expression in female patients.

1379W

Association of rare variants with anorexia nervosa by whole exome sequencing. *J. Connolly[1], D. Li[1], H. Hakonarson[1, 2].* 1) Ctr Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Anorexia nervosa (AN) is a perplexing illness characterized by low body weight and persistent fear of weight gain during period of growth, resulting in extreme emaciation. People with AN usually manifest with symptoms of depression, anxiety, and obsessive-compulsive behaviors that are common features in other neuropsychiatric disorders. Multiple bodies of evidence now suggest the role of genetic influences to AN. Family studies have consistently demonstrated that AN occurs in families and twin studies have revealed the contribution of additive genetic factors to the observed familial aggregation, but despite many studies conducted so far, the genetic architecture underlying AN susceptibility remains largely unknown. Here we have completed analysis of 10 extreme cases samples and multiple control samples with where an average coverage of 65X was established. A total of 133,955 single nucleotide variants (SNVs) and 70,678 small insertions/deletions (indels) were identified in the 10 case samples that underwent whole exome sequencing (WES), of which about 4% of the variants are novel. Two novel variants were identified in previous candidate genes that involved in the mood control and two in previous genome-wide association signals. Also, we performed association analysis using both internal and 1000 genomes data as control after combining several Caucasian populations. Due to excessive rare variants in WES results, burden test was applied. The total number of rare variants across a gene is tabulated in each individual and these totals are compared between cases and controls. The top association signals were detected in C7orf23, DMTF1, COL18A1, PCNT and ERMN. Interestingly, PCNT gene previously associated with an increased risk of developing psychiatric disorders such as schizophrenia and depression, was fourth significant (3.65E-03).

1380T

Detection of de novo mutations in schizophrenia patients and their unaffected siblings. *S. de Jong[1], N. Tran[2], E. Strengman[1], E-J. ten Dam[1], R.S. Kahn[3], R.A. Ophoff[1,3,4].* 1) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience & Human Behavior, University of California Los Angeles, Los Angeles, California, USA; 2) Informatics Center for Neurogenetics and Neurogenomics, University of California Los Angeles, Los Angeles, California, USA; 3) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Utrecht, the Netherlands; 4) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California, USA.

Schizophrenia is a common disease, affecting ~1% of the population with an estimated heritability of up tot 80%. Recent studies have shown that in addition to a polygenic model of disease, single de novo mutations may also contribute to disease susceptibility. In order to test whether there is an increased de novo mutation rate in patients compared to unaffected siblings, we applied whole exome sequencing in a family-based design. We included 19 families, consisting of proband with both parents, and at least one unaffected sibling. Whole exome capture was performed using Illumina TruSeq kits followed by paired end (100 bp reads) sequencing on the HiSeq2000 platform, resulting in ~30million readpairs per sample. Reads were aligned to hg19 using BWA. Single sample variant calling was performed with SAMtools. Concordance rates with SNP array for a subset of the data were ~98%. De novo variants were called per family using DeNovoGear and Polymutt. The unaffected sibling in each family served as an extra filtering step, excluding calls appearing in both siblings, which are likely to be false positives. DeNovoGear is a Bayesian algorithm that starts with an a priori probability of 1×10−8/bp/generation on haploid germline point mutation rate. Putative variants with a posterior probability of >0.98, mapping quality >20 and sequence read depth >30 across all family members were selected. Variants not overlapping between siblings and also called with Polymutt (~60%) were subsequently filtered for heterozygote genotypes in offspring. We completed the preliminary analyses using these criteria. Based on our results thus far the average predicted de novo variant is 7 per meiosis. The number of predicted de novo SNVs varied greatly by subject and family. Validation using Sanger sequencing needs to be performed on these predicted variants to exclude sequencing artifacts. The preliminary results suggest a slight overrepresentation of the overall de novo variants in coding regions in the affecteds. We did not, however, observe a difference in the distribution of nonsynonymous SNPs (damaging or benign) between probands and unaffected siblings. In both the unaffected and the affected group we find a double hit in the same gene. Our preliminary results indicate that although the number of de novo variants might not differ, the distribution of types of SNVs seems to be different between schizophrenia patients and their unaffected siblings.

1381F

Genome-wide profiling of DNA-protein interactions and multiple histone methylations in the cultured olfactory cells from Schizophrenia.
Z. Deng[1], M. Deng[2], O.V. Evgrafov[1], J.A. Knowles[1]. 1) Psychiatry & Behavioral Sci, Univ Southern California, Los Angeles, CA; 2) Undergraduate, Brown University, Providence, RI.

Schizophrenia (SCZ) is a strongly heritable complex disorder. The discovery of candidate biomarkers and genetic risk factors in schizophrenia has proven challenging. The great difficulty in the search of genes and biomarkers for schizophrenia can be ascribed to a combination of high disease heterogeneity, the absence of prominent and unique alteration, and the complex interplay of genetic predisposition and environmental influences. We hypothesize that epigenetic variations (DNA methylation and histone modifications), together with particular genetic variations (SNPs, insertion/deletions), play roles in the etiology of Schizophrenia. Furthermore, epigenetic modifications are responsive to environmental factors (including antipsychotic treatments) and could be a link between genetic predisposition and environmental influence on the development of schizophrenia. To reduce the complexity and limit genetic heterogeneity, we choose a subgroup of SCZ with olfactory deficits and focused on the epigenetic alteration using a genome-wide ChIP-seq of the neuronal precursor cell culture from SCZ nasal biopsy samples. We have performed seven different genome-wide epigenetic profiles (H3K4me1, H3K4me3, H3K27ac, H3K27me3, H3K9ac, CTCF and RNA pol II) in four SCZ patients and two controls. We observed more epigenetic heterogeneity among the SCZ samples, while the patterns were more consistent within the control samples. We find several abnormal epigenetic peaks (genome-wide FDR<0.01) are associated with some new schizophrenia loci identified in a mega-analysis combining genome-wide association study (GWAS) data from 17 separate studies. (Schizophrenia Psychiatric Genome-Wide Association Study Consortium, 2011). These epigenetic profiles have been subsequently analyzed together with genome-wide transcriptional profiles from the RNA-seq results of the cases and controls. We have compiled a list of candidate genes, biomarkers and chromosome regions identified in our epigenetic study and transcriptional study.

1382W

Examining De-novo mutation rates and patterns from whole-exome sequencing of sporadic cases of Schizophrenia from Taiwan.
D. Howrigan[1,2,7], B. Neale[1,2,7], J. Moran[2], K. Chambert[2], S. Rose[2], N. Laird[6], H.-G. Hwu[5], W.-J. Chen[5], C.-M. Liu[5], C.-C. Liu[5], J. Nemesh[2,7], E. Bevilacqua[2], A. Hansen[7], S.V. Faraone[3], S. Glatt[3], M. Tsuang[4], S. McCarroll[2,8]. 1) Massachusetts General Hospital, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) SUNY Upstate Medical University, Syracuse, NY; 4) University of California, San Diego, CA; 5) National Taiwan University, Taiwan; 6) Harvard School of Public Health, Boston, MA; 7) Harvard Medical School, Boston, MA; 8) Harvard University, Cambridge, MA.

Recent studies have implicated that exonic de-novo mutations play a convincing role in developmental disorders such as autism, intellectual disability, and epilepsy. For sporadic cases of schizophrenia, early reports have pointed towards promising de novo candidates; however larger numbers of sequenced trios are required to identify specific genes, as de novo events arise at a low rate in the population (roughly one per trio). Under the collaboration of multiple centers, whole-exome sequencing has been performed on 1,135 complete trios from a Taiwanese cohort, making it one the largest de novo sequencing projects to date. Exome sequencing data were generated using the Illumina HiSeq sequencing platform with the Agilent SureSelect exome capture platform, and the Illumina Miseq platform was chosen as the method for validating putative de novo calls. Preliminary results suggest that the overall rate of mutation in affected offspring falls in line with the expected mutation rate. Upon examination of high-quality putative de novo events (those with twenty or more reads in the full trio), multiple de-novo mutations have been found in thirty-nine separate genes, with multiple loss-of-function mutations found in SV2B, a synaptic vesicle glycoprotein gene primarily expressed in the brain. These findings, however, do not surpass exome-wide significance after incorporating gene size and site-specific mutation rates into expectations of de novo mutation. Further analyses examining de novo events in conserved gene sets show a 1.79-fold higher enrichment of loss-of-function events and a 1.19-fold higher enrichment of non-synonymous events. However, these levels only reach suggestive significance (p = 0.08 and 0.1, respectively). Overall, our findings do not clearly identify any single gene as an unequivocal risk factor for schizophrenia when disrupted by de novo mutation, although a number of genes and gene-set analyses show suggestive signals. We also integrate the results from these trios with the other available trio sequencing data from the community to provide the clearest evaluation to date of the role that de novo events play in the etiology of schizophrenia.

1383T

Deep re-sequencing of *TREM2* identifies novel rare variants associated with late-onset Alzheimer's disease.
S. Jin, T. Skorupa, B. Cooper, D. Carrell, J. Norton, B. Benitez, C. Cruchaga, A. Goate. Psychiatry, Washington University in St. Louis, ST. LOUIS, MO.

Recent studies have found heterozygous rare variants in *TREM2* (triggering receptor expressed on myeloid cells 2), which has been reported to be involved in inflammation in the brain, significantly affect risk for late-onset Alzheimer's disease (LOAD). Although several rare variants have been associated with LOAD risk, large scale deep re-sequencing studies have not been conducted to comprehensively identify novel rare variants in *TREM2* that affect LOAD. We performed pooled-DNA sequencing of all exons and flanking regions in *TREM2* in 2,074 LOAD cases and 1,388 cognitively normal elderly controls of European descent from the National Cell Repository for Alzheimer's disease, the Knight Alzheimer's Disease Research Center, and the Alzheimer's Disease Neuroimaging Initiative using Illumina Miseq sequencing. We used the SPLINTER algorithm to perform alignment and call variants in the pooled samples. SIFT2, SeattleSeq and Ensembl databases were used to annotate variants. We then confirmed rare variant calls in all sequenced individuals using Sequenom iPLEX or KASPar genotyping systems. Of the 122.8 million reads generated, 69.7 million (56.7%) mapped back to the reference genome with a 30-fold minimum coverage. Eight novel or potentially functional rare variants passed the filtering quality controls and were selected for direct genotyping. Six of the eight variants were validated (sensitivity=75%), four of which are novel. Five rare variants (4 missense and 1 stop-gained) were present only in cases and not in controls. Among them, four were predicted as probably-damaging by PolyPhen or SIFT2. We also observed one missense mutation present only in controls and predicted to be tolerated. When collapsed, these six rare variants in *TREM2* were associated with a significant increase in LOAD risk (OR=6.04; P=0.04) which suggests that some could be functional and have dramatic effects on LOAD risk. This study suggests deep re-sequencing is an effective and accurate approach to identify novel rare variants associated with LOAD. The identified heterozygous rare variants may cause a loss-of-function of *TREM2*, consistent with the notion that heterozygous *TREM2* mutations contribute to LOAD.

1384F

Mutations in the *CASR* gene in Idiopathic Generalized Epilepsy.
M. Kaur[1], P. Satishchandra[2], K. Radhakrishnan[3], A. Kapoor[1], A. Anand[1]. 1) Molecular Biology and Genetics Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, Karnataka, India; 2) Department of Neurology, National Institute of Mental Health and Neurosciences, Bangalore, Karnataka, India; 3) Department of Neurology, Sree Chitra Tirunal Institute for Medical Sciences and Technology, Trivandrum, India.

Idiopathic generalized epilepsy (IGE) is a common type of epilepsy with substantial genetic basis to its etiology. Genetic studies have identified 12 IGE loci, and at 6 of these, causative genes have been found. We conducted detailed sequence analysis of an IGE locus, EIG8 (MIM612899) which was identified in a family from south India with several of its members affected with epilepsy (Kapoor *et al*. *Ann Neurol* 2008). EIG8 maps at chromosome 3q13-q21. We used a combination of Sanger sequencing and next generation sequencing to analyze transcripts for 234 genes in the critical genomic region. New single nucleotide variants were found in the *NSUN3, EPHA6, ABI3BP, TRAT1, KIAA1407, IQCB1, CASR* and *ADCY5* genes. We studied segregation of the variants in the epilepsy family, examined their allele frequencies in the control individuals and conducted *in silico* pathogenicity analysis. These studies suggested role of c.2693G>A (R898Q) in *CASR* (extracellular calcium sensing receptor) in causation of epilepsy in the family. Additionally, we examined *CASR* in 480 IGE/JME patients and 252 control individuals, and detected 22 uncommon variants (m.a.f≤0.005). Of the variants identified, 7 were missense variants leading to E354A, D433H, S580N, I686V, R898Q, A988G, A988V. While *CASR* is known to play a role in maintenance of systemic calcium homeostasis, its role in neuronal cells remains unclear. *CASR* may play a role in regulating neuronal excitability in the human brain. We studied functional correlates of the missense variants identified, using a *trans*-reporting MAPK pathway assay and an IP-One ELISA-based assay in HEK293T cells, transiently transfected with the wild type and mutant receptor constructs. Three mutant receptors exhibited significantly enhanced Ca^{2+} responsiveness as compared to wild type CASR, whereas the remaining ones, showed relatively weak significant differences from the wild type protein. We propose CASR's membrane localization/trafficking or its affinity to calcium may be compromised by the variants.

1385W

Trio-based pathway analysis of bipolar disorder. *N. Matoba[1,2], M. Kataoka[1,3], K. Fujii[4], Y. Suzuki[2], S. Sugano[2], T. Kato[1].* 1) Lab. for Molecular Dynamics of Mental Disorder, RIKEN Brain Science Institute, Wako , Saitama, Japan; 2) Dept. of Medical Genome Sciences, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Chiba, Japan; 3) Dept. of Child Neuropsychiatry, Graduate School of Medicine, The University of Tokyo, Hongo, Tokyo, Japan; 4) Dept. of Psychiatry, Dokkyo Medical University, Mibu, Tochigi, Japan.

Bipolar disorder is one of the two major mental disorders and twin studies reported the heritability is around 85%(Cardno et al., 1999, McGuffin et al., 2003). Genome-Wide Association Studies (GWAS) identified a number of common SNPs that are associated with bipolar disorder, but no strong contribution has been shown. Next-Generation Sequencing (NGS) technology enables us to detect causes of rare genetic disorders. However, the way to identify causative genes of complex diseases like bipolar disorder is still under development. To identify molecular pathways related to bipolar disorder, we compared the deleterious mutations transmitted to, or untransmitted to the proband using whole exome sequencing of trio families of bipolar disorder. Fifty trio families were enrolled. Each individuals was interviewed by trained psychiatrists using a structured interview were selected. After target exome were captured from the whole-blood or saliva DNA of participants using the SureSelect Human All Exon V4(Agilent), whole-exome sequencing was carried out using Hiseq2000(Illumina). Reads were mapped to human genome build v37 with BWA and PCR duplicates were removed with Picards. Local re-alignment and variant calling was performed using GATK. All variants were annotated with ANNOVAR. 87.8% of target regions were covered with at least 20 unique reads and we only focused on these regions. The criteria for candidate variants were non-synonymous SNVs, not in dbSNP137(excluding MAF < 0.01 or reported as disease related) and predicted as 'disease causing' by SIFT and 'possibly damaging or probably damaging' by PolyPhen2. All variants observed in each family were divided into two groups, transmitted (found in a proband and one of the parents) or un-transmitted (found in a parent only) variants. In a preliminary analysis of 7 families, 42.86 variants were transmitted to proband and 49.29 variants were un-transmitted to the proband on average. Gene Ontology (GO) term GO:0012502 (induction of programmed cell death) was enriched in transmitted variants while muscle development related GO terms were enriched in un-transmitted variants. Enrichment of apoptosis related genes in transmitted mutations is compatible with the possible role of cellular valunevability in bipolar disorder. Further analysis using other 43 trio families with bipolar disorder and control trio families is ongoing.

1386T

The not-so-silent effect of silence mutations in Autism Spectrum Disorders. *O.A. Moreno-Ramos, M.C. Lattig, LICA (Liga Colombiana de Autismo).* Universidad de los Andes, Laboratorio de Genetica Humana, Bogotá, Colombia.

High locus and allelic heterogeneity found in Autism Spectrum Disorders (ASD) complicate the comprehension of the genetic bases of the disorders. Thousands of clues have emerged from initial exome sequencing studies, identifying many novel de novo mutations in ASD family trio studies. Affected proteins seem to be highly interconnected and expressed mainly in brain. Most of the variants reported to date were found mostly in Caucasian or European descendant cohorts but Latin American cohorts have not been well studied. Therefore, we decided to apply exome sequencing, at a 50X depth, in a cohort of Colombian - South American (admixed population) trios. Although most of exome sequencing studies focus on deleterious mutations such as non-synonymous, missense and frame shift mutations, there is still a big caveat: What about the not-so-silent effect of silence mutations might have? We not only focused on the discovery of harmful variants, but we also evaluated the possible effect of silent mutations, since it is known that synonymous mutations can actually be a cause of different diseases and syndromes altering mRNA stability or translation. The global outcomes guide to a larger range of mutations that are related to ASD.

1387F

The Rare *TREM2* Variant R47H Has a Modest Effect on Alzheimer's Disease Risk. *A.R. Parrado[1], K. Mullin[1], W.K. Yip[2], B. Hooli[1], T. Liu[3], C. Lange[2], L. Bertram[3], R.E. Tanzi[1].* 1) Neurology, Mass General Inst Neurodegenerative Disease, Boston, MA, USA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 3) Dept. Vertebrate Genomics, Max Planck Institute for Molecular Genetics, Berlin, Germany.

Recently, two independent research groups (Jonsson et al. 2013 and Guerreiro et al. 2013) published results reporting a rare missense variant rs75932628 (R47H) in exon 2 of the gene encoding triggering receptor expressed on myeloid cells 2 (*TREM2*) significantly increase the risk for Alzheimer's disease (AD) with an effect size comparable to that of the *APOE* ε4 allele. Subsequently, Pottier et al. (2013) and Benitez et al. (2013) published independent short communications confirming the association between the minor T-allele at rs75932628 and increased risk for AD. Here we attempt to replicate the association between rs75932628 and AD risk by directly genotyping rs75932628 in two independent Caucasian family cohorts, the National Institute of Mental Health Alzheimer Disease Genetics Initiative Family Study and the National Institute on Aging Genetics Initiative for Late Onset Alzheimer's Disease (NIA-LOAD) Family Study, consisting of 927 families (with 1777 affecteds and 1235 unaffecteds) and in the Caucasian NIA-LOAD case-control sample composed of 378 cases and 686 controls. Additionally, we imputed genotypes in three independent Caucasian case-control cohorts (GenADA, TGEN2, and ADNI), containing 1906 cases and 1503 controls. Meta-analysis of the two family-based and the four case-control cohorts yielded a P-value of 0.04 providing additional independent support for the association between the T-allele at rs75932628 and increased AD risk, albeit suggesting a much lower effect size (OR = 1.48, 95% CI 0.94-2.35). In conclusion, our results confirm the association between SNP rs75932628 and AD risk, however, the risk effect is substantially smaller than in the two original reports.

1388W

Sequencing of coding region of the CNTNAP2 in individuals with Autism Spectrum Disorders. *K.P. Pena Gonzalez, L.M. Munera Salazar, O.A. Moreno Ramos, M.C. Lattig, Liga Colombiana de Autismo.* Universidad de los Andes, Bogota, Colombia.

Autism Spectrum Disorders (ASD) are a group of developmental disorders that involve three specific developmental areas: disrupted communication, difficulties in social interaction and repetitive/stereotyped behavior. Even though its etiology is still unknown, evidence suggests a strong genetic component evidenced by twin studies that demonstrate approximately 80% concordance. However, only about 10-20% of non-syndromic ASD cases have been explained by deleterious mutations, but each genetic effect explains only up to 1% of the ASD cases. Contactin Associated Protein-Like 2 (CNTNAP2) [MIM: 604569], encodes a protein from the Neurexin family with various roles in the Central Nervous System. The aim of this study was to search for deleterious variations (no-synonymous, low frequency, rare or private) in the CNTNAP2 gene in ten individuals with ASD by sequencing the coding region of this gen using Sanger technique. We found 25 variations in the CNTNAP2 gene, but we focused on a particular haplotype (rs61232377, rs77025884, and rs9648691) that was found in 4 individuals containing the intron 22/exon 23 region. According to bioinformatics analysis this haplotype suggests a formation of a splicing branch site on exon 23. This could be possibly involved in the formation of new isoforms of the gene, and therefore might be related to ASD.

Parkinson's disease (PD) is the second most common neurodegenerative disorder after Alzheimer's disease, with a prevalence of >1% over age 65. The etiologic landscape of PD is complex. Rare, highly-penetrant mutations in different genes and common risk factors of small size-effects in several loci have been identified in patients with PD. However, additional disease determinants remain to be identified in most patients. Genetically isolated populations offer advantages for dissecting the genetic architecture of complex disorders. Here we report the results of our genetic study on the etiology of PD in Sardinia. We performed exome sequencing in 100 unrelated Sardinian PD patients, using the Agilent SureSelect 50Mb kit and Illumina HiSeq2000 sequencing, at an average coverage of ~30X. We first removed all synonymous, intronic, and intergenic variants. From the remaining variants, we selected the novel SNPs shared by at least five unrelated PD patients, and absent in dbSNP129 and 1000Genomes databases. This approach yielded a total of 4,587 SNPs, that were then genotyped in 500 independent Sardinian individuals (242 PD and 258 controls) using a NimbleGen SeqCap EZ custom platform. Association of each variant with disease status was then tested using Fisher's exact test implemented in PLINK/SEQ. Out of 186 variants with p-value <0.5 and odd-ratio >3, thirty-two were confirmed by Sanger sequencing. These 32 SNPs were then genotyped by TaqMan assays in an independent sample of 2,731 PD patients and 2,673 age- and ethnic-matched controls from Italy, Spain and Portugal. No variants surpassed the required level of significance according to Bonferroni correction for 4,587 tests (p value $< 1.09 \times 10^{-5}$). The lowest p value was 1,16 $\times 10^{-3}$ for a variant with final OR 2,9. However, a catalogue of interesting coding variants present only in PD patients was identified, that might point to novel genetic determinants of PD with moderate/strong effect size, and represents an important resource for replication in follow-up studies. Our study suggests that, with regard to the inspected exome target region, the genetic bases of PD are highly heterogeneous.

Genetic epidemiological study on migraine and episodic ataxia in the Japanese population. *Y. Takahashi, H. Ishiura, J. Goto, S. Tsuji.* Dept Neurology, Grad Sch Med, Univ Tokyo, Tokyo, Japan.

[Background] Migraine is an episodic disorder characterized by severe throbbing headache attacks, which is classified as migraine with aura (MA) and without aura (MO). Genetic background of migraine has been largely unknown, except for familial hemiplegic migraine (FHM). Causative genes for FHM include *CACNA1A*, which is also causative for episodic ataxia (EA) type 2, *ATP1A2* and *SCN1A*. Recently, mutations in *PRRT2*, initially identified as a causative gene for paroxysmal kinesigenic dyskinesia, have been reported in FHM patients. [Purpose] To investigate the genetic epidemiology of migraine and episodic ataxia in the Japanese population. [Subjects and Methods] DNA samples from 11 FHM, 2 sporadic hemiplegic migraine (SHM), 9 MA, 13 MO and 7 EA patients and 260 healthy individuals were included in this study. Mutational analysis for *CACNA1A* and *ATP1A2* were conducted employing a custom-designed resequencing microarray TKYMGN01. Those samples in which mutations in these genes were excluded were further subjected to mutational analysis of *SCN1A* and *PRRT2* employing a direct nucleotide sequence analysis. Novel nonsynonymous variants identified were further screened in 260 controls. [Results] Three of 11 FHM patients (27.3%) harbored causative mutations, including a previously reported mutation p.T666M in *CACNA1A* in 2 patients and a novel mutation p.H916L in *ATP1A2* in a patient. In addition, a known causative mutation c. 649dupC in *PRRT2* was identified in a SHM patient. No mutations were found in patients with MA, MO or EA. Common clinical features of FHM patients with the mutations included relatively long-duration of attacks, disturbance of consciousness, fever, and cerebral edema during hemiplegic attacks. [Discussion and Conclusion] This study indicated that a substantial number of patients with hemiplegic migraine in the Japanese population were accounted for by mutations in known causative genes including *CACNA1A*, *ATP1A2* and *PRRT2*. In addition, this study have raised the possibility that p.T666M in *CACNA1A* might be a relatively frequent mutation in FHM in the Japanese population, as supported by the finding that the two of three previous reports with mutations in *CACNA1A* in the Japanese population represented the p.T666M mutation. Genetic epidemiology of MA, MO or EA, in contrast, have not been accounted for by these known causative genes for FHM, warranting further investigation for genes associated with these common types of migraine.

Whole transcriptome analysis by next generation sequencing in autism spectrum disorders. *C. Zusi[1], P. Prandini[1], G. Malerba[1], L. Xumerle[1], R. Galavotti[1], A. Pasquali[1], C. Patuzzo[1], V. Mijatovic[1], R. Ciccone[2], M. Fichera[3], MC. Bonaglia[4], E. Trabetti[1], PF. Pignatti[1].* 1) University of Verona, Verona, Verona, Italy; 2) University of Pavia, Pavia, Italy; 3) Scientific Institute Oasi Maria Santissima, Troina, Italy; 4) Scientific Institute E. Medea, Bosisio Parini, Italy.

Autism Spectrum Disorders (ASDs) represent a group of childhood neurodevelopmental and neuropsychiatric disorders characterized by deficits in verbal communication, impairment of social interaction, and restricted and repetitive patterns of interests and behaviours. Evidences indicate that ASDs have strong genetic bases. This study is part of a Telethon project involving several Italian research groups; it aims to analyze differences of gene expression level between 27 ASD subjects and 23 control individuals. Nineteen (19) of the 27 ASD subjects are characterized for CNVs potentially involved in the onset of autism and 8 subjects have a deletion in the 22q13.3qter region. EBV transformed lymphoblastoid cell lines have been established for all subjects and transcriptomes have been analyzed through Next Generation Sequencing technology (RNA Sequencing). Differential expression analysis, performed on the whole cohort and the subgroup with the 22qter deletion, identified 295 and 448 differentially expressed genes respectively, at the nominal p-value <0.05. Gene set enrichment analysis (GSEA) revealed that autoimmune disorders and antigen processing and presentation terms are the most enriched ones. Subgroup's GSEA highlights the involvement of axon guidance term, confirming that LCLs could exhibit biomarkers relevant to autism. Further analysis was carried out to identify genes strongly dysregulated in ASD subjects, finding a total of 68 genes. Three dysregulated genes, that cluster within a CNV on chromosome 16p13.1, were identified in one subject. The remaining 65 dysregulated genes did not map on any considered CNV. Additional analysis on differentially expressed genes will help understanding the genetic bases of ASD pathophysiology and unravelling potential new pathways involved in the disease.

1392T

Investigating the association between OPA1-AS1 gene variants and autosomal dominant optic atrophy. *I. Nakata, K. Linkroum, W. Abdrabou, M. Janessian, E. Gaier, D.M. Cestari, S. Lessell, J. Rizzo, J.L. Wiggs.* The Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Boston, MA.

Purpose: Autosomal-dominant optic atrophy (DOA) is one of the most common inherited optic neuropathies causing progressive bilateral degeneration of the optic nerve and ultimately irreversible blindness. Mutations in *OPA1*, encoding a dynamin-like mitochondrial GTPase indispensable for mitochondrial network structure and morphology, are identified to be responsible for DOA in approximately 50% of cases. Genetic abnormalities responsible for the remaining 50% of cases are not yet known. *OPA1* antisense RNA 1 (*OPA1-AS1*) is a long non-coding mRNA located between intron 5 and 7 of the *OPA1* gene that may function to regulate the expression of *OPA1*. To investigate the association between *OPA1-AS1* variants and DOA, we performed a sequencing-based association study. Methods: The study was approved by the Massachusetts Eye and Ear Infirmary Institutional Review Board and adheres to the tenets set forth in the Declaration of Helsinki. Fifty-nine DOA patients from 53 independent families were sequenced in this study. Disease causing *OPA1* mutations were previously detected in 17 of these 59 patients. Genomic DNA was sequenced using primers designed to amplify all 3 *OPA1-AS1* exons. PCR products were sequenced according to standard protocols. Genotypes of known SNPs in the general population were retrieved from the HapMap CEU data sets (n = 174). Results: Four *OPA1-AS1* SNPs were observed in cases: rs9291059, rs34307082, rs3772393, and rs9832709. Of the 59 DOA patients, 2 patients were heterozygous for rs9291059 [minor allele frequency (MAF) = 0.018] and one patient was heterozygous for rs34307082 (MAF = 0.008). Significant linkage disequilibrium was observed between common SNPs rs3772393 and rs9832709 (D' = 1.0 and r^2 = 1.0). We found that the MAF of *OPA1-AS1* rs3772393 was significantly higher in the DOA cases than that in general population controls (0.53 versus 0.42, P = 0.0400, odds ratio = 1.77, 95% confidential interval = 0.84-3.76). Of the 16 patients homozygous for the rare variant of rs3772393, 7 (43.8%) have a disease-causing *OPA1* mutation, although none of these were located in the *OPA1-AS1* exons and are not in linkage disequilibrium with rs3772393. Novel variants in *OPA1-AS1* were not identified by sequencing. Conclusions: These data suggest that *OPA1-AS1* variants may associate with developing DOA and that additional study of the potential role of *OPA1-AS1* in DOA is warranted.

1393F

Exome Sequencing on Samples with Bipolar Disorder: A Preliminary Survey. *T. Zhang[1], F.J. McMahon[2], D.T. Chen[2], J.C. Wang[1], J.P. Rice[1].* 1) Dept. of Psychiatry, Washington University in St. Louis, St. Louis, MO; 2) Genetic Basis of Mood and Anxiety Disorders Unit, National Institute of Mental Health, Rockville, MD.

Bipolar disorder is a psychiatric diagnosis for a mood disorder with lifetime prevalence of about 1%. Previous genetic studies have linked many chromosomal regions and candidate genes appearing to influence the risk of bipolar disorder. In this research, we aim to identify the potential causal variants for bipolar disorder via performing exome sequencing on 6 related case samples from a four-generation family. The sequencing data were released for 195,949 variants, and 20,094 variants (10.25%) were shared among all these six related cases. Genotype data annotation was performed by Annovar and by implementing several standard filtering criteria we have reduced the number of targeted variants to 9,657 variants. To narrow the susceptible regions, we have genotyped 733,202 common SNPs for all these six cases and performed linkage analysis. A preliminary low-density linkage analysis has identified three suggestive peak region in chromosomes 4, 8 and 10 (with LOD score greater than 2.0). We are now performing high-density/ haplotype-based linkage analysis to further narrow down the candidate regions and identify the potential susceptible variants for bipolar disorder in this family.

1394W

Exploration of brain-specific somatic mutations with massively parallel sequencing data derived from human postmortem brain. *M. Nishioka[1,2], M. Bundo[1], J. Ueda[3], S. Murayama[4], K. Kasai[2], T. Kato[3], K. Iwamoto[1].* 1) Department of Molecular Psychiatry, The University of Tokyo, Tokyo, Japan; 2) Department of Neuropsychiatry, The University of Tokyo, Tokyo, Japan; 3) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Saitama, Japan; 4) Department of Neuropathology, Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan.

Accumulating evidence has challenged the conventional assumption that somatic cells in one individual, except for rare cases, have the identical genome. Several groups have reported somatic single nucleotide variations (SNVs) and structural variations (SVs) in normal cells other than oncogenic cells in humans and model animals. Especially, brain cells are supposed to go through characteristic genomic alterations such as retrotransposition and chromosomal aneuploidy during development. We hypothesized that such somatic genomic alterations in brain cells contribute to biological diversity in cognitive and mental traits, and that some somatic mutations are involved in the pathophysiology of neuropsychiatric disorders. We explored brain-specific somatic SNVs and SVs with exome sequencing data derived from human postmortem brain and liver with no neuropsychiatric disorders as a preliminary study. The samples are fresh-frozen postmortem frontal cortex and liver derived from 75-year-old Japanese male. We obtained neuronal genomic DNA by anti-NeuN antibody-based FACS technique. The exome sequencing of neuronal and liver genomic DNA was performed with Illumina GAIIx. The total reads were approximately 100 million reads per each sample, with more than ×100 coverage. We analyzed somatic mutation events using the generated read data with SNV/SV detection software such as RetroSeq, Delly, and SVDetect. We found that sequencing data derived from neuronal nuclei indicated much higher rate of retrotransposition and LTR-related genomic alterations. Although such genomic alterations might be results of sequencing or informatics error, some would be results of somatic mutations occupying very low fraction of sample tissues. We discuss the physiological and pathophysiological meanings of brain-specific somatic mutations and the validity of detection methods, mainly focusing on the results of transposable elements.

1395T

Identification of New Genes and Pathways for Rare Infantile Forms of Spinal Muscular Atrophy and Arthrogryposis. *L. Baumbach-Reardon[1], J.M. Hunter[1], M.E. Ahearn[1], J. Kiefer[2], C. Balak[1], G. Lambert[1], J. Getz[1], D. Duggan[1], B. Wirth[6], W. Tembe[3], C. Legendre[3], W. Liang[5], A. Kurdoglu[4], J. Corneveaux[4], M. Huentelman[4], D. Craig[4], J. Carpten[1], J. Hall[7].* 1) Cancer Genomics, Translational Genomics Res Inst, Phoenix, AZ; 2) Knowledge Mining, Translational Genomics Res Inst, Phoenix, AZ; 3) Center for Bioinformatics, Translational Genomics Res Inst, Phoenix, AZ; 4) Neurogenomics, Translational Genomics Res Inst, Phoenix, AZ; 5) Collaborative Sequencing Center, Translational Genomics Res Inst, Phoenix, AZ; 6) Institute of Human Genetics, University Hospital of Cologne, Germany; 7) University of British Columbia, Vancouver, BC, Canada.

Since discovery of the SMN gene in 1992, many rare clinical variants of SMA have been reported, including a subset associated with AMC. The genetic basis of these disorders remains unknown and continues to present important diagnostic challenges in the newborn period. In 2008, we uncovered the genetic cause of one of these rare lethal, infantile forms {X-linked SMA (SMAX2, OMIM 3018300)} through identification of the first human mutations in UBA1. We continue to evaluate families and affected male cases (AM) with XL-SMA-like phenotypes with the goal of discovering the genetic bases of these diseases. For the past year, our approach has been targeted sequencing of UBA1, followed by whole exome sequencing of UBA1-mutation negative cases. We have sequenced all UBA1 coding regions in all affected individuals in our cohort using a custom designed assay on Ion Torrent. As expected, UBA1 sequencing revealed common variants in each individual, but surprisingly no new disease associated variants were identified. We performed whole exome sequencing of 37 samples (15 families including 15 AM) on Illumina HiSeq 2000/2500. Alignment and extensive variant analysis was performed using custom in-house pipelines. Selected variants of interest were validated by qPCR Taqman assays. Exome sequencing revealed probable pathogenic mutations in many cases; we highlight results from three of these. First, a family with two affected boys revealed novel compound heterozygous deleterious CHRND mutations (OMIM 100720) that cause a form of lethal congenital myasthenic syndrome. We validated that these mutations co-segregate with disease in this family. Second, a novel start loss M1V mutation in SCML2 (OMIM 300208) was detected in the proband and mother of a family with an X-linked history of fetal and neonatal deaths. SCML2 encodes a component of the polycomb transcriptional repressor complex, and has not been previously associated with human any disease. Third, in a singleton affected boy, we identified a rare homozygous mutation in the RNA exosome component, EXOSC3, that is known to cause Pontocerebellar hypoplasia, type 1B. In retrospect, his phenotype is consistent with this diagnosis. This study demonstrates the importance of exome sequencing in identification of causal mutations and clarifiying previously undiagnosed cases of neonatal hypotonia ±AMC, and opens the door to further understanding the underlying genetic complexities of these often phenotypically-related disorders.

1396F

Genetics of spinocerebellar ataxias in Portuguese families: screening for SCA15, SCA28 and SCA36. *J.R. Loureiro[1], A.I. Seixas[1], J.L. Loureiro[1,2], A. Carracedo[3,4], M.J. Sobrido[3], P. Coutinho[1], J. Sequeiros[1,5], I. Silveira[1].* 1) IBMC - Instituto de Biologia Molecular e Celular, Universidade do Porto, Portugal; 2) Serviço de Neurologia, Centro Hospitalar entre Douro e Vouga, Portugal; 3) Fundación Pública Galega de Medicina Xenómica-SERGAS, Santiago de Compostela, Spain; 4) Genomic Medicine Group, School of Medicine, University of Santiago de Compostela, Santiago de Compostela, Spain; 5) ICBAS, Universidade do Porto, Portugal.

The spinocerebellar ataxias are rare neurodegenerative diseases clinically and genetically very heterogeneous. To this moment, 32 autosomal dominant SCAs have been genetically identified and 24 causative genes implicated in these pathologies. Trinucleotide repeat expansions are the cause of nine SCAs (SCA1, 2, 3, 6, 7, 8, 12, 17 and DRPLA). Intronic pentanucleotide repeats, an ATTCT expanded tract or an insertion, are also causative of these pathologies (SCA10 and 31). Besides repeats, classical mutations are the origin of at least 12 of these diseases (SCA5, 11, 13, 14, 15, 18, 19/22, 23, 26, 27, 28, 35). More recently, intronic GGCCTG hexanucleotide expansions have been found in SCA36. Mutation screening in known SCA genes allowed us characterize approximately 200 Portuguese families. Machado-Joseph disease/SCA3 is the most frequent (52%) followed by DRPLA (5%) and SCA2 (2%), whereas the remaining showed very low frequencies or were not found. Thus, more than 100 Portuguese SCA families remain without a molecular diagnosis. Here we present the results of mutation screenings for SCA15, SCA28 and the recently described SCA36 in these Portuguese families. All previously reported SCA15 patients have deletions of several exons of the ITPR1gene; SCA28 is caused by missense mutations or small in/dels in the AFG3L2 gene; GGCCTG hexanucleotide expansions, ranging from 650-2500 repeats, in intron 1 of NOP56, cause SCA36, the most common type of SCA in Galicia, the Spanish region on the border with Northern Portugal. We carried out quantitative real-time PCR, direct sequencing of exons of interest or repeated-primed PCR to screen for ITPR1 genomic deletions, AFG3L2 mutations and NOP56 expansions, respectively, and failed to find pathogenic alterations. In conclusion, SCA15, SCA28 and SCA36 are very rare among Portuguese SCA families and most probably a considerable number of SCA genotypes remain to be identified. Funding: FCT (Project PTDC/SAU-GMG/098305/2008) and COMPETE with co-funding by FEDER; Instituto de Salud Carlos III-FIS PI12/00742.

Repeat interruptions in spinocerebellar ataxia type 10 expansions are strongly associated with epileptic seizures. *K.N. McFarland[1], J. Liu[1], I. Landrian[1], S. Raskin[2], M. Moscovich[1,3], E.M. Gatto[4,5], H.A.G. Teive[3], A. Ochoa[6], A. Rasmussen[7], T. Ashizawa[1].* 1) Dept of Neurology and The McKnight Brain Insitute, University of Florida, Gainesville, FL; 2) Core for Advanced Molecular Investigation, Graduate Program in Health Sciences, Center for Biological and Health Sciences, Pontifical Catholic, University of Paraná, Curitiba, Paraná, Brazil; 3) Movement Disorders Unit, Neurology Service, Hospital de Clínicas, Federal University of Paraná, Centro, Curitiba, PR 80060-150, Brazil; 4) Departamento de Neurología, Sanatorio de la Trinidad Mitre, Buenos Aires, Argentina; 5) Instituto de Neurosciencias Buenos Aires, INEBA, 1428 Buenos Aires, Argentina; 6) Department of Neurogenetics, Instituto Nacional de Neurologia y Neurocirugia Manuel Velasco Suarez, Mexico City, DF, Mexico; 7) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK.

Spinocerebellar ataxia type 10 (SCA10), an autosomal dominant neurodegenerative disorder, is the result of a non-coding, pentanucleotide repeat expansion within intron 9 of the Ataxin 10 gene. SCA10 patients present with pure cerebellar ataxia; yet, some families also have a high incidence of epilepsy. SCA10 expansions containing penta- and heptanucleotide interruption motifs, termed 'ATCCT interruptions,' experience large contractions during germline transmission, particularly in paternal lineages. At the same time, these alleles confer an earlier age at onset which contradicts traditional rules of genetic anticipation in repeat expansions. Previously, ATCCT interruptions have been associated with a higher prevalence of epileptic seizures in one Mexican-American SCA10 family. In a large cohort of SCA10 families, we analyzed whether ATCCT interruptions confers a greater risk for developing seizures in these families. Notably, we find that the presence of repeat interruptions within the SCA10 expansion confers a 6.80-fold increase in the risk of an SCA10 patient developing epilepsy and a 12.92-fold increase in having a positive family history of epilepsy. We conclude that the presence of repeat interruptions in SCA10 repeat expansion indicates a significant risk for the epilepsy phenotype and should be considered during genetic counseling.

1398T

Androgen receptor gene polymorphism is associated with impulsivity in women with alcoholism. *A.M. Manzardo, D. Mettman, E.C. Penick, A.B. Poje, M.G. Butler.* Psychiatry and Behavioral Sciences, Kansas University Medical Center, Kansas City, KS.

The androgen receptor (AR) gene, located on the X chromosome, contains a common polymorphism involving CAG repeats in exon 1 which impacts disease and could contribute to the unequal gender ratio in alcoholism. CAG repeats in the AR gene influence androgen sensitivity and are known to correlate with impulsivity in males. CAG repeat lengths over 35 produce a progressive neurodegenerative disorder (Kennedy disease) in men. We report the first preliminary study examining the association between the number of CAG repeats and measures of impulsivity in females with chronic alcoholism. Thirty-five women and 85 men with chronic alcoholism were previously recruited for a nutritional clinical trial. Twenty-six well-characterized females (19 African-American and 7 Caucasian) and 55 males (41 African-American and 14 Caucasian) with alcoholism agreed to participate for genetic testing. Genomic DNA was isolated from peripheral blood and CAG repeats determined by analyzing PCR amplified products using the polymorphic AR gene assay. The CAG repeat length for males and average CAG repeat length (CAGave) of both X chromosomes for females was correlated with raw scores from the Barratt Impulsivity Scale, version 11 and the Alcoholism Severity Scale. CAGave repeat lengths for Caucasian females [mean (SD) =18.1 (1.5)] were significantly longer than seen in African-American females [mean (SD)= 16.5(1.65); F=5.3, $p<0.03$], but CAG repeat lengths in men did not differ by race [mean(SD)=15.4(2.8)]. The average number of CAG repeats were significantly positively correlated ($p<0.05$) with impulsivity scores in females but not in males. The strongest relationship was observed for Caucasian females who showed a significant correlation for 4 first order factors (Motor Impulsiveness, Self-Control, Cognitive Complexity and Perseverance) and 2 second order factors (Motor Impulsiveness and Non planning Impulsiveness). Women with an average CAG repeat length of $\geq$18 representing the upper quartile of the repeat range showed significantly greater mean raw impulsivity scores. The CAG repeat length appeared to have less effect in African-American compared with Caucasian women possibly due to a shorter average repeat length. The results suggest that increasing CAG repeat length in females may contribute to psychopathology in alcoholism. Replicative studies with more females with alcoholism of both races are warranted.

Miano[1].* 1) Institute of Genetics and Biophysics 'Adriano Buzzati Traverso', CNR, Naples, Italy; 2) Department of Paediatrics, University of Adelaide, South Australia, Australia; 3) Inserm U1091 Diabetes Genetics Team, Nice, France; 4) Inserm U1078 Laboratoire de Génétique Moléculaire et de Génétique Epidémiologique, Brest, France; 5) Institute of Neuroscience, CNR, Milan, Italy; 6) Centre for Epigenetics, University of Copenhagen, Copenhagen, Denmark; 7) Second University of Naples, Naples, Italy; 8) SISSA, Area of Neuroscience, Trieste, Italy.

Malignant Epilepsy linked to Aristaless-related homeobox (*ARX*) mutations presents severe pharmaco-resistant paediatric seizure. ARX is a crucial transcription factor regulating proliferation and migration of GABA-interneurons. We have recently identified a crucial epileptogenesis path, linking functionally ARX to another XLID/Epilepsy gene, Lysine-specific demethylase 5C (*KDM5C*). It encodes an H3K4me2/3 demethylase, which functioning is mediated by interactions with REST/NSRF, a master epigenetic hub critical for neuronal differentiation. We found that ARX Epilepsy-related mutations, which fall in PolyAlanine tracts or in the HD domain, cause a spectrum of functional damages of the ARX-KDM5C interaction, which severity depends on the type of alteration. In *Arx* KO embryonic brain and ES-oriented GABAergic neurons, a defective ARX-KDM5C-H3K4me3 path has been found in association with a mis-regulation of KDM5C Epilepsy-disease targets. *Arx* shRNA injections have been performed in mature neurons and endogenous ARX-KDM5C levels, spine density and morphology have been analyzed. We tested in vitro correction of KDM5C-H3K4me3 defects by exploiting three approaches: transcription factor targeting, gene knock-up and epigenetic modifications. To upregulate the endogenous KDM5C/KDM5C content, in a locus-specific manner, we tested *KDM5C* transcriptional induction by PHF8/ZNF711 stimulation and KDM5C translational increase by SINEUP method, aiming to balance the spectrum of KDM5C defects associated with the hypomorphic ARX PolyAlanine mutants. To achieve KDM5C-H3K4me3 path correction, we also screened a number of compounds targeting chromatin enzymes. We used, as cell disease model, neuronally-differentiated *Arx* KO/*Kdm5c*-depleted ES cells, which show GABAergic abnormalities in association with a global increase of H3K4me3 signal. A strong compensation of *Kdm5C*/KDM5C downregulation has been obtained at crucial time-point of neuronal commitment. Although many other ARX targets could have important roles in the XLID/epilepsy phenotype, we believe that restoring or upregulating the expression of KDM5C gene or protein, ideally through endogenous physiological mechanisms, should accelerate the identification of alternative therapy to cure *ARX* Epilepsy phenotypes and many other neuropathologies with malignant seizure.

Validation of a robust PCR-only assay for quantifying *FMR1* CGG repeats on clinical samples. *J.K. Moore[1], M.J. Basehore[2], G. Filippov[1], K. Adler[1], M.J. Friez[2], M. Schermer[1].* 1) Molecular Diagnostics, PerkinElmer, Inc, Waltham, MA; 2) Molecular Diagnostic Laboratory, Greenwood Genetic Center, Greenwood, SC.

Fragile X syndrome (FXS) is the most common form of inherited intellectual disability and is caused by an expansion of a CGG repeat in the 5' end of the *FMR1* gene. An accurate measurement of the repeat size is part of the classification and diagnosis of FXS and other Fragile X-associated disorders. To date, sizing of *FMR1* trinucleotide repeats in the clinical laboratory has required the use of capillary sequencer instruments to size PCR fragments, or the manual preparation and labor intensive measurement of the number of CGG repeats by Southern blot. Our goal is to validate and establish a simple and robust PCR-only assay for quantification of CGG repeat alleles. **Methods**: A blinded set of 200 archived clinical DNA samples were analyzed by PCR amplification using a FragilEase™ kit (PerkinElmer). The repeat number was calculated from the fragment size measured on a low-cost capillary electrophoresis 2100 Bioanalyzer instrument (Agilent Technologies). The repeat numbers of those samples were interpreted by the use of standards with known repeats in each run. The sample set included both male and female individuals with normal (n=167), intermediate (n=10), premutation (n=11), and full mutation alleles (n=12). Calculated repeat sizes were compared to genotypes originally obtained by the current gold standard of PCR with fragment sizing on a capillary sequencer followed by Southern analysis of no-result PCR samples or single allele females. **Results**: All DNA samples were amplified successfully. The twelve full-mutation samples were successfully amplified with the largest allele size measured at over 653 repeats. The allele classifications from the PCR-only assay were concordant with those obtained with the reference method except for one intermediate sample that was classified as normal by the FragilEase™ assay. The interassay imprecision of the repeat size measurement was within 1-2 CGG repeats for a majority of the samples. The turnaround time is within 6 hours and can handle 10 samples in a single run. **Conclusion**: This new PCR-only method is capable of classifying all different FXS allele types correctly. Our PCR-only method allows Fragile X testing to be performed in a broader spectrum of clinical laboratories and is a fast, robust method for diagnosis and potentially for population screening of the Fragile X syndrome.

AGG interruptions affect the risk of having a child with fragile X syndrome: a follow-up study. *C. Yrigollen[1], B. Durbin-Johnson[2], R. Hagerman[3, 4], L. Zhou[5], E. Berry-Kravis[5], F. Tassone[1, 3].* 1) Biochemistry and Molecular Medicine, University of California Davis, Sacramento, CA; 2) Public Health Sciences, University of California Davis, Davis, CA; 3) MIND Institute, University of California Davis, Sacramento, CA; 4) Pediatrics, University of California Davis, Sacramento, CA; 5) Neurological Science, RUSH University, Chicago, Il.

AGG interruptions in the Fragile X Mental Retardation 1 *(FMR1)* CGG trinucleotide repeat increase the stability of this repetitive locus during transmission. We have previously reported the presence of AGG interruptions within an *FMR1* premutation allele reduces the risk of the allele expanding to a full mutation during maternal transmission particularly in the 60-90 CGG repeat range. It has also been shown that the instability of alleles of 45-69 CGG repeats is less frequent and of a lesser magnitude when AGGs are present. The number of AGGs present inversely correlates with frequency of size instability, frequency of expansion to a full mutation, and magnitude of change in allele size during instability. Our follow-up study includes a larger clinical sample size comprised of 267 mothers previously reported, and 158 newly acquired mothers. The participants of this study were recruited through clinical research studies. Both this study, and that previously published, demonstrate the risk of having a child with fragile X syndrome (FXS) inversely correlates with the number of AGGs that are present the maternal allele particularly in the 60 - 90 CGG repeat size range. Thus, we have refined our previously published risk model using 425 mothers and 584 transmissions. We compared the distribution of AGG interruption patterns in premutation mothers from this clinical cohort to premutation mothers of newborns identified through our pilot study of newborn screening (NBS) for FXS. The number of transmissions is insufficient to determine if the risk model changes depending on observations from samples recruited through clinical settings and those in an unbiased general population collection. We have also determined the AGG patterns within the premutation alleles of 47 newborns identified during our pilot study. Preliminary data indicates no significant differences in the percent of premutation alleles containing 0, 1 and 2 AGGs in subjects seen clinically compared to subjects in the NBS cohort, for any given size range. Although the number of newborns is quite low it appears that less alleles with zero AGGs, are present in the unselected NBS sample relative to alleles from full mutation families. These results are expected as the population alleles from the NBS cohort, unlike those in the clinical cohort, are not biased toward alleles that have expanded to a full mutation in the family already. Larger sample size is needed to fully evaluate these relationships.

1402F

Applying NGS to familial ALS cohorts to identify novel genes. *K.L. Williams[1], J.A. Fifita[1], G.A. Nicholson[1,2], I.P. Blair[1].* 1) Australian School of Advanced Medicine, Macquarie University, Macquarie University, NSW, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, New South Wales, Australia.

Amyotrophic lateral sclerosis (ALS) is a rapidly progressive neurodegenerative disorder. Familial ALS accounts for ~10% of ALS cases with the remainder being sporadic. ALS is genetically heterogeneous, with mutations in known genes explaining 60% of familial cases in Australia. We aim to combine genetic linkage analysis, exome sequencing, high-throughput genotyping and bioinformatic strategies to identify novel causative ALS genes in Australian ALS families. The 66 ALS families used in this study are categorised into Types 1, 2 and 3 based on sample availability. All families are negative for mutations in *SOD1*, *TARDBP*, *FUS* and the hexanucleotide repeat expansion in *C9ORF72*. Exome capture and sequencing (Illumina TruSeq and HiSeq2000) was performed on 79 individuals from these families. Type 1 families (n=3, sample n=9) contain DNA samples from multiple family members including affected, unaffected, obligate carriers, and at-risk individuals. To identify potential ALS loci an 8cM genome-wide microsatellite linkage scan was performed on 70 individuals from these families. Resultant linkage data was coupled with filtered exome data to identify 1, 2 and 4 variants respectively from the Type 1 families. These variants are currently being validated in extended patient and control cohorts, patient tissues, and by *in vitro* and *in vivo* functional studies. Type 2 families (n=3, sample n=10) have DNA samples from either two affected individuals plus a 'married-in' control or >2 affected individuals. Following exome sequencing and filtering, there were 18, 28 and 37 remaining potential causative variants across the Type 2 families. To reduce the number of variants, we are performing high-throughput iPLEX genotyping (Sequenom MassARRAY) in 700 age-matched population controls. Each potential candidate gene was also screened through exome data from family Type 3 index cases (n=60) to search for additional variants in these genes. Scripts are being developed to identify related individuals among family Type 3 index cases. If related individuals are identified they will be combined to create a Type 2 family and reduce the number of potential causative variants. We are implementing new strategies utilising NGS to identify novel ALS genes across three different ALS family types. Identifying novel ALS genes will give insights into the biological basis of motor neuron degeneration, allow development of new disease models and provide new targets for therapeutic development.

Founder Mutation for Huntington Disease in Caucasus Jews. *H.N. Baris[1, 2], O. Melamed[1], C. Bram[3], N. Magal[1], E. Pras[2, 4], H. Reznik-Wolf[4], Z.U. Borochowitz[5], B. Davidov[1], R. Mor-Cohen[2, 6], D.M. Behar[1,7].* 1) The Raphael Recanati Genetic Institute, Rabin Medical Center, Beilinson Hospital, Petah Tikva, Israel; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Van Leer Institute, Jerusalem and University of Florida, Gainesville, FL, USA; 4) The Danek Gartner Institute of Human Genetics, Sheba Medical Center, Tel Hashomer, Israel; 5) The Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, Rappaport Faculty of Medicine and Research Institute, Technion-Israeli Institute of Technology, Haifa, Israel; 6) 6Amalia Biron Research Institute of Thrombosis and Hemostasis, Sheba Medical Center, Tel-Hashomer, Israel; 7) Molecular Medicine Laboratory, Rambam Health Care Campus, Haifa, Israel.

Huntington disease (HD), an autosomal dominant disorder involving HTT, is characterized by a triad of chorea, psychiatric illness and cognitive decline. Diagnosis and age of onset depend on the degree of expansion of the trinucleotide CAG repeat within the gene. The prevalence of HD is known for Europeans but has not been studied in the Israeli population. Between 2006 and 2011 we diagnosed in our adult genetics clinic 11 HD patients from 10 different families. Nine of the 10 probands were Caucasus Jews (CJ) (Azerbaijani), and one was Ashkenazi Jewish. We performed haplotype analysis to look for evidence of a founder mutation, and found that of the nine CJ, eight shared the same haplotype that was compatible with the A1 haplogroup. We calculated the coalescence age of the mutation to be between 80 and 150 years. Ninety percent of our HD patients are CJ, although the CJ comprise only 1.4% of the Israeli population. Our findings suggest a higher prevalence of HD among CJ compared to the general Israeli population and are consistent with a recent founder mutation in this group. This should raise the index of suspicion for HD in CJ, thereby allowing for earlier diagnosis so that prenatal testing can be offered when desired, and treatment once it is available.

TDP43 interact with Pur α and rescue the neurodegeneration caused by Expanded Hexanucleotide GGGGCC Repeat. *J. Li[1,2], M. Poidevin[1], W. Thomas[1,3,4], P. Jin[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 2) Department of Neurosurgery, Xiangya Hospital, Central South University, Changsha, People's Republic of China; 3) Department of Neurology, Emory University School of Medicine, Atlanta, GA, USA; 4) Department of Veterans Affairs Medical Center, Atlanta, GA, USA.

Recently, an expansion of GGGGCC repeats in the first intron of C9orf72 was found to be a common cause of both amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Previously, we found that Pur α interact with GGGGCC hexanucleotide repeat in vitro and in vivo in a sequence-specific fashion that is conserved between mammals and Drosophila. Here we have extended this work to investigate the role of TAR DNA-binding protein (TDP-43), the most common pathological inclusion in ALS/FTD, in riboGGGGCC (rGGGCC) repeat toxicity. To do this, we used Neuro2a and Drosophila models of the expanded hexanucleotide repeat to show that the overexpression of the TDP43 is sufficient to rescue neurodegeneration. Next, we delineated the interaction between Pur α and TDP43. We show that Pur α interacts with TDP43 in an RNA independent manner that is dependent on the N-terminus of TDP43. Finally, we performed a Drosophila RNAi screen using TDP43 interacting protein to identify additional genetic interactors of Pur α / TDP43 complex. Our results suggest that the expanded rGGGGCC repeat may interact with TDP43 indirectly through Pur α, causing the sequestration of TDP43 and others genetic interacting proteins from their normal function. This mechanism could potentially play a role in the pathogenesis of ALS/FTD illness.

1405F

A predictive model for the *MAOA* promoter VNTR and its application in public GWAS datasets. *T. Wang[1], A. Lu[2], V. Rao[1], S. deJong[1], R.M. Cantor[1,2], R.A. Ophoff[1,2,3].* 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, California; 2) Department of Human Genetics, University of California Los Angeles, Los Angeles, California; 3) Department of Psychiatry, UMC Utrecht, The Netherlands.

Monoamine oxidase (MAO) A and B are adjacent genes on chromosome X that encode the main enzymes for neurotransmitter turnover. Many drugs used as treatment for clinical depression and anxiety inhibit the MAO enzymes, this suggests that they have an important role in psychiatric traits. Both *MAOA* and *MAOB* share a common promoter where a 30bp variable number tandem repeat (VNTR) was identified 1.2kb upstream the transcription start site of the *MAOA*. These alleles exist in the 2, 3, 3.5, 4, and 5 repeats (R), where 3R and 4R are the most common within the population. 2R, 3R, and 5R were shown to possess low activation of *MAOA*, whereas 3.5R and 4R were shown to have much higher levels of activation in in vitro studies. However, the reported in vitro promoter high/low activity has poor correlation with in vivo studies examining *MAOA* or *MAOB* expression in post-mortem brain. Furthermore, these in vivo studies are underpowered to detect significant associations. We developed a predictive tool for the *MAOA* promoter VNTR based on an advanced machine learning method, multicategory vertex discriminating analysis (VDA). We PCR genotyped the VNTR in 400 individuals of European descent, including 30 HapMap trios where there was SNP genotype information within 2MB of the *MAOA* promoter region. 300 individuals were used as a training dataset to build a VDA model usingonly overlapping SNPs in all datasets and searched by 10-fold cross validation to optimize the accuracy rate for predicting MAOA promoter VNTR. A test dataset of 87 individuals was used to validate the VDA model. This algorithm highlighted 5 SNPs, along with gender, that correctly classified the VNTR in 97% of our training dataset, and 96.7% in our validation dataset. With the predictor tool we are now able to study the *MAOA* promoter VNTR in available GWAS data sets of neuropsychiatric traits such as major depressive disorder, bipolar disorder and schizophrenia. The predictor tool enables us to establish whether some alleles are indeed high and low expressing (as reported in previous in vitro studies) in large gene expression data sets of human brain. Lastly, analysis is underway to test whether specific *MAOA* VNTR alleles affect monoamine neurotransmitter turnover by examining cerebrospinal fluid (CSF) monoamine metabolite levels in a large cohort of healthy controls.

MSH3 Polymorphisms and Protein Levels Affect CAG Repeat Instability in Huntington's Disease Mice. *S. Tome[1], K. Manley[3], J. Simard[2, 5], G.W. Clark[6, 7], M.S. Slean[2, 5], M. Swami[4], P.F. Shelbourne[4], E.R.M. Tillier[6, 7], D.G. Monckton[4], A. Messer[3], C.E. Pearson[2, 5].* 1) inserm, Paris, France; 2) Genetics and Genome Biology, The Hospital for Sick Children, TMDT Building 101 College St., 15th Floor, Room 15-312 East Tower, Toronto, ON, M5G 1L7; 3) Wadsworth Center, New York State Dept. of Health, & Department of Biomedical Sciences, University at Albany, SUNY, Albany, NY 12208, USA; 4) Institute of Molecular, Cell and Systems Biology, College of Medical, Veterinary and Life Sciences, University of Glasgow, University Avenue, Glasgow G12 8QQ, UK; 5) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 6) Department of Medical Biophysics, University of Toronto, Toronto, ON, Canada; 7) Campbell Family Institute for Cancer Research, Ontario Cancer Institute, University Health Network, Toronto, ON, Canada.

Expansions of trinucleotide CAG/CTG repeats in somatic tissues are thought to contribute to ongoing disease progression through an affected individual with Huntington's disease or myotonic dystrophy. Broad ranges of repeat instability arise between individuals with expanded repeats, suggesting the existence of modifiers of repeat instability. Mice with expanded CAG/CTG repeats show variable levels of instability depending upon mouse strain. However, to date the genetic modifiers underlying these differences have not been identified. We show that in liver and striatum, the R6/1 Huntington's disease (HD) (CAG)~100 transgene, when present in a congenic C57BL/6J (B6) background, incurred expansion-biased repeat mutations, whereas the repeat was stable in a congenic BALB/cByJ (CBy) background. Reciprocal congenic mice revealed the *Msh3* gene as the determinant for the differences in repeat instability. Expansion-bias was observed in congenic mice homozygous for the B6 Msh3 gene on a CBy background, while the CAG tract was stabilized in congenics homozygous for the CBy Msh3 gene on a B6 background. The CAG stabilization was as dramatic as genetic deficiency of Msh2. The B6 and CBy Msh3 genes had identical promoters but differed in coding regions, and showed strikingly different protein levels. B6 MSH3 variant protein is highly expressed and associated with CAG expansions, while the CBy MSH3 variant protein is expressed at barely detectable levels, associating with CAG stability. The DHFR protein, which is divergently transcribed from a promoter shared by the *Msh3* gene, did not show varied levels between mouse strains. Thus, naturally occurring MSH3 protein polymorphisms are modifiers of CAG repeat instability, likely through variable MSH3 protein stability. Since evidence supports that somatic CAG instability is a modifier and predictor of disease, our data are consistent with the hypothesis that variable levels of CAG instability associated with polymorphisms of DNA repair genes may have prognostic implications for various repeat-associated diseases.

***Mlh1* and *Mlh3* modify CAG instability in Huntington's disease mice: genome-wide and candidate approaches.** *R. Mouro Pinto[1], E. Dragileva[1], A. Kirby[2,3], A. Lloret[1], E. Lopez[1], J. St. Claire[1], G.B. Panigrahi[4,5], C. Hou[6], K. Holloway[7], T. Gillis[1], J.R. Guide[1], P.E. Cohen[7], G-M. Li[6], C.E. Pearson[4,5], M.J. Daly[2,3], V.C. Wheeler[1].* 1) Center for Human Genetic Research, Massachusetts General Hospital/Harvard Medical School, Boston, Massachusetts, United States of America; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, United States of America; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, United States of America; 4) Program of Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada; 5) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 6) Graduate Center for Toxicology and Markey Cancer Center, University of Kentucky College of Medicine, Lexington, Kentucky, United States of America; 7) Department of Biomedical Sciences, Cornell University, Ithaca, New York, United States of America.

The Huntington's disease gene (*HTT*) CAG repeat mutation undergoes somatic expansion that correlates with pathogenesis. Modifiers of somatic expansion may therefore provide routes for therapies targeting the underlying mutation. Huntington's disease Hdh^{Q111} mice exhibit higher levels of somatic *HTT* CAG expansion on a C57BL/6 genetic background (B6.Hdh^{Q111}) than on a 129 background (129.Hdh^{Q111}). Linkage mapping in (B6x129).Hdh^{Q111} F2 intercross animals identified a single quantitative trait locus underlying the strain-specific difference in expansion in the striatum, implicating mismatch repair (MMR) gene *Mlh1* as the most likely candidate modifier. Crossing B6.Hdh^{Q111} mice onto an *Mlh1* null background demonstrated that *Mlh1* is essential for somatic CAG expansions and that it is an enhancer of the *HTT* CAG pathogenic process in striatal neurons. Hdh^{Q111} somatic expansion was also abolished in mice deficient in the *Mlh3* gene, implicating MutLγ (MLH1/MLH3) complex as a key driver of somatic expansion. Strikingly, the *Mlh1* and *Mlh3* genes encoding MMR effector proteins were as critical to somatic expansion as *Msh2* and *Msh3* genes that encode DNA mismatch binding proteins. The *Mlh1* locus is highly polymorphic between B6 and 129 strains. While we were unable to detect any difference in base-base mismatch or short slipped-repeat repair activity between B6 and 129 MLH1 variants, repair efficiency was MLH1 dose-dependent. MLH1 mRNA and protein levels were significantly decreased in 129 mice compared to B6 mice, consistent with a dose-sensitive MLH1-dependent DNA repair mechanism underlying the somatic expansion difference between these strains. Together, these data identify *Mlh1* and *Mlh3* as novel critical genetic modifiers of *HTT* CAG instability, point to *Mlh1* genetic variation as the likely source of the instability difference in B6 and 129 strains and suggest that MLH1 protein levels play an important role in driving of the efficiency of somatic expansions.

1408F

Small Molecule Ligand Distorts RNA G-Quadruplex Structure of the Disease-Associated r(GGGGCC)n Repeat of the *C9orf72* Gene and Blocks Interaction of RNA-Binding Proteins. *C.E. Pearson[1, 2], B. Zamiri[3], K. Reddy[1, 3], R. Macgregor[3].* 1) Genetics & Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Program of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada M5S 1A1; 3) Graduate Department of Pharmaceutical Sciences, Leslie Dan Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada M5S 3M2.

Certain DNA and RNA sequences can form G-quadruplexes, which can affect genetic instability, promoter activity, RNA splicing, RNA stability, and neurite mRNA localization. Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) can be caused by expansion of a (GGGGCC)n repeat in the *C9orf72* gene. Mutant r(GGGGCC)n-containing transcripts aggregate in nuclear foci possibly sequestering repeat-binding proteins like hnRNPA1 - suggesting a toxic-RNA pathogenesis, as occurs in myotonic dystrophy (DM1) and fragile X associated tremor ataxia (FXTAS). Furthermore, the *C9orf72* repeat RNA and the FXTAS repeat RNA were recently demonstrated to undergo the non-canonical repeat associated non-AUG translation (RAN-translation) into pathologic peptide repeats in patient brains, a process that is thought to depend upon RNA structure. RAN-translation was initially observed in tissues from DM1 and spinocerebellar ataxia type 8 patients. We previously demonstrated that the *C9orf72* r(GGGGCC)n RNA forms repeat tract length-dependent G-quadruplex structures that can be bound by the splicing factor ASF/SF2. Here we show that a small molecule ligand, which can bind some G-quadruplex forming sequences, can bind and distort the G-quadruplex of the r(GGGGCC)8 RNA, and this ablates interaction of either hnRNPA1 or ASF/SF2. These findings provide proof-of-concept that nucleic acid binding small molecules can distort the secondary structure of the *C9orf72* repeat, which may beneficially disrupt protein interactions, which may ablate either protein-sequestration and/or RAN-translation into potentially toxic dipeptides. Disruption of secondary structure of the *C9orf72* RNA repeats may be a viable therapeutic avenue for various diseases, as well as a means to test the role of RNA structure upon RAN-translation.

Spinocerebellar ataxia type 10 (SCA10) is a neurodegenerative disease characterized by cerebellar ataxia and seizures, due to expansion of a pentanucleotide repeat (ATTCT) in the ATXN10 gene. To date, SCA10 has only been reported in patients from Latin-American countries. The numerous families of Amerindian descent with SCA10 mutations and the absence of this variant in European countries suggest a founder effect for this mutation. The objective of this study was to identify a previously described haplotype, shared by 3 SCA10 Brazilian families, in additional patients from Brazil and new cases from Peru. Repeat primed-PCR was performed to detect expanded SCA10 alleles in Brazilian and Peruvian individuals with a SCA of unknown cause. Haplotypes were constructed, based on polymorphic markers within and outside the gene. We have identified 23 confirmed SCA10 cases: 3 families have been described previously (Alonso et al, 2006; Almeida et al, 2009), while 12 families were newly identified, within a large cohort of patients with ataxia. From those, 3 families were from Peru, while the remaining 9 were from Brazil. The same polymorphic markers and haplotypes were typed in 100 individuals (200 alleles) from the general local population. A different haplotype distribution was found in SCA10 patients and the control group. A common haplotype, 19CGGC14, was found in 11/13 of Brazilian and in 1/3 of Peruvian families. Haplotype 19CGGC16 was found in one Peruvian and one Brazilian families; the remaining two families showed other haplotypes. Individuals with SCA10 mutations have been previously described in Brazil, whereas this is the first report of SCA10 in Peru. We confirmed the presence of a consistently recurrent intragenic haplotype, suggesting a common ancestry for most, if not all patients. Supported by: CNPq, FIPE-HCPA, FAPERGS, INAGEMP, RIBERMOV.

Detailed audiological evaluation of a patient with xeroderma pigmentosum with neural degeneration. *D. Mercer[1], F. Tsien[2], A. Hurley[1].* 1) Department of Communication Disorders, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Department of Genetics, Stanley S. Scott Cancer Center, Louisiana State University Health Sciences Center, New Orleans, LA.

Xeroderma pigmentosum (XP) is a rare autosomal recessive condition characterized by defects in DNA excision repair, leading to extreme sensitivity to ultraviolet light damage and increased susceptibility to melanomas and carcinomas. Approximately 25% of XP patients also exhibit progressive neural degeneration which includes mental deterioration, cortical thinning, and sensorineural hearing loss. We describe a patient with XP complementation subtype D. The patient initially presented in our clinic at 7 years of age after failing a hearing screening. At that time, he was found to have a unilateral mild high-frequency sensorineural hearing loss with a configuration suggestive of noise exposure. He also demonstrated central auditory processing deficits. He was re-evaluated at age 11 years, and his hearing loss had progressed to a bilateral moderate sensorineural hearing loss. At age 13 years, the patient acquired type 1 diabetes. Genetic confirmation of XP was obtained at 18 years of age. XP testing revealed compound heterozygous missense mutations in complementation group D, one of the XP subtypes associated with neural degeneration and sensorineural hearing loss. Serial audiograms and electrophysiological testing have been obtained on this patient over a course of 11 years. His hearing loss has gradually progressed to a bilateral precipitous sloping sensorineural hearing loss that is mild in the low frequencies and severe-to-profound in the high frequencies. Auditory evoked potentials showed deteriorating waveform morphology of the auditory brainstem response and late evoked potentials (P300). The change in P300 recordings may be due to cortical thinning, which has been reported in XP with neural degeneration. In addition to neural degeneration and peripheral neuropathy, the patient has been treated for claw-toe deformity. These findings will further characterize the phenotype of XP type D.

1411F

Characterizing the aging human brain transcriptome. *N. Pochet[1,2,3], D. Borges-Rivera[3], B. Haas[3], S. Rajagopal[1,2,3], J. Xu[1,2,3], C. McCabe[1,2,3], O. Gevaert[4], G. Srivastava[1,2,3], A. Regev[3], J. Schneider[5], D. Bennett[5], P. De Jager[1,2,3].* 1) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Department of Neurology, Brigham and Women's Hospital; 2) Harvard Medical School; 3) Broad Institute of MIT and Harvard; 4) Cancer Center for Systems Biology, Department of Radiology, Stanford University; 5) Rush Alzheimer's Disease Center, Rush University Medical Center.

Aging in humans is often accompanied by cognitive decline which, in many cases, leads to dementia and a syndromic diagnosis of Alzheimer's disease (AD). Our goal is to characterize the aging human brain transcriptome in order to gain mechanistic and functional insights into the neurobiological processes implicated in aging-related cognitive decline and Alzheimer's disease.

We sequenced RNA from the dorsolateral prefrontal cortex (DLPFC) of 550 individuals from two prospective cohort studies of aging that include brain donation at the time of death: the religious order study and the memory and aging project. The subjects are all non-demented at the start of the study and, at the time of death, differ in the extent of aging-related cognitive decline, ranging from cognitively non-impaired individuals to mildly impaired individuals, and to individuals clinically diagnosed with Alzheimer's disease at the time of death. In addition to the transcriptome data, we have genotype data on each individual and DNA methylation data from the same region of the brain in each subject, which inform our RNA analyses.

We applied *ab initio* and *de novo* transcriptome assembly approaches to systematically study the aging human brain transcriptome for differentially expressed genes and isoforms, novel transcripts and (*trans*-)splice isoforms, as well as mutations and RNA editing events in expressed genes. We selected differentially expressed genes and isoforms, by relying on the known annotated genes and isoforms, and we tested these for enrichment in known categories. We identified novel transcripts and (*trans*-)splice isoforms, by comparison to known annotated genes and measures of support at the read, read-pair and expression levels. We detected mutations and RNA editing events, by comparing the transcriptome to the reference genome and genotyping data. Finally, we enhanced the Module Networks algorithm to associate the (epi)genetic changes we found with changes in mRNA levels and (*trans*-)splicing variants, and to compare clinical characteristics between individuals stratified by the combination of aberration and expression/splicing changes.

1412W

Mucolipidosis type IV: progressive gliosis, synaptic dysfunction and cognitive deficits in Mcoln1 knock-out mouse. *Y. Grishchuk[1], S. Sri[2], W. Ma[1], N. Rudinskiy[3], M. Cottle[1], K. Stember[1], E. Sapp[3], A. Muzikansky[4], M. Difiglia[3], R. Betensky[4], B. Hyman[3], R. Kelleher[1], J. Cooper[2], S. Slaugenhaupt[1].* 1) Center for Human Genetics Research, Massachusetts General Hospital/Harvard Medical School, Boston, MA; 2) The Institute of Psychiatry, King's College London, London, UK; 3) MassGeneral Institute for Neurodegenerative Disease, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, USA; 4) Harvard School of Public Health, Harvard Medical School, Boston, Massachusetts, USA.

Mucolipidosis type IV (MLIV) is an autosomal-recessive neurodegenerative disease causing severe cognitive impairment, motor decline and progressive loss of vision. It is caused by mutations in MCOLN1 gene, which encodes a lysosomal/late endosomal non-selective cation channel TRPML1. The mechanism of how loss of TRPML1 leads to severe CNS pathology remains currently unknown and there is no therapy. Therefore, we are performing neuropathological examinations of an MLIV mouse model (Mcoln1 knock-out mouse), starting from very early stages and following disease progression. Using different experimental approaches such us behavioral testing, in vivo imaging, electrophysiology, histochemistry and electron microscopy, we describe structural and functional abnormalities associated with Mcoln1 loss in the mouse brain. Our results revealed that the first signs of motor and cognitive decline are seen at 2 months of age. These early behavioral phenotypes were accompanied by activation of astrocytes and microglia, as well as severe dysmyelination. Estimates of neuron numbers in the regions of the brain with the most astrocytosis and microglyosis revealed no neuronal loss at 2 and 3 months of age, indicating that activation of glia precedes neuronal death. Evaluation of resting Ca2+ activity in the 3 month-old Mcoln1-/- brains in vivo showed no difference between knockouts and littermate controls, implying normal calcium homeostasis at this age. Evaluation of the synaptic function in the Schaeffer collateral pathway revealed elevated paired-pulse facilitation (PPF) and long-term potentiation (LTP) in Mcoln1-/- hippocampi. Changes in LTP were accompanied with impaired learning and memory in the fear conditioning test. Overall, observed changes in synaptic transmission were not a result of neuronal loss in either the CA3 or CA1 fields of the hippocampus, as determined by stereologic counts. However, in the CA1 stratum radiatum we observed changes in synaptic morphology in excitatory synapses, reduced thickness of myelin sheaths and accumulation of abundant aggregates of inclusion bodies. Altogether, here we report for the first time synaptic dysfunction and cognitive deficits associated with TRPML1 loss which could explain the clinical manifestations seen in MLIV patients; and the early involvement of glial cells in MLIV disease pathophysiology, suggesting a new avenue towards the development of therapies for this devastating disease.

1413T

Identifying novel candidate genes for neurological diseases. *K. Summers.* Roslin Inst, Univ Edinburgh, Roslin, Midlothian, United Kingdom.

Over 80% of human genes are expressed in brain. Microdeletion syndromes (where groups of contiguous genes are deleted) almost always involve some form of intellectual disability and suggest that at least one in ten genes is critical for brain development. Within the mammalian genome there are a large number of genes that are not fully annotated and whose function is unknown. To identify such novel genes which are specific to the nervous system, the tool Biolayout *Express*^{3D} was employed to cluster sets of genes with shared expression patterns across mouse neurological cell types. This approach is model-free, since clusters are generated independent of known pathways or functions, and thus has the potential to find new pathway members. Published gene expression microarray data using the mouse MOE-430 platform (Affymetrix) were drawn from GEO-Datasets (NCBI). Tissues and cell types analysed included a range of brain regions, spinal cord, glial cells and non-neuronal cells. Biolayout *Express*^{3D} produced 187 coexpression clusters of more than 10 nodes (microarray probes). There were 16 clusters of genes (1027 probes representing 833 genes in total) expressed highly across the nervous system. Of these, 195 probes had no annotation and 151 had minimal annotation. Thus there was little information for one third of genes showing expression in brain and other neurological tissues. These genes included putative synaptic proteins, transcription factors of unknown target and other genes with no homology to any known protein domain. Knowledge of the other genes in the same cluster provides a functional annotation and identifies novel candidates for diseases affecting this function. Cluster 3 contained *Eno2*, the gene for neuron specific enolase, indicating that this is a neuron-specific cluster, and genes for a number of known synaptic proteins. There were also 96 genes of minimal annotation. For example, this cluster contained *Dbc1* (Deleted in Bladder Cancer 1; OMIM602865), thought to be a tumour suppressor, and now implicated in neuronal/synaptic function. Another gene in this cluster is *Susd4* (Sushi-Domain Containing 4; no OMIM entry), which was discovered by genome sequencing and is deleted in cases of autism and Fryns syndrome. Further analysis using knock-out mouse models, recombinant protein analysis and RNA interference will validate the role of the novel genes as candidates for diseases of the brain and nervous system.

1414F

The genetic architecture of schizophrenia: How do CNVs and polygenic scores contribute to disease risk? *S.E. Bergen[1], J.W. Smoller[2], J. Sebat[3], S. Purcell[4], B. Neale[5], K.S. Kendler[6], ISC, Swedish Schizophrenia Consortium, Psychiatric Genomics Consortium CNV and Schizophrenia groups.* 1) Medical Epidemiology and Biosataistics, Karolinska Institute, Stockholm, Sweden; 2) Psychiatric and Neurodevelopmental Unit, Massachusetts General Hospital, Boston, MA; 3) Department of Psychiatry, University of California San Diego, La Jolla, CA; 4) Mount Sinai School of Medicine, New York, NY; 5) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 6) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

Both rare CNVs and common SNPs contribute to the genetic risk for schizophrenia. Several specific CNV regions and an increased burden of large deletion CNVs have demonstrated associations with schizophrenia. A significantly higher polygenic risk score in subjects with schizophrenia has also been established, confirming that many common SNPs confer risk for this disorder as well. The relationships between these rare and common genetic risk factors have not been thoroughly investigated, and we sought to address the following questions: 1) Do cases with CNVs have lower polygenic risk scores compared to cases without CNVs? 2) Do cases with CNVs have higher polygenic risk scores compared to controls with CNVs? 3) Do controls with CNVs have lower polygenic risk scores than controls without CNVs?

We investigated the polygenic risk score differences within and between case and control groups by CNV carrier status using the Swedish Schizophrenia Consortium (N=4646) as the discovery sample to score the International Schizophrenia Consortium (ISC) (N=4921) subjects. Analyses will be extended to CNV and GWAS data from the Psychiatric Genomics Consortium. CNV carriers were defined by the two classes of CNVs conferring the greatest disease risks: 1) having one of 12 specific CNVs previously associated with schizophrenia or 2) carrying any large CNV deletion greater than 500kb.

Within schizophrenia cases, CNV carriers did not demonstrate significantly lower risk scores than non-carriers. Cases with either class of CNV membership had higher polygenic scores compared to control subjects carrying CNVs. Control subjects with specific associated CNVs had lower polygenic scores than other control subjects, but controls with and without large deletions had similar scores. These initial results are partly inconsistent with an additive model of CNV and polygenic risk. The presence of an associated CNV alone is not sufficient to result in schizophrenia, but also requires a context of increased risk from common variants.

1415W

Copy Number Variants Implicated in Autism Spectrum Disorder Among Individuals of Hispanic Ethnicity. *N. Dueker[1], A.J. Griswold[1], H.N. Cukier[1], J. Jaworski[1], Y.N. Park[1], S. Slifer[1], I. Konidari[1], P.L. Whitehead[1], M. Schmidt[1], J.R. Gilbert[1,2], J.L. Haines[3], M.L. Cuccaro[1,2], E.R. Martin[1,2], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN.

Autism spectrum disorder (ASD) is a developmental disorder characterized by social, communicative and behavioral impairments leading to average yearly medical costs that are 4.1-6.2 times higher for those with an ASD compared to those without. ASD is a highly heritable disorder and numerous copy number variants (CNVs) have been implicated with risk for developing ASD among individuals of European ancestry. However, it is unknown whether CNVs contribute to genetic risk of ASD among those of Hispanic ethnicity. Though Hispanic individuals comprise 16.7% of the current US population and are the largest minority in the US, investigation into genetic risk factors in this population is lacking. Therefore, we performed CNV analyses to identify loci associated with ASD in a large sample of Hispanic individuals. Participants for this study were drawn from a family-based study of ASD that included 291 ASD families and 118 pediatric controls that were genotyped using either the HumanOmni2.5-4v1_c or Human1M-Duo2_B platforms. All participants were self-reported, or had at least one parent of self-reported, Hispanic ethnicity. CNVs were detected using PennCNV and burden analyses were performed in PLINK v.1.0.7 using 284 ASD probands and 110 pediatric controls passing our quality control criteria. Analyses were restricted to CNVs spanning at least 5 SNPs and having length >30 kb. A total of 1,563 deletions and 1,342 duplications meeting our criteria were detected in our ASD probands, as well as 1,302 deletions and 794 duplications in our controls. The average size of deletions was larger in ASD probands compared to controls (ASD probands μ=92.2 kb, controls μ=79.1 kb, Burden p-value=0.04). However, the number of deletions, average size of duplications and number of duplications did not significantly differ between the two groups (Burden p=1). These burden results are similar to previously published data on CNVs in European Ancestry populations. We also detected CNVs in well-established ASD CNV regions in our probands, including a 500kb deletion at 16p11.2, and identified 25 case-unique CNVs in ASD candidate genes including Neurexin 1 (*NRXN1*). Deletions within *NRXN1* have been previously implicated in ASD and we identified 3 probands with deletions overlapping *NRXN1* in our study. These results provide preliminary evidence that CNVs, particularly deletions, may contribute to ASD risk among individuals of Hispanic ethnicity.

1416T

High resolution copy number variation analysis in monozygotic twins discordant for schizophrenia and delusional disorder. *F. Nishimura[1,2], A. Yoshikawa[1], T. Kato[2], T. Sasaki[3], K. Kasai[1], C. Kakiuchi[1,2].* 1) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Wako-shi, Saitama, Japan; 3) Office for Mental Health Support and Graduate School of Education, University of Tokyo, Tokyo, Japan.

Introduction: Schizophrenia is one of the major mental disorders with approximately 1% prevalence rate. It is the most debilitating psychiatric disorder, inflicting much burden upon the patient, the family, and the society. The family, twin and adoption studies have established that the genetics play a significant role in the etiology of schizophrenia. Disease concordance rate of schizophrenia within monozygotic twin is about 50% and on the other hand, disease concordance rate of schizophrenia within dizygotic twin is about 15%, suggesting that the genetic determinant and non-genetic factors play an important role. Copy number variation have been attracted a lot of attention lately and possibly plays a role in the etiology of schizophrenia. In this study, we examined the copy number variation differences within each twin that may potentially contributed to the etiology of schizophrenia. **Method:** We performed array comparative genomic hybridization on genomic DNA derived from peripheral blood obtained from two pairs of monozygotic twins discordant for schizophrenia and one pair discordant for delusional disorder using SurePrint G3 Human CGH 1x1M microarray from Agilent Techologies. All hybridizations were performed in duplicate, with the Cy3 and Cy5 dyes being swapped between the twin members of each pair to eliminate a possible dye-specific bias. Analyses of the data were carried out using the manufacturers' software, called Agilent Genomic Workbench. The objective of this study was clearly explained and written informed consent was obtained from all subjects. The study was approved by the Ethical Committee of the Faculty of Medicine, the University of Tokyo. **Results:** We found no differences in copy number variants between the three pairs of monozygotic twin. **Conclusion**: We have undertaken the high resolution copy number variation analysis in monozygotic twins discordant for schizophrenia and delusional disorder and identified no copy number variation differences within each monozygotic twin. CNV may not play a role in discordance of the development of psychosis in this present three monozygotic twin pairs.

Characterization of age-related expression of the interleukin-1beta gene in immature zebrafish brain after pentylenetetrazole evoked-seizures. *P. Barbalho, D. Nakata, C. Maurer-Morelli.* Department of Medical Genetics, State University of Campinas (UNICAMP)), Campinas, Sao Paulo, Brazil.

Introduction: Clinical and experimental evidence have demonstrated that seizures activate the inflammatory response increasing the release of interleukin-1 beta and that this activation is age-regulated in the developing brain. In this study, we aimed to investigate the interleukin-1 beta (il1b) transcript response after seizures in immature zebrafish brain. Material and Methods: Zebrafish were maintained according to standard procedures and all experiments were approved by the Animal Ethics Committee/UNICAMP. Seven and 15 days post-fertilization (dpf) zebrafish larvae were separated in Seizure (SG) and Control (CG) groups. Animals from SG group were individually exposed to Pentylenetetrazol (PTZ) 15mM for 20min. Animals from CG were exposed to same handling condition, but in normal bath water. A pool of 20 heads was used to compose a single larvae sample (n=5 each group). One hour after PTZ exposure animals were crioanesthetized and their heads were immediately isolated, frozen in N2(L) and total RNA extracted by Trizol (Invitrogen). Reverse transcriptase quantitative-PCR amplifications were carried out in triplicates with efla as endogenous control (TaqMan®, Applied Biosystems). The relative quantification (RQ) was calculated by the equation RQ=2 -ΔΔCT and the statistical analysis was performed by Mann-Whitney test. Results: The mRNA profile of the il1b gene showed an up regulation in SG when compared with the CG in both 7 dpf [(CG1h 1.44 ± 0.34; SG1h 2.46 ± 0.17 (p= 0.02)] and 15 dpf [(CG1h 1.86 ± 0.27; SG1h 3.63 ± 0.68 (p= 0.02)]. The i1lb transcript levels were 1.5 times more pronounced in 15dpf than in 7dpf larvae. Conclusion: This is the first study investigating age-related response of il1b gene after seizure in immature zebrafish brain. Our results showed that seizures induced in immature zebrafish brain promote an age-specific cytokine expression. This study contributes for a characterization of zebrafish as an experimental model of epilepsies. Support: FAPESP, CNPq.

1418W

A corrective gene silencing by RNA interference to control over-expressed *SNCA*. *M. Takahashi[1], M. Suzuki[2], N. Fujikake[2], M. Murata[3], K. Wada[2], Y. Nagai[2], H. Hohjoh[1].* 1) Dept. of Molecular Pharmacology, National Inst. of Neurosci., NCNP, Kodaira, Tokyo, Japan; 2) Dept. of Degenerative Neurological Diseases, National Inst. of Neurosci., NCNP, Kodaira, Tokyo, Japan; 3) National center Hospital, NCNP, Kodaira, Tokyo, Japan.

An over-expression of the wild-type *alpha synuclein* (*SNCA*) gene has the potential for developing Parkinson's disease (PD). For reduction of the over-expressed *SNCA*, the gene silencing against the wild-type *SNCA* by RNA interference (RNAi) may be a possible strategy for treatment for such an *SNCA*-over-expressed PD. However, a conventional RNAi that thoroughly silences *SNCA* may be unsuitable for such a treatment, and previous studies suggested that the wild-type *SNCA* plays an important role in neuronal functions. In this study, we attempted to establish a new RNAi technique to control the level of the over-expressed *SNCA* to its normal level. Various siRNAs were designed and subjected to an *in vitro* assay to examine their RNAi activities. From the screening, siRNAs that conferred approximately a half of inhibition of the expression of wild-type *SNCA* were selected as potential candidates for the particular RNAi. To further assess the effects of such an RNAi treatment *in vivo*, we focused on *Drosophila* model of PD, and then we examined the siRNAs in cultured *Drosophila* S2 cells and slightly modified the siRNA sequences such that they could confer an appropriate RNAi activity in *Drosophila* cells. As for establishment of transgenic RNAi flies, the selected siRNA was converted into a shRNA-expression construct (plasmid) that is controlled by an *elav*-GAL4 driver for pan-neuronal expression. Using the resultant shRNA expression plasmid, we are currently generating transgenic flies, which express *SNCA* and the shRNA in neurons. We would like to present and discuss the data of the fly models as well as the selected siRNAs for controlling the over-expressed *SNCA* in the meeting.

1419T

Partitioning the Heritability of Tourette Syndrome and Obsessive Compulsive Disorder Reveals Differences In Genetic Architecture. *L. Davis on behalf of the Tourette Syndrome Association International Consortium for Genetics (TSAICG).* Section Genetic Medicine, The University of Chicago, Chicago, IL.

Despite the completion of the first genome-wide association studies in Tourette Syndrome (TS) and obsessive compulsive disorder (OCD), very little is known about the genetic architecture of these two phenotypcially related early-onset neuropsychiatric disorders. The direct estimation of heritability from genome-wide common variant data as implemented in the program Genome-wide Complex Trait Analysis (GCTA) has provided a means to quantify and partition heritability attributable to all interrogated variants or to specific variant subsets of interest. We conducted multiple partitioning analyses to identify genomic elements that concentrate TS and OCD heritability. We partitioned by chromosome, MAF bin, and by annotation of variants that regulate gene expression in the brain. In addition, we assessed heritability for early onset and adult onset OCD and finally tested for genetic overlap between TS and OCD. After extensive quality control, we proceeded with analysis on a final data set of 617 TS cases and 4,116 TS controls genotyped on 393,387 SNPs, as well as 1,061 OCD cases and 4,236 OCD controls genotyped on 373,846 SNPs. Our analysis yielded a heritability point estimate of 0.58 (se = 0.09, p=5.64e-12) for TS, and 0.37 (se = 0.07, p=1.5e-07) for OCD. Among other notable results, we found that SNPs with a minor allele frequency of less than 5% accounted for 21% of the TS heritability and 0% of the OCD heritability. We discovered a disproportionately large contribution to OCD heritability originating from chromosome 15. Additionally, results showed that parietal eQTLs accounted for significantly more TS heritability (p=5.36e-46) and OCD heritability (p=2.80e-16), and cerebellum eQTLs accounted for significantly more TS heritability (p=4.02e-15) and OCD heritability (p=1.37e-14) than expected based on the number of SNPs tested under a uniform distribution model. Finally, we found a bivariate genetic correlation of 0.41 (SE=0.15) between TS and OCD. These findings suggests that 1) very little, if any, heritability is truly missing (i.e., unassayed) from TS and OCD GWAS studies of common variation and 2) shared environment does not result in excessive bias in twin and family studies of TS and OCD. The results further indicate that while there is some genetic overlap between these two phenotypically-related neuropsychiatric disorders, the two disorders have distinct genetic architectures. We present genomic characterization of both phenotypes.

1420F

Association of *DLG4* haplotype with increased risk of schizophrenia. *S. Balan[1], K. Yamada[1], E. Hattori[1], Y. Iwayama[1], T. Toyota[1], T. Ohnishi[1], M. Maekawa[1], M. Toyoshima[1], Y. Iwata[2], K. Suzuki[2], M. Kikuchi[3], T. Yoshikawa[1].* 1) Laboratory for Molecular Psychiatry, RIKEN- Brain Science Institute, Saitama, Japan; 2) Department of Psychiatry and Neurology, Hamamatsu University School of Medicine, Shizuoka, Japan; 3) Department of Psychiatry and Neurobiology, Kanazawa University Graduate School of Medicine, Kanazawa, Japan.

The post-synaptic density (PSD) of glutamatergic synapses are characterized by the expression of an array of proteins critical for maintaining synaptic dynamics. Alteration of protein expression levels in this matrix is a marked phenomenon of neuropsychiatric disorders including schizophrenia, where cognitive functions are impaired. To query the genetic predisposition of the genes expressed in the PSD with schizophrenia, a family-based association analysis of genetic variants in PSD genes viz; *DLG4, DLG1, PICK1* and *MDM2*, was performed, in Japanese pedigree samples (124 pedigrees, n = 376 subjects). A significant association of the variant rs17203281 in the *DLG4* gene was observed, with preferential transmission of the C allele (p = 0.02), although significance disappeared after correction for multiple testing. However replication analysis of this variant, yielded no association in a Chinese schizophrenia cohort (293 pedigrees, n = 1163 subjects) or in a Japanese case-control sample (n = 4182 subjects). Further the *DLG4* expression levels between postmortem brain samples from schizophrenia patients showed no significant changes from controls. Interestingly, a five marker haplotype in *DLG4*, involving rs2242449, rs17203281, rs390200, rs222853 and rs222837, was enriched in a population specific manner, where the sequences A-C-C-C-A and G-C-C-C-A accumulated in Japanese (p = 0.0009) and Chinese (p = 0.0007) schizophrenia pedigree samples, respectively. None of the variants in other examined candidate genes showed any significant association in these samples. The present study highlights a putative role for *DLG4* in schizophrenia pathogenesis, evidenced by haplotype association, and warrants further dense screening for variants within these haplotypes.

1421W

MGluR gene network alterations confer risk for Autism Spectrum Disorder in 22q11.2 Deletion Syndrome. *T.L. Wenger[1, 2, 3], C. Kao[2], D.M. McDonald-McGinn[1], A. Bailey[1], R.T. Schultz[3], B.S. Emanuel[1], B.E. Morrow[4], E.H. Zackai[1], H. Hakonarson[2].* 1) Division of Human Genetics and Molecular Biology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Translational Genetics, Albert Einstein College of Medicine, Bronx, NY.

Children with 22q11.2 Deletion Syndrome (22q11.2 DS) are at elevated risk for Autism Spectrum Disorder (ASD), with 20% of individuals receiving a diagnosis. The medical and psychiatric manifestations of 22q11.2 DS are quite variable between individuals, despite most having involvement of the same 3 Mb region encompassing ~45 genes. Genetic modifiers for the risk of ASD in 22q11.2 DS as well as all other forms of syndromic ASD are poorly understood. We previously showed that copy number variants in the metabotropic glutamate receptor (mGluR) network are associated with an elevated risk of syndromic ASD and are uncommon in typically developing children. We hypothesized that alterations in the mGluR network outside of the deleted region may provide a ‘second hit’, conferring greater risk for development of ASD. The purpose of this study was to determine whether alterations in the mGluR network outside of 22q11.2 are associated with an increased risk of ASD in children with 22q11.2 DS. METHODS: DNA from 75 children with 22q11.2 DS were selected, including children with clinical diagnosis of ASD (n=25) and without ASD (n=50). High density microarray and custom gene chip were used to determine whether children had copy number variants in genes in the mGluR network, including those in the canonical pathway and the mGluR interactome. RESULTS: Among children with 22q11.2 DS, 20% of those with ASD had an alteration in an mGluR network gene, compared with 2% (1/50) of those without ASD. (p= 0.014) DISCUSSION: Approximately 20% of cases of ASD occur in the context of another genetic syndrome. We previously demonstrated alterations in the mGluR network are enriched in children with many forms of syndromic ASD. All individuals with classic 22q11.2 DS are missing one copy of RANBP1, an mGluR network gene located within the deleted region. Decreased expression of RANBP1 is also found following prenatal exposure to thalidomide and valproic acid, which are both associated with increased risk of ASD. While all individuals have one missing copy of RANBP1, the rate of ASD in 22q11.2 DS is only 20%, similar to the rate in younger siblings of children with ASD. This suggests that additional factors contribute to risk of ASD in 22q11.2. Our data suggest that CNV alterations in the mGluR network may be one important factor in determining which children with 22q11.2 DS will develop ASD.

Autism spectrum disorder (ASD) is a complex developmental syndrome of unknown etiology. De novo loss of function mutations, detected by exome sequencing, have recently led to the identification of nine high-confidence ASD genes (hcASD). Working on the hypothesis that these pleiotropic genes must disrupt shared biological processes to result in a common phenotype, we have attempted to identify brain regions and developmental periods at which they converge. We have constructed co-expression networks around these hcASD ‘seed’ genes, leveraging a rich expression dataset encompassing multiple human brain regions across the lifespan. By assessing enrichment of a second, independent set of ASD genes within spatio-temporally defined subsets of this data, we demonstrate convergence in mid fetal layer 5/6 cortical projection neurons. The approach provides critical information on when, where and in what cell types specific mutations in specific genes may be most productively modeled to further clarify ASD biology.

Schizophrenia (SC) and bipolar disorder (BP) are two complex disorders where the inheritance pattern is likely to be complicated by epigenetic factors yet to be elucidated. Using next-generation sequencing, we quantitatively compared the DNA methylation landscapes of SC and BP to normal controls using blood samples (N=10) and two brain regions, Brodmann area (BA)9 and BA24 (N=36), from the Latino population, the largest minority group in the U.S. We first identified the substantial differentially methylated regions (DMR) in SC and BP. The DMRs identified from the peripheral blood samples preferentially occurred at gene regions with specific features, including promoters, 3'-UTRs, and 5'-UTRs. In particular, we identified distinct patterns of promoter aberrant methylation around transcription start sites, where aberrant methylation occurred not only on CpG-islands (CGIs), but also on flanking regions and CGI sparse promoters. To our surprise, different brain regions showed completely distinct distributions of DMRs across the genomes. In the BA9 region of both SC and BP, we observed widespread hypomethylation, in comparison to normal controls, preferentially targeting the terminal ends of chromosomes. In contrast, in the BA24 region, both SC and BP displayed extensive gain of methylation. Notably, in the two brain regions of SC and BP, only a few DMRs overlapped with promoters, whereas, a greater proportion occurred across introns and intergenic regions. Pathway analysis highlighted that many pathways relevant to psychiatric disorders were associated with DMRs located at introns. Transcriptomic analysis revealed consistent dysfunctional pathways with those determined by DMRs. Furthermore, DMRs in the same brain regions of SC and BP could distinguish BP and/or SC from normal controls while differentially expressed genes could not. The results from the brain regions support a major role of brain region-dependent aberrant DNA methylation in the pathogenesis of the disorders. Pathway analysis of genes with distinct promoter aberrant methylated patterns identified in the peripheral blood samples showed a significant enrichment of epigenetic changes in biological pathways directly relevant to psychotic disorders and neurodevelopment. This comprehensive methylome-map from peripheral blood and postmortem brain provide the precise genomic locations that undergo methylation changes and further our understanding of epigenetic regulation in the etiology of SC and BP.

Neuronal cellular models of 22q11.2 DS exhibit disruptions to the miRNA regulatory pathway and may increase the rate of schizophrenia in individuals with 22q11.2 DS. *W. Manley[1], M.R. Ababon[2], M.P. Moreau[3], P.G. Matteson[2], J.H. Millonig[2], L.M. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway, New Jersey 08854-8095, USA; 2) Center for Advanced Biotechnology and Medicine, Piscataway, NJ 08854, USA; 3) RUCDR, Rutgers University, Piscataway, New Jersey 08854-8095, USA.

Schizophrenia is a complex and poorly understood disease caused by the interplay of many environmental and genetic factors. The 22q11.2 deletion syndrome is a disorder that is caused by the microdeletion of part of chromosome 22 leading to a 25-fold greater chance of developing schizophrenia in affected individuals versus the general population. The missing 22q11.2 region contains the DGCR8 gene, which is required for the initial step of miRNA biogenesis. However, the 22q11.2 deletion itself is not sufficient to cause schizophrenia, since 75% of individuals with this deletion do not develop the disease. We hypothesize that the 22q11.2 deletion increases the risk of schizophrenia through alterations in miRNA regulatory networks via depletion of multiple miRNAs. These miRNAs may serve as a protective buffer against the accumulation of deleterious mutations at other schizophrenia risk loci. We have profiled miRNAs in multiple cell lines from individuals with 22q11.2 that are haploinsufficient for DGCR8. Additionally, we have also developed neuronal human cellular models of disruptions to the miRNA regulatory network caused as a result of DGCR8 deficiency. The neuroblastoma cell line SH-SY5Y was transfected via electroporation with GIPZ lentiviral shRNAmir constructs specific for DGCR8 (Open Biosystems). The GIPZ constructs were prepared using PureYield Plasmid MaxiPrep System (Promega) and sequenced (GeneWiz) prior to use. For selection purposes, all constructs contained genes for GFP and puromycin resistance. The levels of DGCR8 gene expression was quantified using the 7900HT Fast Real-Time PCR System (Applied Biosystems) along with Taqman Gene Expression Assays to ensure DGCR8 reduction. We have characterized disruptions to the miRNA regulatory network in these DGCR8 deficient cell lines using Taqman Array Human Microarray Cards Version 3.0. Here we will present the miRNAs that we have identified to be differentially expressed in DGCR8 deficient cells. We predict that these miRNAs found to be differentially expressed could be involved in the elevated risk of developing schizophrenia in individuals with 22q11.2 deletion syndrome versus the general population. We have also performed RNA-seq using Illumina TruSeq protocols to characterize differences at the RNA level between DGCR8 deficient cells and otherwise healthy control cells. Future studies will focus on determining the biological targets of these miRNAs using miRNA target prediction software.

1425T

A case of monozygotic female triplets diagnosed with autism: comprehensive genomic analyses. *Z. Talebizadeh, S. Soden, A. Gadashova.* Pediatrics, Children's Mercy Hospital, Kansas City, MO.

Twin study design is a classical approach commonly used in many genetic studies; in particular, it may enhance the power of conventional strategies for detecting genetic causes of complex disorders. Autism is a common early onset neurodevelopmental disorder belonging to a group of conditions known as autism spectrum disorders (ASDs). Although there is strong evidence for genetic involvement in susceptibility to ASD, the etiology of most cases remains unknown. We present a case of female triplets diagnosed with autism, and discuss results of their genomic data analyses, including genome-wide copy number variations (CNVs) and expression profiling. No pathogenic CNVs were detected in the triplets' peripheral blood samples. Genome-wide microRNA and exon array profiling were performed, and compared with three unaffected females as controls, to examine the potential abnormalities at the noncoding or alternative splicing levels. The exon arrays were analyzed at both exon and gene levels. One hundred thirty five genes showed differential exon expression in the triplets, compared with controls. By correlating expression levels of microRNAs with their predicted target mRNA(s), differential expression was detected in 51 genes (i.e., inversely correlated with microRNAs). Pathway analysis using the 135 potentially alternatively spliced genes and the 51 genes obtained from microRNAs and mRNAs correlation showed enrichment in biologically relevant pathways. All three female triplets had skewed patterns of X chromosome inactivation. The absence of pathogenic CNVs along with microRNAs and alternative splicing profiles and X inactivation skeweness highlights the potential role of epigenetic factors in this case of female triplets with autism. Family history showed evidences of a maternal familial diabetes and overweight, which is in agreement with the recent report of the association between maternal obesity and autism. This comprehensive case report demonstrates the value of utilizing rare triplet cases with autism to further delineate the underlying mechanism of this complex disorder. Despite growing interest in utilizing twins in genetic and epigenetic studies, triplets and higher-order multiples have been rarely included in these studies. Our study demonstrates that while triplets are less common than twins, they present a valuable and potentially stronger resource for understanding the underlying genetic and epigenetic factors in autism.

Does Presymptomatic testing changes Age at ONset : a prospective study in Huntington disease (PAON study). *A. Durr[1,2,3,4,5], S. Tezenas du Montcel[2], MF. Jutras[3], C. Jauffret[1,3], S. Benaich[1,3], A. Herson[1], J. Feingold[1], M. Gargiulo[1].* 1) APHP Genetic Department, Groupe Hospitalier Pitié-Salpêtrière Charles-Foix, Paris France Paris, France; 2) AP-HP, Groupe Hospitalier Pitié-Salpêtrière Charles-Foix, Department of Biostatistics and Medical Informatics, Paris, France; 3) ICM (Brain and Spine Institute), Groupe Hospitalier Pitié-Salpêtrière Charles-Foix, Paris France; 4) Inserm, UMR_S975, CRICM, F-75013, Paris, France , Groupe Hospitalier Pitié-Salpêtrière Charles-Foix, Paris France; 5) UPMC Univ Paris 06, UMR_S975, F-75013, Paris, France.

In PAON, we studied prospectively the impact of presymptomatic testing (PT) on the onset of symptoms in Huntington disease (HD). The goal of our study was to estimate a possible test-effect on age at onset in carriers of the mutation who choose to know their genetic status. Does knowledge about being a carrier of the pathological mutation changes age at onset or onset modalities? In Paris, at the Salpêtriere University Hospital - Genetic Department, 1634 at-risk persons for HD requested genetic testing since 1992 and entered multistep and multidisciplinary care and counseling. We went back to those who received a test result before 2009, in order that their age at examination was reaching the mean expected onset of 40 years. Among them, 463 were non carriers and 302 carriers of an abnormal expanded CAG repeat. Detailed follow up examination was available for 208 individuals (69%). We interviewed and examined additional 62 persons (PAON cohort), using a self-administered questionnaires (to explore their carrier condition) and the UHDRS evaluation score. We estimated age at onset with the Langbehn formula (personal communication of Doug Langbehn and Clin Genet. 2004 Apr;65(4):267–77). Among the PAON cohort, there were 35 affected with UHDRS >5 (mean 18.3 +/– 11.9) and 27 unaffected (mean 2.9 +/– 1.8). Surprisingly, age at onset observed was 6.0 +/– 8.7 years earlier than onset calculated. Among those followed more regularly, 60 were affected (mean 26.1 +/– 18.3) and had ages at onset 5.2 +/– 7.2 years earlier than calculated. This did not differ significantly from a retrospective cohort of patients who did not have PT (n=522) where age at onset was 3.6 +/- 9.6 years earlier (p= 0.13 and p= 0.12, respectively). In conclusion, onset observed in a prospective cohort was earlier than that estimated based on CAG repeat length and age. This could be due to 1) a greater self-observance and a rising burden after PT, but the comparison with onset in patients without PT was not significant; 2) the fact, that the Langbehn formula underestimates onset. Importantly, for carriers of the mutation, knowledge about the genetic status after PT does not allow better awareness of the onset. Affected carriers did not always acknowledge symptoms related to the disease (44%) and unaffected carriers did feel affected (18.5%). A subjective anticipation (self-observation) of the onset was observed for both, affected (96%) and unaffected carriers (70%).

1427W

Genome-wide expression changes in a higher state of consciousness. *M. Ravnik-Glavac[1], S. Hrasovec[1], J. Bon[2], J. Dreo[2], D. Glavac[1].* 1) Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia; 2) Department of Neurology, University Medical Centre, Ljubljana, Slovenia.

Higher states of consciousness in which the human mind can transcend the boundaries of logic and reason are envisioned as natural to the experience and potential growth of every human being. So far they have been mostly monitored by electrophysiological methods. In this study we were particularly interested in discovering the molecular transcriptional basis of higher states of consciousness. In addition to phenomenological reports of meditators who participated in this study the generated higher states of consciousness were also EEG recorded. We assessed the whole genome gene expression analysis of long-term meditators in four separate trials and detected significant differential gene expression in association with higher states of consciousness. The number of differently expressed genes as well as high proportion of genes themselves differed between meditators. Despite this, gene ontology enrichment analysis found significant biological and molecular processes shared among meditators' higher state of consciousness.

1428T

Differences in gene expression and DNA methylation in drug-naïve first-episode psychosis patients. *V.K. Ota[1], C.S. Noto[2], A. Gadelha[2], M.L. Santoro[1], B.B. Ortiz[2], R.S. Stilhano[3], E.S. Gouvea[4], P.N. Silva[1,2], C.G. Olmos[4], L.M.N. Spindola[1], E.H.S. Andrade[2], M.I. Melaragno[1], M.A.C. Smith[1], S.W. Han[3], Q. Cordeiro[4], R.A. Bressan[2], S.I. Belangero[1,2].* 1) Morphology and Genetics, UNIFESP, Sao Paulo, Brazil; 2) Psychiatry, UNIFESP, Sao Paulo, Brazil; 3) Interdisciplinary Center for Gene Therapy, UNIFESP, Sao Paulo, Brazil; 4) Psychiatry, ISCMSP, Sao Paulo, Brazil.

Schizophrenia is a severe mental health disorder with a high heritability. The study of gene expression levels in blood of patients in the beginning of the disease, such as first-episode of psychosis (FEP) may be useful to detect changes in gene expression despite treatment effects. In this study we aimed to analyze gene expression in whole blood, comparing: a) drug-naïve FEP patients and healthy subjects; and b) drug-naïve FEP patients before and after treatment with antipsychotic drugs. Also, we investigated if those differentially expressed genes were regulated by DNA methylation. All the patients (n = 38) were evaluated by a trained psychiatrist, twice (at admission and 8 weeks after beginning antipsychotic treatment), and the healthy controls (n = 38) were also evaluated to exclude any psychiatric disorder. Whole blood was collected from each participant during clinical assessments. Expression levels of 40 genes related to neurotransmission and neurodevelopment were quantified with a customized RT2 Profiler™ PCR Array, which is based on SYBR Green detection of cDNA amplification. For methylation analysis, bisulfite sequencing was performed. For data analysis, we compared $2^{-\Delta}$Ct or DNA methylation percentage values using t-test (FEP patients x healthy controls) or paired t-test (before x after treatment). Significant downregulation of *GCH1* gene was observed (Fold regulation (FR)= −1.34, p=0.007) comparing FEP and controls. Downregulation of *GABRR2* (FR = −1.33, p=0.01) and upregulation of *GCHFR* (FR = 1.18, p=0.008) were found in FEP after treatment. Also, a significant hypermethylation in *GCH1* was detected in FEP comparing to healthy controls (p=0.034). *GCH1* codes for GTP cyclohydrolase I, an enzyme involved in the synthesis of BH4, which is an essential cofactor for tyrosine, serotonin and L-Dopa. Moreover, its expression is regulated by GCHFR, which seemed to be upregulated after treatment with antipsychotic drugs. Also, GABRR2, which is a GABA receptor, seems to be dysregulated after treatment. Therefore, *GCH1* may have a role in the genesis of psychosis whereas *GABRR2* and *GCHFR* may be related to the treatment leading towards a better understanding of illness. Funding for this study was provided by FAPESP 2010/19176-3; 2010/08968-6 and 2011/50740-5.

Investigating the role of the Histidine Decarboxylase Gene in Tourette Syndrome etiology. *I. Karagiannidis[1], H. Potamianou[1], G. Heiman[2,3], L. Deng[2,3], J. Xing[2,3], N. Sun[2,3], C. Nasello[2,3], P. Sandor[4], C. Barr[4], P. Paschou[1].* 1) Molecular Biology & Genetics, Democritus University of Thrace, Alexandroupoli, Greece; 2) Department of Genetics, Rutgers University, Piscataway, NJ, USA; 3) Human Genetics Institute of New Jersey, Piscataway, NJ, USA; 4) 4-Toronto Western Research Institute, University Health Network, Toronto, Ontario, Canada.

Gilles de la Tourette Syndrome (TS) is a childhood onset neurodevelopmental disorder with complex genetic background that manifests as multiple motor and vocal tics and high comorbidity rates with other neurodevelopmental disorders. While previous studies suggest that genetic and environmental factors contribute to the etiology of the disorder, its pathophysiology remains largely unknown. Recent studies report the possible implication of the histamine decarboxylase (HDC) gene, which is the key enzyme in histamine production, suggesting histaminergic dysfunction may play a role in the etiology of TS (Ercan-Sencicek et al., NEJM 2010; Fernandez TV et al., Biol Psychiatry 2012). We recently investigated variation across the HDC gene for association with TS by interrogating 12 tagging SNPs (tSNP) across the region in a large sample of 520nuclear families originating from seven European populations as well as Canada. Strong over-transmission of alleles at two SNPs (rs854150 and rs1894236) in the joint dataset was observed, as well as statistically significant associated haplotypes (Karagiannidis et al., J Med Genetics 2013).Using a subset of these samples, we sequenced the complete HDC gene in 384 individuals with TS using NextGen high-throughput sequencing technology and validation by Sanger sequencing. Our results may help elucidate the role and relative contribution of this pathway in TS etiology and will facilitate the study of the HDC gene in different populations of European ancestry.

1430W

Identification of target genes for the language-related FOXP2 and its isoform. *T. Ohta[1], N. Niikawa[1], T. Oikawa[2].* 1) Res Inst, Personal Hlth Sci, Hlth Sci Univ Hokkaido, Tobetsu, Japan; 2) Dept Comm Dis, Sch Psychol Sci, Hlth Sci Univ Hokkaido, Sapporo, Japan.

FOXP2 is the first key gene involved in the development of human languages. FOXP2 protein is a highly conserved transcription factor in any animals. Only two amino acids are different between human and chimpanzee FOXP2 proteins, and this difference was supposed to be associated with neuron development for language skill between the two species. Previous study demonstrated that the *FOXP2* gene was expressed not only in neuronal cells but also in multiple tissues. The aim of the present study is to identify genes targeted by FOXP2. We first generated various transgenes (Tg) in hek293-derived cells, using the flip-in recombinase system for the gene integration at the identical chromosome region and the Tet-ON/OFF systems to minimize transfection artifacts. The Tg included human *FOXP2* (Hum), a human *FOXP2* isoform (Iso), chimpanzee *Foxp2* (Chimp), or a negative control (CAT). This Iso was encoded by an alternative transcript with the complete open reading frame for a human FOXP2 with extra 25 amino acids, and was confirmed to be expressed in multiple human adult tissues, such as heart, brain, placenta, lung, liver, skeletal muscle, kidney and pancreas, but not in any mouse tissues. We analyzed expression of the *FOXP2* from the transgenes (*FOXP2*-Tg) in Tet-ON or in Tet-OFF cells. The expression of *FOXP2*-Tg in each Tet-ON cells was higher than in Tet-OFF cells, and *FOXP2*-Tg in Tet-ON cells were 5-10 times more highly expressed than that in CAT. Using these cell lines, we performed microarray screening to pick up altered expression pattern among these 8 groups. Then, we confirmed the expression pattern again in GOTO cells, which is inducible into glial cells and neuronal cells, with stable and random integration of each Tg, using real time PCR. Consequently, results of the microarray analysis and real time PCR suggested several candidate target genes: *CRYAB*, GABA receptor genes, *UBE3A*, *GFRA* and *EDNRB*. The *CRYAB* gene was upregulated in all Tet-ON cells, and the gene was more highly expressed in Hum and Chimp Tet-ON than the CAT Tet-ON cells. Similar expression patterns were confirmed with Tg in GOTO cells. Interestingly, genes for some GABA receptors and the *UBE3A* gene were observed to be downregulated, while glial cell related genes, *GFRA* and *EDNRB* were upregulated in hek293 derived cells and in GOTO cells containing Hum Tg and Iso Tg. These affected genes could contribute to the human language development.

1431W

Reference-free quality assessment and complexity estimation of next-generation sequencing data. *S.Y. Anvar[1,2], L. Khachatryan[1], M. Vermaat[1,3], M. van Galen[1], I. Pulyakhina[1], Y. Ariyurek[2], K. Kraaijeveld[2,4], P.A.C. 't Hoen[1], J.T. den Dunnen[1,2], P. de Knijff[1], J.F.J. Laros[1,2,3].* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Leiden Genome Technology Center, Leiden University Medical Center, Leiden, Netherlands; 3) Netherlands Bioinformatics Center, Nijmegen, Netherlands; 4) University of Applied Sciences, Leiden, Netherlands.

Current methodologies for determining the quality and complexity of next-generation sequencing (NGS) data heavily rely on alignment-based quality measures. However, reference genomes are not always available and genomic information about complex regions of the genome such as large duplications or structural rearrangements are likely to be overlooked by alignment-dependent approaches. To address these limitations, we have developed a new methodology (kMer) that is independent of a reference sequence in determining the quality of NGS data and allows for pairwise comparison across a series of samples. kMer provides various tools to systematically and dynamically assess the NGS data after generating k-mer profiles. In addition, kMer provides a framework to estimate the complexity of the sequence library as well as estimating if the sample is sequenced in sufficient depth. We have applied kMer on four sets of NGS data that consist of 59 targeted resequencing, 43 whole-exomes, 49 full-genomes, and 665 RNA-Seq samples. In each set, kMer could precisely detect and separate samples based on various technical variations that were introduced during sample prep or sequencing such as high duplication rate, low capture performance, differing capture protocols, and high amount of library chimaeras. Notably, some of the aforementioned artefacts could only be characterised after vigorous quality assessments and have otherwise been missed by standard NGS QC tools. These often hidden artefacts undermine the potential application of NGS in clinical diagnostics as they may result in obscured downstream analysis. In addition, we show that kMer allows for estimating the complexity of NGS data, a vital property of NGS in diverse studies ranging from de novo assembly applications to detection of a shift in abundance in a series of microbiomes. In particular, we show that the complexity of NGS data is reflected on the distribution of k-mer profiles, with the resolution of separating differing exome capture kits, as full-genome, whole-exome, and RNA-Seq NGS data exhibit distinctive profiles with differing complexity. The various techniques that constitute this new paradigm allow for robust evaluation of the quality and complexity of NGS data and reliable and unsupervised view of genomic information.

1432T

RNA-seq reveals increased expression of other Osteogenesis Imperfecta (OI)-causing genes in diaphyseal bone from the *Col1a2*$^{p.G610C}$ mouse model of OI. *U.M. Ayturk[1, 2], C.M. Jacobsen[3, 4], A.G. Robling[5], M.L. Warman[1, 2, 6].* 1) Department of Orthopaedic Surgery, Boston Children's Hospital, Boston, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Division of Endocrinology, Boston Children's Hospital, Boston, MA; 4) Division of Genetics, Boston Children's Hospital, Boston, MA; 5) Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN; 6) Howard Hughes Medical Institue, Boston, MA.

Osteogenesis Imperfecta (OI) is a disease characterized by increased skeletal fragility. Most patients with OI have defects in the synthesis of type I collagen caused by mutations in either *COL1A1* or *COL1A2*, which encode the α1(I) and α2(I). collagen chains. We developed an RNA-sequencing (RNA-seq) method for mouse diaphyseal bone and used this method to identify differences in gene expression between wild-type mice and mice with a p.G610C missense mutation in *Col1a*2 that models human type IV OI. Tibia diaphyseal bones from 12-week-old male wild-type and *Col1a2*$^{p.G610C/+}$ mice (3 mice/genotype, 2 tibiae/mouse), were used to create individual bar coded libraries. We obtained ~14 million RNA-seq reads per library. We then compared the RNA-seq data between OI and WT mice. We identified 21 genes whose expression was significantly increased by more than 2-fold in diaphyseal bone from the *Col1a2*$^{p.G610C/+}$ mice compared to wild-type mice. Interestingly, 5 of these genes (*Serpinf1, Serpinh1, Smpd3, Bmp1* and *Ifitm5*) have also been found to cause OI when mutated. Eight other differentially expressed genes (*Bglap, Bglap2, Id3, Ptprs, Cdkn1a, Creb3l1, Itga10* and *Col13a1*) have skeletal phenotypes when mutated in mice. The other differentially expressed genes (*Rcn3, Vasn, Nupr1, Olfml3, Metrnl, Cacnb3* and *Slc22a17*) have not yet been studied with respect to their roles in the skeleton. These data suggest that RNA-seq in mouse models of OI can identify differentially expressed genes that are also likely to have important roles in the development and/or maintenance of the skeleton.

1433F

SoftSearch: a tool to identify genomic structural variations from paired-end Illumina reads. *S. Baheti, S.N. Hart, V. Sarangi, R. Moore, J.D. Bhavsar, JP. Kocher.* Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN.

Genomic structural variation (SV) represents a significant, yet poorly understood contribution to an individual's genetic makeup. Advanced next-generation sequencing technologies are widely used to discover such variations, but there is no single SV detection algorithm that is considered a community standard. In response to this challenge, we developed a memory-efficient algorithm called SoftSearch, for discovering genomic rearrangements in Illumina paired-end next-generation sequencing data. SoftSearch simultaneously utilizes multiple strategies for detecting SV including split-read, discordant read-pair, and unmated pairs. Split-reads and read pairs that are co-localized and supporting the same directionality are used to refine the breakpoints and classify them according to their type, e.g. large insertions-deletions, inversions, duplications and balanced or unbalanced inter-chromosomal translocations. SoftSearch outputs predicted structural variants in universally accepted VCF format. After extensive comparisons we attempted to recall known structural variants that have previously been validated in the HapMap NA12878 sample. SoftSearch recalled the most true positive results (n=660), 4 times more variants than BreakDancer (n= 165). DELLY identified a comparable number of variants (n=654) variants, while CREST had the fewest (n=505). CREST and DELLY took the most amount of time to complete with more than 230 and 194 hours, respectively. The memory usage was also highest with these tools (5.2, and 7.1GB, respectively). BreakDancer was faster and used less memory requiring 48 hours and 1.5GB memory. Strikingly, SoftSearch completed the analysis in less than 20 hours using only 0.7GB memory. Only a small number of soft-masked bases from split reads and a few discordant read-pairs are necessary to identify an SV, which on their own would not be sufficient to make an SV call. Key features of SoftSearch are 1) not requiring secondary (or exhaustive primary) alignment, 2) portability into established sequencing workflows, and 3) is applicable to any DNA-sequencing experiment (e.g. whole genome, exome, custom capture, etc.). We show that SoftSearch can identify more true SVs with less evidence, including clinically relevant SVs in the BRCA2 gene missed by other SV tools while offering significantly improved overall performance.

1434W

Thousand Genomes And HLA Typing By NGS: Hidden Treasures In Public Short Read Data. *A. Berces[1], E. Major[1], K. Rigo[1], S. Juhos[1], T. Hague[1], P. Gourraud[2].* 1) Omixon Biocomputing, Budapest, Hungary; 2) University of California, San Francisco, US.

One of the important goals of the 1000 Genomes project was to find common mutation in diverse populations with the help of next generation sequencing. Earlier, the HapMap project with similar goals made it possible not only to map frequent mutations but there are already publications about sequencing based HLA typing using NGS. We are presenting a sufficiently fast algorithm using 1KG Illumina data to obtain HLA types for HLA-A, B, C, DRB1 and DQB1 genes. For validation the results of Sanger capillary sequencing based HLA typing was used for over thousand Coriell samples. According to our results it is possible to determine the correct HLA types from public 1KG whole-exome Illumina data with 90% or higher concordance if proper quality check measures are applied. We are also presenting the possible causes of mistypings. The method opens perspectives for typing other systems like MICA, MICB and KIR.

1435T

A consolidated genotype quality control reporting pipeline. *J. Boston, Y. Bradford, J. Haines, W. Bush.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Quality control is a critical part of any genetic analysis and must be performed in a reproducible, well-documented, and interactive way. To improve the throughput and reliability of this QC process, we developed a Clojure-based pipeline for generating quality control reports and plots in a systematic fashion. From a command-line interface, analysts submit data files to a centralized server and specify options for QC procedures. These include typical operations such as sex concordance, genotype call rate, sample efficiency, allele frequency distributions, Hardy-Weinberg tests, identity by descent calculations for relatedness, sample concordance checks, and tests for Mendelian inconsistencies. QC jobs are submitted to a scheduled computing cluster through portable batch system (PBS) scripts. Once completed, results from all operations are compiled into a single report of relevant information, complete with appropriate plots, eliminating the possibility of data transcription (through cut and paste operations) or other data processing errors. Because genotype QC is an iterative process, changes to the filtering process can be made after examining patterns in the original report, simply by reissuing the PBS script with new parameter settings. As such, the entire QC process is much more standardized and less prone to error. This consolidated workflow also improves and facilitates communication between analysts, study designers, and technicians about QC-related issues through a standardized report with multiple visualizations. While the pipeline was implemented for processing of genome-wide association data, the application is also applicable to next-generation sequence data.

1436F

Variome-based identification of Crohn's disease predisposition. *Y. Bromberg.* Biochemistry and Microbiology, Rutgers University, New Brunswick, NJ., USA.

Crohn's disease (CD) is an auto-inflammatory disorder and one of the main subtypes of inflammatory bowel disease. CD affects over half a million people in North America alone. Tens of thousands of new CD cases are diagnosed every year, mostly in young adults in their twenties and early thirties. Human and animal models of CD illustrate strong familial patterns of disease predisposition, suggesting interplay of genetic and/or environmental causes. Recent GWA studies highlight key CD pathogenic pathways, but the discovered susceptibility loci account for less than 25% of disease heritability. Rather than the result of a single very severe malfunction, most Crohn's manifestations are thus likely due to 'unlucky' summations of many variants of individually small functional effects, as is the case with many other complex diseases. We have started building VariAD (Variome Analysis of Disease) - a novel computational tool for annotating an individual's CD disease predisposition on the basis of a combination of genome variants (individual variome). Disease associated variants often act by disrupting the sequence and the molecular functionality of the affected gene-product. Our method assumes that a genome-specific set of functionally significant coding single nucleotide polymorphisms (cSNPs) in CD genes is sufficient to describe an individual's CD susceptibility. We collected an expanded set of CD genes by mining scientific literature for phenotypic descriptors of CD. We annotate the 'broken-ness' of extracted disease genes based on their corresponding variants, taking into account the specific locus genotypes. The genome-specific combination of affected disease-genes drives the prototype CD prognosis engine. This research represents a unique way of looking at the variation in a single human genome, informed by molecular mechanisms of disease and achieves over 75% accuracy of prediction on the two data sets tested (122 case/control individuals). VariAD will motivate new testable hypothesis regarding the biological mechanisms of CD and provide a means for earlier prognosis, diagnosis and development of better treatments.

Clinical exome quality assurance through comprehensive coverage analysis improves the utility of exome sequencing. *C.J. Buhay[1], Q. Wang[1], M. Wang[1], Y. Han[1], H. Dinh[1], H. Doddapaneni[1], Y. Yang[2], Y. Ding[2], M. Bainbridge[1], E. Boerwinkle[1], J. Reid[1], D. Muzny[1], R. Gibbs[1].* 1) Baylor College of Medicine - Human Genome Sequencing Center, Houston, TX; 2) Baylor College of Medicine - Whole Genome Sequencing Laboratory, Houston, TX.

It is important for whole exome sequencing in a clinical setting to continually increase probability of diagnosis and improve clinical utility. Comprehensive coverage improvements of clinical exomes occur in three phases: annotation of targets of interest in the exome, automatic detection of inadequately covered exons, and development of methods to rescue clinically significant low coverage regions. To better characterize coverage across one popular whole exome design (VCRome2.1), targeted gene regions across 34 clinical exome samples were scrutinized. We focused on the performance of relevant diagnostic genes across the HGMD, Genetest, and COSMIC lists. Results show that >90%; of genes in the list have a base-depth coverage of 20X or better in our clinical samples. Leveraging the coverage tools developed in the process, we have implemented the Exome Coverage and Identification (ExCID) Report in our research pipeline. This workflow assesses exome coverage, annotates target regions with gene and exon coverage depth, as well as reports inadequately (<20X) covered exonic regions for every exome coming through the production pipeline. This tool allows investigators to efficiently assess performance across regions of interest. As part of a pilot project in the DNAnexus cloud platform, we are aggregating coverage plots from >5000 whole exome samples from our production pipeline. The implications of analyses at this scale are twofold: unsurpassed granularity of aggregate base coverage that leads to precise targeting and rescue of inadequately covered bases.

1438T

Tumorgraft DNASeq and RNASeq analysis. *J. Calley[1], R. Higgs[2], P. Ebert[1], T. Barber[1].* 1) Tailored Therapeutics, Lilly Research Labs, Indianapolis, IN; 2) Discovery Statistics, Lilly Research Labs, Indianapolis, IN.

Development of appropriate models for evaluation of novel oncology therapeutics remains a difficult challenge for drug development. While initial evaluation of potential therapeutics is largely carried out in monocultures of a particular cell line in vitro, xenograft/tumorgraft models implanted either subcutaneously or orthotopically are believed to provide a more realistic evaluation of the ability of the therapeutic to perform in vivo. Knowledge of the mutation status of the tumor tissue being studied is a critical component of the evaluation of efficacy in many models/histologies, particularly when the therapeutic is targeted toward a specific signaling molecule (i.e. EGFR). Determination of the mutation status of tumorgrafts cultured in mice presents unique challenges compared with either pure cell lines or primary tumors derived from humans due to mixture of the tumor DNA with mouse DNA from stromal tissue, as well as lack of a matching normal sample for 'subtraction' of germline variants. We have developed methods designed to mitigate the impact of mouse stromal DNA/RNA contamination, while potentially also allowing investigation of the unique function of the stroma in a given model.

1439F

Pathogenicity prediction of genomic variants using the gene-level frequency of variation in asymptomatic individuals. *C.A. Cassa[1], D.M. Jordan[2], M.S. Lebo[3], S.R. Sunyaev[1].* 1) Division of Genetics, Harvard Medical School/Brigham and Women's Hospital, Boston, MA; 2) Program in Biophysics, Harvard University, Cambridge, MA; 3) Lab for Molecular Medicine, Partners Center for Personalized Genetic Medicine, Cambridge, MA.

The clinical importance of novel genomic variation is often characterized using in silico techniques, which rely on the exclusion of common variation or inclusion of variants with deleterious effects predicted using evolutionary and functional considerations[1, 2]. We extend these techniques by considering the expected variation in each gene in asymptomatic individuals to predict the robustness of each gene to variation. Genes vary greatly in the number of missense and nonsense variants present in asymptomatic individuals, which provides important context about selective pressure and significance of new variants that are observed. Using data from asymptomatic individuals in the Exome Sequencing Project (N=6503), we calculate the expected numbers of heterozygous, homozygous rare, and compound heterozygous variants in each gene. We then used these data to rank-order genes, for different variant types (missense, nonsense) and minor allele frequency bins, across two populations. We then use these expected numbers of variants per gene to annotate a known list of variants that have pathogenicity classifications from a clinical genetics laboratory (Lab for Molecular Medicine). We use these variants to train a general pathogenicity classifier, using the random forest method with 10 trees and 5 attributes per tree (out of 24 total attributes)[3]. We trained and tested this classifier using 10-fold cross validation on missense variants that were classified as either pathogenic, likely pathogenic, likely benign or benign (N=3,373). The cross-validated accuracy of the classifier is over 90%, when predicting either the benign or pathogenic classes. This demonstrates that the gene-based expected variation has a high predictive value of pathogenicity. We have tested this method in additional independent datasets with similar results. We are attempting to improve these predictions using additional variant and gene-level metadata and other variant-based in silico predictive techniques, such as PolyPhen and SIFT. These findings indicate that the background variation in asymptomatic individuals has high predictive value for variant pathogenicity assessment. This technique may be used to prioritize and filter observed variants for further review by researchers or clinical geneticists. This is one of the most urgent needs in clinical genomic interpretation[4] as a number of clinical labs[5-7] and direct-to-consumer groups[8] are providing WGS interpretation.

1440W

Estimation of Isoform-specific and Allele-specific Expression from RNA-seq Data of Genetically Diverse Population. *K. Choi, N. Raghupathy, S.C. Munger, D.M. Gatti, G.A. Churchill.* Gary Churchill's group, The Jackson Laboratory, Bar Harbor, ME.

The Diversity Outbred (DO) mouse population is a new heterogeneous stock derived from the same eight inbred founder strains as the Collaborative Cross (CC) recombinant inbred strains. The DO mice have uniformly high levels of heterozygosity and genetic diversity, and thus provide a high-resolution mapping resource for identifying key genetic factors underlying complex traits and disease. Further, application of RNA-seq technology to the DO is adding an unprecedented resolution to our understanding of the transcriptome, generating valuable information about alternative splicing, allele-specific expression, RNA editing, noncoding RNAs, and strain-specific structural variation. Caution is warranted however, as the integrity of all downstream analyses depends on robust read alignment and quantitation methods.

Numerous RNA-seq analysis methods are publicly available, however they are not well-suited for aligning and quantifying gene expression in highly heterogeneous populations like the DO. Most existing tools rapidly align reads against a single reference genome or transcriptome, and then summarize the alignment results into expression abundance. But, as each DO is a unique animal with a large number of SNPs and indels, this generally-accepted strategy of aligning to a common reference genome is often error-prone. Quantitation of allele specific expression is particularly problematic as misalignment due to unaccounted strain variation is common and skew estimates in many cases.

We present a flexible statistical model for estimating haplotype-specific expression abundance in genetically diverse populations like F2, DO, or even more complex crosses. Our method incorporates both alignments to the custom founder strain genomes and external genotype probability into a hierarchical Bayesian framework. Our approach also takes into account the population-level expression abundance and allele frequency to improve quantitation at the level of individual sample. Our model offers a unique opportunity to study sequencing data from genetically diverse populations, delivering a balanced summary of expression abundance as well as allele specificity by combining the estimates of individual samples and the population as a whole.

1441T

Web-based tools to support the clinical genetics lab. *D.M. Church[1], L. Kalman[2], V. Ananiev[1], N. Bouk[1], C. Chen[1], A. Doubintchik[1], M. Halavi[1], M. Landrum[1], P. Meric[1], L. Phan[1], D. Shao[1], D. Slotta[1], J. Trow[1], M. Ward[1], D.R. Maglott[1].* 1) NIH/NLM/NCBI, Bethesda, MD; 2) CDC, Atlanta, GA.

Many clinical laboratories that once relied on Sanger based sequencing are migrating to new high-throughput and low cost sequencing technologies. While these new sequencing technologies promise improved efficiencies for genetic testing, the approach introduces new challenges for laboratories that must be addressed. The analytical validity of sequencing based approaches is of concern to clinical laboratories. It is clear that variant calling concordance rates vary between technologies and analytical pipelines. As laboratories develop and validate new tests, it is critical to provide resources that allow them to assess the false positive and the false negative rate of their tests. To facilitate this we have collected data from numerous clinical and research testing laboratories that have analyzed two publicly available human genomes, NA12878 and NA19240 based on alignment to GRCh37. In addition to collecting variant calls, we gathered details about the experimental protocols as well as the sequence evidence used to determine the variants. This data is available and can be compared to user data on a publicly available genomic browser (http://www.ncbi.nlm.nih.gov/variation/tools/get-rm). Another area of concern involves the interpretation of called variants. As laboratories move to exome and genome testing, the number of variants to be assessed can quickly become overwhelming. To address this need we have developed the Variation Reporter (http://www.ncbi.nlm.nih.gov/variation/tools/reporter). This tool allows users to upload their own variant calls and receive a report that integrates information known to databases maintained at NCBI such as dbSNP, dbVar and ClinVar. Lastly, the management of reference sequences can be a challenge because there are differences in the version of the reference assembly used by laboratories for analysis. Additionally, even when laboratories compute variation using the current reference assembly, they often wish to report variation on a RefSeqGene/LRG sequence or on a transcript or protein sequence. Using the NCBI Remap tool (http://www.ncbi.nlm.nih.gov/genome/tools/remap) users can map features from one coordinate system to another. We anticipate that this tool will be especially important with the upcoming reference assembly update (GRCh38).

1442F

Project Mercury: provenance and repeatability through encapsulation of experiments and experiment software. *N.A. Clarke, M. Pollard, I. Colgiu, J. Randall.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom.

It has been widely observed that, since at least the start of the century, the cost of genome sequencing has been decreasing following an exponential curve. Assuming this trend continues, the next ten years could see the cost of sequencing drop below the expected costs for storage and, potentially, for processing of the generated data. Even should we fall off the curve, we are already at the stage where access to storage and compute can form an impediment to carrying out experiments. Current operational and cost models which treat sequencing as expensive whilst largely ignoring storage and computation will prove inadequate to dealing with the increasing volume of data being produced. Independently, with more and more of an experiment taking place in software, there is a growing need to be able to accurately monitor and control the computation taking place. Where particular versions of software may have meaningful effects on an experiment's outcome, we would like to be able to capture the full processing stack: understanding how results are produced and being able to package a means of producing them for storage or publication. In contrast to Stein[1], who proposes cloud computing as the solution to the increasing volume of sequence data, we argue that this situation calls for a new operating model incorporating full knowledge of sequence, storage and compute costs. Alongside this, we will need to develop tools capable of using such a model to intelligently manage sequencing data. Such a system will require greater introspection of the computation involved in running analyses of genetic data, and as such we gain the ability to capture the steps with which to replicate our results. Project Mercury is a system under construction at the Sanger Institute to encapsulate our analysis pipelines in such a controlled and introspected environment. Through capturing various metrics (CPU hours, memory, IO, external resources) as well as recording the steps involved in an analysis we are able to quantify the cost of generating a dataset, and to transparently replicate the experiment at another time or place. This ability to replicate analyses allows our system to trade-off between storage, compute and sequencing. We discuss the design and implementation of Mercury, as well as our initial experiences using it in human genetics pipelines. [1] Lincoln D Stein: The case for cloud computing in genome informatics Genome Biology 2010, 11:207.

1443W

Refining quality control for detection of rare structural variants with SNP arrays: presenting the 'plumbCNV' R Package with an application to Type I Diabetes. *N.J. Cooper, J.A. Todd.* Medical Genetics, Diabetes and Inflammation Laboratory, Cambridge, UK.

Detection of rare copy number variants (CNVs) is increasingly seen as an important step towards understanding genetic influences on human disease. It has been shown that comprehensive quality control for Log-R-Ratio (LRR) intensity data is required to reduce the high false positive rate for rare CNV detection (Shtir et al, 2013). Such a pipeline should include examination of LRR distributions for problematic samples, followed by LRR-based principal component analysis (PCA) correction of batch effects. Once CNVs are called, additional tests should be applied to filter the set of CNVs detected. 'plumbCNV' is presented as an R package that automates these procedures. The code is open source, and scalable to deal efficiently with very large datasets exceeding system memory limits. Parameters are highly customisable and diagnostic plots and tables are produced throughout to allow the researcher to remain in control of the filters and thresholds being applied. This scripted pipeline provides a robust and necessary prerequisite for detection of rare CNVs using SNP arrays. Further assessment of CNV association with disease and phenotypes can therefore be readily and reliably conducted without using CGH or dedicated CNV arrays. The procedure is demonstrated with a comparison of rare CNV rates and characteristics between 6,292 Type I diabetes and 8,332 Healthy samples.

The Transition to Clinical NGS: How Well Do You Know Your Sequencing Pipeline? *D. Corsmeier[1], B. Kelly[1], P. White[1,2].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) The Ohio State University, Columbus, OH.

As next generation sequencing technologies are rapidly adopted in clinical genetics settings, higher expectations must be placed on the bioinformatics pipelines used to transform hundreds of gigabytes of raw read data into the few lines of meaningful genetic variation that is useful to the clinician. Reducing these data by several orders of magnitude is a complex process rife with the capacity for error and inadvertent deviation from a best practices approach. Notwithstanding these potential pitfalls, even if secondary analysis is performed correctly using accepted methods, parallelization and downsampling techniques can introduce nondeterminism in the resulting variant call set. This brings into question the utility of a given computational approach in a clinical setting.

Churchill, our fully automated pipeline for secondary analysis, uses one of the most popular software combinations: the Burrows-Wheeler Aligner (BWA) for short read sequence alignment together with the Genome Analysis ToolKit (GATK) for variant calling and genotyping. Using novel parallelization approaches, we have overcome the computational bottleneck created by the exponential growth in the generation of genomic sequencing data, reducing analysis time from weeks to hours. In developing an algorithm so innovative in performance and efficiency, the validation of results is a necessity and the final hurdle towards potential clinical utility.

Commited to the repeatability of test results based on discrete digitized genomic data, we investigated three pipelines that use the BWA/GATK combination for secondary analysis: Churchill, GATK Queue, and HugeSEQ. Somewhat surprisingly, we discovered that nondeterminism can be introduced at virtually every step in the analysis if configuration parameters are not carefully selected. Of the analysis approaches tested, only Churchill preserved determinism while adhering to best practices, regardless of the level of parallelization. Further, we demonstrate that Churchill's speed and precision do not come at the expense of quality of the output variant call set.

1445F

Overcoming genetic heterogeneity in rare Mendelian disease gene discovery: an improved network analysis approach. *N. Dand[1], F. Sprengel[2], V. Ahlers[2], M.A. Simpson[1], R. Schulz[1], R.J. Oakey[1], T. Schlitt[1,3,4].* 1) Department of Medical and Molecular Genetics, King's College London, United Kingdom; 2) Department of Computer Science, University of Applied Sciences and Arts Hannover, Germany; 3) Institute for Mathematical and Molecular Biomedicine, King's College London, United Kingdom; 4) Novartis Institutes for BioMedical Research (NIBR), Basel, Switzerland.

In the past few years a number of groups have undertaken exome-sequencing studies and successfully identified genes responsible for rare Mendelian diseases, typically by sequencing a small number of unrelated patients and identifying shared genetic variants after filtering out those less likely to be causal. However, this strategy is not always successful and in particular can be limited by genetic heterogeneity, where a variant in any of several genes is sufficient to cause the same disease (for example due to shared functionality). We recently presented BioGranat-IG, a software tool which addresses this problem using gene or protein networks. BioGranat-IG identifies parsimonious, highly connected components in the network, each containing variants (after filtering) for all (or most) patients. We hypothesised that these components correspond to likely disease-causing protein complexes and/or pathways. We demonstrated the validity of our method using simulated data for two rare Mendelian diseases known to have a genetically heterogeneous cause.

Since publication of this work, application to real disease data has highlighted three main areas where further improvement is possible: (i) large and highly polymorphic genes tend to be over-represented in proposed pathways; (ii) 'hub' genes, which are highly-connected in the network, also tend to be over-represented, and (iii) the correct filtering criteria for input gene lists are unclear. In the present work, we develop an entirely different algorithmic approach, using a score-based network prioritization method which removes the need for variant filtering, but retains the information from individual patients. Instead of simulating data, we use randomly rearranged exome sequence data generated at the KCL GSTT Biomedical Research Centre along with variant information obtained from the Online Mendelian Inheritance in Man (OMIM) database to generate realistic estimates of the power and type-I error for our new approach. We show significant improvement over the performance of the original BioGranat-IG tool, and propose that our new approach provides an efficient way to identify genetic mechanisms which, when disrupted, can result in disease.

1446W

SG-ADVISER tools: de-identification, identification and visual analytics of SG-ADVISER data. *G. Erikson, P. Pham, W. Shipman, A. Torkamani.* Scripps Translational Science Institute, La Jolla, CA.

Following variant annotation, a major task in genome interpretation is the identification and prioritization of relevant variants. Scripps Genome Annotation and Distributed Variant Interpretation Server (SG-ADVISER) is a web-server developed at The Scripps Translational Science Institute for the annotation of genetic variant data. To facilitate the interpretation of the SG-ADVISER output, we have developed two additional tools: SG-ADVISER UI and the SG-ADVISER Deidentification tool. The SG-ADVISER UI is a visualization tool that allows scientists with little or no programming experience to easily and quickly view, manipulate, sort, and filter the SG-ADVISER output file. A variety of custom and advanced filters allow filtering based on any combination of sample and annotation information. For example, it is possible to sort or filter on Coding Variants, Novel Variants, Cancer Genes or Chromosome Position etc. At any point during the process, the tool can provide summary statistics, and output the filtered results to a new file. The tool is written in Java and uses multi-threaded architecture and paginated view to make data analysis of large files (3GB+) possible on a desktop computer. To protect one's privacy we created SG-ADVISER Deidentificator, which is a tool that extracts the genotype(s) from the VCF files and implants clinically associated variants into the list of transmitted variants. For the clinically associated variants we used the Flagged SNPs 132 table from the UCSC Genome Browser. Identificator strips the clinically associated variants previously implanted and imports the genotype(s) back into SG-ADVISER annotated file. Both tools are cross-platform compatible and can be downloaded from the website: genomics.scripps.edu/ADVISER. This web portal can also be used for uploading de-identified data to the SG-ADVISER pipeline for annotation.

1447T

Novel set of bioinformatics tools for performing distributed down-stream data analysis in very large GWAS and NGS projects.
L. Eronen, T. Kanninen, P. Sevon. Biocomputing platforms Ltd, Helsinki, Finland.

The amount of data produced in large GWAS or NGS studies today can be measured in Terabytes. Complex data analyses, like imputing and down-stream analysis of imputed data as well as NGS data alignment and variation calling takes considerable amount of CPU time and may become a research bottleneck.

For many analysis tasks performance can be increased by data level parallelization: distributing data analyses by genomic regions, subjects and phenotypes. However, limited bandwidth between the database and external calculation resources, saturation of the disk system and task of dividing data set to smaller segments significantly limit the performance gains from distributed analysis. On the other hand, there's often a lot of manual work involved in setting up a massively parallel run.

BC|TOOLS is a software suite intended to reduce this overhead. Key components of the suite are a set of command line tools for submitting and managing distributed workflows, a workflow engine that can utilize different kinds of calculation resources (local servers, different calculation clusters or cloud), a set of file format converters that are applied automatically to make output of one analysis tool compatible with the next tool, and a set of split and merge tools for parallelizing the workload and merging results from subjobs. The system provides an API that enables easy integration of new tools.

To facilitate the massively parallel analysis of very large data sets we have developed a compressed virtual file system (BCFS), where massive data files are partitioned into tiles of manageable size, each covering only a subset of the genome, subjects and/or traits. All data files required during analyses are stored to BCFS, providing unified access to data from all calculation nodes. Physical storage may be distributed; e.g. imputation results can be stored as tiles on disks near the computation resources, while storing all clinical data on a local workstation.

In this presentation we evaluate feasibility and performance of BC|TOOLS by performing a distributed analysis workflow of a dataset with 100,000 subjects, consisting of imputation and association analysis of the imputed data in a cloud environment.

A Bayesian hierarchical model to detect differentially methylated loci from single nucleotide resolution sequencing data.
H. Feng[1,2], K.N. Conneely[1], H. Wu[2]. 1) Department of Human Genetics, School of Medicine, Emory University, Atlanta, GA 30322, U.S.A; 2) Department of Biostatistics and Bioinformatics, Rollins School of Public Health, Emory University, Atlanta, GA 30322, U.S.A.

DNA methylation is an important epigenetic modification that has essential roles in cellular processes including genome regulation, development, and disease, and is widely dysregulated in most types of cancer. Recent advances in sequencing technology have enabled the measurement of DNA methylation at single nucleotide resolution through methods such as whole-genome bisulfite sequencing and reduced representation bisulfite sequencing. In sequencing studies of DNA methylation, a key task is to identify methylation differences under distinct biological contexts, for example, in comparisons of tumor vs. normal tissue. A common challenge in these studies is that the number of biological replicates in each comparison group is limited due to the high costs of sequencing experiments. The small number of replicates leads to unstable estimation of within-group variation, which can reduce accuracy to detect differentially methylated loci (DML). The variance shrinkage method has been widely applied to alleviate this type of problem since the microarray days. However, the nucleotide resolution DNA methylation data are discrete and are typically modeled by distributions where the variances are dependent on means. This brings some technical difficulties to variance shrinkage. Here we propose a novel statistical method to detect DML when comparing two treatment groups in studies of nucleotide resolution DNA methylation data. The sequencing counts data are described by a lognormal-beta-binomial hierarchical model, which provides a basis for information sharing across different CpG sites. This model can be used to obtain empirical Bayes shrinkage estimates of the within-group variances, which are then plugged into a Wald test procedure for DML detection. We show through simulation that the proposed method provides greater power to detect true DML compared to existing methods, particularly when the number of replicates is very low. The proposed method has been implemented in freely available Bioconductor package DSS.

VAAST+ VSQR: making effective use of INDELs in disease-gene searches.
S. Flygare[1], B. Kennedy[1], C. Huff[2], M. Reese[3], L.B. Jorde[1], M. Yandell[1]. 1) Human Genetics, University of Utah, Salt Lake City, UT; 2) MD Anderson Cancer Center, University of Texas, Houston, Texas; 3) Omicia, Inc., Emeryville, California 94608, USA.

The Variant Annotation Analysis and Search Tool - VAAST - is a widely used tool for discovering disease-causing variants in personal genome data (Yandell et al., 2011). VAAST was used to discover a new human disease using next-generation sequencing data (Rope et al., 2011). Most recently, VAAST was used to identify the cause of Sturge-Weber Syndrome (Shirley et al., 2013). Despite its power, VAAST (and every search tool) is limited by the quality of its input data. Here we describe a new version of VAAST that addresses this problem. It works by employing VQSLOD scores provided by the GATK Variant Quality Score Recalibration procedure. We show that employing VQSLOD scores within VAAST results in a 30% increase in VAAST's power to identify disease-causing mutations, particularly disease-causing indels. VAAST is thus a powerful search tool that can effectively use indels in disease-gene searches. We have also developed a second quality measure that extends the VQSLOD approach to allow identification of what is termed 'induced false positives'. These induced false positives result from reads containing real, but rare, variants that drive the read's alignment to an incorrect region of the genome, producing falsely induced variants with misleading high VQSLOD scores. Preliminary results indicate that these scores used alone improve VAAST's power by 50%, compared to the 30% improvement seen with VQSLOD scores. Work is underway to integrate both quality scores into the VAAST algorithm, and even greater improvements are expected. As we will demonstrate, these new augmentations to VAAST make it an effective tool for identification of disease-causing variants using even the noisiest indel calls.

1450T

Sherlock: A Comprehensive Approach to Discovering Gene-Disease Associations in GWAS Using eQTL.
C. Fuller[1], X. He[2], H. Li[1]. 1) Department of Biochemistry and Biophysics, University of California at San Francisco, San Francisco, CA 94143, USA; 2) Lane Center of Computational Biology, Carnegie Mellon University, Pittsburgh, PA 15213, USA.

The genetic mapping of complex disease has traditionally relied on the identification of variations that perturb either the function or expression of nearby genes. A strong body of evidence suggests that many distal (i.e. trans-acting) loci influence gene expression, but such associations are typically ignored in the standard gene-disease association paradigm. Moreover, large numbers of potentially informative associations from genome wide association studies (GWAS) are discarded when filtering for only genome-wide levels of significance. We recently introduced a Bayesian method and online service (Sherlock) that addresses both of these issues by matching association patterns between GWAS and expression quantitative trait loci (eQTL) to implicate genes that cannot be identified by GWAS alone. Here, we present an alternate statistical test that uses the empirical distribution of GWAS p-values to identify disease genes from a panel of eQTL data sets. This new approach permits a robust comparison of association patterns without assumed priors and in the presence of the systematic inflation that is common in real-world GWAS. We discuss the results from a matrix of tests spanning a dozen diseases and numerous eQTL tissue types. We identify candidate disease genes that replicate across different input GWAS and eQTL data sets. Importantly, we note instances of correlated regulation among trans-acting loci: the risk alleles for the set of SNPs that implicate a given gene all push its expression in the same direction. In isolation, GWAS tend to generate large numbers of low-to-moderate effect loci, often poorly annotated and lacking any obvious functional consequence. Our method permits robust mapping of these loci to more functionally informative genes, providing a gain in both mechanistic insight and statistical power over the GWAS results alone. The approach is broadly applicable and could easily incorporate other molecular associations, such as metabolites, non-coding RNAs, and epigenetic modifications. It represents a straightforward means of mining both current and future data repositories (e.g. the NIH Genotype-Tissue Expression initiative) to inform research that is starved for insight amidst a sea of data.

Screening genome variants for disruption of regulatory activity with ZoomReG: capture, sequencing and computational identification of regulatory variants. *T. Gaasterland[1,2], L.E. Edsall[2,3], A.N. Dubinsky[4], R. Chappel[5], P. Ordoukhanian[5], S.R. Head[5], The NEIGHBOR Consortium.* 1) Institute for Genomic Medicine, University of California San Diego, La Jolla, CA; 2) Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA; 3) Ludwig Institute for Cancer Research, University of California San Diego, La Jolla, CA; 4) Department of Pediatrics, University of California San Diego, La Jolla, CA; 5) Next Generation Sequencing Core Facility, The Scripps Research Institute, La Jolla, CA.

Purpose: To detect, validate, and rank genome variants likely to disrupt regulatory activity, including microRNA control of protein expression, RNA-binding protein (RBP) control of alternative splicing, and DNA-binding protein (DBP) influences. Background: Genome-wide sequencing identifies many variants in untranslated regions (UTR), near intron/exon splice junctions, and near gene structures. Efficient computational screens and low false positive rates are imperative for complete interpretation of the impact in individuals or disease cohorts. Methods and Results: Genome variants with potential to alter regulatory activity are screened through three computational modules comprising the ZoomReG process. ZoomReG was applied to 420 exomes sequenced with protocols optimized for reliable near-target capture. Collectively, over 7M chromosome sites were observed as variant in the 420 exomes with 93 pct present in 1000 Genomes. Results showed ZoomReG returned known regulatory variants and ranked them reliably for degree of disruption. ZoomReG applies its ZoomMiR module to determine which UTR and coding region variants are contained within potential seed sites for microRNA::mRNA binding. ZoomReG uses the prior HOMER algorithm and a database of RBP motifs to determine whether variants overlap RBP motifs. It uses HOMER to evaluate whether SNPs overlap DNA-binding motifs and ENCODE DNase-sensitive regions. ZoomReG focuses on 50 bases upstream and downstream of each variant site and returns a disruption score that reflects whether binding centers on the site. E.g., a microRNA disruption prediction requires a SNP to appear in a satisfactory 'seed'. RBP binding is enhanced by tandem binding site motifs (e.g., YCAYCAY is stronger for Nova binding than YCAY). For RBP site disruption, SNPs in single motif matches have greater weight than in tandem matches. For a 3'UTR SNP shown in earlier work (NEIGHBOR GWAS of primary open angle glaucoma (POAG)) as associated with optic neuropathy, ZoomMiR in ZoomReG predicted a novel seed site disruption by the minor allele, validated through luciferase assay. Conclusion: ZoomReG provides critical screening functionality to identify genome variants that disrupt microRNA, RBP and DBP binding sites. Its ZoomMiR module revealed a molecular mechanism for a risk-associated SNP found in the NEIGHBOR POAG GWAS demonstrating this functionality is critical for complete genome sequence interpretation.

W4CSEQ -- a web server to process enzyme-based and sonication-based 4C-Seq data. *F. Gao[1,2], W. Lu[1], K. Wang[2].* 1) Eli and Edythe Broad Center for Regenerative Medicine and Stem Cell Research, Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA 90089, USA; 2) Zilkha Neurogenetic Institute, Department of Psychiatry and Department of Preventive Medicine, University of Southern California, Los Angeles, CA 90089, USA.

Circular chromosome conformation capture, when coupled with next-generation sequencing (4C-Seq), can be used to identify genome-wide interaction of a given locus with all of its interacting partners. Both restriction enzyme digestion and sonication methods can be used to fragment cross-linked chromatin for proximity-based ligation. We recently applied 4C-Seq to characterize the interactome of an enhancer element of Pou5f1 gene in pluripotent stem cells. We compared replicate consistency as well as similarity of 4C-Seq data generated by both enzyme-based and sonication-based fragmentation methods. In general, we found good correlation ($r>0.6$) for inter-chromosomal interactions identified by both methods when comparing biological replicate data. However, sonication generated less distal intra-chromosomal interactions compared to enzyme-based method. As note, data generated by both methods showed correlation with DNA early replication timing and enrichment of active histone marks in the enhancer interactomes. In addition, the interacting sites identified from sonication-based data are enriched with ChIP-Seq signals of transcription factors Oct4, Klf4, Esrrb, Tcfcp2i1 and Zfx that are key regulators for reprogramming and pluripotency. We found both methods are valuable tools for exploring long-range chromosomal interactions. To help bench scientists with minimal NGS experience to utilize 4C-Seq technique in the research, we have integrated our bioinformatics pipelines into a web-based server that can automatically process 4C-Seq raw data (FASTQ format) generated by a high-throughput Illumina sequencer, such as HiSeq 2000. This web server (w4cseq.usc.edu) automatically takes user specified input file(s), performs read mapping to the selected reference genome (currently only human and mouse genomes are included), calculates statistically significant interacting genomic regions, and generates relevant plots for illustration. For an input FASTQ file containing 10 million reads, the user is expected to receive the result in one day.

Multi-genome analysis improves individual genome annotation and powers disease elucidation. *G. Glusman, A.F.A. Smit, J.C. Roach, L. Rowen, D.E. Mauldin, R. Hubley, H. Li, H.C. Cox, A.B. Stittrich, S. Ament, J. Caballero, E. Bone, M. Brunkow, R. Gelinas, L. Hood.* Institute for Systems Biology, Seattle, WA.

Current genome annotation pipelines frequently yield misleading results due to sequencing technology-specific biases, errors in the reference genome and other causes. Here we introduce a suite of tools for 'multi-genome analysis' that improve the identification and interpretation of genomic variants in the context of disease. The Family Genomics group (familygenomics.systemsbiology.net) at the Institute for Systems Biology has undertaken multiple collaborative projects related to understanding the genetic basis of disease, with special emphasis on neurodegeneration. We currently have high quality whole-genome sequence (WGS) data from 1,000 individuals, produced by Complete Genomics, and funded by the University of Luxembourg (wwwen.uni.lu/lcsb). We analyze the data using custom workflows and the Ingenuity Variant Analysis platform (www.ingenuity.com/variants). Our collective WGS dataset serves as a superb resource for modeling systematic failures and biases in the technology. Use of multi-genome models improves our ability to analyze each individual genome, leading to fewer false positive and false negative findings. Simultaneous coverage analysis of several hundred genomes enables detailed normalization of the coverage profiles of individual genomes. This enables precise analysis of CNVs and the identification of large deletions that were previously undetectable. Some of the deletions we discovered explain the observed pattern of disease inheritance in the families we are studying. When analyzing personal genomes, certain genes frequently show up as mutated. We identified a set of >30,000 genomic segments significantly enriched in detrimental rare variants. Fine-grained annotation of these problematic regions leads to fewer spurious findings ~ a particular concern in clinical settings. We compiled genome-wide maps of regions prone to accumulating 'no call' failures and Mendelian and state consistency inheritance errors, to displaying extreme heterozygosity, and to being identified as 'identical by descent' among unrelated individuals. We make available several resources for improving the quality of personal genome analyses, individually and in the context of family pedigrees. The resulting improvements to sensitivity and specificity are crucial for achieving clinical-grade genome interpretation.

PhaseLift: a novel procedure to save time in imputing study genotypes.
M.M. Gorski[1,2], T.W. Winkler[1], K. Stark[1], M. Müller-Nurasyid[3,4,5], J.S. Ried[3], B.H. Weber[6], I.M. Heid[1,3]. 1) Department of Epidemiology and Preventive Medicine, Medical University Center Regensburg, Regensburg, Bayern, GermanyDepartment of Genetic Epidemiology, Institute of Epidemiology and Preventive Medicine, University of Regensburg, Regensburg, Germany; 2) Department of Internal Medicine II, University Medical Center Regensburg, Regensburg, Germany; 3) Institute of Genetic Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany; 4) Department of Medicine I, University Hospital Groβhadern, Ludwig-Maximilians University, Munich, Germany; 5) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Epidemiology and Chair of Genetic Epidemiology, Ludwig-Maximilians-University of Munich, Munich, Germany; 6) Institute of Human Genetics, University of Regensburg, Regensburg, Germany.

Genome-wide association (GWAs) studies usually apply imputation techniques to complement genome-wide SNP chip genotypes. The recent genotype imputation methods separate phasing from imputing. This allows for updating the imputation when a new reference panel is released without repeating the phasing step. When the study data is on an older genome build than the reference data, the current lift-over procedure is to harmonize on the genotype-level (pre-phasing lift-over) with consecutive re-phasing and re-imputing which does not fully utilize the advantage of the current two-step imputation method. We propose a novel lift-over procedure that phases genotypes on the original build and harmonizes the study haplotypes with the reference data (post-phasing lift-over; implemented in the software PhaseLift). This avoids re-phasing of study data when switching to a new reference panel. We use the KORA study (1,644 unrelated individuals) to compare imputed SNPs based on the 500K Affymetrix GWA array with additionally typed variants from the Illumina Cardio-Metabochip. To contrast the performance of both procedures, we imputed the GWA SNPs with both procedures and compare the estimated allele dosages with the additionally typed genotypes. We found that both approaches perform equally well with mean concordances of 93% and 93.4%. To see if one procedure yields higher imputation qualities (RSQs), we computed the difference of RSQs imputed by both procedures and found little difference (mean diff= 0.007, sd = 0.079). To investigate, whether the difference depends on minor allele frequency (MAF), we categorized the SNPs by low, medium and high MAF and again observed small differences (for MAF $\leq$ 0.05; 0.05 < MAF $\leq$ 0.2; MAF > 0.2: mean = 0.006, 0.008, 0.001; sd = 0.084, 0.051, 0.065). To examine, if the difference depends on RSQ, we compared SNPs imputed by both procedures, categorized by RSQ. We found that a comparable number of SNPs is poorly (RSQ $\leq$ 0.3: 78.75%, 78.78%), medium well (0.3 $\leq$ RSQ $\leq$ 0.8: 9.99%, 9.97%) and well imputed (RSQ > 0.8: 11.26%, 11.25%) in the pre- and post-phasing procedure, respectively. By using our new procedure you can save nearly 2 months of parallel computing on an 8 core-cluster, when re-imputing 3 times with the 1000G GIANT ALL reference panel. We demonstrate that our proposed post-phasing lift-over approach might encourage study partners to quickly accommodate updated reference builds to improve the information content of their data.

CIDRSeqSuite 4.0: A Toolbox for Next-Generation Sequencing Workflow Development. *S.M.L Griffith, D. Leary, J.D. Newcomer, K. Hetrick, M. Barnhart, K. Roberts, B. Marosy, B. Craig, D. Mohr, M. Zilka, A. Robinson, J. Goldstein, L. Watkins, K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDRSeqSuite is a set of software tools that has been used to aid in next-generation sequence analysis at CIDR since 2009. A core feature of CIDRSeqSuite is a set of sequencing analysis workflows. These workflows have evolved to keep pace with changes to the predominant sequencing analysis tools used by the community, and similarly the choice of underlying technologies used in the implementation of these tools has evolved to keep pace with the larger number of analyses that must be done in parallel and in a fault-tolerant fashion. The initial workflow implemented for CIDRSeqSuite was designed to run on a single large server; samples were processed a few at a time in a single process. The current version of CIDRSeqSuite, however, focuses on individual tasks and the interdependencies among them. When an analysis is submitted to the CIDRSeqSuite server, all required tasks and their interdependencies are stored in a relational database. Such tasks include alignment, variant annotation, and even the demultiplexing of an individual tile from a flowcell lane. Tasks are submitted by the server process to an SGE-enabled cluster of over 25 nodes. As each task finishes, its status is stored in the database; any tasks whose dependencies are complete are then submitted themselves. Should a task fail to complete, it is immediately resubmitted to the compute cluster; if the number of allowable retries for a given task is exceeded, an email notification is sent to lab and informatics personnel to aid in troubleshooting. Notifications are also sent when analyses finish so that the data generated can be reviewed. Tasks can be submitted to the compute cluster via command line tools or a graphical user interface. Advantages to this distributed task-based approach include considerably faster demultiplexing: processing time is reduced from 6-8 hours to 30 minutes per flowcell. In addition to providing the apparatus for workflow development and execution, CIDRSeqSuite also encompasses several other tools including the generation of various QC reports, concordance reports (both between sets of sequencing data and between sequencing and genotyping data), and stand-alone paired-end and single-end demultiplexers.

Aneuploidy and normal cell contamination aware approach to detect copy number variations in cancer using next generation sequencing data. *R. Gupta, S. Katragadda, D. Vyavahare, K. Sandhu, V. Veeramachaneni, R. Hariharan.* Strand Life Sciences, 5th Floor, Kirloskar Business Park, Bellary Road, Hebbal Bangalore - 560024, Karnataka, India.

Background and Objectives: Recent growth in next generation sequencing (NGS) data has enabled us to detect copy number variation (CNV) at an unprecedented resolution. The objective of this study is two-fold: 1) Identify the CNV regions in the cancer genome and assign absolute copy number (CN); and 2) Compare CNV regions from different patients to identify regions that are commonly amplified or deleted, there by highlighting genes implicated in cancer. **Challenges:** Several technical and biological challenges inhibit the discovery of true segments and assignment of absolute CNs. In Particular, biological challenges include 1) Aneuploidy of cancer cells but many approaches assume diploid genome; 2) Contamination by normal and stromal cells compresses all signals towards CN state of 2; and 3) Heterogeneity in tumor cells i.e. there may be polyclonal tumors with in a tumor with each clone having different CNVs. **Methods:** Most of the approaches for detecting CNVs using NGS data are based on 1) read depth; 2) distance/orientation of read pairs; and 3) split reads. We used a method based on read depth and first compute the log-ratio of read depth in cancer and normal samples for fixed length windows, followed by Wavelet transformation of ratios to reduce the effect of random noise. An EM algorithm based probabilistic Gaussian mixture model is then built to model different CN states, and biological parameters of the sample, average ploidy and % normal cell contamination, are estimated. Finally, we used two segmentation approaches on the ploidy and contamination corrected log-ratio to obtain segments and corresponding CNs. First is naïve and heuristic approach, which quickly identifies gain/loss regions without quantifying the degree of gain or loss; and 2) popular CBS approach, which can distinguish different gain (or loss) regions. This CNV detection approach is integrated in Avadis NGS, which is our software tool for the processing and comprehensive end-to-end analysis of NGS data. **Experiments and Results:** We demonstrated the efficacy of the CNV detection approach on both simulated data and publicly available real sequencing data. For simulation set, we simulated log-ratio data to cover different scenarios by varying sample ploidy, % of normal cell contamination, number of CN states, % of data noise, etc. We also used publicly available sequencing data of cancer cell lines and tumor samples from NCBI SRA and construct CN profiles for multiple cancer types.

Assigning KIR Types From NGS Short Read Data. *T. Hague, E. Major, A. Berces, K. Rigo, S. Juhos.* Omixon, Omixon Biocomputing, Budapest, Hungary.

Killer-cell immunoglobulin-like receptors (KIRs) are one of the most polymorphic genes, and besides their sequence diversity there also a high homology among these receptors. This makes KIR typing exceptionally difficult and the picture is even more complex since not all KIR genes are present in an individual and one gene can be present in many copies. As next generation sequencing have spread to most of molecular genetic laboratories, there is a need for a method for KIR typing based on short reads. We are presenting an algorithm to determine the KIR type from NGS samples. The method is capable to predict the copy number of genes and we are also presenting quality check measures to estimate the goodness of typing.

1458W

Estimating exome genotyping accuracy by comparing to data from large scale sequencing projects. *V. Heinrich[1], T. Kamphans[2], J. Stange[3], D. Parkhomchuk[1], J. Hecht[4,5], T. Dickhaus[3], P.N. Robinson[1], P.M. Krawitz[1,5].* 1) Institute for Medical Genetics and Human Genetics, Charité Berlin, Germany; 2) Smart Algos, Berlin, Germany; 3) Department of Mathematics, Humboldt University Berlin, Germany; 4) BCRT, Berlin, Germany; 5) Max Planck Institute for Molecular Genetics, Berlin, Germany.

Next-generation sequencing (NGS) based methods, such as exome analysis, are currently being introduced as a tool for mutation detection into routine diagnostics. This increases the need for platform-independent methods of quality control. To date, quality scores have been used on a base- or genotype-level to indicate the reliability of single base or variant calls. However, the great variety of NGS platforms and analysis pipelines hinders the direct comparison of genotype-specific quality scores between platforms or for entire data sets and currently no criteria exist for assessing the overall quality of an exome. We present a genotype-weighted metric to compare all exome variants identified in a single sample together to an appropriate high-quality reference data set, with which we estimate the exome-wide genotyping accuracy based simply on the reported variants and without any further knowledge about the data generation. Our method represents a new way to evaluate the quality of entire whole-exome sequencing data in addition to current recommendations for sequencing depth and genotype likelihoods. The distance value of our metric corresponds to a quality parameter for an entire exome and allows comparing the quality of multiple exome datasets from the same or different NGS platforms. Based on simulated accuracy groups for variant calls we were able to assess the quality of an exome sample without detailed knowledge about the applied enrichment and sequencing technology or about the bioinformatics pipeline that was used to align the reads and call the genotypes. We envision that our approach to estimate the genotyping accuracy of exomes will facilitate the quality assessment of NGS data.

1459T

Highlander: variant filtering made easier. *R. Helaers, M. Vikkula.* Laboratory of Human Molecular Genetics, de Duve Institute (Université catholique de Louvain), Brussels, Belgium.

The field of human genetics is being revolutionized by exome and genome sequencing. A massive amount of data is being produced at ever-increasing rates. Targeted exome sequencing can be completed in a few days using NGS, allowing for new variant discovery in a matter of weeks. The technology generates considerable numbers of false positives, and the differentiation of sequencing errors from true mutations is not a straightforward task. Moreover, the identification of changes-of-interest from amongst tens of thousands of variants requires annotation drawn from various sources, as well as advanced filtering capabilities. We have developed Highlander, a Java software coupled to a MySQL database, in order to centralize all variant data and annotations from the lab, and to provide powerful filtering tools that are easily accessible to the biologist. Data can be generated by any NGS machine (such as Life Technologies' Solid or Ion Torrent, or Illumina's HiSeq) and most variant callers (such as Life Technologies' LifeScope or Broad Institute's GATK). Variant calls are annotated using DBNSFP and SnpEff, then imported into the database. The Highlander GUI easily allows for complex queries to this database, using shortcuts for certain standard criteria such as 'sample-specific variants', 'variants common to specific samples' or 'combined-heterozygous genes'. Users can then browse through query results using sorting, masking and highlighting of information.

1460F

Comparison of Unified Genotyper and SAMTools as variant callers across 84 exomes. *K. Hetrick II, H. Ling, E. Pugh, S. Griffith, B. Craig, B. Marosy, K. Doheny.* CIDR, Johns Hopkins Univ, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR has been utilizing samtools (v0.1.18) to perform variant calling on exomes (Barnhart, 1693/Poster, ASHG 2011). Calls were made and filtered per individual and then all unique calls within a study were back-genotyped for all samples from the samtools bcf output to create a multi-sample vcf for SNVs. We evaluated the Genome Analysis Toolkit 2 (GATK), to see if the significant advances in the GATK 2 framework (namely the addition of recalibrating indels with Base Call Quality Score Recalibration (BQSR) and creation of Reduced Reads Bams (RR) for analysis) improved variant calls. Briefly, 84 exomes (Agilent® SureSelect™ XT Human All Exon v4, Illumina® HiSeq™ 2000), were aligned with BWA-0.5.10 using the 1000 genomes phase 2 reference genome, duplicate molecules flagged with Picard (v1.74), Local Realignment, BQSR (GATK 2.1-5, 2.1-9) and RR (GATK 2.1-9) to create analysis BAM files. Multi-sample calling and filtering was done with Unified Genotyper (UG) and Variant Quality Score Recalibration (VQSR) (GATK 2.1-9). These calls were then compared to calls made from our existing samtools pipeline. The mean per sample on exon Ti/Tv for known SNVs (dbSNP 129) for both sets was ~3.2 and for novel snps, the Ti/Tv per sample mean was 2.8 for the UG+VQSR calls and 2.1 for the samtools calls. The mean per sample count of exon SNVs was 20,521 (GATK) and 20,628 (samtools). Across 9 trios in the sample set, the on exon per variant site mendel error rate was 3.15% (GATK), 2.79% (samtools). The variant concordance rate between a HapMap replicate was 99.17% (GATK), 98.20% (samtools). Across 3 siblings, the mean non-reference homozygote concordance, percent heterozygote concordance and sensitivity to heterozygote Illumina Exome Array genotypes (GATK,samtools) was 99.77%,99.37%; 99.97%,99.98%; 96.94%,98.10%, respectively. We have phased in a new workflow utilizing the GATK 2 framework which incorporates multi-sample calling/filtering with UG and VQSR and continue to evaluate all components to the NGS analysis pipeline to provide high-quality variants calls for NGS applications.

postMUT: A Statistical Tool for Combining Predictions of Missense Mutation Functionality using Capture-Recapture Methods. *S. Hicks[1], S.E. Plon[2], M. Kimmel[1,3].* 1) Department of Statistics, Rice University, Houston, TX; 2) Departments of Pediatrics and Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Bioengineering, Rice University, Houston, TX.

Computational or *in silico* methods such as SIFT or PolyPhen-2 have been widely used to predict the impact of missense mutations on protein function, but these methods often report conflicting results. This leaves researchers without guidance in how to prioritize the mutations identified for further evaluation. Ad hoc combinations of *in silico* methods (e.g. at least two out of three) to prioritize missense mutations have been suggested, but these decision rules vary between groups and are not based on any statistical models. Other solutions such as 'consensus tools' have been developed based on a weighted average of scores from the individual methods to prioritize missense mutations, but these approaches do not account for the accuracy of each *in silico* method and are also not based on rigorous statistical principles. This work develops two statistical models referred to postMUT and postMUT (simple) which combine the conflicting functional predictions in a statistically rigorous manner. Both models estimate a unified posterior probability of functionality or pathogenicity for each missense mutation based on maximum likelihood estimates of the sensitivity and specificity of each individual *in silico* method in the absence of a gold standard by analyzing the subsets of data on which different algorithms agree or disagree. Our probabilistic approach requires no training set or calibration and is based on a mixture model with the weight parameter representing the overall proportion of deleterious mutations. We test the algorithms using missense mutations with known functional impact on protein function and show improved estimates of sensitivity and specificity using postMUT compared to postMUT (simple) which employs fewer parameters. We apply the postMUT models to estimate the overall proportion of deleterious mutations extracted from matched tumor/normal breast cancer genomes in categories such as normal cells only, tumor cells only, and normal and tumor cells. As the interpretation of missense mutations remains a difficult task, we show our statistical tool is scalable to the exome, provides a unified posterior probability of pathogenicity for individual variants to infer the functionality of missense mutations and can be incorporated in downstream analyses such as disease gene prioritization, ultimately inferring candidate genes. Supported by CPRIT grant RP101089, NCI grant CA155767, NCI T32 training grant CA096520 and NCN (Poland) grant 519579938.

1462T

Improved access to data sets via metadata-driven searches of experimental conditions at the new ENCODE Portal. *E.L. Hong[1], B.C. Hitz[1], E.T. Chan[1], D.T. Erickson[1], N.R. Podduturi[1], G. Roe[1], K. Rosenbloom[2], L.D. Rowe[1], C.A. Sloan[1], J.S. Strattan[1], G. Barber[2], G.A. Binkley[1], J. Garcia[2], D. Karolchik[2], .K. Learned[2], B. Lee[2], S. Miyasato[1], G. Moro[2], M. Simison[1], E. Weiler[2], W.J. Kent[2], J.M. Cherry[1].* 1) Department of Genetics, School of Medicine, Stanford University, Stanford, CA 94305; 2) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA, 95064.

The Encyclopedia of DNA Elements (ENCODE) Project is a collaborative project to create a comprehensive catalog of functional elements in the human and mouse genomes. Now in its 8th year, the ENCODE Project has grown to include additional experimental techniques and genomic elements to survey. All experimental data (using more than 40 different experimental techniques to survey DNA-binding proteins, RNA-binding proteins, the transcriptional landscape, and chromatin structure in 400+ cell lines and tissues) and computational analyses of these data are submitted to the Data Coordination Center (DCC) for validation, tracking, storage, and distribution to community resources and the scientific community. Metadata describing important experimental conditions, such the biological samples, specific reagents, and protocols necessary to replicate the assay, have been expanded and are being submitted to a newly-formed DCC. As the volume of data increases, the identification and organization of data sets becomes challenging. Here, we describe the design principles of how metadata are organized and annotated at the ENCODE DCC in order to facilitate the identification and comparison of data sets generated by the ENCODE project. The organization of the metadata will allow flexible and powerful searches on the revamped ENCODE Portal, the public website of the ENCODE project, as well as support intuitive displays of biological samples, reagents, and protocols used for an experiment. Data from the ENCODE project can be accessed via the ENCODE portal (http://www.encodeproject.-org) and the UCSC Genome Browser (http://genome.ucsc.edu/cgi-bin/hgGateway).

Network analysis on established schizophrenia loci reveals significant genetic overlap with autoimmune and cardiometabolic disease. *L.M. Huckins, E. Zeggini.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The investigation of shared genetic factors underpinning diverse complex traits can aid the identification of common aetiopathology and give insights into shared biological pathways. We have developed a network-based method which searches for potential links between genes based on published GWAS co-citation. In order to investigate a set of association signals, we create a network in which each node represents a gene. Genes are selected on the basis of the position of the index associated variant, for example all genes within a recombination interval or genes residing either side of the signal of interest. We then create an edge between all pairs of genes which have previously been co-cited in a GWAS of any trait, or which have been cited in two separate GWAS for the same trait. We group genes into three categories; those which had been cited with a p-value lower than 10^-4, 10^-6 and 10^-8. This type of analysis is hypothesis-free, using only previous GWAS to define edges between genes. Our initial analysis focused on the database of GWAS associations reported in [1]. We tested the network analysis method on a set of 14 established schizophrenia (SCZ) loci. We computed clustering coefficients and compared these to the coefficients found when generating a million random gene sets of the same size. We found that the SCZ gene set was significantly enriched for genes which had been co-cited in GWAS of other traits at all three significance thresholds ($p=0.00015$ at the 10^{-4} association threshold). We observed overlap (4/14 genes) between GWAS of autoimmune diseases (Crohn's disease, rheumatoid arthritis, multiple sclerosis, amyotrophic lateral sclerosis, and type 1 diabetes) and SCZ. In addition, we also observed overlap between cardiometabolic-related disease GWAS loci (type 2 diabetes, glucose levels, coronary artery disease and hypertension) and SCZ (5/14 genes). Both of these findings reflect well-established epidemiological links; studies have shown a possible autoimmune etiology for schizophrenia and non-affective psychosis [2], as well as indicating a possible shared genetic basis for schizophrenia and T2D[3]. We are extending our analyses to the full NHGRI catalog of published GWAS. [1] AD Johnson, CJ O'Donnell (2009) BMC Med Genet 10:6 [2] WW Eaton et al. (2010) Bipolar. Disord. 12(6): 638-646 [3] P.I LIN, A.R. SHULDINER (2010) Schizophr res 123, no2-3, pp. 234-243.

1464W

SNP discovery in family sequencing datasets using Bayesian networks. *A. Indap, G. Marth.* Biology, Boston College, Chestnut Hill, MA.

Genome wide association studies are well powered to detect SNP variants that segregate at intermediate frequency with modest effect for complex traits. There has been increased interest in discovering rare alleles of large effect to see if these variants can explain the heritability of complex traits. Since rare alleles are potentially enriched in families with multiple affected individuals there has been increased interest in family based sequencing studies. Yet, most variant discovery methods do not explicitly model family relatedness when analyzing data. Here we describe a variant discovery method, Pgmsnp, which models the pedigree relationships and sequencing data as a Bayesian Network (BN). A BN represents the dependencies of the data as a directed acyclic graph. The application of a belief propagation algorithm to compute posterior genotype probabilities on a simulated trio dataset of 1 Mbp shows that per sample detection sensitivities (100-90%) and genotype discrepancies (0–15%) vary as a function of average read coverage (20x-5x), with the offspring sensitivity and accuracy performing the best. Further work is actively being pursued to improve the performance metrics of Pgmsnp and to apply it to different pedigree structures as well as empirical datasets.

1465T

Mapping Diagnostic Test Requisition Data to the Human Phenotype Ontology. *R. James, C. Shaw.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The clinical implementation of sequencing diagnostics encompassing coding regions (i.e., 'whole exome') has great potential to contribute to the diagnosis of human disease. The exome approach is made difficult because of the large number of variants observed in individual patients. Efficient use of available clinical information on patients may improve the curation and prioritization of observed variants. Unfortunately, phenotypic clinical inputs for genetic testing are rarely complete and often do not strictly adhere to a controlled vocabulary. We hypothesized that natural language processing applied to clinical notes, indication forms and/or elements of medical records can standardize and improve indication data. We used these techniques in conjunction with hierarchical semantic relationships of The Human Phenotype Ontology to develop methods for processing indication data. Improved similarity metrics were developed and systematically evaluated via their performance in Monte Carlo simulations of possible feature combinations that may occur in patients being sent for genome wide diagnostics. These methods can be applied to analyze the correspondence between the requisition content and the ultimate diagnosis obtained. We conclude that such approaches are useful to improve the speed and accuracy of exome analysis.

1466F

Multiple Testing Correction method for Linear Mixed Model. *J.W. JOO[1], E. Kostem[2], E. Kang[2], B. Han[3,4], E. Eskin[1,2,5].* 1) Bioinformatics phD program, University of California, Los Angeles, Los Angeles, CA, USA; 2) Computer Science, University of California, Los Angeles, Los Angeles, CA, USA; 3) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 5) Department of Human Genetics, University of California, Los Angeles, CA, USA.

Multiple hypothesis testing is a major issue in genome-wide association studies which often analyze millions SNPs. There are several methods to estimate a per-marker p-value threshold in order to obtain a significant result given multiple markers. The permutation test is widely believed the gold standard for multiple testing correction for traditional association tests and accurately takes into account the correlation structure of the genome unlike the traditional Bonferroni correction. Since the permutation test is computationally very expensive, several alternative methods have been presented to speed up the permutation test. Recently, mixed model association has became a popular approach for genome wide association studies as it can correct for population structure. Population structure complicates association analysis by inducing spurious correlation between genotypes and phenotypes and may cause false positive associations. Unfortunately, permutation is not applicable for mixed models because if we either permute phenotypes or genotypes, the true correlation structure between individuals is eliminated and leads to an inflation of p-values. Theoretically, bootstrapping can be applied to mixed model, however, it is often computationally impractical for large datasets. In this paper, we propose an efficient and accurate multiple testing correction method for linear mixed model, slideLMM. The key idea behind slideLMM is that we utilize the kinship matrix to transform the correlation structure between the variants and then take advantage that the statistics will then follow a multi-variate normal distribution. Utilizing this approach, slideLMM corrects for the population structure to give an accurate per-marker threshold even the individuals have different degrees of relatedness. Applied to a the Hybrid Mouse Diversity Panel(HMDP) which is a mouse association study panel with significant amounts of population structure, our method shows better performance in both speed and accuracy compared to previous methods.

1467W

Filtering for compound heterozygous sequence variants in non-consanguineous pedigrees. *T. Kamphans[1], P. Sabri[1], A. Knaus[1], V. Heinrich[2], P. Krawitz[2], P. Robinson[2].* 1) Smart Algos, Berlin, Germany; 2) Medical Genetics, Charite, Berlin, Germany.

The identification of disease-causing mutations in next-generation sequencing (NGS) data requires efficient filtering techniques. In patients with rare recessive diseases compound heterozygosity of pathogenic mutations is the likeliest inheritance model if the parents are non-consanguineous. We developed a web-based compound heterozygous filter that is suited for data from NGS projects and that is easy to use for non-bioinformaticians. We analyzed the power of compound heterozygous mutation filtering by deriving background distributions for healthy individuals from different ethnicities and studied the effectiveness in trios as well as more complex pedigree structures. While usually more then 30 genes harbor potential compound heterozygotes in single exomes, this number can be markedly reduced with every additional member of the pedigree that is included in the analysis. In a real data set with exomes of four family members, two sisters affected by Mabry syndrome and their healthy parents, the disease-causing gene PIGO, which harbors the pathogenic compound heterozygous variants, could readily be identified. Compound heterozygous filtering is an efficient means to reduce the number of candidate mutations in studies aiming at identifying recessive disease genes in non-consanguineous families. A web-server is provided to make this filtering strategy available at www.gene-talk.de.

Big Data Management in the Era of Genomic Medicine. *J. Kaufman, S. Fuchs, D. Healey, A. Hopkins, L. Louie, D. Maltbie, C. Martin, M. Penley, M. Wong.* Annai Systems, Los Gatos, CA.

As sequencing technologies continue to evolve and the use of sequencing data makes its way from research into the clinic and hospital, the proliferation of data will continue to accelerate. With this trend and the application of this data to personalized medicine, new challenges in data storage, sharing, security, analysis and retrieval of information will arise. While many of these issues are only now starting to be addressed and anticipated, there is a considerable dearth of readily available solutions to these problems. The creation of data repositories capable of managing genomic information in a manner that enables streamlined access to data has emerged as a critical requirement as the application and use of such data progresses. One highly relevant example of a data repository solution that fulfills multiple needs for a variety of different users is The Cancer Genomics Hub (CGHub). CGHub is a genomic data repository built to support all three major NCI cancer genome sequencing programs: TCGA, TARGET, and the CGCI. CGHub was launched in 2012, hosted by UC Santa Cruz and with only TCGA data online, has more than 44,000 data files totaling more than 500 Terabytes with capacity to grow quickly to 5 Petabytes as additional datasets become available. CGHub is co-located with a biocompute farm that enables cancer researchers the ability to seamlessly access the data files for subsequent analysis using a variety of commercially and/or freely available tools. This repository was built with products and technologies developed at Annai Systems. In the CGHub example, data are stored in a vast public repository enabling widespread access to a large number of researchers and clinicians. There are also a growing number of smaller sized private repositories used to inform drug discovery, disease diagnosis and patient treatment. While some of the requirements of these repositories are quite similar to one another, there are a number of differences with respect to how the data are used, who will access it, and what type of regulatory and security considerations must be adhered to. Because of these differences, having a set of tools that can be used to provide flexible, scalable solutions that can address multiple use cases is of paramount importance. We will discuss how Annai Systems' portfolio of products and services can be used to create 'big data' repositories that can facilitate access to, and sharing of, sequence data and related meta-data.

Churchill: A Cloud-Enabled, Ultra-Fast Computational Approach for the Discovery of Human Genetic Variation. *B. Kelly[1], J. Fitch[1], D. Corsmeier[1], D. Newsom[1], P. White[1,2].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) The Ohio State University, Columbus, OH.

Next generation sequencing (NGS) has revolutionized genetic research, empowering dramatic increases in the discovery of new functional variants. The technology has been widely adopted by the research community and is now seeing rapid adoption clinically, driven by recognition of NGS's diagnostic utility and enhancements in quality and speed of data acquisition. Compounded by declining sequencing costs, this exponential growth in data generation has created a computational bottleneck. Current analysis approaches can take weeks to complete resulting in bioinformatics overheads that exceed raw sequencing costs and represent a significant limitation for those utilizing the technology. Churchill is a computational approach that overcomes these challenges, fully automating the analytical process required to take raw sequencing instrument output through the complex and computationally intensive processes of alignment, post-alignment processing, local realignment, recalibration and variant calling. Through implementation of novel parallelization techniques we have dramatically reduced the analysis time for whole human genome resequencing from weeks to hours, without the need for specialized analysis equipment or supercomputers. As increasing numbers of molecular diagnostic laboratories implement NGS in clinical settings, Churchill provides a solution to the data analysis challenges these laboratories will immediately face. Compared with alternative analysis pipelines, Churchill is simpler, faster, deterministic and capable of running on all popular Linux environments. Furthermore, Churchill optimizes utilization of available compute resources and scales in a near linear fashion, enabling complete human genome resequencing analysis in ten hours with a single server, three hours with our in-house cluster and under two hours using a larger HPC cluster. Churchill is cloud-compatible and we demonstrate the expansive degree of parallelization Churchill can achieve using Amazon's Elastic Cloud Compute (EC2) instances. Not only does this allow laboratories to potentially reduce analysis time by leveraging the cloud's ability to easily scale, but it also enables low-cost resequencing analysis without needing to invest in the required infrastructure to build their own high-performance computing cluster. Churchill eliminates the NGS bioinformatics overhead and is a prime candidate to overcome the bottleneck even faster sequencing will create.

Accessing more human genetic variation with short sequencing reads. *C. Kennedy, N. Chennagiri, B. Breton, M. Umbarger, P. Saunders, V. Greger, C. Micale, G. Porreca.* R&D, Good Start Genetics, Cambridge, MA.

Despite advancements in analysis methods, considerable human genetic variation remains inaccessible to short read sequencing. We combine targeted assembly and alignment of short reads with coverage- and base quality-enabled genotyping on the Amazon Elastic Compute Cloud to re-analyze exome data from the 1000 Genomes Project, benchmarking our results against Sanger sequences for a subset of samples and disease associated genes. Our results demonstrate high detection accuracy for variants, including insertions and deletions, up to 99.7% sensitivity with 1.7% false discovery. Applying our method broadly revealed significant population-dependent allelic diversity in regions previously considered inaccessible to variant detection. Specifically, microsatellite polymorphisms and pathogenic alleles in genes associated with Niemann-Pick disease, maple syrup urine disease, Usher syndrome, cystic fibrosis, and heritable amyotrophic lateral sclerosis. Scalable computational resources and highly accurate analyses, such as those described here, should accelerate clinical adoption of short read sequencing technologies by improving the power to detect variants.

Genomics in Clinical Research on the DNASTAR Cloud. *M. Keyser[1], J. Carville[1], T. Schwei[1], T. Durfee PhD[1], A. Pollack-Berti PhD[1], D. Nash[1], J. Stieren[1], S. Baldwin[1], R. Nelson PhD[1], K. Dullea[1], J. Schroeder[1], P. Pinkas PhD[1], G. Plunkett III PhD[1,2], F. Blattner PhD[1,2,3].* 1) DNASTAR, Inc., Madison, WI; 2) University of Wisconsin, Department of Genetics, Madison, Wisconsin, USA; 3) Scarab Genomics LLC, Madison, Wisconsin, USA.

DNASTAR offers an integrated suite of software for assembling and analyzing sequence data from all major next-generation sequencing platforms supporting key workflows on both a desktop computer as well as the DNASTAR Cloud. The cancer genomics workflow that integrates some of the most powerful functionality in the software includes assembling and analyzing multiple samples using one reference template; probabilistic identification of SNPs, small indels and genotype calls with known variants correlated to their dbSNP and COSMIC IDs and GERP reference data; review and filtering of SNPs from multiple samples within a single project; identification of structural variations; and, for large multi-sample projects with hundreds of individual data sets, tools for SNP quantitation, filtering, set comparison, clustering and indication of the gene disruption impact from called SNPs. In addition, DNASTAR offers multi-sample copy number variation reporting for further analysis. Interactive views within the software facilitate fast, comprehensive analysis, helping scientists move quickly from raw next-gen sequencing data to genetic and genomic impact, including gene ontology. By using innovative algorithms within the software, scientists can have all of the assembly and analysis capabilities available to them on either their desktop computer or the DNASTAR Cloud, supporting large data sets generated by any or all of the next-gen sequencing instruments and platforms.

1472F

A general framework for estimating the relative pathogenicity of human genetic variants. *M. Kircher[1], D.M. Witten[2], G.M. Cooper[3], J. Shendure[1].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Hudson Alpha Institute for Biotechnology, Huntsville, AL.

As genetic information is insufficient to unambiguously implicate many disease-causal variants, annotations that enrich for causal variation are essential. Current annotations tend to exploit a single information type (e.g. conservation) and/or are restricted in scope (e.g. to missense changes). A broadly applicable metric that objectively weights and integrates diverse information is needed. Here, we describe Combined Annotation Dependent Depletion (CADD), a framework that integrates multiple annotations into one metric by contrasting variants that survived natural selection with simulated mutations. We implement CADD as a support vector machine, trained to use 63 annotations to differentiate 14.7 million variants derived on the human lineage from 14.7 million simulated variants. We pre-compute CADD-based scores (C-scores) for all 8.6 billion possible single nucleotide variants of the reference genome and enable scoring of short insertions/deletions. C-scores strongly correlate with allelic diversity, pathogenicity of both coding and non-coding variants, and experimentally measured regulatory effects, and also highly rank causal variants within individual genome sequences. Finally, C-scores of complex trait-associated variants from genome-wide association studies (GWAS) are significantly higher than matched controls and correlate with study sample size, likely reflecting the increased accuracy of larger GWAS. Thus, the ability of CADD to quantitatively prioritize functional, deleterious, and disease causal variants across a wide range of functional categories, effect sizes and genetic architectures is unmatched by any current annotation and will be widely useful for the identification of causal variation in both research and clinical settings.

1473W

Gene-set test for rare variants. *J. Lee, B. Min, S. Lee, J. Ka, T. Park, T2D-Consortium.* Seoul National University, Seoul, South Korea.

Recently, many methods have been developed for the association studies of rare variants. However, current rare variants studies have focused only on gene-level association with diseases. We investigate gene-set-level association in order to sum up the effect of rare variants on diseases from the same gene set. We first present a new unified quadratic test which is shown to be generally more powerful than or as powerful as other tests. Using this quadratic test, we then develop the gene-set-level association tests for rare variants. This gene-set test is capable of handling the different directions of effects. It can also perform association test for the data including both common and rare variants. Through simulation studies, the proposed test was shown to outperform other rare variants tests in terms of average power under the various scenarios. We applied the proposed gene-set test to discover the association between the lipid-related traits and 2.5 million variants from 10,000 exome sequencing data from five major ethnic groups (African American, East Asian, European, Hispanic and South Asian) in T2D-GENES consortium. Using 1452 canonical pathways from MSigDB (v3.1) database, we identified several known gene sets at the 5% significance level after Bonferroni adjustment, which are related to the lipid including asparagine(N)-linked glycosylation, lipoprotein metabolism, and HDL-mediated lipid transport pathways. Within these pathways, B4GALT2 and PLTP were identified as most significant genes.

Monitoring, analyzing, and exploring Ion Torrent™ NGS data with Torrent Suite™ Software. *D. León.* Ion Torrent by Life Technologies, South San Francisco, CA.

Torrent Suite™ Software is specifically designed to allow Ion PGM™ and Ion Proton™ Instrument users to monitor, analyze and explore Ion Torrent™ NGS data. This report illustrates how instrument users can plan a sequencing run that includes not only instrument settings, but it also enable users to preset configurations for data analysis, variant calling and exporting to other annotation software. The Torrent Suite™ Software is accessed through the Torrent Browser, the associated web-based interface for monitoring, planning, reviewing and managing sequence data in real time. As sequence data are being generated, users can monitor a sequencing run and the quality of their data. After a sequencing run is complete, the main data analysis step of the software includes base calling and mapping of the sequence data to a reference genome. Variant calling for homozygous/heterozygous SNPs and small/large indels is the next automated step in the data analysis process with interactive tables of identified variants may be visualized and evaluated using Broad Institute's Integrative Genomics Viewer and two validation assay search sites (TaqMan® SNP Genotyping Assays and PCR/Sanger Sequencing Primers) on Lifetechnologies.com. The architecture of the software also enables users to create plugin applications that perform custom analyses and can connect to third-party providers. The plugins that are included in the Torrent Suite™ Software installation include: Alignment,CoverageAnalysis,ERCC_Analysis,FastQCreator,FilterDuplicates,IonReporterUploader, RunRecognitION,SampleID,SFFCreator,TorrentSuiteCloud,and variantCaller. In addition to providing data quality information and summary analysis reports, Torrent Suite™ Software provides customers the option to further annotate and filter their list of variants. Specifically, they can choose to run a pre-set workflow with Ion Reporter™ software after a sequencing run is complete. This step in the analysis can be pre-configured in the Torrent Browser when planning a sequencing run. This optional annotation step provides biological associations for the variants of interest and allows customers to extend the data analysis capabilities of Torrent Suite™ Software. In summary, this report demonstrates, how with a single web interface, Torrent Suite™ Software enables Ion Torrent ™ instrument users the ability to start a sequencing run by setting up the sequencing parameters and the desired downstream analyses. (Research Use Only).

FERRET: a User Friendly Tool to Quickly Extract Data from the 1000 Genomes Project. *S. Limou, G. Nelson, P. An, C. Winkler.* Basic Science Program, SAIC, Frederick National Laboratory for Cancer Research, Frederick, MD.

By sequencing individual genomes from several reference populations, the 1000 Genomes (1KG) Project provides a valuable and near-comprehensive resource on human genetic variation for the scientific community. Raw and annotated data are regularly and rapidly released on an ftp server, and variants may be accessed directly through the 1KG browser. Even though the 1KG browser is well-designed, accessing data of interest can become a tedious process requiring both a good knowledge of the website architecture and many clicks. Data accessible from the 1KG browser are not updated as quickly as the data released into the ftp server. Further, the 'VCF to PED' tool available from the 1KG browser does not support indels nor provide variant frequencies. We developed Ferret, a user-friendly tool to quickly extract data from the latest release on the 1KG ftp server. Ferret is a Perl script parsing the 1KG vcf files to extract allelic frequency and genotype data for each variant (SNP and indel) located in the region of interest for the reference population of interest. Genotype data are recapitulated into map, ped and info files, which may be loaded in PLINK or HaploView for further exploration of linkage disequilibrium pattern, haplotypes, and eventually tagSNP design for customized genotyping arrays. The main advantages of Ferret are (1) the handling of indels, (2) the user-friendly interface, (3) the output format, and (4) calculation of allele frequencies. Ferret is thus a straightforward program, even for non-specialists who are not adept at the 1KG bioinformatics tools: this software permits easy manipulation and visualization of 1KG data with well-known pre-existing tools. Ferret is publicly available at: https://ccrod.cancer.gov/confluence/display/BCGC/BCGC+Software. You may contact the first author (during and after the meeting) at sophie.limou@nih.gov.

dbNSFP v2.0: A Database of Human Non-synonymous SNVs and Their Functional Predictions and Annotations. *X. Liu, X. Jian, E. Boerwinkle.* Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX.

dbNSFP is a database developed for functional prediction and annotation of all potential non-synonymous single-nucleotide variants (nsSNVs) in the human genome. This database significantly facilitates the process of querying predictions and annotations from different databases/web-servers for large amounts of nsSNVs discovered in exome-sequencing studies. Here we report a recent major update of the database to version 2.0. We have rebuilt the SNV collection based on GENCODE 9 and currently the database includes 87,347,043 nsSNVs and 2,270,742 essential splice site SNVs (an 18% increase compared to dbNSFP v1.0). For each nsSNV dbNSFP v2.0 has added two prediction scores (MutationAssessor and FATHMM) and two conservation scores (GERP++ and SiPhy). The original five prediction and conservation scores in v1.0 (SIFT, Polyphen2, LRT, MutationTaster and PhyloP) have been updated. Rich functional annotations for SNVs and genes have also been added into the new version, including allele frequencies observed in the 1000 Genomes Project phase 1 data and the NHLBI Exome Sequencing Project, various gene IDs for different databases, gene functional description, domains/conserved sites, pathways, tissues/organs the gene expressed in, other genes the gene interacted with, estimated probability of haploinsufficiency/recessive-disease-causing, etc. A companion java program is provided for quick local query of SNVs/positions/genes with support of using a vcf file directly as input. dbNSFP v2.0 is freely available for download at http://sites.google.com/site/jpopgen/dbNSFP.

NCBI's Conserved Domain Database as a tool for the interpretation of human sequence variation. *F. Lu, C.J. Lanczycki, Z. Wang, G.H Marchler, M. Gwadz, S.H. Bryant, A. Marchler-Bauer.* National Center for Biotechnology Information, Bethesda, MD., USA.

NCBI's Conserved Domain Database (CDD) is a protein classification and annotation resource. Manually crafted multiple sequence alignments (MSAs) are the foundation for domain models that are annotated with functional descriptions, links to the literature, and functional sites based on 3D protein structure or experimental evidence. Functional sites often have highly conserved sequence and/or structure and are closely linked to particular structural or functional roles. We investigate the prevalence of single nucleotide polymorphisms (SNPs) with human diseases at such functional sites and demonstrate how pre-computed sequence annotation available from CDD may assist in understanding phenotypes caused by sequence variation. We employ the medically important nuclear receptor (NR) family as an example for this analysis. Nuclear receptors are ligand-modulated transcription factors that act in the nucleus to regulate target gene transcription through the interaction of cofactor proteins. Aberrant receptors result in a wide range of prevalent human diseases and disorders, such as cancer, diabetes, obesity. About 10% of the most prescribed drugs act through nuclear receptors, reflecting their medical importance. Nuclear receptors share a common structural organization with a central well conserved DNA binding domain (DBD), a variable N-terminal domain, a non-conserved hinge and a C-terminal ligand binding domain (LBD). We have classified LBD and DBD into approximately 50 unique subfamilies. The domain models representing these subfamilies were manually curated to add functional sites annotations, specifically ligand binding sites, DNA binding sites, co-activator/repressor binding sites and residues involved in oligomerization. Genes corresponding to the human members of the NR family and non-synonymous SNPs collected for these genes were extracted from the NCBI's Entrez database. The SNPs were mapped to the domain footprints and functional sites annotated by CDD. We report on the correlations between genetic variations that overlap the annotated functional sites and human diseases.

1478F

H3M2: a novel algorithm for the detection of Runs of Homozygosity from second generation sequencing data. *A. Magi[1], L. Tattini[1], P. Flavia[2], M. Benelli[3], M. Seri[4], G.F. Gensini[1], G. Romeo[4], T. Pippucci[2].* 1) Department of Experimental and Clinical Medicine, University of Florence, Florence, Italy; 2) U.O. Medical genetics Polyclinic Sant'orsola malpighi, Bologna, Italy; 3) Diagnostic Genetic Unit, Careggi Hospital, Florence, Italy; 4) Department of Medical and Surgical Sciences, University of Bologna, Bologna, Italy.

Runs of Homozygosity (ROHs) are genomic stretches that appear in homozygous state, showing both alleles as identical in a diploid genome. ROHs are medically relevant. In rare autosomal recessive disorders (ARD), a homozygous highly penetrant mutation will probably reside in an unusually long homozygous haplotype originated from recent consanguinity. In complex disorders, recessive risk variants can be associated to shorter ROHs in inbred/outbred populations. To date, ROH discovery has been performed using microarray-based technologies. We introduce a novel computational approach based on heterogeneous hidden markov model, H3M2 (Homozygosity Heterogeneous Hidden Markov Model), for the identification of ROHs from HTS data. To develop this method, we used whole-exome sequencing (WES) data produced by the 1000 genomes project (1000 GP) consortium previously genotyped by the HapMap consortium. As a mesure of homozygosity/heterozygosity for each polymorphic position i, we used the B-allele frequency (BAF) that is defined as the ratio between B-allele counts (NB the number of reads that match with the allele with minor frequency at position i) and the total number of reads mapped to that position (N, the depth of coverage). Then, based on the population allelic frequency of all the polymorphic positions tested, we calculated for each detected homozygous region a so-called Regional Diplotype Score (RDS) as a measure of statistical significance. To test the ability of our algorithm to identify ROHs of different size and/or number of SNPs, we applied it to WES data of six individuals sequenced by the 1000GP Consortium. H3M2 was able to identify more than 90% of the ROHs detected with HapMap SNPs array data, outperforming state of the art methods. We also applied the algorithm to 100 1000GP individuals from different populations, showing that the total lengthof ROHs per individual increases with the distance of a population from East Africa, in agreement with previous observation. Finally, we tested the algorithm on 10 offspring to consanguineous families affected with ARD. In those subjects for whom the disease-mutation was known we found that the RDS of the surrounding region ranked among the highest subject's ones (>95%ile), demonstrating that the proposed algorithm is a valid tool also for disease-locus mapping. H3M2 is a highly performing algorithm aimed at the identification of differently sized ROHs from HTS data, in populations as well as in individuals.

1479W

PRIOR: a bioinformatics tool for prioritization of candidate genes. *V. Makarov, I. Ionita-Laza.* Mailman School of Public Health, Columbia University, New York, NY.

Increasing volumes of next-generation sequencing data and the growing costs of experimental validation of detected changes call for the development of bioinformatics tools that can help prioritize genes for further analysis. We have developed a computational pipeline (PRIOR) that combines two published bioinformatics tools (snpEff and AnnTools) with additional methods developed by our group. Variant annotation is performed with the snpEff and AnnTools and parsed with the AnnTools' parser. The effects with the highest impact are considered candidates for experimental validation, while all other effects are preserved for possible future studies. The pipeline accepts input data in the standard VCF format and annotates the variants to include only novel (not in the dbSNP), potentially disease-causative mutations in the coding regions, which include non-synonymous single nucleotide substitutions (SNP/SNV) and short insertions/deletions (INDEL). The tool makes predictions of the potential importance of each gene based on the overall mutation rate in a study cohort, and calculates the mutation rate for each gene adjusted, firstly, for its length and, secondly, for mutation rate in general population based on the rate of novel SNP/SNV and INDEL reported by NHLBI Exome Sequencing Project (ESP) in 6500 exomes. For studies that involve related individuals, further adjustment is made to add more weight to variants found in not related individuals compared with those found in the family members. Additional annotation for each gene includes function description, functional pathways, and known disease association as reported in the dbNSFP database. The application is freely available for public use; the package includes installation scripts and a set of helper tools.

1480T

Shortcut to Analysis of Genomic Data. *D. Maltbie, S. Fuchs, D. Healey, A. Hopkins, J. Kaufman, L. Louie, C. Martin, M. Penley, M. Wong.* Annai Systems, Los Gatos, CA.

Finding and accessing the ever-growing amount of genomic data and meta-data can be difficult for researchers and clinicians. Once a target data set is identified, extracting that data set from repositories and running analyses can tax or overwhelm available information technology resources such as compute power, storage and networks. By leveraging specialized software tools and an information technology infrastructure designed specifically for genomic data, commonly encountered challenges can be overcome, resulting in a shortcut to data analysis. As organizations struggle with increasing demands from researchers for access to high performance compute platforms, they often experience reduced throughput during peak times, coupled with hardware that is woefully underutilized during non-peak times. Network limitations and firewall issues, manifested as lengthy, error prone Internet downloads are common when migrating datasets from external systems to compute centers. At the compute centers, temporary storage can be inadequate for the ever-increasing amount of data that must be migrated in preparation for analysis, creating yet another obstacle to the utilization of genomic data. A shortcut is needed to overcome these ubiquitous problems in compute, storage and networks. One solution is setting up optimally architected data repositories co-located with high performance compute centers on highly efficient networks. Annai Systems' web based reQuest data portal plus GNOS web services is one such solution. Researchers can locate target datasets through customized searches in reQuest across multiple GNOS enabled repositories. The GTFuse access tool allows access to specific regions of data without downloading the whole genome sequences. For example, TCGA credentialed researchers can swiftly compile datasets and run analyses on Annai System's BioCompute Farm. This is a GNOS web based service that provides elastic compute and storage, and is co-located with the Cancer Genomics Hub, the largest cancer genome repository. Scientists using the Cancer Genome Atlas data via the reQuest portal and working in the BioCompute Farm with GTFuse are able to extract specific gene segments from hundreds of whole genome sequences in hours as opposed to the days or weeks it could otherwise take. We will discuss how scientists and clinicians are empowered by shortcuts to finding, accessing and analyzing genomic data through the use of the tools described above.

1481F

High Throughput Exome Coverage and Capture of Clinically Relevant Cardiac Genes. *D. Manase[1,3], L. D'Alessandro[2], A.K. Manickaraj[1,3], S. Mital[2].* 1) Heart Centre Biobank Registry , Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Cardiology, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

Background: High throughput whole-exome sequencing (WES) technologies have been used to identify variants in human disease. However, variant identification is limited by the overall coverage provided by WES. We sought to quantify the overall capture and read depth (RD) coverage of clinically relevant cardiac genes in WES data obtained using state of the art sequencing platforms. Methods: Data from 200 human exomes sequenced via Illumina HiSeq using Agilent SureSelect for capture were obtained in raw sequence format and aligned to the human genome version 19 using Burrows-Wheeler Aligner. Of these, 45 BAM files were analyzed using SAMTOOLS. Fifty clinically relevant cardiac genes were selected for analysis including 31 genes on the American College of Medical Genetics list for reporting of incidental findings and an additional 19 genes associated with congenital heart disease. Gene coordinates were obtained for all protein coding regions on Ensembl and filtered for unique chromosomal locations. Both the RD across all coding exons and the BED file coverage from the sequencing capture kit were compared with the reference genome to assess observed versus potential capture. Results: Preliminary results of 50 cardiac genes analyzed on 45 exomes sequenced at 50X coverage revealed that a RD coverage of 50X was seen only on 24% of all exonic regions. RD between 0 to 9 reads was the predominant coverage observed in these genes occurring at 41% of all exonic regions. Of note, none of the 50 genes had more than 70% of all isoform regions covered to a RD of 50X or greater, and 1 gene had 100% of its isoforms covered at less than 10X reads. APOB and MYH11 were the only genes with at least half of all regions covered ≥ 50X. ACTC1, CFC1, GATA4, KRAS, NRAS, PTPN11, SMAD3, SOS1, TBX5, TGFBR1, TGFBR2, and TMEM43 had the least coverage in RD with 50% of the regions covered by only 0-9 reads. Conclusion: Low capture and read depth may impact variant analysis and interpretation, including false negatives wherein potential heterozygous mutations may not present within the reads that are sequenced while true calls may be ignored through low read depth filtering or even interpreted as artifact or misaligned read. A study bias towards well-covered genes may result in greater attribution of disease causation to mutations in well-represented genes with more confident calls. Improvements in WES technology are needed before widespread clinical use of exome data.

1482W

A Cloud Computing Based Open Science Platform for Analysis, Presentation, and Collaboration in Bioinformatics. *G. Manglik, J. Yeager.* CliQr Technologies, Sunnyvale, CA.

As the cost of sequencing continues to drop, the amount of bioinformatics data researchers need to manipulate and store increases exponentially, creating an ever-increasing demand for the computational methods required to manipulate data, perform statistical analyses, create graphics, and share results. For the majority of researchers this involves selecting the most relevant packages and either purchasing proprietary software or finding and compiling an appropriate open source equivalent. Maintenance of any such setup can become burdensome and the software support role can grow to dominate the time spent on actual research. We have developed a new and better method for quickly importing software applications to any Cloud computing provider such as Amazon AWS, HP Cloud, Rackspace, or Microsoft Azure, and have used this to create an Open Science Platform for use by researchers. This platform takes on the burden of compiling and supporting the common applications. Using the CliQr Open Science Platform researchers can share data and results with collaborators in an easy and unprecedented manner. Using our web browser based platform the bioinformaticist can create and import applications in addition to the open source tools within the Open Science Platform. The bioinformatist also has full access to the underlying Cloud computing system if desired. The portal enables the bioinformatics researcher to bypass maintaining and compiling software and concentrate on their investigations. The Open Science Platform can significantly reduce the analysis timeframe and cost to researchers. Pricing for the open source software is based upon the compute and storage resources consumed, reducing the barrier to use significantly and encouraging experimentation. We will discuss the technical challenges in the creation of this platform, issues around Cloud computing and bioinformatics, and how computation and storage requirements drive choice of Cloud. Use of multiple applications taking data from its raw form through to final presentation will be demonstrated. The benchmarking capabilities of the Open Science Platform will be presented, and the rapid transition of applications between Clouds to allow for optimum performance or cost behavior.

1483T

Liftover of Short Reads from Next Generation Sequences Aligned to Non- Canonical References as a Step towards a Diploid Alignment.
T.C. Markello[1,2], T.R. Gall[1], A.J. Brandt[1], P.J. Pemberton[1], D.R. Simeonov[1], E.D. Flynn[1], W.P. Bone[1], A.E. Links[1], D.R. Adams[1,2], C.F. Boerkoel[1], W.A. Gahl[1,2,3]. 1) Med Gen Branch, NIH/NHGRI, Bethesda, MD; 2) Undiagnosed Diseases Program, NIH, Bethesda, MD; 3) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD.

Using a canonical reference genome for aligning short reads to a template is less computationally intensive than *de novo* assembly, but the alignment may be inaccurate if the reference is too dissimilar to the genome from which the reads were derived. Previous work has shown that it is possible to modify a canonical reference to more closely match the unknown sequence by applying corrections derived from hybridization experiments or imputed from population based haplotypes. The biggest unsolved challenge is to relate the alignment performed onto a modified reference back to the canonical reference. This is required in order to annotate the discovered variants for their significance to cause disease. A chain file contains all the information required for mathematical transformation of coordinates between references and is generated when modifying a genome sequence. If modifications are restricted to changing nucleotides from one base to another, then there is a one to one correspondence between reference positions. When modifications generate length discrepancies between the two sequences by including copy number variations, then positions in the modified reference must be lifted over back onto the canonical reference in chain blocks. After short reads are aligned to a modified reference their record includes a Compact Idiopathic Gapped Alignment Report (CIGAR) string that can span two or more chain file blocks and require modification to account for length differences during the liftover process. The bioinformatics group of the Undiagnosed Diseases Program (UDP) has written and implemented an extension to existing bioinformatic suites that preforms the CIGAR string liftover function. We have extended this code to liftover the complex variant combinations arising from the correction of alignment references in a sequenced parent-parent-child trio. We present an analysis of the challenges associated with this lift-over process, including examples of local alignments that are improved by our current process. A successful liftover of short reads aligned to a modified reference, or to reads simultaneously aligned to two differentially modified parental references, has the potential to improve read mapping in regions previously found to be problematic in Next Generation Sequencing. This approach is particularly important when striving to generate a complete list of candidates for novel undiagnosed diseases using genome-scale sequencing.

1484F

Workflows for variation detection and filtering using NGS data from targeted resequencing, whole genome analysis, and RNA-Seq.
M. Matvienko[1], C. Boysen[1], A. Joecker[2], A. Joecker[2], S. Monsted[2], R. Forsberg[2]. 1) CLC bio, Cambridge, MA; 2) CLC bio, Aahus, Denmark.

CLC Genomics Workbench provides a graphical and user-friendly framework for creating, distributing, installing, and running workflows. A workflow consists of a series of tools where the output of one tool becomes the input to another tool. In this way, the user can set up a workflow to go through multiple steps of analysis. For example, the read trimming output is used for mapping to reference, the mapping file is used for variant detection, and the resulting variant track is filtered against a standard variation track. Once the workflow is set up, it can be installed on the Workbench or on a Server. The workflow files are distributable and can be sent to other CLC bio users. Workflows can be run in batch mode like many of the Workbench tools, and allow for the analysis of multiple samples using the same pipeline. Any or all of the workflow parameters can be locked, so standard procedures can be used in production or regulated environments. Workflows created in CLC Genomics Workbench can also be installed on CLC Genomics Server. He re we show the example workflows created in Workbench for variation analysis on NGS data from human whole genome resequencing, targeted resequencing, and RNA-Seq data.

Choice of transcripts and software has a large effect on variant annotation.
D. McCarthy[1,2], A. Kanapin[2], M. Rivas[2], K. Gaulton[2], P. Humburg[2]. 1) Department of Statistcs, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Functional annotation of variants is a crucial step in the analysis of whole-genome sequencing data. In disease studies, functional annotation results can have a strong influence on the ultimate conclusion of the study. Incorrect or incomplete annotations can cause researchers both to overlook potentially disease-relevant DNA variants and to dilute truly interesting variants in a pool of false positives. Researchers are aware of these issues in general, but until now the extent of the dependency of final results on the choice of transcripts and software used for annotation has not been appreciated to the extent it should.

We quantify the extent of differences in annotation of 10 million variants from a whole-genome sequencing study. We compare results using the RefSeq and Ensembl transcripts sets as the basis for variant annotation with the annotation software Annovar, and find only 63% agreement in annotations for putative loss-of-function variants. The rate of matching annotations remains low for loss-of-function and nonsynonymous variants combined (81%) and all exonic variants (86%). Further, we compare the results from Annovar and VEP when using Ensembl transcripts and see matching annotations for only 85% of exonic variants, with particularly large differences in the annotation of splicing variants. Using these comparisons, we characterise the types of apparent errors made by Annovar and VEP and discuss their impact on the analysis of DNA variants in whole-genome sequencing studies.

Our results show that variant annotation is not yet solved. Choice of transcript set has a large effect on the ultimate variant annotations obtained in a whole-genome sequencing study. Choice of annotation software has a smaller, but nevertheless important, effect. The annotation step in the analysis of a genome sequencing study must therefore be considered carefully, and a conscious choice made as to which transcript set and software are used for annotation.

Joint GWAS Analysis Demonstrates Increasing Similarity among Disparate Diseases as Genomic Resolution Rises from SNP to Gene to Pathway.
M. McGeachie[1,2], G. Clemmer[1], J. Lasky-Su[1,2], H.H. Chang[2,3], B. Raby[1,2], S. Weiss[1,2]. 1) Channing Div Network Med, Dept of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Children's Hospital Informatics Program, Children's Hospital Boston, Boston, MA.

Network models of genetic diseases, polygenic modeling, clinical comorbidity and gene pleiotropy studies have lead to a broader conception of the genetic causes of complex human diseases: one including increased relationships and interdependencies between disparate disorders. To assess the value of combining existing GWAS of separate cohorts and separate complex human genetic diseases for discovering additional disease-relevant biology, we compared six different GWAS from the WTCCC (bipolar disorder, cardiovascular disease, Crohn's disease, rheumatoid arthritis, and type 1 and 2 diabetes). We developed a novel methodology called Joint GWAS Analysis that is based on the enrichment of top SNPs among two GWAS for different diseases. We used Joint GWAS Analysis to examine the similarity of diseases at the SNP level, gene level, and biological pathway level. We demonstrate that this new method identifies more disease-relevant biology than could be obtained from single GWAS alone by comparing Joint GWAS Analysis and traditional single GWAS to the SNPs and genes reported in the NHGRI catalog of published GWAS for each disease. After running DAVID enriched pathway cluster analysis on known NHGRI catalog genes for each disease, Joint GWAS Analysis identified significantly more pathway clusters than single GWAS, showing gains of 27% to 100% in bipolar disorder, cardiovascular disease, and type 1 and 2 diabetes. Such gains were not realized at the SNP and gene level. These results imply that complex human genetic disorders, such as those assessed by WTCCC GWAS, show broad similarity at the functional level in enriched biological pathways, even in cases of disorders not traditionally considered to have common genetic or etiological underpinnings. We also make concrete hypotheses regarding novel pathway associations for several of the complex disorders considered, based on the results of Joint GWAS Analysis. Furthermore, the success of Joint GWAS Analysis indicates that meta-analysis of GWAS need not be limited to GWAS of the same phenotype.

Clinicall - A variant analysis tool for next generation clinical sequence data. *S. McGee, T. Kolar, M.O. Dorschner, J.D. Smith, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

Next-Generation Sequencing (NGS) has revolutionized molecular diagnostics. Test complexity and data volume have increased exponentially, creating significant challenges for clinical laboratories. Each test requires the comprehensive review of primary and variant data in a number of databases. To facilitate analysis, interpretation and reporting, we have developed an integrated tool to view sequence alignments, quality metrics and variant annotation. BAM and VCF files are easily uploaded, and variants filtered by user-defined gene sets, and settings for variant type, allele frequency and presence or absence in specific databases and functional annotations and ranking. This platform summarizes data for multiple samples simultaneously and links to existing databases to make quantitative decisions regarding validity and categorization of the variants. This is done by utilizing an extensive set of exome sequences to report a statistical measure of confidence for each newly discovered rare variant based on the quality of all calls previously seen at that site in more than 5,000 exomes. Data can be exported to one of the application's summary templates to create comprehensive reports that include the reported variants and pertinent commentary that can be accessed. This tool provides an easy and efficient way to integrate a myriad of data into a single viewable format for clinical genetics.

1488W

Streaming Algorithms for de Bruijn Graph Statistics. *P. Melsted.* Faculty of Industrial Eng., Mechanical Eng. and Computer Science, University of Iceland, Reykjavik, Iceland.

We present a streaming algorithm which can find key statistics for de Bruijn graphs without constructing the de Bruijn graph. The algorithm requires one pass over sequence data and uses a constant amount of memory, independent of the size of the dataset. The streaming algorithm can report the statistics to an arbitrary precision at the cost of increased memory usage. The statistics reported include the total number of k-mers and number of repeated k-mers. These statistics can be used to determine the per-basepair sequencing error rate without mapping to a reference. Additionally we can estimate average contig length for the de Bruijn graph, both when all k-mers are included and when unique k-mers are filtered.

1489T

Detection of Hereditary Mutations in the Mitochondrial Genome for Clinical Diagnosis. *M. Middha, M. Klebig, E. Highsmith, E. Klee.* Mayo Clinic, Rochester, MN.

Mutations in the mitochondrial genome are known to be associated with various pathological conditions and disorders caused by defects in components of the respiratory chain, including neurological disorders, maternally inherited diabetes & deafness (MIDD), among others. To improve clinical diagnosis, we are developing a Next-Generation Sequencing (NGS) test to analyze the whole mitochondrial genome (mtDNA). The definition and characterization of the analytical approach used to interpret the NGS data is a critical component of the test development process. Here we report on two critical analytical components related to the mitochondrial test development: cross-platform validation and large deletion detection. Using a dual-sequencing strategy, we sequenced ~35 mtDNA samples on both Illumina MiSeq and Ion Torrent PGM instruments. MiSeq data was analyzed using the CLC Bio Server. For the Ion Torrent data, we evaluated two methods, using the Torrent Server plug-ins or using the CLC Bio Server, to identify optimal analytics. Our goal is to use one NGS platform as an orthoginal confirmation platform for variants detected on the other. Variants can occur selectively in any percentage of mitochondrial copies (heteroplasmy), which can contribute to high variability in disease severity. Given the high coverage of sequencing in our samples, we are able to observe as low as 5% heteroplasmy. To define our false negative rate, we also sequenced 12 Hapmap samples and compared the concordance of variant calls. Mitochondrial DNA deletion syndromes such as Kearns-Sayre Syndrome & Pearson's Syndrome are caused by large deletions. To assess large deletion detection limits, two samples with known large deletions were diluted with a control mtDNA sample, to simulate heteroplasmy of 50%, 20%, 10%, 5%. We used two methods to detect large deletions, an internally developed SV detection tool, SoftSearch, and a coverage based analysis method. SoftSearch is designed to detect break points using split reads and discordant read pairs. For normalized coverage plots, we plot percent variation comparing it to the control sample to detect deletions 1kb & more. As next generation sequencing is transforming diagnostic testing, it is vital to establish a well-defined approach for analysis and interpretation of a clinical test. We provide a comprehensive clinical evaluation for the mitochondrial clinical NGS test characterizing sensitivity, specificity and confirmation of variant detection.

1490F

Accelerating Whole Genome Sequencing Bioinformatics for Clinical Application. *S. Middha, S. Baheti, S. Hart, J.P. Kocher.* Mayo Clinic, Rochester, MN.

Whole Genome Sequencing (WGS) has the potential to transform diagnostic testing in very near future. However, it is computationally expensive to align millions of short reads to the whole genome. This could be prohibitive for routine use in a clinical setting where speed of analysis can impact patient outcome. Although the time consuming steps of WGS bioinformatics are highly computational, clinical applicability can be improved by prioritizing reports based on clinical decision-making. Current clinically relevant information is largely related to protein coding regions of the genome. Based on that observation, we have designed a sequence alignment and variant calling workflow focused on protein-coding exon-only regions before processing the data over whole genome. Our **2-step workflow** significantly decreases turn-around time making it pertinent for clinical screening and diagnostics from WGS data. Our workflow first selects clinically relevant reads by aligning the entire sequencing data to the coding exons, limiting the initial reference to less than 2 percent of the whole genome. The resulting significantly reduced set of reads is then aligned to the whole genome to correct alignment artifact produced by the use of a reduced exon-only reference sequence. The data is re-aligned and re-calibrated followed by variant calling. The process thus uses a smaller reference sequence for all the sequence reads and then uses a smaller set of sequence reads to align to the whole genome. By using this 2-step approach we are able to reduce the turn-around time for whole genome alignment and variant calling from **~80 hours to ~15 hours**, a gain of more than 80 percent. The results are highly concordant to a standardly aligned WGS analysis apropos both the aligned reads as well as called variants. We repeated the analysis and generated results on 3 samples from a well characterized HapMap trio. Variant calls were also validated against SNP array data. We present those results and metrics.

1491W

Locus Reference Genomic (LRG) record: reference resource for the reporting of clinically relevant sequence variants. *J. Morales[1], J.A.L. MacArthur[1], R. Tully[2], L. Gil[1], A. Astashyn[2], E. Bruford[1], R. Dalgleish[3], E. Birney[1], P. Flicek[1], D. Maglott[2], F. Cunningham[1].* 1) European Bioinformatics Institute, European Molecular Biology Laboratory, Cambridge, UK; 2) National Center for Biotechnology Information, Bethesda, MD, USA; 3) Department of Genetics, University of Leicester, Leicester, UK.

A Locus Reference Genomic record is a manually curated resource designed specifically for the reporting of variants on clinically relevant genomic loci. An LRG provides a stable and non-versioned genomic DNA sequence for a region of the human genome, along with transcripts used as reference standards and their protein products. These sequences are selected in collaboration with the diagnostic and research communities, locus specific database curators, and mutation consortia. The genomic sequence of each LRG represents a fixed version of the RefSeqGene. Only transcripts required for reporting of disease-causing variants, and for which there is currently good biological understanding, are included. Manual curation ensures that each record fulfils the unique demands of each gene. Once an LRG is made public, this core content will not change. Other content, such as mapping information, annotation of additional transcripts, overlapping genes and legacy exon numbering systems, is periodically updated. The LRG's stable nature enables unambiguous reporting of variants in LRG genomic DNA (e.g. LRG_1:g.8463G>C), LRG coding DNA (e.g. LRG_1t1:c.572G>C) or LRG protein (e.g. LRG_1p1:p.Gly191Ala) coordinates. LRGs can be viewed in the Ensembl (www.ensembl.org) and NCBI genome browsers (http://www.ncbi.nlm.nih.gov), while tools such as Mutalyzer (https://mutalyzer.nl) facilitate remapping from other coordinates to LRG coordinates. New improvements include the addition of a stable LRG-specific exon numbering system based on the transcripts included in the fixed section. So far, 653 LRGs have been created. Of these, 392 are public and 261 are pending approval. An additional 82 are under creation. Recently made public are LRGs for genes involved in cancer predisposition, such as BRCA1, BRCA2, and TP53, inherited cardiac disease, mismatch repair, the Fanconi anemia pathway, and other diseases. It is our hope that widespread use of this resource will ensure that variant reporting is consistent over time. LRGs are compiled and maintained by the NCBI and EBI, originally as part of the GEN2PHEN (http://www.gen2phen.org) and RefSeqGene (http://www.ncbi.nlm.nih.gov/refseq/rsg) projects. All LRG records are available on the LRG website (http://www.lrg-sequence.org), which also provides instructions on requesting LRGs and the complete LRG specification.

RNA-seq alignment to individualized genomes. *S.C. Munger[1], N. Raghupathy[1], K. Choi[1], A.K. Simons[1], D.M. Gatti[1], D.A. Hinerfeld[1], K.L. Svenson[1], M.P. Keller[2], A.D. Attie[2], M.A. Hibbs[3], J.H. Graber[1], G.A. Churchill[1], E.J. Chesler[1].* 1) The Jackson Laboratory, Bar Harbor, ME; 2) University of Wisconsin, Madison, WI; 3) Trinity University, San Antonio, TX.

The emergence of high throughput sequencing of RNA has yielded a wealth of information regarding transcriptional regulation. Alignment of short read sequences to a common reference genome or transcriptome is a standard first step in the analysis of RNA sequencing data. We demonstrate that genetic variation away from the reference sequence can cause reads to be assigned to the wrong location. The source of most read alignment errors is in the duplicated structure of the transcribed genome and cannot be corrected by fine-tuning the alignment algorithm. We have developed a method, implemented as the software package Seqnature, to construct the imputed genomes of individuals (individualized genomes) of experimental model organisms including genetically unique outbred animals. Alignment to individualized diploid genomes increases read mapping accuracy and improves transcript abundance estimates. In an application to expression QTL mapping, this approach corrected erroneous linkages and unmasked hidden associations. Individualized genomes will be useful for other applications of high throughput sequencing technology that currently employ a reference sequence for alignment.

Bioinformatics and Data Management of High Throughput Sequencing Data from Prospective Cohort Study at Tohoku Medical Megabank Project. *M. Nagasaki, N. Nariai, K. Kojima, Y. Yamaguchi, I. Sato, J. Yasuda, O. Tanabe, N. Fuse, K. Kengo, R. Yamashita, J. Yamagishi, I. Danjo, M. Matsumoto, K. Igarashi, K. Nakayama, F. Katsuoka, S. Saito, I. Motoike, N. Ishida, M. Shirota, M. Yamamoto.* Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan.

Tohoku University Tohoku Medical Megabank Organization (ToMMo) was founded to establish an advanced medical system to foster the reconstruction from the Great East Japan Earthquake. The organization will develop a biobank that combines medical and genome information during the process of rebuilding the community medical system and supporting health and welfare in the Tohoku area. The information from the brand-new biobank will create a new medical system, and, based on the findings of its analysis, the organization aims to attract more medical practitioners from all over the country to the area, promote industry-academic partnerships, create employment in related fields, and restore the medical system in Tohoku. A blueprint for Tohoku University Tohoku Medical Megabank Organization is a ten-year project including three main activities: a biobank combining medical and genome information; an online platform for the coordination of community medical information; and training program designed for a varieties of highly specialized professionals and experts such as researchers of bioinformatics and science communicators. The biobank to be developed will be utilized to analyze the local heredity information so that it can establish an advanced medical system based on genome information with cutting-edge information and communication technology. The first goal of ToMMo is to understand the genetical detailed background of population in this area including population specific rare variants. Thus, we will apply deep coverage whole genome sequencing of thousands people who applied to this prospective genome cohort project within years. This poster presents the poster main presenter's responsible part; the data management and the analysis of massive amount of high throughput sequencing data on this project and the research position availability of this very exciting project as a graduate student or a research staff.

1494W

Transcript isoform abundance estimation method with gapped alignment of RNA-Seq data by variational Bayesian inference. *N. Nariai[1], O. Hirose[2], K. Kojima[1], M. Nagasaki[1].* 1) Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Faculty of Electrical and Computer Engineering, Institute of Science and Engineering, Kanazawa University, Kakuma, Kanazawa, Ishikawa, 920-1192, Japan.

Many human genes express multiple transcript isoforms through alternative splicing, which greatly increases diversity of protein function. Although RNA sequencing (RNA-Seq) technologies have been widely used in measuring amounts of transcribed mRNA, accurate estimation of transcript isoform abundances from RNA-Seq data is challenging, because reads often map to more than one transcript isoforms or paralogs whose sequences are very similar to each other. We propose a statistical method to estimate transcript isoform abundances from RNA-Seq data. Our method can handle gapped alignments of reads against reference sequences so that it allows insertion or deletion errors within reads. The proposed method optimizes the number of transcript isoforms by variational Bayesian inference through an iterative procedure, and its convergence is guaranteed under a stopping criterion. On simulated data sets, our method outperformed the comparable quantification methods in inferring transcript isoform abundances, and at the same time its rate of convergence was faster than that of the expectation maximization (EM) algorithm. We also applied our method to RNA-Seq data of human cell line samples, and showed that our prediction result was more consistent among technical replicates than those of other methods.

1495T

Detecting epistasis in NRXN1 pathway with permutation-based variable importance measures used in Ramdom Forests(RF). *L.A. Neira Gonzalez[1], D. Tropea[1], D. Morris[1], G. Donohoe[1], M. Gill[1], F. O'Neill[2], K. Kendler[3], D. Walsh[4], B. Riley[2], A. Corvin[1], K. Nicodemus[1], WTCCC2.* 1) TCD, Ireland; 2) Queen's University Belfast, UK; 3) VCU, USA; 4) HRB, Ireland.

The RF algorithm is designed for use with high dimensional data and can be used for predicting new observations. CNVs in NRXN1 have been shown to be strongly associated with schizophrenia (SZ), so we used RF to detect epistasis in a training (80%) and independent test (20%) sample. However, recent work has shown contradictory conclusions with permutation-based variable importance measures (VIMs) used in RF as far as which VIM is the best to use when there is correlation. Therefore, we also performed a simulation study to compare the behavior of different VIMs with different numbers of predictors correlated and different strength of correlation and to assess which was most powerful. This VIM was applied that to the NRXN1 pathway to test for epistasis. In our simulation study, we generated 500 continuous and binary datasets for each correlation 0.80, 0.40 and 0.10 and for 10, 20 and 40 variables correlated. We compared 3 types of permutation VIM (PVIM), 2 scaled PVIM, 1 AUC PVIM, 1 conditional PVIM and the original Gini VIM. The unconditional PVIM outperformed all others for correlated data and it was more powerful for binary predictors than continuous. Thus, in our NRXN1 study we used it to take the top 10 predictors ranked in the top 10 of the training data across 100 runs of RF to follow up with logistic regression interaction models in our test sample. We detected two significant interactions between the genes NPAS3 and NEBL and between NRXN1 and DSP in our independent test dataset. In NPAS3/NEBL, epistasis was detected between rs1958053 and rs4556442 (LRT p-value = 0.017 and R^2 = 1,7%) and between rs7149368 and rs4556442 (LRT p-value = 0.012 and R^2 = 1.9%). Significant epistasis in DSP/NRXN1 was found between rs2237103 and the two SNPs rs972112 and rs988179 with LRT p-values 0.044 and 0.031 with R^2 0.012 and 0.013, respectively. We found significant epistasis that influenced risk of SZ in NRXN1 pathway in an independent test dataset. NRXN1 has been associated with schizophrenia, brain structure and cognition. NPAS3 is a transcription factor involved in neurogenesis, and a translocation breakpoint in this gene was observed in a family with schizophrenia. The use of RF on the training data produced a small number of interacting SNPs to assess in our test data (45 vs 17585415), thus reducing multiple testing.

1496F

CIDRVar: A Next-Generation Sequencing Database Linking Samples, Variants, and Annotations. *J.D. Newcomer, S.M.L. Griffith, E. Pugh, D.R. Leary, J.L. Goldstein, L. Watkins Jr., K.F. Doheny.* JHU/Center For Inherited Disease Research 333 Cassell Drive Triad Technology Building, Suite 2000 Baltimore, MD 21224.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. In April 2011, CIDR's software development team implemented an ANNOVAR aggregation report generator as part of our software toolbox, CIDRSeqSuite. This report aggregation tool automates the process of running ANNOVAR over a directory of VCF files, annotating these samples against an arbitrary number of flat-file databases, and aggregating the output files into summary reports. Along with several custom databases, we use the gene-, region-, and filter-based annotations provided with ANNOVAR. This tool has been in production for over two years; in that time, we have accumulated more than 50 databases against which users may annotate based on their preferences. The accumulation of many very large annotation databases has caused scalability issues. To solve these problems, we have implemented our own solution: CIDRVar. A software tool backed by a relational database, CIDRVar serves two interdependent purposes: to track the variant genotypes found for all of our sequencing samples and to store data against which those variants can be annotated. Internally tracking the variants found for all of our sequencing samples allows us to answer quickly and easily important questions such as: /Which samples had a variant at a given genomic position? /Which variants were found at a given genomic position? /What are the annotations for a particular variant or genomic location? /How many samples had each variant? /Which samples share a given genotype? Initially, report generation required server-grade hardware. Now that we are storing in a relational database all of the annotation data that were previously stored as flat-files, we can generate a variant annotation report with a much smaller resource footprint.

1497W

Improving the accuracy of novel sequence search in de novo human genomes with NSIT. *B. Pupacdi[1], A. Javed[2], M.J. Zaki[3], M. Ruchirawat[1].* 1) Chulabhorn Research Institute, 54 Kamphaeng Phet 6, Laksi, Bangkok, Thailand 10210; 2) Genome Institute of Singapore, 60 Biopolis Street, Genome, #02-01, Singapore 138672; 3) Department of Computer Science, Rensselaer Polytechnic Institute, Troy, New York, USA 12180-3590.

The idea of building the human pan-genome was first introduced in Li et al (2010). The authors estimated that each individual's whole genome harbors about 5 Mb of novel DNA sequences that are neither known repeats nor present in the human reference sequence. These were shown to be potentially functionally important and consistent with known human migration paths. When combined, the complete human pan-genome is gauged to contain as much as 19–40 Mb of novel sequences. Subsequent independent research findings also identified 2 - 3 Mb of novel sequences per individual via different computational techniques. In this work, we showed that 1) the amount of novel sequences per individual is not as high as previously anticipated, i.e., only around 1.7–2.0 Mb per person, 2) the novel sequences among different individuals largely overlap, and 3) DNA sequence contaminations from other species in a de novo assembly can get falsely reported as novel sequences. We used our software NSIT (Novel Sequence Identification Tool) to align individually 3 de novo human genome assemblies (NA18507, YH, and NA12878) to the GRCh37 reference assembly. Repeats were masked with RepeatMasker and BLASTn was used for the final refined search steps. We found 1.9 Mb, 2.0 Mb, and 1.7 Mb of novel sequences in the aforementioned de novo assemblies, respectively. A further investigation revealed that these sequences are 60 - 80% overlapped among themselves as well as with the HuRef and CHM1 assemblies. Lastly, we found that as high as 129 kb of our NA18507 novel sequence candidates did not match with any existing human genome assemblies, or any other closely related species, but aligned with extremely high confidence and near perfect sequence identity to the Epstein-Barr virus (EBV) genome instead. More importantly, these 129 kb were also included in the novel sequences of NA18507 reported in Li et al. We speculate that these DNA sequence contaminations are present because EBV was used as the transformant when generating the cell lines. Our results therefore suggest that the size of the human pan-genome may not be as large as previously expected. NSIT is a highly efficient and accurate software for the task of detecting novel sequences in a large de novo genome assembly. For the above experiments with human genomes, NSIT required <2GB of memory and finished in 1–2 hours on a commodity desktop. To the best of our knowledge, it is the only software designed specifically for this task.

1498T

ScatterShot; a Java program for creating cluster plots from Affymetrix and Illumina genotype data. *N.W. Rayner[1,2,3], N. Robertson[1,2], M.I. McCarthy[1,2,4].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Churchill Hospital, University of Oxford, Oxford, United Kingdom; 3) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 4) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom.

With the increased interest in rarer variants (<1% minor allele frequency) the number of these polymorphisms appearing on the newer genotyping chips from both Affymetrix and Illumina has grown dramatically. This growth, and the uncertainty around the efficacy of calling of these variants, has greatly expanded the number of genotype cluster plots that need to be examined. To address this issue we have developed a cluster plotting program, ScatterShot, that is simple to run and is more flexible than existing programs in the data input formats required and display options available. ScatterShot is a Java program run from the command line, supporting multiple OS platforms (Windows, Unix, Mac OSX), and makes use of Java's asynchronous IO libraries to facilitate parallel processing and increase throughput; the program will scale to make use of any available processors. A wide variety of input formats are supported such as the binary .chp files from Affymetrix's genotyping console as well the Final Report from Illumina's GenomeStudio. Also supported is a generic mode, taking genotype calls from a plink format ped or binary ped file coupled with a separate XY coordinate data table. The format of the XY data table is flexible allowing one row per SNP or one row per sample. An advantage of the program over others is that when using these multiple files, the ordering of the SNPs and samples between the files is unimportant. To save space all input files, including the binary ped and chp files can be read from gzipped versions. Plots are output using Scaleable Vector Graphics (SVG) which can be viewed directly using modern HTML5 web browsers, or statically rendered into images files (JPEG, TIFF) or PDF files for printing. As an XML-based format, SVG also offers the opportunity to embed other annotations such as gender, cohort and batch information. Once embedded the SVG plot can be controlled dynamically using interactive JavaScript controls allowing for dynamic filtering of the display. This can be, for example, removing samples with no genotype call assigned, or all samples from one cohort out of many. The plots use a consistent colouring tied to the genotype call and include basic SNP QC metrics such as HWE, call rate and heterozygosity. To date we have been using ScatterShot to quickly examine and investigate the cluster plots from the new Illumina Exome and Affymetrix Axiom BioBank chips both of which contain a high number of low frequency SNPs.

1499F

Functional annotation of non-coding variants. *G.R.S. Ritchie[1,2], P. Flicek[1,2], E. Zeggini[2], UK10K Consortium.* 1) European Bioinformatics Institute, European Molecular Biology Laboratory, Hinxton, Cambridge, Cambridgeshire, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, Cambridgeshire, United Kingdom.

Identifying functionally relevant variants against the background of ubiquitous genetic variation is a major challenge in human genetics. For variants that fall in genic regions our understanding of splicing and the genetic code allow us to readily interpret possible functional effects, and several computational methods exist to further prioritise non-synonymous variants that are likely to affect protein function. There are, however, currently few methods to interpret variants that fall outside of coding regions and yet these are increasingly being identified as causally relevant in human disease. Efforts such as ENCODE and the Roadmap Epigenomics Project are producing a wide range of annotation in non-coding regions but it is not yet clear how to integrate these data into variation studies. To establish if any of these annotations might be informative when interpreting variants, we use the wealth of rare variants discovered in the whole genome sequencing arm of the UK10K project to quantify constraint in annotated regions across the genome, including non-coding genic elements, transcription factor binding sites and DNase1 hypersensitive sites. We identify a number of annotations, such as binding sites for the transcription factors BRF1 and BDP1 that appear to be under comparable constraint to coding sequence (mean derived allele frequency (DAF) 0.0414 (95% CI: 0.0359-0.0469) and 0.0457 (95% CI: 0.0412-0.0502) respectively, compared to 0.0379 (95% CI: 0.0374-0.0383) for coding regions and a genome-wide average of 0.0676 (95% CI: 0.0676-0.0677), Wilcoxon rank-sum $p < 1e\text{-}8$ in both cases comparing the DAF of variants falling in the binding site with variants not falling in this annotation). We use the results from this analysis to develop a classification system that prioritises variants based on the constraint on overlapping annotations. We demonstrate that scores from this system can help identify likely functional variants using a number of validation data sets, including non-coding somatic mutations from the COSMIC database where we find we can discriminate recurrent from non-recurrent mutations with an area under the receiver operating characteristic curve of 0.75.

CLINGIE: a user-friendly Clinical Genome Interpretation Engine on the web. *R. Robison, K. Wang.* Tute Genomics Inc., Los Angeles, CA.

Given the recent development of next-generation sequencing technologies on personal genomes, functional interpretation of genetic variants has become one of the major obstacles faced by biomedical researchers, clinicians and individual consumers wishing to analyze whole genome/exome sequencing data. Many research laboratories are flooded with high-throughput sequencing data sets, but the limited ability to process these data sets significantly delays the progress to infer biological insights. More and more consumers and patients are now sequencing their own genomes, but they often lack the ability to understand the hidden health-related information buried under the variant calls provided by sequencing companies or command-line software tools. Although several software tools (such as ANNOVAR) have been developed, they suffer from a number of limitations, including the lack of a user friendly interface, the lack of functionality to organize and store many VCF files, the lack of clinically oriented evidence-based annotations, and the slow speed to handle massive amounts of data. To overcome these limitations, we developed a web application called CLINGIE (Clinical Genome Interpretation Engine, see www.tutegenomics.com), to process, store and annotate personal genomes provided by researchers, clinicians and consumers. CLINGIE accomplishes this through its clinical genome interpretation pipeline using: (1) annotation, which provides simple and intuitive interface to help users determine the functional significance of variants, (2) filtering, used to identify disease causal variants, (3) probabilistic modeling, an alternative method to score all genes in a personal genome by their likelihood of causing particular Mendelian phenotypes and (4) storage, an ultrafast data querying system for real-time retrieval and organization of user files and annotations. Users can upload genome variants files (in VCF and other common formats) via a secure web interface, and obtain comprehensive annotation information from these files. The CLINGIE application can also perform case-control and family-based analysis on a collection of personal genomes, to help identify or prioritize disease-related genes and genetic variants. We believe that CLINGIE will help researchers expedite scientific discoveries, help clinicians generate clinical genetics reports, and help consumers embrace the next-generation sequencing technology to better understand their health and disease risk.

The Cincinnati Analytical Suite for Sequencing Informatics (CASSI) is a tool to identify disease-causing variants from Next Generation Sequencing studies. *A.M. Rupert[1], L.C. Kottyan[2,3], M. Kohram[1], M. Wagner[1], M.T. Weirauch[1,2,3], K.M. Kaufman[2,3], J.B. Harley[2,3].* 1) Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA; 2) Center for Autoimmune Genomics and Etiology, Division of Rheumatology, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, University of Cincinnati, Cincinnati, Ohio, USA; 3) Cincinnati Veterans Affairs Med. Ctr., Cincinnati, Ohio, USA.

High coverage whole genome and exome sequencing projects create large quantities of data that require storage, versioning, filtering and annotation. We are developing the Cincinnati Analytical Suite for Sequencing Informatics (CASSI) to meet these needs. CASSI is an application that seamlessly integrates file storage, metadata storage (e.g. family structure), and downstream processing with a web-based front-end that contains a user-friendly query interface. The web interface of CASSI enables biologists and clinicians without any computer science background to launch sophisticated analytical workflows to analyze next-generation sequencing data. For example, the interface allows users to directly interface with state-of-the-art annotation and filtering packages (such as vcftools, variant tools, and ANNOVAR), which are executed on a high-performance cluster. The key technical component in CASSI is the LONI pipeline engine from UCLA, which is a graphical user interface for executing complex workflows on a cluster that can be launched directly from a web browser. Query results obtained through the CASSI web interface are made available as a data source in the LONI pipeline, and users can choose from a large number of filtering and annotation workflows to analyze variant data. In particular, CASSI can be used to assess concordance between samples and to identify de novo, rare recessive, and compound heterozygous variants. The flexibility of the pipeline facilitates the implementation of new analytical strategies directly from the interface. In a particularly informative example, we uploaded the exomic sequence from a child with a severe, pediatric-onset lupus and her two healthy parents in the form of a Variant Call File (VCF) and a FAM file with pedigree information. CASSI validated the VCF file and allowed the user to pick from easily customized filters based upon the information present in the VCF file and external annotation. This analysis led to the identification of a de novo, non-synonymous variant in a DNA repair gene. Follow-up biological assays using the child's cells confirmed a defect in the radiation-induced DNA damage repair pathway and implicated the DNA-repair pathway in the etiology of lupus in this child. CASSI is a powerful analytical suite that allows users with varying degrees of programming sophistication to perform documented, reproducible studies with Next Generation Sequencing data to gain insight into the etiology of disease.

1502F

Fast and high-resolution evaluation tool of Illumina high throughput data considering spatial organization of the sequencing clusters. *Y. Sato, K. Kojima, N. Nariai, Y. Yamaguchi-Kabata, M. Nagasaki.* Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Miyagi, Japan.

We developed a tool for fast and high-resolution evaluation of Illumina sequencing data by considering spatial organization of the sequencing clusters on a flowcell. The tool was designed as a part of quality control pipeline of the Tohoku Medical Megabank Project, and analyzes the sequence data generated by the Illumina HiSeq2500 High Output mode (HCS 2.0.05) and Rapid Run mode (HCS 2.0.x), and MiSeq v2 flowcells. This tool takes fastq, Casava fastq, and SAM/BAM files as input, and outputs heatmap plots of base quality per each cycle, read density, and mapping quality. The heatmap arrangement corresponds to the shape of the flowcell used (automatically detected). Each tile within the flowcell is divided up to 100×100 resolution and shown as respective cells of the heatmap plot. The heatmap visualizes technical errors of the sequencing, e.g., air bubbles and cracks in the flowcell, providing useful information for the improvement of sequencing procedure. In addition, this tool can convert to N base from nucleotide bases obtained from low-quality spots within the tile/flowcell. Such data processing based on the errors of flowcell or sequencing procedure would highly improve the downstream analyses, such as exploration of TF binding sites or low-frequency somatic mutations that requires high-quality read and mapping information.

Exome Database. *T. Schwarzmayr[1], T. Wieland[1], A. Schmittfull[1], E. Graf[1], T. Meitinger[1, 2], T.M. Strom[1, 2].* 1) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 2) Institute of Human Genetics, Technische Universität München, Munich, Germany.

Next-generation sequencing of coding regions was successfully used to identify rare variants over the last couple of years. We developed a pipeline to analyze exome sequencing data for variations and a database to store the resulting SNVs and indels along with pedigree information. Data populated in the database can be queried interactively via a corresponding web interface. It provides a variety of standard queries to search for rare heterozygous, compound heterozygous, homozygous, de novo and somatic variants. Thus, filtering the variations by minor allele frequency and mode of inheritance allows to identify putative candidate variants for Mendelian diseases. Furthermore, all stored variants are linked with several annotations like position in transcripts, amino acid change, functional predictions, and presence in dbSNP, HGMD and the 1000 Genomes data. Quality scores, mapping scores, read depth and links to external databases are provided additionally. As controls, publically available frequency data as well as variants identified in in-house exomes of individuals with unrelated phenotypes are used. In addition to frequency based searches, one can also perform gene and disease-based searches, thus displaying the variation content of genes or focusing the search on known disease genes or HGMD mutations. Furthermore, the database comprises information of the average read depth per exon and the proportion by which each exon is covered at least 20-times. These data are useful in a diagnostic context to define the regions of a gene which have been appropriately analyzed and to identify genes carrying possible deletions of entire exons. On top of this, the database is connected with a LIMS and provides basic quality statistics, such as amount of sequence, read depth, sample contamination and discordance between specified and identified sex.

1504T

eXtasy: variant prioritization by genomic data fusion. *A. Sifrim[1,2], D. Popovic[1,2], L-C. Tranchevent[1,2], A. Ardeshirdavani[1,2], R. Sakai[1,2], P. Konings[1,2], J.R. Vermeesch[3], J. Aerts[1,2], B. de Moor[1,2], Y. Moreau[1,2].* 1) Department of Electrical Engineering, KU Leuven, Heverlee, Vlaams-Brabant, Belgium; 2) iMinds Future Health Department, Leuven, Belgium; 3) Laboratory of molecular cytogenetics and genome research , KU Leuven, Leuven, Belgium.

Massive parallel sequencing greatly facilitates the discovery of novel disease genes causing Mendelian and oligogenic disorders. However, many mutations are present in any individual genome, and identifying which ones are disease causing remains a largely open problem. We introduce a novel computational approach, called eXtasy, to prioritize nonsynonymous single nucleotide variants (nSNVs) by integrating variant impact prediction, haploinsufficiency prediction and phenotype-specific gene prioritization that allows significantly improved prediction of disease-causing variants in exome sequencing data. To train our method we use the Human Gene Mutation Database (HGMD) as our source of disease-causing variants and 3 control sets ranging from common polymorphisms to rare variation in healthy individuals. By integrating phenotype-specific gene prioritization information we are able to greatly increase the area under the receiver-operator curve (ROC AUC) by at least 30% compared to classical deleteriousness prediction methods (e.g. SIFT, Polyphen, MutationTaster).This is likely due to eXtasy's ability to discriminate between phenotype-specific and phenotype-unrelated deleterious variants. Although our performance estimates are likely overestimated due to prior information bias in a retrospective benchmark, we show that even controlling for these biases we obtain a substantial performance increase. We believe that the presented approach will greatly facilitate the analysis of exome sequencing data in human disease by efficiently prioritizing nSNVs in the light of the phenotype in question. eXtasy is publicly available at http://homes.esat.kuleuven.be/~bioiuser/eXtasy/.

1505F

PHEVOR: Integration of VAAST with Phenomizer and the Gene Ontology for accurate disease-gene identification using only a single affected exome. *M. Singleton, L. Jorde, M. Yandell.* Human Genetics, University of Utah, Salt Lake City, UT.

Accurate identification of disease-causing genes using only a single exome is major analytic challenge. For recessive rare diseases, when only a single affected individual's exome is available, VAAST and Annovar typically rank the disease-causing gene among the top 10 candidates only 15% and 2% of the time, respectively. To improve disease-gene identification, we have developed PHEVOR, an algorithm that integrates three popular tools: (1) Phenomizer, which provides powerful means to generate candidate disease-gene lists based upon phenotype data, (2) the Gene Ontology (GO), which provides function, location and biological process descriptions for more than 18,000 human genes, and (3) VAAST a probabilistic disease-gene finder that uses variant-frequency information together with amino acid substitution (AAS) frequencies to identify disease-causing variants in personal genome sequences. We benchmarked PHEVOR using 50 known recessive disease-causing variants spiked into otherwise healthy exomes. On this dataset, VAAST identifies the disease-gene as the top candidate only 2% of the time and places it in the top 10 candidates 15% of the time. Phenomizer does about as well, ranking the disease-gene first 3% of the time and in the top 10 candidates 14% of the time~but with an important caveat: Phenomizer's candidate list is restricted to 2,528 known human disease genes. If the disease-causing alleles do not reside in one of these genes, they will be missed no matter how informative the phenotype and genomics data. PHEVOR overcomes this limitation by propagating phenotype information across the Gene Ontology, extending Phenomizer's candidate list to more than 18,000 human genes. PHEVOR also provides probabilistic approaches to incorporate personal genome data using VAAST's proven statistical methodology. The improvement is dramatic. Using the same benchmark dataset described above, (note that 54/100 genes are not included in Phenomizer's gene list) and only a single affected exome, PHEVOR is able to identify 56% of disease-causing genes as the top candidate genome-wide, and 79% of the time the disease-gene is within the top 10 candidates. PHEVOR thus provides an effective new means for single exome-based diagnosis.

1506W

Multiagent-based SNP Annotation for Large-Scale Genetic Diversity Analyses: An Application to the Brazilian EPIGEN Initiative. *G.B. Soares-Souza[1], E. Tarazona-Santos[1], A. Pereira[2], M.L. Barreto[3], B.L. Horta[4], M.F. Lima-Costa[5], A. Horimoto[2], N. Esteban[2], F. Kehdy[1], W.C.S. Magalhaes[1], M.R. Rodrigues[1], The Brazilian EPIGEN Consortium.* 1) General Biology Department, Federal University of Minas Gerais, Belo Horizonte, Brazil; 2) Laboratory of Genetics and Molecular Cardiology, Heart Institute, Medical School of University of São Paulo, São Paulo, Brazil; 3) Instituto de Saúde Coletiva, Federal University of Bahia, Salvador, Brazil; 4) Universidade Federal de Pelotas, Pelotas, Brasil; 5) Centro de Pesquisas René Rachou, Fundação Oswaldo Cruz, Belo Horizonte, Brazil.

Despite the great amount of genetic diversity data available, the study of variants with biomedical interest requires their association with other types of biological data, such as pathways, pharmacogenetics, GWA, and so on. Since these heterogeneous data are fragmented in different databases, it is necessary to develop tools to integrate different sources of biological data in order to move forward with genetic studies of diseases or populations. Although there are annotation tools that solve this problem, the management of large scale data is still a challenge in terms of execution time. Computer technologies that incorporate parallel execution of the code are a promising solution for processing large scale data, since they are able to reduce execution time by dividing the execution load into independent processing units. One such technology is the agent-based technology. Here, agents are autonomous programs that perform a particular task and can communicate with other agents in a Multiagent system to delegate tasks, share results or get complementary information. Agents in a Multiagent system execute concurrently, as independent threads. Given the heterogeneity of biological data and their distribution over distinct sources, we have chosen this technology to development a SNP annotation system for large scale data. In our system, Database Agents encapsulate databases of interest, such as dbSNP, pharmGKB, OMIM, UCSC and GO. The annotation process works as follows: (i) a Coordinator Agent receives a list of SNPs to be annotated and passes them on to each Database Agent; (ii) the latter Agents then retrieve, concurrently, relevant information from their encapsulated database to annotate the list of SNPs and return it to the Coordinator; (iii) after all annotated SNPs are received, the Coordinator agent merges the annotations and passes them on to the Interface Agent to generate an annotation report. Our Multiagent annotation system is being used to thoroughly annotate data from the Brazilian EPIGEN initiative, which involves the genotyping of 2.3 M SNPs in 6600 individuals, 4.3 M SNPs in 270 individuals and 30 complete genomes. So far, tests showed that the distributed architecture of the Multiagent system significantly reduces the annotation execution time. As a follow up study, we will investigate the population genetics of different SNP classes to understand the implications of its allelic spectrum on GWAS studies, and new GxG and GxE approaches.

Comprehensive network and pathway analysis of RNA sequencing of triple negative breast cancers. *J.P. Solzak[1], R. Atale[1], B.A. Hancock[1], J.N. Billaud[2], M. Radovich[1].* 1) Surgery, Indiana University School of Medicine, Indianapolis, IN; 2) Ingenuity Systems, Redwood City, CA.

Introduction: Triple-negative breast cancers (TNBCs) account for 15% of all breast cancers cases and are defined by an absence of actionable therapeutic targets (ER-,PR-,HER2-). Using RNA-seq data, we compared TNBCs to microdissected normal breast epithelium from healthy volunteers and to normal tissue adjacent to tumor followed by comprehensive network and pathway analysis. Methods: RNA-seq data from 94 TNBCs (from Indiana University and TCGA), 20 microdissected normal breast tissues (Komen Tissue Bank), and 10 adjacent normal tissues (TCGA), were merged and imported into Partek Genomics Suite. The merged transcript RPKMs were transformed, batch effect corrected, and analyzed for differential expression. Statistically significant genes were imported into Ingenuity Pathway Analysis (IPA) Spring 2013. Results: IPA analysis of differentially expressed genes of TNBCs compared to microdissected normal breast tissues identified key pathways in DNA damage, cell cycle, and immune signaling. We then employed Upstream Regulator and Causal Network Analysis which predict the activation or inhibition state of regulators based on downstream differentially expressed genes and known directionality of expression. From this analysis, two statistically significant upstream regulators with known roles in metastases were identified: IRF7 (interferon regulatory factor), and FOXM1 (cell-cycle transcription factor). In particular, FOXM1 is predicted to drive the activation of a multitude of genes involved in cancer cell proliferation. In addition, we identified two causal networks centered on inhibited SPDEF (Ets transcription factor), and on activated HOXB4 (developmental transcription factor). Of note, HOXB4 has not previously been described in TNBC and may play a role in the stem cell phenotype of TNBC. In contrast, when TNBCs were compared to adjacent normal tissue, some of the same pathways and regulators were identified, but other pathways involved in fibrosis, atherosclerosis, metabolism, and edema were also observed, likely secondary to the stromal nature of adjacent normal tissue. Conclusion: By using RNA-seq data from TNBCs and microdissected normal epithelium coupled with comprehensive network and pathway analysis we demonstrate the utility of these methods to uncover novel biological insights into TNBC biology. In particular, we observe that IPA's Causal Network Analysis has unique capabilities to identify master regulators useful for drug target discovery.

1508F

GrabBlur - a framework to facilitate the secure exchange of whole-exome and -genome sequencing data sets. *B. Stade[1], D. Seelow[2], A. Franke[1].* 1) Institute of Clinical Molecular Biology, University Hospital Schleswig-Holstein, Kiel, Germany; 2) NeuroCure Clinical Research Centre, Charité - Universitätsmedizin, Berlin, Germany.

With 'GrabBlur' we developed a tool to collect, aggregate and share SNV (single nucleotide variant) data of hundreds of samples with a special trait/ phenotype in a public database, while keeping each individual sample unidentifiable. First, 'GrabBlur' helps a submitter to combine SNV data from samples with phenotype and sequencing information (VCF files) using a local web interface or command line operations. Examples are HPO terms (Human Phenotype Ontology), sample traits, information about the applied sequencing technology and the submitting institute / laboratory. Most of the information is optional - the submitter can decide for himself what he wants to and can share. In the second step 'GrabBlur' merges and aggregates the data. For example, if it turns out that a SNV is rare - every submitter sets the proper threshold for his own data - all sample information is replaced with contact information of the submitter. In further steps the data will be highly aggregated so it can be shared while adhering to data privacy. It will not be possible to recover the exome/ genome of a sample or to identify a single individual in the dataset. After checking that the individual genetic information is sufficiently 'blurred' the data can be uploaded into a public database, where the sample sets will be aggregated again, thus adding another 'blurring' step. If another researcher finds an interesting SNV in the dataset he should now be able to get in contact with the original submitter to exchange information on the individuals, e.g. if his patient has a similar phenotype as the individual in the database. A webinterface exists for querying the database and to derive also gene-wise SNV information. In summary, our tool will facilitate large-scale data exchange between researchers as the genetic identity of individuals is sufficiently protected. The database will be of help for human geneticists who seek to distinguish between incidental or population-specific findings and truly disease-causing mutations. Moreover, the data in the database will aid to drive case-control association studies employing large-scale SNV data. Finally, exome/genome data can be shared as promiscuous as done for GWAS studies, which will help to drive well-powered analyses.

1509W

Detection of Informative Variants in Low Coverage Next Generation Sequencing Data as a Quality Control Tool to Ensure Sample Integrity. *L. Timms, P. Ruzanov, J.K. Miller, N. Buchner, D. Pasternack, J.D. McPherson.* Ontario Institute for Cancer Research, Toronto, Ontario, Canada.

Next generation sequencing (NGS) allows for the rapid generation of exome or whole genome coverage across multiple samples. Tracking of matched samples (eg tumor/normal pair) and multiple lanes of samples that are combined to generate sufficient coverage must be monitored early in the process to avoid costly sequencing of misidentified samples and lanes. Pooling of sequencing data for even a single unmatched lane within a sample severely affects downstream variant detection. Short tandem repeat (STR) analysis, such as AmpFISTR Identifiler ®, is a standard, PCR-based human genotyping method used in the field of forensics. This genotyping method has also been effectively applied as an early quality control step for NGS to prevent processing of misidentified samples; however, the STRs are not efficiently captured with short read NGS technologies and difficult to apply to fragmented DNA samples such as those derived from formalin fixed paraffin embedded material. Single nucleotide genotyping methods can also be used for identification requiring as few as 50 informative variants for identification. We have implemented a per lane level method for efficient library identification as a quality control measure prior to variant detection. We have identified a list of 150 polymorphic (MAF 0.49) SNVs that can be detected in low-coverage sequencing data. Homozygous variants can be called at a minimum of 8X, and heterozygous variants must have a minimum of two reads per allele. Pairwise comparisons are then made between sequencing lanes of the same sample or matched sets utilizing an overlapping subset of the targeted loci with sufficient coverage in both samples. Such analyses can be done as part of an initial quality control check of the data prior to starting complex analysis that requires more time and computer resources.

1510T

Consensus Genotyper for Exome Sequencing: Improving the Quality of Exome Variant Genotypes. *V. Trubetskoy[1], R. Madduri[2], A. Rodriguez[2], J. Scharf[3], P. Dave[2], I. Foster[2], L. Davis[1], N. Cox[1].* 1) Medicne/Genetic Medicine, UNIVERSITY OF CHICAGO, CHICAGO, IL; 2) Computation Institute, University of Chicago, Chicago, IL; 3) Department of Neurology, Massachusetts General Hospital, Boston, MA.

With the rise of next generation sequencing methods, there are now a variety of tools available to researchers for detection and genotyping of sequence variants. However, the concordance among variant sets between these disparate approaches has been shown to be poor. Recently, researchers in the machine learning community have shown that combining the output of multiple models can dramatically improve performance of a classifier. Collectively, these techniques are referred to as ensemble methods. Here we describe a novel variant calling approach based on an ensemble of variant calling algorithms which we call Consensus Genotyper for Exome Sequencing (CGES). Our method employs a two-stage voting scheme among a set of three algorithm implementations, GATK2.0, Freebayes, and Atlas2.0, which were used to identify variant sites and determine genotypes in the study. We apply CGES to a dataset consisting of 123 samples sequenced at the Center for Inherited Disease Research (CIDR) using the Agilent SureSelect3 Exome Capture and Illumina sequencing technology. Samples were drawn from extended pedigrees, allowing us to compare individual and family based quality metrics across all algorithms. The CGES approach is shown to outperform its constituent parts in many key quality metrics without a significant loss in the number of variant sites called. In particular we are able to achieve a threefold reduction in Mendelian inconsistencies between the best performing variant caller and our consensus approach (CGES = 240.14/trio and Atlas2.0 = 699.59/trio). For callers with comparable QUAL scores, our CGES set of variants has an average QUAL score 11% (GATK) and 70% (Freebayes) higher than the unfiltered output set of each respective variant caller. Additionally, the consensus set outperforms all individual callers in the study with regard to expected exome-wide transition-transversion ratio(CGES = 3.07 and Atlas2.0 = 2.98). For the purpose of accessible, efficient, and reproducible analysis, we provide implementation of CGES as a stand alone command line tool, as well as a set of parallel Galaxy tools and workflows for accessible and efficient use by the research community (see **Implementing a High Performance, Reusable Consensus Calling Pipeline for Next Generation Sequencing using Globus Genomics**, Madduri et al., ASHG 2013).

1511F

DRAW+SneakPeek: Analysis Workflow and Quality Metric Management for DNA-Seq Experiments. *O. Valladares[1,2], C.-F. Lin[1,2], D.M. Childress[1,2], E. Klevak[3], E.T. Geller[1], Y.-C. Hwang[2,4], E.A. Tsai[4,5], G.D. Schellenberg[1], L.-S. Wang[1,2].* 1) Department of Pathology and Laboratory Medicine, University of Pennsylvania. Philadelphia, PA; 2) Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA; 3) Department of Physics, University of Washington, Seattle, WA; 4) Genomics and Computational Biology Graduate Group, University of Pennsylvania. Philadelphia, PA; 5) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA.

We report our new DRAW+SneakPeek software for DNA-seq analysis. DRAW (DNA Resequencing Analysis Workflow) is based on commonly used open source programs for analyzing sequencing experiment data. DRAW implements the Best Practice Variant Detection from Genomic Analysis Toolkit (GATK) and automates the workflow of processing raw sequence reads including quality control, read alignment, and variant calling on High-Performance Computing (HPC) facilities such as Amazon Elastic Compute Cloud (EC2). SneakPeek provides an effective interface for reviewing dozens of quality metrics reported by DRAW, so users can assess the quality of data and diagnose problems in their sequencing procedures. We evaluated DRAW on Amazon EC2 using a single flowcell WES dataset of 350.2G nucleotides from 34 multiplexed samples using Nimblegen SeqCap EZ Human Exome Library, 100bp pair-end reads on a HiSeq 2000 sequencer. DRAW processed the whole dataset in 1,943.2 core-hours, or 17.4 hours/core on 14 Quadruple Extra Large Instances with 112 cores, generating 1.1TB of data. The total cost was $528 including storage, computing, and data download. Both DRAW and SneakPeek are freely available under the MIT license, and are available as Amazon Machine Images to be used directly on Amazon Cloud with minimal installation. Instructions and codes can be obtained from the NIA Genetics of Alzheimer's Disease Data Storage Site (NIAGADS) at https://www.niagads.org/content/drawsneakpeek.

Performance of two imputation methods on large scale data: experiences in the eMERGE network. *S. Verma[1], G. Armstrong[1], M. Ritchie[1], D. Crawford[2], Y. Bradford[2], M. Andrade[3], I. Kullo[3], G. Tromp[4], H. Kuivaniemi[4], L. . Armstrong[5], G. Hayes[5], B. Keating[6], D. Crosslin[7], G. Jarvik[7], B. Namjou[8], E. Bookman[9], R. Li[9], eMERGE Network.* 1) Center for Systems Genomics, The Pennsylvania State University, University Park, PA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Mayo Clinic, Rochester, MN; 4) Geisinger Health System, Danville, PA; 5) Northwestern University, Chicago, IL; 6) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 7) University of Washington, Seattle WA; 8) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 9) Division of Genomic Medicine, National Human Genome Research Institute.

The eMERGE network, an NHGRI funded initiative comprises nine sites each with DNA biobanks linked to electronic health records (EHRs). Approximately 39,206 unique DNA samples have been genotyped using either Affymetrix or Illumina genome-wide SNP arrays. Led by the Coordinating Center and the eMERGE genomics workgroup, we have developed an imputation pipeline for merging genomic data across the different SNP arrays used by the eMERGE sites, to maximize sample size and the power to detect associations. We performed imputation using the 1000 Genomes Cosmopolitan reference panel - which includes 1092 individuals and over 36 million SNPs. We compared accuracy of imputation results from two software packages - Beagle and Impute2 (phasing performed with ShapeIt2). For the comparison we used the following metrics: accuracy of imputation, allelic R2 (estimated correlation between the imputed and true genotypes for all imputed SNPs), and relationship between allelic R2 and minor allele frequency across all imputed SNPs. Since imputation is computationally intensive, we compared computation time and computing resources required by the two software packages. We have also outlined the major challenges and lessons learned due to the complexity of using these two approaches and different platforms. Finally, we will present lessons learned as we conducted our quality control process, as many of the pipelines are unique and cleaning of imputed data is essential for further analysis. This imputed dataset will serve as a valuable resource for variant discovery, leveraging the wide range of medically relevant phenotypes that can be mined from the EHR.

1513T

FILTUS - a versatile and user-friendly program for filtration and statistical evaluation of variants in high-throughput sequencing projects. *M. Vigeland.* Medical Genetics, Oslo University Hospital, Oslo, Norway.

We present FILTUS, a program for working with variant files resulting from sequencing projects, e.g. exome sequencing. Various options for filtering and summarizing statistics are available, as well as exploratory tools like pairwise sharing among the samples. Several statistical methods for evaluation of variants are implemented, aiding the identification of causal variants in Mendelian disease projects. Both case-control and family based sequencing designs are supported, as well as dominant/simple recessive/compound recessive disease models. Homozygous regions can be identified (via PLINK), and the program offers conversion of variant files to MERLIN format, facilitating linkage analysis. FILTUS accepts variant files in any format, as long as the user identifies essential columns like chromosome, position, gene and genotype. Files in VCF format are automatically recognized and given special treatment. The implementation allows several hundred complete exomes to be analyzed simultaneously on a standard laptop. FILTUS has an easy-to-use GUI accompanied with a user manual, and does not require particular bioinformatic skills. It is written in Python and runs on Windows, Mac and Linux.

1514F

DeMix: Deconvolution for Mixed Cancer Transcriptomes Using Raw Measured Data. *W. Wang[1], J. Ahn[1], Y. Yuan[2].* 1) Bioinformatics & Comp Biology, Univ Texas MD Anderson Cancer Ctr, Houston, TX; 2) Biostatistics, Univ Texas MD Anderson Cancer Ctr, Houston, TX.

Tissue samples of both tumor and stromal cells cause underdetection of gene expression signatures associated with cancer prognosis or response to treatment. In silico dissection of mixed cell samples is essential for analyzing expression data generated in cancer studies. Currently, a systematic approach is lacking to address three challenges in computational deconvolution: 1) violation of linear addition of expression levels from multiple tissues when log transformed microarray data are used; 2) estimation of both tumor proportion and tumor-specific expression, when neither is known a priori; and 3) estimation of expression profiles for individual patients. We have developed a statistical method for deconvolving mixed cancer transcriptomes, DeMix, to address the above issues in array-based expression data. We demonstrate the performance of our model in synthetic and publicly available real datasets. Our method can be applied to ongoing biomarker-based clinical studies, as well as to the vast expression datasets previously generated from mixed tumor samples.

üRRBS-Predictor, a webtool to guide enhanced reduced-representation bisulfite (RRBS) analysis of genomic DNA methylation patterns. *T.R. Ward[1, 2], X. Zhu[1, 2], A.E. Urban[1, 2].* 1) Genetics Dept, Stanford, Stanford, CA; 2) Dept of Psychiatry, Stanford, Stanford, CA.

üRRBS-Predictor is a bioinformatics tool that predicts which parts of a given genome sequence will be included in an RRBS experiment if a given size-fraction of DNA fragments is chosen during the RRBS sample preparation step. Genome-sequencing after bisulfite conversion is a powerful approach to understanding genomic DNA methylation. But whole genome bisulfite sequencing is costly and inefficient at today's sequencing and computing speeds, due to GC poor regions in many genomes that will be included in the analysis without contributing much if anything at all in terms of insight regarding the question at hand. RRBS uses restriction cutting at recognition sites containing CpG dinucleotides (typically with the restriction endonuclease MspI) followed by size selection for genomic DNA fragments in order to enrich for the CG-rich parts of a genome before next-generation sequencing. However, the size fraction taken during the selection step of standard RRBS protocols seemed somewhat arbitrarily chosen and allows for only a very small portion (often just around 1%) of a typical genome to be included in the analysis, with little or no ability to assure that given regions of interest such as certain genes or regulatory regions are covered. üRRBS-Predictor is centered around an algorithm that will analyze the whole genome and report back where in the genome MspI will cut (fragment start and stop positions), the fragment lengths and the number of CpGs found in each fragment. The user can then explore which portion and percentage of a genome would be covered by RRBS sequence data if a given size fraction of DNA fragments is selected during RRBS sample preparation (in 50 bp increments between 50 and 800 bp, based on experimental limitations). At first this can be done for the human genome and the genomes of the most common model organisms such as mouse, rat, fruit fly, zebrafish, C. Elegans (later-on additional genomes can be included in the webtool). The script produces a BED file that can be uploaded to the UCSC Genome Browser that will display the fragments in their locations and color-coded based on the size of the fragment. Alternatively, the user will be able to select a genomic region of interest and will be given all the fragments that cover that region along with their sizes. [üRRBS-Predictor is just a working title, ü for über, could be enhanced-RRBS-predictor/eRRBS-predictor, variable-RRBS/vRRBS - or something entirely different].

Analysis of archived residual newborn screening bloodspots after whole genome amplification, using Genformatic's genomic medicine tool suite. *D. Weaver[1], B. Cantarel[1], J. Reese[1], R. Finnell[2, 3].* 1) Genformatic, Austin, TX; 2) University of Texas, Austin; 3) Dell Pediatric Research Institute.

A wealth of genomic health information is archived in residual newborn blood samples originally collected and used for routine newborn screening for common genetic diseases. Where legally and ethically permissible, exome or whole genome analysis of archived samples could potentially reveal valuable epidemiological, population genetic and personal genomic information. However, the quantity of residual sample material in many biobanks is relatively small and may present an impediment to whole genome or exome analysis. Nonetheless, the information that could be gleaned from large-scale analysis of archived residual newborn blood is tremendous, provided current methodological impediments can be overcome. In our study, we compared the recovery of variant calls from NGS of amplified DNA to the variant calls generated in standard exome analysis of non-amplified material from the same individuals, using Genformatic's cloud-based genome analysis suite. While some data fall-out from whole genome amplified DNA is evident, the extent of concordance between variant call sets demonstrates that valuable genomic medicine information may be obtained from sequencing residual newborn screening bloodspots after whole genome amplification. The information which could be generated in a broad survey of currently archived newborn samples is vast and complex, requiring extensive computing capabilities, including large amounts of storage space and memory. We offer a cloud-based genome analysis and comparison suite of tools enabling users to (i) detect variation, (ii) annotate and filter SNPs, (iii) share encrypted genome data with collaborators, and (iv) compare multiple genomes to identify shared ancestry or common variation. Our analysis tools allow users to analyze their data in a secure and scalable fashion, without building a complicated server infrastructure. Applying our methods, we have determined that approximately 80% of the SNPs are concordant between the amplified and the PCR-free sequence data. Additionally, we evaluated SNPs predicted from the same individual using alternative capture kits, and discover a surprisingly high level of discordance in SNP calls - only 15-70% SNP concordance, depending on which SNP detection method is employed.

Visualizing Multiple Types of Genomic Information Across Chromosomes With PhenoGram. *D. Wolfe, S.M. Dudek, M.D. Ritchie, S.A. Pendergrass.* Center for Systems Genomics, The Pennsylvania State University, University Park , PA.

With the abundance of information and analysis results being collected for genetic loci, user-friendly and flexible data visualization approaches can inform and improve the analysis and dissemination of these data. An ideogram is a graphic representation of chromosomes, and these plots have been used with the addition of overlaid points, lines, and/or shapes, to provide summary information of various kinds coupled with genomic location information. For instance, the results of multiple published genome-wide associations have been plotted on ideograms (www.genome.gov/gwastudies), where lines identify chromosomal location and colored circles indicate associations with different phenotypes/traits. We have developed a flexible software tool PhenoGram, which exists as a web-based tool and also a command-line program, providing a way to visualize data in multiple ways via ideograms. Initially conceived as a method to highlight SNP-phenotype association results across the genome through the use of color-coded circles linked by lines to genomic locations like the NHGRI GWAS catalog plots, the software has been expanded with many unique features. With PhenoGram users can plot lines at specific base-pair locations, or base-pair to base-pair regions of chromosomes, with the use of color, with or without other annotation. This feature has been used in several ways to highlight locations or regions of interest. For example, we have used PhenoGram to produce plots showing the genomic coverage of SNPs from a genotyping array, plots highlighting the chromosomal coverage of imputed SNPs, as well as plots showing the location of sequenced loci. We have also successfully used this software to plot regions covered by two different copy-number variant detection methods, visually contrasting overlapping regions between the two approaches. PhenoGram allows users to annotate chromosomal locations and/or regions with shapes in different colors. This feature can be used to indicate different traits associated with specific loci, and users can choose different shapes to highlight ancestry or another study attributes related to specific data points. Further, users can annotate an ideogram with gene identifiers or other text, as well as create plots showing expanded detail for specific chromosomal locations. PhenoGram is a versatile software, further fostering the exploration and sharing of genomic information. For full details see: http://visualization.ritchielab.psu.edu.

1518W

Massively parallel sequencing as a tool for HLA typing. *W. Yang[1,2], Y. Huang[1,2], J. Yang[1,2], P.C. Sham[2], Y.L. Lau[1].* 1) Paediatrics & Adolescent Med, Univ Hong Kong, Hong Kong, 10000, Hong Kong; 2) Centre for Genomic Sciences, the University of Hong Kong.

It has been shown that massively parallel sequencing(MPS) for HLA typing has the potential to become a more accurate, high throughput, and highly flexible HLA typing platform for both clinical laboratories and research settings. We introduce the two areas we have made progresses in using MPS for HLA typing, including improvement in using genome-wide sequencing (GWS) data to make HLA calls and pooling of a large number of samples for HLA typing using MPS technology. HLA typing from GWS data using available tools has many issues, often because they don't fully account for the polymorphic nature of this group of genes and enormous allelic differences. Thus we developed a multiple references-based mapping approach for defining HLA types from GWS and identified large number of previously unmapped sequencing reads, which allowed a much more complete HLA calling from GWS data. A toolkit was developed to facilitate using this method for HLA typing from GWS. Making use of the available whole exome sequencing data we have and using this novel HLA mapping and calling method, we were able to gather detailed information on the sequences of the polymorphic exons of the major HLA genes and to design PCR primers for amplifying these exons. The primers are particularly suited for East Asian populations. In research laboratories, we often need to type certain HLA genes on a large number of samples, which is quite different from the practices in clinical laboratories. This is especially important for genetic studies of autoimmune diseases and population screening for certain HLA gene alleles to avoid adverse drug responses. Making use the method and primers we have developed, together with an innovative barcoding system to allow pooling of up to a thousand PCR amplicons together for next generation MPS sequencing, we were able to increase throughput of HLA typing and reduce sequencing cost significantly, while providing flexibility and automation needed for research projects. These innovations will enhance the development of using MPS technology for HLA typing for both clinical laboratories and research settings, and the results are particularly suited for East Asian populations.

1519T

PHV: A highly accurate SNP and INDEL variant detector based on the Profile Hidden Markov Model. *M. Zhao, W. Lee, G.T. Marth.* Biology, Boston College, Chestnut Hill, MA.

Accurately calling single nucleotide polymorphisms (SNPs), insertions and deletions (INDELs) is crucial to medical and population genetics. A variety of algorithms have been developed to detect SNPs and have been successfully applied to large-scale re-sequencing projects, but detecting INDELs still presents significant problems. Moreover, most of the existing algorithms are designed for high-quality short-read data with a low INDEL sequencing error rate whereas upcoming technologies such as Ion Torrent sequencing technique produces long reads at the cost of an increased sequencing error rate. This leads to more challenging variation detection, and is beyond the scope of present variant detection algorithms. We have developed PHV based on the Profile Hidden Markov Model (PHMM) for accurately calling SNPs and INDELs from data with varying quality. This method jointly models sequencing and alignment uncertainties, which are overlooked or not properly modeled by most existing variant calling algorithms. The high time complexity of the PHMM algorithm is reduced by the banded approach, so at the same time of achieving high accuracy, the running time of PHV is comparable with other variation detection tools. While this tool is designed for long read technologies, it also demonstrates an improvement in variation detection when deployed on currently available short read technology data. We used both simulated Illumina data and a single sample (NA12878 from the 1000 Genomes Project) with deep sequenced whole genome data (Illumina and LS454) to test the algorithm. Comparing with SNPs called by the Genome Analysis Toolkit (GATK), Samtools and Freebayes, PHV's results have the best receiver operating characteristic (ROC) curve on the simulated data. Moreover, comparing with the other tools, PHV shows higher sensitivity and specificity for INDEL detection and higher specificity for SNP detection for the real data, especially in the genomic regions with poorly aligned reads. PHV will be further tested with real PacBio and Ion Torrent data.

1520F

Resolving complex structural genomic rearrangements using a randomized approach. *X. Zhao[1], S.B. Emery[2], J.M. Kidd[1,2], R.E. Mills[1,2].* 1) Department of Computational Medicine & Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Genetics, University of Michigan, Ann Arbor, MI.

Structural variants (SVs), defined as the deletion, duplication, insertion, inversion or translocation of genomic regions, are both a major source of genetic diversity in human populations and are also directly responsible for the pathogenesis of numerous diseases. Many studies have been conducted in the past decade to discover and analyze SVs, however these have predominantly focused on unbalanced (copy number variant) events involving only one or two breakpoints. In contrast, more complex rearrangements resulting from multi-step or overlapping events involving three or more breakpoints have received considerably less attention or have been incorrectly interpreted. We have developed an algorithm, metroSV, which accurately analyzes and resolves complex rearrangements using whole genome, paired-end sequencing data. This method first identifies regions of the genome suspected to involve a complex event and then delineates putative breakpoints using aberrant sequence alignments. The resulting segments are then iteratively rearranged in a randomized fashion and scored against expected models of sequence characteristics using a Markov chain Monte Carlo approach to infer the underlying architecture of these variants. We have applied our algorithm to well-characterized genomes including the high coverage Illumina Platinum CEPH pedigree that has been deep sequenced and compared our results to previously reported complex events in these samples. We are in the process of broadening the scale of our algorithm to assess the entire genome concurrently and are also expanding our analysis to other large-scale, publicly available datasets as well as pathogenic samples associated with germline or somatic chromothripsis-like events. We believe metroSV represents a significant advancement towards resolving these complex chromosomal structural rearrangements and furthering our understanding of their mechanistic origins and functional impact.

1521W

Systematic integration of functional and computational genomics suggests that the indel rs79240969 in the DNM3 gene influences both bone- and obesity-related traits. *M. Claussnitzer[1], X. Chen[1], D. Karasik[1], LA. Cupples[2], DP. Kiel[1], YH. Hsu[1].* 1) Inst Aging Res, Hebrew Senior Life, Harvard Medical School, Boston, MA; 2) Boston Univ Sch Pub Hlth, Boston, MA.

Recent studies suggest shared etiologies of bone and adiposity phenotypes. Previously, we conducted a multivariate genome-wide association study (GWAS) of bone mineral density (BMD) at different skeletal sites and metabolic syndrome risk factors, and identified 31 bivariate genome-wide significant loci ($p<5\times10\text{-}8$, p(bivariate)<p(univariate)/10). However, signals emerging from GWAS are merely markers for large genomic regions in linkage disequilibrium (LD), harboring the disease-causing variant. Identifying the shared causal variants is central to elucidate the molecular mechanisms underlying the genetic correlation between bone and fat. We applied an integrative bioinformatics approach leveraging tissue-specific functional and computational genomics and sequence data to narrow-down the potential causal variants. We identified all reported sequence variants (from the 1000 Genomes Project) within the identified bivariate GWAS loci (physical boundaries LD r2>0.7). We merged data on sequence variants with bone- and adipose-specific genome-wide epigenomic profiling data, reported from the ENCODE project, that allow for chromatin state-dependent analyses of regulatory variation. Within predicted regulatory regions, we discovered cis-regulatory modules (CRMs) by analyzing cross-species conserved patterns of transcription factor binding sites (TFBS) across 16 vertebrate species. Using our approach, we identified potential causal variants within the bivariate association loci that may be responsible for the association with BMD and obesity traits. One example is the bivariate signal at DNM3, 1q24.3 (GWAS SNP rs10489290, bivariate association test p=8.4 x 10-11 for femur neck BMD with waist-to-hip ratio). We pinpointed an intronic insertion/deletion variant rs79240969 (-/TCA, MAF=0.296, LD r2=1.0), specifically mapping within predicted osteoblast and adipocyte gene regulatory regions. The cell-type specific TFBS pattern analysis revealed rs79240969 localizing within a cross-species conserved CRM relevant to bone and fat. The rs79240969 insertion allele creates a perfect binding site for the zinc-finger protein Zfp521 which has been previously shown to control bone mass. Our bioinformatics analysis may represent a useful step toward pinpointing causal variants from potentially pleiotropic loci for direct laboratory validation and ultimately for improving therapeutic strategies addressing shared etiological mechanisms of BMD and obesity-related phenotypes.

1522T

The Developmental Brain Disorders Database (DBDB): A curated neurogenetics knowledge base with clinical and research applications. *G. Mirzaa[1], AJ. Barkovich[2], WB. Dobyns[1], KJ. Millen[1], AR. Paciorkowski[3].* 1) Deparmtent of Human Genetics, Seattle Children's Hospital, Seattle, WA; 2) Department of Pediatrics, University of California San Francisco, San Francisco, California; 3) Depts of Neurology, Pediatrics & Biomedical Genetics, Center for Neural Development & Disease, University of Rochester Medical Center, Rochester, NY.

The number of genes associated with neurodevelopmental disorders has risen dramatically over the past decade, with the discovery of many genes associated with intellectual disability, autism, epilepsy, and others. The maturation of copy number studies and the use of whole exome sequencing (WXS) have further increased the number of genes associated with neurodevelopmental phenotypes. For geneticists, this rapid expansion of knowledge increases the difficulty of arriving at diagnoses in a timely and cost-effective manner. Given rapidly advancing technology, the genetics community has moved most of its molecular and clinical resources online to assure more rapid dissemination of information. The currently available resources, while encyclopedic, are limited by the state of organization of the knowledge base. There is no system of levels of evidence for gene-phenotype associations, making it difficult to judge which genes ought to be tested first. Also lacking is a neurodevelopmental phenotype ontology. Finally, laboratories working with WXS data would benefit from a well-curated source of genes associated with disorders of brain development. To address these issues, we designed and implemented a publicly available web-based tool that curates the body of knowledge regarding genes associated with neurodevelopmental phenotypes, assembled the first ontology of those phenotypes, and developed a system of levels of evidence for gene-phenotype associations. This tool is called the Developmental Brain Disorders Database (DBDB), an on-line curated repository of genes, phenotypes, and syndromes associated with neurodevelopmental disorders available at https://www.dbdb.urmc.rochester.edu/home. The current release contains over 700 evidence-ranked gene-phenotype associations, 70 neurodevelopmental phenotypes, and 150 syndromes. While DBDB augments existing web-based resources such as OMIM and GeneReviews, it uniquely offers an online evidence system for neurodevelopmental disorders that is transparent, dynamically linked to the literature, and curated by recognized experts. As new literature emerges, DBDB is easily updated. References remain current as they are served directly from PubMed. When used with other resources, DBDB will streamline the genetic workup of children with relevant disorders for clinicians. For researchers, it provides an evidence-ranked gene list against which results of WXS may be filtered, and facilitates more advanced pathway-based analyses.

1523F

Identifying putative functional variants from GWAS by utilizing ENCODE Consortium data. *J. Hayes[1,2,3], X. Xu[1,2,4], J. Farber[1,2], M. Setty[5,6], A. González[6], A. Perez[6,7], V. Joseph[1,2], K. Offit[1,2], S. Raychaudhuri[8,9], C. Leslie[6], R. Klein[1,2].* 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA; 2) Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY, USA; 3) Biochemistry, Cellular, and Molecular Biology Program, Weill Cornell Graduate School of Medical Sciences, New York, NY, USA; 4) Immunology and Microbial Pathogenesis Program, Weill Cornell Graduate School of Medical Sciences, New York, NY, USA; 5) Physiology, Biophysics and Systems Biology Program, Weill Cornell Graduate School of Medical Sciences, New York, NY, USA; 6) Computational Biology Program, Memorial Sloan-Kettering Cancer Center, New York, NY, USA; 7) Tri-institutional MD-PhD Program, Weill Cornell Medical College, New York, NY, USA; 8) Divisions of Genetics & Rheumatology, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 9) Partners Healthcare Center for Personalized Genetic Medicine, Harvard Medical School, Boston, MA, USA.

The first genome-wide association study (GWAS) was published in 2005. Since then, there have been over 1,300 published GWAS papers spanning over 200 diseases and more than 3,000 disease susceptibility loci identified. However, one of the major challenges of the field is that over 90% of these identified risk variants do not result in an amino acid change, thus failing to explain the mechanism for increased risk. We hypothesize that the GWAS-identified risk-SNPs, or those variants highly correlated with them, increase risk is by altering transcriptional regulatory elements. We tested this hypothesis by analyzing identified risk-SNPs for both lymphoma and chronic lymphocytic leukemia (CLL) together. The lymphoblastoid cell lines (LCLs) in ENCODE make for an ideal dataset in which to test these risk SNPs for B-cell malignancies as LCLs are derived from B cells. When combined, there are 29 non-HLA lymphoma risk SNPs published to date. When we identify tagged SNPs that are in LD with the original SNP with an $r^2 \geq 0.8$ the number of SNPs to be analyzed increases to 352. When we compare these with DNase hypersensitivity data, 23 SNPs lie in hypersensitivity regions. We then overlapped these DNase-SNPs with ChromHMM data and found 11 SNPs that may be functional: 3 SNPs were classified in 'Active Promoter' sites and 8 SNPs classified in 'Strong Enhancers.' The analysis is not limited to DNase-seq and ChromHMM data; the system is being built with flexibility to take in many different types of ENCODE data, including transcription factor ChIP-Seq and histone methylation marks. Additionally, we are developing discriminatively trained transcription-factor binding models to predict the impact that these variants may have on binding. We plan to identify which regulatory marks, or combination thereof, are important in identifying putative functional SNPs and provide a framework by which other groups can accurately and quickly select these SNPs for preliminary experimental follow-up.

1524W

Prioritization of Pathways, Genes and Polymorphisms for Dental Caries. *A. Nicolaou[1,2], M. Shibata[2], SR. Diehl[1,2].* 1) Center for Pharmacogenomics and Complex Disease Research, New Jersey Dental School, UMDNJ, Newark, NJ; 2) School of Health Related Professions, UMDNJ, Newark, NJ.

The main goal of this study was to identify genetic variation that may explain why some individuals are more susceptible than others to dental caries (tooth decay or 'cavities'). The discovery of causal genes and awareness of risk factors is essential for development of personalized prevention and early detection of this major oral disease. Although oral bacteria play an important role in the development of caries, there is strong evidence for genetic risk of dental caries from human twin and family studies. Our study used two sources for selection of genes and Single Nucleotide Polymorphisms (SNPs): 1) the biological roles of genes as reported in Gene Ontology (GO) and 2) genetic association studies reported in literature. We found that GO was limited in the coverage of oral biology. However, good candidate genes were found for enamel, antimicrobial and saliva pathways. After the first Genome Wide Association Study (GWAS) for caries in children was published, an in silico validation of the selected genes/SNPs was done by evaluating the findings. Recently, we have extended this to data from a new GWAS publication for caries risk in adults. No overlap was found between the selected genes/SNPs from our study and those obtained from the GWAS. However, it should be noted that the associations found in the GWAS show only weak to moderate statistical support. Therefore, it appears likely that common variants with small effects cannot account for the high estimated heritability for caries and the candidate genes obtained in our study may be helpful for prioritization of rare variants identified by Whole Exome Sequencing (WES) approaches.

1525T

The human Genome Clinical Annotation Tool (h-GCAT): enabling clinicians with little bioinformatics background to analyze whole exome data. *K. Wierenga[1], Z. Jiang[2], N.F. Tsinoremas[2].* 1) Pediatrics, OUHSC, Oklahoma City, OK; 2) Center for Computational Science, University of Miami, Miami, FL.

Background. Whole exome sequencing (WES) and whole genome sequencing (WGS) are the most powerful technologies currently available to clinicians to provide patients and families with an etiologic diagnosis that remained elusive until then. Currently, only a few laboratories provide WES for clinical diagnostics. The clinician involved in the care of patient(s) and family is typically not involved in the data analysis. These developments risk demoting the clinical team to bystanders, and could disrupt physician engagement. Approach/Results. We developed the human Genomic Clinical Annotation Tool (h-GCAT), a server-based software tool that allows the user to upload a variant call format file (vcf), containing the variants of patient(s) and relevant family members. The tool allows quick selection of relevant cut-offs for sample sequencing depth and genotype quality, minor allele frequencies (using 1kG and ESP5600), and of relevant chromosomes. Subsequently, the user continues to filter using pedigree information and type(s) of mutation(s) to be ascertained (known/novel SNPs, gene/exon/coding region, synonymous/non-synonymous SNPs). The user can also filter by clinical annotation, using tools as HGMD, DO, OMIM and HPO. Regions of homozygosity can be analyzed in cases with consanguinity. At the end of this process, the user can review the calls that 'survived' these iterative filters. The result page provides relevant information of these calls: genomic location of the candidate calls, dbSNP status, cDNA location of calls for the various transcripts, as well as residue change by protein isoform(s), if applicable. Link Outs to the NCBI, UCSC Genome Browser, OMIM, HGMD and DO entries are provided for review. We tested our tool on various training sets given certain inheritance patterns. Within less than 10 minutes results similar to other WES analysis tools were obtained. Conclusion. While the software underlying the various algorithms of filtering activities in h-GCAT is intricate, the process of filtering out (likely) irrelevant calls and performing a directed search for relevant mutation(s) and associated phenotypes is easily understood and accomplished by a clinician with little bioinformatics background. The clinician is aware of key clinical features that can inform phenotyping, becoming more important with continued identification of Mendelian disorders. It is our opinion that variant call files should be made available to the clinician when requested.

SeqSIMLA: An efficient simulation software for generating sequences and phenotypes for complex disease studies. *R.H. Chung, C.C. Shih.* National Health Research Institutes, Zhunan, Taiwan.

Association studies based on next-generation sequencing (NGS) technology have become popular, and statistical association tests for NGS data have been developed rapidly. A flexible tool for simulating sequence data in either unrelated case-control or family samples with different disease and quantitative trait models would be useful for evaluating the statistical power for planning a study design and for comparing power among statistical methods based on NGS data. To our knowledge, the software SimRare is the only tool designed specifically to simulate sequence data with phenotypes. However, SimRare focused on generating unrelated samples. As family-based association studies using NGS are also important, software that can simulate sequence data in families will be very useful for evaluating the properties of family-based NGS analysis. We developed a simulation tool, SeqSIMLA, which can simulate sequence data with user-specified disease and quantitative trait models. We implemented two disease models, Models 1 and 2, based on logistic functions. In Model 1, the user can flexibly specify the odds ratios of disease variants and disease prevalence. In Model 2, the user can specify the overall population attributable risk for disease variants and the baseline penetrance. Risk and protective variants can also be simulated. We do not have restrictions on the number of disease loci to be simulated. We also implemented a quantitative trait model, in which the user can specify the number of quantitative trait loci (QTL), proportions of variance explained by the QTL, and genetic models. We compiled recombination rates from the HapMap project so that genomic structures similar to the real data can be simulated. Both unrelated case-control and three-generation family data can be simulated. Java threads are used to parallelize the code. SeqSIMLA can efficiently generate a replicate of 500 extended families in a 5MB region containing 50 haplotype blocks in 4 minutes. SeqSIMLA will be very useful for evaluating statistical properties for new study designs and new statistical methods using NGS. SeqSIMLA can be downloaded at http://seqsimla.sourceforge.net.

1527W

RegScan: a tool for rapid estimation of allele effects on continuous traits and their combinations. *T. Haller[1], M. Kals[1], T. Esko[1,2,3], R. Mägi[1], K. Fischer[1].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Broad Institute, Cambridge, MA, USA; 3) Children's Hospital Boston.

Genome-wide association studies (GWAS) are becoming computationally more difficult with the ever-increasing number of samples, markers, and traits. The combinatorial traits (for example the ratios of metabolite concentrations) can increase the data size beyond what the current GWAS tools can handle. At the same time the scientific interest to study combinatorial traits is rapidly increasing and the field needs a quick analytical tool. We addressed the issue of increasing need for computational power in GWAS by creating an application called RegScan. Our tool is designed for performing basic linear regression analysis with very large data sets maximally fast. It performs association analysis between markers and continuous combinatorial traits ten to hundreds of times faster than the other tools. RegScan specifically targets association analysis of combinatorial traits in metabolomics, however, it is not limited to that. Another area of use is studying marker associations with gene expression. RegScan can automatically create the combinatorial traits for analysis. It also comes with several supporting functions used for filtering of the results and additional analysis of the detected associations with the focus to determine their significance. RegScan has been successfully tested in linear regression analyses of large data sets such as 1000 Genome imputed data for thousands of individuals with over 6000 combinatorial traits. The analyses that have typically taken several weeks or months can now be carried out in just days. The results allow researchers to investigate the links between genetic markers and biological pathways. RegScan is an open source project. It can be freely downloaded together with the instructions and examples at www.biobank.ee/regscan.

1528T

Shortening the Diagnostic Odyssey: Integrating Genomic, Structural, and Phenotypic Information to Reduce Time of Rare Disease Diagnosis. *R. Hariharan[1], M. Bhat[2], S. Agarwal[1], S. Krishna[1], B. Panda[1], V. Veeramachaneni[1].* 1) Strand Life Sciences, Bangalore, India; 2) Center for Human Genetics, Bangalore, India.

Genomic sequencing for diagnosis of rare, and often complex, diseases is gaining traction to help end what is often a diagnostic odyssey for families and patients. However, knowledge of genetic variants alone is often not enough to diagnose disease - understanding the effects of variants on gene and protein structure inform how the variant may affect the role in biological function while incorporating phenotypes and symptoms help explain how the variants manifest in patients. To that end, we are developing software that combines our own tool for analysis of NGS data (AVADIS NGS) with systematically curated literature content and bioinformatics databases (to integrate genomic, structural and phenotypic information) to enable data to report generation in one single step. This will substantially compress the time needed for clinicians to correctly diagnose patients and start them on the right treatment regimen. Here, we present a case study wherein, through collaboration with a clinical geneticist, we have sequenced and applied our approach to a family in India. The young couple, of a consanguineous marriage, had previously given birth to two boys with pulmonary hypertension and respiratory problems who died suddenly under two years of age. The couple was again pregnant and wanted to determine whether this child would experience similar outcomes. Through analysis of whole exome sequencing data of the parents, fetus, and one of the deceased brothers with our software, we were able to provide an answer.

1529F

Gene Expression Deconvolution using Single-cells. *J. Lindsay[1], I. Mandoiu[1], C. Nelson[2].* 1) Department of Computer Science and Engineering, University of Connecticut. Storrs CT; 2) Department of Molecular and Cell Biology. University of Connecticut. Storrs CT.

Obtaining whole-transcriptome expression profiles of closely related cell types is challenging for stem-cell biologists. Here we present an approach that utilizes single-cell qPCR probing of a small number of genes to aid in the deconvolution of whole-transcriptome profiles of mixed samples. Typically the expression profiles of a given mixture of cells is modelled as linear combination of the signature of its constituent cells multiplied by the concentration of each each cell type in the mixture. Existing approaches to deconvolution methods attempt to estimate both the cell type signatures and concentrations simultaneously, or separately if knowledge of one is know beforehand. Our method first obtains a reduced profile of constituent cell-types from single-cell samples by using k-means clustering and then averaging all cell-types in each cluster. Then we apply a robust quadratic programming method to inferring mixture proportions of mixed sample. Finally we have implemented a second quadratic program for inferring cell-type specific expression levels of genes not measured directly in single-cells based on mixture proportions derived for each mixed sample. Using real single-cell data obtained from the posterior Node-Streak-Border region of a mouse embryo and 100 simulated mixtures, a leave-one-gene-out experiment found our method estimates of concentrations had a RMSE of 0.03 and the missing gene estimates had a correlation of 0.997.

1530W

Implementing a High Performance, Reusable Consensus Calling Pipeline for Next Generation Sequencing using Globus Genomics. *R.K. Madduri[1], A. Rodriguez[1], V. Trubetskoy[2], L.K. Davis[2], P.J. Dave[1], N.J. Cox[2], I.T. Foster[1].* 1) Computation Institute, University of Chicago, Chicago, IL; 2) Section Genetic Medicine, University of Chicago, Chicago, IL.

We developed Globus Genomics (http://globus.org/genomics/), an end-to-end hosted service designed to efficiently and easily analyze large quantities of Next Generation Sequencing (NGS) data using state of the art algorithms, efficient data management tools, a graphical web-based workflow environment and on-demand computing infrastructure.Globus Genomics leverages a collection of existing cloud-based services. Globus Genomics users, however, can build new analysis workflows from scratch. Users can analyze large amounts of data using computationally efficient analytical pipelines and cutting edge tools that leverage the power and flexibility of on-demand cloud computing resources~without being exposing to the complexities of managing large scale infrastructure; deploying and configuring analysis tools; transferring data between sequencers, analysis nodes and storage systems; or managing their own users and groups. To this end, we use elastic computational infrastructure provided by Amazon Web Services. We use the Condor scheduler to manage a dynamically assembled pool of hosts. We outsource high performance data transfer and user, group and credential management to Globus Online, a platform as a service (PaaS) provider also developed and operated by our team. Finally, we host a Galaxy workflow system to enable easy to use graphical workflow orchestration. We created computational profiles for multiple variant calling and genotyping algorithms available for academic use (i.e., GATK2.0, Atlas2.0, and FreeBayes toolkits). These profiles enable high performance, scalable execution of algorithms on hundreds of raw data sets. We built reusable, robust pipelines using different computational modalities that best suited the underlying analysis. The resulting variant calls from each pipeline can then be fed to a consensus-calling algorithm (Consensus Genotyper for Exome Sequencing CGES; see Trubetskoy et al., ASHG 2013) resulting in high quality variant and genotype calls. We have run these three pipelines in parallel calling variants on over a hundred raw BAM files in the course of three days. Atlas2.0 and the GATK pipelines took a little over two days to finish execution while Freebayes pipeline took a little over three days. In conclusion, we present the workings of Globus Genomics, a robust, powerful, and user-friendly suite of tools for NGS analysis empowering geneticists and enabling translational discovery relevant to human disease.

Genome-wide structural variation analysis with genome mapping on nanochannel arrays. *A.C.Y. Mak[1], J.J.K. Wu[2], Y.Y.Y. Lai[1], K.Y. Yip[3,5], T.F. Chan[4,5], E.T. Lam[1], T.P. Kwok[3], J.W. Li[4,5], A.K.Y. Leung[4], A.K.Y. Yim[4,5], M. Xiao[6], P.Y. Kwok[1], S.M. Yiu[2].* 1) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 2) Department of Computer Science, The University of Hong Kong, Hong Kong; 3) Department of Computer Science and Engineering, The Chinese University of Hong Kong, Hong Kong; 4) School of Life Sciences, The Chinese University of Hong Kong, Hong Kong; 5) Hong Kong Bioinformatics Centre, The Chinese University of Hong Kong, Hong Kong; 6) School of Biomedical Engineering, Science & Health Systems, Drexel University, Philadelphia, PA.

Despite recent advances in next-generation sequencing technology, genome-wide structural variation (SV) detection using 'short reads' remains challenging. Detection of large and/or balanced SV such as inversion or translocations is difficult, if not impossible. To overcome the limitations of short reads, we generated genome maps using a novel approach that allows very long DNA molecules (> 150kb) fluorescently labeled at Nt.BspQI sites (GCTCTTCN/) to be linearized and imaged in highly parallel nanochannel arrays [1]. We obtained data to 50X genome coverage on NA12878, a member from a CEPH CEU trio extensively sequenced in the 1000 Genomes Project. To detect structural variations from these genome maps, we have developed a BreakPoint sensitive Optical Map Dynamic Programming algorithm (BP-OMDP). Data for each DNA molecule is represented as an array of inter-label distances or segments. BP-OMDP allows molecules to be partially aligned to the hg19 in silico Nt.BspQI reference with mismatching segments on either end of the molecules. Potential SV regions and their breakpoints are identified by observing a clear drop in the number of aligned molecules to the reference. SV regions are then reconstructed and verified by de novo assembly and re-alignment of partially mapped and originally unmapped molecules. Using BP-OMDP, we detected 78 putative inversions, of which 59% overlap with known inversions found in NA12878. Extension of our method to detect other balanced and unbalanced SV is underway.

GeneZip: A gzip-based C library for compact imputed genotype storage in RAM. *C. Palmer, I. Pe'er.* Center for Computational Biology & Bioinformatics, Columbia University Medical Center, New York, NY.

Genome-wide association studies directly assay ~10^6 single nucleotide polymorphisms (SNPs) in a study population. With access to phased reference samples of common ancestry that have genotype information at a denser panel of variants, a sample of 10^6 SNPs can be extended probabilistically by a factor of 10- to 40-fold. These resulting datasets are standardly stored as text files that detail imputed genotype probabilities, requiring 12 characters per SNP per sample, thus are too large to be simultaneously stored in RAM losslessly as is. Instead, the maximum likelihood genotype at each site is used, or SNPs are processed and discarded one at a time. Neither of these adaptations are optimal: missingness at individual sites may be informative to a trait, and multi-locus testing is complicated. Here, I present a C/C++ library that dynamically compresses probabilistic genotype data as they are loaded into memory. This method uses a customization of the DEFLATE (gzip) algorithm, and maintains constant-time access to any SNP (but linear O(# individuals) access to a given genotype). Briefly, the probabilistic genotype matrix is stored one SNP at a time, with each SNP data being compressed. Genotype calls for individuals for a particular SNP require serial access, but indexing the compressed matrix for where does information for each SNP reside allows random access to any marker. Average compression ratios of ~90% are observed in test data.

1533W

VariantMaster: a novel platform to identify causative variants from HTS data in familial, denovo and somatic genetic disorders including cancer. *F.A. Santoni[1], P. Makrythanasis[1], S. Nikolaev[1], M. Guipponi[2], D. Robyr[1], A. Bottani[2], S. Antonarakis[1,2,3].* 1) Department of Medical Genetics and Development, University of Geneva, Geneva, Switzerland; 2) Geneva University Hospital - HUG; 3) . iGE3 institute of Genetics and Genomics of Geneva, Switzerland.

There is a fast growing interest in clinical genetics to the employment of High Throughput Sequencing data for accurate diagnosis of monogenic diseases. Furthermore, whole exome sequencing data introduced a significant advance in the comprehension of cancer development by the identification of driver somatic variants. To the aim of providing an accurate and efficient methodology in these contexts, we developed VariantMaster, an original and comprehensive methodology that extracts likely causative variants in familial and sporadic genetic diseases considering different modes of inheritance: X-linked, autosomal dominant, and recessive (homozygosity or compound heterozygosity), denovo germline and somatic mutations including cancer. For the highest accuracy the algorithm takes into account predicted variants and integrates the phenotypes with family pedigrees. A probabilistic approach based on row data is furthermore applied to robustly evaluate the likelihood of the occurrence of a putative causal variant in each family member. Additionally, VariantMaster can incorporate several layers of information as, for example, genotypes, allelic frequencies and damaging scores. VariantMaster is already employed as an effective tool in the clinical genetics department of the Geneva University Hospital (HUG) and in several research projects as the identification of the burden of denovo mutations in a cohort of 58 trios to elucidate the molecular basis of schizophrenia and in the identification of novel causative genes in Primary Ciliary Diskinesia (PCD). Furthermore, to prove the effectiveness of the methodology on the detection of somatic variants we extract 9 random samples of colorectal cancer tumors from the TCGA consortium. Remarkably, 80% of the variants identified by VariantMaster were validated and annotated in COSMIC. Moreover, VariantMaster detected two novel putative 'driver' variants. In general VariantMaster demonstrated to be more flexible and accurate compared with previously published algorithms and we believe it has the potential to become an indispensable tool in the investigation of genetic diseases and molecular cancer profiles.

1534T

Accuracy of predictions of deleterious effects on protein function of multiple dominant negative and activating mutations in STAT3: comparison of nine computational methods. *M.S. Smith.* Research and Development, Viracor-IBT Laboratories, Lee's Summit, MO.

Purpose: STAT3 is activated in response to external signals. After tyrosine phosphorylation of the receptor, STAT3 is recruited by its SH2 domains, is phosphorylated, dimerizes and translocates to the nuclease and binds to specific promoter sequences. Many dominant-negative STAT3 mutations have been identified from cases of hyper IgE syndrome, and activating mutations from large granular lymphocytic leukemia (T-LGL) and chronic NK cell lymphoproliferative disorder (CLPD-NK). We investigated the ability of 9 computational methods to predict the effect of these mutations on protein function. Methods: Nonsynonymous mutations were initially detected in two patient specimens by STAT3 sequencing. These and other known STAT3 hyper IgE syndrome mutations, as well as activating mutations from T-LGL and CLPD-NK cases were examined using programs designed to predict the pathogenicity of amino acid substitutions. The programs were PolyPhen-2, SIFT, MutPred, fathhm, SNPs&Go, nsSNP Analyzer, EvoD, SNAP, and PON-P. These methods vary widely in approach, from protein alignments, statistical approaches, and biochemical aspects such as solvent accessibility and predicted residue flexibility. In the literature, many of these programs were previously tested by benchmarked experimental data sets of neutral and pathogenic mutants from proteins such as E. coli LacI repressor, phage T4 lysozyme, and HIV-1 protease mutations. Summary: For 32 hyper IgE mutations in the STAT3 DNA-binding, SH2, and transactivation domains (the majority reported in multiple patients each) and 10 mutations in the dimerization interface of the SH2 domain from leukemia patients, we examined agreement across all programs or among a subset of programs with reported higher accuracy levels. For Hyper IgE syndrome, the use of an overall score from 5 (SIFT, MutPred, SNPsGo, SNAP, and PON-P) or all 9 programs was in general agreement for the most common mutations, including some predicted in contact with DNA or involved in SH2 domain dimerization; however, not all common mutations showed a significant score in this way. For the somatic mutations seen in T-LGL, CPLPD-NK, and hepatic adenomas, where the mutations are thought to be activating, there was poor agreement with the scoring by these programs. Thus, for a large set of dominant negative and activating mutations of STAT3, no single or small group of analysis programs were found to be able to accurately predict the effect of a mutation.

1535F

A Graphical Quality Control Tool for Next Generation Exome Sequencing. *J.D. Smith, S. McGee, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

The wide-scale application of massively parallel sequencing requires the development of new approaches to automate data quality control. These approaches should accurately and efficiently pinpoint potential problems and evaluate quality throughout the process. Additionally, the quality metrics associated with the data need to be presented in a concise but informative format to facilitate rapid decision-making about whether to proceed to interpretation, or to remove or hold a sample for further assessment. To facilitate this process, we have developed a "QC Dashboard" that presents an overview of quality metrics, and is currently in use for exome sequencing at the Northwest Genomics Center (NWGC). The QC Dashboard is a graphical and textual display of statistical information extracted from BAM files, and uses multiple open-source analysis tools. Plots include overall number of reads, reads mapped to target and number of unique reads; allele distributions at each sequencing cycle; plots for read depth coverage, uniformity and insert size distribution. Per sequencing cycle error rates and read qualities are also plotted and summarized. Sample complexity is quickly and accurately extrapolated from a subset of data and displayed. Each dashboard is adaptable to individual- or merged-lane data and can easily be implemented in any analysis pipeline for automatic display.

1536W

Evaluation of imputation method for classical HLA-DRB1 using a Finnish dataset. *E. Vlachopoulou[1], E. Lahtela[1], A. Wennerström[1], A.S. Havulinna[3], P. Salo[3,4], M. Perola[3], V. Salomaa[3], M.S. Nieminen[2], J. Sinisalo[2], ML. Lokki[1].* 1) Transplantation Laboratory, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) HUCH Heart and Lung Center, Division of Cardiology, Helsinki University Central Hospital, Finland; 3) National Institute for Health and Welfare, Helsinki, Finland; 4) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland.

HLA genes are located at the MHC region (6p21) revealing high degree of gene density and polymorphism. Allelic structures of HLA genes show broad linkage disequilibrium and are inherited as haplotypes with significantly different frequencies between populations and ethnicities. HLA genes have been associated with many autoimmune, infectious and inflammatory diseases. Due to vast amount of alleles, the high-resolution HLA typing is expensive and time-consuming. Scientists have attempted to develop computational approaches to define HLA alleles with high confidence. We tested the reliability and performance of a widely used software HLA*IMP (versions HLA*IMP:01 and HLA*IMP:02) for imputing classical HLA-DRB1 alleles in the Finnish material. Unrelated samples (n=161) from Finnish subjects were selected from the FINRISK 1997, 2002 and 2007 cohorts. The samples were SNP genotyped with Illumina 610K genotyping chip and the genotypes were called in the quality control (QC) using Illuminus. The cleaned dataset was imputed with MACH 1.16 using HapMap 2 release 22 CEU reference haplotype set. The results of imputed HLA-DRB1 alleles were compared with the high-resolution results obtained from sequence-based typing. The frequencies of the imputed HLA-DRB1 alleles were similar to the frequencies from sequence-based typing. However, the per-individual success rate was 27.64% using either HLA*IMP:01 or HLA*IMP:02 having mean Q and Q2 posterior probabilities for correct inferences of 0.9539 and 0.9286, respectively. When we used the posterior probability of 0.95 as a threshold for both imputed alleles simultaneously, the per-individual success rates were as low as 23.74% and 23.39% with HLA*IMP:01 and HLA*IMP:02, respectively. Hence, the higher confidence decreased the correct inferences. One of the most prominent example was HLA-DRB1*01:01 allele showing approximately 30% success rate while being the most common wrongly imputed allele. In Finland, isolation and migration history have shaped the gene pool narrower showing HLA haplotype frequencies typical to Finnish population when compared to Europeans. When we used HLA*IMP having different European populations as references, the imputation success for HLA-DRB1 alleles was very low pointing to the importance of population specific reference material.

1537T

An adaptive permutation procedure to estimate the significance threshold for the minimum p-value of multiple permutation tests. *P. Yajnik, M. Boehnke, H. Jiang.* Dept Biostatistics, University of Michigan, Ann Arbor, MI.

The analysis of modern genetic association studies often involves testing multiple hypotheses. The Bonferroni correction is commonly used to approximate p-value significance thresholds to maintain the familywise type I error rate. When tests are correlated, the Bonferroni correction may be conservative and permutations can be used to estimate significance thresholds.

Permutation based estimates are computationally expensive. The computational burden is exacerbated if p-values of the tests also need to be obtained by permutation when analytical values based on asymptotic theories are unavailable/inaccurate. We propose an adaptive permutation procedure which can greatly reduce the total number of permutations needed to estimate the minimum p-value of multiple permutation tests. At each iteration, the pool of tests included in the procedure may be reduced by discarding tests whose estimated p-values are much larger than the currently estimated minimum p-value. The likelihood-ratio test (LRT) statistic is used to discard tests. The proposed estimator is the minimum estimated p-value amongst the tests that remain at the end.

We performed 10000 simulations to assess the performance of the procedure. The simulation parameters included the number of multiple tests (100, 200, 500, 1000 or 10000), the correlation between blocks of tests (0, 0.2, 0.4, 0.6, 0.8 or 0.95) and the stringency used to discard tests (LRT statistics exceeding 2.7, 3.8, 6.6 or 10.8). At the highest stringency, the proposed method required on average only 0.2%-5% as many permutations as the naive method (the relative efficiency increasing with number of multiple tests). At this stringency, the proposed method achieved the exact minimum p-values found by the naive method in 99% of the simulated cases.

We also applied this procedure to a real dataset. A burden test (SKAT) was performed with each of 13 correlated phenotypes regressed on variants from 62 genes (806 tests with a Bonferroni corrected threshold of 6e-05). It took our procedure 12 hours with 40 CPUs to provide an estimated threshold of 7e-05. Per our simulations, the naive approach would take 20~500x longer than the proposed approach. Based on a modest estimate of 100x, the naive approach would require 1200 hours.

1538F

BDgene: a genetic database for bipolar disorder and its overlap with schizophrenia and major depressive disorder. *S. Chang, L. Guo, J. Wang.* Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences. 16 Lincui Road, Chaoyang District, Beijing, China.

Bipolar disorder (BD) is a common psychiatric disorder with complex genetic architecture. It shares overlapping genetic influences with schizophrenia (SZ) and major depressive disorder (MDD). Large numbers of genetic studies of BD and cross-disorder studies between BD and SZ/MDD have accumulated numerous genetic data. There is a growing need to integrate the data to provide a comprehensive data set to facilitate the genetic study of BD and its highly relevant diseases. To fulfill this demand, BDgene database was developed to integrate BD-related genetic factors and shared ones with SZ/MDD from profound literature reading. Through depth-mining of 796 papers, BDgene contains multiple types of literature-reported genetic factors of BD with both positive and negative results, including 797 genes, 3119 SNPs, and 789 regions. Shared genetic factors such as SNPs, genes, and regions from published cross-disorder studies among BD and SZ/MDD were also presented, including 285, 120 and 49 shared genes for BD-SZ, BD-MDD and BD-SZ-MDD respectively. On the basis of data from the literature, in-depth analyses were performed for further understanding of the data: gene prioritization analysis for literature-origin genes obtained 43 BD core genes; pathway-based analysis for genome-wide association study data identified 70 BD candidate pathways; intersection analysis of multidisease candidate genes got 127, 79, and 107 new potential cross-disorder genes for BD-SZ, BD-MDD, and BD-SZMDD respectively; pathway enrichment analysis for BD core genes showed the majority of the pathways were involved in synaptic transmission, membrane and ion channel activity; pathway enrichment analysis for literature-reported positive genes shared by BD-SZ and BD-MDD showed two rhythmic related pathways were enriched by both gene lists. As a central genetic database for BD and the first cross-disorder database for BD and SZ/MDD, BDgene provides not only a comprehensive review of current genetic research but also high-confidence candidate genes and pathways for understanding of BD mechanism and shared etiology among its relevant diseases. To facilitate better usage of the database, BDgene provided powerful search tools to access the data, and a forum to share or exchange ideas. BDgene will be updated quarterly for both the literature-origin data and in-depth data analyses result to maintain an update-to-date resource. BDgene is freely available at http://bdgene.psych.ac.cn.

1539W

PhenoVar: an innovative approach in clinical genomics for the diagnosis of polymalformative syndromes. *C. Buote[1], Y. Trakadis[2], JF. Therriault[1], H. Larochelle[3], S. Lévesque[1].* 1) Dept. of Paediatrics, division of medical genetics, Faculty of Medicine and Health Sciences, University of Sherbrooke, Sherbrooke, Canada; 2) Dept. of Medical Genetics, McGill University Health Center, Montreal, Canada; 3) Dept. of Informatics, Faculty of Sciences, University of Sherbrooke, Sherbrooke, Canada.

BACKGROUND: Widespread clinical use of Exome Sequencing (ES) requires an approach addressing issues such as incidental findings and accurate prediction of causal mutations among massive amount of variations. We have previously proposed a phenotype-driven analysis of exome data to address these issues and predict diagnosis in the clinical setting. Here we provide a more extensive validation of our software PhenoVar and present a pilot study of 15 patients with undiagnosed polymalformative syndromes. METHODS: We tested the efficiency of our software, PhenoVar, in predicting diagnoses of simulated test-patients with known polymalformative syndromes. Control exome variants files, modified to include a previously published mutation, were combined to the corresponding published phenotypic data of twenty patients with varied polymalformative syndromes. For each test-patient, modified variant file was input along with blindly selected phenotypic traits in PhenoVar for diagnosis prediction. PhenoVar calculated phenotypic similarity, using Human Phenotype Ontology terms, between the test-patient and a database consisting of simulated and real patients for each OMIM phenotype with known molecular basis. Final diagnostic score, assigned to a given OMIM entry, took into consideration both the patient's phenotype and variations. Resulting OMIM entries list was sorted according to diagnostic score and filtered using a minimal phenotypic weight threshold to prevent undesired discovery of incidental findings. In the pilot study, we recruited 15 patients with unknown polymalformative syndrome, after chromosome microarray and standard molecular investigations were done. ES was performed on a HiSeq 2000 (Illumina), following target enrichment using Sureselect All Human exon v4 (Agilent). Variations were called using GATK pipeline. Resulting variants file and phenotypic traits were input in PhenoVar to perform diagnostic prediction as described. RESULTS: In 15/20 simulated test-patients, the expected diagnosis ranked within top 5 predicted most likely diagnoses and this was the case in 18/20 test-patients when known pathogenic variants were priorized. No incidental findings were found using our minimal phenotypic threshold. The analysis of the pilot study 15 patient's exomes is underway. CONCLUSION : Results suggest that this 'phenotype-driven' approach could be applied effectively in the clinical setting for the diagnosis of polymalformative syndromes.

1540T

A joint latent factor model for gene expression data with confounders. *C. Gao[1], C.D. Brown[4], B.E. Engelhardt[1,2,3].* 1) Institute for Genome Sciences and Policy, Duke University; 2) Department of Biostatistics and Bioinformatics, Duke University; 3) Department of Statistical Science, Duke University; 4) Department of Genetics, University of Pennsylvania.

With high dimensional sequencing data being generated at an exploding rate, interpretability is especially critical for problems in genome sciences. One important goal is to understand the relationships between genes from gene expression data, where there may be substantial biological and technical noise associated with measurements of expression levels. Sparse latent factor models have been used successfully to extract interpretable relationships from high dimensional data, but generally the data are preprocessed using principal components, for example, to control for these confounders. In this work, we develop a Bayesian sparse latent factor model that uses a three parameter beta prior to flexibly model regularization on the loading matrix. We add a simple two-component mixture to model each factor loading as a sparse or a dense component. In this setting, sparse factors select small numbers of co-regulated genes, such as genes that are co-regulated by a single transcription factor, whereas dense factors identify confounding factors that impact the expression levels of large numbers of genes simultaneously, such as sex or batch effects. This framework has three advantages over the traditional approaches: i) it represents a joint model of confounders and signal; ii) it avoids the problem of overfitting by regularizing both sparse and dense factors; iii) each factor has an explicit posterior probability for whether it is dense or sparse. Furthermore, our approach automatically estimates the number of sparse and dense factors from the data. To address the known identifiability issues for factor analysis models, we developed measures to quantify robustness for both sparse and dense factors. Using simulated data featuring both sparse and dense structure, we found that we are much more successful at recovering the true latent structure relative to two-stage approaches and other factor models. We applied our model to gene expression data and found that it identifies known covariates and small groups of co-regulated genes. We use additional methods to validate the identified sparse and dense clusters, and find interesting overlap in the genes involved in sparse clusters. Finally, we performed an eQTL analysis to the identified co-related subsets of genes, and we find that we can identify a large number of eQTL hotspots that are not identified in a univariate analysis.

1541F

A Clinical History Weighting Algorithm Accurately Classifies BRCA1 and BRCA2 Variants. *K.R. Bowles[1], B. Morris[2], E. Hughes[2], J. Eggington[1], L. Esterling[1], B. Robinson[1], A. Van Kan[1], B. Roa[1], E. Rosenthal[1], A. Gutin[2], R. Wenstrup[1], D. Pruss[2].* 1) Myriad Genetic Laboratories, Inc., Salt Lake City, UT; 2) Myriad Genetics, Inc., Salt Lake City, UT.

Genetic testing, including full gene sequencing and large rearrangement analysis for germline *BRCA1* and *BRCA2* mutations, can identify individuals with Hereditary Breast and Ovarian Cancer syndrome. Current genetic analysis identifies *BRCA1* and *BRCA2* deleterious mutations as well as variants of unknown clinical significance. Reclassification of uncertain variants to more clinically interpretable categories is critical for patient management. We have developed a statistical algorithm that aids in the assignment of clinical classifications to uncertain variants. This algorithm is based on the premise that disease-associated mutations will be observed more often in individuals at high risk for carrying a mutation, as determined by personal and family history. Statistical analysis weights the family histories of each proband carrying the variant of interest and compares these histories to those of control probands carrying variants known to be benign or deleterious. Data from over 400,000 probands were utilized for algorithm development. This technique was validated by and used to analyze over 6000 *BRCA1* and *BRCA2* variants. The algorithm successfully classified well-documented variants such as *BRCA1* c.181T>G (Deleterious), *BRCA1* c.1065G>A (Polymorphism), and *BRCA2* c.2808_2811del (Deleterious). The *BRCA1* c.5096G>A (Suspected Deleterious with reduced penetrance) and *BRCA2* c.7878G>C (Suspected Deleterious with reduced penetrance) mutations were classified as "Not Callable" by the algorithm, consistent with their previous hypomorphic interpretations. This 'history weighting' algorithm allows for the accurate reclassification of *BRCA1* and *BRCA2* uncertain variants and improved clinical management of at-risk patients. The history weighting algorithm has also been successfully applied to reclassification of variants in the Lynch syndrome-associated genes *MLH1* and *MSH2*, and it is currently being modified to allow for analysis of germline variants in *MSH6*. With additional modifications, this algorithm is expected to be applicable to other autosomal dominant cancer-associated and non-cancer-associated genes.

1542W

GenAP: automated analysis of genetic HTS data for clinical diagnostic use. *M.C. Eike[1], T. Håndstad[1], E. Nafstad[2], T. Hughes[1], T. Grünfeld[1], D.E. Undlien[1].* 1) Department of Medical Genetics, Oslo University Hospital, University of Oslo, Oslo, Norway; 2) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway.

High-throughput sequencing (HTS) presents both great opportunities and challenges for use in clinical diagnostic settings. One of the most pressing needs is efficient analysis of the increasing volumes of generated data, without compromising quality. In response to this, we are developing a system for rules-based, semi-automated analysis of sequence variation data for diagnostic use, as part of the project *Norwegian clinical genetic Analysis Platform* (genAP). The aim is not only to speed up the analytic process, but also to achieve higher levels of reproducibility and integrity of results.

The input consists of annotated sequence variants, including various sequence and variant calling quality metrics and annotation data from external sources (including frequency data, pathogenicity prediction, mutation databases and literature references). Importantly, when available, variants are also annotated with results from previous analyses stored in an in-house database, which are given a higher priority than external data. The system then uses this information to classify variants along the axis pathogenic-neutral, generating suggested conclusions for each variant. The rules applied in this classification process are specific for each clinical question (but easily editable) and are based on standard operating procedures at our department. The generated results are presented in a graphical user interface, which includes a structured display of all annotation information. Here, variants are prioritized according to their likely involvement in disease, and key information underlying the suggested classification is highlighted. The user then has the choice to edit or approve the results, which upon approval are added to the in-house database.

We aim to make the source code for the system publically available, with a beta release planned by the end of 2013. Although the release will be tailored for our department and particular clinical questions (currently breast/ovarian cancer and cardiomyopathy), it is our goal to make the system flexible enough to be adapted by other parties.

This presentation will demonstrate the logic of the system, with specific examples and an overview of the general architecture.

Variation data services at NCBI: archives, tools, and curation for research and medicine. *S. Sherry, K. Addess, V. Ananiev, C. Chen, D. Church, M. Feolo, J. Garner, T. Hefferon, D. Hoffman, B. Holmes, M. Kholodov, A. Kitts, J. Lee, J. Lopez, D. Maglott, R. Maiti, L. Phan, G. Riley, W. Rubinstein, D. Rudnev, Y. Shao, E. Shekhtman, K. Sirotkin, D. Slotta, R. Tully, R. Villamarin-Salomon, Q. Wang, M. Ward, H. Zhang, C. Xiao.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

NCBI operates several archives for sequence variation data that are increasingly relevant for medical research. These archives contain general variation data in the public domain and high density surveys of genetic diversity in medical study populations. Small scale variations are accessioned and distributed through dbSNP at http://www.ncbi.nlm.nih.gov/snp/ and larger structural variations (greater than 50bp) are accessioned and distributed through dbVar at http://www.ncbi.nlm.nih.gov/dbvar/. Research participant genotypes, participant phenotypes and analysis results are distributed through the dbGaP controlled access system http://www.ncbi.nlm.-nih.gov/dbgap/. Assertions of clinical significance for variants and alleles are accessioned and distributed through ClinVar at http://www.ncbi.nlm.nih.gov/clinvar/. Tools for exploring and visualizing variation data include the 1000 genomes browser http://www.ncbi.nlm.nih.gov/variation/tools/1000genomes/, the 1000 genomes data slicer http://trace.ncbi.nlm.nih.gov/Traces/1kg_slicer/ and the phenotype-genotype data integrator http://www.ncbi.nlm.nih.gov/gap/PheGenI. The clinical remap tool at http://www.ncbi.nlm.nih.gov/genome/tools/remap#tab=rsg will provide sequence coordinates for variations on a clinical RefSeqGene record, and the variation reporter service at http://www.ncbi.nlm.nih.gov/variation/tools/reporter will provide a list of known variants and the functional consequences for a region of interest in BED format or set of variants in HGVS or GVS format. The presentation will show how these services are organized in relation to the primary data archives of GenBank, SRA, GEO, dbSNP, dbVar and dbGaP, and how they can be used as input into external services for research, clinical practice or cloud-based analysis projects.

T2D2seq: An enhanced, novel algorithm to determine differential expression in RNA-Seq data. *E.D. Au, M.H. Farkas, J.A. White, E.A. Pierce.* Ocular Genomics Institute, Berman-Gund Laboratory, Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA.

As RNA-Seq methods continue to evolve, and the technology continues to be more widely used, it is imperative that data analysis becomes more uniform. RNA-Seq studies are unmatched in terms of the wealth of information they provide; the ability to study differential expression on the level of individual exons and introns allows for a more precise analysis of the effect of mutations and has promise to offer new insight into the potential cause of disease. The amount of data generated by sequencing studies and the potential knowledge that can be gained is constantly increasing, but analysis algorithms have not kept up with the high demand of these studies to date. While many algorithms are available, the discordance among the results produced is highly concerning. Using real RNA-Seq data as a guide, we have developed a novel method to determine differential expression that is both efficient and precise. A limiting factor in the development of analysis algorithms is the quality of model datasets used to test their performance. Currently published synthetic datasets are poor models of RNA-Seq data: they contain far fewer features than found in real transcriptomes, and fail to properly control background levels of noise, levels of differential expression, and outliers. To address this, we use real RNA-Seq data as a model to generate test datasets, following a negative binomial distribution, with five levels of noise. We introduce 5% true positive features with fold changes between 2 and 20X, and 2% false positive outliers, while verifying that the remaining features are indeed true negatives. Using these datasets, we compare the performance of our algorithm with that of currently available algorithms. We are able to detect 99.5% of true positive features in the dataset with the lowest level of variation, and 83.5 % true positives at the highest level of variation, with less than 0.5% false positive rate. While other algorithms perform well at low levels of noise, with the best finding 99% true positives, most also call 50% of outliers as differentially expressed. Further, at higher levels of noise, they are unable to properly distinguish true and false positives, with the most accurate finding only 64% true positives, and most calling greater than 25% false positives. When compared to a variety of currently available algorithms, T2D2seq shows higher sensitivity and specificity, and is more computationally efficient.

Statistical model for the prioritization of causal genetic variants in next generation sequencing data. *J.A. Chen[1], G. Coppola[1,2].* 1) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, CA; 2) Department of Psychiatry and Semel Institute for Neuroscience and Human Behavior, David Geffen School of Medicine, University of California, Los Angeles, CA.

The majority of the 10,000+ risk-associated SNPs identified in genome-wide association studies (GWAS) have small effects, and much of the postulated genetic contribution to most diseases or traits is still unaccounted for. Most of the GWAS SNPs are hypothesized to tag common and rare variants with true functional effect. Under these assumptions, next generation sequencing (NGS) approaches can be used to identify all variants in a region with single base pair resolution. However, few of these associations have been defined and their existence is largely theoretical, as there are no rigorous statistical methods to uncover causal variants and disentangle their respective contributions to disease risk. We propose the use of structural equation modeling and Bayesian model selection procedures to prioritize likely causal variants from NGS data in GWAS-associated regions. The statistical method was used on synthetic data that was generated using the 1000 Genomes Project data, and on NGS data from neurodegenerative disease. The method identified the causal variants with high accuracy in the synthetic data, and prioritizes variants for further follow-up from the neurodegenerative disease data.

The database of Genotypes and Phenotypes: dbGaP. *M. feolo, R. Bagoutdinov, S. Dracheva, L. Hao, Y. Jin, M. Kimura, M. Lee, J. Mena, N. Popova, S. Pretel, N. Sharopova, S. Stefanov, A. Stine, A. Sturcke, K.T. Tryka, Z. Wang, M. Xu, L. Ziyabari, S.T. Sherry.* National Center for Biotechnology Information, National Institutes of health, Bethesda MD.

The National Center for Biotechnology Information's database of Genotype and Phenotype (dbGaP) is an NIH sponsored repository charged to archive, curate and distribute information produced by studies investigating the interaction of genotype and phenotype. The data submitted to dbGaP includes: individual level molecular and phenotype data; analysis results; medical images; general information about the study; and documents that contextualize phenotypic variables, such as research protocols and questionnaires. The molecular data includes array-based, sequence-based or imputed genotypes; expression, as well as next-generation sequencing (NGS) performed to produce whole exome; whole genome; RNA seq; and epigenomic data. NGS sequence submitted to dbGaP, mostly in the form of BAM files, are processed by NCBI's Short Read Archive (SRA). Phenotypic data pertaining to study participants or samples consists of any combination of cross-sectional or longitudinal demographic; clinical; laboratory; exposure; or treatment variables. Medical images such as CT; MRI; and retinal scans of the eye are also stored and distributed by dbGaP. Analysis results include summary-level statistical evaluations of the association between the phenotypic variables and the molecular data. All documents, analysis, phenotypic and molecular data are accessioned with stable, unique identifiers that support update of the same clinical study with successive genetic investigations. For example, high-throughput genotyping by one research group, followed by exome sequencing by another group. These identifiers also make it possible to cite the primary data used by published genome association studies in a very specific and stable way. The dbGaP provides unprecedented access to very large genetic and phenotypic datasets, both funded by National Institutes of Health, and other funding agencies worldwide. Public access includes summary data on specific phenotype variables which is linked to study documents; statistical overviews of the genetic information and the position of published associations on the genome. Through controlled access, approved researchers from across the globe may obtain complete statistical analyses, individual phenotype and molecular measures. This presentation will review new dbGaP features that support high-throughput submission, open access data sets, improved query services and tools to download subsets of data for selected individuals.

Explore genetic components underlying dental caries through geneset- and network-assisted approaches. *Q. Wang[1], P. Jia[1], K.T. Cuenco[2,3], Z. Zeng[4], E. Feingold[2,4], M.L. Marazita[2,3], L. Wang[5,6], Z. Zhao[1,6,7,8].* 1) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 5) Department of Biostatistics, Vanderbilt University School of Medicine, Nashville, TN; 6) Center for Quantitative Sciences, Vanderbilt University Medical Center, Nashville, TN; 7) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN; 8) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN.

Dental caries is a common, chronic, and complex disease leading to a decrease in quality of life worldwide. The impact of genetic factors in dental caries has been recognized for a long time. Here we adopted two strategies attempting to dissect the genetic components underlying dental caries, namely the gene set enrichment and protein-protein interaction (PPI) network analyses. For the former strategy, we applied four complementary gene set enrichment methods to a major dental caries genome-wide association study (GWAS) dataset, which consists of 537 cases and 605 controls. After analyzing 1331 Gene Ontology (GO) terms, we identified 13 significantly associated and 17 marginally associated gene sets, including 'Sphingoid metabolic process,' 'Ubiquitin protein ligase activity,' 'Regulation of cytokine secretion,' and 'Ceramide metabolic process.' For the network-assisted strategy, we first prioritized 1214 candidate genes that were collected and curated from four major genetic or genomic approaches (association studies, linkage scans, gene expression analyses, and literature mining) according to the magnitude of evidence related to dental caries. Then we searched for dense modules in the prioritized list of candidate genes by incorporating PPI data, and discovered 23 significant modules that are enriched with genes of great interest. Three major gene clusters were observed among the 23 dense modules, including cytokine network relevant genes, matrix metalloproteinases (MMPs) family, and transforming growth factor-beta (TGFB) family. Both the GO terms and dense modules we identified encompass broad functions that potentially interact and contribute to the oral environment related to caries development. Collectively, our gene set enrichment and PPI network analyses provided complementary insights into the molecular mechanisms and polygenic interactions in dental caries.

Variant Association Tools for association analysis of large scale sequence and exome genotyping array data. *G. Wang[1], B. Peng[2], S.M. Leal[1].* 1) Baylor College of Medicine, Houston, TX; 2) The University of Texas MD Anderson Cancer Center, Houston, TX.

Currently there is great interest in detecting associations of complex human traits with rare single nucleotide variants (SNVs) using large scale sequence and exome genotyping array data. The analysis and quality control for rare variant data obtained from sequencing is quite different from the analysis of common SNVs in traditional genome wide association studies. . Data quality control for sequence data uses information from a variety of difference quality matrices, e.g. genotype quality score, read depth. Statistical association tests for the analysis of rare variants aggregate variants across a genetic region which is usually a gene. Within the gene region the variants which are analyzed is usually limited to missense, nonsense and splice site variants; therefore before the commencement of association testing the variants must be annotated To address the specialized analysis of rare variants we developed variant association tools (VAT), a pipeline that implements best practices for rare variant association studies. Major features of VAT include variant site/call level quality control, summary statistics, phenotype/genotype based sample selections, variant annotation, selection of variants for analysis and the implementation of rare variant association methods for analysis of qualitative and quantitative traits. The association testing framework implemented in VAT is regression based which readily allows for flexible construction of association models with multiple covariates, weighting (based on allele frequencies or predicted functionality), interactions terms and models for pathway analysis. VAT is capable of rapidly scanning through data using multi-processes computation, adaptive permutation and simultaneously conducting multiple association tests. Results can be view as text or graphically. Additionally a programming interface is provided to readily facilitate user implementation of novel association methods. The VAT pipeline can be applied to sequence, imputed and genotyping array, e.g. exome chip data. VAT can perform association analyses on small to large scale complex trait studies making use of the latest genotyping and sequencing technologies.

1549T

Variant calling in low-coverage whole genome sequencing of a Native American population sample. *C. Bizon[1], M. Spiegel[1], S. Chasse[2], I.R. Gizer[3], Y. Li[2], E. Malc[4], P. Mieczkowski[4], J. Sailsbery[1], X. Wang[1], C.L. Ehlers[5], K.C. Wilhelmsen[1,2].* 1) Renaissance Computing Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Psychological Sciences, University of Missouri-Columbia; 4) University of North Carolina High Throughput Sequencing Facility; 5) Department of Molecular and Cellular Neuroscience, The Scripps Research Institute.

For a given sequencing budget, the Low-Coverage Whole Genome Sequencing (LCWGS) strategy allows more samples to be sequenced, and therefore potentially finds a greater number of rare variants. However, the low coverage makes variant calling with standard tools difficult, possibly canceling out any such gains in detection of rare variants. Linkage-disequilibrium (LD) aware variant callers may provide calling rate and accuracy to make LCWGS viable. We examined the performance of LCWGS in 708 whole genome sequences from a population sample of Native Americans. Most of the sequences have coverage between 3X and 12X. We called variants with the LD-aware variant caller Thunder, as well as the single-sample and multi-sample GATK Unified Genotyper. We assessed variant calling through a comparison of the sequencing results to genotypes measured in 641 of the same subjects using a fixed content exome array, which contains variants across the frequency spectrum. The median concordance for Thunder is 97.5%, compared to 85.5% and 90.4% for single-sample and multi-sample calls with the non-LD aware caller. The median improvement of LD-aware calling over the other methods is dependent on depth; for samples with less than 5X coverage, the median improvement is approximately 30%, decreasing to only 2% for samples with greater than 10X coverage. LD-aware variant callers are expected to perform less well for rare variants; for variants at which a single minor allele appears in the data, the multi-sample Unified Genotyper identifies approximately 57% of the variant sites, while Thunder identifies only 41%. Our results indicate viability of the low-coverage strategy for WGS studies can be achieved through use of LD-aware callers.

Finding the Clinical Answer in Genomic Sequence: Narrowing the Search Space for Disease-Causing Mutations. *S. Garcia[1], G. Chandratillake[1], M. Clark[1], A. Patwardhan[1], S. Chervitz[1], R. Chen[1,2], E. Ashley[1,3,4], R. Altman[1,4,5], J. West[1], R. Chen[1].* 1) Personalis, Inc., Menlo Park, CA; 2) Icahn School of Medicine, Mount Sinai, New York, NY; 3) Department of Medicine, Division of Cardiovascular Medicine, Stanford University, Stanford, CA; 4) Department of Genetics, Stanford University, Stanford, CA; 5) Department of Bioengineering, Stanford University, Stanford, CA.

Diagnosis via genomic sequencing relies on identification of causative disease variants from the tens of thousands of variants present in an exome. Protocols typically apply hard filters to exclude variants by applying expectations concerning which variant types could be disease-causing. Sensitivity suffers when criteria are too strict, missing cases that expand the phenotypic or genotypic spectrum of known diseases. Conversely, relaxation of filtering criteria may result in overwhelming numbers of candidates, delaying or preventing diagnosis. We investigated whether a knowledge-based ranking system linking reported clinical information with curated phenotype information combined with ranked genotype expectations based on family history could facilitate the identification of causally related variants without sacrificing the ability to detect novel candidates. Samples with clinical features and known causative variants representing a broad range of conditions and variant types (including structural variants of various sizes) were sequenced, and had variants aligned and called. A newly developed database linking clinical features to genes was used to identify and rank candidate genes for each sample. Identification of all possible inheritance patterns, allowing for *de novo* events and non-penetrance, yielded genotype expectations ranked by likelihood. We compared a standard approach using variant pathogenicity predictions combined with simple genotype predictions to our novel approach. Our approach reduced the number of candidate variants requiring manual review. For example, in a trio segregating an autosomal dominant trait, 597 candidate variants were identified using the standard approach, while our approach ranked 41 candidates. Similarly, in a trio segregating an autosomal recessive trait, our approach ranked four candidates; the standard approach identified 58. In these, and all cases tested, the known causative variant was ranked first by our approach. The use of our novel, knowledge-based ranking successfully identifies the most likely causative variants in genomic data, reducing manual review time. With current estimates in the range of 20-60 minutes required for review of each variant, this approach has potential to dramatically improve turnaround time for exome/genome sequencing without sacrificing the potential for novel discovery.

Detecting disease-causing alleles with the human gene connectome.
Y. Itan[1], J-L. Casanova[1,2,3], L. Abel[1,2], S-Y. Zhang[1,2], L. Quintana-Murci[4], G. Vogt[2], D. Fried[5], P. Nitschke[3], M. Herman[1], A. Abhyankar[1]. 1) The Rockefeller University, New York, NY; 2) Necker Hospital for Sick Children, Paris, France; 3) Paris Descartes University, Paris, France; 4) Pasteur Institute, Paris, France; 5) Ben-Gurion University of the Negev, Beer-Sheva, Israel.

Infectious diseases have historically been the greatest killer of mankind. They still account for about 25 percent of all human mortality worldwide. At any time, new epidemics or pandemics can significantly increase this proportion. Only a small proportion of infected individuals develop clinical disease; the collective burden of infection is high because there are many infectious agents. It has become increasingly clear that human genetic background is a key determinant of infectious diseases. To determine the disease-causing allele(s), high-throughput genomic methods are applied and provide thousands of gene variants per patient. However, current methods for validating the true disease-causing single allele at the single patient level are inefficient and extremely time consuming. Moreover, there is no available method for automating the selection of candidate disease-causing alleles at the cohort level, posing a major bottleneck in the field in high-throughput clinical genomics. Resolving this problem will revolutionize the field. We recently developed a novel approach, the 'human gene connectome' (HGC) - a concept, method and database that describes the set of all in silico-predicted biologically plausible routes and distances between all pairs of human genes (Itan Y et al. PNAS, 2013). With the HGC, we generated a 'gene-specific connectome' for each human gene - the set of all human genes ranked by their predicted biological proximity to the core gene of interest. We demonstrated that the HGC is currently the most powerful approach for prioritizing high-throughput genetic variants in Mendelian disease studies, by effectively identifying novel herpes simplex encephalitis (HSE) morbid alleles in whole exome sequencing (WES) patients data. We hypothesize that within a cohort of patients with the same Mendelian (or nearly Mendelian) disease, the cluster that contains the true disease-causing gene for each patient is the HGC-predicted biologically smallest cluster. Investigating a cohort of 108 exome sequenced HSE patients, we developed and applied a Mendelian clustering algorithm, which approximates the biologically smallest HGC-predicted cluster that contains one allele per patient. By that we approximate a solution for an NP-complete algorithmic problem and estimate the disease causing allele for each individual in the cohort.

1552T

Incorporating phenotypic information to improve Mendelian disease-gene predictions.
A. Javed, S. Agrawal, P.C. Ng. Genome Institute of Singapore, A*STAR, 60 Biopolis Street, Genome, #02-01 Singapore 138672.

We introduce a method which combines phenotypic and genotypic information, within Bayesian framework, in a holistic prediction implicating the gene(s) involved. The patient symptomology is mapped to a list of known disorders using Human Phenotype Ontology. The significance of the match is translated into probability and assigned to the genes implicated for the disorders. The putative role of similar genes is included using random walk with restart of a probabilistic gene-gene interaction network. This network was constructed by combining multiple data sources and exhibits strong enrichment of known genetic heterogeneity; pvalue<1e-16 using HGMD and OMIM. Next the patient's sequencing data is analyzed for genotypic predictions. Co-segregation of the disease within pedigree, and allelic frequency in public data, helps prune the list to candidate rare mutations. Among coding variants, different predictors are used to estimate damaging role of nonsynonymous, splice-site, and indel mutations. The performance is quantified using HGMD as positive set and common variants in dbSNP as neutral set. For noncoding mutations positive set was bolstered by known GWAS hits and neutral set by common mutations in CGI public data. In each category a threshold can be set to achieve 80% (or more) true positives, with 3% (or less) false positives. The variant predictions are pooled within genes for coding and noncoding mutations separately. 1000 Genomes samples were used to define the null distribution of loss of functionality of each gene. The performance was evaluated in in-silico patients. 39 diseases from HGMD were selected and patient's symptom and genomes simulated; the former by randomly sampling the symptoms of the disease, and the later by adding an implicated variant in a healthy sample from 1000 Genomes. Causal gene was selected as top ranked in 79% simulations. Next the method was compared against state of the art algorithm VAAST restricting to nonsynonymous causal variants only. Our results compared favorably, the causal gene was lone top ranked in 68% (and top-5 in 73%) of simulations. VAAST, working only with the genotypic information, was able to identify the causal gene as top ranked in 67% cases; however the top rank was assigned to 14 genes (on average) in each simulation. Our method is the first comprehensive effort which incorporates disease symptoms and estimates the deleterious role of both coding and regulatory mutations in the prediction.

VHB: a web-based Visualization tool to compare the Haplotype Blocks of a study sample with the 1000 genome project data.
C.C. Lai[1], Y.T. Chen[2], W.P. Hsieh[3], C.Y. Tang[1,4]. 1) Department of Computer Science, National Tsing Hua University, No. 101, Section 2, Kuang-Fu Road, Hsinchu, Taiwan 30013, R.O.C; 2) Supercomputing research center, National Cheng Kung University, 1 University road, Tainan, Taiwan 701; 3) Institute of Statistics, National Tsing Hua University, No. 101, Section 2, Kuang-Fu Road, Hsinchu, Taiwan 30013, R.O.C; 4) Department of Computer Science and Information Engineering, Providence University, No. 200, Sec. 7, Taiwan Boulevard, Shalu Dist., Taichung City 43301 Taiwan.

The haplotype blocks constructed with variations detected from the 1000 genomes project help us to improve the association analysis. The linkage between the point mutations (SNPs, Indels) and traits can be further refined with information of haplotype blocks. It is useful to compare the haplotype blocks of a new study sample to the ones of the same ethnic group in the 1000 genome project. We developed a web tool, Visualization of Haplotype Blocks (VHB), to provide better visualization of the big data with the plots of pairwise linkage disequilibrium (LD). Researchers could upload the variation data of one or several samples in a Variant Call Format (VCF). The statistics of pairwise LD in the selected region are calculated from the variations of study samples and data the 1000 genome project which will be stored in the database of the VHB. Then all variation data of the samples will be parsed and imported into the database schema for temporary storage (30 days). Genome regions and ethnic groups of the 1000 genome project are selected in the web interface and the results can be displayed in the Generic Genome Browser locally, or exported as the general feature format (GFF) file, which is the standard output for the genome browser and one type of annotation data format of ANNOVAR software. The VHB web-based tool is available at http://safe.cs.nthu.edu.tw/VHB/. It is implemented in Perl programming language and MySQL relational database, and an Intel Core i7 CPU and 8GB memory computer is used under Linux platform.

Inferring HIV Quasispecies from Deep Sequencing Data.
S. Mangul[1], N. Wu[1], N. Mancuso[2], A. Zelikovsky[2], R. Sun[1], E. Eskin[1]. 1) University of California, Los Angeles; 2) Georgia State University.

Human immunodeficiency virus (HIV) exhibit high genomic diversity within infected hosts, which may explain resistance to existing drugs. Monitoring and quantifying the HIV population requires inferring set of closely related viral variants , referred to as a quasispecies, and estimating their relatives frequencies. Next-generation sequencing (NGS) is a promising technology for characterizing viral diversity due to its ability to generate large numbers of reads at low cost. However, there is a trade-off among throughput, read length and accuracy for different high throughput sequencing platforms. Error rates in next-generation sequencing platforms, such as Illumina, make it infeasible to use this technology for reconstructing HIV quasispecies and inferring their relative abundances. We suggest to use barcode technique during library preparation allowing to distinguish sequencing error from true variants. Using this technique we are able to obtain high accuracy sequencing reads. Here, we introduce a method for inferring HIV quasispecies from high accurate paired-end reads obtained using the barcoding technique described above. Method consists of the following key steps: (a) build consensus from reads; (b) map reads to consensus; (c) build conflict graph and assemble quasispecies; (d) infer relative abundances of quasispecies using EM algorithm. To build a consensus from paired-end Illumina reads Vicuna tool is used. Vicuna is de novo population consensus assembly software able to produce single consensus from deep viral sequencing data. We use Mosaik tool with default parameters to map reads to assembled consensus. Based on the read mapping we construct a conflict graph which is used to represent HIV quasispicies in a sample. A conflict graph is a directed acyclic graph where each vertex represents unique read. Two reads are connected by an edge if they overlap but disagree on the overlap. To solve the quasispicies assembly problem it is necessary to partition the conflict graph into a minimal number of independent sets. This problem also known as graph coloring problem which is NP-hard. To solve this problem we iteratively partition the vertices of the graph into two disjoint subsets using greedy algorithm that maximizes cut between this subsets. Preliminary experimental results on synthetic datasets show that our method is able to reconstruct HIV quasispecies from deep sequencing Illumina paired-end data.

1555T

Detection of sample-level contamination in next generation sequencing experiments. *T.E. Scheetz[1,2], A.P. DeLuca[1,2], E.M. Stone[1,2], T.A. Braun[1,2].* 1) Dept Ophthalmology, Univ Iowa, Iowa City, IA; 2) Institue for Vision Research, Univ Iowa, Iowa City, IA.

The goal of the this research project is to detect contamination of genomic DNA samples used in next-generation sequencing applications. When performing massively parallel sequencing in a clinical setting, it is critical to ensure that any variations detected result from the correct patient sample - and *only* from that sample. Known genotype fingerprints can help validate sample identity. But additional quantitative measures are required to ensure sample integrity.

We used the Genome Analysis Toolkit (GATK) to call variations. The relative number of supporting reads (supporting / cover) was calculated for each variation. The distribution of the relative number of reads supporting each variant was compared to a distribution derived from a cohort of control samples. Contamination was detected as an increase in variations with a relative number of supporting reads below 35%.

The system we have developed is a systematic approach for identifying contamination in samples used in next-generation sequencing experiments. Contamination presents as a substantial and distinctive increase in the fraction of variations for which the relative fraction of supporting reads is below 50%. We have evaluated several dozen of our own exomes, as well as thousands of publicly available exomes, for evidence of sample-level contamination. Our analysis correctly identified two positive controls (known/intentional contaminated samples) within our own dataset. In addition, we identified several exomes from publically available datasets that show all of the hallmarks of sample contamination. Together with our collaborators we will be validating samples that appear contaminated to evaluate our algorithm's specificity and sensitivity.

We have developed a simple method for identifying contaminated samples in exome sequencing experiments. Further research in this area is needed to determine the power of this method in identifying and quantifying the extent of contamination, and the amount of contamination that can be tolerated without compromising accuracy.

New Mixed Model Estimates Drug-Effect or Disease Onset in Association with Covariates. *M. Xu, Y.Y. Shugart.* Unit on Statistical Genomics, Intramural Research Program, National Mental Health, Bethesda, MD.

Many statistical models have been developed to associate human diseases with genetic or environmental factors. Previously, the disease is often described by only one measurement. Until recently, studies seeking to associate genetic and environmental factors with human disease have relied on disease phenotypes characterized by only one measurement. The task of determining how longitudinal measurements are associated with a disease's driving factor and with other covariates requires more sophisticated type of analysis. To meet these new needs, we have developed a 'mixed model' approach, that not only pinpoints the turning-point when disease becomes manifest or therapeutic drugs begin to take effect but also delineate associations over time with such potentially confounding factors as genotype and disease subtype. Our new model therefore describes covariance for repeated measurements over time and incorporates a correlation structure for a stationary time series. The phenotypic data used here include sequenced measurements taken during the period before a drug effect or disease symptom becomes manifest, and also after the first effects or symptoms appear. It should be noted that for most diseases and drugs, the precise time of onset marking the change between these two sequences is not known. Inasmuch as sequenced data covering the whole time course from naïve to full-blown effects is more readily available for drug effects than for the development of diseases, we demonstrated our new model by estimating the distribution of drug effect onset and analyzing these estimated time points' association with key covariate factors. Using a pilot data set, we conducted data-driven computational experiments and evaluative simulations to test our new framework's ability to estimate the onset of a drug's effects. The working example we will present demonstrates that our new statistical approach successfully predicted the onset of a drug's effects on baseline anxiety in a subgroup of STAR*D participants. Our results also confirm that the new approach can calculate the required depth for a targeted power with only a nominal rate of type I errors. Finally, our demonstration shows that with our new statistic, researchers including those working with publicly available data~to pinpoint the onset of a specific disease or a specific drug and to determine how onset may be affected by such potentially influential covariates such as genotypes or sub-phenotypes.

Fast and Accurate Diploid Genotype Imputation via Segmental Hidden Markov Model. *L. Zhang[1], Y.F. Pei[1], H.W. Deng[2], Y.P. Wang[2].* 1) University of Shanghai for Science and Technology, Shanghai, Shanghai, China; 2) Biostatistics and bioinformatics, Tulane university, New orleans, LA.

Fast and accurate genotype imputation is necessary for facilitating gene mapping studies, especially with the ever increasing numbers of both common and rare variants generated by high throughput sequencing experiments. However, most of the existing imputation approaches suffer from either inaccurate results or heavy computational demand. In this study, aiming to perform fast and accurate imputation analysis, we propose a novel, fast and yet accurate method to impute diploid genotypes. Specifically, we extend a hidden Markov model that is widely used to describe haplotype structures. But we model hidden states onto single reference haplotypes rather than onto pairs of haplotypes. Consequently the computational complexity is linear to size of reference haplotypes. We further develop an algorithm to speed up the calculation. Working on compact representation of segmental reference haplotypes, the algorithm always calculates an exact form of transition probabilities regardless of partition of segments. Both simulation studies and real data analyses demonstrated that our proposed method was comparable to most of the existing popular methods in terms of imputation accuracy, but was much more efficient in terms of computation. The developed algorithm can further speed up the calculation by several folds without loss of accuracy. The proposed method will be useful in large scale imputation studies with a large number of reference subjects. The implemented multi-threading software FISH is publicly available.

1558T

CeRNA interactions cooperate with genomic variability to modulate drivers of tumorigenesis. *H.S. Chiu[1,2,3], X. Yang[1,2,3], M.R. Martínez[1,2,3], P. Sumazin[1,2,3], A. Califano[1,2,3].* 1) Columbia Initiative in Systems Biology, Columbia University, 630 West 168th Street, New York, NY 10032; 2) Center for Computational Biology and Bioinformatics, Columbia University, 630 West 168th Street, New York, NY 10032; 3) Department of Biomedical Informatics, Columbia University, 630 West 168th Street, New York, NY 10032.

Recent evidence suggests that RNAs compete for binding and regulation by a finite pool of microRNAs (miRNAs), thus regulating each other through a competitive endogenous RNA (ceRNA) mechanism. Using a kinetic model, we show that pathophysiologically relevant regulation occurs when ceRNA interactions are mediated by multiple miRNAs, while interactions mediated by a single miRNA may have negligible magnitude. Furthermore, our model predicts that ceRNA interactions mediated by multiple miRNAs are largely independent of the individual miRNA's expression and thus highly conserved across distinct cellular states. Indeed, we predict and validate an ultra-conserved network that includes more than 160,000 ceRNA interactions, which are conserved across tumor and non-tumor related cellular contexts. We show that this network integrates genetic and epigenetic alterations of cognate ceRNA regulators to dysregulate established oncogenes and tumor suppressors, accounting for a large fraction of the missing genomic variability in tumors.

1559F

MITOCHONDRIAL DISEASE SEQUENCE DATA RESOURCE (MSeqDR) CONSORTIUM: A Global Grass-Roots Effort to Compile, Organize, Annotate, and Analyze Whole Exome and/or Genome Datasets from Individuals with Suspected Mitochondrial Disease. *X. Gai[1], D. Krotoski[2], M. Gonzalez[3], D.C. Wallace[4], M. Parisi[2], S. Zuchner[3], M.J. Falk[5].* 1) Center for Biomedical Informatics, Loyola University Stritch School of Medicine, Maywood, IL 60153; 2) NICHD, NIH, Bethesda, MD 20892; 3) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL 33136; 4) Center for Mitochondrial Medicine, The Children's Hospital of Philadelphia and University of Pennsylvania Perelman School of Medicine, Philadelphia, PA 19104; 5) Division of Human Genetics, The Children's Hospital of Philadelphia and University of Pennsylvania Perelman School of Medicine, Philadelphia, PA 19104.

The success of whole exome sequencing (WES) for highly heterogeneous disorders, such as mitochondrial disease, is limited by the substantial technical and bioinformatic challenges of identifying and prioritizing the extensive sequence variants present in each patient. Success rates can be greatly improved if a large cohort of patient exome data from both clinical and research laboratories are assembled to permit systemiatic sequence variant analysis, annotatation, and informed interpretation. Since June 2012, we have established a grass-roots effort facilitated by the United Mitochondrial Disease Foundation (UMDF) and NIH called the 'Mitochondrial Disease Sequence Data Resource (MSeqDR) Consortium'. We have engaged more than 100 mitochondrial disease experts to identify and prioritize specific WES data analysis needs of the global mitochondrial disease community. Currently, we are moving forward toward our common goal of establishing a central data resource for the coherent compilation, organization, annotation, and analysis of WES data in dual genomes from all patients with suspected mitochondrial disease. Exome and phenotype data is united in a publicly accessible, secure, and user-friendly web-based tool that is accessible from a central website. MSeqDR prototype development is now underway with support from the UMDF and North American Mitochondrial Disease Consortium involving investigators from 9 countries in North America, Europe, Australia, and Asia. A global MSeqDR will fill the existing void in bioinformatics tools and knowledge necessary for efficient WES data analysis in the mitochondrial disease community. This resource will potentially support reliable genetic diagnosis in individual cases, facilitate identification of additional cases of rare genetic disorders, provide evidence to exclude from consideration sequence variants of unknown significance that are unlikely to be disease-causing, permit identification of modifier genetic factors underlying disease variability, and even identify genetic variants that are likely to alter response to emerging therapies.

Detection and characterization of mutations due to DNA damage and PCR amplification errors in targeted ultra-deep next-generation sequencing data. *J. Eboreime, N. Arnheim, P. Calabrese.* Molecular and Computational Biology, University of Southern California, Los Angeles, CA.

Next-generation sequencing (NGS) has been used to estimate the genome average mutation frequency. The coverage of such NGS studies is insufficient to provide a mutation frequency estimate at individual nucleotide sites so variation among sites is unknown. Deep NGS sequencing has the capability to accurately estimate mutation frequencies at hundreds of different nucleotides simultaneously in hundreds of thousands of copies of a small relevant gene DNA segment. This could allow for the detection of germline mutation hot spots. One problem is that NGS deep sequencing suffers an error rate higher than the expected mutation rate. To improve NGS fidelity we adapted a new protocol called the Safe-Sequencing System (SSS), developed in the Vogelstein laboratory, and applied it to a 150 bp region in FGFR3 that includes the site of a common de novo disease mutation transmitted in an autosomal dominant fashion. SSS utilizes a unique identifier (UID) to distinctly tag each original genomic DNA molecule. During testis library preparation, PCR of each distinctly tagged template molecule creates a UID family. NGS reads with the same UID and disease mutation are candidates for being true mutants. We divided the testis of an unaffected 68 year old man into 192 pieces, and measured the somatic mutation frequency in 32 of the pieces. Using SSS we detected an unexpectedly high average mutation frequency (4.6×10^{-5}). We observed that among the sample of 32 pieces there were cases where some pieces had significantly higher mutation rates at certain nucleotides compared to other sites. We also observed many C>A/G>T transversions consistent with oxidation of guanine to 8-oxo-guanine and deamination of cytosine to uracil (C>T/G>A) but other mutations were also unexpectedly frequent. Not correcting for these high frequencies, presumably due to DNA damage and other artifacts, can greatly affect the accurate detection of rare in vivo mutants. The Duplex Sequencing method, developed in the Loeb laboratory, improves the SSS method by not only uniquely tagging each molecule with a UID but also tagging each strand of the molecule with the same sequence (or its complement). Comparing both original strands of a DNA duplex can exclude premutagenic lesions that arose before library preparation. In addition, our data allows us to estimate, and correct for, errors that arise during the PCR amplifications required for NGS library formation.

1561T

Comparison of the performance of read mappers and assembly methods on indel calling. *H. Lin, Y. Shen.* Columbia University, New York, NY.

The primary technique for detecting genomic variations from next generation sequencing data is to map reads to a reference genome and call potential variants based on the aligned reads. Although this approach has worked well for detecting SNP's, the problem of detecting insertions and deletions from short read data remains challenging, especially if the insertions and deletions are large. A number of new techniques have been developed for mapping reads more effectively in the presence of insertions and deletions. In this work, we compare the performance of a number of new read mappers and their ability to detect indels (i.e. insertions and deletions) from real sequencing data. Our data consists of sequencing from trios consisting of a proband and his or her parents. This trio data provides a unique opportunity to evaluate the quality of the indels called from different read mappers, in addition to measuring the overall number of indels called. In general, measuring the accuracy of indels called from real sequencing data can be a challenge, but with sequencing from trios, we can measure the mendelian concordance and the transmission ratio of the indels called, which provides a reasonable measure of precision. In addition, for each read mapper, we also measure the number of novel indels called, which are not found in existing databases, such as dbSNP, and also measure their mendelian concordance and transmission ratios. Lastly, we also explore the performance of some newly developed assembly based approaches for indel calling, and the impact of error correction on the methods.

1562F

A Bayesian framework for de novo mutations calling in trios. *Q. Wei[1], Y. Liu[2], Y. Han[2], X. Zhan[3], W. Chen[4], B. Li[1].* 1) Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Center for Human Genetic Variation, Duke University, Durham, NC; 3) Department of Biostatistics, University of Michigan, MI; 4) Department of Pediatric, University of Pittsburgh, PA.

For most human complex diseases, although numerous loci have been identified, the genetic basis remains largely unknown. For sporadic cases without family history, increasing evidence shows that de novo mutations play an important role in the genetics of thesediseases such as neurodevelopment disorders. Identifying de novo mutations in such cases will not only help directly find genes implicated in disease etiology but also provided candidate genes or pathways for mappinginherited variants associated with the disease. High-throughput next-generation sequencing enables a genome- or exome-wide detection of de novo mutations by sequencing proband-parents trios.Since de novo mutations are extremely rare, e.g. 50-100 per generation, it is challenging to sifttrue mutations throughsequencing error and alignment artifacts. Traditional approaches infer individual genotypes and identify putative de novo mutations by comparing proband's and parental genotypes. Recently an efficient likelihood-based framework (polymutt) was proposed and shown to outperform standard approaches dramatically. A limitation of polymutt is that the pre-specified prior mutation rate has a significant impact on the de novomutation calling,resulting inreduction of sensitivity and specificity when improper priors are assigned. To address this problem, we developedtriodenovo, a Bayesian framework that separatesde novo calling from the mutation rate for trio data so that the prior mutation rate can be adjust post-hoc.Through extensively simulations we showed that this new method has higher sensitivity and specificity than polymutt and standard approaches, especially when the depth of coverage is low (e.g. 20X). Coupled with machine learning approaches to filtering false positive candidates due to alignment artifacts, we showed that triodenovoachieves increased specificity without scarifying sensitivity on real data.We hope that this new framework is useful to the research community toefficiently identify de novo mutations to facilitate the association mapping of genes for human diseases.

PhenoExplorer: a tool to help researchers identify relevant studies and phenotypic variables in dbGaP. *J. Ambite[1], L. Lange[2], S. Sharma[1], S. Voinea[1], C. Hsu[1], Y. Arens[1].* 1) Information Sciences Institute, University of Southern California, Marina del Rey, CA; 2) Department of Genetics, School of Medicine, University of North Carolina, Chapel Hill, NC.

The National Institutes of Health (NIH) created the dbGaP resource as a repository for genetic and phenotypic data. dbGaP provides the scientific community an unprecedented opportunity to gain access to data from multiple studies, but identifying the pertinent subset of studies and phenotype variables in dbGaP is often challenging. The true utility of this resource is thus limited by a user's ability to identify the specific data relevant to their own research. Some studies include thousands of phenotype variables, many being study-derived variables measuring similar traits, with descriptions varying widely across studies. For example, hypertension status is described variously as 'HTN', 'high blood pressure', and 'high BP', causing many exact text searches to fail to identify all relevant variables. Moreover, a search for hormone replacement therapy should also return studies with variables about estrogen intake, which requires a semantic search. In addition, users often wish to limit phenotype searches to studies with certain features, such as those with African Americans and/or with sequence data. To address these issues, we developed PhenoExplorer.org, a free online tool that allows researchers to identify dbGaP studies containing phenotypes of interest and the corresponding phenotypic variables. Specifically, a researcher can search for studies along a set of dimensions, including race/ethnicity, sex, study design, type of genetic data, genotype platform, and diseases studied. Crucially, the researcher can also enter free text describing the phenotype of interest. The tool returns all studies satisfying the metadata constraints and containing phenotypic variables relevant to the user-described phenotype. Our core novel contribution is the semantic similarity metric used to identify phenotypic variables related to the user's search string. This metric uses an ensemble of similarity predictors based on information retrieval and machine learning techniques. One predictor is a semantic text similarity function automatically learned from manual phenotype harmonization done for the NHLBI CARe consortium. Since variable descriptions in dbGaP are typically short (1-10 words), the tool expands them with definitions and synonyms from the Unified Medical Language System. Other predictors use variations of information retrieval text similarity techniques (TF-IDF, cosine similarity). In summary, PhenoExplorer enhances access to the wealth of data at dbGaP.

1564T

How to reduce false positives: A quality assurance pipeline for phenotype data. *A. Matchan[1], NW. Rayner[2], AE. Farmaki[3], K. Hatzikotoulas[1], E. Tsafantakis[4], M. Karaleftheri[5], L. Southam[1,2], K. Panoutsopoulou[1], G. Dedoussis[3], E. Zeggini[1].* 1) Applied Statistical Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 3) Harokopio University Athens, Athens, Greece; 4) Anogia Medical Centre, Anogia, Crete, Greece; 5) Echinos Health Centre, Echinos, Greece.

High quality phenotype data are an essential component of studies examining the association between rare variants and complex traits. Population isolates are being increasingly used to empower these studies due to the reduced amount of genetic and environmental variability within these groups. We are studying two isolated populations in Greece (HELlenic Isolated Cohorts study, www.helic.org). The main aims of the project are to link phenotype to genotype for traits of medical relevance and to enable population genetics studies. An extended set of phenotype data (~350 traits) has been collected for all samples (n~3000). This includes anthropometric, cardiometabolic, biochemical, haematological and diet-related traits. Collection of these data relies, primarily, on interview-based questionnaire methods followed by manual double blind entry of the data. This process can introduce errors, including keying errors, misinterpretation of questionnaire answers, language translation problems, duplicate data collection and the issue of how missing data (as opposed to unanswered questions) should be interpreted in downstream analysis to avoid misleading results. To address these issues we have developed a phenotype cleaning pipeline to remove errors and inconsistencies in the data as much as possible. The double-blind data entry procedure enables automated checking for discrepancies and captures the majority of user input errors. Outliers in quantitative traits are programmatically identified and data values are assessed against normal ranges as published in the literature. Cross-trait checking is additionally employed to assess the integrity of the data e.g. checking height and BMI versus gender. Genotype quality control information is also used to identify duplicates (4.4% of samples in the HELIC cohort) and assess the robustness of the genotype-phenotype link based on gender. We find that ~10% of entries in the HELIC dataset contained an error. The clean phenotype data are centrally stored and changes are tracked using a version control system. As a result of this pipeline we have a broad range of high quality phenotype data available for 99.8% of the HELIC samples, enabling powerful genotype-phenotype association studies. The effect of phenotype errors on false positive and false negative associations can be substantial. We have put in place a data cleaning pipeline which minimises error and therefore empowers locus discovery in downstream analyses.

Reconstructing Pedigrees from Estimates of Genomic Sharing in Admixed Populations. *J.E. Below[1], J. Staples[2], A. Reiner[3], L. Ekunwe[4], E.L. Akylbekova[5], S.K. Musani[5], J.G. Wilson[5], C.R. Hanis[1], D. Nickerson[2].* 1) Human Genetics, University of Texas Health Science Center, Houston, TX; 2) University of Washington, Genome Sciences, Seattle, WA; 3) University of Washington, School of Public Health, Seattle, WA; 4) Jackson State University, Jackson, MS; 5) University of Mississippi Medical Center, Jackson, MS.

Understanding and correctly utilizing relatedness among samples is essential for all genetic analysis. However, records of sample relatedness are often incorrect, incomplete, or unavailable. PRIMUS is an algorithm that utilizes genome-wide estimates of identity by descent (IBD) to assign relationship categories and leverages these pairwise relationships to identify all possible pedigrees consistent with the observed genetic sharing. Reconstructing pedigrees in admixed populations is complicated by the fact that many algorithms for estimating IBD from genome-wide SNP data assume sampling from a single homogeneous ancestral population. The presence of ancestry informative markers (AIMs) in estimating IBD using a method of moments can strongly bias relationship classification, resulting in inaccurate or failed pedigree reconstruction. We have implemented a principal component analysis within PRIMUS to identify signatures of admixture, appropriate reference population minor allele frequencies, and identify and remove AIMs prior to IBD estimation. Controlling for multiple ancestral groups, we reconstructed pedigrees for all 1,985 Mexican Americans from the Starr County Health Study (SC) as well as 3030 African Americans from the Jackson Heart Study (JHS). PRIMUS unambiguously identified 197 previously undescribed pedigrees in SC and reconstructed pedigrees for 338 families within JHS. Our method provides accurate reconstruction in genetically heterogeneous samples. We present data for the resulting pedigrees, and show that PRIMUS is powerful for both identifying novel pedigrees in large admixed genetic cohorts and for validating known pedigrees.

Detecting Differentially Expressed Genes in RNA-Seq Data with Unknown Conditions. *G. Klambauer, T. Unterthiner, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Upper Austria, Austria.

Methods that identify differential expression in RNA-Seq data are currently limited to study designs in which two or more sample conditions are known a priori. However, these biological conditions like activated regulatory and metabolic pathways are typically unknown in genetic studies such as the HapMap or the 1000 Genomes project. We suggest DEXUS for detecting differential expression in RNA-Seq data for which the sample conditions are unknown. In a Bayesian framework DEXUS models read counts as a finite mixture of negative binomial distributions in which each mixture component corresponds to a condition. Evidence of differential expression is measured by the informative/non-informative (I/NI) value, which allows differentially expressed transcripts to be extracted at a desired specificity (significance level) or sensitivity (power). DEXUS performed excellently in identifying differentially expressed transcripts in data with unknown conditions. On 2,400 simulated data sets, I/NI value thresholds of 0.025, 0.05, and 0.1 yielded average specificities of 92%, 97%, and 99% at sensitivities of 76%, 61%, and 38% respectively. In cohorts with genetic and RNA-Seq data, DEXUS was able to detect differentially expressed transcripts that could be related to genetic variants via the identified conditions. These genetic variants can be classified into structural variants like copy number variations and single nucleotide variants, that is, eQTLs.

Development of quality control processes for next-generation sequencing technologies. *P. Ebert, J. Calley, R. Higgs, X. Ma, T. Barber.* Eli Lilly and Company, Indianapolis, IN.

The use of next-generation sequencing (NGS) as a tool for interrogation of somatic/germline variation in DNA and differential expression in RNA pervades many areas of biology. With the adoption of this technology has come the ability to detect many types of experimental variation that were essentially invisible with previous technologies. The sampling process for RNASeq is very different than that for DNASeq, which leads to different challenges. We have developed rapid and sensitive methods to detect and quantitate the sources of variation which occur during the 'wet-lab' stage of NGS. These include methods to detect and remove contaminating sequences, detect 3' bias often observed in RNA sequencing data, and resolve sample identity issues. These processes are providing critical information about the quality of samples generated from internal projects (as well as data acquired from external sources) which is providing significant value to our research efforts.

1568F

MAPRSeq - Mayo Analysis Pipeline for RNA Seq: A comprehensive workflow for RNA-Sequencing data analysis. *A. NAIR, K. KALARI, J. BHAVASAR, X. TANG, J. DAVILA, J. NIE, D. O'BRIEN, JP. KOCHER.* Mayo Clinic, Rochester, MN.

RNA-Sequencing (RNA-Seq) technology is information-rich; the breadth of information gained spans from large structural changes to single nucleotide variants (SNVs). By efficiently analyzing RNA-Seq data, we can query and obtain a variety of genomic features, such as gene expression, novel and fusion transcripts, alternative splice sites, long non-coding and circular RNAs, SNVs etc. Majority of the RNA-Seq bioinformatics tools output one or two genomic features for downstream analysis. There is no extensive workflow that can be used to obtain a number of features from RNA-Seq data. Therefore, at Mayo Clinic, we have developed MAPRSeq - a computational workflow that takes the utmost advantage from an RNA-Seq experiment and provides comprehensive reports on genomic features for secondary data analysis. MAPRSeq workflow integrates a suite of open source bioinformatics tools along with in-house developed methods to analyze paired-end RNA-Seq data. Read alignment is performed with Tophat which uses Bowtie - a fast, memory efficient, short sequence aligner. Tophat aligns reads to the transcriptome and further to the genome to report both existing and novel junctions. Along with the alignment (BAM) and junction (BED) files, Tophat also provides a list of expressed fusion transcripts using the TopHat-Fusion algorithm. The BAM file is processed using HTSeq to summarize expression at gene level. Exon quantification is obtained with in-house methods that leverage BEDTools. In addition to raw gene and exon expression counts, MAPRSeq also provides normalized values (RPKM). For accurate variant detection, GATK is used to call SNVs that are further annotated with quality score, coverage and additional criteria using VQSR. MAPRSeq workflow reports several analytical functions, including alignment statistics, in-depth quality control metrics, gene and exon expression levels, fusion transcripts and SNVs for each sample. Circos plots are also provided to visualize fusion transcripts. MAPRSeq incorporates Integrated Genomics Viewer (IGV) to visualize alignment and coverage along the transcriptome as well as exon-exon junctions. MAPRSeq incorporates UCSC tracks on transcription and regulation in IGV as well to facilitate user interpretation. MAPRSeq is available at https://code.google.com/p/maprseq/.The workflow is well optimized to run on a single Linux machine as well as in a cluster environment to fully leverage multiple processors.

Assessment of the Impact of Read Length on RNA-seq Results: An ABRF Consortium Study. *J.A. Rosenfeld[1,2], G. Rudy[3], S. Chhangawala[4,5], P. Wu[6], S. Tighe[7], M.D Wang[6], D.A. Baldwin[8], G. Grills[9], C.E. Mason[4,5], The ABRF-NGS Consortium.* 1) Medicine, Rutgers - New Jersey Medical School, Newark, NJ; 2) American Museum of Natural History, New York, NY; 3) Golden Helix, Bozeman, MT 59718; 4) The Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY; 5) Department of Physiology and Biophysics, Weill Cornell Medical College, New York, NY; 6) The Wallace H. Coulter Dept. of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA 30332; 7) Vermont Cancer Center, University of Vermont, Burlington, VT 05405; 8) Pathonomics LLC, Philadelphia, PA 19104; 9) Institute of Biotechnology, Cornell University, Ithaca, NY 14853.

RNA sequencing is a rich assay for delineating the information of the transcriptome. However, few RNA-seq standard data sets exist to help evaluate methods for the quantification of gene or splice form expression. Moreover, each next-generation sequencing (NGS) platform has unique aspects of library synthesis, sequencing, alignment, and data processing. Little is known about the cross-site reproducibility, technical variance and interoperability of NGS platforms for RNA-seq. The goals of the Association of Biomolecular Resource Facilities - Next Generation Sequencing (ABRF-NGS) Study are to evaluate the performance of NGS platforms and to identify optimal methods and best practices. As part of this evaluation, we analyzed the utility of short vs. long reads, and single vs. paired reads from each end of a template, for identifying differentially expressed genes and novel isoforms. Read length and pairing are critical parameters affecting experimental design, analysis and cost, and longest available reads are often used in paired-end mode by default, whether or not these most expensive choices are necessary for the accurate RNA-seq profiling. To test this question, we used two standard ABRF RNA-seq libraries that were used throughout the ABRF-NGS project and the preceding MAQC project. To confirm our results on an independent dataset, we utilized data from ENCODE on 2 cell lines. In order to mitigate the influence of a particular computational algorithm, we utilized 3 separate pipelines to analyze the data. In order to further control the data, we used paired-end 100bp reads and computationally produced synthetic shorter and single-end reads from these real reads by trimming their length. The results were extremely consistent, but not in a positive way. We found that read-length and paired or single-end status are important factors in determining the results of an RNA-seq experiment. We found that the number of differentially expressed (DE) genes varied greatly as the read length changed. For many of the genes, there was a slight shift in FPKM, which was sufficient to move a hit from being DE to being insignificant This study indicates that while RNA-Seq is a powerful method which can produce useful results, the current technique yields a substantial variability in results that cannot be dismissed. Critical improvements are needed in RNA-seq sample preparation, data generation, and bioinformatics analysis tools.

Enlight: a web-based tool for integrating GWAS results with biological annotations. *Y. Guo[1,2], D. Conti[1,2], K. Wang[1,2,3].* 1) Preventive Medicine, University of Southern California, Los Angeles, CA; 2) Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA; 3) Psychiatry & the Behavioral Sciences, University of Southern California, Los Angeles, CA.

Genome-wide association studies (GWAS) have revealed thousands of variants associated with diverse human diseases and traits, butmost of the top hits are believed to beproxy markers for the true causal variants. Identifying causal variants remains a key challenge in post-GWAS era. Many identified regions fall into non-coding regions, making it especially hard to associate statistical significance with predicted functionality. Results from the ENCODE project, Epigenome Roadmap project, and other large-scale projectsmay help provide biological insights and generate hypotheses, but individual researchers do not have strong informatics skills or familiarity with these databases toleverage the massive amounts of annotation data in their own studies. To overcome this problem, we created a web-based tool, Enlight, for investigating and visualizing the relationships between all variants within a GWAS loci and available annotation information. It is ideal for non-coding variants, and is equally applicable for coding variants.Its 'GWAS plotting' function was modified from the LocusZoom software, which outputs publication-ready graphs with GWAS-specific information such as linkage disequilibrium, effect sizes and/or p-values, for genotyped and imputed variants. Additionally, its 'annotation plotting' function overlays functional annotation information to GWAS variants and adjacent variants (such as those from 1000 Genomes Project and NHLBI-ESP project), to help identify functional elements such as enhancers, promoters, methylation patterns, HiC-Seq region, ChIP-Seq peaks, RNA-Seq peaks and other relevant epigenetic information. Users have the flexibility to select a specific tissue or cell line of their own interest, and then load the tissue-specific annotation information into the graph. Users can choose from a number of pre-made trackscompiled by the UCSC genome browser, but can also upload custom data tracks in BED format. Enlight is freely available at http://enlight.usc.edu.

RNA-Seq Analysis of Alternative Splicing Events in Drosophila melanogaster. *Y. Li[1,2], X. Rao[1], C. Amos[2], B. Liu[1].* 1) The Center for Genetics and Genomics, University of Texas MD Anderson Cancer Center; 2) Center for Genomic Medicine, Department of Community and Family Medicine, Geisel School of Medicine, Dartmouth College.

Alternative splicing is an important biological process in the generation of derivative functional transcripts with same genomic sequences. RNA-seq technology has been widely used for researches in transcriptomics. The profile of gene differential expression and alternative splicing can be analyzed by the various statistical analytical methods. In this article, we are reporting a protocol for differential analysis of splicing junctions and intron retentions. The DEXSeq, an R bioconductor originally designed for gene exons expression analysis (Anders S, Reyes A, Huber W, Genome Res, 2012 Oct; 22(10):2008-2017), was adopted on splicing junctions and intron retentions analysis. The design of reference files for splicing junctions and intron retentions was introduced to fulfill the DEXSeq analysis. To evaluate the protocol, the public RNA-seq datasets generated from the Drosophila melanogaster S2-DRSC cells with RNAi depletion of RNA binding proteins (Brooks AN et al., Genome Res 2011 Feb; 21(2):193-202) have been analyzed. With the further study on the differential analysis of splicing junctions and intron retentions, sequence motifs were identified at the flanking sequence of significant splicing junctions and intron retentions. Ingenuity Pathway Analysis (IPA) of the vertebrate homologs of the genes with significant splicing events may provide functional information. The results from this study show that DEXSeq package can be applied on alternative splicing analysis on RNA-seq data; conserved DNA sequence motifs may imply the possible roles of the RNA binding proteins during the splicing events.

Modeling complex autoimmune disease susceptibility in the skin with regulatory and genetic-genomic interface networks. *J.C. Chen[1,2], A.M. Christiano[2,3].* 1) Joint Centers for Systems Biology, Columbia University, New York, NY; 2) Department of Genetics and Development, Columbia University, New York, NY; 3) Department of Dermatology, Columbia University, New York, NY.

Autoimmune diseases that present in the skin and hair, such as Alopecia areata and psoriasis, are complex genetic diseases whose pathogenesis resides at the interface between two distinct organs: the immune system and an affected 'end organ'. While research has shown that certain genetic variants affecting immune response genes can lead to disease in patients and that these variants can be are shared across different autoimmune diseases, the symptomatic organs vary from patient to patient. This indicates that there can exist genetic factors in the end organs that render them susceptible to aberrant autoimmune response. Since multiple autoimmune diseases can present in the skin, and can sometimes present concomitantly in a single patient, the skin serves as an ideal model to study the molecular regulatory processes that contribute to the onset of autoimmune disease in a specific organ. Historically, human diseases have been modeled by large, complex gene expression panels or physiological traits. While informative, this approach does not provide direct insight into the regulation and induction of these signatures. In order to understand the molecular regulation of autoimmune disease susceptibility in end organs such as the skin, we have created a molecular regulatory model for the skin based on reverse-engineered transcriptional and genetic-genomic interface networks. We used the systems biology algorithms ARACNe and DIGGIn to generate integrative networks of gene regulation in human skin using gene expression and genomic microarrays. We have implemented an integrative approach that allows us to leverage both genetic and genomic data to model autoimmune disease sensitivity in the skin as a set of key molecular regulators inferred from emergent networks and the mutations that affect these key regulators. Importantly, our method provides a way to model autoimmune disease as a function of its molecular regulators, rather than its biomarker panels or physiological traits. This perspective allows us to parse causal genes from their effects, and how they directly link to autoimmune disease susceptibility. This systems biology perspective invites both novel methodologies in studying complex, polygenic gene expression patterns, and the development of novel therapeutic strategies informed by regulatory networks.

Network Communicability: An Effective Alternative Metric for Genome Analysis. *C. Shaw, I.M. Campbell.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

Network similarity metrics are increasingly utilized to productively analyze genome-wide data. Conventional approaches such as shortest path and clique-based techniques have been useful but are not well suited to all applications. Recently, computational scientists in other disciplines have developed network communicability as a complementary method to analyze network relationships. Network communicability considers all paths between two network members. Given the success of previous analyses of the human protein-protein interaction network, we sought to apply network communicability to this complex data. As a challenging test case, we sought to partition human protein products into disease classes using communicability together with a set of training genes with known disease annotations based on OMIM. Our analysis reveals that communicability has several key advantages over shortest path and other previous methods. Additionally, we used copy number variation data from our diagnostic lab to show that the disease classes of genes deleted in patients correlate with their respective phenotypes. Our data suggest that metrics based on network communicability have considerable utility in the analysis of large-scale biological networks and may be fruitfully applied to a number of computational problems.

1574F

Quantifying gene expression and allele specific expression simultaneously using personal human genomes. *N. Raghupathy, K. Choi, S.C. Munger, G.A. Churchill.* The Jackson Laboratory, Bar Harbor, ME.

Large-scale genome and transcriptome sequencing efforts have characterized millions of common genetic variants across human populations. However development of tools that can effectively utilize this individual-specific variation to inform quantitation of gene abundance and allele-specific expression (ASE) have lagged behind. Current approaches employ two steps to quantify gene expression abundance and ASE from RNA-seq data; gene-level abundance is estimated from alignment of all reads genome-wide, while ASE is assessed separately by analyzing only reads that overlap known SNP locations. To address limitations of current RNA-seq alignment and quantitation methods, we developed the complimentary tools Seqnature and EMASE. Seqnature incorporates known polymorphisms and short indels from genetically diverse and heterozygous model organisms into reference genomes, and can construct individualized haploid or diploid transcriptomes suitable for read alignment by common aligners. EMASE is a model-based quantitation approach that employs an Expectation Maximization (EM) algorithm to apportion multi-reads at the level of the gene, isoform, and allele. Here we extend Seqnature to construct personalized diploid human genomes and transcriptomes from phased genetic variation data, and apply EMASE to estimate allele-specific and gene expression abundance simultaneously in human samples. We show that accounting for individual genetic variation by modeling as diploids at the alignment step and using an EM approach for abundance estimation improves RNA-seq alignment, gene expression and allele specific expression estimates.

A Comprehensive Resequence-Analysis of 250kb Region of 8q24.21 in Men of African Ancestry. *C.C. Chung[1,3], A.W. Hsing[2], E. Yeboah[4], R. Biritwum[5], Y. Tettey[6], A. Adjei[6], M.B. Cook[1], A. De Marzo[7], G. Netto[7], J.F. Boland[1,3], M. Yeager[1,3], S.J. Chanock[1,3].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, MD; 2) Infections and Immunoepidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, MD; 3) Cancer Genomics Research Laboratory, Division of Cancer Epidemiology and Genetics, Advanced Technology Program, SAIC-Frederick Inc., NCI-Frederick, MD; 4) Department of Urology, University of Ghana, Ghana; 5) Department of Epidemiology, University of Ghana, Ghana; 6) Departmnet of Pathology, University of Ghana, Ghana; 7) Department of Pathology, Johns Hopkins University, Baltimore, MD.

Genome-wide association studies (GWAS) have identified that a ~1M region centromeric to the *MYC* oncogene on chromosome 8q24.21 harbors at least 5 independent loci associated with prostate cancer risk as well as additional loci associated with cancers of the breast, colon, bladder, and chronic lymphocytic leukemia (CLL). Because GWAS identify genetic markers that may be indirectly associated with disease, fine-mapping based on sequence analysis in distinct populations provides important insights into the differences in patterns of linkage disequilibrium (LD) and is critical in defining the optimal variants to nominate for biological follow-up. In order to catalog the genetic variation in individuals of African ancestry, we resequenced a region (250kb; chr8:128,050,768-128,300,801, hg19) containing several prostate cancer susceptibility loci as well as a locus that is associated with CLL. Our sample set included a total of 125 samples, including 78 samples from a population-based study in Ghana and 47 samples of African-Americans from Johns Hopkins University. We have identified 1,838 SNPs of which 285 were novel. Using genotypes derived from sequencing, we refined the LD and recombination hotspots within the region and determined a set of tag SNPs to be used in individuals of African ancestry in future fine-mapping studies. Based on LD, we annotated putative risk loci and their surrogates using ENCODE data, which could be important in establishing priorities for future functional work designed to explain the biological basis of associations between SNPs and both prostate cancer and chronic lymphocytic leukemia.

1576T

Integrating multiple reference sequences, known variation and de novo assembly for personal genome inference. *A.T. Dilthey[1], Z. Iqbal[1], C. Cox[2], M.R. Nelson[3], G. McVean[1].* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Quantitative Sciences, GlaxoSmithKline, Stevenage, United Kingdom; 3) Quantitative Sciences, GlaxoSmithKline, Research Triangle Park, North Carolina, United States of America.

The genome of a species typically encompasses great diversity, reflecting the mutation processes and selective forces experienced within its evolutionary history. A single sample may be used as a canonical exemplar, leading to a reference genome as the basis for analysis. This is a good first approximation and is the basis of sequence assembly for most high throughput sequencing experiments. However, this approach typically fails in regions where the sample is highly diverged from the reference and does not take advantage of known variants. We have developed an approach that combines multiple reference sequences, previously known variations and de novo assembly for inferring genome sequence. The first step is to infer a diploid reference using a Hidden Markov Model on an ordered graph representing a multiple sequence alignment of known references. These may be entire genomes, long haplotypes, divergent exons or short variants and are augmented with sequence from the sample under study. A diploid genome corresponds to a paired path through the graph. The second step is to map reads to the pair of personal references and infer variants by standard approaches. By doing so, we improve sensitivity to novel variant detection, particularly in regions that diverge from the standard single reference. We demonstrate the value of the personal reference approach in the analysis of the human Major Histocompatibility Complex , particularly in its ability to characterise structural variation and regions of extreme polymorphism frequently found in this region.

1577F

Genotyping of Exotic Structural Variants Using BWA and Pindel in Whole Genome and Exome Sequence Data. *D.S. Hanna[1], J.D. Smith[1], D.A. Nickerson[1], J.M. Swanson[2], E.M. Faust[3].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Child Development Center, University of California, Irvine, CA; 3) Department of Environmental & Occupational Health Sciences, University of Washington, Seattle, WA.

Insertions, deletions and other structural variants, such as inversions and segmental duplications, leave specific signature patterns within the sequence alignments that usually go undetected, or are often genotyped incorrectly as clumps of single nucleotide variants. However, these signatures are often discernible and unique, and can, therefore, be detected using sophisticated algorithms. These variants are not well assessed because of the difficulty in their detection, and have already been shown to be associated with disease and contribute to unique phenotypes. Using a combination of the latest BWA-MEM aligner, GATK recalibration tools and Pindel, we show improvements in the identification of novel variants in the population by pinpointing the exact breakpoints of structural variants, and thus finding the length of the variation. The genotype of each sample can then be ascertained by examining the sequence allele balance at the breakpoints. Using a population consisting of 50 trios of mixed ethnicities obtained for the National Children's Study,, we have identified and traced exotic variation in the families and, when possible, we validated our results with genotyping arrays. By robustly identifying these variants, we were able to increase our power to discover putatively causal variation in family-based studies and to identify new associations in population studies. An added benefit is to gain insight into how to increase true positives while decreasing false negatives, and how variables such as sequence quality, allelic depth and sequence read length affect these metrics.

1578W

HIGH-COVERAGE WHOLE GENOME SEQUENCING OF THIRTY BRAZILIAN ADMIXED INDIVIDUALS. *M. Machado[1], R. Moreira[1], E. Tarazona-Santos[1], A.C. Pereira[5], M.L. Barreto[4], B.L. Horta[3], M.F. Lima-Costa[2], A. Horimoto[5], N. Esteban[5], F. Kehdy[1], M. Rodrigues[1], W.C.S. Magalhaes[1], Brazilian Epigen Consortium.* 1) Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Centro de Pesquisas René Rachou, Fundação Oswaldo Cruz, Belo Horizonte, Minas Gerais, Brazil; 3) Universidade Federal de Pelotas, Brasil; 4) Instituto de Saúde Coletiva, Federal University of Bahia, Brazil; 5) Laboratory of Genetics and Molecular Cardiology, Heart Institute, Medical School of University of São Paulo.

The Brazilian Epigen Initiative is a genetic epidemiology project which main aims are to infer population structure and genomic ancestrality of the three largest Brazilian cohorts as well as investigate the genome-wide association among a set of different clinical outcomes. In order to reach these objectives, the project focused on three different approaches: Genotyping of 4.3 M SNPs (HumanOmni5) for 270 samples; Genotyping of 2.3 M SNPs (HumanOmni2.5) for 6496 samples and Whole genome sequencing for 30 Brazilian admixed samples (Pelotas from Southern Brazil (n=10), Bambuí from the South East (n = 10) and Salvador from North East (n = 10)), which were obtained by paired-end reads strategy using Illumina technology. Sequencing whole genomes across multiple samples in a population provides an unprecedent opportunity for comprehensively characterize polymorphic variants in a population. Even though the 1KGP has offered brief insights into the importance of population-level sequencing, the low coverage of the pilot project has impaired the ability to confidently detect rare and low frequency variants. Studying private variants, in particular in admixed populations, are necessary in order to catalogue the human genome diversity, especially those responsible to complex diseases. Here we report preliminary results regarding the sequencing section of the project: Data quality: on average, each genome was sequenced 42 X (mean coverage), which 128 GB (on average) of bases successfully passed filter and aligned to the reference genome (NCBI37); 82% of bases that showed quality (QScore) >= 30 and 96% of Non-N reference bases with a coverage >= 10X; Polymorphisms: we identified 15033927 SNPs, out of which 13333782 have been previously reported by dbSNP (build 137) and 1700145 have not; Summary of identified SNPs annotated using ANNOVAR: UTR3(10625), ncRNA_exonic (3759), intergenic (924842), splicing (60), ncRNA_intronic (51526), ncRNA_UTR3 (216), upstream (11897), upstream;downstream (426), ncRNA_splicing (17), exonic (7467), ncRNA_UTR5 (79), UTR5 (3668) ,downstream (9379), intronic (543793)and UTR5;UTR3 (5). The high-coverage strategy of the EPIGEN-Brazil initiative complements the information that is being obtained from the 1KGP, increasing the number of sequenced individuals with African and Native American ancestry.

1579T

Multi-platform and cross-methodological reproducibility of transcriptome profiling by RNA-seq in the ABRF Next-Generation Sequencing Study (ABRF-NGS). *C.E. Mason[1,2], S. Li[1,2], S.W. Tighe[3], C.M. Nicolet[4], D. Grove[5], S. Levy[6], W. Farmerie[7], A. Viale[8], C. Wright[9], P.A. Schweitzer[10], Y. Gao[11], D. Kim[11], J. Boland[12], B. Hicks[12], R. Kim[13], S. Next-generation sequencing (NGS) technology applications such as RNA-sequencing (RNA-seq) have dramatically expanded the potential for novel genomics discoveries, but the proliferation of platforms and protocols has created a need for reference data sets to help gauge their performance. Here we describe the ABRF-NGS Study on RNA-seq, which leverages replicate experiments across multiple sites using two reference RNA standards tested with four protocols (polyA selected, ribo-depleted, size selected, and degraded RNA), and examined across five NGS platforms (Illumina HiSeq 2000/2500, Life Technologies PGM/Proton, Roche 454 GS FLX+, and PacBio). These results show high intra-platform consistency ($R2 > 0.9$), high inter-platform concordance ($R2 > 0.8$), and a large set of novel splice junctions observed across all platforms. Also, we observe that ribosomal RNA depletion can both salvage degraded RNA samples and also be readily compared to polyA-enriched fractions. These data provide a broad foundation for standardization, evaluation and improvement of RNA-seq methods.

1580F

Identifying Genomic Copy Number Alteration and Loss of Heterozygosity in Next-Generation Sequence Data. *S. Rozen[1], J.R. McPherson[1], Y. Wu[1,2], P. Tan[1,3,4].* 1) Duke-NUS Graduate Med Sch, Singapore, Singapore; 2) Singapore-MIT Alliance in Research and Technology; 3) National Cancer Centre, Singapore; 4) Genome Institute of Singapore.

Losses and duplications of large genomic regions resulting in copy number alterations or loss of heterozygosity (LOH) are common drivers of cancer development. Until recently, these aberrations have been characterized primarily by means of SNP and copy-number oligonucleotide arrays. However, next-generation sequencing has become a dominant approach for detecting mutations in cancer genomes, and the read data generated in these studies can also be used for characterizing genomic aberrations in cancers. We developed an analytical approach and software that considers read depth and read counts for each allele to identify genomic regions with copy number alteration or LOH. The approach, 'RDAAC' (Read Depth and Allele Counts) requires aligned sequencing reads from matched malignant and non-malignant DNA. RDAAC simultaneously estimates the proportion of non-tumor genomes in the sample and the number of copies of each SNP allele in the tumor sample. We assessed RDAAC's performance in two ways. First, we compared its results to results from analyzing SNP arrays. Second, we assessed its performance on simulated data, for which true copy number alterations, regions of LOH, and admixture of non-malignant DNA were known. RDAAC functioned well on whole-exome sequencing data even in the presence of generalized polyploidy and >50% admixture of DNA from non-malignant cells. We developed an R package that implements (1) RDAAC on top of SAMTtools(Li, et al. 2009) and ASCAT (which was designed for microarray data, Van Loo et al., 2010) and (2) the simulator for synthetic data.

1581W

Reducing platform bias in next-generation sequencing. *L. Saag[1,2], U. Gerst Talas[1], M. Mitt[1], R. Villems[1,2], M. Metspalu[2].* 1) University of Tartu, Tartu, Estonia; 2) Estonian Biocentre, Tartu, Estonia.

Next-generation sequencing platforms enable re-sequencing of the human genome at high speed and relatively low cost. At the same time, there are discrepancies in base calls from different sources - the platform bias. The relatively low concordance between the results from different sequencing platforms has been reported (Lam et al. Nature Biotechnology 30, 78-82; Ratan et al. PLOS One 8: e55089). This can be a serious problem when data from various sources need to be pooled, especially, for example, in cases where different populations (or cases and controls) are sequenced with different technologies. We compared the concordance of the base calls of four human genomes, produced on the widely utilized Illumina and Complete Genomics (CG) platforms, sequenced at average coverage of 26x and 40x, and processed with BWA plus GATK and CG proprietary pipeline, respectively. The effect of various filters on the platform bias was evaluated. As expected, the bias was much larger concerning indels (at least 20% of the variants after initial QC) than compared to single nucleotide polymorphism (SNP) calls, however, significant discrepancy was detected also for the latter (at least 5% of the variants after initial QC). It is known that the next-generation sequencing errors are mostly due to mismapping of the sequence reads. Recently Lee and Schatz (Bioinformatics 28, 2097-2105) and Derrien and others (PLOS One 7: e30377) proposed tools that can help to avoid such errors by identifying and excluding regions of the genome with low mappability. We built on similar in-house efforts. Applying the resulting poor-mapping windows together with adjusted quality and coverage filters, we were able to minimize the platform bias significantly. We work towards further reducing the discordance including evaluating the effect of other sequence read mappers (Bowtie2, GATK2, etc).

1582T

Customized and Personalized Next Generation Genomics. *A.N. Singh.* Computer Science, Virginia Tech, Blacksburg, VA.

Structural variations, SVs, with size 1 base-pair to several 1000s of base-pairs with their precise breakpoints and single-nucleotide polymorphisms, SNPs, were determined for members of a family of four. It is also discovered that the mitochondrial DNA is less prone to SVs re-arrangements than SNPs and can have paternal leakage of inheritance which proposes better standards for determining ancestry and divergence between races and species. Sex determination of an individual is found to be strongly confirmed by means of calls of nucleotide bases of SVs to the Y chromosome. SVs would serve as fingerprint of an individual contributing to his traits and drug responses. These in silico techniques for analysis would become such a widespread application that a total transformation of the bio and medical industry would go through.

Identifying Mendelian Disease Genes; an Analysis Tool of PhenoDB.
N. Sobreira[1], F. Schiettecatte[2], D. Valle[1], A. Hamosh[1]. 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) FS Consulting, Salem, MA.

WES has been the main method used to search for Mendelian disease genes in the last 3 years. But identifying the pathogenic mutation among thousands to millions of genomic variants is a challenge, and variant prioritization strategies are required. The choice of these strategies depends on the availability of well-phenotyped patients and family members, the mode of inheritance, the severity of the disease and its population frequency. Here we describe the PhenoDB analysis tool developed to rapidly identify a list of candidate variants by applying various strategies for disease variant prioritization. PhenoDB is a Web-based portal for managing and analyzing phenotypic/clinical information and WES/WGS data. The VCF and ANNOVAR files, genotyping array data, QC report, and final results file are available in the Analysis module, in which the user can choose the family members to include, the inheritance mode, what kind of variants to filter on (missense, nonsense, splicing, 3'UTR, 5'UTR, synonymous), optionally exclude variants found in the dbSNP 126, 129 and/or 131, the MAF value for exclusion of variants in the 1000 genome and EVS databases, and exclusion of chrX variants. The analysis runs in less than 1 minute and generates a list of candidate genes plus a log of the prioritization strategy. We also add information from external databases such as OMIM, MGI, GeneCards, etc. Multiple analyses with different prioritization strategies can be saved. Any saved ANNOVAR file or analysis result can be filtered using the 57 genes listed in the ACMG incidental findings list or compared against the genes in an OMIM phenotypic series. The user can also compare analysis results across families for overlapping mutated genes and cohorts (with or without locus heterogeneity) can be analyzed. A Sandbox is provided where ANNOVAR files from families not in PhenoDB can be uploaded and analyzed. Genes and variants can be searched across families in the analysis results. The phenoDB analysis tool has been proved to be easy, fast and efficient. In the Baylor-Hopkins Center for Mendelian Genomics we have now analyzed 83 families using this tool. We have identified the causative gene in 14 families and suggested candidate genes that are being further investigated in 39 other families. PhenoDB including the analysis tool is freely available through the Johns Hopkins McKusick-Nathans Institute of Genetic Medicine (http://phenodb.net).

The European Genome-phenome Archive (EGA).
V. Kumanduri, A. Datta, J. Almeida-King, L. Clarke, I. Lappalainen, P. Flicek, J. Paschall. EMBL-EBI, EMBL-EBI European Bioinformatics Institute, Hinxton, United Kingdom.

The European Genome-phenome Archive (EGA) V. Kumanduri, A. Datta, J. Almeida-King, L. Clarke, I. Lappalainen, P. Flicek and J. Paschall EMBL-EBI Wellcome Trust, Cambridge, United Kingdom The European Genome-phenome Archive (EGA) provides a permanent archive for genetic and phenotypic data and a secure means to share subject level data. EGA contains data collected from individuals for the purpose of medical or genetic research and whose consent agreements require security and request management. Data access decisions are not made by the EGA but by a submitter defined Data Access Committee (DAC). Once DAC authorization to the data has been granted, the EGA provides secure tools for downloading and decrypting the authorized files and general support for questions related to the data content. The EGA is available at http://www.ebi.ac.uk/ega/. Data from more than 350 studies, comprising 500 datasets and 200,000 individuals have been submitted to the EGA and is made available to authorized researchers. These studies include data from array-based genotyping experiments as well as raw DNA sequence data from re-sequencing or transcriptomics projects. While continuing to perform the main function of archiving datasets exactly as submitted, EGA is now developing an option for submitters to choose value-added processing steps. Specifically, we aim to apply a defined analysis pipeline to provide standardized variant call sets that can aid in comparisons of methods and in the combining of data from multiple sources. In order to achieve this, the EGA is building a data analysis workflow that allows us to align reads against a reference, provide high quality variant calling and distribute phased genotype information for the analysed samples. For those submitters who request this standardized processing, these features will be run in addition to archiving of the primary data files and analysis products. Anyone interested in further information about the EGA in general should contact ega-helpdesk@ebi.ac.uk.

1585T

THE MEDICAL EXOME PROJECT: From concept to implementation.
A. Santani[1], S. Gowrishankar[3], C. da Silva[2], D. Mandelkar[1], A. Sasson[1], M. Sarmady[1], R. Shakhbatyan[3], S. Tinker[2], D. Church[5], B. Funke[3,4], M. Hegde[2]. 1) Department of Pathology and Laboratory Medicine, Childrens Hospital of Philadelphia, Philadelphia, PA; 2) Emory Genetics Laboratory, Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 3) Laboratory for Molecular Medicine, Cambridge, MA; 4) Department of Pathology, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 5) National Center for Biotechnology Information, NLM, NIH, Bethesda, MA.

Next Generation Sequencing (NGS) is being rapidly adopted by clinical laboratories and has allowed development of disease targeted gene panels and more recently exome and genome sequencing. One drawback of gene panels is their suboptimal clinical sensitivity, which is often only marginally increased by adding novel genes, leaving the need for additional testing if no mutation is identified. In contrast, exome and genome sequencing (ES/GS) interrogates all genes, but is flawed by incomplete coverage and interrogates a significant number of genes with no clinical relevance. THE MEDICAL EXOME project was launched to bridge the gap between gene panels and ES/GS by curating the genes of clinical relevance and improving the technical performance of exome capture assays by enhancing their coverage. Candidate medically relevant genes were drawn from three primary sources: HGMD, OMIM (morbid map) and ClinVar. Additional genes were chosen from Cosmic, Jackson lab's MGI database, Gene Tests, Orphanet and locus specific databases (LOVDs). This draft medical exome was further enhanced by adding disease risk loci (NHGRI GWAS catalog) and pharmacogenetic targets (PharmGKB). A pilot curation project removed genes that had no evidence for a role in disease by developing a scoring grid from 0 (no evidence) to 3 (definitely associated with disease). In addition, exons with conserved paralogous sequences were excluded to avoid technical and analytical challenges. Over 5,000 genes were extracted from the above databases, 877 of which were removed due to lack of evidence for a role in disease. A pilot analysis of an enhanced version of the Agilent V5 exome indicated optimal coverage (all bases >20x) for ~2/3 of the exons, insufficient coverage (<40% of bases >20x) for ~10% and various gradations of completeness for the remaining ~20%. Alternate approaches are being employed to enhance the coverage of suboptimal genes. We will present the development of a curated gene list using an evidence-based gene scoring approach and preliminary results of the enhanced medical exome. This list will be made available to the community through public resources such as the ICCG consortium and resources maintained at NCBI. The availability of a curated medical exome will improve sensitivity and specificity of NGS based exome and genome sequencing and will provide a stepping stone for standardizing interpretation of genetic test results by clinical testing laboratories.

1586F

Accurate identification of allele imbalances in samples with limited genotype information available. *M.L. Buchkovich[1], K.E. Eklund[1], Q. Duan[1], Y. Li[1,2,3], K.L. Mohlke[1], T.S. Furey[1,4].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 3) Department of Computer Science, University of North Carolina, Chapel Hill, NC; 4) Biology Department, University of North Carolina, Chapel Hill, NC.

Quantitative sequence data that detect epigenetic modifications, transcription factor binding and nucleosome depletion identify regions of transcriptional regulation. At heterozygous sites within regulatory regions, enrichment of sequence reads containing one allele, or allele imbalance, can indicate allelic differences in regulatory activity. Allele-aware aligners map sequences containing either allele with equal probability to a reference genome. We have shown previously that when sequencing-based genotypes are available, allele-aware aligners map sequences to heterozygous sites with increased accuracy compared to traditional aligners. We now have expanded our allele-aware alignment methods to identify allele imbalance in additional samples with more limited genotype information available. We aligned 20 bp DNase-seq sequences from GM12878, a human lymphoblastoid cell line, including complete (genomic sequencing-based), and limited (Human1M-Duo genotyping + imputation) genotype information. To increase alignment accuracy, we created custom reference genomes using the complete or limited genotype data by changing hg19 to match the allele present in GM12878 at ~1.2M-1.3M homozygous sites. We aligned sequences to these references using the allele-aware aligner GSNAP and heterozygous sites from each genotype set. Requiring at least two sequences containing each allele, we identified (binomial test, P<.001) 191 sites of allele imbalance when using complete genotype data and 70 sites when using limited genotype data. Identifying imbalances in GM12878 data using limited genotype information had a positive predictive value of 84% (62/70), a sensitivity of 32% (62/191), and a specificity of 99.99% (69,505/69,513). Only 3 of 129 imbalanced sites identified solely with complete genotypes were predicted by imputation to be heterozygous, suggesting that imputation missed the other variants. Testing for allele imbalance at additional heterozygous sites detected in the DNase-seq alignment could increase our ability to identify imbalances at the 126 missed sites and improve sensitivity. In conclusion, this approach accurately identifies sites of allele imbalance without using complete, sequence-based genotype information. The ability to identify these imbalances in a broader range of datasets from multiple tissues will be particularly useful in understanding how variants with allelic differences in gene transcription regulation influence complex traits and diseases.

1587W

Scalable variant identification and imputation across large multigenerational pedigrees from high-throughput sequencing data by joint Bayesian variant calling. *F.M. De La Vega[1], S. Malakshah[1], R. Littin[2], L. Trigg[2], A. Jackson[2], D. Ware[2], J.G. Cleary[2].* 1) Real Time Genomics, Inc., San Bruno, CA, USA; 2) Real Time Genomics, Ltd., Hamilton, New Zealand.

Whole-genome sequencing (WGS) is being applied in research and clinical studies to identify variants for rare diseases and complex traits. Often these studies sequence related individuals to varying sequencing depths across a pedigree. However, variant calling methods for high-throughput sequencing (HTS) ignore such relationships or are not scalable to multigenerational pedigrees. We present a Bayesian framework that jointly calls variants across a pedigree implicitly leveraging shared haplotypes. When calling variants at a given position for a nuclear family, we look-up the alignment data of all family members simultaneously, scoring genotypes across pedigree members with priors based on Mendel's laws of variant segregation, and handling sex chromosomes as special cases. As validation, we analyzed data from a 17 individual, 3-generation CEPH pedigree sequenced to 40X average depth. We focus our analysis on NA12878, a female in the second generation and for which extensive orthogonal validation data is available from the 1000 Genomes Project and other efforts. Compared to singleton calling, our family caller produced more high quality variants and eliminated spurious calls as judged by standard quality metrics such as Ti/Tv, Het/Hom ratios, and dbSNP/OMNI array data concordance. Through the analysis of the segregation of variants to the 11 offspring of the third generation called independently, we estimate less than 1%, 2.5% and 2.75% of false positive calls for SNV, indels, and MNPs, respectively. Family designs should allow identifying de novo mutations, which are of great interest in neurodevelopmental and other disorders. By allowing a small prior for de novo mutations and scoring specifically for this type of mutations, we observed 100% and 96% sensitivity in identifying previously validated germline and somatic de novo mutations in NA12878, respectively, concurrent with a 10X reduction in Mendelian errors. Simple Mendelian scoring would scale exponentially across multi-generational pedigrees. Instead, we implemented a method for acyclic prior propagation beyond nuclear families, approximating the full pedigree Bayesian solution in linear time. Our results show that our joint pedigree calling method outperforms singleton and population variant calling in pedigrees, allows for the identification of de novo mutations with greater specificity, and is scalable to large genomics and human disease studies.

1588T

Advantages of Single-Molecule, Solid-State Nanodetectors for Genome Mapping. *B. Galvin, B. Bready, D. Dederich, A. Forget, J. Frietas, H. Geiser, P. Goldstein, D. Goryunov, H. Heaton, D. Hevroni, M. Jouzi, M. Kaiser, H. Lee, T. Leffert, D. Lloyd, S. Marappan, E. Olejnik, J. Oliver, L. Seward, A. Snider, J. Tang, J. Thompson, M. Zhang.* Nabsys, Inc., Providence, RI.

Next-generation sequencing systems have revolutionized the use of sequencing for answering many biological questions. However, the limited read lengths and requirement for DNA amplification in order to detect signals cause the data quality and completeness to suffer significantly. Complete de novo sequencing of even relatively short prokaryotic genomes is not possible with current NGS systems which must be supplemented with other data or reference genomes to even make an attempt at producing a finished genome. Optical mapping technologies have arisen to fill the long-range information gap but methods introduced thus far have limited resolution and low throughput relative to what is needed for routine mapping of human genomes. In contrast, solid-state, silicon-based nanodetectors have been developed that use electronic measurement to distinguish DNA features and thus are not limited to the resolution limits imposed by the wavelength of light. This, coupled with the high throughput that can be attained using detectors that translocate DNA at greater than 1 million base pairs per second, provide a path to routinely generating de novo assembled maps of human and similar size genomes. The ability to generate high resolution maps for single DNAs 10s to 100s of kilobases long will be shown. Performance characteristics of our detectors demonstrating high signal-to-noise characteristics, sub-diffraction limit resolution, and massive throughput will be discussed.

Validation of the second and the third generation sequencers by *de Novo* assembling using AT rich, repetitive, homopolymeric Human BAC DNA. *T. Hirano[1,2], Y. Terabayashi[3], K. Teruya[3], M. Teruya[4], M. Shimoji[3], H. Tamotsu[3], A. Arasaki[3], K. Nakano[3], A. Shiroma[3], K. Satou[3], Y. Yamaoka[5,6], A. Sekine[7].* 1) Fellow, Okinawa Science and Technoogy Promotion Center, Okinawa, Japan; 2) Founder, Okinawa Institute of Advanced Sciences, Okinawa, Japan; 3) Research and Development Division, Okinawa Institute of Advanced Sciences, Okinawa, Japan; 4) Okinawa Industrial Technology Center, Okinawa, Japan; 5) Division of International Health, Oita University, Oita, Japan; 6) Department of Medicine, Baylor College of Medicine, Houston, TX; 7) EBM Research Center, Kyoto University, Kyoto, Japan.

The sequencing technology is indispensable for any field of genomic analysis. Human Genome Project was drastically accelerated by sequencing and assembling technology. These technologies have been continuously advancing with the appearance of the second and the third generation sequencers. With increase of the number and the kinds of sequencers, the standardization of genome sequencing is coming to be important. The reference materials, reference data, and reference methods for the assessment of performance of genome sequencing are developed in the "Genome in a bottle Consortium" organized by NIST. Culture cells were often used as the Standard Reference Material in typical experiments. But in genome sequencing, the stability of DNA is the most required characteristics. Genomic mutations are often produced during its cultivation. In this study, the second and the third generation sequencers were validated using Human BAC clone of RP-11 library which is used in Human Genome Project and mapped on CYP gene coding locus. By using BAC clone, the performance of each sequencer was properly accessed without effects of ploidy. The selected clone involves AT rich, repetitive, and homopolymeric locus. The clone was sequenced by Capillary, 454, Illumina, Ion Torrent, and PacBio. The read coverage bias, and raw read accuracy, including specific errors on homopolymeric locus were evaluated by using the result of mapping analysis on RefSeq. The sequence produced by each sequencer was de Novo assembled using Arachne, Newbler, Velvet, Mira, and HGAp, respectively. The unique contig which covers whole length without gap was constructed by using only the sequence of PacBioRS, because of long reads and equal coverage. The established method of de Novo assembling was applied for other clones or stomach cancer causing microbial, Helicobacter pylori. Additionally, our recent result of de Novo assembling of using PacBioRS II which represents the enhancement of read length and the improvement of read quality will be shown.

Developing 400-base Sequencing for the Ion PGM® System. *A.I. Kraltcheva, D.J. Mazur, G. Luo, X. Peng, T.L. Lincecum, G. Lowman, M.A. Landes, B. Strohecker, K.N. Aguinaldo, T. Nikiforov, E. Tozer, J.J. Shirley, P. Vander Horn.* ION Torrent, LIFE Technologies, Carlsbad, CA.

The utility of long sequencing reads for enhanced genomic annotation and assembly has been a key differentiator for successful next generation sequencing applications. Through optimization of both the sequencing and amplification biochemistries, we have significantly improved Ion Torrent's semiconductor chip-based sequencing system. Along with improvements in engineering and software, these innovations result in robust high quality 400-base sequencing reads on the Ion Torrent PGM™ platform. Using this improved 400 bp biochemistry on a 318 chip, we have produced >3G aligned Q20 bases with even coverage on the *Escherichia coli* genome. Additionally, with optimized emPCR conditions we have rapidly improved coverage uniformity of the more challenging *Rhodobacter sphaeroides* genome from 88% to 95%. Compared to the previous PGM™ sequencing protocols, the Ion Torrent 400bp Template/Sequencing kits give nearly double the read length and throughput. Such improvements in the PGM® system enable a broader range of applications, such as enhanced de novo genome assemblies, Human Leukocyte Antigen (HLA) sequencing, bacterial identification, and meta-genomic analysis. *For Research Use Only. Not for use in diagnostic procedures.

GenomeBrowse: Visual analytics and false-positive discovery for DNA and RNA-seq NGS data. *G. Linse Peterson, G. Rudy, S. Gardner, M. Thiesen, A. Laughbaum.* Golden Helix, Bozeman, MT.

High-throughput sequencing (HTS) has recently provided price competitive alternatives to microarrays for both RNA expression profiling with the RNA-seq protocol and DNA genotyping with whole genome and whole exome sequencing. Although the bioinformatics tools have matured for secondary analysis of sequence data, including alignment, variant calling, and gene and transcript level quantification, the outputs of these tools often require inspecting the 'raw read alignments' for putative variants and genes with interesting expression profiles. Investigating these variants in their VCF format and the alignments in BAM format allows for detection of false-positives as well as aiding the interpretation process by providing a rich genomic context.

We introduce Golden Helix GenomeBrowse™, a free visualization tool for DNA and RNA sequence alignment and variant calls along with annotations tracks from a rich catalog of pre-curated public data. GenomeBrowse is built from the ground up with the guiding principles of (1) working seamlessly with cloud-hosted data as fluidly and quickly as local files, (2) being intuitive to use for non-bioinformaticians to utilize in their research, and (3) having a multi-threaded architecture to make big-data visualization and analysis accessible to anybody capable of navigating Google Earth. By including integration with a rich repository of public data, users have no barriers to the process of interpreting their sequencing results. In particular, we demonstrate the ability of GenomeBrowse to stream exome sequencing of a trio from the Amazon Cloud from whole genome views down to the gene level with annotation tracks ranging from 1000 Genomes, dbSNP, genes, and miRNAs. We show how GenomeBrowse can highlight false-positive Single Nucleotide Variants and small Insertion/Deletions, confirm the inheritance pattern of putative functional variants, and aid in the interpretation of a variant's impact.

1592F

Improving the robustness of personal genome variant discovery: the impact of technical replicates, sample source and analysis method. *D. Mittelman[1], A. Del Duca[2], R.M. Iwasiow[2], N. Leibovich[3], J. Wang[3], M. Tayeb[2].* 1) Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA; 2) DNA Genotek Inc. (A wholly owned subsidiary of OraSure Technologies Inc.), Ottawa, ON, Canada K2K 1L1; 3) Arpeggi, Inc., Austin, TX, USA 78749.

Background: Whole genome sequencing (WGS) promises to disrupt prognostic and diagnostic genetic testing in the clinic. Although the adoption of WGS is accelerating, the standards and acceptance criteria for clinical WGS are not fully defined. Variant calling robustness and reproducibility of WGS analysis was assessed across routinely used biological sample types, among technical replicates, and between sequencing library preparations. Consideration was also given to sample-to-result costs. **Methods:** Two multigenerational families comprising a total of 7 individuals were enrolled in the study based on low (<5%), medium (6-20%) and high (>21%) levels of non-human DNA content in their saliva as measured by qPCR. Matched sample pairs of blood (EDTA, Becton Dickinson, Inc.) and saliva (Oragene, DNA Genotek Inc.) were prepared from each participant and sequenced through the Illumina Genome Network (IGN), generating a total of 20 whole genome datasets. Multiple variant discovery pipelines, including CASAVA and GATK were used to interrogate reproducibility of biological and technical replicates and Mendelian consistency in parent-offspring trios. The computational burden (i.e. cost from DNA-to-result) between sample types was also compared. **Results:** A direct linear correlation (R^2= 0.88) between non-human DNA content in a saliva sample and the proportion of unmapped reads after read alignment was found, suggesting that reads derived from non-human DNA are often not mapped. The average difference in unmapped reads between paired blood and saliva samples from the same individual was 8.7%. On average, 4% of variant calls (SNPs and small indels) were discordant between technical replicates of blood samples. Likewise, discordant variant calls between saliva and blood averaged 4%. Finally, QC parameters, such as minimum read depth, are suggested, which help maximize variant calling consistency among technical replicates and across different sample types. **Conclusion:** Variant concordance between matched pairs of saliva and blood is equivalent to concordance between technical replicates of blood. This strongly suggests that saliva sampling is an effective alternative to blood for whole genome sequencing analysis.

Genome in a Bottle Consortium: Update on a Public-Private-Academic Consortium Developing a Standards Infrastructure for Human Genome Sequencing. *S.A. Munro, J. Zook, M. Salit, Genome in a Bottle Consortium.* National Institute of Standards and Technology, Gaithersburg, MD.

In 2012, NIST convened the Genome in a Bottle Consortium (www.genomeinabottle.org) to develop the reference materials, reference methods, and reference data needed to assess confidence in human whole genome variant calls. We will report on progress of the four consortium working groups. The Reference Material (RM) Selection and Design group has selected the first 4 genome families from the Personal Genome Project for whole genome RMs, a candidate cancer/normal cell line pair, and artificial structures for point mutations. The Measurements for Reference Material Characterization group has initiated experiments to characterize a pilot RM (NA12878) using multiple sequencing methods, other methods, and validation of selected variants using orthogonal technologies. The Bioinformatics, Data Integration, and Data Representation working group has developed data integration and analysis methods, data sharing protocols, and representation formats. The Performance Metrics and Figures of Merit group has initiated collation of proposed performance metrics and figures of merit from consortium members, leveraging existing resources. The products of these working groups will be a set of well-characterized whole genome and synthetic DNA RMs along with the methods (documentary standards) and reference data necessary for use of the RMs. These products will be designed to help enable translation of whole genome sequencing to clinical applications by providing widely accepted materials, methods, and data for performance assessment.

1594T

Change can be good: updating the human reference genome assembly. *V.A. Schneider[1], P. Flicek[2], T. Graves[3], T. Hubbard[4], D.M. Church[1] for the Genome Reference Consortium.* 1) NCBI/NIH, Bethesda, MD 28092; 2) EBI, Hinxton, Cambridge, CB10 1SD, U.K; 3) The Genome Institute at Washington University, St. Louis, MO 63108; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, CB10 1SA, U.K.

Since its publication in 2003, the human reference genome assembly has become an integral reagent in biological research. In today's era of next generation (NGS) and personal genome sequencing, it is the framework upon which individual genome analysis is based as well as a common coordinate system for genomic annotation. While the human reference retains its distinction as the highest quality mammalian genome, studies in the past decade have demonstrated that the linear chromosome model initially used for the assembly is insufficient in its ability to represent population variation. Within this model, the insertion of sequences from multiple haplotypes at complex variant locations led to non-existent allele combinations and artificial gaps. To provide a more accurate genome representation and better represent variation, the Genome Reference Consortium (GRC), the group responsible for the upkeep of the human reference assembly, developed a new assembly model. First implemented for GRCh37 (hg19), the new model retained the linear chromosomes but introduced alternate loci, scaffold sequences placed into chromosome context via alignment, as a mechanism for providing alternate sequence representation at complex or variant genomic regions. The new assembly model also introduced patches, operationally similar to the alternate loci, as a means for providing users access to assembly corrections and new variant sequence representations without coordinate-disrupting full assembly updates. Since the production of GRCh37, the GRC has released patches to 170 genomic regions, representing 3% of the chromosome sequence and adding more than 6 Mb of novel sequence and over 180 gene models not found on the chromosome assembly. This model necessitates an update to current analysis tools that cannot yet accommodate allelic duplication. We will present data demonstrating the added benefit of using the full assembly, including alternate loci and patches, with respect to gene annotation, NGS read alignment and variation analyses. Nonetheless, coordinate-changing major assembly releases remain vital as underlying mis-assemblies in the chromosome assembly can still confound analysis. The GRC is planning to release GRCh38 in the fall of 2013. We will present our progress on the new assembly and illustrate several of its features, including the large-scale correction of erroneous bases, addition of missing sequences and retiling of misassembled regions.

1595F

A Fast Solution to NGS Strand-specific RNA Library Prep. *C. Sumner, D. Munafo, P. Liu, L. Apone, B. Langhorst, E. Yigit, F. Stewart, E. Dimalanta, T. Davis, J. Bybee, L. Mazzola, D. Rodriguez, V. Panchapakesa.* New England Biolabs, Ipswich, MA.

RNA-Seq is a powerful technique that allows for sensitive digital quantification of transcript levels, and enables the detection of noncanonical transcription start sites as well as termination sites, alternative splice isoforms and transcript mutation and editing. Standard 'next-generation' RNA-sequencing approaches generally require double-stranded cDNA Synthesis, which erases RNA strand information. Strand information is important for correct annotation of novel genes, identification of antisense transcripts with potential regulatory roles, and for correct determination of gene expression levels in the presence of antisense transcripts. To obtain high quality stranded sequence information, RNA sequencing libraries must be highly-strand-specific and highly diverse. Ideally, they should be produced at high yield and by a fast protocol. To address these challenges, we have developed the NEBNext® Ultra Directional RNA Library Prep Kit for Illumina, which is based on labeling second strand cDNA with dUTP, allowing for subsequent excision to retain RNA strand information. This approach is incorporated into a streamlined workflow, enabling directional RNA library construction in ~5 hrs with minimal hands on time. Here, we provide an analysis of library quality (library complexity, continuity of gene coverage, strand specificity, and 3' and 5' bias), as well as demonstrate compatibility with NEBNext®96 barcode strategy and ribosomal RNA removal.

1596W

Targeted Sequencing for Preterm Birth Associated Genes. *A. Uzun[1,2], I. Kurihara[1], B. McGonnigal[1], J.F. Padbury[1,2].* 1) Pediatrics, Women and Infants Hospital, Providence, RI; 2) Pediatrics, Brown Medical School, Brown University, Providence, RI.

Despite significant advances in the care of pregnant women and low birth weight infants, preterm birth remains the leading cause of newborn morbidity and mortality as well as the main cause of hospitalization in the first year of life in the United States. We hypothesize that rare variants in the genes that contribute to the risk of PTB can be identified using new bioinformatics approaches coupled with high-throughput technologies applied to appropriate cohorts of patients. Understanding of the complex pattern of gene expressions, which enhance or attenuate the risk of Preterm Birth (PTB) will require new strategies. We have developed an alternative approach to identify a more manageable set of genes for preterm birth, which nonetheless incorporates some elements from the discovery in genome wide investigations. We analyzed genotype information from a large GWAS which included >660,000 SNPs from 1,000 mother and infant controls and 1,000 mother and infant preterm birth cases, We used gene set enrichment analysis (GSEA) to investigate the individual contribution(s) of biological pathways to the genetic architecture of preterm birth. We used both our curated genes and a genome-wide approach in the pathway analysis. We identified 329 genes nested within 69 pathways that are highly associated with preterm birth. For a proof of concept, we used long-range PCR to generate a DNA library from the top 11 genes from this gene set. We sequenced gDNA from 4 women with 3 generations of preterm birth and 8 term controls. High quality sequence data from well balanced pools was observed. There were an average of 22,000,000 reads from each patient, with an average of 99 perfect index reads and a Q30 of 91%. The mean Phred score for each patient was 36. A total of 2669 initial variants were reduced to 1015 following filtering for the quality indices described above. 760 were already identified in one of several database archives, including 1000 Genomes, the Exome Sequencing Project or dbSNP. 255 were unique of which 5 were exonic and 4 predicted to be deleterious in genomic regions encompassing PTGS2 (1 deleterious), AKT1 (2 deleterious), and TP53 (1 deleterious). There have been too few samples sequenced to date for valid statistical comparisons but these results nonetheless confirm the importance of not restricting the library construction to exonic sequences alone.

1597T

Well-characterized genomes for understanding genome sequencing performance: integrating datasets from multiple sequencing platforms to form highly confident snp and indel calls. *J.M. Zook[1], B. Chapman[2], O. Hofmann[2], W. Hide[2], D. Mittelman[3], J. Wang[4], M. Salit[1], Genome in a Bottle Consortium.* 1) Biosystems and Biomaterials Division, National Institute of Standards and Technology, Gaithersburg, MD; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) Virginia Bioinformatics Institute, Blacksburg, VA; 4) Arpeggi, Inc., Austin, TX.

Clinical translation of genome sequencing requires methods to understand accuracy of genotype calls at millions or billions of positions across a genome. Previous work showing high discordance between sequencing methods and algorithms has highlighted the need for a highly confident set of genotypes across a whole genome that could be used as 'truth' for understanding accuracy. Therefore, we have developed methods to make highly confident SNP, indel, and homozygous reference genotype calls for NA12878, the pilot genome for the Genome in a Bottle Consortium (www.genomeinabottle.org). To minimize bias towards any sequencing method, we integrate 9 whole genome and 3 exome datasets from 5 different sequencing platforms (Illumina, Complete Genomics, SOLiD, 454, and Ion Torrent). We also integrate variant calls from variant callers using only mapping, mapping with local de novo assembly, and global de novo assembly. The resulting genotype calls are more accurate than calls from any individual dataset, and allow performance assessment of more difficult variants than using microarrays. In addition, regions for which no confident genotype call could be made are identified, so that both false positive and false negative error rates can be assessed. We are integrating our highly confident variants into the GCAT website (www.bioplanet.com/gcat) so that anyone can interactively generate performance metrics for different combinations of sequencing datasets, mapping algorithms, and variant callers. In addition, as part of the Genome in a Bottle Consortium, we plan to continue to improve the characterization of the pilot genome and additional genomes, expanding the characterization to additional variant types and more difficult regions of the genome.

1598F

Exome Sequencing Facilitated by A Fast Library Preparation Method with Low Nanogram DNA Input. *P. Liu[1], C.L. Hendrickson[2], B. Boone[2], B. Langhorst[1], L. Apone[1], D. Munafo[1], Y. Yigit[1], C. Sumner[1], V. Panchapakesa[1], D. Rodriguez[1], F. Stewart[1], T. Evans Jr[1], N. Nichols[1], S. Levy[2], E. Dimalanta[1], T. Davis[1].* 1) New England Biolabs, Ipswich, MA; 2) HudsonAlpha Institute for Biotechnology, Huntsville, Alabama.

Even as the cost of next generation sequencing decreases, exome sequencing continues to have substantial value as an effective, lower-cost alternative to whole genome sequencing. Indeed, the use of exome sequencing in clinical diagnostic applications is rapidly increasing, and recent reports of the diagnostic use of exome sequencing have shown its ability in identifying disease-causing mutations for conditions such as congenital deafness and intellectual disabilities, which were formerly undiagnosable. The hope is that such sequencing will enable guidance of physicians on the proper course of treatment, determine personal response to a drug, assess risks for siblings, and possibly predict disease before it starts. A major challenge of exome sequencing-based clinical diagnosis is the limited quantities of sample DNA available. To address this limitation, we have developed a fast library preparation method using novel reagents and adaptors, including a DNA polymerase that has been optimized to minimize GC bias. This method enables exome sequencing of libraries constructed from low nanogram quantities of DNA amplified with limited PCR cycles, and can be used for both intact and fragmented DNA including FFPE and circulating plasma DNA. Moreover, the workflow is compatible with multiple NGS platforms.

1599W

Power and Limitations of RNA-Sequencing. *F. Staedtler, E.J. Oakeley.* Biomarker Development, Novartis Institutes for BioMedical Research (NIBR), Basel, Switzerland.

On behalf of the Sequencing Quality Control Consortium (SEQC). In the FDA-led SEQC (i.e., MAQC-III) project, different RNA-Seq platforms were tested across more than ten sites using well-established reference RNA samples with built-in truths in order to assess the discovery and expression-profiling performance of platforms and analysis pipelines. The results demonstrate that novel exon-exon junctions can still be discovered beyond existing comprehensive annotations and sequencing depth. With various investigations encompassing diverse performance metrics (accuracy, precision, reproducibility, mutual information, titration consistency, and mixing ratio recovery) and comparisons to qPCR and microarray platforms, we found high levels of inter-site and cross-platform concordance for differentially expressed genes. However, performance is clearly platform and pipeline dependent, and transcript-level profiling shows larger variation. The SEQC data sets with over 100 billion reads (10 TB) represent the deepest characterization of the transcriptome for any samples and thus provide a unique resource for testing future developments of RNA-Seq in clinical and regulatory settings.

1600T

Evaluation of Ion Torrent-based rapid deep sequencing for mutation discovery and prevalence screening in rare human myeloproliferative neoplasms and brain tumors. *L. Wang[1], S. Yamaguchi[2], L. Lewis[1], M. Holder[1], K. Chang[1], K. Walker[1], H. Dinh[1], H. Doddapaneni[1], D. Muzny[1], R. Gibbs[1], C. Lau[2], D. Wheeler[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Texas Children's Cancer and Hematology Centers, Baylor College of Medicine, Houston, TX.

Tumors usually consist of a mixture of normal and tumor cells and most tumors, if not all, are heterogeneous, containing more than one clonal types. Sensitive and accurate detection of somatic mutations in low-purity and heterogeneous tumors is a challenging problem. Deep sequencing is needed to identify mutations with low allele fraction and to present each clonal type properly. For some rare tumors such as myeloid disease and brain tumors, which only a small amount of DNA can be collected, most sequencing technologies are not applicable. Ion AmpliSeq technology, based on ultra-high-multiplex PCR, requires as little as 10 ng of input DNA to target sets of interesting genes, delivers fast library construction and deep coverage on targeted regions, making it ideal for mutation discovery and prevalence screening in these rare, heterogeneous and polyclonal tumors. Here, we selected 40 and 23 interesting genes, respectively, from the discovery studies of myeloid disease and brain tumors, and designed two Ion AmpliSeq arrays targeting the complete coding sequences of interesting genes. A total of 148 samples were sequenced (16 reaction pools/run) on the PGM sequencer and 30 of them were also sequenced on the Proton Sequencers On average, 98.7 percent of complete coding sequences of targeted genes were successfully covered and a 891x coverage was achieved by PGM run. The Proton run produced about 3 times higher coverage than that of PGM. The variant allelic fraction of mutations identified went down to 0.01. We identified JAK2-V617F mutations in tumors that had a negative result for whole exome sequencing method. Interestingly, we identified novel recurrent somatic mutations in rare brain tumors including CBL, encoding the ubiquitin E3 ligase that function as a negative regulator of receptor protein tyrosine kinases including KIT, and BCORL1, a transcriptional corepressor and tumor suppressor. We have systematically compared the performance of AmpliSeq PGM and Proton Sequencers including the throughput, on-target coverage, sensitivity and accuracy for substitutions and indels detection and will present here.

1601F

De novo assembly mapping with single-molecule detection using electronic solid-state detectors. *W.H. Heaton, B. Bready, B. Galvin, P. Goldstein, A. Snider, J. Thompson, J. Oliver.* Nabsys, Providence, RI.

Genome wide physical maps are ideally suited to a variety of applications including scaffolding sequence contigs, genome finishing, structural variant analysis, and haplotype phasing. To date, genomic physical mapping has relied on optical technologies which suffer from cost, speed, and resolution limitations. Even so, the benefit of long range genomic information has been demonstrated by these technologies. To circumvent these limitations, we map DNA by attaching probes to target motifs and localize the positions of these probes using solid-state nanodetectors. DNA passing through the detector causes a drop in the current. Attached probes cause a further transient drop in current denoting their relative locations. We report the first de novo assembly of single-molecule electronic DNA maps. This represents the first scalable technology for physical mapping applications.

1602W

Comparative analysis of six splice-aware alignment and two differential expression assessment tools for RNA-seq data. *J.H. Kim[1], O. Evgrafov[1,2], J. Knowles[1,2], K. Wang[1,2,3].* 1) Zilkha Neurogenetic Institute, University of Southern California, CA; 2) Psychiatry & the Behavioral Sciences, University of Southern California, CA; 3) Preventive Medicine, University of Southern California, CA.

Many bioinformatics software tools have been developed to perform splice-aware alignments, quantitate gene expression levels, or test for differential expression for RNA-Seq data. Despite the wide application of RNA-Seq technologies, it is not well established what are the relative advantages and disadvantages between different analytical approaches. To address this issue, we compared five commonly used alignment tools including Tophat, RNA-STAR, MapSplice, RUM, GSNAP and PerM, and compared two commonly used tools including DESeq and Cufflinks for detecting differential expression levels. The first data set include ~81 million 100bp paired-end reads from a tumor sample. Although four of the tools align more than 97% of reads, TopHat shows a map ratio of only 74%. Speed-wise, RNA-STAR outperformed others with 12 minutes of runtime, while other tools require at least 4 hours in a machine with 12 Intel Xeon 2.66GHz cores. However, RNA-STAR requires more than 20Gb of memory, whereas other tools can run with less than 8Gb memory. We quantitated the gene expression level from each method, compared them to each other and to Illumina HumanHT-12 microarray expression data. Expression data from all tools show more than 0.94 of Spearman's rank correlation between each other, and all have lower correlation with the microarray data (~0.74). The second data set include ~70 million 91-bp pair-end reads on neural stem cells with and without NRXN1 knockdown. We applied DESeq and Cufflinks to evaluate the ability of 6 aligners to identify differentially expressed genes. Both methods showed that all 6 aligners identified knockdown of NRXN1 (P=5.0E-05~1.5E-03 and 3.5E-04~6.9E-04, respectively), and demonstrated that GAPDH has no change in gene expression (P=0.4~0.6 and 0.5~0.6, respectively). However, DESeq identified 54 differentially expressed genes from alignments generated by GSNAP, and 78~120 genes from alignments generated by other 5 aligners, yet Cuffdiff identified 28~47 genes from alignments generated by all aligners, under the same FDR<5% and |log2(Fold change)|>1 thresholds. In summary, all six aligners produce similar alignments and similar correlation to microarray data, but RNA-STAR has a clear speed advantage. Our results may provide a practical guide to readers for selecting aligners, quantifying expression levels and discovering novel splice forms from RNA-Seq data sets.

1603T

Next Generation Sequencing PCR Primer Design Tool for Sanger Sequencing Confirmation. *S. Berosik, M. Wenz, A. Karger, P. Brzoska, F. Hu, X. You, W. Liao.* Life Technologies, South San Francisco, CA.

High quality and high accuracy are characteristic of Sanger re-sequencing projects and are primary reasons that next generation sequencing projects compliment their results by capillary electrophoresis data validation. We have developed an on-line tool called Primer Designer™ to streamline the NGS-to-Sanger sequencing workflow by taking the laborious task of PCR primer design out of the hands of the researcher by providing pre-designed assays for the human exome. The primer design tool has been created to enable scientists using next generation sequencing to quickly confirm variants discovered in their work by providing the means to quickly search, order and receive suitable pre-designed PCR primers for Sanger sequencing. Using the Primer Designer™ tool to design M13-tailed and non-tailed PCR primers for Sanger sequencing we will demonstrate validation of 28-variants across 24-amplicons and 19-genes using the BDD, BDTv1.1 and BDTv3.1 sequencing chemistries on the 3500xl Genetic Analyzer capillary electrophoresis platform.

1604F

Mobile element scanning (ME-Scan) for Alu insertions in families and populations. *D.J. Witherspoon[1], W.S. Watkins[1], M.A. Batzer[2], L.B. Jorde[1].* 1) Dept of Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept of Biological Sciences, Louisiana State University, Baton Rouge, LA.

The human genome carries more than one million copies of the Alu retrotransposon family, the remains of more than 50 million years of activity in our ancestors. Alu retrotransposition and ectopic recombination between Alu copies still generate novel mutations and cause genetic diseases today. A clear understanding of their genomic impact and evolution requires detailed yet comprehensive data on their activity. This is challenging due to the large background of nearly identical sequences in the genome and the modest rate at which new insertions appear in the germline (estimated at 1 per 20 births.) We have developed a targeted high-throughput sequencing technique to efficiently identify novel Alu insertions (Mobile Element Scanning, ME-Scan; Witherspoon et. al BMC Genomics 2010, Witherspoon et al. Genome Res 2013). We have redesigned it to exploit the longer reads and higher capacity of the Illumina HiSeq 2500 platform using standard sequencing parameters. Up to 53 samples can be pooled in a single sequencing library using pairs of custom six-bp indexes. We have applied this design to 290 individuals from diverse populations (HapMap YRI, JPT, TSI, CHB and CEU; Indian Madiga, Mala, Relli and Brahmin; African Alur, Hema, Nande, Luhya and Pygmy) and 85 individuals from 10 parent-offspring pedigrees. The rate of Mendelian inheritance errors (insertions observed in offspring but absent in parents) is <0.5%; no high-confidence de novo Alu insertions have been detected yet. ME-Scan assays of an additional 300 offspring and their parents are underway. Deeper multiplexing and higher sequencing throughput has decreased cost while increasing the coverage (at least 1 million usable mapped reads per individual at cost of ~$55 for reagents and sequencing). In combination with redesigned computational methods, the longer reads and higher coverage increase sensitivity for heterozygous singleton insertions in non-repetitive regions beyond our previously-reported 91%. They also enable reliable identification of novel insertions inside of existing repeated elements. Alu insertion points can be resolved to the exact nucleotide in more than 99% of cases. Strong evidence supporting 5,250 novel Alu insertions was generated. Among the novel singleton insertions, we find 5 embedded in protein-coding exons of METTL20, TUB, TTN, PEG3, and TSC2 (each supported by 200-2400 read pairs.) Twenty additional novel rare insertions are found in noncoding exons.

1605W

Integrative analysis of metabolomics and transcriptomics data: A unified model framework to identify underlying system pathways. *C. Ekstrom[1], K. Brink-Jensen[2].* 1) Biostatistics, University of Copenhagen, Copenhagen, Denmark; 2) Mathematical Sciences, University of Copenhagen, Copenhagen, Denmark.

The abundance of high-dimensional measurements in the form of gene expression and mass spectroscopy calls for models to elucidate the underlying biological system. We propose a statistical method that is applicable to dataset consisting of Liquid Chromatography-Mass Spectroscopy (LC-MS) and gene expression (DNA microarray) measurements from the same samples, to identify genes controlling the production of metabolites. Due to the high dimensionality of both LC-MS and DNA microarray data, dimension reduction and variable selection are key elements of the analysis. Our proposed approach starts by identifying the basis functions ("building blocks") that constitute the output from a mass spectrometry experiment. Subsequently, the weights of these basis functions are related to the observations from the corresponding gene expression data in order to identify which genes are associated with specific patterns seen in the metabolite data. The modeling framework is extremely flexible as well as computationally fast and can accommodate treatment effects and other variables related to the experimental design. We demonstrate that within the proposed framework, genes regulating the production of specific metabolites can be identified correctly unless the variation in the noise is more than twice that of the signal.

1606T

Tissue-specific functional relationship networks effectively predict replicated GWAS discoveries. *C.S. Greene[1], A.K. Wong[2], A. Krishnan[3], D.S. Himmelstein[3,4], O.G. Troyanskaya[2,3].* 1) Department of Genetics, The Geisel School of Medicine at Dartmouth, Hanover, NH; 2) Department of Computer Science, Princeton University, Princeton NJ; 3) The Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton NJ; 4) Biology & Medical Informatics, University of California San Francisco, San Francisco CA.

Modern large-scale human genetics experimental designs take advantage of new technologies that allow for inexpensive high-throughput genotyping to measure genetic variations in hundreds of thousands of individuals. These strategies aim to identify variants in genes associated with important phenotypes. Such unbiased experimental strategies have both benefits, e.g. the opportunity for discovery, but also drawbacks associated with multiple testing considerations. To address these limitations, we developed a method to integrate thousands of publicly available datasets, including gene-expression, protein-protein interaction, and transcription factor binding experiments into networks of tissue-specific functional relationships. We have generated a globally integrated network, as well as networks specific to functional relationships in individual tissues and cell lineages. Such tissue-specific networks encode pathway and functional information in the context of a single tissue or cell lineage. We evaluate the ability of these networks to predict genes associated with disease by using known disease genes from OMIM as seed genes for a state of the art machine learning algorithm. We assess this strategy's ability to predict the replicating discoveries from 198 genome-wide association studies corresponding to 23 diseases. Our evaluation compares the ability to identify genes containing replicated variants over a set of genes matched by chromosomal region. The state of the art learning algorithm is able to effectively use functional relationship networks to prioritize such genes. Furthermore, we observe that tissue-specific networks are better able to identify replicated discoveries than a global network of functional relationships. Such networks also provide the opportunity to prioritize candidates for epistasis analysis by large-scale molecular experiments. We anticipate that this approach will have broad applications for analysis of both main and epistatic effects, including candidate selection for replication and interpretation of overall findings in a molecular context.

A Semantic Computing Platform to Enable Translational and Clinical Omics. *J. Hirsch, J. Carroll, T. Loeser.* Syapse, Palo Alto, Ca.

To bring omics data from benchtop to point of care, labs and clinics must be able to handle three types of data with very different properties and requirements. The first, biomedical knowledge, is highly complex, continually evolving and comprises millions of concepts and relationships. The second, medical data including clinical health and outcomes records, is temporal, unstructured, and hard to access. The third, omics data such as whole-genome sequence, is structured but voluminous. Attempts to bridge the three have had limited success. No single data architecture allows efficient querying of these types of data. The lack of scalable infrastructure that can integrate complex biomedical knowledge, temporal medical data, and omics data is a barrier to widespread use of omics data in clinical decisionmaking. Syapse has built a data platform that enables capture, modeling, and query of all three data types, along with applications and programming interfaces for seamless integration with lab and clinical workflows. Using a proprietary, semantic layer based on Resource Description Framework (RDF) and related standards, the Syapse platform enables assembly of a dynamic knowledgebase from biomedical ontologies such as SNOMED CT and OMIM as well as customers' internally curated knowledge. Similarly, HL7-formatted medical data can be imported and represented as RDF objects. Lastly, Syapse enables federated queries that associate RDF-represented knowledge with omics data while retaining the benefits of scalable storage and indexing techniques. Biologists and clinicians can access the platform through a rich web application layer that enables role-specific customization at any point in the clinical omics workflow. We will describe how biologists and clinicians use Syapse as the infrastructure of an omics learning healthcare system. Clinical R&D performs data mining queries, e.g. selecting patients who share disease and treatment characteristics to identify associations between omics profiles and clinical outcomes. Organizations update clinical evidence such as variant interpretation or pharmacogenetic associations in a knowledgebase that triggers alerts in affected patient records. At point of care, clinical decision support interfaces present internal or external treatment guidelines based on patients' omics profiles. The Syapse platform is a cloud-based solution that allows labs and clinics to deliver translational and clinical omics with minimal IT resources.

Establishing a clinical next-generation sequencing information infrastructure. *A. Hoover, M. Kubal.* GenoLogics Life Science Software, Seattle, WA.

In a relatively short period of time next-generation sequencing has established itself as a clinically informative means to pinpoint otherwise difficult to diagnose disease. While the price of sequencing itself has plummeted and many of the challenges surrounding data analysis and storage volumes are actively being managed and/or solved, the issues associated with integrating and interpreting upfront patient medical data, patient sample processing and analysis information, and downstream diagnostics result delivery are still widely unsolved. In this presentation we discuss the issues of data and patient privacy, multisystem integration touch points, data integration and exchange standards, and provide examples of solutions from a variety of laboratories that may be useful to organizations looking to implement a NGS data ecosystem to support diagnostic NGS.

1609T

From big data to smart data: an open-source solution for genome-scale variant data warehousing and discovery. *M.J. Italia[1], B. Ruth[1], M. Sarmady[1], JC. Perin[1], D. Naegely[1], A. Santani[2], M. Dulik[2], NB. Spinner[2,3], ID. Krantz[4], JW. Pennington[1], PS. White[1,4].* 1) Center for Biomedical Informatics, The Children's Hospital Of Philadelphia, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 4) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA.

NGS-enabled genome-scale diagnostics and research are generating millions of genomic variants on a routine basis. The growth of this data provides the opportunity to derive information content such as local population allele frequencies and variant differentials between samples, patients, and cohorts. However, NGS technologies also present data management and use challenges that overwhelm traditional data and laboratory workflows. We sought to mitigate these challenges and to advance opportunities by developing Varify, a freely-available, open-source integrated variant data warehouse, knowledge base, and analysis suite. We constructed Varify in collaboration with the NHGRI Clinical Sequencing Exploratory Research program and our clinical laboratories. The Varify application was built using Harvest (harvest.research.chop.edu), an open-source, web-based biomedical application development framework. The data warehouse was deployed on the open source PostgreSQL relational database. Unique variants are combined from all patients into one table. This reduces storage requirements while securely linking variants to patients and patient cohorts. Annotation data include RefSeq transcripts, SIFT, PolyPhen, HGVS nomenclature, HGMD, Alamut, and population frequencies from 1000 genomes & EVS. A variant loading pipeline reads .vcf files annotated by snpEff and links variants to annotations based on genomic coordinates and genotypes. We have scaled Varify to store and deliver interactive real-time filtering on over 100 million unique variants across several thousand patients from exome and whole genome sequencing. Initial capabilities enabled by Varify include patient-specific query and filtration of variants using complex annotation criteria; calculation of allele frequency for custom cohorts; capture of analyst decisions and evidence on pathogenicity; and ad-hoc query of variants across patients based on gene, phenotype, and clinical characteristics. Varify is currently deployed in a CAP-compliant clinical diagnostic environment, an enterprise research instance, and as a consortium resource for NICHD's Newborn Screening Translational Research Network. Varify has added value in both the clinical diagnostic and research setting by transitioning from stand-alone, partially annotated variant files into an integrated resource that adds significant new value to diagnostic and discovery projects.

1610F

Integration of ENCODE datasets to epigenomics analysis using colored De Bruijn graphs. *C. Joly Beauparlant, J. Corbeil, A. Droit.* CHU de Québec, Université Laval, Quebec City, Quebec, Canada.

Recently, the ENCODE consortium produced a wealth of genomic data in order to start cataloging functional elements in the human genome. The challenge is now to integrate this information in our day-to-day analysis of smaller scale experiments to better understand the biological data. This is not a trivial task considering the difficulty to handle all this information and the sheer size of the datasets produced. We propose to use colored De Bruijn graphs as a mean to quickly identify genomic regions from epigenomics experiments that overlap regions previously described by the ENCODE project. This data structure that has successfully been implemented in multiple de novo assemblers can be easily adapted to work with genomic regions instead of raw sequencing data. The elements in the graph can then be colored using external datasets, like those produced by ENCODE. The contigs can then be sorted based on their colors to quickly spot specific combination of genomic elements that overlap. A prototype for this algorithm has been developed in Python to demonstrate the feasibility of the project. Even using an interpreted programming language, multiples samples can be compared in a relatively short amount of time (in a few hours). The algorithm is general enough to be able to use any list of sequences for the coloring of the graph. The next development step is to implement the algorithm as a plugin of the Ray software, a massively distributed genome assembler. The distributed nature of the project will give the scientific community a tool to manage and integrate the flow of data provided by the ENCODE project and other next-generation datasets.

The Japanese Reference Genome in Human Variation Database. *A. Koike[1], M. Kawashima[2], Y. Suzuki[3], H. Sawai[2], M. Yoshida[1], N. Nishida[2], I. Inoue[4], S. Tsuji[5], K. Tokunaga[2].* 1) Hitachi, Ltd. Cent. Res. Lab., Japan; 2) Dept. Human Genetics, Univ. Tokyo; 3) Dept. Med. Gen. Sci. Univ. Tokyo; 4) Dept. Mol. Life Sci. and Mol. Med., Nat. Inst. Genet; 5) Dept Neurology, Univ. Tokyo.

The HapMap Project and 1000 genome project have revealed genetic differences among populations. Building a reference genome in each population is a crucial step for exploitation of disease-related variations. We have estimated a Japanese reference genome using whole genome sequencing data of five healthy Japanese samples and Japanese samples of 1000 genome PJ, and Affymetrix 6.0, AXIOM, and Omni-2.5 data of more than 400 healthy Japanese samples. The SNPs and small deletions/insertions, and CNVs are calculated after mapping all reads on the hg19 reference genome. The unmapped reads and clipped reads are assembled and insertion positions are identified using clipped reads whose partial sequences are mapped on the hg19 genome and rest parts of sequences are mapped on the assembled sequences. The variation concordances between different platforms are higher than 99.9%. The built reference genome is provided as one of reference genomes of Human Variation Database in Japanese database project.

The Human Variation Database (http://gwas.biosciencedbc.jp/cgi-bin/hvdb/hv_top.cgi) is a repository database to achieve continuous and intensive management of GWAS/NGS data and data-sharing among researchers. This database also accumulates variations extracted from scientific literatures by manual curation to systematize the disease-related variations and improve our understanding of disease mechanisms. Disease-related 20,000 variation entries are currently registered in the genome level. Furthermore, protein-interaction networks with variations can be drawn by a graphic viewer to facilitate understanding of synergetic effects between multiple variations in the same disease and relationships between similar diseases. In this presentation, we overview the influence of calculation method on the Japanese reference genome and population differences of disease-related variations and phenotype-unrelated variations. Acknowledgement: This work was supported by the contract research fund "Database Integration Program" from the Japan Science and Technology Agency.

***IS_{core}* and *ALT_{rate}*: Inferring human diversity using genome-wide gene-based patterns of nucleotide substitution, insertion and deletion.** *K.Y. Lo[1], Y.R. Lo[2], F.C. Hsiao[2], W.J. Lin[2], Y.D. Chiu[2], C.K. Liu[2], A. Yao[2], C.J. Chen[1], C.Y. Shen[2], C.H. Chen[2].* 1) Genomic Research Center, Academia Sinica, 128 Academia Road, Section 2, Nankang, Taipei, Taiwan 115; 2) Institute of Biomedical Sciences, Academia Sinica, 128 Academia Road, Section 2, Nankang, Taipei, Taiwan 115.

As the technologies of the next-generation sequencing are being developed, large scale of genomic researches, such as the 1000 Genome Project, have carried out using either whole-genome and/or exome sequencing to detect genomic variation. The variants identified include single nucleotide polymorphisms (SNPs), insertions/deletions (indels), copy number variations (CNVs), repeat sequences, and rearrangements in the human genome. These variants may have well preserved genetic evidences of human diversity. Previous studies have demonstrated that the genome-wide patterns of SNPs can successfully infer human diversity at the population level and ancestry information at the individual level. However, such an application with the density of SNPs and the indels has still remained unclear. In this study, we propose two gene-based density ratios being able to result in genome-wide patterns for inferring population diversity and individual ancestry: IS_{core}, the ratio of the number of indels to the number of SNPs in each of the UTR and protein coding regions across the human genome, and ALT_{rate}, an alternative measure of the variant density, the total number of the indels and SNPs in each region. We have calculated IS_{core} and ALT_{rate} on the basis of the sequencing data of the1000 Genome Project. In order to efficiently perform computational analyzing and graphical visualization, we have innovated and extended the functionality of the existing public open resources: cluter and Treeview. Our results show that the distribution of IS_{core} varies among genes across the human genome, but with similar trend among the continental groups at most genes. In particular, some genes show relative higher IS_{core} in all ethnicity groups, which suggests that some segments of the human genome contain more indels than SNPs and some prefer SNPs over Indels. Further clustering analysis identifies genes with different distributions of IS_{core} among ethnicity groups and hence differentiates these ethnicity groups. Similar results were found using the alternative ALT_{rate} scores. We also found that the ratios might be biasedly over-estimated in some regions with much lower depth/coverage of sequencing and they should be corrected before analysis. In summary, these two gene-based density ratios, IS_{core} and ALT_{rate}, can be utilized for inferring human diversity and individual ancestry. The ratios may be useful to screen the polymorphism patterns in both patient populations and normal populations.

Using ontologies to enhance integration and analyses of ENCODE data. *V.S. Malladi[1], J.S. Strattan[1], D.T. Erickson[1], E.T. Chan[1], E.L. Hong[1], G. Barber[2], G. Binkley[1], J. Garcia[2], B.C Hitz[1], D. Karolchik[2], K. Learned[2], B. Lee[2], S. Miyasato[1], G. Moro[2], G.R. Roe[1], K. Rosenbloom[2], L.D. Rowe[1], N.R. Podduturi[1], M. Simison[1], C.A. Sloan[1], E. Weiler[2], W.J. Kent[2], J.M. Cherry[1].* 1) Stanford University, Department of Genetics, 300 Pasteur Dr., Stanford, CA, 94305; 2) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA, 95064.

The Encyclopedia of DNA Elements (ENCODE), Roadmap Epigenomics (REMC), and modENCODE projects, are large collaborative efforts that aim to provide public resources for the scientific community. The goal of ENCODE, now in its 8th year, is to create a comprehensive catalog of functional elements in the human and mouse genomes. The modENCODE project shares this goal but focuses its investigation on the model organisms C. elegans and D. melanogaster, creating a comparative resource to provide insight into human processes. REMC shares similar assays and tissues to ENCODE while investigating the human epigenome. Though each project has distinct scientific goals, these projects complement the data generated by the ENCODE project.

The ENCODE Data Coordination Center (DCC), which collects all data and metadata generated by the ENCODE project, is currently integrating metadata from modENCODE and REMC. To further enhance the analysis that can be performed within and across these three projects, the DCC has made use of ontologies to annotate these metadata. The DCC has used The Ontology for Biomedical Investigations (OBI;http://obi-ontology.org) to facilitate data identification from various assays sharing similar biological objectives to be searched (e.g. epigenetic modification), allowing an investigator to retrieve all data across the three projects matching various assays (e.g. RRBS, MRE-seq). Data identification across shared anatomy, morphology, and development are accomplished by using and developing cross-references between Cell Type Ontology (http://cellontology.org/) and UBERON (http://uberon.org/). Researchers querying for a biological system (e.g. digestive system) will retrieve data generated from tissues and cells that comprise that system (e.g. colon and epithelial cell of stomach). Here we present our implementation of ontologies to integrate these three projects and how it may be used to identify experiments that match the interests of a researcher. Data from the ENCODE project can be accessed via the ENCODE portal (http://www.encodeproject.org) and the UCSC Genome Browser (http://genome.ucsc.edu/cgi-bin/hgGateway).

A web-based framework for querying genomic relational databases using SQL. *S.F. Saccone, P.L. Jones.* Department of Psychiatry, Washington University, St Louis, MO.

Genomic databases are an important resource for the study of human genetics and genomic medicine. These databases are commonly accessed through a wealth of visual tools such as genome browsers and other graphical web-based query interfaces. Our BioQ web application (http://bioq.saclab.net) is an SQL-based query tool that provides a flexible framework for querying a given list of heterogeneous genomic features such as chromosomal segments, genes, transcripts, exons and variants across a number of common genomic databases such as the 1000 Genomes Project, dbSNP, Ensembl, VEGA and the European Nucleotide Archive. We introduce new tools in BioQ that allow users to build SQL queries while utilizing various relationships between genomic features such as genes within genomic regions, transcripts associated with genes, exons associated with transcripts and genetic variants within exons. These relationships and their order of execution can be configured by the user in the BioQ web interface in order to define powerful SQL queries across multiple heterogeneous genomic databases. BioQ provides extensive interactive documentation and visualization tools that help the user understand how schemas from different heterogeneous databases are mapped to one another in order to implement genomic feature interrelationships as well as detailed information on data provenance and experimental process flow for data from individual databases. We will demonstrate how this method can be applied to common data integration tasks such as the annotation of results from whole-genome genetic association studies.

1615T

A Systematic Approach to Large-Cohort Biomarker Discovery. *A. Solomon, S. Sanga, A. Vladimirova, T. Klingler.* Station X, 185 Berry Street, Suite 5503, San Francisco, CA 94107.

Nucleic acid sequencing is becoming ubiquitous, with approximately 2,500 high-throughput (Hi-Seq & Proton) instruments, and 3,800 mid-throughput (PGM and MiSeq) instruments placed in labs around the world. The bottleneck is no longer biochemical; we are now able to rapidly generate large amounts of sequence data that is high-quality and relatively low cost. The bottleneck is analysis. A well-powered study involves hundreds or thousands of individual samples, and requires a multi-dimensional analysis that incorporates transcript levels, mutations, structural changes, as well as clinical information such as time-to-event or magnitude of disease. Robust statistical methods are required that understand concepts such as gene regions, pathways, and functional classifications. Just as important is the ability to access and manage projects, and communicate results. Station X has developed a software environment called GenePool™ for the management, analysis and communication of genomic information for cohort-scale biomarker studies. GenePool has been architected to support thousands of whole genomes, exomes, and transcriptomes in either a cloud environment or stored locally. Best-practice statistical analyses methods are available in a context-specific drop-down menu. GenePool is designed to return results in seconds rather than minutes or hours, which enables users to iterate their analyses quickly. Data can be filtered based on statistical ranges, functional categories, and clinical meta-data. Station X has also developed dynamic visualizations that can communicate large data sets and their results in a single view. Collaboration is facilitated through shared permissions, rather than maintaining multiple copies of the same dataset. One of the most valuable public data resources is the Tumor Cancer Genome Atlas. However, it can be difficult to access and the clinical meta-data is difficult to incorporate. Station X has integrated and curated the entire TCGA dataset and has identified highly significant genomic biomarkers in breast and lung tumors that stratify patients based on disease outcome. Two examples will be shown. GenePool enables rapid genomic biomarker discovery through best-practice analyses accessed via an easy-to-use user interface, management of cohort-scale data sets, and communication of results through visualization and shared data. Highly significant biomarkers of patient outcome have been identified through analysis of the TCGA data.

1616F

Beyond the noise: A case study on optimizing computing performance in the cloud. *J. Yeager, G. Manglik.* CliQr Technologies, Sunnyvale, CA.

Life science researchers are continually using ways to leverage cloud computing, and applications now range from web-based apps to enterprise wide big data/compute. Optimal performance of diverse applications requires a broad set of cloud topologies and developers are often finding themselves locked into clouds that fail to meet their computing, network, or storage demands. Inter-cloud porting would seem the answer and vendors now provide cloud portability services, however most are not specialized to the needs of the life science research or require interim migration steps to run applications on each different cloud. Few provide the researcher with dashboards and a benchmarking system to monitor performance across clouds and researchers again end up in a sub-optimal performance environment. CliQr has developed a new method, which has now been applied to the scientific computing industry, which offers both straightforward app migration and cloud portability. Our system provides dynamic performance monitoring for the applications researchers use in the cloud and minimizes the development timeframe, with many standard components such as Python, R, and Perl already available and optimized. We will present the results of a real-world case study where one such life science company has benefitted from the CliQr deployment of their packages. The two packages in question serve similar components of the medical industry yet have significantly varying infrastructure demands. Both applications required stringent security (HIPAA Compliance) and the ability to deploy as Software as a Service (SaaS). The first package needed to be 24/7 accessible with a fast customer interface at a single institution, but had low bandwidth, storage and computation needs; while the second required scaling to huge storage, high bandwidth, global access and moderate computational needs. We will demonstrate how porting to the cloud using the CliQr platform required less effort than performing the implementation across multiple cloud providers, reducing development costs and time to deployment while ensuring maximum performance for each. Using the CliQr built-in analytics the apps were methodically tested for which cloud provided the best performance for each program within hours. We will summarize the general cases as seen by our customers and present guidelines for choosing the best nodes within a cloud, and the best cloud provider, for the most common types of applications.

1617W

Automatic analysis of personal genomes for clinical advisors. *G.E. Zinman, The Clinical Genomic Expert team.* Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA.

The next generation of medicine is envisioned to specifically tailor treatments for patients based on their unique genetic profile and lifestyle. With the rapidly decreasing cost of DNA sequencing and the large investments of medical institutes in digitizing medical records this vision is almost at reach. This new revolution requires the integration of multiple streams of data from different sources - whole patient genome, condition-specific genomic measurements, clinical data from the medical record, and other information including clinical and medical literature - to diagnose diseases, identify relevant treatment options, and monitor response to therapies. This wealth of information must make use of automated analysis to support physicians in making clinical decisions. In order to address these challenges, we recently launched the 'Clinical Genomic Expert' an initiative to build an open-source framework that will utilize machine learning algorithms that can incorporate genetic and clinical phenotypes to model the relationships between complex diseases and genome variation, identify a patient's susceptibility to disease, and predict which therapies might be most effective or cause the fewest side effects. The framework aims to provide an end-to-end solution for medical centers supporting the processing of variant calls as well as data from the Electronic Medical Records (EMR) or patient genomic data. The Clinical Genomic Expert implements several machine learning algorithms that can efficiently solve regression problems on network or tree structures between multiple phenotypestime as well as time series measurement of traits. These methods account for the inherent structured sparsity in all types of data. The framework also aims to provide a graphical user interface for physicians or clinical researchers to communicate the results of the analysis. Ultimately we hope that the initiative provides a platform for sharing disease models that will allow collaborative work between multiple medical centers without compromising private patient information. URL: http://www.genomicexpert.org/.

Mining human genetic variation with GEMINI - a novel integrative framework for explorative analysis. *U. Paila[1], B. Chapman[2], R. Kirchner[2], A. Quinlan[1].* 1) Department of Public Health Sciences and Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) School of Public Health, Harvard University, Boston, MA.

Advancements in DNA sequencing technologies have given investigators an unprecedented opportunity to rapidly sequence many genomes for studies of the genetic basis of human disease. High-throughput approaches for human genomes have been instrumental in the identification of new DNA variants linked to disease. However, considering the size and complexity of data generated by such studies, it is challenging to isolate relevant variants without integrating genomic 'knowledge' associated with them (e.g. genes, regulatory elements, protein domains, GERP, 1000 Genomes etc.).

Here we introduce GEMINI (GEnome MINIng), a flexible software tool that addresses these analytical challenges by providing a novel framework for exploratory analysis of human genetic variation in the context of crucial genome annotations (e.g., ENCODE, KEGG, OMIM, dbSNP, 1000 Genomes). GEMINI accommodates studies involving thousands of samples, enables the integration of custom annotations, and supports reproducibility by allowing researchers to 'version' their research. By augmenting many large and heterogeneous genome annotations (both coding & non-coding) into a unified database, it provides a powerful tool for data exploration that addresses the demands of large-scale disease research. It allows users to compose complex queries based on sample genotypes (e.g., 'return all loss of function variants that are homozygous for only sample A'), inheritance patterns, and both pre-installed and custom genome annotations to address their specific research needs.

The GEMINI framework facilitates discovery in a broad range of research including studies of the genetic basis of human diseases, personal genomes, unsolved Mendelian disorders, explorations of rare variants in large pedigrees, and genome-wide case-control studies. The portability and flexibility of the tool will allow other developers to leverage GEMINI to create new tools and develop novel approaches to prioritize genetic variation in diverse contexts. We foresee GEMINI as an outstanding future resource for medical and cancer genomics, given the depth and wealth of annotations it carries, as well as those that we expect to add through future development (e.g. novel methods for identifying significantly mutated genes, collapsing methods, network analysis). GEMINI is a self-contained, open source, evolving tool that will benefit the human genetics community.

1619F

A generalized scalable database model for storing and exploring genetic variations detected using sequencing data. *N. Chennagiri, B. Breton, M. Umbarger, P. Saunders, G. Porreca, C. Kennedy.* Good Start Genetics, Cambridge, MA.

With advances in high throughput sequencing, it is common for multiple sequencing centers to detect variants in the human genome and report them through Variant Call Format (VCF) files. There is a growing need for a unified database to store variant information in VCF files from different sources in a way that allows researchers to perform complex allele-, sample- and population-level queries across centers. We describe a data model that unifies the variant information in VCF file from different samples by storing every unique allele in one universal allele table and storing references to associated samples and sample-level meta data. This not only reduces data redundancy but also makes readily available important information like population level allele frequencies among ethnic groups. An added advantage is that annotation on the allele can be performed once and stored in the database and any sample that gets associated with the allele will have this annotation information already available. The metadata in the VCF files are stored as key-value pairs, enabling import of any VCF file with arbitrary tags without changing the underlying data model. We implemented this data model in an Oracle database and loaded VCF files for 15 genes from the Thousand Genomes Project for 607 samples. We also loaded VCF files from 8456 clinical samples for the same genes and performed allele frequency comparisons between the 1000 genome samples and clinical samples using standard SQL. Loading VCF files containing known disease causing variants to the same database enabled us to annotate the clinical samples with disease related information. Additionally, we added variants detected using Sanger sequencing for a set of 13 samples. This allowed us to perform validation of variants detected using other technologies with Sanger as benchmark. The database model and its Oracle implementation allowed us to perform analysis that is otherwise done by processing numerous VCF files using ad-hoc scripts.

1620W

The European Variation Archive (EVA) at the EBI. *I. Lappalainen, D. Spalding, S. Saha, L. Skipper, J. Ameida-King, V. Kumanduri, P. Flicek, J. Paschall.* EMBL-EBI Wellcome Trust, Cambridge, United Kingdom.

The European Bioinformatics Institute (EBI) has launched a new genetic variation service called the European Variation Archive (EVA). The EVA will consolidate, accession and provide new ways to access genetic variation data. This service has been designed to accommodate data flows based on high throughput sequencing technologies and encompasses variation data at all scales from both germline and somatic sources in all species. The EVA uses the same submission and archiving tools as the European Nucleotide Archive (ENA) and the controlled access provision of the European Genome-phenome Archive (EGA) for data requiring such access. For structural and copy number variants, EVA efforts include continued development of the existing Database of Genomic Variants archive (DGVa) with new tools to access genomic variation of all shapes and sizes. The deep integration between these three services will provide complete chain of provenance for variation data from reads, to alignments, and to variants calls. The EVA service accepts variant calls as indexed and compressed VCF files, a common file format exported by the current next generation variation discovery and genotyping pipelines. Archived VCF files will be made directly available through a defined accession based URL for remote access (such as VCFtools) and they can also be accessed as remote data sources by a variety of applications such as genome browsers. The EVA data warehouse layer is under development and based on the NoSQL document centered MongoDB database. This solution manages queries across submitted datasets as well as global data mining functions such as clustering of variants across studies and allele frequency calculation. The use of a document based NoSQL solution to the data warehouse layer benefits from speed of loading, flexible schema changes to keep up with evolving format standards and dramatically simplifies the data architecture as compared with a relational model. The EVA help-desk assists submitters or provides more information about the service at eva-helpdesk@ebi.ac.uk.

1621T

RD-Connect: an integrated platform connecting databases, registries, biobanks and clinical bioinformatics for rare disease research. *R. Thompson[1], I. Gut[2], K. Bushby[1], E. Heslop[1], L. Johnston[1], D. Taruscio[3], L. Monaco[4], C. Beroud[5], M. Hansson[6], H. Lochmüller[1] on behalf of RD-Connect.* 1) The MRC Centre for Neuromuscular Diseases at Newcastle, Institute of Genetic Medicine, International Centre for Life, Central Parkway, Newcastle upon Tyne NE1 3BZ, United Kingdom; 2) Centro Nacional de Análisis Genómico, Baldiri Reixac, Barcelona, Spain; 3) Istituto Superiore di Sanità, Viale Regina Elena, Roma, Italy; 4) Fondazione Telethon, Piazza Cavour 1, Milan, Italy; 5) Inserm U491 - Génétique Médicale et Développement, Faculté de Médecine de la Timone 13385 Marseille Cedex 05, France; 6) Centre for Research Ethics & Bioethics, Uppsala University, Box 564, SE-751 22 Uppsala, Sweeden.

Despite many examples of excellent practice, rare disease (RD) research is still frequently fragmented by data type and disease. Individual efforts often have little interoperability and almost no systematic connection of detailed clinical information with genetic information, biomaterial availability or research/trial datasets. Linking data at both an individual-patient and whole-cohort level enables researchers to gain a better overview of their disease of interest, while providing access to data from other research groups in a secure fashion allows researchers in multiple institutions to compare results and gain new insights. Funded by the EU Seventh Framework Programme under the International Rare Diseases Research Consortium (IRDiRC), RD-Connect is a global infrastructure project which links databases, registries, biobanks and clinical bioinformatics data used in RD research into a central research resource. RD-Connect's primary objectives are: / Harmonisation and development of common standards for RD patient registries by developing a common registry infrastructure and data elements / Harmonisation and development of common standards and catalogue for RD biobanks that collect and provide standardised, quality-controlled biomaterials for translational research / Development of clinical bioinformatics tools for analysis and integration of molecular and clinical data to discover new disease genes, pathways and therapeutic targets / Development of an integrated platform to host and analyse data from omics research projects / Development of mechanisms for incorporating patient interests and engaging with stakeholders / Development of best ethical practices and a proposal for a regulatory framework for linking medical and personal data related to RD RD-Connect will accept data generated by IRDiRC projects such as EURenOmics, which focuses on causes, diagnostics, biomarkers and disease models for rare kidney disorders, and Neuromics, which uses next generation whole exome sequencing to increase genetic knowledge of rare neurodegenerative and neuromuscular disorders. The 'siloed' nature of individual research efforts is a continued bottleneck for cutting-edge research towards diagnosis and therapy development in RD. RD-Connect aims to unite existing infrastructures and integrate the latest tools in order to create a comprehensive combined omics data, biobanking, data analysis and patient registry platform for RD used by researchers across the world.

A comparison of imputation quality: combining different GWAS platforms. *E.P.A van Iperen[1,2], G.K Hovingh[3], F.W Asselbergs[2,4], A.H Zwinderman[1].* 1) Department of Clinical Epidemiology, Biostatistics and Bio-informatics, Academic Medical Center, Amsterdam, The Netherlands; 2) Durrer Center for Cardiogenetic Research, Amsterdam, The Netherlands; 3) Department of Vascular Medicine, Academic Medical Centre, The Netherlands; 4) Division of Heart and Lungs, Department of Cardiology, University Medical Center Utrecht, Utrecht, The Netherlands.

Background: In the past decade many Genome-wide Association Studies (GWAS) were performed which have discovered many new associations between single-nucleotide polymorphisms (SNPS) and different phenotypes. Imputation methods are widely used in GWAS. They facilitate the association of ungenotyped variants with phenotypes. Imputation methods can also be used to combine and analyse data genotyped on different genotyping arrays. In this study we investigated if there is a difference in imputation quality between two different approaches of combining GWAS data from different genotyping platforms. We will investigate if combining data from different platforms before the actual imputation performs better than combining the data from different platforms after imputation.

Methods: Existing genotype data from the AMC-PAS cohort were used for this study. The samples were genotyped on three different platforms. A total of 706 individuals were genotyped on the MetaboChip (220K SNPs), a total of 757 individuals were genotyped on the 50K gene-centric Human CVD BeadChip (50K SNPs) and a total of 955 individuals was genotyped on the HumanExome chip (240K SNVs). After pre-imputation quality control (QC), Minimac in combination with MaCH was used for the imputation of all samples with the 1000genomes reference panel. All markers with an r2 value of <0.3 were excluded in our post-imputation QC.

Results: All three datasets were carefully matched on strand, SNP ID and genomic coordinates. This resulted in a dataset of 979 unique individuals and a total of unique 258925 markers. Our results suggest that the imputation of the different platforms independently performs slightly better than combining the different platforms before imputation. As an example: In the analysis were the three platforms were imputed separately we imputed successfully 55552 unique SNPs on chromosome 22. In the analysis where the 3 platforms were combined before imputation we successfully imputed 50500 SNPs. We observed similar findings for the other chromosomes.

Conclusions: Based on the preliminary results we concluded that combining the data from three different platforms together after imputation performs better than combining the data of the 3 platforms before imputation.

RNA-Seq optimization with eQTL gold standards. *S.E. Ellis[1], S. Gupta[1], F.N. Ashar[1], J.S. Bader[1], A.B. West[2], D.E. Arking[1].* 1) Johns Hopkins University School of Medicine, Baltimore, Maryland; 2) University of Alabama School of Medicine, Birmingham, Alabama.

Over the past decade, there has been intense interest in garnering a more complete understanding of genome-wide gene expression, with RNA-Sequencing (RNA-Seq) having emerged as the gold standard approach to studying the human transcriptome. Accordingly, RNA-Seq experiments have been optimized for library preparation, mapping, and gene expression estimation. These methods, however, have revealed weaknesses in the next stages of analysis of differential expression, with results sensitive to systematic sample stratification or, in more extreme cases, to outliers. To address these issues, we turn to expression quantitative trait loci (eQTLs), or biologically meaningful loci at which gene expression is modified by genotype, to optimize RNA-Seq data analysis. Here, we propose a method in which we utilize previously published eQTLs at the center of our data analysis framework in combination with DNA genotypes and RNA-Seq expression data to demonstrate our ability to assess not only the integrity of sequencing data but also the appropriateness of data handling procedures. Using postmortem brain samples from autism-affected cases and controls, we demonstrate that our method successfully identifies sample outliers and low levels of sample contamination that, if not otherwise identified, would interfere with accurate gene expression quantification. After outlier detection, we assess data normalization procedures, demonstrate the biologic validity of covariate inclusion in RNA-Seq analyses, support the inclusion of UTRs in gene annotation, and highlight the importance of removing outlier samples on a gene-by-gene basis. These steps allow for more accurate approximation of gene expression values that can be confidently used in downstream disease-based comparisons ultimately contributing to understanding of genetic variation, gene expression, and disease.

1624T

A graph-based integration with multi-omics data and genomic knowledge for cancer clinical outcome prediction. *D. Kim[1, 2], J. Joung[2,3], K. Sohn[2,4], H. Shin[5], M.D. Ritchie[1], J.H. Kim[2,6].* 1) Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA, USA; 2) Seoul National University Biomedical Informatics (SNUBI), Div. of Biomedical Informatics, Seoul National University College of Medicine, Seoul 110799, Korea; 3) Translational Bioinformatics Lab (TBL), Samsung Genome Institute (SGI), Samsung Medical Center, Seoul, Korea; 4) Department of Information and Computer Engineering, Ajou University, Suwon, Korea; 5) Department of Industrial & Information Systems Engineering, Ajou University, San 5, Wonchun-dong, Yeongtong-gu, 443-749, Suwon, Korea; 6) Systems Biomedical Informatics Research Center, Seoul National University, Seoul 110799, Korea.

Cancer is a complex disease, which can be dysregulated through multiple mechanisms. Therefore, no single level of genomic data fully elucidates tumor behavior since there are many genomic variations within or between levels in a biological system such as copy number variants, DNA methylation, alternative splicing, miRNA regulation, post translational modification, etc. Nowadays, a number of heterogeneous types of data have become more available from the Cancer Genome Atlas (TCGA), generating multiple molecular levels of omics dimensions from genome to phenome. Given multi-levels of genomic data, information from a one level to another may lead to some clues that help to uncover an unknown biological knowledge. Thus, integration of different levels of data can aid in extracting new knowledge by drawing an integrative conclusion from many pieces of information collected from diverse types of genomic data. Previously, we have proposed a graph-based framework that integrates with multi-layers of genomic data, copy number alteration, DNA methylation, gene expression, and miRNA expression, for the cancer clinical outcome prediction. Here, we propose a new graph-based framework for integrating different levels of genomic data and genomic knowledge in order to overcome variability of diagnostic or prognostic predictors and to increase their performances. As a pilot task, we used an ovarian cancer dataset from TCGA for the stage, grade, and survival outcomes. Integrating multi-omics data with genomic knowledge to construct pre-defined features results in higher performance in clinical outcome prediction and higher stability. For the grade outcome as an example, the model with gene expression data performed with an AUC of 0.7866. However, the models of the integration with pathway, Gene Ontology (GO), chromosomal gene-set, and motif gene-set consistently outperformed the model with genomic data only, attaining AUCs of 0.7873, 0.8433, 0.8254, and 0.8179 respectively. Furthermore, incorporation of genomic knowledge offers more interpretable results from the obtained signatures of pre-defined genomic knowledge and thus provides more insight into the complex molecular mechanisms in cancer. With integration of multi-omics data and genomic knowledge, understanding the molecular pathogenesis and underlying biology in cancer is expected to provide better guidance for improved prognostic indicators and effective therapies.

Phenotype to Genome: Quantitative Trait Loci (QTL) in the Mouse Genome Informatics (MGI) Database. *Y.S. Zhu, D.J. Reed, P. Hale, C.J. Bult, Mouse Genome Informatics database group.* Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME.

The laboratory mouse is an ideal experimental model organism for identifying the genetic basis of complex phenotypes and disease traits. QTL studies in the laboratory mouse have a high degree of concordance with mapped phenotype regions in the human genome but require far fewer resources and time than do mapping studies in human populations. The Mouse Genome Informatics database (MGI; http://www.informatics.jax.org) includes a compendium of over 4,700 published QTL mapping data for the mouse from the peer-reviewed published literature. The database includes descriptions of the QTL mapping experiments along with links to the published literature and, in some cases, links to the underlying genotype and phenotype data maintained by the QTL Archive project (http://www.qtlarchive.org/). The genome coordinates for the markers used to map QTL regions are used to show the genome context of QTLs using MGI's Mouse Genome Browser. The Genome Browser allows users to explore the all of the genome features annotated in the mapped regions. Newly implemented visualization tools at MGI for navigating regions of conserved synteny between mouse and human facilitate comparative genomics approaches to QTL mapping studies. MGI's integration of genome features with their biological attributes (phenotype, expression, function) facilitates the use of the database system to support in silico candidate gene analysis.

Comprehensive analyses of the functional roles of KAO-NASHI genes in the vertebrate organogenesis using medaka model. *Y. Tonoyama[1,3], A. Shimizu[2], N. Iwakura[3], Y. Shimizu[1], N. Shimizu[1,3].* 1) Advanced Research for Genome Super Power Center, Keio university; 2) Iwate Tohoku Medical Megabank Organization, Iwate Medical University; 3) Nagahama Institute for Bio-Science and Technology.

The human genome project has provided a computer-estimation on 23,000 protein-coding genes in the human genome. However, many of these protein-coding genes are not fully proven for their existence by experimental evidence. In general, proteins with known motifs are readily classified, but substantial numbers of protein have no obvious motifs in their deduced amino acid sequences. We previously designated these genes/proteins without obvious motifs as KAO-NASHI (Face-less) and initiated a project to unveil their face (kao) by employing comparative genomics and knockdown analysis. We extracted 1,000 KAO-NASHI genes from human genome sequence by step-wise filtration with InterPro motif analysis, BLAST homology search and PubMed document search. A small fish medaka (Oryzias latipes) was chosen as an experimental system to knockdown medaka orthologs of human KAO-NASHI genes with morpholino-antisense oligos (MO). As an initial study, we designed MOs to target translation initiation sites of 100 medaka KAO-NASHI genes. When these MOs were injected into fertilized medaka embryos, their morphogenesis at early developmental stages was disturbed and morphological changes were observed at significant rates. Here, we present the data on a few KAO-NASHI genes in which the MO injected-embryos exhibited significant defective organogenesis involved in brain formation and/or early embryonic vascular development, whereas almost all 5-base mismatch MO-injected embryos exhibited normal phenotype throughout developmental process. Immunoblot analyses using appropriate antibodies showed protein bands consistent with the estimated molecular weight. These results suggest that these KAO-NASHI genes definitely encode the functional proteins act in vertebrate organogenesis and they are not non-coding RNAs. Additionally, we performed differential expression analyses between Rx3 homeobox gene-depleted medaka embryos and control embryos using medaka DNA-microarray to seek for KAO-NASHI genes involved in the eye development. As a result, the expression of three KAO-NASHI genes was consistently affected after knockdown of Rx3, which generates Anophthalmia medaka (without eye), implicating that these genes play important roles during development of vertebrate eye. Thus, our approach using medaka model provides the functional information on the human KAO-NASHI genes/proteins during vertebrate organogenesis.

1627T

Rapid and Uniform Whole Exome Libraries from 50 ng of DNA. *M. Andersen[1], K. Rhodes[1], S. Roman[1], A. Broomer[1], C. Van Loy[1], D. Topacio[1], M. Allen[1], S. Rozenzhak[1], G. Liu[2].* 1) Life Technologies, Carlsbad, CA; 2) Life Technologies, Foster City, CA.

Exome sequencing is a powerful and cost-effective way to research variants linked to genetic disorders. Pairing simple fast exome selection and library generation with the Ion Proton™ sequencer allows two exome libraries to be prepared, sequenced, analyzed, and annotated in two days. This new method allows for the production of whole exome selection and libraries from as little as 50 ng of DNA in 6 hours with only 30 minutes hands-on time. Eight barcoded libraries can be prepared simultaneously on a single plate from 2.4 million uniformly amplified target regions. Genomic DNA of HapMap samples NA12878 (a female genome of European ancestry) and NA19240 (a female genome of Yoruba ancestry) that have been deeply sequenced by the 1000 Genomes Project were used to assess the performance of the Ion Proton™ System with the new exome selection and library method. Rapid read mapping, determination of exome coverage metrics, and variant calling were automatically performed using the Torrent Suite™ Software and Torrent Variant Caller. Variant annotations were completed with Ion Reporter™ software. Greater than 90% of 58 million bases in each exome were covered at 20X and >99% covered at 1X, with >98% concordance with known SNPs.

1628F

ZoomMiR, a computational method to predict and screen for variants that disrupt microRNA binding and activity. *A.N. Dubinsky[3,4], L.E. Edsall[2,5], A.R La Spada[1,3,4], T. Gaasterland[1,2], The NEIGHBOR Consortium.* 1) Institute for Genomic Medicine, University of California San Diego, La Jolla, CA; 2) Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA; 3) Department of Pediatrics, University of California San Diego, La Jolla, CA; 4) Sanford Consortium for Regenerative Medicine, La Jolla, CA; 5) Ludwig Institute for Cancer Research, University of California San Diego, La Jolla, CA.

Purpose: We developed a computer program and assay procedure to detect and validate genome variants that alter microRNA binding sites on spliced RNA transcripts through high-specificity computational and scalable functional assay screens. Background: Whole genome and exome sequencing identify many variants in untranslated regions (UTR) and introns near exons, i.e., on the order of 25,000 - 30,000 per exome. MicroRNAs bind RNA transcripts predominantly in the 3'UTR and, with some frequency, to coding sequences and 5'UTR. With the abundance of human exomes and complete genomes sequenced in recent years, tools and technologies with low false positive rates are needed for accurate, efficient, reliable screening of microRNA binding site disruption by genome variants. Methods and Results: Available algorithms and databases for computationally predicted microRNA binding sites have limitations that hinder their application to assess binding site differences due to genome variation. Existing binding site predictions require substantial computation and, in some methods, simulation of binding to generate predictive scores. For example, many databases that serve computed sites neglect the second arm of microRNA hairpins, which have been observed to be loaded preferentially into the microRNA RISC complex under tissue- or time-specific conditions. To address this shortcoming we developed a novel, efficient process called ZoomMiR which allows detection of microRNA::mRNA seed sites and ranks potential microRNAs for experimental screens. To validate the computational output of ZoomMiR, we developed a novel method to assay either normal or disrupted miRNA seed sites in a reporter gene system. This dual luciferase-based reporter system permits the quantitation of binding of, and hence regulation by, a computationally ranked miRNA. It is sensitive to the effect of the observed alleles and compares it with a completely disrupted seed site and with a perfect seed site. We applied this method to UTR variations found in 420 exomes from patients with primary open angle glaucoma. Importantly, we analyzed a 3'UTR glaucoma risk SNP in CDKN2B and demonstrated that it disrupted binding of a specific miRNA. Conclusion: ZoomMiR provides critical screening functionality to identify genome variants that disrupt microRNA binding sites and can reveal molecular mechanisms for at risk-SNPs found through GWAS.

Characterization of Human Betacoronavirus 2c EMC/2012 Linked to Acute Respiratory Distress Syndrome in Humans. *C. Olsen, K. Qaadri, P. Meintjes.* Biomatters, 185 Santa Clara St., Suite 101A, San Francisco, CA.

Human betacoronavirus 2c EMC/2012 was isolated from a subject with acute pneumonia in June 2012. This talk will focus on the characterization of the genome sequence, arrangement, and phylogenetic relation with known coronaviruses sampled from around the world including the Middle East respiratory symptom coronavirus (MERS-CoV). The genome contains 30,119 nucleotides and contains at least 10 predicted open reading frames, 9 of which are predicted to be expressed from a nested set of seven subgenomic mRNAs. Phylogenetic analysis of virulence factors of sequenced genomes indicated that HCoV-EMC/2012 is most closely related to species within the genus Betacoronavirus.

1630T

Comparative analysis of whole exome and whole genome DNA sequencing. *M.M. Parker[1], M.A. Taub[2], K.N. Hetrick[3], H. Ling[3], R.A. Mathias[4], J.B. Hetmanski[1], H. Albacha-Hejazi[5], A.F. Scott[6], I. Ruczinski[2], J.E. Bailey-Wilson[7], T.H. Beaty[1].* 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Biostatistics, Johns Hopkins University, Baltimore, MD; 3) Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD; 4) Allergy and Clinical Immunology, Department of Medicine, Johns Hopkins University, Baltimore, MD; 5) Ibn Al-Nafees Hospital, Damascus; 6) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 7) National Human Genome Research Institute (NHGRI), Baltimore MD 21224.

Background: Four subjects were sequenced with both whole exome (WES) and whole genome sequencing (WGS) as part of larger studies to identify causal variants for oral clefts. We assess the effect of exome capture technology on sequencing coverage and discovery of single nucleotide variants (SNV) using these data. Sequencing: WES was performed at the Center for Inherited Disease Research (Baltimore, MD) using Illumina's HiSeq 2000 sequencer, and exome capture was carried out using Agilent's Human All Exon V3 50Mb kit following manufacturer's guidelines. WGS was performed by Illumina (San Diego, CA) using their HiSeq 2000 sequencer. Sequence reads were aligned to the human reference genome hg19, and we performed local re-alignment around indels and base quality score recalibration using GATK (v.2.4). Variant calling was done using GATK's UnifiedGenotyper. Analyses presented here were restricted to regions on chromosome 20 targeted by Agilent's capture kit including 5,203 regions totaling 1,246,339 bases. Results: Mean target coverage of the 4 WES samples (93.2x) was higher than the mean coverage of the 4 WGS samples (40.6x), however the variance in coverage of WGS was over 3 times smaller than that of WES coverage (standard deviations: WES =90.8,WGS=27.2). With WES, 91.5% of targeted bases were covered at 10x, 78.5% at 30x and 65.5% at 50x. With WGS, 99.8% of targeted bases were covered at 10x, 86.8% at 30x, and 15.24 % at 50x. We assessed the effect of percent GC content in a targeted region on mean read depth. Higher GC content in a targeted region is correlated with lower read depth in both WGS and WES data, however the decline in read depth as a function of percent GC content is steeper in the WES data than in the WGS data. A total of 3,014 SNVs were detected in the targeted regions of chromosome 20. The concordance rate between SNV detection in WES and WGS was 76.6%. On average, concordant variant calls had higher genotype quality and higher sequencing depth than discordant variant calls (median depth: concordant: 41, discordant: 37; median quality: concordant: 99, discordant: 96.5). The majority (94.1%) of all discordant SNVs were called as variants in the WGS data, but not in the WES data. Variants detected only by WES or WGS had greater average depth and coverage in their respective detection platform. Overall, WES achieved higher mean coverage than WGS in our 4 samples, but WGS detected additional variants missed by WES.

1631F

A Practical Evaluation of Next Generation Sequencing & Molecular Cloning Software. *K. Qaadri, C. Olsen, P. Meintjes.* Biomatters, Inc, 185 Clara Street, Suite 101A San Francisco, CA 94107.

Biologists increasingly face the arduous process of assessing and implementing a combination of freeware, commercial software and web services for the management and analysis of high-throughput experiments. Laboratories can spend a remarkable amount of their research budgets on software, data analysis, and data management systems. The National Institutes of Health (NIH) and the National Science Foundation (NSF) have emphasized the need for contemporary software to be well-documented, interoperable, and extensible. Laboratories often invest significant resources for personnel to build bespoke bioinformatics tools or they purchase of commercial software. This can have a marked impact on productivity and ROI because software tools often do not perform the way needed or hidden costs arise unexpectedly because of inefficiencies in the software. Below is a framework that Biomatters developed as a practical evaluation process to assist core facility managers and principal investigators to determine the best tools for DNA/RNA/protein sequence analysis and molecular cloning. The evaluation performed on commercial software packages used six criteria: 1) user interface, 2) data management, 3) data analysis, 4) feature availability, 5) extensibility, and 6) support.

Detection of rare variants in degraded FFPE samples using HaloPlex PCR. *F. Roos, E. Åström, M. Danielsson, F. Karlsson, M. Isaksson, L. Forsmark, P. Eriksson, H. Johansson.* Agilent Technologies, Uppsala, Sweden.

Detection of rare DNA mutations from heterogeneous formalin-fixed paraffin embedded (FFPE) tissue samples involves several challenges. The sample amounts retrieved from biopsies are often scarce and the DNA is usually degraded and chemically modified as an effect of the formalin fixation. To maximize the chance of success when performing targeted sequencing studies on such samples, it is imperative to have a well-balanced experimental design as well as high efficiency throughout the enrichment and library preparation in order to ensure the mutations are both sampled and sequenced. The quality of the sample and the expected mutation frequency sets requirements on the minimum amount of input DNA that is needed to ensure that all mutations are sampled. Agilent's FFPE-Derived DNA Quality Assessment protocol is based on a simple multiplex PCR of different amplicon lengths that provide a fast and reliable estimation of the sample quality. Based on the outcome of this assay, measures can be taken to optimize the experimental design to ensure maximum probability of finding all variants. These measures include determining the minimum input DNA amount and required sequencing depth. Increased enrichment and library preparation efficiency will further help minimizing the required DNA input amount while maximizing the number of DNA molecules available for sequencing thus increasing the limit of detection for rare variants. HaloPlex PCR can be used to enrich for customized target regions and to prepare libraries for sequencing on Illumina or Ion Torrent in less than 8 hours with target regions ranging from a single gene up to the complete exome. A standard HaloPlex assay captures and PCR amplifies thousands of amplicons of sizes between 100 and 400 bp. For some degraded DNA samples, the availability of the longer fragments will be significantly lower compared to the shorter fragments leading to non-uniform sequencing depths over the targeted regions. We demonstrate that by focusing on targeting shorter amplicons by design as well as targeting both polarities of the genomic DNA molecules, the efficiency of capture is significantly increased leading to higher and more consistent sequencing coverage between samples of different quality. We demonstrate that improved experimental design combined with an increased capture efficiency enable lower DNA input amounts while keeping a high sensitivity for alleles down to 1% in frequency.

Globus Genomics: Enabling high-throughput analysis and management of NGS data for neurodevelopmental disorders. *D. Sulakhe[1], A. Paciorkowski[3], G. Mirzaa[2], R. Madduri[1], Q. Zhang[2], K. Aldinger[2], J. Bennett[2], L. Lacinski[1], P. Dave[1], W. Dobyns[2].* 1) Computation Institute, University of Chicago, Chicago, IL; 2) Center for Integrative Brain Research, Seattle Children's Research Institute, University of Washington, Seattle, WA; 3) Center for Neural Development and Disease, University of Rochester Medical Center, Rochester, NY.

The availability of low-cost high-throughput sequencing methods in the form of next-generation sequencing is revolutionizing translational research. However, handling such large volumes of sequencing datasets and their analyses introduce great challenges including secure and reliable data transfers, availability of scalable computational resources for analysis, and defining reproducible and reusable analytic workflows. To address these challenges, we have developed a translational research platform called 'Globus Genomics'. Globus Genomics provides an end-to-end solution by integrating state-of-the-art technologies and infrastructures such as Globus Online for data-transfer, Galaxy for workflow management, and AWS for on-demand computational resources. Globus Genomics has established data endpoints at various widely used sequencing centers including the Broad Institute and Perkin-Elmer, to enable electronic transfer of data directly into or between research labs for immediate analysis or collaborations. The platform hosts an enhanced Galaxy instance with hundreds (539 tools) of widely used next-gen sequence analysis tools and many pre-defined best practices pipelines for whole exome, RNA-Seq, or Chip-seq data analysis. Unlimited scalability, enabling analysis of numerous exomes simultaneously, is possible due to the platform's ability to provision on-demand compute clusters on Amazon and submit workflows to that cluster from Galaxy. Globus Genomics allows dynamic tool specific provisioning of Amazon EC2 nodes, thus accommodating a wide range of CPU and memory intensive analytical tools requiring varying compute capabilities that helps in dramatically reducing execution times. This platform has been used successfully at the Dobyns laboratory at the University of Washington to transfer hundreds of exomes amounting to tens of terabytes from Perkin-Elmer sequencing center and local servers to Amazon AWS, allowing data to be ready for analysis a few hours after sequence generation. The use of Globus Genomics successfully cut back on data transfer time from a few weeks to a few hours. Furthermore, the platform has provided a 20X performance improvement in the upstream analysis by allowing the simultaneous analysis of 20 exomes in parallel. The Globus Genomics platform offers a powerful and efficient tool for the transfer and analysis of nextgen data for clinical and research purposes.

1634F

Detecting Contamination in Next Generation DNA Sequencing Libraries. *M.A. Umbarger, M.J. Coyne, E.D. Boyden, G.J. Porreca.* Research and Development, Good Start Genetics, Cambridge, MA.

The massive amount of data generated by next generation DNA sequencing (NGS) systems frequently necessitates sample multiplexing to reduce cost. As a result, sample library construction is often performed in parallel in high-density plate format, thereby increasing the probability of sample cross-contamination. In clinical settings, such contamination can cause important disease-causing mutations to be missed. It is therefore imperative that clinical labs employing sample multiplexing develop strategies that allow contamination to be detected.

We have developed an approach that enables the detection of contaminated samples run through targeted sequencing assays. This approach is based upon the assumption that contamination will skew the allele fractions measured at genomic positions where the contaminated and contaminating samples differ in genotype, and therefore that skewed allele fractions can be used to detect contaminated samples. To implement this approach we have supplemented a set of molecular inversion probes that capture the coding regions of genes associated with recessive genetic disorders with probes designed to capture single nucleotide polymorphisms that have high minor allele frequencies. Thus, for each assayed sample, we measure the allele fractions at a set of commonly variant positions. These measured values are subsequently compared to a set of reference distributions generated from non-contaminated samples to derive a score that indicates the degree to which the observed fractions deviate from the reference distributions. Simulation and spike-in experiments illustrate that these scores are correlated with contamination levels and therefore can be utilized to flag samples that are contaminated at levels relevant to clinical sequencing. Thus, we conclude that our allele-fraction based system represents a promising new tool that can be utilized to discern contamination and therefore improve the accuracy of targeted sequencing assays.

1635W

Cluster solutions to the analysis of large genetic datasets. *D.J. Van Booven[1], A. Mehta[1], R.F. Acosta Lebrigio[1], E.R. Martin[1], R.H. Ulloa[1], J. Zysman[2], G.W. Beecham[1].* 1) John P Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Center for Computational Sciences, University of Miami, Miami, FL.

Recent technological advancements in genomic sequencing have resulted in vast amounts of genetic data being produced at a rate that outgrows traditional computational methods. Even the smallest sequencing projects now produce data that cannot easily be analyzed on desktop machines. To combat the large data problem, several high performance computing (HPC) methods have been developed; these range from 'embarrassingly parallel' implementations of simple algorithms to more current platforms and frameworks - Hadoop/MapReduce, MongoDB, etc. For many applications Hadoop framework has become the model for parallel processing of large datasets. To investigate the utility of these platforms to perform the analysis of next-generation sequencing data (NGS), we are implementing and comparing a variety of these methods to NGS problems. Specifically, we are comparing a traditional HPC approach with the Hadoop framework and with a MongoDB framework. These approaches are applicable to a variety of NGS methods, and can be implemented on local HPC clusters, or in commercial 'cloud' architectures such as Amazon's Web Services. We are focusing on two primary NGS analysis areas: sequence assembly and post-bioinformatics pipeline operations (i.e., variant annotation and genotype-level analyses). Sequence assembly is a multiple node/file comparison that may benefit from this type of technology; group genotype calling may also benefit from this approach. The more repetitive post-pipeline processing jobs such as annotation and statistical analyses likely will benefit from a NoSQL Databases like MongoDB. We do not focus on sequence alignment and basic quality control because they are largely one-off, 'embarrassingly parallel' tasks that would not greatly benefit from existing big data tools. We investigate these approaches on real-world NGS data, including both exome and whole genome samples. The approaches are evaluated based on processing and real time taken to perform tasks, memory usage, long term disk space considerations, as well as an overall cost, and ease of use and implementation. This analysis provides guidance on the implementation of various NGS approaches, and aids in cutting time and computational costs for NGS analysis.

1636T

High-throughput CNV Analysis for Translational Research. *G. Geiss, B. Birditt, J. Gerlach, J. Beechem.* NanoString Technologies, Seattle, WA.

The nCounter® Analysis System from NanoString Technologies is a proven tool for precise, highly multiplexed analysis of DNA, RNA, and miRNA. The system is ideal for large translation studies since it requires no amplification (except for single cell analysis) or cloning, works well on clinically relevant sample types (e.g. archival FFPE tissue), and has an automated workflow. Recent updates and improvements have been focused on delivering higher sample throughput while minimizing the amount of input required. Here, we describe the ability to measure up to 200 CNV regions on 4 DNA samples per imaging lane using unique sets of color-coded molecular barcodes. This increases sample throughput by 4 while maintaining assay performance. In addition, input requirements for all sample types and nCounter assays have been reduced via optimization of the post-hybridization processing protocol. We demonstrate the performance of the enhanced protocols by measuring gene expression and CNV in matched FFPE and frozen tissue from tumor and normal samples. Results demonstrate that a 4-fold increase in sample throughput with lower sample input requirements can be realized without diminishing CNV assay performance.

1637F

Genome Analysis of Individual Cells. *C. Korfhage, E. Fisch, E. Fricke, S. Baedker, U. Deutsch, D. Loeffert.* R&D, QIAGEN GmbH, Hilden, Germany.

DNA sequence analysis and genotyping of biological samples using next-generation sequencing (NGS), microarrays, or real-time PCR is often limited by the small amount of sample available. A single cell comprises only one to four copies of genomic DNA, depending on the organism (haploid or diploid organism) and the cell cycle phase. The DNA amount of a single cell ranges from a few femtograms in bacteria to picograms in mammals. However, a thorough analysis of the genome requires a few hundred nanograms up to micrograms of genomic DNA. Consequently, accurate whole genome amplification (WGA) is required for reliable genetic analysis (e.g., NGS) when genomic DNA is limited, as in the case of single cell DNA. Usually single-cell genomic analysis, and in particular single-cell sequencing suffers from incomplete or biased genome amplification with missing or underestimated sequence information. In order to overcome these typical drawbacks, we developed an easy-to-apply single cell WGA method. This method is based on isothermal multiple displacement amplification (MDA) and consists of an innovative lysis and use of an optimized form of the Phi 29 Polymerase. To prove the method's robustness for single cell amplification, we amplified a variety of human and bacterial single cells, and checked the resulting genome coverage with NGS and qPCR methods. Discussed are experiments on cell-to-cell variations, GC content in comparison to genomic DNA, percentage of genome coverage with respective error rates, and genome-wide real-time PCR analysis. Overall the new method results in the effective lysis of cells, complete DNA denaturation, and reliable amplification of the whole genome of a single cell with high accuracy and minimal amplification bias.

Subcellular Fractionation Proteomics Is An Indispensable Tool for Polypharmacology Studies for the Identification of Molecular Targets and Transcription Modulator - A Case Study on the Anticancer Auranofin. *S. Tian, F.-M. Siu, Y.M.E. Fung, C.-N. Lok, C.-M. Che.* Department of Chemistry, State Key Laboratory on Synthetic Chemistry and Open Laboratory of Chemical Biology of the Institute of Molecular Technology for Drug Discovery and Synthesis, The University of Hong Kong, Pokfulam Road, Hong Kong SAR, China.

In the era of polypharmacology, identify mechanisms of action (MOAs) and molecular targets of drug is highly important. Typical proteomics study determines the protein expression changes in the whole cell lysate of the cancer cells upon drug treatments. This method suffers from problems of low coverage and lack of subcellular location information, and renders identification of molecular targets or MOAs difficult. In the present study, we have developed a subcellular fractionation (SCF) based proteomics approach, and applied to study the MOAs of the anticancer Auranofin (AuRF). Compare to that of the typical proteomics study, SCF approach increase the proteome coverage by 4.8-folds: the number of non-redundant proteins identified using LTQ-Orbitrap Mass Spectrometer by this SCF approach is over 2,700, compared to that of 567 proteins in the typical approach. The enriched proteome revealed HMGCR (3-hydroxy-3-methylglutaryl-Coenzyme A Reductase) as the potential inhibitory target for AuRF. This finding was verified by enzyme inhibitory assay with IC_{50} values of 3.5 μM. Using the nuclear sub-proteome, our analysis revealed that $p14^{ARF}$ (gene as *CDKN2A*) was enriched in 2.5 fold as a transcription modulator upon the AuRF treatment. We hypothesized that the up-regulation of $p14^{ARF}$ was associated with E2F-dependent transcription and p53 pathway. This hypothesis was further verified by luciferase reporter system and western blotting assay. Collectively, the subcellular fractionation proteomics is an indispensable tool for polypharmacology studies.

A Complete System for Next-Generation Sequencing Workflow: from Automated Assay Design and Library Preparation to Superior Sequencing Results. *J. Walker, C. Egidio, X. Wang, K. Datta, R. Ramakrishnan.* Fluidigm, South San Francisco, CA.

Objective: To match the increased throughput and decreased turnaround time associated with next-generation sequencing (NGS) platforms, it is essential to have an efficient method for library preparation. The Access Array System is capable of generating amplified material from up to 480 genomic regions across 48 unique samples per IFC. The unique design of the Access Array IFC permits efficient DNA amplification in multiplex reactions and enables successful amplification of challenging DNA samples, such as those from FFPE tissues. In this study, we demonstrate the flexibility and performance of the Access Array System in producing libraries from both high quality and FFPE-derived DNA samples, with consistent results on multiple Illumina and Ion Torrent NGS platforms. Methods: 301 primer pairs were designed covering all exons of the genes for BRCA1, BRCA2, TP53, EGFR and MET. These primer pairs were used in multiplex format with the Access Array system to target-enrich samples for NGS. Samples used included high quality genomic cell line DNA (50 ng/sample) and FFPE-preserved lung tissue DNA (with an input of 100 copies of DNA). Results: The libraries prepared were tested on the Illumina (MiSeq, HiSeq) and Ion Torrent PGM platforms. Differences in performance were observed for each of the platforms tested. Results across Illumina platforms were very consistent, with between 95% to 97% of all reads mapping to the human genome, as compared to up to 85% on the PGM. Of the reads mapping to the human genome, 99.8% of the reads consistently mapped to the specific target region in all platforms. On the MiSeq, 85-96% of all assays tested generated a number of reads within five-fold from the average (median 95%, variance 5%) compared to 88-98% (median 96%, variance 4%) on the HiSeq. On the PGM 314 chip, 85-98% of all assays tested generated a number of reads within five-fold from the average (median 96%, variance 6%), compared to 96-98% (median 97%, variance 1%) on the PGM 316 chip. Comparable results were obtained with FFPE-derived DNA samples. Conclusion: These results demonstrate that the Access Array System is capable of generating excellent data regardless of sequencing platform. This system is also a powerful tool to obtain DNA sequence information from FFPE samples, with over 85% of the target regions detected, from as little as 100 DNA copies, comparing very favorably with published reports.

Rapid Preparation of Exome Sequencing Libraries Using HaloPlex. *H. Johansson, B. Skarpås, E. Agné, A. Karlgren, K. Zetterman, M. Isaksson, P. Eriksson, L. Forsmark, F. Roos.* GSD, Agilent, Uppsala, Sweden.

The current amount of data generated from benchtop NGS instruments allows for comprehensive sequencing experiments in a single run. HaloPlex can be used to enrich for customized target regions and to prepare libraries for sequencing on Illumina or Ion Torrent in less than 1.5 days with target regions ranging from a single gene up to the complete exome. The HaloPlex protocol consists of four main steps. In the first step the genomic DNA is fragmented using restriction enzymes followed by the second step where HaloPlex probes are hybridized to targeted fragments. The third step involves DNA ligation of a common primer motif to all targeted fragments which is then used in the final step for multiplex amplification all targeted fragments using one single primer pair. Samples are barcoded during ligation and can thereby be pooled to optimize use of the sequencing capacity on the sequencing chip. To further improve the HaloPlex Exome kit we have developed a new protocol that requires only 50 ng input and that provides coverage of 99% of the target region with less than 5 gigabases of sequencing. Furthermore, we demonstrate a novel protocol where target molecules can be prepared for sequencing without the need for PCR amplification. Using this approach we are able to avoid amplification artifacts by sequencing the actual sample molecules. The content of the exome kit is based on relevant regions from CCDS, Refseq gene, GENCODE, Vega, UCSC, TCGA and MirBase. A total 37 Mb region is targeted in the hybridization reaction which contains over 2 million HaloPlex probes complementary to a redundant set of target molecules covering the ROI. To improve uniformity and thereby reduce the amount of sequencing capacity required, we have focused on efficiency of probes in regions with low coverage. In common with other DNA capture technologies, regions with high GC content (>70%) are less efficiently captured than average GC regions. To compensate for this we have optimized the hybridization conditions and developed a new probe design algorithm were this difference in efficiency is taken into account.

1641W

Use of a Targeted Next Generation Sequencing Approach for the Study of a Cardiac Valve Malformation With Complex Polygenic Heritability. *E.M. Bonachea[1], G.A Zender[1], D. Corsmeier[2], S.M. Fitzgerald-Butt[1], D. Newsom[2], P. White[2,3], V. Garg[1,3], K.L. McBride[1,3].* 1) Center Cardiovascular & Pulmonary Research, Nationwide Childrens Hospital, Columbus, OH; 2) Center for Microbial Pathogenesis, Nationwide Childrens Hospital, Columbus, OH; 3) Dept Pediatrics, Ohio State University.

Purpose. Bicuspid aortic valve (BAV) is the most common type of heart defect with a population prevalence of 1-2%. BAV is highly heritable with a complex polygenic etiology, however few causative genes are known. Current methods of elucidating the genetic contributors have limitations. Sanger sequencing is time and labor intensive, while next-generation sequencing (NGS) remains costly for large cohorts and requires extensive bioinformatics processing. Here, we describe a novel approach to targeted multigene sequencing of pooled samples that allows for focused sequencing of a large number of genes relevant to cardiac development in a well-phenotyped cohort in a cost-effective manner. **Methods.** Candidate genes were selected based on known causal role, mouse models and cardiac developmental biology. A custom capture of 97 candidate genes was designed using the Agilent SureSelect system to probe whole gene intervals. The cohort of 82 unrelated individuals with echo confirmed BAV was combined into 19 pools with a unique overlapping design; a given variant could be attributed to a single individual on the basis of which pools contained the variation. Sequencing was performed on the Illumina HiSeq2000, followed by bioinformatic processing for basecalling, alignment, variant identification, and in-silico analysis of pathogenicity of identified variants. The standard GATK algorithm was compared to CRISP, an algorithm designed to identify variants in pooled samples. Sanger sequencing of one of the genes was used to validate results. **Results.** Targeted capture identified 99 rare exonic variants involving 34 of the 97 candidate genes. GATK calling using an allele frequency threshold of 2.5% compared favorably to the CRISP algorithm. CRISP was able to identify all exonic variants found by Sanger sequencing, while 2 variants were not called by GATK. The approach resulted in a cost savings of $78,750 as compared to whole exome sequencing of individuals or $509,000 as compared to whole genome sequencing. **Conclusion.** Targeted capture allowed for decreased bioinformatics processing by focusing only on those gene pathways thought to be pertinent to the disease under investigation. In addition, the pooling design reduced overall sequencing costs. The CRISP algorithm provided a higher sensitivity than GATK in this design. The data suggest a role for targeted NGS of pooled samples when investigating birth defects which are proposed to have a complex and polygenic inheritance.

1642T

An integrated approach for accurate calling and assessment of structural variations for clinical diagnostics. *H. Lam[1], M. Li[1], S. Chervitz[1], D. Newburger[1], S. Garcia[1], G. Chandratillake[1], M. Clark[1], N. Leng[1], J. Harris[1], M. Pratt[1], M. Snyder[1,2], J. West[1], R. Chen[1].* 1) Personalis, Inc., Menlo Park, Ca; 2) Stanford University, Stanford, Ca.

Structural variants (SVs)~inversions, translocations, deletions, and duplications~play a central role in both rare and common diseases. However, the ability to accurately detect and characterize SVs in genomic sequence data remains poor. We have developed a highly sensitive approach to identify SVs and score these variants based on their predicted likelihood of causing disease. Our approach integrates four orthogonal methods with targeted local reassembly to improve SV detection and determines the genomic context, zygosity, and exact breakpoints of the SVs when possible. SVs are quantitatively scored based on their occurrence within genes known to cause disease using public and proprietary gene-to-disease databases. Their similarity to previously reported SVs is assessed utilizing a comprehensive set of >2 million unique SVs annotated with population frequency, pathogenicity, and associated phenotypes, if known. We determined the accuracy of our SV detection approach by analyzing deletions from both simulated and experimental genomic data. Our approach achieved very high sensitivity while maintaining very low false discovery rate (FDR). With simulated data (46X sequencing coverage), its sensitivity and FDR were 96.3% and 1.4% respectively, compared to an average of 55.6% and 27.6% for the four methods used independently. Experimental data (>60X) from a trio was used to construct a 'gold standard' SV call set from three replicates of the child, vetted by heritability of these variants from the parents. The SVs detected in each replicate were compared to this gold standard. The average sensitivity for SV detection in these data was 96.8% and the FDR was 1.4%, consistent with the results from simulation. We demonstrated the utility of this algorithm for medical interpretation by using our method to identify, annotate and prioritize SVs of various sizes in samples known to harbor pathogenic SVs. For example, a <5kb pathogenic deletion in the ATM gene was detected and ranked as the most likely deleterious SV in an ataxia telangiectasia sample. Utilizing our knowledge-based ranking system for disease variant discovery, we integrated the SVs with SNVs and short Indels to correctly detect biallelic mutations in ATM as causative of the observed clinical phenotype. We have used our approach to correctly identify these causative variants underlying other disease samples and are currently extending our approach to support exome analysis.

1643F

Direct selection of microbiome DNA from host DNA. *E. Yigit[1], G. Feehery[1], S. Oyola[2], B. Langhorst[1], L. Apone[1], P. Liu[1], D. Munafo[1], C. Sumner[1], J. Bybee[1], L. Mazzola[1], F. Stewart[1], M. Quail[2], T. Davis[1], E. Dimalanta[1], S. Pradhan[1].* 1) New England Biolabs, Ipswich, MA., USA; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinton, Cambridge, UK CB10 1SA.

Nucleic-acid based techniques such as hybridization, PCR, qPCR and next generation sequencing offer a rapid and highly sensitive option for direct metagenomic detection from specimens when compared with culture-based techniques. Currently, 16S rRNA gene sequencing is the method of choice for metagenomic studies. However, this approach lacks the sensitivity to detect rare members of the microbial community with divergent target sequences, and is not adequate to detect virulence factors in individual strains. Aside from these inherent limitations of amplification and identification of biological samples, the non-microbial host genome itself may interfere with the detection and diagnosis of pathogens due to the higher percentage of host genomic DNA relative to the target microbiome. Therefore, analyses of a metagenome or microbiome directly from host samples by next generation sequencing or PCR are inefficient, difficult and time consuming.

To address this problem, we have developed a unique method for separating large pieces of host DNA from microbial DNA using a methyl-CpG binding domain fused to the Fc portion of a human antibody heavy chain (MBD2a-Fc). This MBD2a-Fc protein is then bound to a protein A magnetic bead and used to separate methylated host DNA from microbial DNA that is unmethylated or methylated at low levels. As a demonstration of the efficacy of this methodology, DNA samples from various sources, such as human saliva, blood, and *Plasmodium falciparum* contaminated human DNA, were enriched and sequenced on different next generation sequencing platforms. Sequencing data showed that non-microbial host DNA reads decreased 50-fold, corresponding to ~90-95% microbiome DNA in the enriched fraction. Importantly, microbiome diversity after the enrichment remained intact. This simple methodology can be used to analyze entire microbiomes in a cost-effective manner utilizing established next generation sequencing platforms, as well as newer single molecule sequencing technologies.

1644W

In solution HLA capture and high-resolution NGS-based typing method and an automated, integrated analysis framework. *M. Wittig[1], J.A. Anmarkrud[2], M. Forster[1], E. Ellinghaus[1], K. Holm[2], L. Wienbrandt[3], S. Sauer[5], M. Schimmler[3], M. Ziemann[4], S. Görg[4], T.H. Karlsen[2], A. Franke[1].* 1) Christian Albrechts University, Institute of Clinical Molecular Biology, Kiel, Germany; 2) Norwegian Primary Sclerosing Cholangitis Research Center, Medical Department, Oslo University Hospital, Rikshospitalet, Oslo, Norway; 3) Christian Albrechts University, Institute of Technical Informatics, Kiel, Germany; 4) University of Lübeck, Institute of Transfusion Medicine, Lübeck, Germany; 5) Max Plank Institute for Molecular Genetics, Berlin, Germany.

The human leukocyte antigen (HLA) locus contains the most polymorphic genes in the human genome. These genes play an important role in immune response and much is already known about their role in autoimmunity and infectious disease. The classical characterization of these genes is based on Sanger- or next-generation sequencing (NGS) of a limited amplicon repertoire or labeled oligonucleotides, which identify allele-specific sequences. Using these traditional methods, the rate of possible ambiguities is high and requires manual evaluation of the results, which is also an error-prone process. Here, we introduce a highly automated method, which employs comprehensive insolution targeted capturing of the complete classical class I and class II loci in combination with NGS. Our implemented fully automated analysis allowed for the accurate characterization of HLA-A (0.99 allele calling rate), HLA-B (0.99), HLA-C (0.99), HLA-DRB1 (0.98), HLA-DQA1 (0.99), HLA-DQB1 (0.99), HLA-DPA1 (0.98) and HLA-DPB1 (0.96). Including possible ambiguities and manual verification allowed for the exact HLA typing of all our reference samples. The reference sample set comprises 261 samples so far and were derived from the International Histocompatibility Working Group (IHWG) biobank and from another German center. The allelic diversity of the reference sample was maximized before enrichment and NGS. For HLA-A we identified 66 different alleles, for HLA-B 106, HLA-C 49, HLA-DRB1 71, HLA-DQA1 20, HLA-DQB1 17, HLA-DPA1 5 and HLA-DPB1 39, respectively. In summary, our method provides a straight-forward workflow, which is mainly due to the use of in-solution targeted capturing rather than traditional amplicon-based techniques. The fully automated allele calling delivers high confident allele calls and the number of possible ambiguities is drastically reduced compared to traditional typing (e.g. class I with on avg. 2.5 possible alternatives per sample). At this very early stage of development, one technician can characterize 182 samples in one week with high confidence and high resolution (6-8 digits).

1645T

The New Sequencer on the Block: Comparison of Life Technology's Proton Sequencer to an Illumina HiSeq for whole-exome sequencing. *J. Boland, M. Yeager, M. Dean, D. Roberson, J. Mitchell, S. Chanock.* Cancer Genomics Research Laboratory, NCI Frederick, Gaithersburg, MD.

We assessed the performance of the new Life Technologies Proton sequencer by comparing whole exome sequence (WES) data in a CEPH trio (family 1463) to the Illumina HiSeq instrument. The Proton identified 96% of single nucleotide polymorphisms (SNPs) detected by the HiSeq but only 40% of small insertion and deletion variants (indels). Further comparison of the trio data with Complete Genomics sequence data and Illumina SNP microarray genotypes documented high concordance and accurate SNP genotyping of both Proton and Illumina platforms. However, our study underscored the problem of accurate detection of indels for both the Proton and HiSeq platforms.

1646F

New automated systems for size-selection in NGS library construction. *C. Boles, S. Singh, T. Barbera, E. Abrams.* Sage Science Inc., Beverly, MA.

Virtually all genomic library construction methods use some kind of size-selection in order to avoid adapter artifacts, and to place boundaries on the library fragment size. The gold standard method for size-selection is preparative agarose gel electrophoresis, a procedure that is laborious, irreproducible, and difficult to automate. In response to this need, Sage Science introduced its Pippin Prep automated preparative electrophoresis system in 2010. Since that time, three trends in library construction have been notable: 1) library chemistry has become much more efficient, enabling a reduction in the amount of genomic DNA needed for library construction, 2) the need for high quality genomic libraries in clinical research and medicine has increased dramatically, 3) high quality sequence data are easier to obtain if multiple libraries with different insert sizes are sequenced. To address these trends, Sage is introducing two new preparative electrophoresis systems. The first is a higher-throughput version of the original Pippin Prep system. Like the Pippin Prep system, the high-throughput system is designed to select one or two size fractions from a genomic DNA sample. The channels of the new system have been dramatically reduced in size, a change enabled by the reduced DNA requirements of new efficient library protocols. The disposable agarose gel cassette will fractionate 12 samples per cassette, and the instrument can process two cassettes (24 samples) per run. Runtimes are typically 0.5 - 1 hour. The second system is designed to fractionate a single genomic sample into 12 contiguous size fractions. The system uses a two-dimensional process to separate DNA through an agarose column in a first direction, and then move the separated DNA fragments sideways into a linear array of elution modules that are positioned alongside the separation column. Each disposable cassette will process a single sample, and the instrument will process two cassettes per run. The instrument can operate in direct current mode for samples up to mid-single kilobases in size, or in pulsed field mode for samples up to 50 kilobases in size. Performance data for the two systems will be described.

1647W

Further improvements in sequencing technologies on Illumina platforms. *H. Duckworth, J. Weir, G. Smith, J. Betley, P. McInerny, P. McCauley, K. Ahmad, D. Bond, S. Robinson, L. Kangas, M. Fabani, A. Iyer, K. Hall.* Illumina Inc., San Diego, CA.

The application of Illumina's sequencing by synthesis (sbs) technology has proved to be very powerful in next generation sequencing and has also been shown to have a high level of headroom for improvements. Illumina has produced platforms that range from systems that: /can generate 600 Gbases of high quality data from libraries in 11 days (HiSeq2000) /produce a 30x coverage of a human genome in less than 27 hours which includes cluster formation (HiSeq2500) /enable short read (36 bases) data in less than 4 hours or data with paired 250 base reads with the MiSeq system The HiSeq 2500 incorporated features that enable (in the rapid run mode) clusters to be produced on the instrument with the flowcell in situ greatly simplifying the workflow. The instrument can be used as either a high output (>600G) or rapid run (120G in <27 hours) instrument. Recently announced future improvements include extending the read length to 2x250 cycles enabling up to 300G of data to be produced in <60 hours. The MiSeq system has recently been extended to enable paired 250 base sequencing with a high numbers of reads (~7M). It is extremely easy to use, the workflow allowing for cluster formation, paired end and data analysis on instrument and can be combined with a very rapid sample preparation using Nextera technology that takes less than 90 minutes. Run lengths can be selected as needed from single 36 base to paired 250 base reads. The system has also been made easier to use by the incorporation of a Cloud platform called BaseSpace that reduces the need for IT infrastructure. In a further extension of MiSeq the number of reads has been increased to 25M and the read length extended to 2x300 bases enabling yields of >15G. Also together with a new chemistry we have been able to demonstrate even longer read lengths. The use of Illumina's sbs technology is ubiquitous and since its launch in 2006 over 3300 peer cited papers have been published. Here we present some recent advances in the use of Illumina's sbs technology and its applications to both whole genome and exome human sequencing.

Towards the 24 hour medical genome. *K. Hall[1], J. Weir[1], S. Humphray[1], Z. Kingsbury[1], E. Tsogi[1], P. Smith[1], S. Macarthur[1], E.E. Margulies[1], J. Betley[1], J. Peden[1], N. Miller[2], E. Farrow[2], L. Willig[2], J. Petrikin[2], D. Dinwiddie[2], C. Saunders[2], G. Twist[2], L. Smith[2], S. Soden[2], M. Gibson[2], S. Kingsmore[2].* 1) Illumina Cambridge Ltd., Saffron Walden, Essex, United Kingdom; 2) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO, 64108.

Clinical settings exist where a point-of-care genome sequence is needed, such as in a neonatal intensive care unit (NICU). 5% of US newborns are admitted to a NICU, and 30% of these may benefit from a rapidly interpreted genome sequence for differential diagnosis of a single gene disorder. To influence medical decision making in NICU babies, a molecular diagnosis must be made very rapidly. For most genetic diseases, a definitive (molecular) diagnosis is a prerequisite for specific treatment, prognostic assessment and genetic counseling. Theoretically, genome sequencing can allow an acutely ill baby to be tested for all 3,736 known genetic diseases at once. Currently, causative associations have been determined between the genetic disease phenotypes and 2973 genes. In response, we are developing STAT-seq and have previously reported proof-of-concept for 50-hour return of provisional results in 8 newborns. Essential to this is electronic entry of clinical features by the ordering physician, thereby defining a superset of differential diagnoses and genomic regions to be tested. We report that we have now expanded this clinical genome ordering interface to structured vocabularies of over 5,000 diseases and 8,000 clinical terms. We also report improvements in the overall workflow that shorten return of provisional test results to 24 hours. In particular, methods have been developed to shorten the times for sample preparation, sequencing, alignment and variant calling. We will also demonstrate the use of 2 x 250 read lengths for better alignment in repetitive regions and identification of polynucleotide mutations. Finally, we report clinical utility in 25 cases.

1649F

Droplet digital partitioning improves amplicon coverage of multiplexed assays in NGS library construction. *N.J. Heredia, S. Hodges, S. Cooper, S. Tzonev, D. Skvortsov, E. Hefner.* Bio-Rad Laboratories, Digital Biology Center, 7068 Koll Center Pkwy Ste 401, Pleasanton, CA., 94566.

Droplet Digital PCR reduces biases and improves representation of amplicons in next generation sequencing libraries. The amplicons generated by multiplexing assays are improved when partitioned, compared with standard single tube multiplex NGS methods. Partitioning the sample into droplets reduces biases that arise in PCR such as competition between assays. Custom multiplexed assays as well as standard commercial cancer panels were tested for improvements in read coverage when comparing standard workflows and Droplet Digital PCR. Here we present a facile methodology which easily integrates in to current NGS amplicon library workflows for improvement in reducing amplification bias.

1650W

Accelerated sample prep workflow for target enrichment from low input. *H. Hogrefe[1], B. Arezi[1], A. Belyaev[1], M. Borns[1], M. Corioni[2], J. Fox[1], C. Hansen[1], E. Lin[2], B. Novak[2], C. Pabon[2], B. Rogers[1], D. Roberts[2], F. Useche[2].* 1) Agilent Technologies, La Jolla, CA. 92037; 2) Agilent Technologies, Santa Clara, CA 95051.

We describe an accelerated sample prep workflow that supports whole genome and targeted sequencing from low input amounts of DNA. Genomic DNA libraries are prepared from 50ng DNA using Agilent's novel transposition technology and Herculase II DNA polymerase, which together provide robust yields and greater coverage of AT-rich sequences compared to another vendor's transposon sample prep method. Modified for samples prepped by *in vitro* transposition, SureSelect target enrichment was further accelerated by reducing hybridization time (to 16 hours) and number of pipetting steps. In less than 24 hours, researchers can prepare dual-barcoded (post-capture) libraries for targeted sequencing on the Illumina HiSeq or MiSeq platforms. The automation-friendly workflow supports both whole-genome and targeted sequencing using SureSelect catalog and custom (1kb -24Mb) capture sizes. We routinely achieve >60% on-target, >98% coverage at 1x depth, >75% at 20x depth, and <15% duplicates with the Human All Exon V5 bait set. Performance metrics will be presented for additional libraries (bacterial genomes of varying GC content; 96-plex dual-barcode sequencing; human kinome) and competitor kits using the same input material.

1651T

Performance Evaluation of Bench-top Next Generation Sequencers Using Microdroplet PCR-Based Enrichment for Targeted Sequencing in Patients with Autism Spectrum Disorder. *E. Koshimizu[1], S. Miyatake[1], N. Okamoto[2], M. Nakashima[1], Y. Tsurusaki[1], N. Miyake[1], H. Saitsu[1], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan.

Next-generation sequencing (NGS) combined with enrichment of target genes enables highly efficient and low-cost sequencing of multiple genes for genetic diseases. The aim of this study was to validate the accuracy and sensitivity of our method for comprehensive mutation detection in autism spectrum disorder (ASD). We assessed the performance of the bench-top Ion Torrent PGM and Illumina MiSeq platforms as optimized solutions for mutation detection, using microdroplet PCR-based enrichment of 62 ASD associated genes with RainDance technologies. Ten patients with known mutations were sequenced using NGS to validate the sensitivity of our method. The overall read quality was better with MiSeq, largely because of the increased indel-related error associated with PGM. The sensitivity of SNV detection was similar between the two platforms, suggesting they are both suitable for SNV detection in the human genome. Next, we used these methods to analyze 28 patients with ASD. We validated a total of 57 (PGM) and 30 (MiSeq) SNVs. These SNVs were confirmed by Sanger sequencing, with 21 (PGM) and 22 (MiSeq) shown to be true positives. In contrast, after filtering to exclude rare variants, no indel mutations were detected by either PGM or MiSeq. All 21 SNVs detected by PGM were also detected by MiSeq. We analyzed the ability of each platform to detect variants and found that both platform can identify true variants, but PGM produce more false variant calls. The true positive call rates in the entire coding region were 36.8% (PGM) and 73.3% (MiSeq). Based on web-based prediction software, 72.7% of the detected SNVs (16/22) were seemed pathogenic by either PolyPhen-2 (36.3%; 8/22 SNVs), SIFT (50%; 11/22 SNVs), or MutationTaster (13.5%; 3/22 SNVs). Five out of 28 patients had multiple SNVs. Following the multigenic contribution theory in ASD, these could be associated with the onset or the severity of this disease. Thus, our results support the combination of target gene enrichment and NGS as a valuable molecular method for investigating rare variants in ASD.

1652F

Comparison of enzymes, shear time and capture products to improve whole exome sequencing workflow. *B. Marosy, B. Craig, K. Hetrick, H. Ling, A. Robinson, S. Griffith, J. Romm, K.F. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR is continually seeking new ways to improve its workflow and generate high quality data. A major obstacle in next generation sequencing is the ability to amplify through GC/AT rich regions of the genome. Current methodologies for library preparation and targeted capture rely on PCR to enrich for the prepared libraries. In addition, increased sequencing read length capability has also required changes to the workflow to increase insert sizes. Here we tested two different enzymes (Agilent© Herculase II Fusion DNA Polymerase & Kapa Biosystems HiFi DNA Polymerase) and implemented a different shearing strategy to optimize our current workflow. We also applied these improvements to a NimblegenTM workflow to compare exome captures between the Nimblegen SeqEZCapTM v3 and the Agilent SureSelectTM XT Human All Exon v4. Four unrelated HapMap samples with DNA inputs of 500ng were processed in parallel using 1)Agilent SureSelect XT library prep (XT) & Herculase enzyme; 2) XT library prep & HiFi enzyme; 3) XT library prep & HiFi Enzyme w/shearing modifications; 4)Kapa Library prep & HiFi enzyme w/shearing modifications. Library methods 1, 2 and 3 were hybridized for 24hrs using the Agilent v4 exome and library method 4 was hybridized for 72hrs using the Nimblegen v3 exome. All libraries were clustered using the Illumina® cBOTTM Cluster Generation system. One hundred bp paired end sequencing was performed on the Illumina HiSeqTM2000 platform. Sequencing data was downsampled to ensure an equal comparison between methods. In addition, a product-neutral UCSC exon bed file was used as the 'on target' bed file to more accurately compare the capture products. Preliminary sequencing data analysis of methods 1 and 2 yielded 92.4% and 92.2% of targeted bases covered >= 8x; a molecular duplication rate of 5.1% and 4.8%; mean insert size of 175bp and 193bp; respectively. GC plots indicated improvement when using the HiFi enzyme for normalized coverage and base quality at GC/AT rich regions. Preliminary sequencing data analysis comparing the two capture methods (3 and 4) yielded 92.7% and 94.2% of targeted bases covered at >=8x; 98.5% and 98.4% in dbSNP; 3.11 and 3.13 TiTv ratio; 96.3% and 96.3% sensitivity; 49x and 36x mean bait coverage; respectively.

1653W

Simplified and improved methods for preparing high quality genomic libraries for use on Illumina® sequencing systems. *V.P. Smith, S.J. Humphray, R.M. Sanches-Kuiper.* Illumina UK Ltd, Nr Saffron Walden, Essex, United Kingdom.

Simple, affordable and reliable methods for the preparation of high quality genomic libraries are essential for cost-effective whole genome sequencing (WGS). When selecting a library preparation method for WGS, key performance metrics to consider include (i) simplicity and duration of the workflow; (ii) DNA input requirement; (iii) yield of the final library; (iv) uniformity of coverage and (v) library diversity or complexity. We will present results obtained with the latest versions of Illumina's TruSeq® DNA Sample Prep workflows, TruSeq PCR-free and TruSeq Nano, used in combination with the HiSeq® 2500 and MiSeq® sequencing systems. The PCR-free method produces robust yields from moderate DNA input quantities and generates very high quality genomic libraries with sufficient diversity to support deep sequencing of human and other large genomes. Elimination of PCR-induced biases results in libraries that exhibit uniform coverage across the full range of GC contents . The TruSeq Nano workflow produces relatively unbiased, high yield and high diversity libraries from large and complex genomes starting with as little as 100ng of DNA. These workflows are gel-free, straightforward to execute, automation-compatible and can easily be completed in less than a day, making them ideally suited to the fast turnaround times of the HiSeq 2500 and MiSeq systems. The difficulty of meeting the performance requirements described above is increased substantially when working with degraded DNA such as that extracted from FFPE samples. We will also report on the development of methods for obtaining high quality WGS datasets from practical quantities of FFPE DNA.

1654T

Successful whole-exome sequencing of genomic DNA isolated from preserved mixed-placental tissues. *M.K. Veerapen[1, 2], L. Pelaez[3], M.M. Rodriguez[3], J.E. Potter[4], E. Rampersaud[1], O.A. Bodamer[1, 2].* 1) Hussman Institute of Human Genetics, University of Miami, Miami, FL; 2) Department of Biochemistry and Molecular Biology, University of Miami, Miami, FL; 3) Department of Pathology, University of Miami, Miami, FL; 4) Department of Obstetrics and Gynecology, University of Miami, Miami, FL.

Studies on the genetics of obstetrics and gynaecology have previously focused on utilizing fresh placental tissue (PT) for downstream genetic analysis. However, fresh PT would rarely be histopathologically evaluated for deep-phenotyping purposes and cannot be stored for long-term. Therefore, the use of fixed and paraffin embedded PT would be of interest due to the increasing importance for retrospective genetic studies. With the technological advancement of DNA isolation methods and next-generation sequencing, this could increase the efficiency in variant identification from the preserved PT samples. Due to the fact that the placenta contains a mix of maternal and fetal tissue, the experimental and variant identification challenges are significantly increased. We propose to isolate DNA from preserved PT and successfully perform variant identification. We obtained deidentified PT: non-crosslinking UMFix fixed and paraffin embedded (UMFFPE) foetal membrane (FM) and umbilical cord (UC) samples of mother-foetal (son) dyad pairs from Jackson Memorial Hospital, Miami, FL. The UMFFPE-UC 20 µm curls, containing only foetal surface, were processed for DNA isolation. The UMFFPE-FM containing both maternal-foetal (son) surfaces were separated using laser-capture microdissection (LCM) and DNA isolation. Genomic DNA (gDNA) obtained from UMFFPE-LCM-FM and UMFFPE-UC were then processed for library construction, capture and hybridization using the Roche Nimblegen V3 and Agilent SureSelect 50 Mb V4 respectively for sequencing. Paired-end reads were mapped and aligned with the Burrows-Wheeler aligner according to the Genome Analyzer Tool Kit (GATK) v2.5 pipeline. We successfully isolated gDNA from both UMFFPE-LCM-FM and UMFFPE-UC samples of good gDNA yields and quality. The UMFFPE-LCM-FM samples tested negative for foetal contamination using a PCR-based method. Preliminary sequencing results have shown a capture of an average of 78%; and a read of depth of 71%; at 20X. To the best of our knowledge, this is the first report of the successful whole-exome sequencing and gDNA isolation from preserved PT samples. Potentially, this protocol can be utilized for retrospective genetic studies related to obstetric conditions such as preterm births, intrauterine growth restrictions, intrauterine foetal demise, preeclampsia and chorioamnionitis.

Nextera® Rapid Capture: The Fastest In-Solution Capture Assay for Whole Exome and Custom Targeted Enrichment. *M. Virata, S. Snow, S. Melnyk, L. Galver, E. Allen, S. Kumar, R. Shen, S. de Rozieres.* Illumina, San Diego, CA.

Targeted resequencing provides a cost-effective approach to identify variants by isolating specific genomic regions of interest within a whole genome library. However, high-throughput sample processing and fast time-to-answer can be affected by lengthy library preparation and enrichment procedures. Here we describe the Nextera Rapid Capture Enrichment assay that allows researchers to go from genomic DNA (gDNA) to targeted enrichment data in less than 2.5 days when accompanied by sequencing on a HiSeq2500. By requiring only 18 hours of hybridization time, a single enrichment wash solution, and rapid fluorometric sample quantification procedures, sequencing ready samples can be prepared in 1.5 days with no more than 5 hours of hands-on time. We present data, from a familial CEPH pedigree trio (Mother NA12892, Father NA12891, Child NA12878), showing how the Nextera Rapid Capture Enrichment assay can be used to target ~37 Mb of focused exonic content that covers at least 98% of coding sequences from RefSeq, CCDS, Ensembl, and GENCODE. Despite the low 50 ng gDNA requirement, highly uniform and specific data is generated from only 4 Gb of sequencing (>80% of targeted bases covered by at least 10x). Variants identified in these samples show a high degree of overlap with standard curated databases like dbSNP (98% for SNPs and 70% for Indels). The sensitivity of these variant calls was assessed by comparing these variants to WGS datasets. Similarly, comprehensive coverage of ~62Mb of exons, UTRs, and miRNA targets is shown to require up to 8 Gb of sequencing. Finally, enhancements to Illumina's web-based design tool, DesignStudio, are discussed which enable new design functionality for custom panels utilizing the Nextera Rapid Capture Enrichment Assay.

1656W

Comparison of conventional and PCR-free library preparation methods for next generation sequencing. *P.D. Witmer, B. Marosy, B. Craig, K. Hetrick, A. Robinson, K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University School of Medicine, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to human disease. As part of our continuing effort to implement emerging NGS technologies, we now offer whole genome sequencing (WGS) as a complement to whole exome sequencing (WES) within the suite of services available at CIDR. Furthering our aim to evaluate improvements in methodology, we have been focusing on DNA library preparation methods for sequencing on the Illumina HiSeq2500 platform. Standard library preparation methods include a PCR enrichment step prior to cluster generation. Biases inherent in PCR amplification result in uneven read coverage and increase the numbers of duplicate fragments present in the library. For the HiSeq instruments in particular, coverage of sequence reads is known to be notably lower in GC rich regions, which can affect mapping quality and variant calling. To compare library preparation methods that employ PCR directly to methods that do not, we constructed libraries for NGS with DNA from a well characterized HapMap Trio (NA12878, NA12891 & NA12892) using a conventional DNA library preparation kit from Kapa Biosystems and the TruSeq DNA PCR-Free Sample Preparation Kit available from Illumina. Our QC metrics indicate that library size increased using the PCR-free kit (2.5 fold), improving the complexity of the sample. We also observed significant decreases in read pair duplicates (2 fold) and chimeric molecules (3 fold) compared with samples enriched by amplification. GC plots demonstrate more uniform coverage for PCR-free libraries albeit with a slight reduction in the total number of bases covered above 20X. For mean coverage, Ti/Tv, homozygous concordance and sensitivity to SNP genotyping arrays, there were no appreciable differences between the two methods. However, for PCR-free libraries, there were notable increases in unmapped reads (3 fold), unpaired read duplicates (2 fold) and the percentage of reads containing adapter sequences, which likely reflect broken mate pairs and a smaller insert size (350 vs. 460 bp). Although the omission of PCR shortens the work flow for library preparation, qPCR is required for quantitation. This added step, coupled with the large amount of DNA starting material needed (1ug), could offset the advantages of PCR-free methods when processing clinical samples for WGS.

1657T

A complete workflow from sample preparation to analysis using SureSelect target enrichment system for Ion Proton semiconductor sequencing. *K. Jeong[1], J. Ong[2], E. Agne[3], F. Karlsson[3], A. Ashutosh[1], C. Cocq[1], F. Useche[1], J. Ghosh[1], H. Johansson[3], S. Happe[2], D. Roberts[1].* 1) Agilent Technologies, Santa Clara, CA; 2) Agilent Technologies, Cedar Creek, TX; 3) Agilent Technologies, Uppsala, Sweden.

Whole exome or targeted sequencing for protein-coding regions has provided a cost effective way to identify common and rare polymorphisms that are associated with Mendelian disorders and complex diseases. With increased capacity of semiconductor sequencing, highly multiplexed samples can be studied in a single sequencing run. However, a complete workflow processing raw DNA samples to identify DNA variants in target regions is not easily accessible. Here we describe an analysis workflow to study multiplexed samples in semiconductor sequencing for several target sizes: 50Mb (Human All Exon), 3.2Mb (Human Kinome) and a 1Mb custom design. The workflow includes library preparation, SureSelect target enrichment, semiconductor sequencing, and variant calling with SureCall software (beta version). Improved and simplified steps for library preparation and target enrichment maximize multiplexing and produce consistent results in the Ion Proton sequencer. Sequencing output can be easily analyzed, visualized and summarized in a report with SureCall which is optimized for use with Agilent's target enrichment system. We demonstrate high capture efficiency, uniformity, and reproducibility of enrichment. The results from different capture sizes show comparable high performance regardless of various targeted regions. The combination of efficient target enrichment system, semiconductor sequencing, and SureCall software provides a fast and convenient tool to assess DNA variants in genomic regions of interest.

1658F

Accurate Modeling of Indel Genotype Likelihoods from Sequencing Data. *A. Tan, HM. Kang, GR. Abecasis.* University of Michigan, Ann Arbor, MI.

Short indels are the second most common class of genetic variants. Next generation sequence data and alignment-based indel calling algorithms allow efficient discovery and genotyping across a large number of samples, while retaining high power to detect rare variants. However, the current state-of-the-art methods for analysis of indels are not as accurate as their counterparts for analysis of SNPs. One of the reasons is that indels vary much in length and sequence complexity and thus require more careful handling to cater for the variety of forms. Here we address the problem of bias towards reference alleles when modeling the likelihood of short indels. We observed that in widely used indel calling algorithms, genotype likelihoods lean preferentially towards reference alleles, and the bias becomes larger as allele length increases for indels. For example, for high quality 5-bp indel sites, the proportion of reference alleles in aligned reads from individuals with heterozygous genotypes ranges from 53% to 73%, compared to the expected value of 50%. In our improved algorithm, we carefully construct appropriate local haplotypes with respect to each candidate allele and use a local hidden Markov model that keeps track of flanking sequences and insertion/deletion fragments to qualify and quantify the evidence for each allele. Our procedure allows us to attain an allele balance close to 50% and reduce genotype likelihood discordance substantially compared to analyses using GATK, samtools, and other callers; particularly for longer alleles. As a result, our model also provides us with improved filtering of variants as it results in a more robust distribution of variant features against the confounding due to allele length. Our indel pipeline performs variant calling, genotyping, and filtering while modeling contamination and systematic alignment artifacts. The complete process is incorporated in the updated version of GotCloud pipeline. Along with other independent efforts to improve the existing indel calling algorithms, we anticipate that our method will contribute to increasing our understanding of the genetic risk factors beyond single nucleotide variants.

1659W

Dissecting Gene Regulation Networks at Single-Cell Resolution. *X. Wang, J. Shuga, P. Chen, J. Wang, S. Weaver, N. Li, L. Szpankowski, B. Fowler, A. Leyrat, G. Sun, M. Unger, J.A. West.* R&D, Fluidigm Inc, 7000 Shoreline Court, Suite 100 South San Francisco, CA 94080.

Gene regulation is central to the life of a cell. Sophisticated programs of gene expression trigger developmental pathways in response to environmental stimuli and cell disorders. Even in nominally homogeneous cell populations, cell-to-cell differences are observed. These differences represent different gene expression patterns driven by modular gene regulation. However, due to technical limitations, biologists traditionally investigate gene regulation by utilizing bulk-scale methods to measure average gene expression values in populations of cells. Therefore, the ensemble gene expression profile of a population may mask the behavior of gene regulation in any individual cell. The Fluidigm C1™ Single-Cell Auto Prep System allows researchers to investigate whole transcriptome profiling of individual cells with a simple, automated workflow. In this study, we used the C1 System to prepare mRNA-Seq libraries from >10 different cell types (e.g. HL60, iPS, NPC, primary neuronal cells), with an average sample size of 24 single cells per cell type, and we then conducted deep sequencing on the Illumina HiSeq platform. Sequence depth of 5-10 million reads per cell was obtained and systematically analyzed for gene expression profile correlation at the single-cell level across diverse cell types. We found that extremely deep sequencing (10-30 million reads) was not required to conduct differential gene expression analysis, and that even with read depths of only 1 to 5 million reads, we were able to develop robust gene expression profiles from single cells. Our results indicate that many highly correlated gene expression profiles can only be observed at the single-cell level and are masked in bulk data. Furthermore, the data revealed that gene correlations in single cells are cell-type dependent while highly correlated genes in single cells enrich for relevant biological pathways. Using the validated transcription factor binding site (TFBS) data from the ENCODE project, we further confirmed that some of these highly correlated genes share common TFBS in their promoter regions. Our study suggests gene co-profiling analysis at single-cell resolution is a powerful tool that can help biologists precisely dissect gene regulation networks and better understand cellular heterogeneity.

1660T

Efficient and Accurate Whole-Genome Human Phasing. *T. Blauwkamp, V. Kuleshov, D. Pushkarev, S. Swamy, A. Halpern, K. Singh, R. Sit, A. Granat, J. Zhang, A. Young, K. Kuhn, R. Shen, M. Kertesz, G. Smith.* Technology Development, Illumina Inc., San Diego, CA.

High throughput DNA sequencing allows whole human genomes to be resequenced rapidly and inexpensively producing a comprehensive list of variants relative to the reference genome. However, short read sequencing technologies are limited in their ability to determine phasing information, thus resulting in heterozygous calls being represented as the average of the maternal and paternal chromosomes. Phasing information is of critical importance to personal medicine as it provides a better linkage between genotype and phenotype, permitting new advances in our understanding of compound heterozygote linked diseases, pharmacogenomics, HLA typing, and prenatal genome sequencing. Here, we describe a new sample prep method that enables whole human genome haplotyping at high accuracy using only 30Gb of sequence data. Genomic DNA was fragmented into ~10Kb fragments, end repaired, and ligated to adapters. Hundreds of aliquots with approximately 50MB of DNA in each were amplified, fragmented and converted into individual shotgun libraries. The pooled libraries were sequenced in a single lane of a HiSeq2500 at 2×100bp to generate ~30Gb of sequence. The resulting sequence information was analyzed to obtain a set of long blocks of ~10Kb, covering multiple heterozygous SNPs, allowing phasing of these SNPs relative to each other. An HMM-based phasing algorithm was used to compute the most likely phase and confidence intervals based on the observed coverage and sequencer quality scores. Phasing of those blocks relative to each other was done by another HMM-based algorithm which uses a panel of previously phased genomes. Comparing our results with phase information inferred by transmission from the parents, we found that over 98% of heterozygous SNPs were phased within long blocks (N50=500kb) at a switch error rate below 1 switch per megabase of phased sequence. We present results obtained from multiple cell lines and human samples. This new library prep method and data analysis pipeline enables whole human genome phasing with only 30Gb of raw sequence, which represents only ~30% more sequencing than current 30x baseline run for human sequencing. Compared to other published reports, this method is capable of phasing a greater fraction of SNPS with ~75% less sequencing. Coupling our higher percentage of SNPs phased with high accuracy and the lowest sequencing requirement, this new technology is the most affordable approach to generating completely phased whole human genomes.

1661F

A Complete Work Flow for Single Cell Next Generation Sequencing: from Flow Sorting, Library Preparation, to Sequencing Analysis. *X.Y. Wang[1], R. Li[2], I. Khrebtukoba[2], J. Crane[1], C. Mason[1], G.P. Schroth[2].* 1) BD Biosciences, San Jose, CA; 2) Illumina Inc, Hayward, CA.

Single cell genome-wide transcriptome analysis is a powerful tool to define cell-to-cell variations, either within a cell population or among different cell populations. However, the accurate delivery of single cells or small numbers of cells with distinct phenotypic profiles to perform next generation sequencing remains a challenge. BD fluorescence activated cell sorting (FACS) technology is a powerful tool to separate single cells based on their unique cell surface marker combinations. Here we applied BD FACS technology to deliver cells for next generation sequencing. Single or small numbers (5, 10, 20, 40, 80) of monocytes, T lymphocytes, B lymphocytes, and NK cells were sorted from normal blood into 96-well PCR plates, based on their specific cell surface markers. Then the cells were hypotonically lysed, mRNAs were reverse transcribed and PCR amplified, and genome-wide transcriptome analyses were performed on each cell by using Illumina robust Smart-Seq technology. Good sequencing libraries were successfully generated from all cell types using Smart-Seq, down to single cell levels. Differential gene expression patterns were reproducibly observed. The in-depth transcriptome analysis showed that although gene expression analysis of single cells had increased noise, hundreds of differentially expressed genes were identified, and different cell types gave cell specific gene expression patterns. These results demonstrate that the combination of flow cytometry and next generation sequencing provides a powerful tool for genome-wide gene expression analysis.

1662W

Improved Computational and Experimental Methods for Targeted DNA Sequencing with Molecular Inversion Probes. *E.A. Boyle, B.J. O'Roak, B.K. Martin, A. Kumar, A.P. Lewis, J. Shendure.* Genome Sciences, University of Washington, Seattle, WA.

Robust target enrichment strategies for next-generation sequencing are necessary for cost-effective clinical genomics as well as for validating the contribution of rare or de novo variants in candidate genes to complex diseases. Hybridization-based capture technologies are limited in that they scale poorly to very large numbers of samples and routinely fail to capture about 5% of the exome, typically in regions of high GC content. Recent studies of sporadic cases of autism spectrum disorder demonstrated the utility of Molecular Inversion Probes (MIPs) for identifying genes in which recurrent de novo mutations contribute to disease risk (O'Roak *et al.*, Science, 2012). However, in this project and others, the utility of MIPs for targeted gene sequencing has been limited by design constraints and poorly captured regions. We sought to address these challenges by developing a flexible new approach to MIP design that better explores the search space of possible designs *in silico* to reduce dropout of GC-rich targets. We first synthesized and tested 12,000 MIPs whose designs explored a broad range of parameter space, and then used these results to empirically train a logistic model for predicting MIP performance. On an unrelated test set, MIP scores from the predictive model were highly correlated with the relative capture efficiencies of individual MIPs (Spearman rank correlation of 0.67). Head-to-head comparisons against previous MIP sets showed improved coverage of poorly captured genes, boosting the proportion of sites meeting per-sample coverage thresholds by as much as 20%, with median per-base coverage rising from 98.4% to over 99.9%. Furthermore, comparison to coverage levels reported on the Exome Variant Server showed comparable or, in some cases, superior coverage across targeted regions. Independent of MIP design, a series of optimizations of the capture protocol improved the relative efficiency of capture of high GC targets tenfold or greater. This work demonstrates that improved modeling of the features affecting MIP capture can be used to successfully predict relative MIP capture efficiencies and, coupled with optimizations of the capture protocol, have the potential to push coverage of target sequences close to 100%. Further improvements to MIP methodology are expected to enable the application of MIP-based sequencing to clinical diagnostics.

1663T

A novel In situ isothermal amplification method for next generation sequencing. *Z. Ma, R. lee, S. Goyals, J. Erikson, K. Lao.* Life Technologies Inc., South San Francisco, CA.

We report a novel alternative approach to generate immobilized monoclonal templates for next generation sequencing applications. This in situ isothermal amplification method can generate over a billion of sub-micrometer size colonies in one lane of 5500 flowchip without multiple cycles. We also demonstrate an alternative paired-end sequencing method using an interstrand DNA photo cross-linking reagent to covalently link the complementary strands of the original templates onto the solid surface. We believe that these approaches could potentially be used on other sequencing platforms and simplify the working flow for clinical genomic applications.

1664F

Enhanced solution based target enrichment using oligonucleotide probes and a novel composition of blocking oligonucleotides. *S.D. Rose, K.L. Popp, C.C. Locklear, A.N. Dvorak.* Product Development, Integrated DNA Technologies, Coralville, IA.

Targeted pull-down enrichment using oligonucleotide probes has become an important tool for those researchers interested in isolating a smaller subset of loci defining a particular pathway or disease state. Using hybridization probe-based enrichment has its advantages over PCR based methods. Probes that are long enough, approximately 120 nucleotides in length are impervious to smaller base variations which allows for discovery of undocumented SNPs. Unlike PCR amplification, deletions or rearrangements can be detected without any additional information about chromosomal location. The improved on target capture percentage through the use of blocking oligonucleotides as part of the hybridization step has been previously demonstrated. A new generation of modified blocking oligonucleotides shows 10-25% increase of 'on target captures' using libraries made with TruSeq™ adapters. Furthermore these new blockers have universal barcoded domains alleviating the need for individual barcode specific blockers.

1665W

A Fast Solution for NGS Library Prep with Low Nanogram DNA Input, for Multiple Sequencing Platforms. *F.J. Stewart, P. Liu, G.J.S. Lohman, E. Cantor, B.W. Langhorst, E. Yigit, L.M. Apone, D.B. Munafo, C. Sumner, D. Rodriguez, V. Panchapakesa, J. Bybee, L.M. Mazzola, T.C. Evans, N.M. Nichols, E.T. Dimalanta, T.B. Davis.* New England Biolabs, Inc., Ipswich, MA.

Next Generation Sequencing (NGS) has significantly impacted human genetics, enabling a comprehensive characterization of the human genome as well as a better understanding of many genomic abnormalities. By delivering massive DNA sequences at unprecedented speed and cost, NGS promises to make personalized medicine widespread in the foreseeable future. To date, library construction with clinical samples has been a challenge, primarily due to the limited quantities of sample DNA available, but also due to the low quality of some samples, such as FFPE samples. To overcome this challenge, we have developed NEBNext® Ultra DNA Library Prep Kit for Illumina, a fast library preparation method using novel reagents and adaptors, including a DNA polymerase that has been optimized to minimize GC bias. This method enables library construction starting with nanogram quantities of DNA, and can be used for both intact and fragmented DNA, such as that found in FFPE samples. Moreover, the workflow is compatible with multiple NGS platforms, enabling use of a single library prep kit for creation of a variety of sequencing libraries. Illumina, 454, and SOLiD 5500 libraries were successfully generated and sequenced on the corresponding platforms to produce high quality sequencing data.

1666T

Profiling of the T-cell receptor variable region gene segment usage in tissue biopsies using Nanostring nCounter. *T. Peters, T. Valensise, N. Cheung, A. Seguin, V. Petitjean, E.J. Oakeley, S. Starck-Schwertz, M. Letzkus, K.J. Johnson, F. Staedtler.* Human Genetics & Genomics, Biomarker Development, Translational Medicine, Novartis Institutes for BioMedical Research (NIBR), Basel, Switzerland.

In order to generate a broad and structurally diverse adaptive immune repertoire, T and B-cell receptor genomic loci undergo non-precise somatic V(D)J segment rearrangements, including templated and non-templated nucleotide additions and deletions. Several studies observed that even in healthy subjects certain TCR V segments are commonly utilized while others are quite rare, also thereby reflecting a snapshot of the currently active adaptive immune system. A shift towards mono- or oligoclonality and the associated usage of dominant TCR V segments is often observed in infection, chronic inflammation, autoimmune disease and cancer. Recently, Zhang et al. described a Nanostring nCounter based "direct TCR expression assay" that allows a rapid and sensitive screen for the usage frequencies of all functional TCR Vα and Vβ segments. Here we report on the modification of the initially described codeset for inclusion of TCR Vγ and Vδ segments as well as the exemplary application for TCR V usage screening of colon and skin biopsies obtained from Crohn's disease and psoriasis patients. As TCR transcripts make up only a minority in total RNA from biopsies, our analysis involved PCR amplification of TCR transcripts and re-transcription to sense RNA for subsequent Nanostring nCounter analysis. We compare the obtained patterns of TCR V segment usage to corresponding profiles generated by massive parallel immune repertoire sequencing. In summary, profiling of TCR V segment usage in tissue biopsies using Nanostring nCounter enables the rapid and efficient detection of expanded T cell clones associated to disease.

Evaluation of whole genome amplified DNA and reduced genomic DNA for high performance of Illumina SNP microarrays. *C.L. Dagnall[1,2], L.M. Morton[1], B.D. Hicks[1,2], W. Zhou[1,2], X. Deng[1,2], M. Yeager[1,2], S.J. Chanock[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), National Institutes of Health (NIH), Bethesda, MD; 2) Cancer Genomics Research Laboratory, SAIC-Frederick, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD.

The high genomic DNA input requirements for whole genome single nucleotide polymorphism (SNP) microarrays can limit the scope of molecular epidemiological studies. We evaluated alternatives to reduce input DNA requirements for Illumina® Infinium® SNP microarrays, using reduced genomic DNA (gDNA) amounts and whole genome amplified DNA (wgaDNA) as inputs into the Infinium® assay protocol. These alternate inputs reduce gDNA template requirements by 75% and 96.67%, respectively. 192 DNA samples from 71 individuals were obtained from multiple biospecimen sources and genotyped using standard and alternative inputs. When compared to genotypes obtained from the standard input amount, we observed 99.98% and 99.73% median concordance with reduced gDNA and wgaDNA, respectively. Our results demonstrate that carefully conducted studies with alternative inputs can yield high-quality genotyping results. These findings enable investigators to consider expansion of ongoing studies, including genome-wide association studies, challenged by small amounts of available DNA.

1668W

Utilizing the QuantStudio™ 3D Digital PCR System for BRAF V600E Mutation Detection in Papillary Thyroid Carinoma and Malignant Melanoma. *K. Hayashibara[1], L. Degoricija[1], E. Springer[2].* 1) Genetic Analysis, Life Technologies, South San Francisco, CA; 2) Institut für Pathologie, Universitätsmedizin der Johannes Gutenberg-Universität, Mainz, GERMANY.

BRAF V600E mutations are present in a high percentage of papillary thyroid carcinomas and malignant melanomas. Problems in routine diagnosis include limited sample quantities, ambiguous results, and the presence of PCR inhibitors, particularly in melanomas. A sensitive, rapid, and inexpensive method for detecting these and other mutations that is not affected by these limitations will be of great utility. Several papillary thyroid carcinoma and malignant melanomas from formalin fixed and native samples were analyzed using both a highly specific amplification refractory mutation system (ARMS) and digital PCR. Comparison of results indicates that digital PCR on the QuantStudio™3D System is able to detect BRAF V600E mutations in all samples where the mutations were detected by ARMS PCR, even when preamplification was required for mutation detection in some samples. Digital PCR was able to detect mutations in samples from melanomas that contained PCR inhibitors. The digital PCR results are also quantitative, allowing the determination of the mutant to non-mutant ratio of the samples.

1669T

Desktop Sequencing Using A Single-Use Cartridge-Based Consumable That Includes Target Enrichment, Amplification and Sequencing. *T. Raz[1], A. Gulamali[1], F. Zhuang[1], H. Ghandour[1], J. Sram[2], J. Healy[1], J. Downer[1], M. Griesbach[1], N. Nerkizian[1], P. Mary[1], S. Haserlat[1], V. Chellappa[1], J. Boyce[1].* 1) GnuBIO Inc., Cambridge, MA; 2) City of Hope, Duarte, CA.

Several major challenges have impeded the widespread application of targeted sequencing assays in the clinical setting. Foremost among these challenges are the high cost and complexity of sample preparation for the next generation sequencing platforms. Current technologies for target enrichment require between two to four days of preparation before samples are ready for the sequencing run. Furthermore, in order for current solutions to approach cost effectiveness, many samples need to be batched in a single run, adding to the complexity, increased likelihood of error and increased turnaround time. The GnuBIO unique desktop sequencer uses a single-use cartridge-based consumable that incorporates all of the preparation steps that are typically performed separately including target enrichment, amplification and sequencing. This drastically simplifies clinical workflows and reduces the operator hands-on time to less than 5 minutes, an unprecedented total. Biochemical reactions take place in a cascading manner, with individual reactions contained inside minute emulsion droplets, which flow through microfluidic channels where they are injected with assay reagents, incubated at the required temperatures, and finally detected for sequencing. Each droplet results in a single DNA sequence read, with reads up to 1000nt long. GnuBIO is collaborating with the City of Hope to develop an oncology targeted gene panel for detection of actionable mutations on the GnuBIO platform. The system is designed to achieve the following: /Starting material: genomic DNA from FFPE samples or other types of samples. /Total run time of less than 4 hours /Sample preparation requires only genomic DNA extraction (no DNA library preparation, enrichment or amplification required). /Robust detection of low frequency alterations (~1%-5%). /High accuracy - with average per base accuracy of 99.999% /Ease of integration with existing analytic and sample tracking workflows /Low per sample cost - $200 per sample /Low instrument cost - $50,000 In addition, the cartridge consumable is a closed system, and can be readily adapted to new panels. The cartridge is a dry consumable, containing all reagents needed to run a single DNA sample, reducing the risk of contamination and error.

1670F

The Advantage of Cold Plasma in Genomic Analysis. *C. Lunn, J. Shieh, P. Hensley.* IonField Systems, Moorestown, NJ.

Technological advances have significantly increased the sensitivity of genomic assay systems. Such advances have placed a premium on lab processes that keep samples contaminant free. That requirement for sample transfer is usually satisfied with costly single use plastic tips. As an efficient and cost effective alternative, IonField Systems has developed the TipCharger™ plasma treatment system, a microplate sized module that uses cold plasma to clean plastic pipette tips. Data shows that a 30-second plasma treatment removes DNA to undetectable levels without generation of any liquid or solid wastes. Use of the TipCharger can provide a valuable alternative that will speed analysis and decrease costs associated with modern genomic analysis.

Enhanced performance of whole exome and other targeted sequencing of small clinical samples. *J. Langmore, E. Kamberov, S. Yerramilli, T. Tesmer, J. Jessman, M. Carey, M. Carroll.* Rubicon Genomics, Inc, Ann Arbor, MI.

Next generation sequencing (NGS) enables analysis of any or all parts of the human genome in a way that opens new opportunities for clinical research and testing that is at more comprehensive, faster and less expensive than previously possible. For diagnostic applications that require deep sequencing such as cancer mutation discovery or detection from FFPE tissue or plasma, target enrichment by amplification or capture is critical to reach the goals for sequence accuracy and economy of sequencing time and reagents. Target capture using Agilent SureSelect or Roche NimbleGen SeqCap EZ reagents use a recommended amount of about 1000 ng of unamplified input DNA for a successful outcome. Thus it is difficult to use those methods on unamplified FFPE or plasma samples, because the amount of total DNA available is only 1 - 300 nanograms of total DNA. Manufacturer-recommended library amplification protocols specify at least 100 ng input. We have optimized library synthesis, amplification and capture protocols to achieve excellent whole exome and whole kinome results using less than 10 ng unfixed tissue or plasma DNA inputs, or larger quantities of FFPE DNA. We used the Rubicon ThruPLEX-FD library reagents, the Agilent and Roche target capture reagents, and modified protocols (when necessary). Sequencing metrics such as percentage reads on target, target coverage, and SNP or variant calling were equivalent to results using unamplified libraries or other library kits using substantially larger amounts of input DNA recommended using manufacturer-recommended protocols. Libraries made from the smallest amounts of input did produce the expected higher percentages of duplicate reads. The optimized reagents and protocols will be available to researchers and will enable high-quality targeted sequencing to be achieved starting with substantially less input of clinical DNA samples.

1672T

SureSelect strand specific RNA library prep kit provides a fast and streamlined workflow for preparing directional libraries from total RNA. *B. Arezi[1], B. Hsue[1], F. Useche[2], A. Tsalenko[2], B. Novak[2], A. Lucas[2], K. Chen[1], H. Tang[1], H. Hogrefe[1].* 1) Agilent Technologies, La Jolla, CA 92037; 2) Agilent Technologies, Santa Clara, CA 95051.

RNA-Seq is a revolutionary technology for whole transcriptome analysis. Deep sequencing of cDNA has been used to quantify transcript levels, confirm gene annotation, and identify novel transcripts, splice variants, and SNPs. RNA-Seq protocols that preserve strand information are critical for identifying antisense transcripts that play a role in gene regulation, determining the exact boundaries of genes transcribed on opposite strands, and accurately measuring expression levels of overlapping genes. Here, we present the SureSelect Strand Specific RNA Library Prep Kit, which includes all reagents required for isolating polyA RNA and preparing directional RNA libraries for Illumina sequencing from as low as 50ng total RNA, using the dUTP marking method (Parkomchuk et al (09) NAR 37: e123). In a comprehensive comparison of directional RNA-Seq methods, the dUTP marking method was found to provide the most compelling overall balance across all sequencing metrics examined, including strand specificity, library complexity, evenness and continuity of coverage, and accuracy of gene expression profiling (Levin et al (10) Nature Methods 7: 709-715). With our streamlined automation-friendly protocol, which includes master mixes and combined enzymatic steps, researchers can prepare directional cDNA libraries with >99% strand specificity from total RNA in about 5 hours, without the need for gel size selection. A comparison of RNA-Seq to gene expression array shows good correlation (R>0.8) between differential gene expression ratios (MAQCA and B) obtained using Agilent's SureSelect Strand Specific RNA Library Prep kit and SurePrint G3 Human Gene Expression Microarray 8x60K. Finally, we show that SureSelect Strand Specific RNA Library Prep is compatible with target enrichment by performing capture using the SureSelect Human Kinome bait library. Enriched libraries show high target and strand specificity (80% on-target reads; >99% strand specificity), and correlation of mean gene RPKM values between target-enriched and un-enriched libraries (R>0.8).

1673F

A Complete Work Flow for Single Cell Transcriptome Analysis: from Flow Sorting to Gene Expression Analysis. *C. Mason[1], L. Dennis[2], M. Krouse[2], J. Beechem[2], D. Mittar[1], E. Park[1], X.Y. Wang[1].* 1) BD Biosciences, San Jose, CA; 2) NanoString Technologies, Seattle, WA.

Once thought homogeneous populations of cells have recently revealed a startling amount of gene expression variation. New understanding has largely been driven by recent advances in the sensitivity of technologies such as next generation sequencing and sequence detection analysis, which are now capable of analysis at the single cell level. Here we describe how the power of flow cytomery can be exploited to isolate, characterize, phenotype, and purify multiple cell populations at the single cell level. We describe a complete workflow starting with heterogeneous cells that can be isolated at rapid speed by single cell depositions into 96-well plates using the newly developed BD FACSJazz™ flow cytometer from BD Biosciences. We demonstrate the use of new analytical tools such as index cell sorting, which can help track those individual cells during and after sorting. Finally we describe how, using single cell gene expression with the NanoString® platform, we can demonstrate high fidelity of the sorted cells.

1674W

Streamlined Methods for miRNA and Strand Specific RNA Library Construction for the Ion Torrent PGM. *D. Munafo, L. McReynolds, B. Langhorst, C. Sumner, P. Liu, E. Yigit, L. Apone, F. Stewart, J. Bybee, L. Mazzola, E. Dimalanta, T. Davis.* New England Biolabs, Inc., Ipswich, MA.

The Ion Torrent PGM has made it possible to generate large amounts of sequence data in relatively short run times. Consequently, it has become increasingly important to be able to generate large numbers of libraries from a variety of samples quickly and inexpensively. Here we present a fast workflow for construction of RNA libraries for whole transcriptome analysis. miRNA libraries can accommodate low total RNA input with no need for enrichment and are free of adapter-dimer contamination. mRNA libraries retain strand specificity for accurate gene expression quantification and discovery of antisense transcripts. The strand-specific libraries are compatible with poly(A) mRNA as well as ribosomal RNA-depleted total RNA. Using this simple and rapid procedure, library construction time is reduced to one day and the yield of the library is significantly improved. To reduce cost and increase sample throughput, libraries can be barcoded during amplification. The multiplexed libraries can then be pooled before size selection, reducing the number of steps in the workflow.

1675T

Novel Method for Multiplex Small-RNA Library Preparation with Improved Performance and Higher Sensitivity. *D. Rodriguez, D. Munafo, L. McReynolds, B. Langhorst, L. Apone, P. Liu, V. Panchapakesa, C. Sumner, E. Yigit, F. Stewart, E. Dimalanta, T. Davis.* New England Biolabs, Inc. 240 County Road, Ipswich, MA 01938, USA.

Identification and analysis of small RNA by deep sequencing requires preparation of a di-tagged cDNA library. Most library preparation methods for di-tagged cDNA are based on sequential ligation of adaptors. The excess of adaptors required to provide sufficient library yield leads to adaptor-dimer formation that strongly contaminates the library (unless several gel purification steps are performed to remove unligated adaptors). We have developed a novel method to generate di-tagged small RNA libraries free of adapter-dimer contamination without introducing any additional enzymatic steps or gel purifications. Using this simple and rapid procedure, library construction time is reduced to one day and the yield of the library is significantly improved by enabling the addition of a high concentration of adaptors, thereby increasing the percentage of small RNA molecules included in the library. To reduce sequencing cost and increase sample throughput we have developed a barcode strategy to tag samples during library construction. Up to 24 multiplexed libraries can then be pooled together before size selection, reducing the number of steps in the workflow. Additionally, gel-free size selection greatly simplifies the overall workflow. Our method for generating multiplexed small RNA libraries reduces bias by ligation, increases representation of modified small RNAs and simplifies the workflow during library construction for small RNA analysis and discovery.

1676F

Molecular Indexing for Improved RNA-Seq Analysis. *M. Toloue, J. Risinger, P. Nakashe*. Bioo Scientific, Austin, TX.

Most current Next Generation Sequencing (NGS) library prep methods introduce significant sequence bias. The use of enzyme processing and fragmentation steps can introduce errors in the form of incorrect sequence and misrepresented copy number. Conventional RNA sequencing library construction involves the ligation of a population of cDNA molecules with adapters prior to amplification and sequencing. An inherent weakness of conventional RNA-Seq analysis is that cDNA fragments that amplify more efficiently will unavoidably result in a higher number of reads than cDNAs that do not amplify as well during the library construction PCR step. Therefore, when multiple reads mapping to the same transcript are encountered, it is not possible to determine whether sequenced reads originate from the same or different cDNA molecules. With molecular indexed libraries, each molecule is tagged with a molecular index randomly chosen from ~10,000 combinations so that any two identical molecules become distinguishable (with odds of 10,000/1), and can be independently evaluated in later data analysis. Analysis using molecular indexing information provides an absolute, digital measurement of gene expression levels, irrespective of common amplification distortions observed in many RNA-Seq experiments. This type of indexing requires no additional steps in RNA-Seq workflow and increases the precision of downstream analysis. At low sequencing depths, analysis use of molecular indices is identical to conventional analysis and generates equivalent RPKM values in all applications. As sequencing depth increases, individual molecular resolution also increases. In quantitative RNA-Seq experiments, the molecular indices distinguish re-sampling of the same molecule from sampling of a different molecule. At high sequencing depths, each molecule can be distinguished and the entire library can be analyzed to provide absolute numbers of each molecule. Resolving individual clones of molecules is critical for increasing sequencing accuracy, measuring bias, PCR duplication rates and identifying mutations in complex sample types. While it is well known that library prep methods introduce bias, tools for measuring it are needed if we are to start using NGS for accurate and quantitative gene expression measurements. Toward achieving that goal, we propose the use of molecular indices for all RNA-Seq experiments.

1677W

The Fluidigm® biobanking panel sensitively identifies gender contamination, sample degradation and low quality samples. *M.M. Lee, N.Y. Tuason.* Fluidigm Inc., 7000 Shoreline Court, Suite 100, South San Francisco , CA, 94080.

The lack of standardization and high quality samples from biorepositories can impede the progress of disease and basic research exposing a need for quality control and assessment methods to determine sample utility. The Fluidigm biobanking panel facilitates quality control and assurance studies on DNA samples. The panel consists of 96 assays selected by Dr. Andrew Brooks of Rutgers University to provide critical information regarding sample identity, integrity and quality. In this set of experiments, we will determine the limit of detection for gender contamination, assess DNA degradation detection and evaluate the performance of low quality samples assayed by the Fluidigm biobanking panel on the 96.96 genotyping integrated fluidic circuit in the BioMark™ HD system.

SNP genotyping using Affymetrix Axiom® Genotyping Solution. *M. Shapero, H. Loi, J. Law, A. Yan, D. Nguyen, C.S. Yu, M. Purdy, R. Kurapati, M. Shirazi, L. Bellon.* Genetic Analysis, Affymetrix, Santa Clara, CA.

The use of high-density DNA microarrays for accurate, cost-effective genotyping of single nucleotide polymorphisms (SNPs) and insertion/deletion polymorphisms (indels) plays an important role in the identification of the underlying genetic basis of common, complex human diseases. As the catalog of both common and rare variants in multiple worldwide populations continues to expand, microarrays are well positioned to capitalize on this evolving information content for targeted genotyping. Here we present an overview of Axiom® 384HT Genotyping Solution in which 384 individual arrays, contained in the footprint of a standard microtiter plate, offer the capability to simultaneously genotype 384 samples at 50,000 variants per sample with a throughput greater than 3,000 samples per week. The solution thus offers a novel technological capability to genotype large numbers of markers at a very high sample throughput in a cost-effective manner. Axiom® Genotyping Solution enables complete automation of DNA target preparation, including DNA amplification and enzymatic fragmentation of post-amplification products, on liquid-handling workstations. Following target preparation, arrays are processed using GeneTitan® Multi-Channel (MC) Instrument. The Axiom® myDesign™ Custom Arrays in the 384-layout can be designed with markers from the Axiom® Genomic Database or from *de novo* SNP discovery initiatives. Axiom 384HT Genotyping Solution retains full compatibility with the existing Axiom instrumentation platform and downstream data analysis software. Genotyping performance consistently achieves an average sample call rate ≥99.0%, average sample concordance to independent DNA genotype information (HapMap) ≥99.5%, and intra- and inter-run reproducibility ≥99.8%. In summary, new Axiom advances with the 384-array layout further extend the platform's capabilities for highly multiplexed genotyping of variants in a single assay. This offers high sample throughput coupled with minimal manual intervention enabling multiple applications including biomarker discovery, sample QC and tracking for large cohorts, and post-GWAS fine-mapping and causal variant analysis.

Successful Illumina Infinium Beadchip high-density genotyping from fragmented and low concentration samples. *J.C. Tackney[1], D.J. Witherspoon[2], L.B. Jorde[2].* 1) Dept. of Anthropology, University of Utah, Salt Lake City, UT; 2) Dept. of Human Genetics, University of Utah, Salt Lake City, UT.

Currently, high-density and high-quality SNP genotype data cannot be consistently assayed from small amounts of degraded DNA samples. DNA quality and concentration remain a bottleneck both in SNP microarray and next-generation sequencing library creation. While sequencing libraries have successfully been processed from degraded ancient DNA samples, costs are still prohibitively expensive for wide use in forensic DNA laboratories. Generating SNP genotype data from such samples remains a goal in identification of human remains and in crime scene investigations.

Towards that end we created panels of human DNA samples varying in concentration and fragmentation profiles. We first processed these samples through Illumina's proprietary Infinium FFPE DNA Restoration Solution and genotyped them on the HumanOmniExpress-FFPE BeadChip. We determined that we could genotype 1 ng of DNA fragmented to 300 bp with an ~84% call rate and, when compared to genotypes from 100 ng of non-fragmented control DNA, a ~2.2% discordant call rate. Obtaining more than 500,000 usable SNP genotypes from DNA of this quality has not been previously reported and suggests that this method can be applied to forensic DNA samples. This would allow accurate inferences of genetic relationships between samples.

We further processed 100 bp fragmented samples at lower input amounts. We investigated alternatives to Illumina's WGA step by creating sequencing libraries using a standard library preparation technique and a high-sensitivity single-stranded approach (Gansauge, M.T. and Meyer M. 2013. Nat. Protoc. 8(4), 737-48). We report on sequencing libraries as an alternative input for Illumina Beadchips.

This research was supported by DOJ award 2012-DN-BX-K037 and University of Utah Research Foundation and Interdepartmental grants to LBJ.

Computational pipeline for whole genome sequencing data analysis -- an application to trio families with 22q11 deletion. *J. Cai[1], K. Coleman[2], Z. Zhang[1], B. Morrow[1].* 1) Genetics Dept, Albert Einstein College of Medicine, New York, NY; 2) Human Genetics Dept, Children's Healthcare of Atlanta and Emory University School of Nursing, Atlanta, GA.

Whole genome sequencing (WGS) has become a viable strategy to discover variants associated with human disease. To facilitate WGS data interpretation, we established an automated pipeline for genetic variant (SNVs, INDELs) identification and annotation, using BWA, PICARD, GATK and ANNOVAR. For nonsynonymous SNPs, we predict the effect of amino acid changes by combining the output of BLOSUM62, SIFT and Polyphen2. We derive the MAF of known variants from the 1,000 Genomes Project or the NHLBI Exome Sequencing Project. We also utilize multiple tools including CNVnator, ERDS, and BreakDancer, which consider both depth and split-read information to generate CNV calls. To obtain a reliable set of CNVs, we follow up CNVs that are reported by at least two tools. We annotate known CNVs according to the Database of Genomic Variants. We applied this approach to WGS data from two unrelated families in which the child has velo-cardio-facial/DiGeorge/22q11.2 deletion syndrome and both parents are normal. One child has a heart defect (tetralogy of Fallot; TOF) and the other has a normal heart and aortic arch. The known 22q11.2 deletions were verified by WGS. We identified 3,372,285 SNVs and 762,680 INDELs per sample. A total of 98% and 80.9% of them, respectively, are previously known SNPs found in dbSNP. We phased SNVs and INDELs using both trio and alignment information. This approach allows us to aggregate single base-pair level variants into gene level and dissect compound mutations within one gene. After phasing, we focused on highly possible deleterious variants, including nonsynonymous SNVs that at least one program predicted to be deleterious, stop gain/loss, splicing SNVs and frame-shift INDELs. We also filtered them with MAF <=1% from 1,000 Genomes Project. For each child, we counted the number of deleterious haplotypes for each gene and identified 20 candidate genes with two deleterious haplotypes in the child with TOF but not in the control. As we previously collected 303 heart related genes from literature, we examined whether these genes in the child with TOF were enriched with deleterious haplotypes compared to control, but resulted in no significant difference. We checked the other alleles of 22q11.2, we did not find any highly possible deleterious variants. For CNVs, we detected 1,256 novel deletions and 215 novel duplications per sample. Overall, this approach can be applied to large datasets to identify genetic modifiers of 22q11DS.

1681T

Blueprint: Resources provided by the large-scale Epigenomics project. *L. Clarke, D. Richardson, S. Wilder, P. Flicek, The Blueprint Consortium.* Vertebrate Genomics, European Molecular Biology Laboratory, European Bioinformatics Institute, The Wellcome Trust Genome Campus, Cambridge, United Kingdom.

Blueprint is a large-scale epigenomics project funded through the EC Framework Program 7 as the European Union's entry in the International Human Epigenome Consortium (IHEC). Blueprint aims to provide epigenomic data on several blood cell types both normal and diseased to help the scientific community improve its understanding of haemopoesis. This poster described the pipeline used to analyse the sequence data generated by our experiments and how the community can access the data. Blueprint is generating RNA-seq, ChIP-seq, DNase1-Seq and WGBS-seq data on several different blood cell types. This sequence data is aligned to the genome and and then appropriate signal calling analyses for the data type is undertaken. For the RNA-seq data expression levels are quantified, peaks are called for the ChIP-seq and DNase1-Seq data and the WGBS-seq has hypo- and hyper-methylated regions identified. We also perform some integrated analyses that include differental expression analysis and segmentation of the histone marks using ChromHMM. Blueprint releases new data regularly. On data release the raw sequence data and analysis alignments associated with the release are made available via the European Genome-phenome Archive (EGA) to users given permission by the Blueprint Data Access Committee (DAC). There are three primary mechanisms for release of the non-unique data types, such as expression levels, chromatin states and methylation levels. Our ftp site: (ftp://ftp.ebi.ac.uk/pub/databases/blueprint) holds the raw files and a Track Hub that can be associated with both Ensembl and the UCSC Genome Browser to allow easy visualisation of the data. This poster will primarily focus on these resources. We also provide a BioMart instance (http://blueprint.bsc.es/) to allow users to query the data and a Genomatix Browser (http://blueprint.genomatix.de/) for data visualisation. This Poster gives an overview of the Blueprint project as well as giving details of our analysis pipelines and information about data availability and accessibility for the project.

1682F

Exome sequencing identifies de novo mutations in patients with intellectual disability and epilepsy. *J. Halvardson, A. Zaghlool, AC. Thuresson, L. Feuk.* Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala University, Uppsala, Sweden.

Exome sequencing has proven to be an effective method to identify disease genes and have lead to the identification of causative genes in a large number of syndromes in recent years. Here we present the results of exome sequencing on 25 trios on a subset of patients with intellectual disability (ID), with additional symptoms of either epilepsy (19 trios) or congenital heart defects (6 trios). All trios have a negative family history and the parents are non-consanguineous. All patients have previously been screened for copy number aberrations using arrays, without clinically relevant findings.

We can report validated *de novo* single nucleotide variants (SNVs) or indels in coding regions in 11 of the 25 trios (44%). Of the 11 genes with validated *de novo* mutations, only two have previously been associated with ID or epilepsy (SCN2A and KCNA1). Thus, a high number of our findings are potentially novel disease genes. A subset of the genes have mouse knockout data that mirrors the patient phenotype, supporting a causative role for the *de novo* mutations. In one patient with severe ID we found a mutation in a highly conserved chromatin remodeling factor, which we are now following up with functional studies. This adds to a growing list of genes involved in chromatin remodeling that have been linked to intellectual disability and neurodevelopmental syndromes. The majority of the validated SNVs were missense mutations of conserved nucleotides in genes expressed in the brain. Several genes are involved in basic cell functions and we are currently investigating the possibilities of performing RNA sequencing on peripheral blood cells from trios to find patterns of expression in patients compared to healthy controls.

During this work we have created an in-house database of all sequenced exomes. This database contains several SNVs seemingly unique as compared to dbSNP, but common in the Swedish population. For example, when only counting SNVs present in 10 or more of the individuals sequenced in our trio project, about 14,000 of these SNVs are not occurring in the dbSNP database. Using this database as a filtering step leads to a significant reduction in the number of false positive SNV calls. Our data highlights the importance of a population specific filtering database when doing trio sequencing.

1683W

An ensemble genotyping approach for whole genome sequencing to reduce erroneous variant calls. *I.H. Lee[1], J.H. Park[1], Y. Choe[1], M.B. Neu[1], K. Lee[2], T. Hambuch[3], I.S. Kohane[1,2], R.C. Green[4], S.W. Kong[1], The MedSeq Project.* 1) Boston Children's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Illumina, Inc., San Diego, CA; 4) Brigham and Women's Hospital, Boston, MA.

Whole-genome sequencing (WGS) has been effective in identifying causal genomic variants of rare and common complex diseases as well as developing personalized treatment strategies. Accurate genotyping is essential to utilize genome sequence information in clinical settings as aimed by the MedSeq Project, a randomized clinical trial for integrating WGS in medicine. The current consensus is to sequence using multiple platforms to achieve the highest level of accuracy, then to validate all disease-associated variants for a clinical report using Sanger sequencing. In the course of exploring the plausibility of reducing erroneous variant calls in clinical settings, we deployed an ensemble of 8 variant calling algorithms to 17 publicly available paired WGS samples prepared using 2 different platforms. Our ensemble approach significantly reduced possible false positives by 48.8% for single nucleotide variants (SNVs), 50.5% for loss-of-function SNVs, 77.2% for small indels, and 96.4% for de novo mutation (DNM) candidates when we assumed higher false positive rates among platform-specific variants. Among 10 independently validated DNMs in the same trio dataset, 8 somatic or germline mutations were accurately detected by our proposed method compared to none by a pedigree-aware variant calling algorithm. Moreover, we could increase the sensitivity for detecting known disease-causing mutations by combining the results from each algorithm. Our results suggest that the use of multiple variant calling algorithms is a cost-effective way to reduce both false positive and false negative variant calls. The source code of our ensemble genotype calling approach is freely available to the academic research community.

1684T

Investigating the significance of genetic proximity for HLA matched donors and recipients in unrelated allogeneic stem cell transplantation. *A. Madbouly, V. Paunic, M. Maiers.* Bioinformatics Research, National Marrow Donor Program, Minneapolis, MN.

Survival after hematopoietic cell transplantation is dependent on HLA matching between donors and recipients, ethnicity and other factors, most of which are unknown. Donors and recipient ethnic origin is usually self-reported, and it is not clear if matching based on genetic ancestry would result in better survival. While an individual's genetic composition is relatively fixed, self-identified race and ethnicity (SIRE) is a result of self-perception and can change over time. We aimed to investigate the effect of multiple measures of pairwise donor/recipient (D/R) genetic distance, using ancestry informative markers (AIMs), on transplant outcome. The AIMs panel selected for this pilot study consists of 500 autosomal SNPs. DNA samples from 300 fully HLA matched D/R pairs were genotyped for AIMs and were initially clustered using Structure and the 1000 Genomes dataset for reference parental populations. A genetic vector distance was estimated based on the distance between the D/R Structure vectors (describing individual ancestral proportions) in Euclidean space. Additionally, principal component analysis (PCA) was performed on the D/R genotypes for mapping genetic variation and Euclidean distance between D/R pairs was calculated on the PCA map to reflect genetic proximity. While a plateau was not explicitly reached, the optimal number of Structure clusters was estimated at K=5 based on the ad hoc delta(K) measure. The average Euclidean distance between donor and corresponding recipient Structure vectors was 0.347 (range [0.001, 1.376], p = 1). For the PCA, the first, second and third PCs accounted for 3.7%, 1.5% and 0.9% of the total variance respectively. The average PCA distance based on the first, second and third PCs was estimated at 1.4 (range [0.017, 9.18], p = 0.02), 2.05 (range [0.06, 10.3], p = 0.29) and 2.66 (range [0.19, 10.52], p = 0.786). Additionally, the average PCA distance was higher for SIRE mismatched D/R pairs (for the first PC, mean = 2.6, range [0.06, 9.2], p = 0.015) than SIRE matched D/R (mean = 1.14, range [0.01, 5.9], p = 0.99). Further analysis is being conducted on Caucasian sub-populations within the studied D/R cohort and a multivariate transplant outcomes analysis is underway. A power analysis will be performed to estimate the cohort size needed for the second (larger) phase of this study. Genetic-ancestry based analyses are expected to decrease the effect of confounding factors associated with self-reported ethnicity.

1685F

Heterogeneity of global gene expression microarray designs in detecting differentially expressed genes. *G. Malerba[1], D. Noel[2], A. Ferrarini[2], L. Xumerle[1], V. Mijatovic[1], P.F. Pignatti[1], M. Delledonne[2].* 1) Department of Life and Reproduction Sciences, University of Verona, Verona, Italy; 2) Biotechnology Department, University of Verona, , Verona, Italy.

Microarray technology is widely used for gene expression studies by many laboratories worldwide. Microarrays vary for the type of substrate used and for the type and number of oligonucleotide probes implemented. Moreover a disparate list of procedures to subtract background noise (BS) and normalize data (DN) among samples is available. All these factors help to make these reliable tools quite heterogeneous and heterogeneity may play an important role in identifying or not the differentially expressed (DE) genes when conducting global gene expression studies. To address this issue we essayed 4 different microarray platforms to analyze two Vitis vinifera berry developmental stages. Microarray data were processed using 20 different BS-DN combinations. The same RNA samples were also analyzed by RNASeq whose results were used as reference values. Microarray performances in detecting DE were assessed using several measures including correlation between fold-change, classification functions and the area under curve (AUC) of receiver operating characteristic (ROC) curves. The number of DE genes changed from one microarray design to another. Although arrays are commonly deemed reliable tools for gene expression studies their performances are not all the same when conducting studies of differential gene expression.

1686W

Representation of Medical Variation at NCBI: ClinVar, Gene, and MedGen. *D. Maglott, M. Landrum, J. Lee, W. Rubinstein, K. Katz, W. Jang, D. Hoffman, S. Chitipiralla, M. Ovetsky, J. Garner, R. Tully, L. Phan, D. Shao, R. Maiti, R. Villamarin, S. Gorelenkov, S. Sherry, D.M. Church.* Natl Ctr Biotech Info, NIH/NLM, Bethesda, MD.

Genetics professionals need access to organized information about reported relationships among sequence variation, genes, and phenotype to translate advances in genomic technology into medical practice. This presentation summarizes how ClinVar, Gene, MedGen and related tools interoperate to centralize the data, standardize its representation, and facilitate access.

ClinVar aggregates and archives information about sequence variation and assertions made about its clinical significance. ClinVar reports the data in multiple ways to support both interactive queries and integration into workflows. For example, clinicians and researchers may search a DNA or protein location to learn what is known about the clinical significance of variation, both now and previously. Users can access the evidence for or against an asserted phenotype based on its level of expert curation, and how an interpretation may have changed over time. Expert panels and professional societies can also submit assertions about pathogenicity, e.g. in a practice guideline. Aggregation and centralization of variant data from diverse sources such as testing laboratories, genome-wide research and curatorial groups will reduce the burden on professionals who no longer need collate this information independently and enable them to perform an informed and comprehensive assessment.

NCBI's **Gene** database organizes information that defines or is related to a gene: sequence, phenotypes, citations, pathways, interactions, and variations. For example, the reference sequences section, especially the RefSeqGene, reports the sequence standards against which variation is reported. The phenotype section summarizes the names of disorders related a gene, and information about dosage sensitivity. The pathways and interactions sections report other genes with products that, based on their interactions, may contribute to the same phenotype.

MedGen organizes information about conditions such as clinical features, related genes, practice guidelines, ontologies, GeneReviews, OMIM, published literature, consumer resources, and tests registered in the NIH Genetic Testing Registry (GTR). Synonyms and term hierarchies support querying and navigation to related information. The advanced search option allows retrieval based on combinations of clinical features and other concepts, including existence of related sequence variation.

1687T

Meta-analysis of FMRP mRNA Target Datasets Reveals Highly Associated mRNAs Mediated by G-quadruplex Structures Formed by Clustered WGGA Sequences. *J. Suhl[1], P. Chopra[1], S. Warren[1,2].* 1) Dept. of Human Genetics, Emory University, 615 Michael St, Atlanta, GA; 2) Dept. of Biochemistry and Pediatrics, Emory University, Atlanta, GA.

Fragile X syndrome (FXS), a common cause of inherited intellectual disability and a well known monogenic cause of autism spectrum disorder (ASD), is the result of loss or dysfunction of the selective RNA-binding protein FMRP. Since FMRP appears to modulate activity-dependent translation of its target mRNAs at the synapse, a major research effort has been to identify these mRNA targets. Three large-scale studies have attempted to characterize the mRNAs bound by FMRP, each using different methods and each generating lists of putative target genes, leading to distinct hypotheses by which FMRP recognizes its targets either by RNA structure or RNA sequence. However, very little in depth analyses have been performed to identify the level of consensus among the studies. Here, we describe a meta-analysis of these three large-scale FMRP target studies. Consensus lists comprised of mRNAs found to consistently interact with FMRP among the independent methods were generated, conferring a higher likelihood of bona fide association. Additionally, we examined all datasets for sequence elements within the target RNAs to validate the recently reported FMRP binding sequences ACUK and WGGA. We discovered that the sequence WGGA was significantly enriched in multiple FMRP target datasets, supporting this motif as a strong candidate recognition sequence. Unlike WGGA, the ACUK pattern was not enriched in the datasets suggesting that this motif may not be directly recognized by FMRP. The strong enrichment of WGGA in FMRP targets, coupled with the previous suggestion that G-rich secondary structure serves as a recognition element, indicates that the motif may be able to form a G-quadruplex secondary structure. We observed that the WGGA motifs in the FMRP targets are highly clustered and are consistent with the requirements for the G-quadruplex configuration, thus implicating the involvement of both structure and sequence as recognition elements for FMRP. Our analysis identifies the mRNA targets most likely affected by the loss of FMRP and, consequently, the genes critical for neuronal development and synaptic plasticity.

Real-world performance of five long-range PCR enzymes to amplify ~10kb amplicons from human genomic DNA. *H. Jia, K. Wang.* Zilkha Neurogenetic Institute and Department of Psychiatry, Keck School of Medicine, University of Southern California, Los Angeles.

Long-range PCR remains a flexible,fast,efficient and cost-effective choice for sequencing candidate genomic regions or genes,especially when combined with personal genome sequencers such as MiSeq and Ion Torrent.-Several long-range DNA polymerases are available commercially, and all of them are advertised as being able to amplify up to 15kb or longer genomic DNA.Although it is likely that they may all work well for specific genomic regions under highly optimized conditions,it is unclear what are their real-world performance on randomly chosen amplicons in human genomic DNA. Knowing the different characteristics of these enzymes help select enzymes for use in next-generation sequencing experiments. In the current study,we evaluated five long-range DNA polymerases to amplify three amplicons, with sizes of 5.8kb, 9.7kb, 12.9kb and Tm values of 54.5 ºC, 63.3ºC and 54 ºC respectively.These five long-range polymerases include Invitrogen SequalPrep Long PCR and AccuPrime Taq DNA Polymerase, TaKaRa PrimeSTAR GXL DNA Polymerase, KAPA long Range HotStart DNA polymerase and QIAGEN LongRange PCR Polymerase.The advertised lengths of amplication for these enzymes are 15kb, 20kb, 30kb, 20kb and 40kb, respectively. All experiments were designed according to the reaction mixture and cycling conditions on the manual. We found that PrimeSTAR can amplify all the targets with good quality using two-step unified PCR conditions.SequalPrep and AccuPrime can amplify 5.8kb and 12.9kb but not 9.7kb amplicon,unless PCR conditions are optimized.KAPA can amplify 5.8kb but not the two larger amplicons using their recommended long targets (5kb-18kb) PCR reaction and cycling conditions.QIAGEN cannot amplify any of the three amplicons according to the manual's conditions for very long-range PCR.In practice, many amplicons may need to be amplified at the same time, but primer pairs for them may have very different Tm values.Therefore,we also varied the annealing conditions for selected enzymes, and evaluated how sensitive the enzymes are to alterations of the annealing temperature and extension time.The results indicate that PrimeSTAR polymerase can amplify amplicons with different sizes and Tm values using the same PCR conditions, but others enzymes require alteration of PCR conditions to obtain optimal performance.Our results provided a useful guide to other researchers working on next-generation sequencing of candidate genes or regions by long-range PCR reactions.

Next-Generation Sequencing and Novel Variant Determination in a Cohort of 86 Familial Exudative Vitreoretinopathy Patients. *J. Salvo[1,2], H. Wang[1,3], K. Wang[3], D. Nguyen[5], K. Zhang[5], R. Chen[1,2,3,4].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Structural and Computational Biology & Molecular Biophysics Graduate Program, Baylor College of Medicine, Houston, TX; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Program in Developmental Biology, Baylor College of Medicine, Houston, TX; 5) Department of Ophthalmology, School of Medicine, University of California, San Francisco, CA.

Background Familial exudative vitreoretinopathy (FEVR) is a developmental disease that can cause visual impairment and retinal detachment at a young age. Four genes involved in the Wnt signaling pathway were previously linked to this disease: NDP, FDZ4, LRP5, and TSPAN12. Identification of novel disease causing variants of this disease allows for a deeper understanding of the disease, better molecular diagnosis, and improved treatment.

Methods 86 patients of families with hereditary FEVR were examined in this study. We used a proprietary capture panel to enrich for 294 known or suspected retinal disease causing genes in humans. Samples were processed using next generation sequencing (NGS) techniques followed by data analysis to identify and classify single nucleotide variants and indels. Sanger validation and segregation testing were used to verify suspected variants. This is the largest study of a FEVR cohort utilizing NGS that we are aware of.

Results Of the cohort of 86, 47 patients were probably solved (55%). Of these samples, 34 were due to rare variants in known FEVR causing genes, 25 of which were novel. The remaining 13 patients were found to have possible disease causing variants in other retinal disease causing genes, including four variants with a high probability of causation (i.e. stop-gain, frameshift, or splicing site mutations).

Conclusions We were able to determine probable disease causing variants in a large number of FEVR patients, the majority of which were novel. Knowledge of these variants will help to further characterize and diagnose FEVR.

Evaluation of two commercial exome capture kits on the Ion Proton. *F. Gedge, C. Chan.* Biobank, Sanford Research, Sioux Falls, SD.

With an increasing interest in exome analysis for research and clinical diagnostics the number of exome capture kits are available on the market is increasing. The two most published and commonly used are the Agilent SureSelect and NimbleGen SeqCap EZ kits. More recently Life Technologies released their TargetSeq kit for use on the Ion Proton instrument. NimbleGen has adapted their kit for use on the Ion Proton, while Agilent has yet to release an Ion-compatible SureSelect kit. Therefore, we evaluated the Life Technologies TargetSeq and Nimblegen SeqCap EZ v3 kits for exome sequencing on the Ion Proton. Both kits are liquid-phase capture kits, contain about 2 million capture probes and cover greater than 20,000 of the known coding genes plus varying amounts of RNA genes, miRNA binding sites and UTRs. Due to differences in probe design, TargetSeq has a target region of 46.2Mbases whereas the SeqCapkit targets 64Mbases. We compared the performance of these kits on the Ion Proton in terms of capture ability and specificity, coverage of the intended targets and coverage density sufficient for mutation analysis. Exome captures were performed according to the manufacturer's instructions followed by sequencing on the Ion Proton with the P1 chip. Both kits were able to capture their intended targets fairly sufficiently with about 85% of sequence reads being on target and both kits covered more than 92% of their targets with 1x coverage or greater. The remaining target sequence is either not well captured or there is a PCR bias against them. In order for exome sequencing to reliably identify mutations the amount of target covered with at least 20x or higher is important. In this respect, the two kits differ. With the TargetSeq we can sequence greater than 86% with 20x coverage. The SeqCap runs consistently have significantly lower average coverage as well as lower 20x coverage. This difference is likely due to the fact that the SeqCap kit covers almost 40% more bases than the TargetSeq kit, therefore lowering the average coverage per base. Given the need for sufficient coverage, and the fact that current Ion Proton output is limited with the P1 chip, the TargetSeq kit is preferable. However, since the other performance characteristics are similar, the SeqCap kit can be a valuable kit when sequence output on the Proton instrument is improved in the future.

1691F

A single-tube high-plex PCR approach for targeted massively parallel sequencing applied to FFPE-tumour derived material. *T. Nguyen-Dumont[1], B.J. Pope[2,3], F. Hammet[1], M.C. Southey[1], D.J. Park[1].* 1) Genetic Epidemiology Laboratory, Department of Pathology, Medical Building, The University of Melbourne, Victoria 3010, Australia; 2) Victorian Life Sciences Computation Initiative, The University of Melbourne, 187 Grattan Street, Carlton, Melbourne, Victoria 3010, Australia; 3) Department of Computing and Information Systems, The University of Melbourne, Victoria 3010, Australia.

High-plex PCR, as a sequence enrichment method for massively parallel sequencing (MPS), has been made available recently through a range of commercial solutions. However, protocol complexity, expense, and limited design flexibility, reduce their suitability in settings involving modest target size, or requiring low cost and high-throughput. In addition, methods to sequence DNA extracted from formalin-fixed, paraffin-embedded (FFPE) material have achieved variable success so far.

To address these limitations, we have developed Hi-Plex, a PCR-MPS strategy intended for high-throughput screening of multiple genomic target regions. Our library-building approach integrates a simple, automated primer design software developed in-house, enabling control of product size. Featuring permissive, inclusive thermocycling conditions and 'clamp' amplification bias reduction, our protocol is simple due to its single-tube nature. It is also cost and time-effective, using readily available reagents, is independent from expensive instrumentation, and requires minimal optimisation.

In a 60-plex test setting, targeting the breast cancer predisposition genes *PALB2* and *XRCC2*, Hi-Plex applied to 100 ng LCL-derived DNA resulted in 93.33% (56/60), 98.33% (59/60), and 100% of targeted amplicons represented within 5-fold, 10-fold and 12.5-fold of the mean on-target coverage, respectively, despite a broad range of amplicon sequence contexts. 86.94% of the library that mapped to the whole human genome was on-target. When applied to 100 ng FFPE-derived DNA, Hi-Plex resulted in 78.33% (47/60), 91.67% (55/60) and 100% of targeted amplicons represented within 5-fold, 10-fold and 25-fold of the mean, with 97.33% of reads on-target. With 25 ng FFPE-derived DNA, Hi-Plex resulted in 90% (54/60), 98.33% (59/60) and 100% of targeted amplicons represented within 5-fold, 10-fold and 12.5 fold of the mean, with 95.14% of reads on-target.

Hi-Plex represents a powerful new approach for screening of panels of genomic target regions. The benefits of Hi-Plex have been demonstrated in the context of degraded FFPE specimens and low level input DNA, where sequencing data quality was not compromised. Hi-Plex is efficient, cost-effective, and can be used for high-throughput mutation screening both for research and for molecular diagnostic and clinical purposes.

PhenoTips: Patient Phenotyping Software for Clinical and Research Use. *M. Girdea[1,2], S. Dumitriu[1], M. Fiume[1], S. Bowdin[3,4,5], K. Boycott[6], S. Chénier[7], D. Chitayat[4,8], H. Faghfoury[9,10], M.S. Meyn[3,4,5,11,12], P.N. Ray[3,11,12,13], J. So[9,14], D.J. Stavropoulos[13,15], M. Brudno[1,2,11]*. 1) Department of Computer Science, University of Toronto, Toronto, Ontario, Canada; 2) Centre for Computational Medicine, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Paediatrics, University of Toronto, Ontario, Canada; 6) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa, Ottawa, Ontario, Canada; 7) Centre Hospitalier Universitaire de Sherbrooke, Quebec, Canada; 8) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 9) Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 10) University Health Network, University of Toronto, Toronto, Ontario, Canada; 11) Genetics and Genome Biology Program, Hospital for Sick Children, Toronto, Ontario, Canada; 12) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 13) Department of Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, Ontario, Canada; 14) Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 15) Department of Laboratory Medicine and Pathology, University of Toronto, Toronto, Ontario, Canada.

We have developed PhenoTips, a deep phenotyping tool and database, specifically designed for phenotyping patients with genetic disorders. Our tool closely mirrors clinician workflows so as to facilitate the recording of observations made during the patient encounter. Phenotypic information is represented using the Human Phenotype Ontology; however, the complexity of the ontology is hidden behind a user interface, which combines simple selection of common phenotypes with error-tolerant, predictive search of the entire ontology. The software provides a series of features that help reduce the clinician's workload during the clinical examination. Together with standardized phenotypic data, PhenoTips supports entering demographic information, medical history (including prior laboratory results), family history, various measurements, relevant images depicting manifestations of the patient's disorder, genetic tests and their results, as well as additional notes for each of these categories. A pedigree drawing tool which enables the collection of advanced family histories is currently under development. The software automatically plots growth curves for a variety of measurements, selects phenotypes reflecting abnormal measurements, instantly finds Online Mendelian Inheritance in Man (OMIM) diseases that most closely match the phenotypic description, and can suggest additional clinical investigations that can improve the diagnosis.

PhenoTips is already used both in research studies and in the clinic, including the phenotyping of patients for the FORGE (Finding Of Rare disease GEnes) Canada project (http://care4rare.ca/), and the Undiagnosed Disease Program at the NIH. Our source code and a demo version of PhenoTips are available at http://phenotips.org.

Sequencing single human and bacterial cells at low coverage for aneuploidy, CNV, and genotyping applications. *E. Kamberov, T. Tesmer, S. Yerramilli, J. Jessman, M. Carey, M. Carroll, J. Langmore.* Rubicon Genomics, Inc., Ann Arbor, MI.

Single-cell analysis by using PCR and array assays is well established for determining aneuploidy, CNV, and genotyping single cells. Next-gen sequencing of single cells presents many barriers to complete and reproducible analysis, including incomplete genome coverage and irreproducible results. In some applications the information from multiple single cell experiments can be combined to increase coverage and reproducibility. However a surprising number of applications can be successfully executed using partial coverage of the genome as long as the coverage is reproducible. These technical applications include a) aneuploidy and copy number variation determination, b) SNP or other single nucleotide variations in a fraction of the genome, and c) identification of complex populations of cells. These technical applications are important for commercial applications such as pre-implantation genetic screening and diagnosis (PGS and PGD), prenatal diagnostics from single or small numbers of fetal cells in maternal circulation, cancer diagnostics from circulating tumor cells, and identification of infectious disease. In these applications coverage can be compromised as long as the partial coverage in reproducible. We have sequenced human and bacterial cells using a version of the Rubicon PicoPLEX technology that is being developed as a single-cell NGS library kit. This PicoPLEX-scD single-cell NGS prep is as simple as the PicoPLEX WGA kit, which is currently used for microarray and PCR studies and diagnostics from single cells. The PicoPLEX-scD prototype kits were used for the above technical applications. Sequencing quality, genome coverage, and reproducibility were measured in flow sorted and microdissected human cells. To verify that the MiSeq NGS could be used for PGS/PGD applications, as many as 48 single human cells were multiplexed on a single lane. Megabase losses or gains of copy number were reproducibly measured with as few as 200,000 clusters per sample. Partial genotyping and variant identification using single cells were also measured. Finally, single cells were studied in mixtures of other genomes. The results show that reproducible incomplete coverage was achieved by NGS of PicoPLEX libraries, and that many of the requirements for diagnostics of single cells could be achieved with minimal numbers of sequencing reads.

Cis and trans protein quantitative trait loci (pQTLs) identified using a high-throughput protein assay in 297 individuals from the AddNeuroMed cohort: the European collaboration for the discovery of novel biomarkers for Alzheimer's disease.
J.E. Mollon[1,2], M. Sattlecker[1,2], S. Kiddle[1,2], C. Johnstone[1,2], K. Lunnon[1], P. Proitsi[1,2], J. Powell[1], A. Hodges[1,2], S.K. Nelson[3], A. Stewart[3], S. Williams[3], H. Soininen[4], I. Kloszewska[5], P. Mecocci[6], M. Tsolaki[7], B. Vellas[8], S. Lovestone[1,2], S. Newhouse+[1,2], R. Dobson+[1,2]. 1) Institute of Psychiatry, King's College London, London, United Kingdom; 2) NIHR Biomedical Research Centre for Mental Health and Biomedical Research Unit for Dementia at South London and Maudsley NHS Foundation Trust; 3) SomaLogic, Boulder, Colorado, United States of America; 4) Department of Neurology, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 5) Medical University of Lodz, Lodz, Poland; 6) Institute of Gerontology and Geriatrics, University of Perugia, Perugia, Italy; 7) 3rd Department of Neurology, Aristotle University, Thessaloniki, Greece; 8) INSERM U 558, University of Toulouse, Toulouse, France.

There has been much success in identifying gene expression quantitative trait loci using high-throughput gene expression measures such as array-based methods or sequencing (RNA-Seq), but high-throughput methods for quantifying proteins are not as widely available. In this study we use an aptamer-based protein assay from SomaLogic which quantifies over a thousand proteins from a single sample. Samples from 106 individuals with Alzheimer's Diseases (AD), 90 with mild cognitive impairment (MCI) and 101 healthy elderly controls were selected from the AddNeuroMed study. Genotyping and imputation resulted in 6,345,198 SNPs for analysis, and a total of 1016 aptamers targeting 1001 proteins were assayed in plasma from the same individuals. We applied regression models using QUICKTEST, measuring single-SNP effects after adjusting for age, gender and 5 genetic principle component axes. A Bonferroni threshold was applied ($p<4.93\times10^{-11}$), adjusting for multiple SNPs and proteins. Significant associations were further modelled in R, adjusting for original covariates as well as disease status and a single PC axis derived from the protein data. New associations with 87 proteins were discovered, and we replicated results from a previous study with overlapping samples. Twelve of the new associations were 'cis', defined as SNPs within the coding region of a gene associated with that gene's protein product. A further 14 proteins were associated with SNPs outside the protein-coding gene but on the same chromosome. Sixty-one proteins had associations with SNPs on different chromosomes ('trans'). The top cis association was between MSP and rs3197999 (3.83×10^{-74}), a SNP in the third intron of MST1, the gene encoding MSP. This SNP is predicted damaging in an alternate transcript of MST1, and has been associated with Crohn's Disease, ulcerative colitis and primary sclerosing cholangitis. The top trans association was between MMP8 and rs12614 (p=2.88x10-70), a non-synonymous (predicted damaging) SNP in FBI12 (an alternate splice variant of CFB). We will describe properties of variants we have found to associate with protein plasma levels and highlight those previously identified as being disease related through GWAS studies. We conclude that the study of genetic effects on intermediary phenotypes such as proteins yields promising results, and may allow us to begin to unravel the mechanisms through which genetic effects manifest in disease.

1695T

Non-additive effects of genes in human metabolomics.
Y.A. Tsepilov[1,2], J.S. Ried[3], C. Gieger[3], K. Strauch[3,4], S. Shin[5,6], N. Soranzo[5], T. Spector[7], Y.S. Aulchenko[1]. 1) Institute of Cytology and Genetics SD RAS, Novosibirsk, Russia; 2) Novosibirsk State University, Novosibirsk, Russia; 3) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 4) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Genetic Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 5) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom; 6) MRC University of Bristol Integrative Epidemiology Unit (IEU), Bristol, United Kingdom; 7) Department of Twin Research and Genetic Epidemiology, King's College London, St Thomas' Hospital, London, United Kingdom.

Genome-wide association studies (GWAS) are widely applied to analyze the genetic effects on phenotypes. In most GWAS the SNP effects are assumed to be additive. The applied models have a lower power to detect non-additive effects (such as recessive, dominant, over-dominant). Therefore, the systematic analysis of non-additive effects can lead to the identification of additional SNPs. Moreover, the knowledge of the underlying SNP effect can be important for a more complete understanding of the genetic determination. Large-scale GWAS on metabolite concentrations and ratios assuming additive SNP effects have revealed several loci. In this study we analyzed a large panel of metabolites with a more general model that covers additive as well as non-additive SNP effects. Serum metabolites and genome-wide SNP data of the population-based cohort KORA F4 (N=1,744) were used for discovery. We calculated GWAS on 151 metabolite concentration, as well as all possible ratios of concentrations (total 22,801 traits) using a two degrees of freedom model (genotypic model). Seventeen loci were found to be genome wide significantly associated (Bonferroni corrected p-value $\leq 2.19\times10^{-12}$) with at least one metabolite (ratio). For each of these loci the four models assuming different SNP effects (additive, dominant, recessive, over-dominant) were tested and the results were compared. For five SNPs a non-additive effect model had the best results (for three the genotypic model was the best, for one the dominant and for one the over-dominant). The additive model was not significant for three of them. In the next step, we replicated these findings using independent TwinsUK study (N=846). The study demonstrated that additional SNPs can be identified with the usage of non-additive SNP effects. The presented strategy of using the genotypic model can increase analysis power and the potential to uncover additional loci involved in the control of human traits.

1696F

Integrating population genetic and functional genomic resources for accurate prediction of deleterious protein-altering variants.
P.J. Walter, M. Sampson, H.M. Kang. Biostatistics, University of Michigan, Ann Arbor, MI.

As a wealth of genomics resources becomes available across multiple species, populations, and tissues, an important area of research will consist of answering the question of how best to leverage this complementary information to unravel the etiology of disease traits. Currently there are many different methods to predict conserved elements through multiple sequence alignment and methods to predict functional impact of a protein-altering mutation. In addition, rapidly increasing amount of population-scale sequencing data allows to estimate the level of selection across human population, providing additional information on top of existing functional resources. These resources can then be integrated to prioritize variants that are likely to be causal in gene-level rare variant tests and post-hoc functional analysis.

Here we integrated existing conservation metrics such as PhyloP and GERP++ scores, predicted functional scores of protein-altering variants including SIFT and Polyphen2, using a support vector machine (SVM) approach trained by known pathogenic and non-pathogenic variants deposited in dbSNP and HGMD to collapse predict the likelihood that a mutation is deleterious. Our integrated variant score predicts the functional impact not only of existing variants, but also of every potential allele (>80 million) of protein-altering single nucleotide variant (SNV) that can be annotated by the latest GenCODE database. Using cross-validation, we estimate that our integrated variant score prioritizes 44.4% of known pathogenic variants over variants observed in 1000 Genomes within top 5% quantile, which is 4.01 and 1.52-fold higher than what could be predicted by GERP++ and Polyphen2 scores, respectively. We demonstrate that novel the variants shown to cause Mendelian forms of rare diseases have strong enrichment of high integrated variant score. In addition, we show that using this integrated variant score as a filter in gene-level burden tests can substantially improve power to identify causal genes, compared to the widely used approach relying on minor allele frequency.

1697W

Mixed model approaches for transcriptome profiling of reciprocal dosage imbalances. *A. Ragavendran[1], I. Blumenthal[1], S. Erdin[1], L. Klei[4], K. Roeder[5], B. Devlin[4,5], M.E. Talkowski[1,2,3].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Departments of Neurology and Genetics, Harvard Medical School, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 5) Department of Statistics, Carnegie Mellon University, Pittsburg, PA.

Methods for analysis of RNA-Seq data are still in a nascent stage of development. Current packages for analyzing differential expression (DE) are developed primarily to accommodate low replication and simple designs. Few methods have been established to model family-based designs. We present some insights from ongoing statistical analysis of RNA-Seq count data associated with reciprocal dosage imbalances, which collectively represent a major source of genetic risk for neurodevelopmental disorders. We analyzed data from two parallel study designs: a family based study from multiplex autism families harboring a 16p11.2 deletion or duplication, and mouse models deleted or duplicated for the syntenic region. Counts generated with RNA-Seq are over-dispersed, thus modeled with negative binomial GLMs (nbGLMs). Analysis of ERRC transcripts (synthetic spike-ins) showed that nbGLM was the best-fit model relative to Poisson or quasi-Poisson fits. This implies the process from sequencing to quantitation introduces additional sources of variance independent of biological variation, which bears further investigation. Of 37 ERCC transcripts in mouse, we detected significant DE (p-value < 0.0001) in 35 transcripts among 3 groups of fold-change (FC) (min conc. 7.5 amols/μl), with the least power in the 0.68 FC group (min conc. 14.6 amols/μl). For statistical inferences in family-based designs, correlations due to shared genetic background are accommodated with mixed effects models, which current packages don't handle. Generalized Linear Mixed Models (GLMMs) are a natural extension to GLMs and we use the *pedigreemm* package in R to fit GLMMs on a gene-by-gene basis. We adopt a Poisson-lognormal GLMM and include random effects for family, while correlations between family members are modeled from pedigree-based estimation of relatedness. We show that two complementary models represent a reasonable approach to study effects of reciprocal dosage imbalance in the genome. The first is to evaluate the effects of deletion/duplication using a regression on the copy number for linear trends in DE. The second is to fit contrasts within a cell-means model to delineate effects specific to loss or gain of function. In both systems, the models capture dysregulation of most genes within the 16p11.2 region from dosage compensation due to copy number state. Inference for GLMMs is an ongoing area of research and we explore randomization procedures to generate empirical p-values.

1698T

Statistical inference of eQTL sharing among many tissues. *T. Flutre[1], X. Wen[2], J. Pritchard[1,3], M. Stephens[1,4].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Biostatistics, University of Michigan Ann Harbor, Ann Harbor, MI; 3) Howard Hughes Medical Institute, Chevy Chase, MD; 4) Statistics, University of Chicago, Chicago, IL.

Using gene expression as intermediate phenotype is now a common approach to interpret associations between genetic variants and organismal phenotypes. Until recently, most studies were performed on a single tissue or cell-type sampled in a hundred individuals. Statistical methods were improved so as to now robustly detect genetic variants associated with changes in gene expression (eQTLs). As typical effect sizes are weak, several recent studies analyzed up to one thousand individuals, showing that most genes have at least one eQTL. However, interpretation of such associations is hampered by the fact that easy-to-sample tissues may often be irrelevant to the etiology of organismal phenotypes of interest. This prompted the NIH to fund the 'genotype - tissue expression' pilot project (GTEx) aiming at building the largest, tissue-wide eQTL data resource to date.

In prevision of such a data set, we recently developed a statistical framework to detect eQTLs with high power by jointly analyzing multiple tissues, and to reliably infer the proportion of tissue-consistent and tissue-specific eQTLs (Flutre *et al*, 2013). As part of the GTEx consortium, we applied our model on the current data set of 9 tissues from 100-200 individuals. This analysis, done in close collaboration with other groups in the consortium, is planned to be presented in the GTEx session.

However, most current methods are unable to efficiently cope with the larger number of tissues that will be available in the future. The reason stems from the use of 'configurations', binary vectors representing activity patterns of eQTLs among tissues. Indeed, a data set of 20 tissues generates 2^{20} configurations (> 10^6). Instead of considering each of them, our improved model learns only the subset of configurations present in the data. Moreover, we don't restrict ourselves anymore to genes expressed in all tissues, by directly analyzing gene expression in terms of read counts. The results obtained with this new model will be presented on the 9 tissues comprising the current GTEx data set. To alleviate the need for permutations in such large-scale studies, we also developed an efficient, yet conservative procedure to control the Bayesian FDR, and evaluate it rigorously by doing permutations.

1699F

A genome-wide assay for regulatory functional potential of sequence variants. *J.M. Peralta[1,3], J. Blangero[1], L.J. Abraham[2], E. Moses[3].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX, USA; 2) School of Chemistry and Biochemistry, University of Western Australia, WA, AU; 3) Centre for Genetic Origins of Health and Disease, University of Western Australia, WA, AU.

DNase I hypersensitivity sites (DHSs) are the result of chromatin remodeling processes that create openings in the chromatin which expose the DNA to digestion by DNase I. A considerable proportion, 34-88%, of the disease-associated variants detected by GWAS studies appear to cluster in DHSs. Here we propose that non-coding variants can have a cis-functional effect that changes the local sensitivity to DNase I, which can be detected in heterozygotes as allele-specific DHSs. This would suggest a potential regulatory role for a variant, since DHSs often correlate with cis-located elements that regulate the expression of a gene, like promoters and transcription binding sites. We call this effect the functional potential (FP) of a variant and we define it for a SNP as a significant deviation from the expectation of equal allele depth coverage at DHSs. To test our approach we selected a 2842123 SNP reference panel (RSNP) from SNPs with heterozygous genotypes in Illumina's Platinum Genomes WGS from sample NA12878. We then measured allele-specific genome-wide chromatin accessibility using mpileup from samtools to call SNPs using the short sequencing reads (reads) obtained from DNase-seq mapped DHS reads from five GM12878 lymphoblastoid cell line replicates (R1-R5) for NA12878 released by the ENCODE Project. The read depth of the two alleles (from the DP4 annotation) at each SNP was used to estimated the FP for a total of 54533 variants (46652 distinct SNPs) that were called from DHSs-mapped reads from all replicates that intersected with RSNP. There was large variation in the number of SNPs called per replicate (mean=10907, sd=6065) and little overlap between replicates (3.6% SNPs, n=1675, seen in > 2 replicates). This was expected due to the short read lengths (20bp) and low read coverage at DHSs (mean= 6.32, min=1, max=1195). Nevertheless, we found that the FP estimates for a SNP were well correlated between the replicates where it was seen (mean r=0.88, sd=0.09). We focused on the set of SNPs overlapping more than 2 replicates and observed significant ($p<9.16\times10^{-7}$) FP estimates for 6.9% (n=116) after correcting for multiple testing. These SNPs showed a very strong allele-specific bias in coverage (95.1% on average), within high-coverage DHSs (mean=170, min=18, max=1195), that was consistent across five replicates. These results suggest that our FP approach is feasible and that it can potentially use other measures of regulatory activity (MNase and FAIRE-seq).

Many disease-associated variants affect gene expression levels (expression quantitative trait loci, eQTLs) and expression profiling using next generation sequencing (NGS) technology is a powerful way to detect these eQTLs. We analyzed 94 total blood samples from healthy volunteers with DeepSAGE to gain specific insight into how genetic variants affect the expression of genes and lengths of 3'-untranslated regions (3'-UTRs). We detected previously unknown *cis*-eQTL effects for GWAS hits in disease- and physiology-associated traits. Apart from *cis*-eQTLs that are typically easily identifiable using microarrays or RNA-sequencing, DeepSAGE also revealed many *cis*-eQTLs for antisense and other non-coding transcripts, often in genomic regions containing retrotransposon-derived elements. We also identified and confirmed SNPs that affect the usage of alternative polyadenylation sites, thereby potentially influencing the stability of messenger RNAs (mRNA). We then combined the power of RNA-sequencing with DeepSAGE by performing a meta-analysis of three datasets, leading to the identification of many more *cis*-eQTLs. Our results indicate that DeepSAGE data is useful for eQTL mapping of known and unknown transcripts, and for identifying SNPs that affect alternative polyadenylation. Because of the inherent differences between DeepSAGE and RNA-sequencing, our complementary, integrative approach leads to greater insight into the molecular consequences of many disease-associated variants.

The association of urinary Interferon inducible protein-10 levels with kidney allograft rejection. *S. Firasat[1], A. Raza[1], A. Abid[1], T. Aziz[2], M. Mubarak[3], S.A.A. Naqvi[2], S.A.H. Rizvi[2], S. Khaliq[1,4], S.Q. Mehdi[1].* 1) Centre for Human Genetics and Molecular Medicine, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; 2) Department of Urology, (SIUT), Karachi, Pakistan; 3) Department of Histopathology, (SIUT), Karachi, Pakistan; 4) Department of Human Genetics, University of Health Sciences (UHS), Lahore, Pakistan.

Abstract: Interferon-gamma inducible protein-10 (IP-10) is a chemokine secreted by immune and non-immune cells. IP-10 and its receptor CXCR3 have been shown to participate in the immune response against kidney allograft. We aimed to investigate the association of urinary IP-10 levels with rejection episodes in renal transplant patients during the first year post transplant. A total of 206 samples were included in this study. Of these, 118 samples were taken from 93 renal transplants recipients with various histopathological findings of rejection (acute cellular ACR, borderline BLR and acute vascular rejection AVR) and of no-rejection episodes (NAD). Additionally, 88 urine samples were also collected from 88 controls (renal donors). Urinary IP-10 levels were quantified by using the Human CXCL10/IP-10 Quantikine ELISA kit. The data were analyzed using the Statistical Package for Social Sciences (SPSS) and MedCalc software. Statistically significant differences in the urinary IP-10 levels were found between rejection and control groups (p=0.000) and rejection vs. NAD group (p=0.004) groups. Among rejection groups, the mean IP-10 levels for ACR, BLR and AVR were 256.8±52pg/mL, 196±110pg/mL and 113±54pg/mL respectively. The statistical significant difference for IP-10 was found between ACR vs. NAD group (p=0.001) and ACR vs. BLR (p=0.019). ROC curve analysis showed a significant difference in rejection vs. NAD (p=0.004) and rejection vs. control (p=0.0001). At a cutoff value of 8.5pg/mL, the area under roc curve (AUC) was 0.87 with a sensitivity and specificity of 82.3% and 78.4% respectively. However, rejection vs. NAD showed p=0.0013 with 71.8% sensitivity and a 64% specificity at a cutoff value of 27pg/mL and the AUC was 0.70. Renal graft-survival among different urinary levels of IP-10 showed a significant difference in the mean time of graft survival between <100pg/mL and >200pg/mL (9.26±1.1 vs. 3.7±1.0 weeks; log rank p=0.000) and 100-200pg/mL (9.26±1.1 vs. 3.3±0.8 weeks; log rank p=0.017). The results indicate an increased level of IP-10 in the urine of allograft rejection samples that had different histopathological findings.

1702F

A General Statistic Framework for Identifying Genetic Variants of Clinical Significance. *L. Ma, M. Xiong.* University of Texas School of Public Health, Houston, TX.

Fast and cheaper next generation sequencing (NGS) technologies will generate unprecedentedly massive (thousands or even ten thousands of individuals) and highly-dimensional (up to hundreds of millions) genomic and epigenomic variation data. In the near future, a routine part of medical record will include the sequenced genomes. A fundamental question is how to efficiently extract genomic and epigenomic variants of clinical utility which will provide information for optimal wellness and interference strategies. Traditional paradigm for identifying variants of clinical validity is to test association of the variants. However, significantly associated genetic variants may or may not be usefulness for diagnosis and prognosis of diseases. Alternative to association studies for finding genetic variants of predictive utility is to systematically search variants that contain sufficient information for phenotype prediction. To achieve this, we introduce concepts of sufficient dimension reduction (SDR) and coordinate hypothesis which project the original high dimensional data to very low dimensional space while preserving all information on response phenotypes. We then formulate clinically significant genetic variant discovery problem into sparse SDR problem and develop algorithms that can select significant genetic variants from up to or even ten millions of predictors with the aid of dividing SDR for whole genome into a number of sub-SDR problems defined for genomic regions. The sparse SDR is in turn formulated as sparse optimal scoring problem, but with penalty which can remove row vectors from the basis matrix. To speed up computation, we apply the alternating direction method for multipliers to solving the sparse optimal scoring problem which can easily be implemented in parallel. To illustrate its application, the proposed method is applied to simulation data and the NHLBI's Exome Sequencing Project (ESP) dataset as well as the TCGA dataset.

The n=1 problem in human genetics: identification of rare disease mutations from single genomes. *A.B. Wilfert[1], J.N. Constantino[2], D.F. Conrad[1].* 1) Genetics, Washington Univeristy in St. Louis, St. Louis, MO; 2) Psychiatry, Washington University in St. Louis, St. Louis, MO.

Autism and azoospermia are examples of reproductively lethal diseases with a large population prevalence (about 1%) and extensive genetic heterogeneity (at least 500-1000 genes each). Standard epidemiological methods have begun to falter in the genetic analysis of these traits as cohorts of realistic size will contain many individuals with private, causal mutations that cannot be pinpointed by GWAS or linkage. Likewise, it has been estimated that over 40% of Mendelian disorders remain undiagnosed, which is in part due to sample size limitations. The purest presentation of these challenges is called the 'n=1' problem: given a single genome with a suspected monogenic disease phenotype, can one identify the causal mutation? We have created the first statistical framework that explicitly addresses the n=1 problem. This is an integrative framework that relies heavily on published data sets to consider gene physiology, functional protein-level models and patterns of population genetic variation to model disease and healthy variation. We use variants from the Human Gene Mutation Database (HGMD) and the 1000 Genomes Project to train and test these models. Spike-in analyses show that over 80% of the HGMD variants tested have been prioritized into the top 10 variants within a typical healthy exome and ROC curves show that this integrated prioritization method outperforms each of its component predictors, with an AUC of 0.990. For over 100 Mendelian diseases, each with an average of 5 distinct mutations in HGMD, our method correctly identifies the causal mutation as the most pathogenic event within an otherwise healthy exome, indicating that, in principal, our method solves the n=1 problem for these diseases. We describe applications of this method in two unique cases of autism and azoospermia, identifying candidate mutations in each of these cases, where the genetic etiology was previously unknown. We apply our method to describe the distribution of the most pathogenic mutation detected in 1000 healthy individuals sequenced by the 1000 Genomes Project. We discuss the complications of applying n=1 methodology in the presence of somatic mutation, which may be mistaken as germline variants when sequencing primary cells. While the number of developmentally acquired somatic mutations detectable in a given tissues may be small (e.g. 30-300) we show that these are much more likely to be appear pathogenic than germline variants by pathogenicity assessment tools.

Tamimi[1,15], Markers of Density (MODE) consortium.* 1) Program in Molecular and Genetic Epidemiology, Department of Epidemiology , Harvard School Of Public Health, Boston, MA, USA; 2) Centre for Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK; 3) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 5) Hormonal and Reproductive Epidemiology Branch, National Cancer Institute, Rockville, MD; 6) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, School of Population Health, The University of Melbourne, Melbourne, Australia; 7) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI; 8) Faculty of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, UK; 9) Centro Nacional de Investigaciones Oncologicas, Madrid, Spain; 10) Department of Health Sciences Research, Mayo Clinic, Rochester, MN, USA; 11) Erlangen University Perinatal Center, Department of Gynaecology and Obstetrics, Erlangen University Hospital, Friedrich Alexander University of Erlangen-Nuremberg, Erlangen, Germany; 12) Cancer Epidemiology Centre, Cancer Council Victoria, Melbourne, Australia; 13) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN, USA; 14) Campbell Family Institute for Breast Cancer Research, Ontario Cancer Institute, Toronto, Ontario, Canada; 15) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA.

Mammographic density reflects the proportion of stromal and epithelial tissues in relation to adipose tissue in the breast and is one of the strongest risk factors for breast cancer. Mammographic density phenotypes are defined by the area of a mammogram that consists of stromal and epithelial tissue (dense area), adipose tissue (non-dense area) and the proportion of stromal and epithelial tissue in relation to total breast area (percent density). Mammographic density has been shown to have high but poorly understood heritability. We have previously conducted a genome-wide association study (GWAS) of percent density within the MODE consortium and identified common genetic variants in the breast cancer susceptibility gene ZNF365 to be associated with percent mammographic density. Here we report results from an extended GWAS of percent density as well as the first GWAS of dense area and non-dense area. In the discovery phase, we conducted a meta-analysis of 12 GWAS of percent density, dense area, and non-dense area in more than 7,300 women of European descent. Ten of the studies used linear regression treating the mammographic density phenotype as a quantitative trait adjusting for age, body mass index (BMI) and menopausal status. Two studies selected women based on the extreme categories of mammographic density (one using percent density and the other dense area) adjusted for age, BMI and menopausal status. A total of 205 SNPs that were associated with at least one density phenotype at a significance level of P10-4 were selected for replication in 5,000-8,300 women independent from our discovery phase. We identified novel genome-wide significant ($P<5\times10^{-8}$) loci for percent density at 5q23.2, 8p11.23 and 22q13.2, loci for dense area at 4q13.3, 6q25.1, 10q21.2, 12q23.2 and 22q13.1, and a locus for non-dense area at 8p11.12. Three of these regions have been identified as breast cancer susceptibility loci. In summary, we report novel associations between common genetic variation and three mammographic density phenotypes. Many of the genetic variants found to be associated with mammographic density are also associated with breast cancer supporting the hypothesis that there is a shared genetic basis between mammographic density and breast cancer risk.

Significant Role of Combined Alleles of Hormonal Receptors and Hepatocanalicular Transporter Gene in Susceptibility to Cholesterol Gallstone Disease. *A. Srivastava, A. Mishra, B. Mittal.* Genetics, SGPGIMS, Lucknow, India.

Rationale: Cholesterol gallstone disease (CGD), one of the commonest digestive ailments in westernized and developing countries, is caused by a range of cholesterol flush and supersaturation insults. Although this multifactorial disease involves complex interactions among environmental and genetic factors but apart from female gender and increasing age, very little is known about the genetic interactions underlying the phenotypic expression of CGD. Therefore, one or more variations in genes could play critical roles in the diverse pathways which can further progress to cholesterol crystallization in gallbladder. In the present study, we performed multigene interactive analysis as genotyping score, Multifactor dimensionality reduction (MDR) and Classification and Regression Tree analysis (CART) to identify combinations of alleles among the hormonal, hepatocanalicular transporter and adipogenesis differentiation pathway genes in modifying the risk for CGD. Design: The present study recruited a total of 450 subjects including 230 CGD patients and 220 healthy controls who completed an interview and provided blood. The study was approved by the local ethical committee and we followed the norms of Declaration of Helsinki. We analyzed common ESR1, ESR2, PGR, ADRB3, ADRA2A, ABCG8, SLCO1B1, PPARγ2, and SREBP2 gene polymorphisms to find out combinations of genetic variants contributing to CGD risk. Genotyping was carried out by PCR-RFLP, ARMS-PCR and Taqman Assay. Statistical analysis was performed by using SPSS ver16 Results: Single locus analysis by logistic regression showed positive association of ESR1 IVS1-C397T (rs2234693), IVS1- A351G (rs9340799), PGR I/D (rs1042838), ADRB3- T190C (rs4994), ABCG8 G145C (rs11887534), SLCO1B1 CExon4A (rs11045819) and SREBP2 G1784C (rs2228314) with CGD risk. However, the MDR and CART analysis revealed ESR1 IVS1- C397T (rs2234693), ADRB3- T190C (rs4994) and ABCG8 G145C (rs11887534) polymorphisms as the best polymorphic signature for discriminating between cases and controls. The overall odds ratio for the applied multi-analytical approaches ranged from 4.33 to 10.05 showing an incremental risk for cholesterol crystal formation. Thus, the CART and MDR analyses also showed the importance of ESR1 IVS1- C397T and ABCG8 G145C polymorphism in susceptibility to CGD risk Conclusion: Our multigene interactive analysis suggests that ESR1, ADRB3 and ABCG8 genetic variants confer significant risk for cholesterol gallstone disease.

1706W

Bivariate heritability analyses of cardiac conduction and repolarisation measures show a paucity of shared genetic influences. *J. Alghamdi[1], C. Hastie[1], C. Schulz[1], C. Brown[1], L. Hocking[2], M. Luciano[3], D. Porteous[4], A. Morris[5], B. Smith[5], A. Dominiczak[1], S. Padmanabhan[1].* 1) College of Medical, Veterinary and Life Sciences, University of Glasgow, Institute of Cardiovascular and Medical Sciences, Glasgow, UK; 2) Aberdeen Pain Research Collaboration (Musculoskeletal Research), University of Aberdeen, Aberdeen, UK; 3) Centre for Cognitive Ageing and Cognitive Epidemiology, University of Edinburgh, Edinburgh, UK; 4) Medical Genetics Section, Molecular Medicine Centre, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK; 5) Medical Research Institute, University of Dundee, Dundee, UK.

Genome wide association studies have shown predominantly concordant effects for SNPs associated with ECG conduction traits with shared physiologic processes (PR interval(PR) and QRS duration (QRSd)) and mostly discordant effects between traits that reflect different processes (QRSd and QT interval(QTc)). However, these SNPs explain a small fraction of the population variance. To estimate the proportion of shared genetic influences among ECG cardiac conduction and repolarisation measures we performed bivariate heritability in a large cohort of Scottish families. **Methods:** The Generation Scotland Scottish Family Health Study is a nationwide cohort of families with participants recruited between 2006 and 2011. Digital ECG data were coded at the University of Glasgow ECG Core Laboratory. Exclusion criteria were- use of QT prolonging medications at least two months prior to recruitment (n=619; 3.4%), QRSd>120ms, atrial fibrillation or pacemaker. 13,722 individuals (5,082 families) were included in the analyses. Univariate and bivariate heritabilities were calculated using ASREML adjusted for age and sex. **Results:** The study population included 13,722 individuals (5,082 families). The mean age was 47 (SD ±15) years, QTc 411±23 ms, QRSd 230±90.1 ms P-duration(Pd): 106.1±14.2 ms and PR 162±25.1 ms. The age- and sex-adjusted heritabilities were: QRSd - 0.38(0.02), QTc- 0.39(0.02), Pd- 0.15(0.02); PR- 0.37(0.02) (all P<0.01). Bivariate heritabilities were QRSd/QTc: 4.3%, QTc/PR: 0.1%, QRSd/PR: 5.7%, QRSd/Pd: 20%, QTc/Pd: 1.7%, PR-Pd- 19.1%. Shared genetic factors account for only 1%, 1.1% and 0.5% respectively of the phenotypic correlations - QRSd/Pd (corr=0.049), QRSd/QTc (0.254) and QRSd/PR(-0.097). **Conclusions:** Majority of the genes influencing QTc, QRSd and PR heritabilities are specific for each trait with very few genes common to them. This suggests the presence of other undiscovered variants underlying these traits.

1707T

A signal of polygenic inheritance from low frequency variants in case-control genome wide association studies elucidates genetic architecture of common diseases. *Y. Chan[1,2,3], E.T. Lim[1,2,4], N. Sandholm[5,6,7], A.J. McKnight[8], S. Ripke[2,4], M.J. Daly[1,2,4], B.M. Neale[2,4], R.M. Salem[1,2,3], J.N. Hirschhorn[1,2,3].* 1) Department of Genetics, Harvard Medical School, Boston, Massachusetts, United States of America; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, United States of America; 3) Department of Endocrinology, Children's Hospital Boston, Boston, Massachusetts, United States of America; 4) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Massachusetts, United States of America; 5) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, Helsinki, Finland; 6) Division of Nephrology, Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland; 7) Department of Biomedical Engineering and Computational Science, Aalto University, Espoo, Finland; 8) Nephrology Research, Centre for Public Health, Queen's University of Belfast, Belfast, United Kingdom.

In most complex traits and diseases, much of the heritability remains unaccounted for by common variants discovered from genome-wide association studies (GWAS). Thus it has been postulated that rare and low-frequency variants are likely to play a role in accounting for the remaining heritability. To test this hypothesis, we developed a novel method to test for polygenic inheritance specifically from low-frequency and rare variants from GWAS summary statistics. Our method utilizes the fact that there is more power to detect risk than protective variants especially for variants at lower frequencies. This would result in a higher than expected ratio of risk to protective (R/P ratio) variants at a given P-value threshold. We tested our method on published GWAS results in various complex diseases and observed signals consistent with polygenic inheritance from low-frequency variants in type 2 diabetes, schizophrenia and major depressive disorder, but not in bipolar disorder. We also used our method to explore the shared genetic component in overlapping phenotypes related to inflammatory bowel disease (Crohn's disease (CD) and ulcerative colitis (UC)) and diabetic nephropathy (macroalbuminuria and end stage renal disease (ESRD)). The signal from polygenic low-frequency variants was present in both CD and UC, and an attenuated signal persisted when both phenotypes were jointly analyzed, suggesting that although both phenotypes have distinct genetic components, they also share low frequency variants that contribute to a common genetic component in both diseases. Interestingly, while we observed a polygenic signal from low-frequency variants in both macroalbuminuria and ESRD, the signal was lost when the phenotypes were jointly analyzed, suggesting that the genetic variants underlying these two apparently related phenotypes may not overlap substantially, and that both subphenotypes should be studied separately. Thus, our method may help guide the design of future genetic studies of dichotomous traits and diseases.

1708F

Identification of 6 novel type 2 diabetes susceptibility loci using genome-wide association studies imputed from a 1000 Genomes (June 2012) reference panel. *I. Prokopenko[1], C. Ma[2], A.P. Scott[2] on behalf of DIAGRAM+ consortium.* 1) Department of Genomics of Common Disease, Imperial College London, London, United Kingdom; 2) Center for Statistical Genetics and Department of Biostatistics, University of Michigan, Ann Arbor, Michigan 48109-2029, USA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 4) Department of Biostatistics, Boston University School of Public Health, Boston, Massachusetts, MA 02118, USA; 5) Department of Epidemiology, Erasmus MC, Rotterdam, The Netherlands; 6) Department of Nutrition, Harvard School of Public Health, Boston, MA 02115, USA; 7) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD 21209, USA; 8) Department of Clinical Sciences, Diabetes and Endocrinology, Lund University and Lund University Diabetes Centre, CRC at Skåne University Hospital, Malmö, Sweden; 9) Diabetes Research Centre, Biomedical Research Institute, University of Dundee, Ninewells Hospital, Dundee DD1 9SY, UK; 10) Pharmacogenomics Centre, Biomedical Research Institute, University of Dundee, Ninewells Hospital, Dundee DD1 9SY, UK; 11) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 12) European Genomic Institute for Diabetes (EGID) FR 3508, 59000 Lille, France; 13) CNRS-UMR-8199, Lille Pasteur Institute, 59019 Lille, France; 14) Lille 2 University, Lille, France; 15) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA; 16) deCODE genetics, Reykjavik, Iceland; 17) Estonian Genome Center, University of Tartu, Tartu, Estonia.

To date more than 70 common variant associations have been described for type 2 diabetes (T2D); however these account for <10% of inherited susceptibility. Most T2D-associated variants have minor allele frequency (MAF) >10%. Our goal was to uncover novel sites for T2D by considering lower frequency variation that is not well covered by traditional genome-wide association arrays. To that end, we imputed SNP variants using the 1000 Genomes Phase I reference panel (1,092 individuals, March 2012 release, autosomal chromosomes) within European descent studies with genome-wide association (GWA) data. Following T2D association analysis with/without adjustment for body mass index (BMI), we performed a fixed-effects inverse variance meta-analysis for a total of 17 studies (15 with BMI for adjustment available) representing 19,427 (15,585) T2D cases and 49,483 (39,537) controls. Imputation using the 1000 Genomes reference increased the number of SNPs tested from the previous DIAGRAM+ analysis by >4 fold. 12.1M SNPs were present in at least 50% of the studies. We observed genome-wide significant (p-value<5×10^{-8}) associations at 23 established T2D loci, among which associations at *FTO* and *MC4R* were acting through obesity and were not significant after adjustment for BMI. Within T2D analysis adjusted for BMI, we observed novel associations at 2 common variant loci near *CENPW* (chr6: 126,792,095) and *DGAT1/SCRT1* (chr8: 145,551,200) genes as well as an independent secondary signal within *HMGA2* (chr12: 66,389,968) locus. Analysis of T2D without adjustment for BMI showed 5 novel associations at common variants near *CENPW, ETV1* (chr7:13,887,349), *PLEKHA1/ARMS2* (chr10:124,186,714), *APOE* (chr19:45,411,941) and *HORMAD2* (chr22:30,599,562) not well-tagged in previous imputations. Additionally, we observed an independent secondary association at chr19:46,307,406 within established *GIPR/QPCTL* locus. None of the lower frequency variants outside of known T2D loci was significant at 5×10^{-8}. Imputation with the large multi-ethnic 1000 Genomes reference panel has not revealed novel association signals driven by low MAF variants. However, use of high-density reference SNP set for imputation allowed identification of 6 novel common variant (all MAF>0.08) T2D signals, one of them identified within T2D analysis corrected for the effect of adiposity only.

1709W

Predictive genetic modeling in identifying metabolic syndrome development. *A.T. Kraja, M.A. Province, I.B. Borecki.* Div Statistical Genomics, Washington Univ Sch Med, St Louis, MO.

Metabolic syndrome (MetS) is a combination of risk factors for increased adiposity/ obesity, glucose intolerance/ insulin resistance, dyslipidemia and high blood pressure. To account for non-alcoholic fatty liver disease as a hepatic expression of MetS, we performed a multivariate factor analysis to explore DNA variants associations with 20 interconnected traits in the Family Heart Study, including measures of liver attenuation (LA), alanine transaminase, risk factors for MetS, several measures of fat by CT imaging and a selected number of inflammatory markers. After selecting 133 top SNPs from mixed effects additive association tests with factor scores, the list narrowed further to 45 SNPs when they were tested with each single trait and using a threshold of p-values < 10-6. Of them rs738409 of PNPLA3 associated significantly with LA (p=4.28E-25). Other candidates were also found. But there is no information available in predictive modeling with MetS candidates. We extend this work to predict based on genetic profiles who will develop MetS. We first performed online searches for identifying the pool of variants that influence MetS and its risk factors. Sources of information were: the NCBI Gene Entrez for MetS (332 candidate genes) and MetS risk factors BMI, WAIST, HDLC, TG, INS, GLUC, SBP and DBP, including biomarkers FIB, CRP, PAI-1, IL-6, ICAM-1, ADIP and WBCC. In addition, candidates for MetS (30 genes) and its risk traits from large GWAS were identified. Three main MetS domains were considered: obesity, insulin resistance and dyslipidemia. A variant/ candidate gene was considered to have a contribution to MetS, if it affected at least 2 major domains (obesity (BMI & WAIST) + dyslipidemia (HDLC & TG); glucose intolerance / insulin resistance (INS & GLUC) + HDLC & TG; BMI & WAIST + INS & GLUC). If a variant affects any 2 or more domains, then the MetS score of an individual is represented as the sum of each trait beta coefficient* recoded individual's genotype (0,1,2) * a variable weight. The weight for traits from main domains is 1.0, while for blood pressure and any additional inflammatory marker is 0.25. This creates a MetS index, which can classify individuals with high and low risk for MetS. The scoring system designed is compared with data mining classifying methods (logistic regression, partition trees, k-nearest neighbors, and radial basis machine) on candidate genotypes in the Family Heart Study time 1 and time 2 (~8 years apart).

1710T

Should we account for the random effect of relatedness when using Principal Component Analysis in GWAS? *M. de Andrade[1], J.P. Soler[2].* 1) Div Biomed Statistics & Informatics, Mayo Clinic, Rochester, MN; 2) Depertment of Statistics, University of São Paulo, SP, Brazil.

Studies of human complex diseases and traits associated with candidate genes are potentially vulnerable to bias (confounding) due to population stratification and inbreeding, especially in admixture population. In genome-wide association studies (GWAS) the Principal Components (PCs) method provides a global ancestry value per subject, allowing corrections for population stratification. However, these coefficients are typically estimated assuming unrelated individuals and if family structure is present and is ignored, such sub-structure may induce artifactual PCs. Extensions of the PCs method have been proposed by Konishi and Rao (1992) taking into account only sibship relatedness and by Oualkacha et al. (2012) which can be applied to general pedigrees and high dimensional data. In this work we apply such analysis for estimation of global individual ancestry but admitting PCs extracted from different variance components matrix estimators. For the application we use the GENOA sibship data consisting of European and African American subjects and the Baependi Heart Study consisting of 80 extended families collected from the highly admixture Brazilian population, both with SNPs data from Affymetrix 6.0 chip. All the implementation are done using R package.

1711F

Genome-wide association study of ventricular fibrillation in the setting of acute myocardial infarction. *R. Pazoki[1,2], J.S.S.G. de Jong[2], M.E. Adriaens[2], N. Bruinsma[2], L.R.C. Dekker[3], L. Beekman[2], A.A.M. Wilde[2], M.W. Tanck[1], C.R. Bezzina[2].* 1) Department of Clinical Epidemiology, Biostatistics & Bioinformatics, Academic Medical Center, Amsterdam, The Netherlands; 2) Department of Clinical and Experimental Cardiology, Academic Medical Center, Amsterdam, The Netherlands; 3) Department of Cardiology, Catharina Hospital, Eindhoven, The Netherlands.

Sudden cardiac death from ventricular fibrillation (VF) during acute myocardial infarction (MI) is a leading cause of total and cardiovascular mortality. Although a heritable component plays a role in the determination of risk for VF in the setting of acute MI, the underlying genetic factors remain largely unknown. We previously started exploring the role of common genetic variants in modulation of VF risk by conducting a genome-wide association study (GWAS) in the Arrhythmia Genetics in the NEtherlandS (AGNES) case-control set which consists of individuals with a first acute MI, where cases suffered VF and controls not. The aim of the current study was to carry out GWAS in an extended set of AGNES patients (171 cases, 310 controls) to identify additional susceptibility loci. In total, 1458 patients with a first acute MI, 686 with VF and 767 without VF were included in the current study. The AGNES cases and controls were genotyped using the Human610-Quad and HumanOmni2.5 Illumina arrays. Quality control and principle component analysis were performed using GenABEL package in R. Non-typed single nucleotide polymorphisms (SNPs) were imputed using data from HapMap. Logistic regression models implemented in the ProbABEL program was used to assess differences in the distribution of genotypes among cases and controls. The locus we previously identified on chr21 (rs2824292) exceeded the genome-wide significance threshold for association ($p<5\times10^{-08}$). SNPs exceeding the arbitrary threshold of 1×10^{-05} are currently being meta-analyzed in an independent case-control set of individuals of European descent.

1712W

Genetic determinants of plasma levels of vitamin D binding protein in U.S. black women. *E.A. Ruiz-Narvaez[1,2], L. Rosenberg[1,2], S.A. Haddad[1,2], J.R. Palmer[1,2].* 1) Slone Epidemiology Center, Boston University, Boston, MA; 2) Department of Epidemiology, Boston University School of Public Health, Boston, MA.

Background: Vitamin D plays a key role in the regulation of a variety of metabolic processes such as calcium and phosphate absorption, xenobiotic detoxification, cell proliferation and differentiation, and immunomodulation among others. Vitamin D binding protein (DBP), the major carrier of circulating vitamin D metabolites, determines the free fraction or biologically active component of vitamin D. Genetic polymorphisms may in part determine circulating levels of DBP. **Methods:** In order to identify genetic variants that may explain variation of DBP plasma concentration, we genotyped 23 single nucleotide polymorphisms (SNPs) in vitamin D-related genes in 486 women of the ongoing cohort study Black Women's Health Study (BWHS) who had plasma measure of DBP. We also genotyped 30 ancestral informative markers (AIMs) previously shown to provide a valid estimate of percent African (vs. European) ancestry. We used general regression models with backward stepwise selection process to find the best set of SNPs that explain variation of DBP plasma levels. **Results:** A model that included the 23 vitamin D-related SNPs plus individual African ancestry explained 83% of the variation of DBP plasma concentration; five SNPs were able to explain 82% of the DBP plasma level variation. Most of the DBP variation was explained by SNP rs7041, which represents an Asp-to-Glu change in the position 432 of DBP. The SNP rs7041 explained 74% of DBP plasma concentration variation, and each minor allele was associated with an increase of 2350 nmol/L of DBP (p<0.0001). **Conclusions:** We identified 5 SNPs that explain most of the variation of DBP plasma levels in African American women. These polymorphisms, through their association with DBP concentration, might be predictors of diseases involving vitamin D deficiency.

Patterson[2], A.L. Price[1,2].* 1) Department of Epidemiology, Harvard School of Public Health, Boston; 2) Broad Institute, Cambridge, MA, USA; 3) The University of Queensland, Brisbane, Queensland, Australia; 4) Massachusetts General Hospital, MA, USA; 5) Department of Neurology, Brigham & Women's Hospital, Boston, MA, USA; 6) Division of Genetics, Department of Medicine, Brigham & Women's Hospital, Boston, MA, USA; 7) Harvard Medical School, Boston, MA, USA; 8) Icahn School of Medicine at Mount Sinai, New York, NY USA; 9) UCLA, CA Los Angeles USA; 10) UCSF, San Francisco, CA USA; 11) The University of Melbourne, Parkville, Victoria, Australia.

As sample sizes in genome-wide association studies (GWAS) of common diseases continue to grow, polygenic risk predictions of common diseases are expected to improve (Chatterjee et al. 2013 Nat Genet; Dudbridge 2013 PLoS Genet). Polygenic risk scores, defined as the sum of estimated allelic effects for markers that achieve a given significance threshold, are currently commonly applied to LD-pruned markers for prediction purposes. However, as we show here, they can be suboptimal under realistic genetic architectures. We propose a computationally efficient, Bayesian polygenic risk prediction method that uses GWAS summary statistics as training data, avoiding logistical and computational challenges of large genotype datasets. Our method adjusts the estimated marker effects by explicitly modeling the underlying distribution of causal effect as a Gaussian mixture. It also accounts for effects of linkage disequilibrium (LD) on indirect associations at non-causal markers and sampling noise in estimating marker effects. Under the assumption that there is at most one causal marker in a region of LD we derive an efficient approximate Bayesian shrink that has linear running time, GoLD (Gaussian posterior mean with LD). Notably, unlike LD-pruning, GoLD does not require any LD information from a reference panel. We show that as the sample size goes to infinity, the use of LD pruning results in a prediction r2 that fails to capture all of the heritability explained by genotyped SNPs, whereas our approach succeeds. Using simulated datasets we compare our approach to the standard thresholding approach on pruned markers and observe that GoLD can increase the prediction r2 by up to a factor 1.23 for reasonable choices of genetic architecture (random 1% of all SNPs are causal) and sample size (20,000 samples). Finally we apply the method to real datasets, including a breast cancer dataset and a schizophrenia dataset with GWAS summary statistics for 35,000 and 22,000 samples respectively. The Bayesian shrink proposed here may enable clinically relevant prediction accuracies at smaller sample sizes than other methods.

1714F

Genetic variations in telomere-maintaining genes and adult-onset cancers. *S. Hwang[1], J.M. Murabito[2], A.P. Reiner[3], A. Aviv[4], D. Levy[1].* 1) 1.National Heart, Lung and Blood Institute's Framingham Heart Study, Center for Population Studies, Framingham, MA; 2) Department of Medicine, Section of General Internal Medicine, Boston University School of Medicine, Boston, Massachusetts; 3) Department of Epidemiology, University of Washington School of Public Health, Seattle WA; 4) 4.The Center of Human Development and Aging, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, NJ, USA.

Background: Telomere-maintaining variation, especially rs2736100 at the *TERT* gene locus, has been shown to relate to lung, brain, bladder, and colorectal cancers. GWAS have identified SNPs at the telomerase-relating genes *TERT* and *TERC* that contribute to inter-individual differences in leukocyte telomere length (LTL). The current study tested for association between GWAS identified telomere-maintaining SNPs and cancers in a community-based cohort. Methods: Study population was composed of 5475 Framingham Heart Study participants who participated in the SNP Health Association Resource (SHARe) project and were age 45 years or older at the baseline examination. A total of 1748 subjects had a pathology confirmed malignancy including 217 breast, 257 prostate, 142 lung, 144 colorectal, 90 melanoma, and 84 bladder cancer cases. We used an additive genetic model to test whether genetic variation at the *TERT*, *TERT-CLPTM1L*, *TERC*, *NAF1*, and *OBFC1*, loci region (SNPs rs402710g, rs401681g, rs2736100, rs1006969, rs7675998, rs10936599, and rs9420907) is associated with cancer. Generalized estimation equation adjusted for familial correlation was applied to test for significance of genotype by cancer diagnosis adjusted for age, sex, body-mass-index, cigarette smoking, and multiple cancer diagnosis. Results: SNPs at the *TERT CLPTM1L* locus region were marginally associated with any cancer and significantly associated with lung cancer. For those carrying the minor allele of rs402710, a 60% lower lung cancer risk was observed (p=0.0008). Those carrying the minor allele of rs9420907 at the *OBFC1* had a 1.6 -fold lung cancer risk (odds ratio of 1.6, 95%CI 1.15-2.22, p=0.005). Conclusions and Impact: Our community-based long-term follow up study revealed an association between the telomere-mediating genetic variation and cancer risk, lung cancer. Further validation is warranted.

1715W

Genetic analysis of *TOMM40* and *APOE* for the onset of dementia in the Honolulu-Asia Aging Study. *M.W. Lutz[1], D. Goldgaber[2], D.K. Burns[3], A.M. Saunders[1], L.R. White[4], A.D. Roses[1,3].* 1) Duke University Medical Center, Department of Neurology, Durham, NC; 2) Stony Brook University, Stony Brook, NY; 3) Zinfandel Pharmaceuticals Inc., Durham, NC; 4) Pacific Health Research and Education Institute, Honolulu, HI.

Understanding the impact of genetic factors on the onset of dementia and Alzheimer's disease requires longitudinal studies with accurate determination of age of symptom and/or disease onset. Recent work by Roses et al. showed the genetic association of variants in both *APOE* and *TOMM40* with the age of onset of Alzheimer's disease in a prospectively studied, longitudinal Caucasian cohort. Specifically, an informative intronic poly-T variant (rs10524523 or '523) in the *TOMM40* gene was shown to provide more precise stratification of age of onset of Alzheimer's disease than *APOE* alone. This work was the basis for the development of a biomarker risk assignment algorithm that utilizes '523 genotype, *APOE* genotype, and chronological age to predict the risk of developing cognitive impairment within 5 years. *APOE* and '523 allele frequencies differ between ethnicities, and this presentation describes the genetic analysis of *APOE* and '523 for the onset of dementia (time course up to 18 years, median 9 years) in an elderly (>72 years) Asian male cohort (n=649), the Honolulu-Asia Aging Study (HAAS). The HAAS collected data on the development of dementia, risk factors, and neuropathologic abnormalities over a 21-year time frame. In this study, *APOE* and *TOMM40* genotypes were compared to the age of onset of dementia in this prospectively ascertained Asian series. There is a highly significant (p<0.0001) difference in '523 allele frequencies between the Caucasian and HAAS cohorts, with the most significant difference being a two-fold enrichment for the VL allele in the HAAS. VL/VL carriers have been shown to have a late age of onset for dementia: 92 years for 50% affected in both Caucasians and the HAAS cohort. '523 VL/VL carriers have the most common APOE 3/3 genotype, 61% for Caucasians and 69% for Asians. Kaplan-Meier analysis confirmed both *APOE* and '523 as predictors for the onset of dementia, with the '523 genotype providing a resolution of approximately 2-10 years between the median age of onset for dementia where 50% of the carriers of each genotype are affected. This study provides comparative data on *APOE* and '523 genotypes and age of onset of dementia that supports the generalization of the biomarker risk assignment algorithm to the Japanese ethnicity. Further work is needed to generalize the relationship between '523 genotype and age of onset of dementia across multiple ethnicities.

Molecular screening of CFTR Gene mutations in North Indian Asthmatic Children; a case-control study. *P. Dixit[1], S. Awasthi[1], N. Maurya[1], S. Agarwal[2], M. Srinivasan[2].* 1) Dept. of Paediatrics, King George's Medical University, Lucknow, India; 2) Dept. of Medical Genetics, S.G.P.G.I.M.S., Lucknow.

Background & Objective: Asthma is a complex genetic disorder. Cystic Fibrosis trans-membrane conductance regulator (CFTR) gene is an asthma susceptibility gene and carriers for this gene may develop obstructive pulmonary disease like bronchial asthma. Therefore, the objective of the study was to assess the association of CFTR gene mutations in genetic susceptibility to asthma. Material and methods: It was a hospital based case-control study, 250 bronchial asthma cases and 250 age and sex matched controls, aged 5 months-15 years were recruited for the study. Cases included were those children presenting symptoms of asthma and excluded were clinically suspected cystic fibrosis (CF) or sweat chloride level > 60 mmol/L or suffering from other respiratory diseases. Spirometery and sweat chloride test were performed in all subjects. All cases were further categorized into four different categories as per Global Initiative for Asthma criteria (GINA) guidelines: mild intermittent (83), mild persistent (96), moderate persistent (52), and severe persistent (19). Genotyping was performed for 24 CFTR gene mutations; R553X, N1303K, 621+1G>T,1717-1G→A, R668C, L997F, G576A, R75Q, R560T, V520F, Q493X, Δ1507, 3849+10KbC→T, R1162X, 3659delC, G85E, Y122X, 1078delT, 1898+1G→A, R347P, R347H, A455E, 2183AA→T, 2789+5G→A by ARMS- PCR and PCR- RFLP method. Data was statistically analyzed by Chi-square and student t test. Two-sided P value considered significant. Results: Of 250 cases and 250 controls, heterozygous allele of R553X mutation was found in 4 (1.6%) asthmatic cases and 2 (0.8%) controls. Value of FEV1/FVC ratio was significantly lower in heterozygous individuals compared to wild type homozygous individuals (P value<0.05). No significant difference was observed in the genotype and allele frequency of R553X mutation among cases and controls (P value - 0.685; Odds Ratio -1.339, Confidence Interval: 0.755-2.374). Similarly, no significant difference was observed in sweat chloride levels in heterozygous and wild type individuals among cases and controls (P value- 0.059 and 0.116 respectively). Furthermore, all wild type homozygous alleles were observed in remaining 23 CFTR gene mutations. Conclusion: We conclude that, R553X mutation of CFTR gene was not significantly associated with bronchial asthma in North Indian asthmatic population. This may imply that heterozygosity may be related with a silent obstructive pulmonary profile.

1717F

The Association of HLA-DQB1 Alleles with Nonalcoholic Fatty Liver Disease in Turkish Population. *S. Katrinli[1], L. Doganay[2, 3], Y. Colak[2], E. Senates[4], O. Ozturk[3], C. Ulasoglu[2], N. Karatas[1], I. Tuncer[2].* 1) Molecular Biology and Genetics, Istanbul Technical University, Istanbul, Turkey; 2) Department of Gastroenterology, Medeniyet University, Goztepe Teaching and Research Hospital, Istanbul, Turkey; 3) Department of Gastroenterology, Umraniye Teaching and Research Hospital, Istanbul; 4) Department of Gastroenterology, Dicle University, Medical School, Diyarbakir, Istanbul.

Introduction: Nonalcoholic fatty liver disease (NAFLD) is probably the most common liver disease in western and westernized countries, with an overall prevalence up to 30%. The spectrum of NAFLD grades from simple fatty liver (hepatic steatosis) to nonalcoholic steatohepatitis (NASH) which is its more progressive form. Hepatocellular apoptosis caused by activation of immune cells is an important feature contributing to the pathogenesis of NAFLD. Highly polymorphic human leukocyte antigen (HLA) gene is closely associated with immune response. The role of HLA class II molecules is to present antigens to CD4+ T lymphocytes which are recently shown to be increased in Nash patients (Inzaugarat *et al.*, 2011). Moreover, recent studies emphasize that HLA-DQB1 polymorphisms influence individual immune response and thus involve in the outcome of chronic viral liver diseases and drug induced liver injury. Hence, we thought that HLA-DQB1 polymorphisms may also have an effect on the progression of NAFLD and thus, we aim to investigate the association between HLA-DQB1 alleles and NAFLD in Turkish population. **Methods:** A study group of 93 biopsy proven NAFLD patients (46 male and 47 female, mean age 42±10,2 years) and a gender and age matched comparison group consisting 101 healthy people (48 male and 53 female, mean age 41±9.5) are recruited. The alleles of HLA-DQB1 are detected by sequence-specific primers-polymerase chain reaction (SSP-PCR) (Olerup *et al.*, 1993). **Results and Conclusions:** Among thirteen HLA-DQB1 alleles analyzed in this study, DQB1*0604 is significantly more frequent among the NAFLD patients compared to healthy controls (12.9% vs 2%, ψ^2=8.6, P=0.003, OR: 7.3 95% CI: 1.6-33.7). In addition the frequency of DQB1*0302 is significantly higher in the healthy control group than the NAFLD patients (24.8% vs 7.5%, ψ^2=10.4, P=0.001, OR: 0.2, 95% CI: 0.1-0.6). These results suggested DQB1*0604 might be associated with NAFLD and DQB1*0302 might be a protective allele against NAFLD.

1718W

Genetic susceptibility of FCER2 gene variants with asthma and its severity in north Indian children; a case-control study. *N. Sharma[1], S. Awasthi[1], S. R Phadke[2].* 1) Department of Paediatrics, King George's Medical University, Lucknow-UP, Lucknow, India; 2) Department of Medical Genetics, SGPGIMS, Lucknow -UP, India.

Background & objective: Several strong evidences are available for genomic factors predisposing asthma in children. Previous studies have shown that the activated low-affinity IgE receptor (encoded by FCER2 gene) plays a pivotal role in allergic immune response, regulation of immunoglobulin E (IgE) levels and other associated inflammatory mediators. Any disturbance in the delicately balanced immune response due to genetic variations in the form of single nucleotide polymorphisms (SNPs) with in FCER2 gene may result in insufficient functions of this immune modulator gene, which can enhance the susceptibility to asthma and its severity. The present study involves investigation of association of the SNPs rs2834072 and rs7249320 (located 7 bp 3'of exon 9 and intron respectively in FCER2 gene) with asthma and its severity. Methods: Case-control based genetic association study was performed among 550 children (275 asthmatic children and 275 normal controls) from sub-population of north India (Indo-Europeans linguistic subgroup + Caucasoid morphological subtype) using polymerase chain reaction-restriction fragment length polymorphism and DNA sequencing analysis. The diagnosis and classification of the asthma severity was made according to Global Initiative for asthma guideline. Data were analysed using chi-square test and logistic regression model. Results: Statistical analysis demonstrated significant association between asthma and genotypes frequency of both the SNPs rs2834072 and rs7249320. Calculated statistical values for rs2834072 were heterozygous (AG) Odds Ratio (OR) 1.417, 95% Confidence Interval (CI) 0.988 to 2.032, P= 0.058 homozygous mutant (GG) OR 2.130, CI 1.242-3.653, P= 0.006 and combined mutant (AG+GG) OR 1.521, CI 1.110 to 2.185, P= 0.0129. Similarly, significant association observed in rs7249320 for homozygous variant (CC) OR 2.767, CI 1.532 to 4.997, P= 0.001, variant allele (C) OR 1.494, CI 1.158 to 1.928 and combined mutation (AC+CC) OR 1.400, CI 1.00 to 1.959, P= 0.0494. A positive association between asthma and haplotypes AG, CA, CG were also found (P= 0.014, 0.014, 0.000 & OR 1.460, 1.475, 2.503 respectively). Interpretation & conclusions: Our data indicate that the rs2834072 & rs7249320 variations of FCER2 gene are strongly associated with asthma susceptibility and might be risk factor for asthma among north Indian subpopulation.

1719T

Significant association of Perilipin polymorphisms with LDL-cholesterol level. *I. Naka[1], R. Kimura[2], T. Inaoka[3], Y. Matsumura[4], J. Ohashi[1].* 1) University of Tsukuba, Tsukuba, Ibaraki, Japan; 2) Transdisciplinary Research Organization for Subtropics and Island Studies, University of the Ryukyus, Okinawa, Japan; 3) Department of Environmental Sociology, Faculty of Agriculture, Saga University, Saga, Japan; 4) Faculty of Health and Nutrition, Bunkyo University, Kanagawa, Japan.

Perilipins and hormone-sensitive lipase (HSL) play key roles in the cellular regulation of triglyceride deposition and mobilization. Perilipins, which are encoded by perilipin 1 gene (*PLIN1*) on 15q26, are primarily expressed at lipid droplet surface in adipocytes and steroidogenic cells. Phosphorylation of perilipins allows HSL to break down triglycerides in lipid droplets into glycerol and fatty acid chains. Several single nucleotide polymorphisms (SNPs) of *PLIN1* have been shown to be associated with levels of lipid fractions. In this study the associations of three *PLIN1* SNPs (rs2289487, rs894160, and rs1052700) and an *HSL* SNP (rs34845087) with total-cholesterol, HDL-cholesterol, LDL-cholesterol, and triglyceride levels were evaluated in 127 adult subjects living in Tonga. A multiple regression analysis adjusted for age, sex, and body mass index (BMI) revealed that a copy of rs894160-T allele significantly decreased serum LDL-cholesterol by 11.04 mg/dl (*P*-value = 0.0350) and also a copy of rs1052700-T allele significantly decreased serum LDL-cholesterol by 12.39 mg/dl (*P*-value = 0.0248). No other significant associations were observed. The rs894160 and rs1052700 were in linkage disequilibrium with each other (D '= 0.87 and r^2 = 0.73). The haplotype analysis revealed that a copy of risk haplotype (rs894160-T and rs1052700-T) was significantly decreased serum LDL-cholesterol by 12.33 mg/dl (*P*-value = 0.0193). Our results suggest that *PLIN1* polymorphisms affect the levels of serum LDL-cholesterol in Tongan adults.

1720F

Genetic risk models: model size and confidence intervals of the risk estimates. *Y. Shan[1,2], D.T. Smelser[3], G. Tromp[3], H. Kuivaniemi[3], D.E. Weeks[1,2].* 1) Department of Biostatistics, Graduate School of Public health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 3) The Sigfried and Janet Weis Center for Research, Geisinger Health System, Danville, PA, USA.

Disease risk estimation plays a very important role in disease prevention. With more precise risk estimates, people can make more informed decisions about disease prevention and treatment. Many studies, which estimate disease risk using logistic regression models applied to a given set of risk SNPs, have found that the larger the number of risk SNPs in the risk model, the greater the ability to predict the risk. However, the width of the confidence interval (CI) is often not considered in the evaluation of the risk model. In fact, when risk estimates are based on meta analysis results, confidence intervals are often not even estimated. Furthermore, a risk estimate with a larger CI from a larger model may not be practically better than a similar risk estimate with a smaller CI from a smaller model. Here, we explore the relationship of predicted disease risk, the size of the model, and the width of the CI of the risk using both simulated data and real data. We developed a formula and conducted a simulation of how much a person's risk could change when a single SNP was added into the model. We found that the width of the CI depended strongly on the magnitude of the estimated risk. In addition, we found that the CI width appeared to be positively correlated with the size of the model at the population level, but at the individual level, the CI width did not necessarily follow the size of the model. In other words, there was larger proportion (approximately 60%) of individuals having a bigger CI than a smaller CI, when one more SNP was added into the model. This study contributes to our understanding of relationship of disease risk, size of the model and the width of CI. This work was supported by a Collaborative Research Award on Translational Genomics, part of The Commonwealth Universal Research Enhancement (CURE) program of the Pennsylvania Department of Health.

Genetic Risk Score Modeling in Age-Related Macular Degeneration.
J.N. Cooke Bailey[1], J.D. Hoffman[1], L.M. Olson[1], W. Cade[2], N. Schnetz-Boutaud[1], P. Mayo[1], M. Allen[1], A. Agarwal[3], M.A. Brantley[3], W.K. Scott[2], M.A. Pericak-Vance[2], J.L. Haines[1]. 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Hussman Institute of Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 3) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration (AMD) is a progressive neurodegenerative disease that is the leading cause of blindness in elderly individuals in developed countries. AMD risk is mediated by genetic and environmental factors. The majority of identified genetic risk for AMD appears to be influenced by single nucleotide polymorphisms (SNPs) in ARMS2/HTRA1 and CFH genes, which account for approximately 50% of the genetic risk for AMD. These along with several additional loci of lower size effect account for less than 65% of the genetic component of AMD. Most recent publications implicate 19 SNPs as the known mediators of AMD risk (Fritsche et al, Nat Gen 2013, 45: 433). In a Caucasian sample of 1196 AMD cases (individuals with intermediate and/or advanced [non-exudative and/or exudative AMD, AREDS grades 3-5, respectively] AMD in at least one eye) and 726 non-AMD controls, we genotyped these 19 SNPs and evaluated them for association with AMD, using a logistic regression model adjusting for age of exam and gender. SNPs associated at a Bonferroni-corrected P<0.0026 included rs10790924 in ARMS2, rs9542236 in B3GALTL , rs429608 in C2/CFB, rs2230199 in C3, and rs10737680 in CFH; several others trended toward significance. Including smoking status (available for 76% of individuals), as a covariate did not alter inferences of association. To evaluate overall genetic risk for AMD, we generated a weighted genetic risk score (GRS) based on the 19 SNPs and their published effect sizes and compared GRSs between cases and controls. We detected a significant difference in mean risk scores between the groups (P<1×10-5), indicating that these SNPs aid in differentiating between cases and controls. Interestingly, when patients with exudative AMD were stratified based on unilateral (n=378) or bilateral (n=341) disease, we detected a significant difference in cumulative risk scores between the groups (P=3×10-4, age and gender included as covariates; P= 5×10-4 when smoking status was also included as a covariate). Additionally, comparing the unilateral exudative AMD patients (AREDS grade 2-4 in the fellow eye) to those with bilateral exudative AMD, the risk score trended significantly higher as AMD severity rose in the fellow eye. These results highlight not only the utility of GRSs in AMD, but also that there may be a significant difference in genetic risk between individuals with different subtypes of this disease.

Genetic variation at the *CY2C19* gene associated with Metabolic Syndrome susceptibility in a South Portuguese population.
V. Gaio[1], A. Fernandes[2], F. Mendonça[3], F. Horta Correia[3], A. Beleza[2], A. Gil[1], M. Bourbon[1], A. Vicente[1], C. Dias[1], M. Barreto da Silva[1]. 1) Instituto Nacional de Saude Doutor Ricardo Jorge, Lisboa, Portugal; 2) Laboratório de Saúde Pública Dra. Laura Ayres, Faro, Portugal; 3) Administração Regional de Saúde do Algarve, Faro, Portugal.

Metabolic syndrome (MetS) is a cluster of conditions ~ increased blood pressure, high blood glucose level, excess body fat around the waist and abnormal cholesterol levels ~ that occur together, increasing the risk of heart disease, stroke and diabetes. In Portugal, the MetS prevalence is estimated to be 27,5% with regional variations, being highest in the Alentejo (30,99%) and lowest in the Algarve (24,42%), constituting a public health problem. Although for clinical settings, a binary definition of MetS enabling a yes or no diagnosis is useful, it is clear that dichotomizing a continuous outcome variable reduces the statistical power of the MetS association studies. Therefore, the aim of the present study is to identify genetic risk factors involved in MetS etiology, using a continuous MetS score. To achieve our goal, a principal component analysis was performed to compute a score using the six normalized risk factors for MetS (waist circumference, diastolic and systolic blood pressure, glucose, triglycerides and HDL blood levels), with a higher MetS score indicating a less favorable MetS profile. After calculating this score, an association study was performed using 37 SNPs in candidate genes involved in MetS related diseases. A total of 206 subjects, including 119 women and 87 men (mean age: 56,31± 16,37 years, range: 26-91 years) were included in this analysis. We found 4 SNPs significantly associated with higher MetS scores (rs4244285 (*CYP2C19*), rs279871(*GABRA2*), rs1647(*NPY*) and rs1142345(*TPMT*)). P-values are $4{,}36\times10^{-4}$, $1{,}3\times10^{-2}$, $1{,}7\times10^{-2}$ and $9{,}76\times10^{-3}$ respectively. After correcting for multiple testing only rs4244285 (*CYP2C19*) remains significant (p=0,016). In addition, we have performed a multiple regression analysis considering the *CYP2C19* genotype as the independent variable, adjusted for age. The resulting model explains 17% of the MetS score variance. After adding the remaining SNP genotypes that do not survive the multiple testing correction, the same model is able to explain 23,1% of the score. Our findings support the evidence of an association between *CYP2C19* rs4244285 gene polymorphism and the MetS score, emphasizing the importance of lipid metabolism, thought cytochrome P450 enzymes, in the MetS etiology. However, further studies will be necessary to replicate these findings in different populations as well as functional studies to clarify the role of this variant in the etiology of MetS.

Hearing function and loss: `A complex multistep strategy' to identify genetics and environmental factors.
G. Girotto[1], D. Vuckovic[1], A. Buniello[2], K. Steel[2], P. Gasparini[1]. 1) Medical Genetics IRCCS 'Burlo Garofolo'-DMS, Univ.Trieste , Trieste, Italy; 2) King's College London, Guy's Campus, London, United Kingdom.

The analysis of complex genetic traits/diseases such as normal hearing function (NHF) has long been an enigma of genetic biology and medical sciences and the majority of genes/loci and environmental/lifestyle factors involved still need to be detected. Here we propose a multistep approach based on: A) Genome-Wide association study (GWAS), B) expression studies, C) replication with general association studies and D) pathway analysis and E) genotype-phenotype relationship to detected genetics factors. As regards environmental factors a linear/logistic regression has been performed. For the genetic studies, we have selected a list of 19 genes recently identified in a large GWAS on different quantitative hearing traits (step A) carried out on 3417 individuals from isolated populations/communities located in Europe. These genes have been evaluated at the expression level, 12 of them showing a clear staining in the mouse cochlea of wild-type mice (at 4 and 5 days postnatal). In particular, 5 of them (Arsg, Slc16a6, Dclk1, Gabrg3, Csdm1) show strikingly specific expression in the cochlea (e.g. at the top of sensory hair cells and in the marginal cells of the stria vascularis) while the other 7 (Ptprd, Grm8, GlyBP, Evi5, Rimbp2, Ank2, Cdh13) are located in multiple cell types in the cochlea (step B). In the next step (C), 9 out of these 12 genes have been successfully replicated in independent cohorts from Caucasus and Central Asia. Moreover, 8 of these replicated genes fit in the same pathway which include a known HL gene (*MARVELD2*) (step D); finally, to look for genotype-phenotype relationship, the audiometric profiles (i.e. mean values at each frequency) of the 3 genotypes of the most associated gene-variant have been analyzed. In particular, 7 genes out of the 9 replicated (*CDH13, GRM8, ANK2, SLC16A6, ARSG, RIMBP2 and DCLK1*) showed a peculiar audiometric pattern with relevant differences for each genotype further supporting their role in NHF (step E). As regards environmental factors, among all the investigated variables (smoking, chocolate, coffee, tea, wine, beer, dairy products, spirits), only coffee consumption was associated at low and high frequencies (p=0.006) while the intake only at high frequency (p=0.003). These data demonstrate the usefulness of these combined methods in providing new insights into the molecular basis of NHF and may suggest new targets for hearing impairment treatment and prevention.

GWAS on an admixed Chilean sample of Cases and Controls to identify the genetic basis of the phenotypic variability in 22q11 microdeletion syndrome. *S. Eyheramendy[1], F. Manevy[1], M. Ramirez[1], C. Vial[2], K. Espinoza[2], J.C. Rivera[2], G. Repetto[2].* 1) Statistics, Pontificia Univ Catolic, Santiago, Chile; 2) Center for human genetics, Faculty of Medicine, Clinica Alemana, Universidad del desarrollo.

In this study we are interested in finding the genetic basis of the incomplete penetrance of the cardiovascular phenotype in 22q11 microdeletion syndrome (22q11DS) in a Chilean admixed sample of cases and controls. Genome-wide association studies (GWAS) have been a popular strategy to try to localize the genes or mutations that increase/decrease disease susceptibility in homogeneous populations. Unfortunately, the standard methodology utilized in GWAS needs to be adapted in the study of admixed populations. In order to assess for the association of a genetic variation witha disease, it is necessary to know the disease status of the individuals as well as the local ancestry of the mutations on the individuals. Chilean history shows that the general Chilean is mainly a mixture between Europeans (predominantly people from Spain but also from Germany, France, UK, Croatia, etc.) and Native Americans, in contrast with other Latin Apopulations which have an African component as well. In this study we performed a comparison of local ancestry estimation methods in terms of their performance and sensitivity towards different choices of ancestral populations in the association outcome. We consider ancestral populations from Native American, Europe and Africa to perform the comparison and show that indeed the association outcome can be sensitive to the choice of ancestral populations and local ancestry estimation algorithm. We also performed a genetic structural analysis to estimate distances between individuals of different ancestry. Funded by Fondecyt-Chile Grants 1120813, 1100131 y 1130392.

1725T

Multi-step LASSO approach identifies a chromosomal segment associated with working memory. *V. Freytag[1], L. Gschwind[1], A. Milnik[1], D. de Quervain[2,3], A. Papassotiropoulos[1,2,4], C. Vogler[1,2,4].* 1) Molecular Neuroscience, University of Basel, Basel, Switzerland; 2) Psychiatric University Clinic, University of Basel, Basel, Switzerland; 3) Cognitive Neuroscience, University of Basel, Basel, Switzerland; 4) Department Biozentrum, Life Sciences Training Facility, University of Basel, Basel, Switzerland.

Background: Working memory is a heritable trait, likely to involve a large number of variants with small effect sizes as it has been reported for other complex traits, e.g. human height. Several studies have already applied GWAS, starting to elucidate the molecular underpinnings of human working memory. Yet, a large fraction of the genetic contribution remains to be unraveled. Multidimensional approaches (MDA), capable of simultaneously modeling the effects of multiple SNPs, are a proposed solution to deal with the polygenic architecture of complex traits. MDAs can identify associations between phenotypes and a subset of markers, whose individual marginal effects cannot be detected by the standard univariate analytical approach. Due to the high number of genetic markers in comparison to the number of individuals, dimensionality reduction is often a prerequisite for the application of MDAs, which can be achieved by taking advantage of a priori biological knowledge. Here we exploit the fact that in mammalian genomes, colocalized genes have a tendency to be co-expressed and functionally related.

Methods: An initial sample of N=1039 healthy young Swiss individuals that underwent working memory assessment using the n-back paradigm was subsequently subjected to genotyping with the Affymetrix SNP Array 6.0. We followed a multi-step approach, starting with pruning SNPs for strong LD ($r^2>0.8$) on a genome-wide level. SNPs showing an uncorrected nominal ($p<0.05$) association signal were partitioned into chromosomal segments of 20 MB pairs. Within each segment a penalized regression model (LASSO) was trained on the remaining SNPs and combined with a bootstrap-based stability selection procedure to identify subsets of informative SNPs. Statistical significance of the subsets of SNPs was assessed in a second independent replication sample of N=719, by testing the correlation (unilateral Pearson's correlation test) between the model prediction and the actual observed phenotype. Resulting p-values were corrected for the number of multiple tests performed.

Results: Several subsets of SNPs reached nominal significance. On chromosome 5q34-35, a set of 46 markers exceeding a stability fraction of 0.9 survived correction for multiple comparisons (uncorr. $p < 0.00003$, corr. $p < 0.007$), suggesting involvement of this region in working memory. Among those, 19 SNPs mapped to intragenic regions, yielding 10 candidate genes for further investigation.

1726F

Genetic Dynamic Model for Temporal Quantitative Trait with both GWAS and Next-Generation Sequencing Data. *G. Getie, M. Xiong.* University of Texas School of Public Health, Houston, TX.

Traditional quantitative genetics has primarily studied traits that are measured at a specified location or time. The traits are investigated as isolated and static variables. However, in real biologic world, many quantitative traits change over time. These quantitative traits are repeatedly measured as functions of time or complete curves. In other words, these traits are observed either as continuous random functions, or on a dense grid. In the past several decades, researchers have primarily focused on (1) the role of individual genetic variation in determining the diseases and (2) the steady-state molecular and clinical phenotypes. Little attention has been paid to determining how the genetic variations and environmental perturbation act together to dynamically alter regulations and metabolism leading to the emergence of complex phenotypes and diseases. The concept of a dynamic system that originally arose from the Newtonian mechanics is now widely used as a basic framework for scientific research. Dynamic models not only focus on functional values themselves, but also focus on the rates of changes of functions. We term the rate of changes of a function as a derivative of the function. Dynamic models allow us to simultaneously model both the function itself and its derivatives that can be used as either responses or predictors. Therefore, they can capture information on both the curve and its derivatives. Genetics incorporating both functions and their derivatives into the model is referred to as dynamic genetics. There is increasing recognition and appreciation of modeling dynamics of quantitative traits and studying how the quantitative traits are evolved in response to perturbation of the genetic and environmental factors. In this talk, we will present a general dynamic genetic model for functional quantitative with both GWAS and NGS data. Two stage methods will be developed to estimate the parameters in the dynamic genetic model and test statistic will be proposed to test association of genetic variants with a temporal quantitative trait. By intensive simulations we show that the proposed test statistic has the correct type 1 error rates and much higher power to detect association than the current existing methods. The proposed method is applied to Starr County Sleep Studies where oxygen saturation of 767 individuals with 795,736 SNPs were measured for 380 minutes on average.

Does Haplotype Tests Gain More Power than Collapsing Tests in Pedigree-based Association Studies for Detecting Rare Variants. *W. Guo, Y. Yao.* Division of Intramural Division Program, National Institute of Mental Health, National Institute of Health, USA.

It has been well known that both common and rare variants contribute to complex disease etiology. Recent genome-wide association studies (GWAS) have been successfully applied in investigating the effects of common variants in explaining the genetic factors in human common diseases. However, it is still a challenge to identify the impact of rare variants, which are abundant (1 every 17 bases) in human population as the development in next-generation sequencing technologies. A number of statistical tests have already been developed to analyze collapsed rare variants identified by association tests. Here, we propose a weighted haplotype-based approach under the statistical frame of pedigree disequilibrium test, to test for the effect of rare variants with sequencing data in general pedigrees. We evaluated our method and compared it with the common collapsing strategy in the sequencing setting through extensive simulations. The new method clearly show enhanced statistical power over existing collapsing method when the variants are extremely rare, or the proportion of causal variants is large as well as the proportion of variants that increase risks. Following testing and evaluation, we have submitted weighted haplotype-based pedigree test in a computer program to the Comprehensive R Archive Network (CRAN) for general use.

1728T

Localization of causal variants at loci with multiple signals of association.
F. Hormozdiari[1], E. Kostem[1], E. Kang[1], B. Pasaniuc[3,4], E. Eskin[1,2,4]. 1) Computer Science, UCLA, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles, CA; 3) Department of Pathology and Laboratory Medicine, Geffen School of Medicine, UCLA, Los Angeles, CA; 4) Inter-Departmental Program in Bioinformatics, UCLA, Los Angeles, CA.

Although genome-wide association studies have successfully identified thousands of risk loci for complex traits, only a handful of causal variants have been successfully identified. Several fine-mapping studies are currently underway in an effort to pinpoint causal variants for common disease. Although several loci have been shown to contain multiple causal variants, current statistical methods for fine-mapping rely on simplistic assumptions of a single causal variant per locus to estimate posterior probability of variants being causal (WTCCC et al Nature Genetics 2012). In this work we propose a new framework for statistical fine-mapping for causal variants. As opposed to current approaches that make assumptions about the number of causal variants at a given locus, our framework considers all models with arbitrary number of causal variants to properly estimate the posterior probability of a SNP being causal. A direct benefit of our approach is that we provide well-calibrated confidence sets of SNPs that are guaranteed to contain the true casual SNPs with high confidence (i.e. 95% confidence). In other words not all the SNPs picked in our set are casual but we claim we capture the true casual SNPs with high probability (probability higher than 95%). We assessed the performance of our method using both simulated and real data. We indicate in this work the idea of peaking the top significant SNPs or using the conditional method, which are the common methods to find the casual SNP, have high false negative rate. Using the simulation data we can illustrate our methods obtain a set of SNPs which contain the true causal SNPs with 95% probability and the average number of SNPs picked by our method is only twice the number of true casual SNPs implanted in the region.

A Phenome-Wide Association Study (PheWAS) Exploration of Multiple Traits at Baseline in AIDS Clinical Trial Group (ACTG) Protocols.
C.B. Moore[1,2], A. Verma[2], D.H. Johnson[1], E.S. Daar[3], R.M. Gulick[4], R. Haubrich[5], G.K. Robbins[6], S.A. Pendergrass[2], D. Haas[1], M. Ritchie[2]. 1) Vanderbilt University, Nashville, TN; 2) Center for System Genomics, The Pennsylvania State University, University Park, PA; 3) Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 4) Weill Cornell Medical College, New York, NY; 5) University California San Diego, CA; 6) Harvard University, Cambridge, MA.

Phenome-wide association studies (PheWAS) evaluate the associations between genetic variation and wide range of complex traits. We applied this approach to the baseline data from four AIDS Clinical Trial Group (ACTG) protocols using > 30 pre-treatment laboratory measures from 2547 individuals of mixed ancestry. We imputed data using Impute2 and a cosmopolitan reference panel, resulting in 5,954,294 SNPs. Due to the unique nature of this cohort, we divided the data to seek replication of our PheWAS results. We used linear regression to calculate associations for each laboratory measure, adjusting for top principle components, age, and sex. To assess replication we compared results from study A5095 to the results from combined studies A384, A5142, and A5202. A total of 1319 SNPs had replicating significant associations (test p-value ≤1e-03, replicated p-value ≤1e-01). Top results were associated with total bilirubin and mapped to UDP- glucuronosyltransferase (*UGT*), responsible for glucuronidation (top result: test p-value 5.44e-35, replicated p-value 7.69e-30). Members of the *UGT* family have been previously associated with Gilbert syndrome and hyperbiliruninemia. The second cluster of SNPs were associated with high-density lipoprotein (HDL), located on chromosome 16 near or in *CETP* (top result: test p-value 5.60e-07, replicated p-value 3.65e-07). These SNPs have been previously associated with serum cholesterol and metabolic measures. A total of 49 SNPs were associated with more than one measurement. For example, 35 SNPs were found to be significant for low-density lipoprotein measurements (LDL) and total cholesterol. These SNPs mapped to *COPG2*, *TSGA13*, and *FAR2*. The coatomer gamma subunit (*COPG2*) is a component of the protein complex required for budding from Golgi membranes. It influences the Golgi structural integrity and processing, activity, and endocytic recycling of LDL receptors. *TSGA13* is in close proximity to *COPG2*. *FAR2* encodes a dehydrogenase/reductase enzyme involved in converting fatty acids to fatty alcohols. In summary, we were able to identify robust SNP associations for multiple baseline laboratory measurements. Our results serve as a validation of whole-genome PheWAS, and show the utility of this approach for clinical studies. Future work includes PheWAS with additional ACTG data, including on-treatment data.

1730W

Fast And Robust Association Testing For High-Throughput Testing.
Y.H. Zhou, F.A. Wright. Biostatistics, University of North Carolina, Chapel Hill, NC.

In the analysis of genotype-phenotype associations, the investigator often relies on parametric testing for high-frequency variants, but must resort to exact testing or permutation analysis for low-frequency variants. Such a two-stage procedure is cumbersome, and this difficulty is compounded for datasets with numerous rare variants. We describe the moment-corrected correlation (MCC) method for association testing, which provides a close approximation to exact test p-values, but with greatly reduced computation. The approach can be used for any phenotype distribution, and covariates can be handled by residualization or using covariate stratification. MCC is very fast, and can perform the association analysis for a genome scan in minutes. MCC is also, very general and it can be applied on others type of high dimensional ‘omics data, including gene expression data from microarrays or RNA-Seq. We illustrate the wide applicability of MCC as a screening and testing tool using a variety of ‘omics datasets.

1731T

A Novel General Framework for Imaging Genetics Analysis with Next-generation Sequencing Data.
N. Lin, M. Chen, M. Xiong. University of Texas School of Public Health, Houston, TX.

Imaging Genetics is to investigate the relationship between the individual genetic variation and variation in brain wiring (connections), structure, and intellectual function. The traditional statistical methods for imaging genetic data analysis often simply summarizes three dimensional image data into an overall image measurement and tests association between a single genetic variant with the summarized simple statistic. These methods ignore image variation at positional level. In addition, the traditional statistical methods for imaging genetic data analysis are originally designed for common variants and are difficult to be applied to next-generation sequencing (NGS) data for their low power, large number of tests and high proportion of missing data. To overcome these limitations, we develop a novel general framework for imaging genetics analysis with NGS data in which we offer creative mathematical formulation of the imaging-genetic analysis as a new functional linear model with three dimensional functional responses and a functional predictor. We will take image variation at the positional level into account and use high dimension data reduction techniques to develop a statistic that collectively test association of all genetic variants within a gene or a genomic region with medical images. By intensive simulations, we demonstrate that the three dimensional functional linear model for imaging genetics analysis has the correct type 1 error rates and much higher power to detect association than the current methods. The proposed method was applied to glioblastoma (GBM) dataset where we extract MRIs of 78 GBM patients present in the Cancer Imaging Archive (TCIA) corresponding to patients in the Cancer Genome Atlas (TCGA) and RNA-seq and Exom sequencing data of 78 same GBM patients from TCGA dataset. Our preliminary results show that the proposed statistic has much smaller P-value than that of traditional method.

1732F

A Bayesian Approach to Expression Quantitative Trait Loci (eQTL) Mapping Based on Biological Pathway Knowledge. *I.S. Chang[1,2], T.Y. Chen[3], C.H. Chen[1], C.A. Hsiung[2].* 1) National Institute of Cancer Research, National Health Research Institutes, Miaoli, Taiwan; 2) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Miaoli, Taiwan; 3) Institutes of Statistics, National Tsing-Hua University, Hsinchu, Taiwan.

While genome-wide association studies (GWAS) have successfully discovered and replicated thousands of SNPs associated with various traits/diseases, it is a challenge to gain biological insights regarding this association, because over 80% of them are not in coding region. One of the main approaches in the follow up of a GWAS is to examine whether these SNPs from GWAS are associated with the expression levels of certain genes. This leads to the so-called expression quantitative trait loci (eQTL) studies. In the current approaches, it is common to consider the expression data of 25K probes and as many SNPs as possible simultaneously so as to explore new phenomena or generate new hypotheses. While intuitive, these approaches often ignore the correlation between the gene expressions and do not make use of biological pathway information. We propose a Bayesian approach to eQTL that alleviate these concerns. In particular, the prior distribution makes use of the classical heritability concept in genetics and the pathway information from biological databases like GO, KEGG, BIOCARTA, etc. The former helps to avoid the often too conservative practices in genomic studies and the latter helps to provide biological interpretation and avoid reproducibility issue. In addition, the true-path rule is considered in the model construction, which says that if a gene is associated to a pathway, it is also associated to all the pathways along the path up to the root in the database. A carefully designed MCMC algorithm is proposed to sample the posterior distribution for inference. Our algorithm can handle 25K expression probes and 1000 SNPs. Simulation studies and real data analyses are conducted to evaluate the performance of this method.

1733W

A Novel Exact Test for Association for Small Sample Case-Control Studies. *L. Ehwerhemuepha, S. Alexandria, C. Rakovski.* Chapman University, Orange, CA.

We propose a novel exact test for association between a multiallelic marker and a phenotype with small sample case-control data. In these settings, the case-control genotype data follow multinomial distributions but classical large-sample chi-square contingency table methods are not applicable. The approach enumerates all samples under the non-completely specified null hypothesis of equality of the underlying multinomial distributions and calculates p-values as the sum of the probabilities of the samples as likely or less likely to occur than the observed data. We performed an extensive simulation study to assess the type I error rates under various null hypothesis and at several alpha levels. The number of all possible samples is a product of large binomial coefficients that make the full calculation computationally intensive. Thus, we developed a fast version of the algorithm that reduces the computational time by a factor of 1000 based on the idea of a selective removal of samples with very low probabilities while controlling the precision of the estimated exact p-values. Our results show that the new method possesses a conservative type I error in all scenarios due to the absence of adjustment in this nonparametric technique for the estimation of common multinomial probabilities under the null. It is a viable association approach that attains moderate power to detect deleterious mutations with very large effect sizes even with small sample data. The proposed method is readily extendable to haplotype data and even multimarker genotype data with haplotypes phase uncertainty. In the latter case, the EM algorithm can be implemented to determine weighted haplotype assignments of all subjects based on the haplotype pairs compatible with the unphased genotypes.

1734T

SNPx: fast testing of SNPxSNP interactions using only summary statistic data. *S. Bacanu, T. Bigdeli, D. Lee.* Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

Analyses of genome wide association studies (GWASs) and meta-analyses have mainly focused on detecting univariate association between trait and single nucleotide polymorphisms (SNPs). However, SNPxSNP interactions are likely to play important role in the etiology of complex phenotypes/diseases and, thus, detecting such interactions might provide new insights into the biological basis of these phenotypes. Nonetheless an exhaustive testing for these interactions has been prohibitively difficult due to i) the lack of access to individual level genotype data used in GWASs/meta-analyses and ii) extremely heavy computational burden required for a) the imputation of unmeasured SNPs and b) testing of all pairwise SNP interactions. To alleviate the burden of testing SNPxSNP interactions, we propose a novel method/software for detecting interaction between SNPs in a genome scan (GWAS or whole genome sequence scan), by using only summary statistics. The proposed method employs the conditional expectation formula for multivariate normal variates to impute i) summary statistics of unmeasured SNPs and ii) interaction statistics between all nominally significant SNPs. Based on these univariate summary statistics and their correlations, as estimated from a relevant reference panel (e.g. 1000 Genomes and UK10K), we construct the omnibus SNPxSNP test. We applied the method to summary statistic data from the Psychiatric GWAS Consortium (PGC) stage 1 and detected a number of interesting and unexpected interactions among SNPs in various pathways.

1735F

Efficient and powerful set tests using phenotype prediction. *C. Lippert, C. Kadie, J. Listgarten, D. Heckerman.* Microsoft Research, Los Angeles, CA.

Set tests are rapidly gaining in importance, proving useful for testing associations between phenotypes and sets of (possibly rare) variants defined by genes, pathways, or regions of the genome. We introduce a new methodology for such tests that yields improved power over widely-used kernel-based methods (such as SKAT), while controlling for type-I error. The test we consider uses a test statistic that is the difference in out-of-sample (cross-validated) phenotype prediction accuracy between using all and no variants in the set. This statistic has been used previously, but obtaining *P* values has been computationally inefficient for genome-wide testing, because it has required a huge number of permutations for reliably estimating the extreme tail of the null distribution, the region of most interest. Here, we introduce a substantial speed up of the permutation approach, wherein test statistics for a small number of permutations are computed (typically, 10 permutations per test), and then the tail of the distribution of pooled test statistics is fit to a simple parametric null distribution. One example of a parametric distribution that we have found to work well in practice is a mixture distribution between a constant zero component and a gamma distribution. We illustrate the approach on several synthetic and real datasets, including data from the Wellcome Trust Case Consortium. The approach is extremely general as it can be used with various linear and nonlinear classification/regression models and various measures of prediction accuracy and does not rely on asymptotic assumptions.

1736W

Analyzing genome-wide associations with high dimensional phenotypes in the GALA II study. *C.R. Gignoux[1], J.M. Galanter[1], K.A. Drake[1], H. Aschard[2], D.G. Torgerson[1], L.A. Roth[1], S.S. Oh[1], P. Kraft[2], C.D. Bustamante[3], N.A. Zaitlen[1], E.G. Burchard[1], The GALA II Investigators.* 1) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 3) Department of Genetics, Stanford University, Stanford, CA.

Studies of complex traits often measure a large number of phenotypic variables beyond the specific measurement of interest. Ideally these can help power studies of disease severity and identify potential disease heterogeneity. However, these measurements often contain missing data and can be highly correlated, noisy and difficult to interpret on their own. To identify genetic associations with high dimensional phenotypes, we leveraged an extensive number of measurements in the GALA II study of childhood asthma in Latinos.

We used a modified principal component analysis (PCA) capable of handling missing data to decompose the 75 phenotypes into uncorrelated components and performed a genome-wide association study for each PC using standard linear regression. We then performed a meta-analysis across all PC-GWASes to identify variants associated with any phenotype variables.

We found that for most PCs, scores were drawn from continuous distributions. Importantly the structure was not defined by a small number of PCs: PC1 explained ~8% of the total variance, while the top 10 PCs together still explained less than 40%. Yet the orthogonality ensured that PCA separated different components of the disease process: the top three PCs related largely to severity of disease (including frequency of symptoms and exacerbations), lung function, and anthropometrics (age, height, weight, and obesity). We also identified lower PCs emphasizing other aspects of atopic disease (e.g. eczema/skin rash).

We identified several genome-wide significant hits in our combined GWAS across all PCs. These variants tended to be less common (frequencies of 1-5%), and clustered in several pathways relevant to asthma - including a variant in *SMAD3*, a gene in the *TGF*-β signaling pathway previously associated with asthma in Europeans and European Americans. Additional associations involved the trafficking of toll-like receptors and a gene targeted in COPD treatment. Importantly, identifying these biologically relevant genes requires joint examination of the full spectrum of measurents in GALA II. By taking advantage of the data-rich sampling performed in GALA II we were able to efficiently identify novel significant variants important in the disease process, even across a large number of phenotypes.

1737T

A flexible association model for the analysis of multiple diseases, and its application to inflammatory bowel disease. *L. Jostins, G.A. McVean, International IBD Genetics Consortium.* Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

There is growing interest in understanding the shared and distinct genetic risk pathways that underlie different human diseases. However, these investigations can be confounded by differential power and control sharing, making loci falsely appear distinct and shared respectively. To address these issues we need a cross-phenotype model that is capable of combining evidence across multiple diseases for both locus discovery and fine-mapping, and testing specific hypotheses about locus sharing (e.g. showing a signal to be phenotype-specific). It must also be robust to differences in power, sample size and control sharing between cohorts, and be computationally efficient.

We propose a Bayesian multinomial logistic regression approach that fulfills the above criteria. Diseases are modeled as independent categories, with per-disease log odds ratios drawn from a multivariate normal prior representing correlations in risk across diseases. Global model parameters are fitted across all established loci, and are in turn used to calculate per-locus Bayes factors (BFs) summarizing the combined evidence for association, and for locus sharing or phenotype specificity. For tens of thousands of samples these calculations run genome-wide in a few hours on a laptop. The method allows regression techniques such as covariates, conditional analysis and pairwise epistasis (e.g to test for phenotype-specific interaction).

We apply this method to 30,837 inflammatory bowel disease (IBD) patients and 22,442 controls genotyped using the Immunochip by the International IBD Genetics Consortium. IBD is largely made up of two diseases (Crohn's disease, CD, and ulcerative colitis, UC): 101 loci were shown with high confidence (BF > 10) to be shared by both forms, compared to 12 CD specific, 14 UC specific and 36 inconclusive loci. For example, a SNP upstream of *GIPC2*, previously believed to be CD specific, was shown to be shared. While the UC association alone was not significant (OR=1.05, $p = 0.07$, compared to OR = 1.13, $p < 10^{-5}$ in CD), the joint analysis showed strong evidence of sharing (BF > 100). We also use this method to test for differential enrichment of functional terms (GO and KEGG) in CD and UC. Finally, we fine-map 78 densely genotyped loci by simultaneously considering data from both CD and UC, and compare the results to standard fine-mapping techniques.

1738F

Association study of genetic polymorphisms of SLC5A11 and ISYNA1 gene with the risk of Neural Tube Defects in a high-risk Chinese population. *J. Guo, JH. Wang, XW. Wang, C. Ji, Z. Guan, Q. Xie, ZQ. Zhu, B. Niu, T. Zhang.* Capital Institute of Pediatrics, Beijing, China.

Neural tube defects (NTDs) are among the commonest and most severe disorders of the fetus and newborn. Maternal nutritional status is associated with the occurrence of NTDs. Myo-inositol (MI) deficiency during embryonic development can cause cranial NTDs in both rats and mice, and some human NTD pregnancies also have lower maternal MI concentrations than unaffected pregnancies. In the inositol metabolic pathway, Solute carrier family 5 (Sodium/Glucose Cotransporter), Member 11(SLC5A11) is exclusively responsible for apical MI transport and absorption in intestine and the encoded protein of Myo-Inositol 1-phosphate synthase A1 (ISYNA1)plays a critical role in the myo-inositol biosynthesis pathway by catalyzing the rate-limiting conversion of glucose 6-phosphate to myoinositol 1-phosphate. Our hypothesis is that SNP of SLC5A11 and ISYNA1 gene may affect the maternal MI concentration and then disturbances the process of neural tube close. In the present study, we carried out a case-control study in a Chinese population of Shanxi Province, a high-risk area for NTDs. The case group was consisted of 150 pregnant women with NTDs and there were 279 pregnant women with normal newborns in the control group. Totally 8 tagSnps of SLC5A11 and ISYNA1 gene were genotyped by the MassARRAY platform and analyzed. The result showed the all the 8 SNPs in the present study were in Hardy-Weinberg equilibrium. In SLC5A11 gene, CC+CT genotype of rs274077 decreased risk for NTDs compared with those harboring the TT genotype (OR=0.64, 95%CI: 0.42-0.96, P = 0.029). After stratifying NTDs group into anencephalus, spina bifida and cenencephalocele, AG+GG genotype of rs8057788 increased 3.24 times risk of NTDs compared with AA genotype (OR=3.24, 95% CI, 1.11-9.47, P = 0.023). In ISYNA1 gene, none of the SNP was associated with the NTDs risk. Then we predicted the binding capacity to the potential transcription factor of the different genotype of the above 2 SNP using the bioinformatics method. The rs274077 is located in the conserved sequence of signal transducers and activators of transcription (STATx), and rs8057788 is located in the conserved sequence of transcription factor c-Rel and NF-kappaB. Our result suggested the polymorphism in SLC5A11 may affect the transcription factor binding ability, therefore, might regulate the expression and transcription of SLC5A11 gene to increase the risk of NTDs.

Established susceptibility loci do not infer cognitive impairment as measured by TICS-M in multiple sclerosis patients. *M.F. George[1], E. Elboudwarej[1], F.B.S. Briggs[1], H. Quach[1], R. Whitmer[2], L. Shen[2], A. Bernstein[3], C. Schaefer[2], L.F. Barcellos[1,2].* 1) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, University of California, Berkeley, CA, USA; 2) Kaiser Permanente Division of Research, Oakland, CA, USA; 3) Palm Drive Hospital, Petaluma, CA, USA.

The prevalence of cognitive impairment may be as high as 70% in individuals with multiple sclerosis (MS), and has been shown to affect social and emotional function, maintenance of employment, and overall quality of life. The identification of genetic variants that predict severe clinical MS outcomes is critical to understand disease mechanisms and guide development of effective therapeutics. We investigated the association between established risk loci and disease progression measured by cognitive impairment. In total, 932 white MS patients and 576 controls identified from the Kaiser Permanente Medical Care Plan, Northern California Region were studied. A weighted genetic risk score (wGRS) combined the weighted odds ratio (OR) from each of 52 established MS risk loci. The weight for each variant was the natural log of the OR for each allele determined from a previous GWAS (N≈30,000, Nature 2011). An unweighted genetic risk score (GRS) was calculated to capture variant allele counts per person. HLA-DRB1*15:01 carrier status was also examined. Cognitive status was determined using a validated telephone interview cognitive status (TICS-M) assessment tool, and accounted for level of education. Each participant was questioned regarding orientation; registration and free recall; attention and calculation; comprehension; language and repetition; and delayed recall. These seven areas of cognition were also examined as sub-scores. Linear regression models were utilized; adjusted models controlled for age, gender and known environmental risk factors. As expected, overall cognitive score was lower among cases compared to controls ($p=4\times10^{-4}$), as well as several sub-scores (orientation $p=3\times10^{-5}$; registration p=0.013, comprehension p= 0.048, and delayed recall $p=2\times10^{-3}$). When testing in cases only, no association between individual risk variants, wGRS, GRS, or HLA-DRB1*15:01 and cognitive score was observed. This study is the first to investigate the relationship between genetic risk scores (weighted and unweighted) and established MS risk loci on cognitive status in MS cases. Results suggest genetic factors contributing to cognitive impairment in MS are different from those that predispose to disease onset.

The role of rare genetic variants in host genetic control of anti-mycobacterial immunity. *J. Manry[1,2], A. Cobat[1,2], E. Schurr[1,2].* 1) McGill International TB Centre, Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 2) Departments of Medicine and Human Genetics, McGill University, Montreal, Quebec, Canada.

The tuberculin skin test (TST) measures the intensity of anti-mycobacterial acquired immunity and is used to diagnose latent infection (i.e. without clinical symptoms) with Mycobacterium tuberculosis. In a previous genome-wide linkage study, we identified two loci that have an impact on TST reactivity. The TST1 locus impacts on TST zero versus nonzero while TST2 impacts on the intensity of the developing immune response. Present experimental data do not support a strong effect of variants with a minor allele frequency (MAF) > 2% on both phenotypes leading to the conclusion that TST responses are under control of rare variants. Exome sequencing was performed on 96 individuals from the founder generation of the families that led to the detection of the TST1 and TST2 linkage peaks. A bioinformatic pipeline for variant discovery was setup, and 2461 variants were identified in genes located within the two linkage intervals (1305 in the TST1 locus and 1156 in the TST2 locus). To reduce the number of candidate variants, several filters were applied to identify those variants that are most likely to impact on the two phenotypes. In a first step, the exclusion of variants that corresponded to synonymous amino acid changes or that were not in Hardy-Weinberg equilibrium allowed us to reduce the list to 430 variants. Next, variants that had previously been genotyped in a high resolution scan of common variants of the linkage intervals were eliminated reducing the list to 351 variants. Interestingly, 239 of these 351 variants were found in families contributing substantially to linkage (maximum LOD score for the family > 0.1). Indeed, 51 variants in 26 genes in the TST1 locus and 25 variants in 11 genes in the TST2 locus were only present in those families.. This genotyping effort will allow us to identify genes with enrichment of variants that segregate with TST reactivities.

The Empirical Assessment of Statistical Power of Rare Variant Association Methods. *K. Hao[1,2,3], H. Chen[4], H. Zhou[4], C. Molony[4], H. Dai[3,4].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Icahn Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Asian Cancer Research Group, Inc., Wilmington, DE; 4) Merck Research Laboratories, Boston, MA.

Backgrounds The role of rare genetic variation in the etiology of complex disease remains as an active research field. The next-generation sequencing technologies were powerful in identifying genetic variants responsible to Mendelian disorders, but had limited success in dissecting complex diseases. Several novel statistical methodologies have been recently proposed to assess the contribution of rare variation to complex disease etiology. So far, their statistical power was assessed mainly on simulated phenotypes. Methods We quantified the statistical power of popular rare variants association methods empirically using the eQTL framework. That is the relative statistical power is proportional to the number of eQTLs captured at fixed FDR. Results On N=100 human non-tumor liver tissues, we measured gene expression trait with Affymetrix HU133 Plus2 chip, and conducted whole genome DNA sequencing (WGS) at 30X coverage. Also, we measured the genotype using Illumina 650Y array. Results of conventional GWAS methods with 1000G imputation was compared to those of rare variants association methods, including cohort allelic sum test (CAST), weighted sum test (WST) and SKAT. When only focusing on SNV of MAF<5%, none of the rare variants association methods have meaningful statistical power. When including all SNVs, rare variants association methods offer comparable power to single marker test (ie, GWAS methods) Conclusion WGS has no advantage in term of statistical power over SNP array in identifying eQTLs. Gene-level tests offer higher power due to less multiple testing penalties. SNVs on exons, splicing site or UTRs were more likely to control gene expression levels.

Enhanced ability to replicate findings as a rationale for conducting marker-set tests. *J. Arbet[1], K. Grinde[2], C. Fu[3], A. Benitez[4], M. O'Connell[5], N. Tintle[6].* 1) Winona State University, Winona, MN; 2) St. Olaf College, Northfield, MN; 3) Massachusetts Institute of Technology, Cambridge, MA; 4) Brown University, Providence, RI; 5) Miami University of Ohio, Oxford, OH; 6) Dordt College, Sioux Center, IA.

Over the last decade numerous approaches have been proposed to simultaneously analyze multiple individual variants for association with a phenotype. These approaches span methods which combine rare variants (minor allele frequency less than 5%), common variants, rare and common variants and pathway based approaches. All of these methods hope to provide improved power versus single variant approaches by (a) reducing multiple testing penalties and (b) aggregating evidence from multiple causal variants by creating biologically meaningful sets. While simulation studies have shown that for particular genetic architecture and based on the proportion of non-causal variants, multi-marker approaches can provide improved power in a discovery (stage 1) analysis, little work has explored the impact of single vs. multi-marker tests on the power to replicate findings in an independent (stage 2) study. We present general results for power in independent samples when using multiple marker tests vs. single marker tests, and demonstrate that the advantages of multiple marker approaches are a function of the number of markers combined, the proportion of non-causal variants, the strength and direction of the causal variant association with the phenotype and the multiple testing penalty being used. Practical guidance on use of multiple marker tests with a goal of maximal power for replication is provided.

1743T

Maximizing the power in Principal Components Analysis of Correlated Phenotypes. *H. Aschard[1], B. Vilhjalmsson[1], C. Wu[1], N. Greliche[2], PE. Morange[3], B. Wolpin[4], DA. Tregouet[2], P. Kraft[1].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) INSERM UMR_S 937, ICAN Institute for Cardiometabolism And Nutrition, Pierre et Marie Curie University, Paris 6, France; 3) INSER UMR_S 1062, Aix-Marseille Université, Marseille F-13385, France; 4) Dana-Farber Cancer Institute, department of Medical Oncology, Boston, USA.

Background: Principal Component analysis (PCA) is a useful tool that has been widely used for the multivariate analysis of correlated variables. It is usually applied as a dimension reduction method: the few top principal components (PCs) explaining most of total variance are tested for association with a predictor of interest, and the remaining PCs are ignored. This strategy has been widely applied in genetic epidemiology, however some aspects of this analytical technique are not well appreciated in the context of single nucleotide polymorphisms (SNPs) testing.

Method: We reviewed some of the theoretical basis and behavior of PCA when testing for association between a SNP and two correlated traits under various scenarios. We then evaluated through simulations the power of a few different PCA-based strategies when analyzing up to 100 traits. We applied these methods for the genome-wide association test of five coagulation traits in 685 subjects from the MARTHA study, and the association test of 700 candidate SNPs with 79 metabolites levels in 1190 individuals from four U.S. prospective cohorts.

Result: We show that contrary to widespread practice, testing the top PCs only can be dramatically underpowered since PCs explaining a low amount of the total phenotypic variance can harbor a substantial part of the total genetic association. We also demonstrate that PC-based strategies can only achieve a moderate gain in power in the presence of positive pleiotropy, but have great potential to detect negative pleiotropy (e.g. positive correlation and opposite genetic effects) or genetic variants that are associated with a single trait highly correlated to others. Real data applications confirm these results: the combined analysis of the five PCs from the coagulation traits identified two new potential candidates SNPs, which had strongest associations with the 5th PC, while the combined analysis of half of the PCs from the metabolite traits explaining the less of the total variance (12% of the total when combined) identified two new variants that likely affect a single trait.

Conclusion: We identified major improvements to standard PCA-based strategies for the analysis of correlated traits. Their implementations led to the identification of new genetic variants that would have been missed by standard approaches.

1744F

What now? Post-hoc approaches for gene-based, rare variant tests of association. *A. Benitez[1], J. Arbet[2], K. Grinde[3], C. Fu[4], M. O'Connell[5], N. Tintle[6].* 1) Brown University, Providence, RI; 2) Winona State University, Winona, MN; 3) St. Olaf College, Northfield, MN; 4) Massachusetts Institute of Technology, Cambridge, MA; 5) Miami University of Ohio, Oxford, OH; 6) Dordt College, Sioux Center, IA.

To date, rare variant testing approaches have focused on maximizing statistical power to identify genes showing significant association with disease. The statistics can accommodate a combination of risk, protective, and non-causal variants and can weight each variant. Although increasingly complex test statistics and weighting strategies may improve power, they also may make interpretation of a significant association result more difficult. Determining which variant(s) in the gene are causal and estimating their effect is crucial toward planning replication studies and characterizing the genetic architecture of the locus. This problem is analogous to the situation in a one-way ANOVA analysis, where evidence in the omnibus test says that 'at least one group mean is different than the others,' but it takes post-hoc analyses to identify specific group means as being different than others. Recent work by our group has classified general characteristics of two large classes of gene-based rare variant tests. Using this framework, we have explored the ramifications of choice of gene-based test statistic on post-hoc analyses attempting to identify causal variants. Furthermore, we have evaluated the overall quality and consistency of different single marker association statistics (e.g. single marker test p-values, difference in allele counts between cases and controls, relative risk estimates) in identifying the most likely causal variants within a gene. Finally, we have explored approaches to identify the most likely subset of causal variants within a gene, when incorporating a priori biological information (e.g., position, function). In this presentation we will present the results of our findings, ultimately providing a set of best practices for applied researchers.

FARVAT: a fast and efficient rare variant association Tool for dichotomous trait with extended families. *S. Choi[1], S. Lee[1], M.M. Nöthen[2], C. Lange[3], T. Park[1,4], S. Won[5].* 1) Bioinformatics Program, Seoul National University, Seoul, South Korea; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany; 3) Dept of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 4) Dept of Statistics, Seoul National University, Seoul, South Korea; 5) Dept of Applied Statistics, Chung-Ang UNiversity, Seoul, South Korea.

Family-based samples are genetically more homogeneous than the population-based samples and the analysis of rare variant with family-based samples have been often recommended. However in spite of the importance of family-based samples for rare variant association analysis, few statistical methods have been suggested. In this report we propose a new statistical method for the analysis of rare variant with extended families. The proposed method is robust against the population substructure, and can be applied to both binary and continuous traits. Depending on the choice of working matrix, our method can be a burden test or variance component test, and this approach is extended to the SKAT-O statistic. We empirically showed that the proposed methods perform better than the existing methods such as PedCMC and FPCA (MC Wu et al. AJHG, 2011). Furthermore the time complexity for the proposed method is O(M3 + N2M) and we found that the analysis of the whole genome sequence data for 1000 individuals in extended family design can be conducted within a few hours. The proposed method is implemented in C, and the proposed method was applied to gene-based analysis of Schizophrenia. All samples were collected from Germany, and the whole genomes for 36 trios which consist of affected offspring and unaffected parents were sequenced. There were 9,216,373 bi-allelic variants available, and 31,046 variants MAF of which minor allele frequencies were less than 0.05. Using 13,053 impact genes, we identified several candidate genes at the 5% significance level after Bonferroni adjustment, which are related to schizophrenia.

1746T

8q24 Risk Alleles and Prostate Cancer in African-Barbadian Men. *C.D. Cropp[1], C.M. Robbins[2], A.J.M. Hennis[3], J.D. Carpten[2], L. Waterman[3], R. Worrell[3], J.M. Trent[2], M.C. Leske[4], S.Y. Wu[4], J.E. Bailey-Wilson[1], B. Nemesure[4].* 1) Statistical Gen Branch, IDRB/NHGRI/NIH, Baltimore, MD; 2) Integrated Cancer Genomics Division, Translational Genomics Research Institute (TGen), Phoenix, AZ; 3) Department of Biological & Chemical Sciences, University of the West Indies, Bridgetown, Barbados; 4) Department of Preventive Medicine, Stony Brook University Medical Center, Stony Brook, NY.

African American men (AA) exhibit a disproportionate share of prostate cancer (PC) incidence, morbidity and mortality compared to other groups. Several genetic association studies have implicated select loci in the 8q24 region as increasing PC risk in AA. We evaluated the association between previously reported 8q24 risk alleles and PC in African-Barbadian (AB) men, also known to have high rates of PC. Ten previously reported tag SNPs were genotyped in 447 AB men with PC and 385 AB controls from the Prostate Cancer in a Black Population (PCBP) study. Only rs2124036 was nominally significant in AB men, (OR = 2.0, 95% CI (1.0-4.3), P=0.06) for the homozygous C/C genotype after correction for multiple testing. We also conducted a meta-analysis including our AB population along with two additional African-Caribbean populations from Tobago and Jamaica for SNPs rs16901979 and rs1447295. A significant association resulted for the rs16901979 A allele (Z score 2.75; p=0.006; summary OR= 1.21 (95% CI: 1.01-1.46)). Our findings may indicate: i) the presence of a founder effect; ii) the selected SNPs not being tagged to an ancestral haplotype bearing the 8q24 risk allele(s) in this population; or iii) inadequate power to detect a true association. Additional GWAS and sequencing studies are underway to further interrogate any potential contribution of the 8q24 region to PC in this West African-derived population.

1747F

Powerful methods for including genotype uncertainty in tests of Hardy-Weinberg Equilibrium. *C. Fu[1], M. O'Connell[2], A. Benitez[3], J. Arbet[4], K. Grinde[5], K. Liu[7], A. Luedtke[8], A. Beck[9], N. Tintle[6].* 1) Massachusetts Institute of Technology, Cambridge, MA; 2) Miami University of Ohio, Oxford, OH; 3) Brown University, Providence, RI; 4) Winona State University, Winona, MN; 5) St. Olaf College, Northfield, MN; 6) Dordt College, Sioux Center, IA; 7) Harvard University, Cambridge, MA; 8) University of California - Berkeley, Berkeley, CA; 9) Loyola University Chicago, Chicago, IL.

Most genotyping technologies now generate posterior probabilities reflecting genotype uncertainty. Increasingly, methodological work seeks to utilize these posterior probabilities in downstream statistical analysis. In many cases, use of posterior probabilities (e.g., the dosage) can yield improved statistical power. Recent work by our group and others has shown that for standard single marker tests of association use of the dosage provides a nearly optimal use of posterior probabilities. However, prior to association testing, a standard quality control step in the analysis of SNP genotypes is to test for departures from Hardy-Weinberg Equilibrium (HWE). In this presentation we propose two novel strategies for testing HWE using posterior probabilities, and compare to a third recently proposed option. We demonstrate that these novel strategies provide improved power and proper control of the type I error rate as compared to existing methods.

1748W

A clustering approach for mapping rare variants based on mutual association. *S. Ghosh, S. Deb.* Human Genetics Unit, Indian Statistical Institute, Kolkata, India.

Although genome-wide association studies have successfully identified a large number of common variants underlying various complex disorders, a substantial proportion of the total genetic variation in a trait still remains unexplained. It is becoming increasingly evident that the 'Common Disease Common Variant' paradigm needs to be modified and the 'missing heritability' may possibly be explained by rare variants that could not be identified using genome-wide association studies. However, the major impediment in identifying rare variants is that one would require huge sample sizes to detect differences in allele frequencies between cases and controls. Thus, most existing methods are based collapsing multiple variant sites using different statistical algorithms. Motivated by the combined multivariate and collapsing (CMC) algorithm, we develop a clustering mechanism of rare variant sites, but based on their mutual extent of association rather than similarity in allele frequencies as proposed in CMC, thereby reducing the possibility of combining functional and non-functional variants. We use the Fisher's exact test to identify blocks of variant sites such that the initial site in each block is associated with all other sites in the block. The test for case-control association is then performed within each block by comparing the proportions of affected and unaffected individuals carrying at least one copy of a rare variant and is based on a variance stabilizing sine transformation. We carry out extensive simulations under different rare variant models and compare the false positive rate and the power of our proposed method with some of the popular competing methods: CMC, adaptive SUM, WSS, TestRare, RareCover and Kernel-based Adaptive Clustering. We find that the proposed test procedure yields more power than the existing approaches, especially with increasing sample size, while maintaining the correct size.

1749T

Evaluating the impact of genotype errors and uncertainty on gene-based rare variant tests of association. *K. Grinde[1], C. Fu[2], J. Arbet[3], A. Benitez[4], M. O'Connell[5], N. Tintle[6].* 1) St. Olaf College, Northfield, MN; 2) Massachusetts Institute of Technology, Cambridge, MA; 3) Winona State University, Winona, MN; 4) Brown University, Providence, RI; 5) Miami University of Ohio, Oxford, OH; 6) Dordt College, Sioux Center, IA.

The new class of gene-based rare variant tests of association have usually been evaluated assuming error-free genotype information. In reality, rare variant genotypes, whether from next generation sequencing or imputation will reflect genotype uncertainty (e.g., genotype likelihoods, dosages or errors), and, ideally, subsequent rare variant tests should be robust to this uncertainty. Errors and uncertainty in SNP genotyping are already known to impact statistical power for single marker tests on common variants and, in some cases, inflate the type I error rate. Recent results show that uncertainty in genotype calls derived from sequencing reads are dependent on several factors, including read depth, calling algorithm, number of alleles present in the sample, and the frequency at which an allele segregates in the population. Imputation accuracy of rare variants is dependent upon the frequency of the allele to be imputed, as well as the size of the reference panel and its genetic relatedness to the study sample. We have recently proposed a general framework for the evaluation and investigation of gene-based rare variant tests of association. We have now extended this framework to incorporate rare variant genotype uncertainty and error models to precisely relate factors affecting genotype uncertainty to the power and type I error rate of rare variant tests. This work provides a realistic framework for assessing power and type I error and suggests genetic disease model, study design (e.g., imputation? sequencing depth?) and test statistic combinations that are particularly impacted by or resistant to genotype uncertainty.

1750F

Meta-Analysis of Gene-Level Associations for Rare Variants Based on Single-Variant Statistics. *Y.J. Hu[1], S.I. Berndt[2], S. Gustafsson[3], A. Ganna[3,4], J. Hirschhorn[5,6,7], K.E. North[8], E. Ingelsson[3,9], D.Y. Lin[10], Genetic Investigation of ANthropometric Traits (GIANT) Consortium,.* 1) Biostatistics and Bioinformatics, Emory University, Atlanta, GA.Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA, 30322, USA; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, Maryland 20892, USA; 3) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University Hospital, 751 85 Uppsala, Sweden; 4) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, 171 77 Stockholm, Sweden; 5) Divisions of Genetics and Endocrinology and Center for Basic and Translational Obesity Research, Children's Hospital, Boston, Massachusetts 02115, USA; 6) Metabolism Initiative and Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts 02142, USA; 7) Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115, USA; 8) Department of Epidemiology and Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC 27599-8050, USA; 9) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN, UK; 10) Department of Biostatistics, University of North Carolina, Chapel Hill, NC 27599-7420, USA.

Meta-analysis of genome-wide association studies (GWAS) has led to the discoveries of many common variants associated with complex human diseases. There is a growing recognition that identifying̀ causal'' rare variants also requires large-scale meta-analysis. The fact that association tests with rare variants are performed at the gene level rather than at the variant level poses unprecedented challenges in the meta-analysis. First, different studies may adopt different gene-level tests, so the results are not compatible. Second, gene-level tests require multivariate statistics (i.e., components of the test statistic and their covariance matrix), which are difficult to obtain. To overcome these challenges, we propose to perform gene-level tests for rare variants by combining the results of single-variant analysis (i.e., p-values of association tests and effect estimates) from participating studies. This simple strategy is possible because of an insight that multivariate statistics can be recovered from single-variant statistics, together with the correlation matrix of the single-variant test statistics, which can be estimated from one of the participating studies or from a publicly available database. We show both theoretically and numerically that the proposed meta-analysis approach provides accurate control of the type I error and is as powerful as joint analysis of individual participant data. This approach accommodates any disease phenotype and any study design and produces all commonly used gene-level tests. An application to the GWAS summary results of the Genetic Investigation of ANthropometric Traits (GIANT) consortium reveals rare and low-frequency variants associated with human height. The relevant software is freely available.

1751W

Recursive organizer (ROR): an analytic framework for sequence-based association analysis. *X. Huang[1], L.P. Zhao[2].* 1) AbbVie Inc., North Chicago, IL. Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA School of Public Health, University of Washington, Seattle, WA.

The advent of next-generation sequencing technologies affords the ability to sequence thousands of subjects cost-effectively, and is revolutionizing the landscape of genetic research. With the evolving genotyping/sequencing technologies, it is not unrealistic to expect that we will soon obtain a pair of diploidic fully-phased genome sequences from each subject in the near future. Here, in light of this potential, we propose an analytic framework called, recursive organizer (ROR), which recursively groups sequence variants based upon sequence similarities and their empirical disease associations, into fewer and potentially more interpretable super sequence variants (SSV). As an illustration, we applied ROR to assess an association between HLA-DRB1 and type 1 diabetes (T1D), discovering SSVs of HLA-DRB1 with sequence data from the Wellcome Trust Case Control Consortium (WTCCC). Specifically, ROR reduces 36 observed unique HLA-DRB1 sequences into 8 SSVs that empirically associate with T1D, a four-fold reduction of sequence complexity. Using HLA-DRB1 data from Type 1 Diabetes Genetics Consortium (T1DGC) as cases and data from Fred Hutchinson Cancer Research Center as controls, we are able to validate associations of these SSVs with T1D. Further, SSVs consist of nine nucleotides, and each associates with its corresponding amino acids. Detailed examination of these selected amino acids reveals their potential functional roles in protein structures and possible implication to the mechanism of T1D.

1752T

Valid permutation tests for genetic case-control studies with missing genotypes. *D.D. Kinnamon, E.R. Martin.* John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Permutation tests are indispensable tools in the analysis of genetic case-control studies. However, many permutation tests proposed in the genetics literature are justified only by heuristic arguments under the assumption of complete genotype data. We therefore developed a rigorous theoretical framework for constructing valid permutation tests for genetic case-control studies with unrelated subjects and missing genotypes arising from a variety of missing data processes. We began by specifying a nonparametric probability model for the observed data in such a study. Using group-theoretic arguments, we then established two conditions that together guarantee an exact level-α Monte Carlo permutation test for data generated under this nonparametric probability model. We showed that one of these conditions is not satisfied for the most frequently used Monte Carlo permutation test and that this test is guaranteed to be level α only for missing data processes with certain characteristics. We therefore proposed an alternative Monte Carlo permutation test that we showed is exact level α as long as all covariates influencing the missing data process are identified and recorded. We supplemented our theoretical development with Monte Carlo simulations for a variety of test statistics and missing data processes. We concluded that, while permutation tests can be extremely useful in genetic case-control studies, they must be constructed with careful consideration of the process generating missing genotypes to avoid inferential errors.

1753F

Heritability of Gene Expression Variation. *Z. Liu[1], J. Huang[1], W. Cookson[2], M. Moffatt[2], L. Liang[1].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) National Heart and Lung Institute, Imperial College, London SW3 6LY, UK.

We proposed a statistical approach to estimate the heritability of global gene expression variability, named variance heritability (abbreviated in this paper as vH2), in Epstein-Barr virus-transformed lymphoblastoid cell lines in two large datasets from nuclear families of British descent recruited through a proband with childhood eczema (MRCE, n=550, based on Illumina platform) and asthma (MRCA, n=405, based on Affymetrix platform). This vH2 estimates additional genetic effects on expression to those captured by narrow sense (additive) heritability, including dominant effect, GxG and GxE interactions. The median heritability of global gene expression variability across all probes in MRCE and MRCA were 0.04 and 0.04, the third quartile (Q3) were 0.12 and 0.14, respectively. Thirty percent of probes in MRCE and 34% of probes in MRCA have estimated vH2 larger than 0.1. Compared with estimates from randomly permuted data (median=0.004, Q3=0.08, 20% probes with H2>0.1 in MRCE; median=0.002, Q3=0.09, 22% probes with H2>0.1 in MRCA), our estimated results implied the existence of genetic variants regulating the variance of gene expression. For probes targeting the same transcript, the heritability estimates were consistent across the two independent datasets (MRCE and MRCA) and were robust to expression array platforms. We further mapped the heritability of gene expression variance to individual genetic loci using Illumina 300K SNPs and 39 millions imputed 1000Genomes SNPs and INDELs. Our results suggest new genetic regulatory variants that might be missed by standard eQTL mapping studies that focused on the mean level of gene expression rather than its variability.

On the simultaneous testing for large genomic regions: A clustering approach for rare variants. *s. Lutz[1], C. Lange[2].* 1) Biostatistics, University of Colorado, Aurora, CO; 2) Biostatistics, Harvard School of Public Health, Boston, MA.

In case-control studies, we propose a general analysis frame-work in which hundreds of genetic loci with allele frequency less than 1% can be tested simultaneously for association with case-control status. The approach is built on spatial- clustering methodology, assuming that rare variants that are associated with the target phenotype cluster in certain genomic regions. In contrast to standard methodology for rare-variant analysis, which has focused on collapsing methods, the proposed approach does not depend on each rare variant being associated with the case-control status in the same direction and with similar effect sizes. Using simulation studies, the properties of the approach are evaluated. In an application to a genome-wide association study (GWAS) for chronic obstructive pulmonary disease (COPD) in the COPDGene study, we illustrate the practical relevance of the proposed method.

1755T

A kernel based multilocus genetic association test for longitudinal quantitative phenotype data. *I. Mukhopadhyay, P.K. Mandal.* Human Gen Unit, Indian Statistical Inst, Kolkata, India.

Technological advances permit us to collect data on thousands of single nucleotide polymorphisms (SNPs) for each individual in a genetic association study. However, current paradigm of analyzing such dataset focuses on looking at association with the phenotype only at a single SNP level. Due to limited success of genome wide association study using this method, some multilocus association methods have been proposed in recent literature. Even then an important issue is often ignored while collecting such data. The phenotype data, whether qualitative or quantitative, is usually collected only once. However, due to medication and other factors like age, food habits etc the quantitative phenotype value may vary over time. Thus a longitudinal phenotype data i.e. repeated measurements on the quantitative phenotype of an individual at different time points might be more informative to get a more vivid picture of the genetic architecture. In this work we have developed a multilocus genetic association testing method using longitudinal quantitative phenotype data to see any genetic association between any genomic region of interest or genes (rather than a single SNP) with the phenotype. Our method explores the association between kernel based genotype similarity and phenotype similarity over different time points and combine information of such association over multiple markers. This method is flexible enough to adjust the effect of other covariates, if any and also can takes care of the missing value for the covariates at some time points. We have also derived the asymptotic distribution of the test statistic that will help to calculate the p-value faster than a permutation technique.

1756F

Adaptive approaches for combining multiple rare variant association tests provide improved power across a wider range of genetic architecture. *M. O'Connell[1], A. Benitez[2], J. Arbet[3], K. Grinde[4], C. Fu[5], B. Greco[8], A. Hainline[6], N. Tintle[7].* 1) Miami University of Ohio, Oxford, OH; 2) Brown University, Providence, RI; 3) Winona State University, Winona, MN; 4) St. Olaf College, Northfield, MN; 5) Massachusetts Institute of Technology, Cambridge, MA; 6) Dordt College, Sioux Center, IA; 7) Vanderbilt University, Nashville, TN; 8) University of Michigan, Ann Arbor, MI.

Over the past five years, numerous gene-based rare variant tests of association have been proposed, each of which attempt to combine variants within a gene or region of interest into a single association statistic, with a goal of providing more power than a strategy which analyzes each variant separately. Simulation results have shown that many of these individual tests provide good power for particular genetic architectures, but not others. We have developed a general strategy for combining any two or more gene-based rare variant tests using an adaptive approach, which yields a single p-value representing the cumulative evidence for association across the set of gene-based tests. For example this strategy can take any threshold based test and turn it into a variable-threshold test, combine similar tests (similar statistic with alternative weighting strategies), or combine substantially different tests (e.g., burden tests and variance components tests). Using simulation we provide guidance on the tradeoff between power gains and test robustness versus the number of tests being combined, a result which is based on the correlation structure of the tests are under the null hypothesis of no association. Finally, we demonstrate how recent results from our group which suggested a substantially different gene-based test which is robust to high proportions of non-causal variants, combined with other popular tests (burden and variance component tests), can provide improved power across a wider range of genetic architecture.

1757W

Genome-wide association study of allergic rhinitis. *C. Schaefer[3], J. Liu[1,2,3], L. Shen[3], T. Hoffmann[1,2], M. Kvale[2], Y. Banda[1,2], D. Ranatunga[3], N. Risch[1,2], J. Witte[1,2], E. Jorgenson[3].* 1) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA.

Allergic diseases are complex and the risk of developing allergies is thought to have a strong genetic basis. To examine the role of genetic factors on allergic rhinitis, we conducted a genome-wide association study in 61,957 non-Hispanic White subjects from the Kaiser Permanente Genetic Epidemiology Research on Adult Heath and Aging (GERA) cohort, which includes genotypes on over 675,000 SNPs. We identified several variants that were associated with allergic rhinitis at a genome-wide significant level. The most significant SNP associations identified are located on chromosome 2 within the gene IL1RL1 (rs2160203, p=3.8*10^-10). IL1RL1 encodes a member of the interleukin 1 receptor family and has previously been reported to be associated with asthma. In addition, three SNPs (rs3806933, rs34624588, and rs1438673) that lay within a region of chromosome 5 containing the genes TSLP and WDR36 reached genome-wide significance (5*10^-8). TSLP promotes T helper type 2 cell responses and is associated with immune response in various inflammatory diseases, including asthma and allergic inflammation. WDR36 is involved in T-cell activation and has been shown to be associated with bronchial asthma and eosinophilic esophagitis. In summary, we detected genome-wide significant SNP associations for allergic rhinitis, in loci that have been previously reported to be associated with asthma and allergic disease.

1758T

Disentangling Pooled Triad Genotypes for Association Studies. *M. Shi, D.M. Umbach, C.R. Weinberg.* Biostatistics Br, NIEHS, Res Triangle Park, NC.

Association studies that genotype affected offspring and their parents (triads) offer robustness to genetic population structure while enabling analyses to probe maternal effects, parent-of-origin effects, fetal-maternal interaction, and gene-by-environment interaction. We study case-parents designs that use pooled DNA specimens to both reduce genotyping costs and make good use of limited available specimens. We assume that the assay for each diallelic autosomal locus counts the number of variant alleles among the 2h copies present in a pool of h individuals. We reduce the genotypes required per pool from 3h to three by randomly partitioning the available triads into pooling sets of h triads each and then creating three pools from every pooling set, one pool each for mothers, fathers, and offspring. Data analysis proceeds via log-linear modeling using the expectation maximization algorithm, where the pseudo-complete data are disaggregated allele counts. The analysis provides relative risk estimates and assessment of maternal and parent-of-origin effects. It also accommodates genotyping errors and missing genotypes. We compare the power of our proposed analysis for testing offspring and maternal genetic effects to that based on a difference approach considered by Lee and that of the gold-standard based on individual genotypes, under a range of allele frequencies, missing father proportions, genotyping error rates and modes of inheritance. Power calculations show that the pooling strategies incur only modest reductions in power if genotyping errors are low, while reducing genotyping costs and conserving limited specimens. We illustrate our procedure with data from a study of oral clefts.

1759F

Meta-Analysis of Genome-Wide Association Studies in Myopia in Nine Populations. *C. Simpson[1], R. Wojciechowski[2], V. Verhoeven[3,4], P. Hysi[5], M. Schache[6], X. Li[7], M. Hosseini[8,9], L. Portas[10], F. Murgia[10], K. Oexle[11,12], A. Paterson[8,9], V. Vitart[13], C. Hammond[5], P.N. Baird[6], M. Pirastu[10], J. Rotter[7], C.C.W. Klaver[3,4], T. Meitinger[11,12], D. Stambolian[14], J.E. Bailey-Wilson[1].* 1) Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, USA; 3) Department of Ophthalmology, Erasmus Medical Center, PO Box 2040, 3000 CA Rotterdam, The Netherlands; 4) Department of Epidemiology, Erasmus Medical Center, PO Box 2040, 3000 CA Rotterdam, The Netherlands; 5) Department of Twin Research and Genetic Epidemiology, King's College London, St. Thomas' Hospital, London, UK; 6) Centre for Eye Research Australia, Royal Victorian Eye and Ear Hospital, University of Melbourne, Melbourne, Australia; 7) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA, USA; 8) Institute of Medical Science, University of Toronto, Toronto, Canada; 9) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada; 10) Institute of Population Genetics, National Research Council, Sassari, Italy; 11) Helmholtz Zentrum München, German Research Center for Environmental Health, Institute of Epidemiology I, Neuherberg, Germany; 12) Institute of Human Genetics, Technical University Munich, Munich, Germany; 13) Medical Research Council Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK; 14) Department of Ophthalmology, University of Pennsylvania, Philadelphia, USA.

Myopia is a common refractive error which affects at least a third of most populations. Both genetic and environmental factors influence myopic development. It has a significant impact on the lives of affected individuals and carries high economic costs associated with treatment, loss of productivity and co-morbidity from vision impairment. Recent genome-wide association studies (GWAS) have identified a number of loci associated with myopia and refractive error. Here we report results of a large meta-analysis of myopia in nine cohorts, for a total of 17,787 individuals of European ancestry and replication in a further 8 cohorts for a total of 7953 individuals. Genotypes in each population were imputed to HapMap2 and analyzed separately by each group. Cases were defined as a spherical equivalent of -1 diopters (D) or worse and controls were defined as > 0D. Individuals between 0 and -1D were coded as unknown. Analyses were performed including age, sex and years of education, plus the first 3 principal components to adjust for population structure. Meta-analysis was performed in METAL using the sample size schema. Due to large differences in numbers of cases and controls for some studies, effective sample sizes were calculated using the formula recommended by the authors of METAL. Genomic control was used to adjust for any residual structural differences between populations. 3 SNPS were identified as genome-wide significant with $P < 5e-8$, rs10113215 on chromosome 8q12.1 and rs1370156 and rs2028099 both in a previously reported locus on chromosome 15q14. For replication, SNPs with $P < 1e-5$ were identified and all SNPs within 500kb each side of that SNP selected, for a total of 20,431 SNPs. The replication threshold was set by calculating the effective degrees of freedom using the Ramos method. SNPs will be considered to replicate where the p value < 0.0026. The replication analyses are ongoing and will be presented.

1760W

Identifying disease susceptibility variants using pleiotropy and independent genome-wide association studies. *A. Skol.* Genetic Medicine, Dept of Medicine, Univ Chicago, Chicago, IL.

Pleiotropy is the phenomenon whereby a single gene influences multiple traits. Given that observing more than one disease cosegregating within a family is not uncommon, and that several studies have mapped the same gene to multiple traits, it would appear that pleiotropy is not an unusual phenomenon in disease genetics. Here, I explore the ability to use pleiotropy to identify variants or genes that are common between diseases using independent GWAS data, meaning that the traits of interest are measured in independent groups of individuals. The rational for looking for pleiotropic loci is two-fold: first, most studies will be insufficiently powered to identify most of the trait or disease influencing variation, however if two traits share a genetic underpinning then we should find contributing variants in the intersection of the studies' marginally significant results, and second, pleiotropic loci will provide novel insights into the common genetic etiology of seemingly disparate disease. I will compare three methods for detection: meta-analysis, intersection among the tails of the GWAS test statistics, and false discovery rate of p-values from one GWAS within the tail of the other. I will present results demonstrating the power of each of these approaches, how to determine significance thresholds that maximize power, what effect sizes are detectable, and how to correctly accommodate linkage disequilibrium.

1761T

An extrapolation approach for estimating genome-wide significance for whole genome sequencing studies and region-based tests. *C. Xu*[1,2] *on behalf of the UK10K Statistics group.* 1) Lady Davis Institute, JGH, Montreal, Canada; 2) Dept. of Biostatistics, McGill University.

Rare genetic variation derived from whole genome sequencing studies is often analyzed by defining a series of windows or genetic regions, and then evaluating the association between phenotype and all the genetic variability in each region. However, the choice of region boundaries, test statistics, and model parameters for such tests may be somewhat arbitrary, and repeated analyses may be performed making different assumptions. Therefore, establishing an appropriate correction for multiple testing is a challenging problem. In recent work, we have used pilot data from the UK10K consortium whole genome sequencing study to propose an empirical approach to establishing significance thresholds. This is combined with extrapolation from small genomic regions to the whole genome to make the empirical evaluations computationally feasible. Here we evaluate the dependence of the resulting estimated significance thresholds on sample size and minor allele frequency. In our investigations, we show that significance thresholds, for a combined analysis including univariate tests for common SNPs and region-based tests for rare genetic variation, are driven by the common SNP variation, and that we saw little dependence of the results on sample size. We recommend a genome-wide significance threshold of 1e-08 for such a combined analytic strategy.

1762F

Methods for Association Analysis and Meta-Analysis of Rare Variants in Families. *S. Feng, D. Liu, M. Zawistowski, X. Zhan, G.R. Abecasis.* Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Recent advances in exome sequencing and the development of exome genotyping arrays are enabling explorations of the contribution of rare variants of clear functional consequence to complex traits. Decreasing cost of sequencing and the low cost of exome chip genotyping allow increasingly large cohorts to be studied. For these rare variants, single variant association tests can lack power and a variety of association tests that group rare variants by gene or functional unit have been proposed as alternatives. Here, we describe family-based association tests for rare variants that allow analysis of a variety of quantitative traits, with or without covariates, and show how these tests can be applied in meta-analysis settings. The key idea beyond our method is that various gene-level test statistics can be reconstructed from single variant score statistics and that, when the linkage disequilibrium relationships between variants are known, the distribution of these gene-level statistics can be derived and used to evaluate significance. This idea can be used to derive a variety of gene-level association tests in families and also to enable meta-analysis. We have implemented family-based burden test, SKAT and variable frequency threshold tests. The methods have been implemented in freely available C++ code. To investigate power, we simulated families with various structures and sizes and genes comprising between 1kb and 25kb of sequence, each explaining 1-5% trait variance. In each gene, 10-30% rare variants were chosen to be causal. Our simulations show that, using alpha=2.5×10-6, when all variants influence the trait in the same direction, the variable threshold method has the largest power. For a sample of three-generation-family of size 10 with 1000 founders or 2500 individuals, VT is predicted to obtain ~80% power when 80% variants are causal for a gene of 1kb explaining 2% of trait variance. When variants influencing traits in both directions co-exist in the same gene, when half of them are trait-decreasing, our implementation of the SKAT test performs the best. For a sample of three-generation-family of size 16 with 2000 founders or 8000 individuals, SKAT is predicted to obtain ~85% power when 80% variants are causal and 50% of them are trait decreasing for a gene of 1kb explaining 4% of trait variance. Type-I error was examined using simulations under the null hypothesis and they were well controlled.

1763W

Testing for differences between multiple groups in high-throughput sequencing data using Bayesian multi-scale Poisson models. *H. Shim*[1], *E. Pantaleo*[1], *M. Stephens*[1,2]. 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept Statistics, Univ Chicago, Chicago, IL.

High-throughput sequencing technologies are now routinely applied at a genome-wide scale to collect a variety of phenotypic data. Testing for differences in these data between multiple groups is frequently encountered in genomics applications (e.g., eQTL mapping using RNA-seq and detecting differences in transcription factor binding across tissues using DNase-seq or ChIP-seq) Most approaches perform a test for differences using summary statistics such as total number of reads mapped to a gene or window although the original data consists of the counts of reads mapped to each base along the genome. These typical approaches have limited power to identify diverse patterns of signals and their results are often sensitive to window size. For example, these approaches could miss associations when different bases within a window show effects in opposite directions and partially cancel each other out, leading to a small overall effect on total number of reads over the window. Here we present statistical methods for testing for differences in the original data, which leads to increased power by using full information from the data. Specifically, our methods consider the data as an inhomogeneous Poisson process and test for differences in underlying intensities using Bayesian multi-scale Poisson models. In addition to testing for differences, our approach aims to provide a better interpretation of the analysis such as which parts and features of the data are driving the observed signals. We illustrate the proposed methods on DNase-seq data from 70 HapMap Yoruba LCLs. Moreover, we modify the proposed method to detect differences in gene expression between multiple tissues measured by paired-end RNA-seq data. Our results demonstrate that the proposed approaches can considerably increase power to detect associations compared with conventional window-based approaches.

1764T

Detecting association of rare variants by testing an optimally weighted combination of variants for censored survival outcomes. *X. Wang, X. Zhao.* Joseph J. Zilber School of Public Health, University of Wisconsin-Milwaukee, Milwaukee, WI. 1240 N 10th Street Milwaukee, WI 53205.

There is increasing evidence showing that rare genetic variants are important for identifying patients with aggressive diseases who need prioritized treatments. Identifying these patients is critical in improving survival outcomes. In addition, knowledge of the rare genetic variants can help us gain further understanding the biological processes underling aggressive diseases progression. Next-generation sequencing technology allows sequencing the whole genome of large groups of individuals with survival outcomes, and thus it makes directly testing prognostic rare variants possible. However, recently developed statistical methods for detecting association of rare variants are not applicable to survival data. Survival data are often subject to censoring and use the Cox proportional hazards model. The score test in a Cox proportional hazards model is seriously anticonservative for rare variants. In this paper, we use the signed square root of the log partial likelihood ratio test statistic to replace the score test and propose a Variable Wight Test for testing the effect of an optimally weighted combination of variants on a survival outcome. Our new test is based on optimal weights which are analytically derived under a certain criterion. Extensive simulation studies show that the type I error rates of the new test are under control. In order to evaluate the performance of the new test, we are conducting extensive simulation studies for power comparisons. Furthermore, we will illustrate the proposed test with a real data application.

1765F

Detecting association for low-frequency variants by the standardized linkage disequilibrium in case-control genome-wide screens. *C. Xing, C-Y. Lin, H-C. Ku.* McDermott Ctr, Univ Texas SW Med Ctr, Dallas, TX.

In genetic association studies a conventional test statistic is proportional to the correlation coefficient between the trait and the variant, with the result that it lacks power to detect association for low-frequency variants. Considering the link between the conventional association test statistics and the linkage disequilibrium measurement r-squared , we propose a test statistic analogous to the standardized linkage disequilibrium D-primer to enhance the power of detecting association for low-frequency variants with moderate to large effect sizes. We examined its validity and showed it is more powerful than the conventional methods to detect association for low-frequency variants in a genome-wide screen setting by both simulation and real data analysis.

1766W

An optimal quasi-likelihood-based burden test for rare-variant association. *X. Wu[1], H. Zhu[1], D. Liu[2].* 1) Department of Statistics, Virginia Tech, Blacksburg, VA; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

With the advent of next-generation sequencing (NGS) technologies, rare-variant association testing is receiving increasing amount of attention in genome-wide association studies. As a single rare variant shows little variation due to low allele frequency, standard testing methods for single-variant suffer insufficient power. A general solution is burden test, which assesses the genetic effect of a collapsed set of variants. However, currently available burden tests are usually proposed for population-based genetic studies thus may not be appropriate in the presence of related individuals. Furthermore, the weighting scheme in those burden tests is often empirical and lacks theoretical justification. In this paper, we propose an optimal MQLS burden test (OMBT), a flexible and computationally efficient method for testing multiple-variant (rare or common) association with disease-related traits (quantitative or dichotomous). OMBT is a generalization of the traditional MQLS/MASTOR test in order to accommodate rare variants under linkage disequilibrium (LD). Compared with other burden tests, OMBT has several advantages: (1) it takes into account dependence among individuals and among variants, (2) it can incorporate individuals with missing data, and (3) it provides optimal weights to guarantee maximized power for association testing. Simulation studies demonstrate that OMBT achieves correct type-I error and improved power over other competing methods. We apply the proposed method to a sequencing-based genetic study using data from the SardiNIA Medical Sequencing Discovery Project.

1767T

An empirical validation of random effects and Bayesian meta-analysis models. *R. Ahn, C. Garner.* Department of Epidemiology, Sprague Hall, Room 318, University of California, Irvine, Irvine, CA 92697-3905.

Genome-wide association study (GWAS) meta-analysis is a statistical method that is now routinely used to combine either individual-level data or summary statistics from multiple studies to increase the power to detect the small genetic effect sizes of common alleles and to decrease the number of false-positive associations. As new samples do not have to be genotyped, the cost to perform a GWAS meta-analysis with sample sizes in the tens of thousands or even in the hundreds of thousands is substantially lowered. As a result, hundreds of GWAS meta-analyses have been performed over the last few years and have substantially increased the number of risk loci discovered and replicated for several different phenotypes. Amongst the many approaches to GWAS meta-analysis, the most popular has been fixed effects meta-analysis because it is the most powerful approach. However, fixed effects meta-analysis ignores the potential heterogeneity that may exist between studies by assuming that the effect of a risk allele is the same across all studies. We have reanalyzed a two-stage GWAS meta-analysis using 292K single nucleotide polymorphisms (SNPs) directly genotyped in 4,533 celiac disease cases and 10,750 controls from 4 different countries in the discovery stage. In the replication stage, 131 SNPs were directly genotyped in 9,451 celiac disease cases and 16,434 controls from 11 countries. In the original study, a fixed effects meta-analysis approach was used. The purpose of our analysis was to determine if a novel random effects or Bayesian meta-analysis that accounts for between-study heterogeneity will yield results that differ from the results that were originally published. Here we present evidence that a SNP at a loci in chromosome 1 (RUNX3) that was previously reported to show genome-wide significance ($P < 5 \times 10\text{-}8$) was not genome-wide significant in either the discovery stage or the replication when the between-study heterogeneity was accounted for by the random effects or Bayesian meta-analysis approaches. This study highlights the need to carefully investigate between-study heterogeneity and the implementation of GWAS meta-analysis models that control for heterogeneity.

1768F

Methods and tools for fast efficient mixed-models based whole-genome association analysis for large cohorts and multiple phenotypes. *Y. Aulchenko.* Lab of recombination and segregation analysis, Institute of Cytology and Genetics SB RAS, Novosibirsk, Russian Federation.

Whole-genome association (WGA) analysis is a tool of choice for identification of loci underlying complex human traits. In WGA scans, association of millions of genetic polymorphisms measured with SNP arrays and/or genome re-sequencing is analyzed in relation to phenotypes in thousands of individuals. The mixed models methodology allows powerful WGA analysis in case when the trait under analysis is highly polygenic and/or when genetic (sub)structure is present in the sample. However, the analysis under mixed models is computationally challenging, especially for large cohorts and/or multi-trait "omics" data sets. Here, I will review recent advances in mixed-models based WGA analyses, and describe a number of methods, algorithms, and software tools we have developed to facilitate the analysis of cohorts including tens of thousands of participants and analysis of "omics" data sets potentially including hundreds of thousands of phenotypes.

1769W

PODKAT: a non-burden test for associating complex traits with rare and private variants. *U. Bodenhofer, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University, Linz, Austria.

High-throughput sequencing technologies have facilitated the identification of large numbers of single-nucleotide variations (SNVs), many of which have already been proven to be associated with diseases or other complex traits. Since association tests considering individual SNVs independently are known to be underpowered, different collapsing strategies have been proposed to consider multiple SNVs occurring in a region simultaneously. Such strategies can be classified into burden tests and non-burden tests, an important representative of which is the acclaimed Sequence Kernel Association Test (SKAT) by Wu et al. Several large sequencing studies, such as, the 1000 Genomes Project, the UK10K project, or the NHLBI-Exome Sequencing Project, have consistently reported a large proportion of private SNVs, that is, variants that are unique to a family or even a single individual. Non-burden tests like SKAT are typically utilizing correlations between SNVs to increase statistical power - a strategy that is not applicable to private SNVs, since singular events are generally uncorrelated. Burden tests are potentially able to deal with private SNVs, but only if the number of private SNVs occurring in a region is correlated with the trait under consideration. Moreover, burden tests have a disadvantage if deleterious and protective SNVs occur together in the same region. We propose the Position-Dependent Kernel Association Test (PODKAT). By means of a position-dependent kernel approach, PODKAT can potentially detect associations of rare and private SNVs with the trait under consideration even if the burden scores are not correlated with the trait. PODKAT assumes that, the closer two SNVs are on the genome, the more likely they have similar effects on the trait under consideration. This assumption is fulfilled as long as deleterious, neutral, and protective variants are grouped sufficiently well along the genome. PODKAT can be applied to testing focused regions as well as to whole-exome and whole-genome association testing. We evaluated PODKAT on simulated genomic data with simulated traits (both quantitative and dichotomous) and real sequencing data with simulated and real traits to illustrate its potential for association testing involving rare and private variants.

1770T

Model-based pathway enrichment analysis and prioritization of genetic variants in enriched pathways yields novel putative susceptibility loci for rheumatoid arthritis and type 1 diabetes. *P. Carbonetto[1], M. Stephens[2].* 1) Dept. of Human Genetics University of Chicago Chicago, IL; 2) Depts. of Statistics and Human Genetics University of Chicago Chicago, IL.

Many common diseases appear to be highly polygenic, modulated by a large number of genetic factors each with a small effect on disease risk. As a result, standard single-marker analyses of genome-wide association studies are unable to identify most variants conferring risk to disease; many individual SNP contributions to disease risk are so subtle that they cannot be distinguished from correlations that occur by chance. To address this problem, researchers have developed statistical methods that aggregate information over groups of related genes, such as genes in common pathways, to identify gene sets that are enriched for variants associated with disease. However, these methods often fail to answer a critical question: which genes and variants in the enriched pathways are associated with disease risk? We have developed a model-based approach that not only systematically interrogates pathways for enrichment of disease associations, but also uses this information to prioritize variants assigned to these pathways, in an attempt to promote these variants above background noise. A key feature of this approach, which distinguishes it from other enrichment methods, is that it is able to uncover additional loci contributing to disease risk. We describe our results from applying this approach to genome-wide studies of Crohn's disease (CD), rheumatoid arthritis (RA) and type 1 diabetes (T1D). These analyses yield many additional putative associations compared to standard single-marker analyses. Because of the predominant role of the MHC in RA and T1D, we developed methods to assess enriched pathways beyond enrichment of disease associations in the MHC, and found that this was important for reliably identifying pathways, and non-HLA associations. For CD and RA, most of the additional disease associations (7 of 8 non-HLA associations) are corroborated by other studies and large-scale meta-analyses, validating the usefulness of the methodology. The one novel disease association with RA is a region near TP73, and it appears to be promising candidate. For T1D, the results very strongly support the connection between IL-2 signaling and development of T1D, and prioritization of IL-2 signaling genes yields strong evidence for 7 additional non-HLA candidate disease regions. Of these, 4 have been validated by other genome-wide studies of T1D (IL2, IL2RA, CLEC16A and C1QTNF6), and 3 constitute novel T1D loci (regions containing RAF1, MAPK14 and FYN).

1771F

Rapid linear mixed model methods for large-scale genome-wide association studies. *W-M. Chen[1], A. Manichaikul[1], S.S. Rich[1], M. Cushman[2], M.M. Sale[1].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Medicine, University of Vermont, Colchester, VT.

Population stratification is known to confound association results in genome-wide association studies (GWASs). Recently, Linear Mixed Models (LMMs) have received attention as a flexible way to adjust for population structure using variance components. Multiple LMM algorithms were recently published that included exact maximum likelihood methods with computational complexity quadratic to sample size and fast approximations with computational complexity linear to sample size. Although existing LMM methods have proven to be computationally feasible for GWAS scans, several limitations exist. First, current methods have inflated type I errors in the presence of missing genotypes and misspecification of polygenic estimators; second, current efficient algorithms for LMM require analyzing one trait, limiting the number of traits that can be analyzed in a reasonable amount of time. Here, we present two novel fast LMM methods with computational complexity linear to sample size: (1) an approximation fast LMM method, and (2) an exact fast LMM method. As score tests, the proposed LMM test statistics are developed to be robust to missing genotypes, missing phenotypes, phenotypic distributional assumptions, and misspecification of polygenic parameters. The computational improvement of our implementations over existing fast LMM methods includes efficient computation of the relatedness matrix using the KING algorithm, rapid regression-based estimation for polygenic analysis in the approximation LMM method, and rapid genome scans in a matter of seconds for both fast LMM methods. In a test dataset consisting of 2,400 samples each typed at ~800,000 SNPs and 1,000 quantitative traits, it takes 40 minutes to perform 1,000 GWAS scans (*i.e.*, 2 seconds per GWAS scan) using the approximation fast LMM method and 9 hours using the exact fast LMM method on a single CPU. The genome scan results using the proposed fast LMM methods are highly correlated (*e.g.*, with correlation 0.994) with the results using the exact maximum likelihood methods, with the same order of significance of association at the top GWAS hits. Efficient implementations in our software tool KING makes it feasible to conduct large-scale GWAS scans for 10,000s of traits with small amount of computing resources.

1772W

An effective association testing procedure incorporating admixture mapping information. *G. Gao, W. Chen.* Department of Biostatistics, Virginia Commonwealth University, Richmond, VA.

Admixed populations are formed by recent admixture of two or more ancestral populations. For instance, African Americans often have recent genetic ancestry from both West Africans and European Americans. As a result of admixture, the variation in genome-wide ancestry (a type of stratification) in admixed populations can be a confounding factor in association tests, causing false positive and false negative findings. This makes gene mapping more complicated in admixed populations than in non-mixed populations (such as Europeans). For gene mapping in admixed populations, admixture mapping tests use admixture linkage disequilibrium (LD) and can only identify a causal variant in a large chromosomal region (several Mbs). Admixture LD occurs during admixture over the past several hundred years when large chromosomal segments are inherited from a particular ancestral population. To identify a causal variant in a small region, association tests that correct for local ancestry have been developed. These tests can use the background LD (traditional LD) existing in the ancestral populations and therefore can often identify a causal variant in a region with less than a few hundred Kbs). However, these tests can have relatively low power. Recently, to acquire increased power, several joint association tests that combine information from admixture mapping tests and association tests that correct for local ancestry have been proposed. However, these joint tests are more appropriate to identify a causal variant in a large chromosomal region (several Mbs). Our simulation studies showed that these joint tests could not control family-wise error rates (FWERs) in genome wide association studies if the null hypothesis is to test if a SNP is in background LD with the causal variants. In this study, we propose an effective association testing procedure for analysis of genome wide SNP data that incorporates appropriate amount of information from admixture mapping into association tests that correct for ancestry. Our simulation studies indicates that the association testing procedure not only controls family-wise error rates, but also can have improved power compared to the association tests that correct for local ancestry. We applied the association testing procedure to association studies in a data set from the Multi-Ethnic Study of Atherosclerosis project.

Mixed model association statistic with correction for case-control ascertainment provides large increase in power. *T. Hayeck[1], N. Zaitlen[2], B. Vilhjalmsson[1], S. Pollack[1], J. Yang[3], G. Chen[3], M. Goddard[4], P. Visscher[3], N. Patterson[5], A. Price[1].* 1) Harvard School of Public Health, Boston, MA; 2) University of California, San Francisco; 3) University of Queensland, Brisbane, Australia; 4) University of Melbourne, Melbourne, Australia; 5) Broad Institute, Cambridge, MA.

We introduce a mixed model association method for ascertained case-control studies that increases test statistics at causal markers by up to 23% vs. existing mixed model methods, with well-controlled false-positive rate. It is widely known that appropriate modeling of case-control ascertainment can produce large increases in power for case-control studies with fixed-effect covariates (reviewed in Mefford & Witte 2012 PLoS Genet), but such increases in power have not yet been obtained for models that include random effects. Here, we improve upon existing mixed model methods (e.g. Kang et al. 2010 Nat Genet, Zhou & Stephens 2012 Nat Genet) using a score statistic computed from posterior mean liabilities (PML) under the liability threshold model. The PML of each individual is conditional not only on that individual's case-control status, but also on every other individual's case-control status and on the genetic relationship matrix obtained from the data. For example, disease cases with higher genetic relationships to other disease cases will be assigned a larger PML than disease cases with lower genetic relationships to other disease cases. The PML are estimated using a multivariate Gibbs sampler, with the liability-scale phenotypic covariance matrix based on the genetic relationship matrix and a heritability parameter estimated via Haseman-Elston regression on case-control phenotypes followed by transformation to liability scale (Lee et al. 2011 AJHG). The Gibbs sampler does not iterate over SNPs, and overall running time is comparable to existing mixed model methods. In simulations of unrelated individuals, our statistic outperformed existing mixed model methods in all scenarios tested, with the magnitude of the improvement depending on the severity of case-control ascertainment. For example, we observed 23%, 8% and 2% improvements in test statistics at causal markers for ascertained case-control studies simulated at thresholds of 3, 2 and 1 (corresponding to disease prevalence of 0.13%, 2.3% and 16%), with well-calibrated test statistics at null markers. In conclusion, a large increase in power over existing mixed model association methods is available for ascertained case-control studies of diseases with low prevalence.

Testing the spatial correlation of association signals from two genome scans. *J. Hecker[1], D. Propopenko[1], P. Costa[1], E. Silverman[2], M. Naylor[3], S. Weiss[2], C. Lange[1,2,3,4], H. Loehlein Fier[1].* 1) Institute of Genomic Mathematics, Bonn, Germany; 2) Channing Laboratory, Brigham and Women's Hospital, Boston, United States; 3) Department of Biostatistics, Harvard School of Public Health, Boston, United States; 4) German Center for Neurodegenerative Diseases(DZNE), Bonn, Germany.

It is widely recognized that complex diseases like i.e. Alzheimer's disease, Cardio-Vascular-Diseases, Diabetes, Asthma, psychiatric diseases, and many others are characterized by a interaction of genetic, environmental and individual factors (e.g. Hunter 2005, Manolio et al. 2006, Risch et al. 2009, Manolio et al. 2008, Goldstein 2009, Thomas 2010).

As a result usually multiple correlated traits exist that describe the syndromes of a complex disease. Pinpointing and quantifying genetic risk factors of a complex disease based on several correlated traits however implies a challenge, since different traits might be differently associated with the genetic profile of the analyzed subjects (e.g. Wang 2012, Yang and Wang 2012). In order to understand the genetic architecture of complex diseases it is therefore crucial to unravel the genetic dependencies between correlated disease traits (pleiotropic effects).

In this communication, we propose a method to test the spatial correlation of two GWAS-association signals. For this, we need to combine the information about the positions and the corresponding p-values. We utilize kernel density estimation based techniques to locate clusters of significant p-values. With this knowledge we can use similarity measures, i.e. the L2-distance, to test the positional overlap of the identified clusters. We conduct a simulation study to assess how well our method is able to detect spatial correlation of GWAS signals and apply our method to real data.

Variable selection for GWAS with linear mixed models yields improved power and control of type I error. *D. Heckerman[1], O. Weissbrod[2], N. Fusi[1], C. Kadie[3], R. Davidson[3], C. Lippert[1], J. Listgarten[1].* 1) Microsoft Research, Los Angeles, CA; 2) Computer Science Department, Technion, Haifa; 3) Microsoft Research, Redmond, WA.

Linear mixed models (LMMs) are now routinely used to correct for genetic structure in genome-wide association studies (GWAS). At their core, LMMs rely on the estimation of a genetic similarity matrix, which encodes the pairwise similarity between every two individuals in a cohort. These similarities are estimated from single nucleotide polymorphisms (SNPs) or other genetic variants. Traditionally, all available variants are used to estimate the matrix. Here, we provide both theoretical and empirical evidence that such use is non-optimal, and that the careful selection of variants can lead to improved results. Theoretically, a linear mixed model is equivalent to a form of linear regression, where the SNPs that determine the genetic similarity matrix in the LMM view are covariates in the linear-regression view. Taking the latter view strongly suggests that the inclusion of variants relevant to the phenotype and the exclusion of variants irrelevant to the phenotype should lead to improvements in analysis. Empirical results confirm this argument, using a simple variant selection algorithm that searches over various sets of SNPs to identify those that maximize cross-validated prediction accuracy. To keep the search practical, we order SNPs for each fold by their univariate linear-regression P values on the training data for that fold. We then use increasing numbers of SNPs by this ordering, measuring prediction accuracy on the out-of-sample test set. Next, we average the prediction accuracy over each fold. Finally, we identify the number of SNPs that optimized this average. Essential to this procedure is out-of-sample optimization of a key parameter of the LMM representing the ratio of the variance explained by noise to the variance explained by the genetic similarity matrix. In-sample optimization of this parameter leads to lower quality GWAS performance. We apply this variant selection algorithm to several phenotypes from the WTCCC1 and WTCCC2 data, demonstrating significant, simultaneous improvements in control of type I error and power.

Association Studies of Imputed Genotypes Using Expectation-Maximization Likelihood-Ratio Test. *K. Huang[1], Y. Li[1,2].* 1) Department of Biostatistics, The University of North Carolina, Chapel Hill, NC; 2) Department of Genetics, The University of North Carolina, Chapel Hill, NC.

Genotype imputation has become standard practice in modern genetic studies. As sequencing-based reference panel continues to grow, we have increasingly more well imputed markers but at the same time also more imputation markers with relatively low quality. Here, we propose new methods that attempt to more elegantly incorporate uncertainty when analyzing imputed genotypes. We consider two scenarios: 1) when posterior probabilities of genotypes are estimated or 2) when only imputed dosages are available. When posterior probabilities are estimated, we developed an expectation-maximization (EM) likelihood-ratio test (LRT) for association studies. When only dosages are observed, instead of modeling dosages directly, we first sample the probabilities of all three possible genotypes and then apply the EM-LRT test on the sampled probabilities for EM-LRT. Extensive simulations have shown that type I error rates of the EM-LRT tests under both scenarios are protected. Regarding power, EM-LRT-Prob offers enhanced statistical power across the whole spectrum of imputed quality and EM-LRT-Dose has similar power performance as EM-LRT-Prob and better than standard methods that model dosages directly, especially for markers with relatively low imputation quality ($Rsq \leq 0.3$). Application to real datasets will also be shown.

1777F

Bayesian sparse models of high-dimensional correlated traits in related and unrelated individuals. *V. Iotchkova[1, 2, 3], J. O'Connell[4], A. Dahl[4], J. Marchini[3, 4].* 1) The EMBL-European Bioinformatics Institute, Hinxton, United Kingdom; 2) The Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 3) Department of Statistics, Oxford University, Oxford, United Kingdom; 4) The Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom.

Genetic association studies of complex traits have yielded a wealth of biologic discoveries. However, up to now studies have been mostly carried out under simplistic assumptions, for instance analyzing one trait and one SNP at the time, thus failing to capture the underlying complexity of these datasets. In order to move beyond simple GWAS the joint analysis of complex, highly-dimensional datasets represents an important extension of phenotype-genotype associations with great potential. The move to high-dimensional phenotypes raises many new statistical problems. For example, how to model the large diversity of possible different types of phenotypes, accounting for sporadically missing phenotype data, modelling sparse signals and hidden factors, how to model relationships and networks between phenotypes and how to assign statistical significance. We have developed a Bayesian model designed to detect association when correlations exist between high-dimensional phenotypes and between individuals due to relatedness. We impose a sparsity assumption through the use of a 'spike and slab' prior on the genetic effect sizes that allows us to learn the subset of traits that are associated with each SNP or genetic region. In this way our method is able to carry out model inference (association testing) and model selection at the same time. To allow for related individuals and/or protect against population structure our method generalizes single-trait linear mixed model analysis to high-dimensional traits. We use variational bayesian methods to efficiently fit our model, which facilitates approximate fully Bayesian inference. A key property of our method is that it can handle missing phenotype data, which we impute as part of the model fitting process. To illustrate the power of our method we have applied it to a study of high-dimensional gylcomics phenotypes on 960 individuals from an isolated population where individuals show appreciable levels of relatedness. At the MGAT5 association on 2q21 (rs1257220), which was originally discovered in a much larger meta-analysis, our method clearly detects an association (log10 Bayes Factor = 5.6), whereas approaches based on combining single-trait analyses uncover little signal. On simulated datasets of high-dimensional traits our approach has significantly more power than simpler approaches when the true signal is sparse, can accurately impute missing phenotypes and control for population structure and relatedness.

Effect size estimation in the stage of planning a replication study. *C. Kuo[1], D. Zaykin[2].* 1) Department of Community Medicine & Health Care, University of Connecticut, Farmington, CT; 2) Biostatistics Branch, National Institute of Environmental Health Sciences, NIH.

Large-scale association and sequencing studies generate millions of results. The top hits usually sorted by P-value are of interest but the smallest P-values can result from true signals or simply occur by chance. A common strategy to separate true effects from null effects is to carry forward a number of top hits to a replication study. In the replication study, the number of top hits can be chosen to control family wise error rate or false discovery rate. The sample size that depends on the effect sizes such as odds ratios or non-centralities must be carefully chosen to achieve a specified power. Due to the winner's curse, the effect sizes that rank on the top tend to be inflated by naive estimates. Previous methods that estimate effect sizes accounting for the winner's curse mainly fall into 'conditional likelihood approaches' or 'Bayesian approaches'. It has been criticized that the conditional likelihood approaches don't use the population information provided by samples. The Bayesian approaches are immune to the winner's curse while they require specifying a prior, which if not correctly specified would bias the results. Motivated by population genetics theory, we assume that the effect sizes follow a Gamma with unknown shape and scale parameters. Following that, it is straightforward to incorporate the distribution in a conditional likelihood and also to derive Bayes estimates. The methods we propose outperform existing methods and are robust to the assumed effect size distribution. Our methods are general in that they are developed for P-value and can be easily adapted for different effect size measures.

1779T

Greater power for kernel-based tests using the likelihood ratio. *J. Listgarten, J. Xiang, C. Kadie, D. Heckerman, C. Lippert.* eScience, Microsoft Research, Los Angeles, CA.

Recently, tests for association between a phenotype and region- or gene-based sets of SNPs have attracted interest, in particular, for rare variants. One of the dominant approaches is to use a variance-component model, with a score test, such as implemented in SKAT. The score test in this setting can easily be computed in closed form, and has known asymptotic results, making computation of P values extremely efficient. In addition, because the score test does not require fitting of alternative model parameters, this test is much faster than a likelihood-ratio test (which does require such fitting). Finally, in light of the fact that asymptotic results for likelihood-ratio tests in this setting require unrealistic assumptions, one might conclude that the score test is the obvious method of choice. Surprisingly, however, we have found that there is good reason to use a likelihood ratio test over a score test in this setting. In particular, we have found that (1) the likelihood ratio test offers a substantial increase in power , and (2) that with just a handful of permutations, and a particular null distribution parametric form, that p-values can be computed reasonably efficiently (while controlling type I error). We systematically examined use of our approach on a number of real and simulated data sets spanning a wide range of important settings including case-control and continuous phenotypes, rare and common variants, and data confounded by relatedness and population structure. Overall, we found power to be greatly increased (about 50%) while still controlling type-1 error. To overcome the computational burden, we also describe a number of speedups for both tests that make genome-wide testing in the presence of population structure and relatedness feasible on data sets involving tens of thousands of samples, even for the likelihood-ratio test.

Bayesian mixed model association statistics in linear time. *P. Loh[1,2], N. Patterson[2], A.L. Price[1,2,3].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Linear mixed models are a powerful statistical framework for identifying associated loci and avoiding confounding. Existing methods rely on the computation of a genetic relationship matrix, which requires time $O(MN^2)$ (where N = #samples and M = #SNPs) and implicitly assumes an infinitesimal genetic architecture in which all variants are associated. Here, we propose a very fast O(MN) coordinate descent algorithm that can achieve the same results as existing methods, but can also be generalized to non-infinitesimal genetic architectures to increase power. In each iteration of the algorithm, the estimated effect size of each SNP is updated with its posterior mean given the estimated components of variance, the prior distribution on SNP effects, and the residual phenotype conditional on current estimates of all other SNP effect sizes. We define a retrospective score statistic computed from the phenotypic residuals upon convergence, which typically occurs in fewer than 10 iterations. When an infinitesimal (normal) prior distribution of effect sizes is used, the posterior mean effect sizes are best linear unbiased predictions (BLUPs) and optimize a ridge regression problem. Our iterative method thus calculates BLUP coefficients and residuals by applying coordinate descent on the vector of SNP effect sizes. In this case our statistic is equivalent to the GRAMMAR-Gamma mixed model association statistic (Svishcheva et al. 2012 Nat Genet); we observed a correlation of 1.000 in simulations. When modeling non-infinitesimal genetic architectures, our method achieves improved power as a consequence of more accurate estimation of sparse SNP effects: for example, in simulations in which only 5% of independent markers are causal (with the number of samples roughly equal to 10 times the number of causal markers), our approach achieves a 10% increase in test statistics at causal markers as compared to existing methods.

1781W

Near equivalent calibration and power of joint and meta-analysis for association analysis of quantitative traits. *C. Ma, T. Blackwell, M. Boehnke, L.J. Scott, the GoT2D investigators.* Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

In genome-wide association studies of quantitative traits (QTs), investigators typically analyze common genetic variants using linear regression within each study, and combine association results across studies using fixed-effects meta-analysis. For common variants (minor allele frequency [MAF] ≥ 5%), linear regression is well-calibrated, and meta-analysis has near comparable power to joint analysis of the combined individual-level data (Lin and Zeng, 2010). In current sequencing and dense chip association studies, investigators wish to identify trait-associated low frequency variants (MAF < 5%), for which the calibration of linear regression analysis and the relative power of joint and meta-analysis has not been investigated. Here, we assess and compare the calibration and power of linear regression in joint and meta-analysis for QT association analysis across all allele frequencies, but in particular for low frequency variants, and examine the impact of sample size, additional covariates, and non-normally distributed QTs.

For common and low frequency variants (with minor allele count ≥ 5), simulation results show that: (1) linear regression-based joint analysis of normally-distributed QTs is well-calibrated; (2) sample-size weighted meta-analysis is well-calibrated and only slightly less powerful than joint analysis; and (3) inverse variance weighted meta-analysis is slightly anti-conservative. These results continue to hold when modeling the effects of additional covariates. For non-normally distributed QTs, joint and meta-analysis can become anti-conservative, but inverse-normal transformation of the QT remedies this problem while resulting in only modest loss of power. We are currently analyzing quantitative trait data from the GoT2D sequencing study to assess the generalizability these simulation-based findings to real data.

1782T

Estimating causal variant allele frequency, and thus efficacy of sequencing, at genetic loci identified by GWAS. *P.F. O'Reilly[1], C.J. Hoggart[2].* 1) Epidemiology & Biostatistics, Imperial College London, London, United Kingdom; 2) Genomics of Common Disease, Imperial College London, London United Kingdom.

Genome-wide association studies (GWAS) have provided a large number of genotype-phenotype associations, but these can only be assumed to highlight genetic regions harbouring causal variants rather than identifying the causal variants themselves. However, sequencing of such susceptibility loci makes identifying the causal variants feasible, which is a crucial step in translating the findings from GWAS into medical application. Most genetic regions identified by GWAS have not been interrogated for the causal variants via sequencing, largely due to the significant cost involved, and when they have, this has tended to be on an 'ad hoc' basis according to the resources of individual studies or the significance of association signals at certain loci. The availability of the 1000G reference panel for imputation means that future GWAS will capture > 95% of common variants, so that subsequent sequencing is only worthwhile if the causal variant(s) is rare and has the power to be detected in the sample. Here, we introduce a novel method that estimates the posterior probability of the allele frequency of putative causal variants at a genetic locus, which can be used to determine whether sequencing is likely to yield causal variants or whether it is more likely that they are already present among the available genotyped or 1000G imputed SNPs. Our method exploits the SNP GWAS association P-values, their minor allele frequency and Linkage Disequilibrium (LD), to calculate the likelihood that the data are consistent with a causal variant(s) of a given effect size and frequency. While the probability computed is dependent on several modelling assumptions, we show how the method can be used to prioritise the sequencing of genetic loci with known effects on human traits or diseases based on GWAS results.

1783F

Testing Association without Calling Genotypes Allows for Systematic Differences in Read Depth and Sequencing Error Rate between Cases and Controls. *G.A. Satten[1], H.R. Johnston[2], A.S. Allen[3,4], Y.J. Hu[2].* 1) Division of Reproductive Health, CDC, Atlanta, GA; 2) Department of Biostatistics and Bioinformatics, Emory University, Atlanta GA; 3) Department of Biostatistics and Bioinformatics, Duke University, Durham NC; 4) Duke Clinical Research Institute, Durham NC.

Background: The quality of genotype calling for next-generation sequence data depends on read depth. Loci with high coverage can typically be called reliably, while those with low coverage may be difficult to call. In an association study, if case participants are sequenced to a greater depth than controls, the difference in genotype quality can introduce a systematic bias. This can easily occur when historical controls (e.g., data from The 1000 Genomes Project) are used as controls.

Methods: We propose directly comparing the proportion of calls for the minor allele between cases and controls, rather than comparing genotypes. We show how this proposal can be used to perform both single-marker test and gene-level test of rare variants (e.g., using modified versions of the burden test, variable threshold test or SKAT). We also show how this proposal can be extended to the situation where the per-call read error rate differs between cases and controls.

Results: Using simulated data and theoretical results, we demonstrate our proposals yield valid tests even in the presence of systematic differences in coverage rate between cases and controls, and show that in these situations, tests based on genotype have inflated size. We also show that power gains are possible using designs where we increase the number of controls while decreasing the read depth (while keeping total reads constant).

1784W

Meta-Analysis of Sequencing Studies Under Random-Effects Models. *Z. Tang, D. Lin.* Department of Biostatistics, University of North Carolina at Chapel Hill.

Meta-analysis of genome-wide association studies (GWAS) has led to the discoveries of common genetic variants for virtually every complex human disease. Recent advances in sequencing technologies have made it possible to extend association studies to rare variants. Because larger sample sizes are required to detect rare variants than common variants (with similar effect sizes), meta-analysis is as important to sequencing studies as to GWAS. Several research groups have recently developed meta-analysis methods for gene-level associations with rare variants under fixed-effect models. Those methods will lose power if the genetic effects are heterogeneous among participating studies. We propose novel multivariate random-effect models which allow the effects of multiple variants within a gene to vary among participating studies and develop the corresponding meta-analysis methods to perform gene-level association tests. Our methods take score statistics as input and thus can accommodate any study designs and any phenotypes. We produce the random-effect versions of all commonly used fixed-effect gene-level association tests, including burden tests, variable-threshold (VT) tests and sequence-kernel association tests (SKAT). We demonstrate through extensive simulation studies that the new methods are substantially more powerful than existing ones in the presence of moderate and high heterogeneity and maintain similar power when the heterogeneity is low. An application to the NHLBI Exome Sequencing Project data led to the discoveries of several genes associated with blood pressures that were previously undetected by fixed-effect methods. The relevant software is freely available.

1785T

A mixed model using both principal components and top markers corrects for population stratification and improves power. *G. Tucker, B. Berger.* Mathematics and CSAIL, MIT, Cambridge, MA.

In recent years, mixed models have been used extensively to calculate GWAS association statistics. Mixed models implicitly assume an infinitesimal genetic architecture, i.e., one in which all SNPs have a small nonzero effect; however, it is widely believed that disease phenotypes do not follow an infinitesimal model and that modeling a non-infinitesimal architecture would increase power. As a step in that direction, Lippert et al. (Sci Rep 2013) developed the state-of-the-art FaST-LMM Select method, which constructs the genetic relationship matrix (GRM) from a subset of the SNPs that are likely to be causal. FaST-LMM Select improves power over standard mixed models, especially when the phenotype is caused by few SNPs. However, limiting the GRM to a subset of the SNPs can result in insufficient correction for population stratification. As a solution to this problem, we propose a novel approach that preprocesses the data using principal components (PCs) and feeds the results to a program such as FaST-LMM Select, thereby leveraging the benefits of FaST-LMM Select, while properly correcting for population stratification.

Through simulation, we show that our framework corrects for population stratification without compromising power. When stratification exists, we observe that Fast-LMM Select inflates statistics on null SNPS (λ_{GC} = 1.32±0.04) whereas our method is properly calibrated (λ_{GC} = 1.00±0.01). Moreover, our method improves power over FaST-LMM Select (as measured by the mean ψ^2-statistic on causal SNPs; 11.4±0.1 versus 10.6±0.2), likely because the PCs reduce noise in selecting subsets of SNPs for the GRM. In addition, our method selects fewer SNPs to include in the GRM, yielding computational savings. In simulations without stratification, both methods perform nearly identically; thus our method retains the advantages of FaST-LMM Select over standard mixed models, such as improving power and correcting for confounding due to rare variants in spatially structured populations (Lippert et al., Sci Rep 2013; Listgarten et al., Nat Genet 2013).

1786F

Use of P-values to evaluate the probability of a genuine finding in a large-scale genetic association studies. *O. Vsevolozhskaya[1], CL. Kuo[2], D. Zaykin[2].* 1) Mathematical Sciences, Montana State University, Bozeman, MT; 2) National Institute of Environmental Health Sciences, National Institutes of Health, USA.

To claim the existence of an association in modern genome-wide association studies (GWAS), a nominal P-value has to exceed a stringent Bonferroni-adjusted significance level. Despite strictness of the correction, a significant P-value does not indicate high probability that the claimed association is genuine. A simple Bayesian solution -- the False Positive Report Probability (FPRP) -- was previously proposed to convert the observed P-value to the corresponding probability of no true association. Although the FPRP solution is highly popular, it does not reflect probability that a particular finding is false. Here, we offer a simple POFIG method -- a Probability that a Finding is Genuine. POFIG enables one effectively to convert a P-value to the probability that a particular association with the trait is genuine. The validity of POFIG is supported by the results of a simulation study and the potential utility of our approach is discussed with reference to future GWAS discoveries.

1787W

A correction strategy for imputation across genotyping arrays. *Y. Xie[1], J. Rice[1], L. Bierut[1], R. Culverhouse[2], N. Saccone[3], E. Johnson[4], D. Hancock[4], COGEND collaborators.* 1) Department of Psychiatry, Washington University in St. Louis, St. Louis, MO 63110; 2) Division of General Medical Sciences, Washington University in St. Louis, St. Louis, MO 63110; 3) Department of Genetics, Washington University in St. Louis, St. Louis, MO 63110; 4) Behavioral Health Epidemiology Program, RTI International, 3040 Cornwallis Road, PO Box 12194, Research Triangle Park, NC 27709-12194.

Genotype imputation methods are widely used to extend the utility of genome-wide association study (GWAS) data. Genotype imputation is a powerful approach because it can potentially identify causal SNPs that are untyped in the study data and can provide higher resolution for associated regions. However, bias can exist if different genotyping arrays are used and are unbalanced for case versus control subjects. Two currently used strategies of imputation across genotyping arrays are: (1) imputation based on the union of genotyped SNPs (i.e., SNPs on one of the two arrays); (2) imputation based on the intersection of genotyped SNPs (i.e., SNPs available on both arrays). Both of these strategies have weaknesses that are addressed by a third strategy we introduce here. We used data from chromosome 22 genotyped on Illumina 2.5M (32,903 SNPs) and 1M (14,071 SNPs) chips to illustrate properties of the three strategies. We demonstrate that the union strategy introduces bias (false positives) for SNPs available only on one array, presumably because the genotypes of some subjects are experimentally determined while others were imputed. The intersection strategy does not introduce this bias, but loses power for SNPs present only on one chip, due to the exclusion of the experimentally determined genotypes. We propose a hybrid approach that utilizes the genotypes for SNPs present only on one chip whenever the SNP has high imputation quality (defined by the Imputation Quality Score (IQS) ≥ 0.9). The IQS is a score we previously introduced based on Cohen's kappa rater agreement statistic. Using this approach led to good results with few spurious associations (5 false positives among 134,293 SNPs). In contrast, replacement of SNPs having high scores according to the IMPUTE2 internal quality metric gave rise to a high proportion of spurious associations (126 false positives among 131,554 SNPs). We compare the increase in power for our new approach to results from imputation based on the intersection of SNPs from the two arrays.

1788T

Testing Genetic Association at Untyped Rare Variants, an alternative to imputation based two-step approach. *K. Ye.* Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY., USA.

In recent years, we saw three important developments that empower us to investigate genetic association of rare variants (whose allele frequencies are below 5%) in genome-wide association studies. The first is the rise of large consortia, in which researches pool their samples together for meta-analysis. The second is the near completion of the 1000 Genome Project that provides detailed population genetic information on those rare variants and produces reference panels of haplotypes for a number of populations. The third, which links the first two, is the development of software tools such as Beagle, IMPUTE and MACH, that use a reference panel of haplotypes to impute untyped variants based on genotyped markers. While imputation provides convenience and flexibility to test association at untyped variants, a large proportion of imputed variants, mostly rare variants, are often excluded in subsequent association test because of poor imputation quality. In addition, the imputations are perform without considering disease status of subject, resulting biases at the risk alleles in disease populations, subsequently lower the statistical power of the genetic association tests at the imputed variants. Here, we present a novel association test that retains statistical powers especially at those rare variants with poor imputation quality. The new approach can be viewed as a special case of haplotype association tests, but it uses the information from haplotype reference panels, the same as those used for imputation. In short, for an untyped risk variant and a set of haplotypes at that locus, the expected frequencies of the haplotypes in a disease population are functions of (i) the relative risk of the risk allele, (ii) the proportion of risk allele on each haplotype. Therefore, once the proportion of a risk allele on each haplotype is known, one can obtain a maximum likelihood estimate of the relative risk, and perform the likelihood ratio test for the association. Recursive tree models are applied on a reference panel to select such set of haplotypes at each untyped locus and to estimate the conditional allele frequency. We will show that compared to the association tests on the imputed genotypes, this approach retains much higher statistical power at variants of low imputation quality. This is because, not only we use the information from a reference panel, the difference between disease population and normal population is also considered.

1789F

The more you test, the more you find: massive multiple testing does not promote spurious findings among top hits of association studies. *D.V. Zaykin[1], C.L. Kuo[1], O.A. Vsevolozhskaya[2].* 1) Biostatistics Branch, NIEHS/NIH, Research Triangle Park, NC; 2) Department of Epidemiology and Biostatistics, Michigan State University.

High throughput whole-genome sequencing technology dramatically increased the multiple testing burden of association studies. High level of multiple testing is thought to promote false positives. To keep spurious findings at bay, it is common practice to require that findings should pass a significance threshold adjusted for the number of tests. As the number of tested variants now approached tens of millions, unrealistically large sample sizes would be needed for associations of modest magnitude to reach statistical significance. Paradoxically, in discovery studies where genetic variants are tested in an agnostic manner, "top hits" of a study become increasingly more likely to be true signals as more tests are performed, without any correction for multiple testing. We show by both statistical theory and simulations that when the rate of occurrence of true signals does not decrease as more tests are performed, findings with the smallest P-values are more likely to be genuine in studies with more tests. Our findings are supported by prior observations that GWA studies with many tests enjoy a lower rate of false claims than traditional epidemiological and candidate gene association studies with fewer tests. This discrepancy has been attributed to the adoption of stringent significance thresholds and replication practices (Ioannidis et al., 2011). Replication is extremely important for eliminating erroneous claims due to study biases and errors unrelated to statistical chance. However, our results demonstrate that type-I error rates among best-ranking results of a study in fact diminish as more tests are performed. Our conclusions will be applicable to a wide variety of high-dimensional testing problems and implications are broad. Epidemiologists who tested effects of one hundred random exposures on disease and reported the smallest of one hundred P-values are more likely to be correct in identifying a truly associated effect than their colleagues who tested only ten exposures. With regard to GWAS and sequencing studies, our findings suggest that for a given sample size, researchers should expect the top hits to be increasingly enriched with genuine associations as more variants are tested.

Efficient Algorithms for Multivariate Linear Mixed Models in Genome-wide Association Studies. *X. Zhou[1], M. Stephens[1,2].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Statistics, University of Chicago, Chicago, IL.

Multivariate linear mixed models (mvLMMs) have been widely used in many areas of genetics, and have attracted considerable recent interest in genome-wide association studies (GWASs). However, existing methods for calculating the likelihood ratio test statistics in mvLMMs are time consuming, and, without approximations, cannot be directly applied to analyze even two traits jointly in a typical-size GWAS. Here, we present a novel algorithm for computing parameter estimates and test statistics (Likelihood ratio and Wald) in mvLMMs that i) reduces per-iteration optimization complexity from cubic to linear in the number of samples; and ii) in GWAS analyses, reduces per-marker complexity from cubic to approximately quadratic (or linear if the relatedness matrix is of low rank) in the number of samples. The new method effectively generalizes both the EMMA (Efficient Mixed Model Association) algorithm and the GEMMA (Genome-wide EMMA) algorithm to the multivariate case, making the likelihood ratio tests in GWASs with mvLMM possible, for the first time, for tens of thousands of samples and a moderate number of phenotypes (<10). With real examples, we show that, as expected, the new method is orders of magnitude faster than competing methods in both variance component estimation in a single mvLMM, and in GWAS applications. The method is implemented in the GEMMA software package, freely available at http://stephenslab.uchicago.edu/software.html .

Combined association and admixture mapping in Latinos. *A. Brisbin[1], A. Boyd[1], S. Rachid[2], G. Lei[1], A.C. Pereira[3], J.E. Krieger[3], M. de Andrade[4].* 1) UW-Eau Claire, Eau Claire, WI; 2) Carleton College, Northfield, MN; 3) Heart Institute, University of Sao Paulo Medical School, Sao Paulo, Brazil; 4) Biomedical Statistics and Informatics, Mayo Clinic, MN.

The use of ancestry information has the potential to enhance association mapping in admixed individuals, such as Latinos. Most existing methods of combining association and admixture mapping have been developed for African Americans, who typically have ancestry from two populations. In this work, we explore a range of possible approaches for incorporating ancestry information from three populations into association mapping. We compare our methods on simulated data, and find that incorporating either genome-wide ancestry proportions or local ancestry provides a similar increase in performance over methods which ignore ancestry. Finally, we apply our methods to identify candidate loci for systolic blood pressure in Brazilians.

Detecting epistasis effects via sliced inverse modeling. *J.S. Liu, B. Jiang, Y. Liu, M. Hu, C. Ye.* Statistics, Harvard, Cambridge, MA.

Expression quantitative trait loci (eQTLs) are genomic loci that regulate expression levels of genes. By assaying gene expression and genetic variation simultaneously on a genome-wide basis, scientists wish to discover groups of genomic loci that can affect the expressions of a subset of genes. The problem can be viewed as a multivariate 'regression' with variable selection on both responses (gene expression) and covariates (genetic markers), including also multi-way interactions (epistasis effects) among covariates. Instead of learning a predictive model of expression levels given combinations of genetic markers, we start with an inverse modeling perspective. By conditioning on gene expression levels, we model the genetic markers via a sliced inverse model. An efficient dynamic programming algorithm is developed to determine the optimal slicing scheme. The inverse modeling approach can be effectively used for both independent screening and joint modeling of interactive genetic markers. Through simulation studies and real data examples in multiple tissues, we demonstrate how the proposed method achieves significantly improved power in detecting tissue-common and tissue-specific eQTLs compared to traditional approaches such as stepwise regression methods.

Admixed-MASTOR: Mixed-Model Association Mapping of Quantitative Traits in Genetically Admixed Samples with Related Individuals. *T. Thornton[1], M.S. McPeek[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Statistics and Human Genetics, University of Chicago, Chicago, IL.

While genetic association studies for complex trait mapping have primarily focused on populations of European descent, more recent studies involve populations with admixed ancestry, such as African Americans and Hispanics. Genetic association studies in ancestrally admixed populations offer exciting opportunities for identifying variants that underlie phenotypic diversity. At the same time, the heterogeneous genetic background and dependencies among sample individuals from admixed populations, including population structure and relatedness, pose special challenges for trait mapping. In these circumstances, it is necessary to devise statistical methods for association mapping that account for the diverse genomes of the sample individuals and are robust in the presence of a variety of complex sample structure settings. We propose ADMIXED-MASTOR, a mixed-model, retrospective score test for genetic association with a quantitative trait in the presence of ancestry admixture and relatedness. ADMIXED-MASTOR appropriately accounts for ancestry admixture by incorporating individual-specific allele frequencies in the mixed-model that are calculated on the basis of ancestry derived from whole-genome analysis. We demonstrate that ADMIXED-MASTOR can provide a substantial improvement over existing association methods, such as EIGENSTRAT (Price et al., 2007) and EMMAX (Kang et al., 2010), in terms of power and type 1 error in admixed samples with related individuals. We further demonstrate the utility of ADMIXED-MASTOR with an application to the minority cohort of more than 12,000 African Americans and Hispanics from the Women's Health Initiative study for the identification of genetic variants for a variety of clinical outcomes and quantitative traits.

Detecting local haplotype sharing and haplotype-phenotype association. *Y. Guan[1], H. Xu[1,2].* 1) Pediatrics and Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Southeast Univeristy, Nanjing, China.

We present a statistical method to detect association between local haplotypes and phenotypes. The method relies on a two-layer hidden Markov model (HMM) developed previously to detect structure of local haplotypes. Briefly, we compute probabilities of (unspecified) haplotypes descending from a set of ancestral haplotype clusters, from which we quantify genetic distance between diploid individuals using local haplotype sharing -- the probabilities of two hapotypes descending from same haplotype clusters. We devise a novel model fitting method for the two-layer HMM, reducing the complexity from quadratic to linear (in the number of haplotype clusters) for diploid individuals; thus, it is feasible to apply our method to current genome-wide association studies (GWAS). We build a random effect model to link the genetic distance and phenotypes to test for association. Because the genetic distance is quantified by local haplotype sharing, the associations detected are between phenotypes and (unspecified) haplotypes. Compare to traditional haplotype association methods, our method integrates out phasing uncertainty and avoids arbitrariness in specifying haplotypes. We recast the random effect model to a fix effect model through eigen decomposition of pairwise local haplotype sharing matrix; this allows us to take advantage of existing framework for association testing. We demonstrate the usefulness of our method by analyzing GWAS data sets from Wellocme Trust Case Control Consortium.

JEPEG: software for testing the joint effect on phenotype of eQTLs in a gene. *D. Lee, V. Williamson, T. Bigdeli, V. Vladimirov, S. Bacanu.* Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA.

Expression of genes is known to affect many phenotypes/diseases. Given that gene expression is perturbed by nearby genetic variants commonly known as expression quantitative trait loci (eQTL), these variants are likely to affect many phenotypes in a multivariate manner. While modelling multivariately the action of eQTL/functional SNPs on phenotype is likely to increase detecting power for many traits, it is impeded by i) not measuring all functional SNPs in a gene and ii) the lack of access to individual genotypes. We overcome these obstacles by proposing JEPEG, a novel method/software testing for the joint effect of eQTLs in a gene by using only reported summary statistics. To achieve its objective, JEPEG i) directly imputes the summary statistics at unmeasured eQTLs and ii) tests for the joint effect of measured and imputed eQTLs. The direct imputation of summary statistics is achieved by employing the conditional expectation formula for multivariate normal variates. The joint testing is achieved by using summary statistics of measured and imputed functional SNPs and their genotype correlation matrix, as estimated from a relevant reference population (e.g.1000 Genomes). To decrease the number of degrees of freedom and, thus, increase power, before testing for the multivariate effect JEPEG first pools the genotypic information within functional categories using weights based on biologically relevant eQTL measures stored in a continuously updated database of human genes and eQTLs/functional SNPs affecting their expression. To decrease computational burden, the software implementing the method is written in C++ and is easily compilable to run on a variety of operating systems such as Linux, Windows and Mac. We used JEPEG to analyze summary statistics from the Psychiatric GWAS Consortium (PGC) stage 1 (PGC1). Besides genes reported to harbor significant signals in PGC1, we detected multiple significant genes not harboring significant signals in PGC1, but subsequently reported to harbor significant findings in PGC stage 2. These results strongly suggest that JEPEG can improve the power to detect trait-associated genes by aggregating the functional information from a gene.

Detection Boundary and Higher Criticism Approach for Rare and Weak Genetic Effects. *Z. Wu[1], Y. Sun[1], S. He[1], J. Cho[2], H. Zhao[3], J. Jin[4].* 1) Mathematical Sciences, WPI, Worcester, MA; 2) Departments of Genetics and of Pediatrics, Yale, New Haven, CT; 3) Departments of Genetics and of Biostatistics, Yale, New Haven, CT; 4) Department of Statistics, CMU, Pittsburgh, PA.

Genome-wide association studies (GWAS) have identified many genetic factors underlying complex human traits. However, these factors only explained a small fraction of genetic contributions to these traits. It was argued that there are many more genetic factors remain undiscovered. These factors, each is individually weak at the population level, distribute sparsely across the genome. In this paper, we adapt the recent innovations on Tukey's Higher Criticism to SNP-set analysis of GWAS and sequencing studies, and develop new theoretic framework in large-scale inference to assess the joint significances of such rare and weak effects for a quantitative trait. In the core of our theory is the so-called "detection boundary", a curve in the two-dimensional phase space that quantifies the effect rarity and effect strength. Above the detection boundary, the overall effects of genetic factors are strong enough and allow for reliable detection. Below the detection boundary, the genetic factors are simply too rare and too weak for reliable detection by any statistical methods. We show that the HC-type methods are optimal in that they reliably yield detection once the parameters of the genetic effects fall above the detection boundary, and that many commonly used SNP-set methods are not optimal. The superior performance of the HC-type approach is demonstrated through simulations and the analysis of a GWAS data set of Crohn's disease.

1797T

A novel method utilizing GWAS data identifies SNPs in the imprinted gene KCNK9 exhibiting parent-of origin effects on BMI. *C.J. Hoggart[1], J.H. Zhao[2], J. Luan[2], F. Gomez[3], G.B. Ehret[4], M. It has been hypothesized that some genetic variants exert different effects on certain phenotypes depending on parental origin. Parent-of-origin effects may be caused by epigenetic factors such as methylation and histone-modification which occur in genomic imprinting regions. Only a few family based linkage studies have explored whether SNPs exhibit parent of origin effects on traits such as body mass index (BMI) and alcohol intake. Many of the findings from these studies remain un-replicated and the identified regions are often too large to provide meaningful interpretation. The only large-scale, genome-wide parent-of-origin study by Kong et al. 2009 focused primarily on type 2 diabetes and identified four loci, however, the discovery methodology required a combination of genealogy information and long-range phasing. Here, we present a novel method that is able to detect parent-of-origin effects using genome-wide genotype data of unrelated individuals. We demonstrate that parent-of-origin effects can be identified by increased phenotypic variance in the heterozygous (het) genotype group relative to that in the homozygous (hom) groups. Our rationale is that in the heterozygous group half of the population is mat-A/pat-B, and the other half is pat-A/mat-B, increasing the phenotypic variance in that group in the presence of a parent-of-origin effect. Sixteen GWAS cohorts participated in our discovery analysis totalling ~48,000 individuals. We tested all SNPs in known imprinted regions for parent-of-origin effects on BMI. One SNP reached significance after adjusting for multiple testing (rs2471083 [T/C], variance (het vs. hom): 1.058 vs. 0.963, P = 1.07×10-6). This SNP is located 100kb upstream of the gene KCNK9. Mutations in this potassium channel gene cause Birk-Barel syndrome. SNPs within 2kb have been shown to be associated with HDL cholesterol, adiponectin, and creatinine levels. We replicated the parent-of-origin association in four family-based studies; the combined analysis (of 3,016 heterozygous individuals) confirmed that individuals who carry the C allele paternally have 0.09 (SD unit) higher BMI on average than those carrying the maternal C-allele (P=0.0031). Currently gene expression experiments are underway to investigate whether the variant may influence KCNK9 expression in a parent-of-origin fashion. Our method opens new avenues to exploit GWAS data of unrelated individuals in order to identify parent-of-origin effects.

Genome-wide imputation in multiple cohorts to study susceptibility to sepsis in Europe. *T.C. Mills[1], A. Rautanen[1], E. Davenport[1], P. Hutton[2], J. Knight[1], T. Meitinger[3], C. Garrard[2], F. Stueber[4], C. Hinds[5], A.V.S. Hill[1], The GenOSept Investigators.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Adult Intensive Care Unit, John Radcliffe Hospital, Oxford; 3) Institute of Human Genetics, Neuherberg, Germany; 4) Berne University Hospital, Berne, Switzerland; 5) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, London.

Sepsis is a major burden to health care worldwide, and severe sepsis still carries a mortality rate of more than 30% in developed countries. In the USA, the number of hospitalisations with severe sepsis more than doubled between 2000 and 2007. In order to better understand the genetic factors which influence susceptibility to sepsis, we have performed a large scale genome-wide association study (GWAS). Community-acquired pneumonia (CAP) sepsis cases were collected and genotyped as part of the GenOSept (European cohort) and GAinS (United Kingdom cohort) projects. These cases were compared to six healthy control GWAS datasets from across Europe. Following stringent quality control, 950 CAP sepsis cases and 5241 healthy controls were included in an association analysis performed using plink. Only those cases and controls which clustered together in multidimensional scaling, and therefore represented similar population ancestry, were included in the final analysis. The value of lambda for this analysis was 1.038 prior to imputation (for an analysis of 36,805 SNPs genotyped in all cohorts), but no SNPs passed the genome-wide significance threshold of 5×10-8. We therefore performed genome-wide imputation using ShapeIT and IMPUTE2, followed by analysis using SNPTEST2. SNPs were removed from the analysis when the minor allele frequency overall or in an individual cohort was less than 2%, and when the info score from imputation in an individual cohort or overall as defined by SNPTEST2 was less than 0.8. Over 5 million SNPs remained following this QC, but the lambda value following imputation was inflated, as imputation across multiple cohorts can generate bias within the data. Only SNPs that showed similar allele frequencies between the two case cohorts were considered to be reliable. This approach enabled us to rule out strong associations that were due to imputation bias rather than true association, highlighting the importance of the second case cohort in this analysis, which could be used as an internal control. Further cleaning of the data is required to better determine which of the associating regions are likely to be real. Replication will be performed using an additional cohort of 564 GAinS CAP sepsis samples to confirm our findings. Our imputation-led approach has allowed multiple cohorts of European ancestry to be analysed and provide what is to our knowledge the first GWAS and the largest study of susceptibility to severe sepsis due to CAP.

1799W

LD Friends: A Method to Disentangle Polygenicity from Population Stratification. *B.K. Bulik-Sullivan[1,2], N. Patterson[1], A. Price[1,4,5], M. Daly[1,2], B. Neale[1,2,3].* 1) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 2) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 3) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Recent large-scale genome-wide association studies (GWAS) such as current meta-analyses of height, schizophrenia and Crohn's Disease have reported inflated distributions of SNP association test statistics. A central question in these studies is the extent to which this inflation is driven by confounding bias such as population stratification versus polygenic inheritance. We propose a novel approach to distinguish between bias and polygenicity by leveraging linkage disequilibrium (LD) and the distribution of test statistics. To assess the quality of the method, we simulate phenotypes with varying levels of population stratification, cryptic relatedness and true polygenic association using genotypes from ~2500 controls from a Swedish schizophrenia cohort. We propose the *LD friends* score, defined for a SNP x as $l_x := 1 + \Sigma\, r^2_{xy}$, where the sum is taken over all SNPs y within 500kb of x. Our simulations show that there is a strong linear relationship between *LD friends* and mean ψ^2-statistic in the context of polygenic association, but that *LD friends* and ψ^2-statistic are uncorrelated in the context of population stratification. Furthermore, we show that in the presence of both true polygenic association and population stratification, the intercept from the linear regression of ψ^2-statistic on *LD friends* is informative about the level of bias remaining after correction for principal components. We apply this method to schizophrenia data from the Psychiatric Genetics Consortium and height data from the GIANT Consortium show that the relationship between ψ^2-statistic and *LD friends* is consistent with highly polygenic genetic architectures for schizophrenia and height, and inconsistent with uncorrected confounding from population structure or cryptic relatedness. In addition, we discuss methods for estimating *LD friends* in the context of multi-ethnic association studies with imputed genotypes, as well as the robustness of our method to violations of our model's assumptions and the applicability of our method to mixed linear model association.

1800T

Extended Mantel test for comparing differences in linkage disequilibrium between population. *N. Tanaka.* Biostatistics Section, National Center for Global Health and Medicine, Tokyo, Tokyo, Japan.

Checking the equality of population linkage disequilibrium (LD) structures is an important and often substantial in genetic association studies, especially if the target region includes disease susceptible genetic variants. This problem can be generalized as comparison of correlation structure between two populations. To solve this problem, the likelihood ratio test is commonly used especially in low-dimensional and regularity settings. In genetics, many researchers have been applying statistical procedures in which only elements of correlation matrices are used to calculate model-free test statistics, because the raw data which is used to estimate LD structures cannot be obtained in some cases. One of these is Mantel test (1967), which is originally proposed to compare distance or dissimilarity matrices for solving the problems inherent in explaining species-environment relationships in ecological studies. Mantel statistic is based on a simple cross-product term of each element of matrices, and the p-value is calculated based on the randomized distribution of 'elements'. Thus this statistics represents not the relationship between populations but distance measures (matrices). However, Mantel test is still used even when investigators have the raw data to calculate correlation structure. Then, extended Mantel test statistic is proposed to compare two population structures, not the matrices. To address the variability of each element of matrices estimated in each population, the p-value for testing the null hypothesis, the correlation structure between two populations is equal, is calculated based on the sampling distribution of the weighted Mantel statistic via permutation of the observation. Proposed test is compared with Mantel test and the bootstrap based test which was proposed by Hrafnkelsson et al (2010). It is shown that this extended test statistic has broad utility and would derive a conclusion that agrees with that from other multivariate methods and intuitive insight from visualized method, such as Haploview, through several real examples.

1801F

Bivariate joint phenotype-endophenotype measured genotype association testing in complex pedigrees. *J.W. Kent, T.D. Dyer, M. Almeida, V.P. Diego, J. Blangero.* Dept Genetics, Tx Biomed Res Inst, San Antonio, TX.

Multivariate approaches to genetic analysis of complex diseases offer the promise of increased power to detect contributing genetic factors, as when affection status is combined with quantitative measures, or endophenotypes, of disease. In addition, analysis of endophenotypes may provide both a more focused search as well as insight into the physiological pathways and processes underlying disease. Bivariate joint association testing allows analysis of the (possibly) pleiotropic effect of a genetic variant while explicitly modeling the correlation between traits. However, (1) joint associations may be dominated by the univariate association of one of the correlated traits with the variant; (2) a test of joint association is often underpowered relative to univariate tests because it has two degrees of freedom; and (3) test results may pose problems of causal interpretation. Here we use simulation in SOLAR of genotypes and phenotypes on pedigree data to distinguish three possible causal relationships between a variant V and two correlated traits A, B: (a) $V \to A \to B$; (b) $V \to B \to A$; (c) $V \to A$ and $V \to B$; where (c) represents a non-pleiotropic relationship between the variant and traits correlated via other effectors. (a) and (b) represent a variant that acts indirectly on one trait via its direct effect on an intermediate; since these are equivalent to instrumental variable (IV) models employed in 'Mendelian randomization', our results offer an efficient method for IV model estimation in complex pedigrees as well as estimates of its Type I and Type II error rates.

1802W

A Multi-Sample U-Statistic for Family-based Association Studies. *M. Li[1], Z. He[2], D. Schaid[3], M. Cleves[1], T. Nick[1], Q. Lu[4].* 1) Pediatrics, Univ Arkansas Medical Sciences, Little Rock, AR; 2) Biostatistics, University of Michigan, Ann Arbor, MI; 3) Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 4) Epidemiology and Biostatistics, Michigan State University, East Lansing, MI.

Family-based study design is one of the most commonly used study designs in genetic research. It has many ideal features, including being robust to population stratification (PS). With the advance of high-throughput technologies and ever-decreasing genotyping cost, the analysis of high-dimensional genetic data has become common for family studies. The yield from the analysis of these high-dimensional family-based genetic data can be enhanced by adopting computationally efficient and powerful statistical methods. In this article, we propose a general framework of family-based U-statistic, referred to as family-U, for family-based association studies. Similar to existing family-based methods, it can offer robust protection against PS. In the absence of PS, it can also utilize additional information (i.e., between-family information) for power improvement. The proposed family-U method makes no assumption of the underlying disease models, and is applicable for different phenotypes (e.g. binary and quantitative phenotypes), and various pedigree structures (e.g., nuclear families and extended pedigrees). Through simulations, we demonstrated that family-U attained higher power over a commonly used method, FBAT, under various disease scenarios. We further illustrated the new method with an application to a large-scale family data from Framingham Heart Study. By utilizing additional information (i.e., between-family information), family-U confirmed a previous association of CHRNA5 with nicotine dependence.

1803T

Robust and powerful sibpair test for rare variant association. *K. Lin[1], S. Zöllner[1,2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Psychiatry, University of Michigan, Ann Arbor, MI.

Background Modern sequencing technology allows investigating the impact of rare variant on complex disease. However, using a conventional case-control design, large samples are needed to achieve sufficient power for testing association of suspected loci to complex disease. In such large samples, population structure and batch effects can cause spurious signals. One approach to overcome stratification is family-based study design. Traditional methods such as the TDT and the FBAT are not especially powerful when applied to rare variants. Thus, there is a need to develop a method to efficiently use of family data to discover association between rare variants and disease phenotypes. **Method** We propose a novel test of a sample of affected sibpairs. In each sibpair, we estimate number of chromosomes shared IBD at the locus of interest. Based on this estimate, we assess the number of minor alleles located on shared chromosomes and the number of minor alleles on non-shared chromosomes. Shared and non-shared chromosomes are equally likely to contain variants that do not affect disease risk, while shared chromosomes are more likely to carry risk variants. Hence we test for an excess of rare variants on shared chromosomes. This test is robust to stratification as siblings have matched ancestries. Moreover, this design can correct for genotyping error and batch effects. As some regions are sequenced multiple times, sequencing error can be estimated by examining how often a sibpair who share two IBD chromosomes has inconsistent genotype calls and adjust the test to take into account the genotype error probabilities. We evaluate the power of this approach analytically as well as with computer simulations using a general model for the effect size of rare risk variants and considering different models of interaction between the locus of interest and the remaining genome. **Result** For most models with cumulative risk allele frequency <0.05, the proposed design shows superior power over the conventional case-control study given the same number of sequenced samples. **Conclusion** We introduce a new method for analyzing rare variants in families that is robust to population stratification and can incorporate other confounders such as genotyping error and batch effects. This new method is more powerful than a standard case-control design under wide-range of scenarios.

1804F

Analysis of Ultra High-Dimensional Data in Imaging Genetics Studies.
J. Kang, Y.J. Hu. Emory University, Atlanta, GA.

Many neurodegenerative diseases such as Alzheimer's Disease (AD) are highly heritable and have been linked to brain regions of cognitive performance. This has spurred major interest in investigation of such diseases based on genetic and neuroimaging biomarkers. Recent advances in neuroimaging and genetics allow imaging genetics studies to collect both highly detailed brain images (>300,000 voxels) and genome-wide genotype information (>12 million variants). However, there is lack of statistical powerful methods and computationally efficient tools to analyze such very high-dimensional data, which has greatly hindered the impact of imaging genetics studies. In this work, we develop methods for genetic dissection of neuroimaging phenotypes. We build a statistical model that assesses the association between genetic variants and neuroimaging traits. Our method is tailored to the brain-wide, genome-wide association discovery, where both the entire genome and the entire brain are searched for dependence patterns. We also build a regression model that encompasses both genetic and imaging markers to predict the overall risk of the disease. A variable selection procedure is incorporated to search over the whole genome and the whole brain for variants that should be included in the regression model. We implement our methods in a user-friendly, computationally efficient, publicly available and well-maintained software package. We adopt the new computer technology, the General Purpose Computing on Graphical Processing Unites (GPGPU), to make our analysis possible even on a personal computer (PC). We illustrate our method and software on simulation studies and analysis of the imaging genetics data from Alzheimer's Disease Neuroimaging Initiative (ADNI).

1805W

A general regression framework for a secondary outcome in case-control studies.
e. Tchetgen Tchetgen. biostatistics, Harvard UBoston, MA.

Modern case-control genome-wide association studies typically involve in addition to the disease outcome and the genetic information, the collection of data on a large number of outcomes, often at considerable logistical and monetary expense. These data are of potentially great value to subsequent researchers, who, although not necessarily concerned with the disease that defined the case series in the original study, may want to use the available information for a regression analysis relating the genotype data to a secondary outcome. Because cases and controls are selected with unequal probability, regression analysis involving a secondary outcome generally must acknowledge the sampling design. In this work, the author presents a new framework for the analysis of secondary outcomes in case-control studies. The approach is based on a careful re-parametrization of the conditional model for the secondary outcome given the case-control outcome and regression covariates, in terms of (a) the population regression of interest of the secondary outcome given covariates, and (b) the population regression of the case-control outcome on covariates. The error distribution for the secondary outcome given covariates and case-control status is otherwise unrestricted. For a continuous outcome, the approach sometimes reduces to extending model (a) by including a residual of (b) as a covariate. However, the framework is general in the sense that models (a) and (b) can take any functional form, and the methodology allows for an identity, log or logit link function for model (a). The approach is illustrated with an extensive simulation study and a genomewide association study of body mass index using data from a diabetes case-control study. The methods are found to be considerably more efficient than inverse-probability-weighting, and generally less biased than an estimator that stratifies or conditions on case-control status using a standard regression parametrization.

Mining the Human Phenome Using Allelic Scores that Index Biological Intermediates.
D.M. Evans[1], M.J. Brion[1,2], L. Paternoster[1], J.P. Kemp[1], G. McMahon[1], M. Munafo[3], N.J. Timpson[1], B. St Pourcain[1], D.A. Lawlor[1], A. Dehghan[4], J. Hirschhorn[5,6], G.D. Smith[1]. 1) Soc Med, Univeristy Bristol, Bristol, United Kingdom; 2) Broad Institute, MIT and Harvard, Cambridge, Massachusetts; 3) School of Experimental Psychology, University of Bristol, Bristol, UK; 4) Department of Epidemiology, Erasmus Medical Centre, Rotterdam, The Netherlands; 5) 6Division of Genetics and Endocrinology and Program in Genomics, Children's Hospital, Boston, Massachusetts; 6) Department of Genetics, Harvard Medical School, Boston, Massachusetts.

It is common practice in genome-wide association studies (GWAS) and their meta-analyses to focus on the relationship between disease risk and genetic variants one marker at a time. When relevant genes are identified it is often possible to implicate biological intermediates and pathways likely to be involved in disease aetiology. However, single genetic variants typically explain small amounts of disease risk. Our idea is to construct allelic scores that explain greater proportions of the variance in biological intermediates, and subsequently use these scores to data mine GWAS. To investigate the approach's properties, we indexed three biological intermediates where the results of large GWAS meta-analyses were available: body mass index, C-reactive protein and low density lipoprotein levels. We generated allelic scores in the Avon Longitudinal Study of Parents and Children, and in publicly available data from the first Wellcome Trust Case Control Consortium. We compared the explanatory ability of allelic scores in terms of their capacity to proxy for the intermediate of interest, and the extent to which they associated with disease. We found that allelic scores derived from known variants and allelic scores derived from hundreds of thousands of genetic markers explained significant portions of the variance in biological intermediates of interest, and many of these scores showed expected correlations with disease. Power calculations confirm the feasibility of extending our strategy to the analysis of tens of thousands of molecular phenotypes in large genome-wide meta-analyses. We conclude that our method represents a simple way in which potentially tens of thousands of molecular phenotypes could be screened for causal relationships with disease without having to expensively measure these variables in individual disease collections.

Evolutionary Triangulation: A Novel Approach for Filtering Association Results.
M. Huang[1], C. Amos[2], L. Muglia[3], S. Williams[1]. 1) Department of Genetics, Geisel School of Medicine, Dartmouth College, Hanover, NH; 2) Department of Family and Community Medicine, Geisel School of Medicine, Dartmouth College, Hanover, NH; 3) Center for Prevention of Preterm Birth, Perinatal Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

GWAS analyses have been successful in identifying many genetic associations with common complex diseases. Despite the successes, much of the heritability of complex disease remains unexplained. One possible explanation is that GWAS analyses suffer from an inflated type II error rate due to overly conservative correction for multiple testing. Thus, it is important to develop methods that can minimize this type of error while still controlling type I error. Our hypothesis is that the distribution of genetic variants that associate with a disease will mirror the distribution of the disease among populations, and therefore, we can use the population genetic structure as a filter to reduce type II error. We propose a method to salvage real or likely associations in GWAS by applying evolutionary differentiation as a metric. This method, Evolutionary Triangulation (ET), requires at least three populations with known disease prevalence data such that two have similar prevalence and the third is disparate. We use overlapping patterns of similarity and differences in F_{ST} to identify putatively associating genes. We tested ET by using three HapMap populations (YRI, CEU and GIH), because two are known to have similar prevalence for some cancers (e.g., in GIH and YRI melanoma and ovarian cancer are rare) but the third (CEU) is distinct and has a higher prevalence. Under stringent F_{ST} thresholds we first identified 33 ET SNPs by overlaps of high F_{ST} between CEU and GIH, high F_{ST} between CEU and YRI, and low F_{ST} between GIH and YRI. Then by mapping SNPs back to genes, we identified 35 genes; five of which associated with melanoma, two with skin and hair color, and one with preterm birth. These diseases and traits are concordant with the discrepancy of phenotype distribution among these populations. This ability to identify genes with prior validated associations for disease provides a proof of principle that distribution of genetic variation can serve as an effective filter to find genes that associate with certain traits or diseases. Using a melanoma GWAS dataset and the previously mentioned three HapMap populations, we showed that an ET SNP subset was significantly enriched for GWAS 'hits' ($p<0.05$) compared to a subset of SNPs generated through random sampling, showcasing ET's ability to identify putative GWAS associations. Our method, which is unbiased in terms of gene function, provides a potential means to address inflated type II error.

Detecting a weak association by testing its multiple perturbations.
M.T. Lo[1,2], W.C. Lee[1,2]. 1) College of Public Health, Graduate Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan; 2) Research Center for Genes, Environment and Human Health, National Taiwan University, Taipei, Taiwan.

Genome-wide association studies (GWAS) have successfully identified several genetic variants associated with complex traits and diseases. Theses variants only account for a small proportion of heritability for traits and have minuscule effects. One therefore needs a study with a very large sample size (the number of subjects, *n*) to detect these weak associations. We refer the method of increasing sample size for power as the 'n-based method'. The n of a study can of course be increased but only to an extent. We propose a novel approach that aims for increasing the sample size in a different direction: the number of variables (*p*), which is denoted as the 'p-based method'. For a putative genetic variant, the p-based method integrates the interactions (or more aptly, the 'perturbations') between the variant and other variables. In contrast to other dimension reduction methods, here we openly take advantage of the very large *p*. Theoretical power calculations and computer simulations show that this p-based method outperforms the traditional n-based method by a wide margin, when *p* can be made very large, say, to the thousands or millions. The method is also applied to a real data from a GWAS of age-related macular degeneration (AMD). The method detects a number of novel genetic variants associated with AMD.

1809T

A Bayesian approach to Detect Differentially Methylated Loci with Next Generation Sequencing using Integrated Nested Laplace Approximation.
L. Shuang, R. Podolsky, D. Ryu, V. George, H. Xu. Georgia Regents University, Augusta, GA.

DNA methylation at CpG loci is an important biomedical process involved in many complex diseases including cancer. In recent years, the development of next-generation sequencing (NGS) has been yielding large amount of sequencing data, which makes the NGS platforms useful for many applications. In this high-throughput sequencing approach, DNA samples are treated with bisulfate, which converts unmethylated cytosines to uracils and leaves methylated cytosines intact. The bisulfate-treated samples are then sequenced with NGS platforms. As a consequence, the NGS data include the counts of methylated molecules or unmethylated molecules at each CpG site for each individual. We introduce a robust Bayesian approach for differential methylation analysis for NGS data, using Integrated Nested Laplace Approximation (INLA) for deriving posterior distributions. We performed extensive simulations to compare our proposed method to existing alternate methods. The simulation results illustrate that our proposed approach can detect more true positive differential methylation sites and less false positives. Additionally, our approach allows us to compute approximations to the posterior marginal directly by using Integrated Nested Laplace Approximation (INLA). Compared to Markov Chain Monte Carlo (MCMC) for generating posterior samples, our approach using INLA is computationally faster, easier to implement and overcomes potential convergence issues associated with MCMC.

Methodology for mitochondrial phenome-wide association studies.
J. Hall[1], W. Bush[1], S. Pendergrass[2], R. Goodloe[1], J. Boston[1], E. Farber-Eger[1], D. Crawford[1], S. Mitchell[1]. 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Center for Systems Genomics, The Pennsylvania State University, University Park, PA.

In this pilot study, we evaluate methods for the analysis of mitochondrial variation on multiple phenotypic outcomes~HDL-C, LDL-C, triglyceride levels, total cholesterol, type 2 diabetes, systolic and diastolic blood pressure, and mean corpuscular hemoglobin. This is a novel application of a phenome-wide association study (PheWAS), a recent innovation in study design where phenotypically rich datasets are examined for relatively few genetic variables. These studies are ideal for detecting pleiotropic effects for susceptibility alleles, which data suggest are prominent for mitochondrial variants. Mitochondrial genetic variation, typically represented as haplogroups, has been associated to a wide variety of traits, though is commonly ignored in genome-wide association studies. Given these associations, and the general biological implications of mitochondrial dysfunction, mitochondrial variants are prime candidates for PheWAS analysis. For this analysis, we accessed data from the Epidemiologic Architecture of Genes Linked to Environment (EAGLE) BioVU study, a subset of the Vanderbilt University biorepository consisting of ~15,000 DNA samples from non-European Americans representing African Americans (n=11,521), Hispanics (n=1,714), and Asians (n= 1,122). Restricting analyses to African Americans only, we estimated the effect of 130 mitochondrial variants captured by the Illumina Metabochip. Using mixed linear models, we calculated the variance explained by mitochondrial genetic variation for each of these phenotypes. We compared models with only nuclear principal components (estimating genetic ancestry) to models containing both nuclear and mitochondrial principal components (representing maternal lineage), additionally adjusting for both age and sex. Addition of mitochondrial principal components did not significantly influence model fits, indicating that adjustment with nuclear principal components is sufficient. Our initial analysis suggests that 2-3% of variance in HDL-C and triglyceride levels may be explained by mitochondrial genetic variation, but that less of an effect is observed for the other phenotypes assessed. In future studies, we will refine the analysis approach and apply it to the full multi-ethnic dataset, for several hundred phenotypes.

Mechanistic Phenotypes: An aggregative phenotyping strategy to identify disease mechanisms using GWAS data. *J.D. Mosley[1], S.L. Van Driest[2], E.K. Larkin[1], P.E. Weeke[1], J.S. Witte[3], Q.S. Wells[1], J.H. Karnes[1], L. Bastarache[4], L.M. Olson[5], C.A. McCarty[6], J.A. Pacheco[7], G.P. Jarvik[8], E.B. Larson[9], D.R. Crosslin[10], I.J. Kullo[11], G. Tromp[12], H. Kuivaniemi[12], D.J. Carey[12], M.D. Ritchie[13], R. Li[14], J.C. Denny[1,4], D.M Roden[1].* 1) Department of Medicine, Vanderbilt University, Nashville, TN; 2) Department of Pediatrics, Vanderbilt University, Nashville, TN; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA; 4) Biomedical Informatics, Vanderbilt University, Nashville, TN; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 6) Essentia Institute of Rural Health, Duluth, MN; 7) Center for Genetic Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 8) Department of Genome Sciences, University of Washington, Seattle, WA; 9) Group Health Research Institute, Seattle, WA; 10) Biomedical and Health Informatics, Seattle, WA; 11) Division of Cardiovascular Diseases, Mayo Clinic, Rochester MN; 12) The Sigfried and Janet Weis Center for Research, Geisinger Health System, Danville, PA; 13) Department of Biochemistry and Molecular Biology, Penn State University, University Park, PA, USA; 14) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

A single mutation can alter homeostatic mechanisms and give rise to multiple clinical diseases. Such variants may be missed in association studies focused on single disease, and we test here the hypothesis that broad disease mechanisms can be identified by detecting associations between genes containing low minor allele frequency (MAF) SNPs and 'mechanistic phenotypes', comprised of collections of related diagnoses. Our overall approach is to rank associations between non-synonymous SNPs (nsSNPs) represented on GWAS platforms and mechanistic phenotypes ascertained from electronic medical records (EMRs), and then seek enrichment in functional ontologies across the top-ranked associations. We studied two mechanistic phenotypes: (1) thrombosis, evaluated in a population of 1,655 African Americans; (2) five groupings of cancer diagnoses were evaluated in 3,009 European Americans. We used a two-step analytic approach whereby nsSNPs were first sorted by the strength of their association with a phenotype. The nsSNPs evaluated were selected solely for having a MAF<0.1. Three separate association approaches that focused on minor allele homozygotes were evaluated: a recessive genetic model and 2 models that assigned p-values based on the probability that the prevalence of the phenotype among the homozygotes for the minor allele (HZMAs) exceeded prevalence values derived from genotype-permuted data. The first utilized diagnoses shared by 2 or more HZMAs while the second utilized diagnoses overrepresented among HZMAs with Fisher's p<0.1. In the second step, the top-ranked SNPs for each model, selected using p-value thresholds of 0.01 and 0.05, were tested for enrichment in functional ontologies. For the thrombosis phenotype, 452 nsSNPs met the initial selection criteria, and the top-ranked nsSNPs were enriched in ontologies related to blood coagulation (>10 fold enrichment, Fisher's p<0.002). Enrichment was driven by the F5, P2RY12, PTAFR, F2RL2, HLA-DP1 and LEP genes. A total of 833 nsSNPs were evaluated for the tumorigenesis phenotypes. Ontological enrichment was only observed with the reverse genetics models. The enriched ontologies were related to DNA repair (9.9 fold, p=9.6×10-6) (FANCI, SLX4/FANCP, XRCC1, BRCA1, FANCA, CHD1L) and microtubule processes (5.1 fold, p=1.6×10-4) (NIN, BRCA1, KIF25, DNAH3, MC1R, SFI1, DST). Mechanism-oriented phenotyping using collections of EMR-derived diagnoses can identify fundamental disease mechanisms.

1812T

Pathway-based analysis for GWAS using the extended propensity score method. *U. Lee, SJ. Finch.* Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY.

Many complex diseases are influenced by genetic variations in multiple genes and non-genetic factors. In order to find the association between SNPs and disease, an extension of genomic propensity score (eGPS) (Zhao et al., 2012) was used to correct for bias due to both genetic and non-genetic factors. Pathway analysis, which identifies biological pathway associated with disease outcome, was also used here to improve the power of eGPS. I hypothesize that the type I error rate of this approach will be closer to its nominal value over a wide range of null conditions and that its power will be greater than the sum statistic and principle component analysis based on the simulation study reported here.

1813F

Accounting for gene-by-sex interactions in genome-wide association studies using random effects meta-analysis. *N. Furlotte[1], EY. Kang[1], B. Han[1,2], JW. Joo[1], E. Eskin[1,3].* 1) University of California Los Angeles, Department of Computer Science, Los Angeles CA; 2) Broad Institute, Cambridge MA; 3) University of California Los Angeles, Department of Human Genetics, Los Angeles, CA.

The prevalence of sex-specific effects complicates the analysis of association studies consisting of both males and females. The traditional approach to address this issue in genome wide association is to regress out sex as a covariate from the phenotype. Unfortunately, this approach ignores the potential for a difference in effect sizes between the two sexes and thus may lead to a loss in power. Furthermore, genome-wide gene-by-sex effects introduce additional background phenotypic variance, leading to both power loss and the introduction of false positive associations. In this paper, we present a novel meta-analytic approach for the analysis of genome-wide association studies consisting of both males and females. In our approach, males and females are analyzed separately and the results are combined using a random effects meta-analysis approach allowing for a difference in effect sizes between sexes. We show that by analyzing males and females separately, our method reduces the overall variance in each study leading to an increase in statistical power when applying meta-analysis. One significant challenge encountered in meta-analysis is the potential for between study population structure, resulting in inflation and spurious associations. To combat this, we propose a novel method to correct between study population structure. We apply our method to the Northern Finland Birth Cohort and the Wellcome Trust Case Control Consortium data and for both studies, we show that our method has increased power over a traditional approach while controlling for false positives.

1814W

Increasing the Power of Association: POPFAM Combines Arbitrary Affected Families, Unrelated Cases, Controls, and Reference Samples. *W. Stewart[1,2], M. Monti[3].* 1) Nationwide Children's, Columbus, OH; 2) The Ohio State University; 3) University of Pavia.

We have extended our genetic association software: POPFAM so that in addition to case-parent triads and unrelated controls, the genotypes of large affected families, unrelated cases, and (optionally) reference individuals (e.g. HapMap samples) can easily be incorporated into a single, more powerful, test of association. Furthermore, in order to maintain POPFAM's speed and flexibility, we have adapted our most recent release: POPFAM-v2.0_beta to a parallel computing environment. In this setting, workloads are distributed across multiple cores of a single machine and/or across multiple nodes of a cluster. Overall, by combining data across heterogeneous designs (e.g. ascertained affected family studies with variable pedigree structures, case-control studies with unequal sample sizes, and unphenotyped individuals), POPFAM-v2.0_beta gives researchers the ability to increase power for detecting genetic associations. Our software is distributed as a part of the larger package EAGLET, which is freely available from the worldwide web at: http://www.mathmed.org/wclstewart/SOFT/soft.html. Based on simulations, we find that POPFAM-v2.0_beta increases power relative to several commonly used methods, and that it compares favorably with WQLS (Bourgain et al. 2003).

1815T

Modified Random Forest Algorithms For Analysis of Matched Case Control Data or Case-parent Trio Data. *Q. Li, J. Bailey-Wilson.* Human Genome Research Institute, NIH, Baltimore, MD.

Random forests (RF) is a machine-learning method useful to detect complex interactions among genetic markers related to a disease trait based on case-control samples. We propose a new modification of the RF algorithm for matched case-control, or family based (trio) data analysis. RF is an ensemble method, which analyzes data and summarizes results using a large number of classification trees. During the procedure, each classification tree uses a proportion of samples and a subset of predictors. An R package, rpart, has functions implementing classification tree analysis and it can be modified to accommodate different study designs by substituting its functions of classification based on a novel criterion. For ease of implementation, our method utilizes the rpart package to conduct classification tree analysis on a subset of the samples and predictors. Then our ensemble code, also written in R, summarizes results from all trees. For matched case-control, or case-parent trio data, we sample the set of samples (in a matched set, or matched case, pseudo-controls set) to be fit to each classification tree. Different classification criteria are also proposed to accommodate the matched study design. To evaluate our method, we simulated matched case-control, and case-parent trio data, and applied our method to select the top 1% most important predictors. The results are compared with other machine-learning methods applicable for matched case-control data, including RF++, MDR, and trio Logic Regression.

1816F

Exploiting network methodology for rare variant association analysis. *H. Fier[1], J. Hecker[1], D. Prokopenko[1], P. Costa[1], S. Won[2,3], K. Ludwig[4,5], E. Silverman[6], M. Mattheisen[7], M.M. Noethen[4,5,8], E. Mangold[4,5], C. Lange[1,6,8,9].* 1) Dept. of Genomic Mathematics, University of Bonn, Bonn, Germany; 2) Department of Applied Statistics, Chung-Ang University, Seoul, Korea; 3) The Research Center for Data Science, Chung-Ang University, Seoul, Korea; 4) Department of Genomics, Life & Brain Center, University of Bonn, Bonn; 5) Institute of Human Genetics, University of Bonn, Bonn; 6) Channing Laboratory, Brigham and Women's Hospital, Boston; 7) Department of Biomedicine, Aarhus University, Denmark; 8) German Center for Neurodegenerative Diseases (DZNE), Bonn; 9) Department of Biostatistics, Harvard School of Public Health, Boston.

In this communication, we propose a new analysis approach for rare variant analysis that exploits network methodology. The approach is designed for large genomic regions, varying effect directions, etc. and enables the analysis of the relationships between the variants. The benefits of incorporating network methodology in genetic research has been shown by a number of current works, e.g. for prioritizing candidate disease genes (Akula et al. 2011, Kacprowski et al. 2013) or protein-protein networks (Guney and Oliva 2012). First, we construct networks based on the aggregated allele counts of rare variants for cases and controls. Subsequently, we introduce a statistic that tests the centralization tendency of the derived networks. In a simulation study, we assess the power of the methodology and compare it with standard rare variant association approaches. We illustrate the practical applicability of the approach by an application to a sequencing study for nonsyndromic cleft lip with or without cleft palate.

1817W

Joint Association Analysis for Family-based Sequencing Data Using a Family-Genetic Random Field Method. *Z. He[1], M. Li[2], M. Zhang[1], X. Zhan[1], Q. Lu[3].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Biostatistics, University of Arkansas for Medical Sciences, Little Rock, AR; 3) Epidemiology and Biostatistics, Michigan State University, East Lansing, MI.

Advance in high-throughput sequencing technologies has revolutionized genetic study of complex diseases, especially the discovery of associated rare genetic variants. However, the high-dimensional feature of the sequencing data and the low frequency of the rare variants limit the power of detecting rare variants in population-based sequencing studies. As rare variants likely aggregate in pedigrees, family-based sequencing studies have substantial potential to enhance the power of detecting rare variants, remaining the advantage of being robust to population stratification (PS). In this paper, we propose a family-genetic random field method (F-GenRF) to test for association of rare and common variants in a region with complex diseases in family while adjusting for covariates. The new method is computationally efficient with following advantages: 1. It accommodates to a variety of disease phenotypes (e.g., quantitative, dichotomized or count phenotypes), and various pedigree structures (e.g., nuclear families and extended pedigrees); 2. It offers robust protection against PS using within-family information, and is able to utilize between-family information for power improvement in the absence of PS; and 3. It is robust to the misspecification of within-family correlation structure. Through extensive simulations, we demonstrated these advantages by comparing the proposed F-GenRF with several existing association methods in family-based sequencing study.

1818T

Simulation study for rare variants approaches in family-based and case-control data. *C. Herold[1,2], H. Fier[3], J. Hecker[3], D. Prokopenko[3], C. Lange[1,3].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA 02115, USA; 2) German Center for Neurodegenerative Diseases (DZNE), D-53175 Bonn, Germany; 3) Department of Genomic Mathematics, University of Bonn, 53127, Germany.

After the great success of genome-wide association studies (GWAS) the current research focus now on the development of high-throughput sequencing technology to address the "missing heritability" problem. The majority of these high-throughput sequencing loci are rare variants i.e. loci with a minor allele frequency of less than 1% and therefore most of the single marker analyses for genetic association, e.g. Armitrage-trend test, do not provide sufficient power [Lange and Laird, 2002]. For this reason, several new approaches for rare variants have been developed like the burden tests Combined Multivariate and Collapsing (CMC) test [Li and Leal, 2008], weighted sum approaches [Madsen and Browning, 2009; Price et al., 2010] and a replication-based strategy [Ionita-Laza et al., 2011] or non-burden tests like SKAT [Wu et al., 2011] and C-Alpha [Neale et al., 2011], but mostly for unrelated individuals. In our study we adopted these methods to family-based data, including a spatial approach which is taking in account the physical location of the variants [Fier et al., 2012; Bonetti and Pagano, 2005]. The advantages of family-based data are the robustness against population structure and they tend to be more powerful due to the increased likelihood of affected relatives to share the same rare disease variants [Laird and Lange, 2010]. Furthermore, the selection appropriate controls for rare variants in case-control studies can be a challenging task because of the very low frequencies. We will present the results of our simulation study for different rare variant approaches in family-based and case-control data which show that the power can be increased using family-based instead of case-control data.

1819F

Finding co-regulated transcripts associated to cooperating eSNPs. *A. Kreimer[1,2], I. Pe'er[3].* 1) Department of Biomedical Informatics, Columbia University, 622 west 168th St. New York, NY 10032, USA; 2) Center of Computational Biology and Bioinformatics, Columbia University, New York, NY 10032, USA; 3) Department of Computer Science, Columbia University, 500 west 120th St. New York, NY 10027, USA.

Associations between the level of single transcripts and single corresponding genetic variants, eSNPs, have been extensively studied and reported. However, most expression traits are complex, involving the cooperative action of multiple SNPs at different loci affecting multiple genes. Finding these cooperating eSNPs by exhaustive search has proven to be statistically difficult. In this paper we utilized sequencing data with transcriptional profiles in the same cohort to identify two kinds of usual suspects: eSNPs that alter coding regions or eSNPs within the span of transcription factors (TFs). We devised a computational framework for examining pairs of such cooperating source eSNPs that are both associated with the same two target transcripts. We characterize such quartets through their genomic, topological and functional properties. We establish that this regulatory structure of quartets is frequent in real data, but is rarely observed in permutations. eSNP sources are mostly located on different chromosomes and away from their targets. In the majority of quartets, SNPs affect the expression of the two gene targets independently of one another, suggesting a mutually independent rather than a directionally dependent effect. Furthermore, the directions of effects within quartets are consistent, so that the two source eSNPs either having the same or opposite effect on the target transcripts. Same-effect eSNPs are observed more often than expected by chance. Overall, our analysis offers insights concerning the fine structure of human regulatory networks.

1820W

Genome-wide association detection power increased by observation of cis-acting mRNA. *A. Renwick[1], J.W. Belmont[2], C.A. Shaw[2].* 1) SCBMB, Baylor College of Medicine, Houston, TX; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Discovery of genetic loci causally associated with a trait of interest is hindered by the small effect typically attributable to any one locus. For alleles whose effect is mediated by a change in level of expression, mRNA offers an intermediate observation which closes the gap between allele status and trait. For such alleles, including mRNA data together with genotype and trait increases the power to detect true association.

1821T

Is the Tie-Corrected Mann-Whitney-Wilcoxon Test a Promising Alternative to the Cochran-Armitage Test in the Analysis of Genetic Association Studies? *S. Wellek*[1,2]. 1) Dept of Biostatistics, CIMH Mannheim/Univ of Heidelberg, Mannheim, Germany; 2) Dept of Medical Biostatistics, Epidemiology and Informatics, Univ of Mainz, Germany.

The most widely used procedure of testing for association between a SNP and disease status in genetic association studies is the Cochran-Armitage (CA) test. As argued by Wellek & Ziegler (2012) (Hum Hered 73:14-17), a conceptually more appealing though asymptotically equivalent variant of the CA test is Wald's maximum likelihood test about the regression coefficient associated with the SNP under analysis. Since none of these tests is uniformly most powerful, the question of possible competitors providing better prower against certain alternatives arises. With a view to ease of implementation in the analysis of GWAS, a promising alternative choice is the classical Mann-Whitney-Wilcoxon (MWW) test corrected for the large amount of ties occurring in SNP data taking on only three possible values (0,1,or 2). The power of both the CA and the MMW test can be computed exactly for sample sizes of up to 50 per group with reasonable execution time of the programs. For larger sample sizes, one has to rely on Monte-Carlo simulation. The objective of this contribution is to identify alternatives against which the MWW test provides higher power as compared with the CA test.

1822F

Urinary monocyte chemoattractant protein-1 (MCP-1/CCL2) and its association with renal allograft rejection. *A. Raza*[1], *S. Firasat*[1], *A. Abid*[1], *T. Aziz*[2], *M. Mubarak*[3], *S.A.A. Naqvi*[2], *S.A.H. Rizvi*[2], *S.Q. Mehdi*[1], *S. Khaliq*[1,4]. 1) Centre for Human Genetics and Molecular Medicine, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; 2) Department of Urology, (SIUT), Karachi, Pakistan; 3) Department of Histopathology, (SIUT), Karachi, Pakistan; 4) Department of Human Genetics, University of Health Sciences (UHS), Lahore, Pakistan.

Abstract: Immune regulatory molecules are major players in renal allograft rejection. Among these, the chemokine, monocytes chemoattractant protein 1 (MCP-1/CCL2), has been reported as an independent predictor for late renal allograft loss. In this study, an attempt to device a non invasive marker, urinary MCP-1/CCL2 levels and their association with rejection episodes were determined in renal transplant patients from Pakistan. A total of 440 urine samples were selected for this study that include biopsy proven cases of rejection (187), non-rejection (48, No abnormality detected; NAD) and interstitial fibrosis and tubular atrophy; IFTA (47). Additionally, stable graft (42) and healthy controls (116) were also analyzed. The study was approved by the Institutional Ethical Review Committee and conformed to the Tenets of the Declaration of Helsinki. The quantification of urinary MCP-1/CCL2 levels was measured using the Human MCP-1/CCL2 Quantikine ELISA kit. The data were analyzed using the Statistical Package for Social Sciences (SPSS) and Med Calc softwares. The mean values of urinary MCP-1/CCL2 levels among rejection, IFTA, stable graft, NAD and healthy controls were 926.2±65.8pg/mL, 306.5±87.8, 253.8±57.3, 297±39.2 and 48.2±20pg/mL respectively. MCP-1/CCL2 levels were significantly different between the rejection vs. controls (p=<0.0001), rejection vs. stable graft (p=0.0001), rejection vs. NAD (p=<0.0001) and rejection vs. IFTA (p=<0.0001). Significant difference were also found among IFTA vs. control (p=<0.0001) and IFTA vs. NAD (p=0.024). The ROC curve analysis also showed significant differences among these groups. The area under curve (AUC) for rejection vs. control was 0.97. At a cutoff value 94.5pg/mL, the sensitivity and specificity were 95% and 91%. However, in the rejection vs. NAD, rejection vs. stable graft and rejection vs. IFTA, the AUC were 0.76,0.82 and 0.82 with a sensitivity of 55%.82% and 78% a specificity of 85.4%,74% and79% respectively. The results showed increased levels of urinary MCP-1/CCL2 in the allograft rejection patients. This non-invasive investigation of MCP-1/CCL2 levels in urine, with others markers, may help in monitoring early rejection episodes.

A nonparametric Bayesian model for clustering time course gene expression profiles. *D. Manandhar*[1], *B. Engelhardt*[1,2,3]. 1) Institute for Genome Sciences and Policy, Duke University, NC 27708, USA; 2) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC 27708, USA; 3) Department of Statistical Science, Duke University, Durham, NC 27708, USA.

Time course gene expression profiles have been used to understand numerous dynamic biological processes involving the cell-cycle, gene interactions, and genomic response to specific biochemical stimuli. In order to analyze these data, we have developed a nonparametric Bayesian mixture model that clusters the gene expression profiles using a Gaussian process (GP) to model gene expression trajectories. Numerous models -- such as mixed-effects model with B-splines, hidden Markov models, and models that treat gene expression values as samples from multivariate normal or t-distributions - have been developed for time-course gene expression data. Each of these models has analytic limitations that our GP-based nonparametric Bayesian mixture model handles efficiently: a) we use a GP prior as the base distribution for Dirichlet process mixture model, where each time series is a continuous distribution instead of discrete time points; b) we let the number of clusters be determined by the data; c) the model is robust to missing or noisy time point measurements; d) GPs naturally capture equally spaced time interval experiments or unequal intervals. This model assumes gene expression levels at adjacent time points are correlated; moreover, we allow cluster-specific models of time-point correlation to capture the dynamic level of interdependence between time-points in different clusters. Each cluster of genes can thus be interpreted, identifying gene products that respond to a stimulus early and fast, and others that respond slowly or not at all. Our model has a natural Bayesian test to quantify whether a specific gene expression trajectory belongs to a cluster, and also implicitly estimates a similarity matrix between genes that can be used in downstream analyses, including gene network models. When we applied this model to gene expression profiles capturing the response of human fibroblast cells to serum, we found dozens of distinct, interpretable gene expression patterns, versus ten clusters identified in the original analysis. We validate the robustness of clusters produced by out-of-sample prediction rates, by looking for enriched biological processes within cluster members, and by analyzing the mechanistic interpretation of each cluster trajectory. The larger number of distinct patterns of gene expression response suggests additional modes of transcriptional regulation in serum-exposed fibroblast cells, which we aim to study further.

Enrichment of functional information (545 annotation tracks) in GWAS hits. *S.A. Gagliano*[1,2], *M.R. Barnes*[3], *M. Weale*[4], *J. Knight*[1,2]. 1) Centre for Addiction and Mental Health, 250 College Street, Toronto, Ontario M5T 1R8 Canada; 2) Institute of Medical Science, University of Toronto, 1 King's College Circle, Toronto, Ontario, M5S 1A8 Canada; 3) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, John Vane Science Centre, Charterhouse Square, London, EC1M 6BQ, UK; 4) Dept. of Medical & Molecular Genetics, King's College London, Guy's Hospital, London SE1 9RT, UK.

There are limits to genetic discovery based on association information alone: the logical next step is to combine sources of information in our search for novel causal variants. We assessed the frequency of Genome-Wide Association Study (GWAS) hits in SNPs on common arrays which directly, or via linkage disequilibrium (r^2>0.8), overlap with functional information to determine whether combining functional information with GWAS data is informative. We looked at 1 936 864 SNPs from the 22 autosomes, which was the total number of SNPs obtained upon the union of three common GWAS panels. Linkage disequilibrium proxies were determined using data from the (N=379) Europeans (Phase I, version 3) in the 1000 Genomes Project. We defined GWAS hit SNPs as those in the Catalogue of Published Genome-wide Association Studies from the National Human Genome Research Institute (Hindorff et al., 2009). After filtering out hit SNPs that were not on the original GWAS panels, we were left with 8405 hit SNPs. Annotations came from several sources. The ENCODE Project data investigated for this project include: transcription factor binding sites, three histone modifications (H3K4Me1, H3K4Me3, H3K27Ac), DNase I hypersensitive sites, and two conservation scores (PhyloP and PhastCons). When applicable, peak data, based on regions of statistically significant enrichment, were used. Expression quantitative trait loci data for cis-acting variants (+/-1Mb of relevant gene) were also used. These data were from the NIH GTEx Roadmap Project and the UK Brain Expression Consortium. Additional information, regarding whether a variant is non-synonymous, within a splice site, or within a gene was also assessed. GWAS SNPs were categorized as annotated or not, except for the conservation scores, which were left as quantitative measures. All functional SNPs showed statistically significant enrichment for hit SNPs, except splice sites, which is likely due to an overall low frequency of splice sites compared to the other annotations. These results are being used to refine a methodology to identify SNPs that are likely to be causal based on their functional attributes, rather than relying solely on statistical results from GWAS.

1825F

Use of complementary expression-based data provides improved gene-based prioritization of Crohn's disease associated loci. *K. Ning, K. Gettler, J.H. Cho, NIDDK Inflammatory Bowel Disease Genetics Consortium.* Digestive Diseases, Department of Internal Medicine, Yale University, New Haven, CT, USA.

Purpose: We have recently identified 144 Crohn's disease (CD) loci containing 1,404 candidate genes in a large case-control meta-analysis. Bioinformatic analyses and gene co-expression networks identified a striking overlap between CD loci and genes implicated in mycobacterial susceptibility and differentiation of macrophage subsets (M1, M2). We sought to improve prioritization of CD-associated genes by integrating GWAS results with a variety of gene features. **Methods:** We developed a reference list of genes with strong evidence of involvement in CD pathology and tested for enrichment of a variety of different gene features, including expression level in the intestine, disease-based differential gene expression, eQTL data, association with other auto-immune diseases and gene-level CD association p-value. We then built a logistic regression model to optimize weights of gene features for prioritizing CD-associated genes. Genes having strong evidence of involvement in CD pathology were used to label the dependent variable and all features under study were used as predictors. Step backward model selection was then carried out to keep the most important predictive features in the model. **Results:** In our final model, six features enriched in the reference genes were kept after model selection and their weights were estimated. After building the regression model, we assessed its performance regarding its statistical fitness and its capacity to provide biological insight: (1) Analyses of area under the model's receiver operator curve with permutations showed that our model fit the data well statistically (AUC = 0.9), (2) Comparison of top genes prioritized by our model and by GWAS-based model showed that, unlike genes implicated solely by association evidence, genes specifically prioritized by our model were more enriched in CD-relevant pathways, notably IFNγ signaling (FDR adjusted p-value<1exp-7), and (3) Genes specifically prioritized in our model were significantly more likely to be differentially expressed between M1-M2 macrophage subsets, (which is modulated by IFNγ) compared with genes implicated by GWAS alone (p-value=2.4exp-5). Taken together, our model successfully integrated GWAS data with other genomic data to prioritize genes involved in CD pathology: by prioritizing genes within genome-wide significant loci and by salvaging genes lacking genome-wide significant association, but still having important roles in disease pathogenesis.

The PhenX Toolkit: discovering and promoting opportunities for cross-study analyses. *W. Huggins[1], H. Pan[1], D.M. Nettles[1], E. Eubanks[1], T. Hendershot[1], J.G. Pratt[1], D. Maiese[1], W.R. Harlan[2], J. Haines[3], H.A. Junkins[4], E.M. Ramos[4], C.M. Hamilton[1]*. 1) RTI International, Research Triangle Park, NC; 2) Retired, Associate Director for Disease Prevention, Office of the Director, National Institutes of Health, Bethesda, MD; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 4) National Human Genome Research Institute, Bethesda, MD.

The PhenX (consensus measures for **Phen**otypes and e**X**posures) Toolkit (https://www.phenxtoolkit.org/) is an online catalog of 339 measures of phenotypes and exposures for use in genomic and epidemiologic research. The PhenX Toolkit has 1,094 Registered Users and has been accessed by more than 100,000 visitors from 150 countries. Covering a broad scope of 21 research domains (Demographics, Cardiovascular, Psychosocial), PhenX measures can be used to expand subject assessment and improve opportunities for cross-study collaboration. Investigators can find measures of interest by browsing or searching the Toolkit using the Smart Query Tool. For each measure, the Toolkit provides a description of the measure, the rationale for its inclusion, detailed protocol(s) for collecting the data, and supporting documentation. The Toolkit also provides custom data collection worksheets to support data collection and custom data dictionaries that support data submission to the database of Genotypes and Phenotypes (dbGaP). To support investigators who want to collect data via the Web, initial efforts have been made to develop Web-based versions of PhenX protocols. To promote cross-study collaborations, the Toolkit includes a new 'Register Your Study' feature allowing registered Users to browse basic information about each registered study (PI, research focus, number of subjects, study design) and a list of the PhenX measures being used. To discover related variables among all completed NIH funded GWAS, PhenX measures have been mapped to 19 studies in dbGaP, and we plan to map to the remaining studies. The dbGaP advanced search tool includes 'PhenX' as a filter option and the dbGaP variable descriptions present dbGaP-PhenX variable classifications (identical, comparable or related). To help researchers find and share data in other resources, PhenX concepts are included in the National Center for Biomedical Ontologies (NCBO) BioPortal. Using BioPortal tools, researchers can search for and identify relationships between PhenX terms and terms from over 200 ontologies, automatically annotate textual descriptions of data with PhenX concepts, and use PhenX terms to simultaneously search across 38 data repositories. PhenX measures are complementary to other ongoing standard measures initiatives and a comparison of available resources that provide researchers with recommended measures and protocols will be presented. Funding provided by NHGRI 5U01HG004597 and 3U01HG004597-03S3.

Kernel Machine Methods for Joint Testing and Integrative Analysis of Genome Wide Methylation and Genotyping Studies. *N. Zhao, M. Wu.* Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC.,USA.

Comprehensive understanding of complex trait etiology requires examination of multiple sources of genomic variability. Integrative analysis of these data sources promises elucidation of the biological processes underlying particular phenotypes. Consequently, many large GWAS consortia are expanding to simultaneously examine the joint role of DNA methylation. Two practical challenges have arisen for researchers interested in joint analysis of GWAS and methylation studies of the same subjects. First, it is unclear how to leverage both data types to determine if particular genetic regions are related to traits of interest. Second, it is of considerable interest to understand the relative roles of different sources of genomic variability in complex trait etiology, e.g. whether epigenetics mediates genetic effects, etc. Therefore, we propose to use the powerful kernel machine framework for first testing the cumulative effect of both epigenetic and genetic variability on a trait, and for subsequent mediation analysis to understand the mechanisms by which the genomic data types influence the trait. In particular, we develop an approach that works at the gene/region level (to allow for a common unit of analysis across data types). Then we compare pair-wise similarity in the trait values between individuals to pairwise similarity in methylation and genotype values for a particular gene, with correspondence suggestive of association. Similarity in methylation and genotype is found by constructing an optimally weighted average of the similarities in methylation and genotype. For a significant gene/region, we then develop a causal steps approach to mediation analysis at the gene/region level which enables elucidation of the manner in which the different data types work, or do not work, together. We demonstrate through simulations and real data applications that our proposed testing approach often improves power to detect trait associated genes, while protecting type I error, and that our mediation analysis framework can often correctly elucidate the mechanisms by which genetic and epigenetic variability influences traits. A key feature of our approach is that it falls within the kernel machine testing framework which allows for heterogeneity in effect sizes, nonlinear and interactive effects, and rapid p-value computation. Additionally, the approach can be easily applied to analysis of rare variants and sequencing studies.

Integrating Multiple Correlated Phenotypes for Genetic Association Analysis Through Heritability. *J. Zhou[1], M. Cho[2,3,4], E. Silverman[2,3,4], N. Laird[1]*. 1) Harvard Sch Public Health, Boston, MA; 2) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA.

In genetic studies of complex diseases, many correlated disease variables may be analyzed in the hope of increasing power to detect causal genetic variants. A common statistical approach involves assessing the relationship between each phenotype and each single nucleotide polymorphism (SNP) individually and using a Bonferroni correction for the effective number of tests conducted. Alternatively, one can apply a multivariate regression or a dimension reduction technique, such as principal components analysis, and test for the association with the principal components of the phenotypes rather than the individual phenotypes. Other previous approaches have developed methods for combining phenotypes to maximize heritability at individual SNPs. These approaches are not practical for population sample with genome-wide scans. In this paper, by taking advantage of the estimated heritability and co-heritability, we construct a maximally heritable phenotype which is a linear combination of the various phenotypes. Our approach estimates heritability globally and is therefore applicable to genome-wide scans. Theoretically, and through simulations, we compare our approach with commonly used methods and assess both the heritability of the overall phenotype and the power. Moreover we provide a guideline of how to choose the phenotypes for combination. Applications of our approach to a COPD genome-wide association study show the practical relevance.

1829W

Analyses assessing enrichment of GWAS variants for non-coding annotations in the genome are upwardly biased. *G. Trynka[1,2], B. Han[1,2], K. Slowikowski[1,2], H. Xu[3], XS. Liu[3], S. Raychaudhuri[1,2,4]*. 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Department of Biostatistics and Computational Biology, Dana-Farber Cancer Institute and Harvard School of Public Health, Boston, MA, USA; 4) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

ENCODE and other efforts are annotating the non-coding genome, e.g with DNase hypersensitivity (DHS) sites. Investigators now commonly assess whether these annotations might link trait-associated variants (e.g from GWAS) to functional, non-coding regions. A ubiquitously applied approach is to quantify the overlap of GWAS SNPs (or SNPs in tight LD) with specific annotations, and assess if it exceeds chance. Standard practice is to assess statistical significance by comparison to randomly sampled SNPs, matched on minor allele frequency (MAF) or distance to transcription start site (dTSS). But, since GWAS is biased towards genomic regions with higher gene density and LD, standard enrichment analysis for annotations that cluster around genes might result in inflated statistics. To investigate this possibility, we compiled publicly available DHS regions from 217 samples collectively spanning 16.4% of the genome. Then to quantify type I error under different models, we simulated six different sets of GWAS catalogs, with all causal variants drawn from a single genomic structure (promoter, coding, intronic, 5' UTR, 3' UTR, or intergenic). Of these, only promoters should overlap with DHS peaks. We then tested significance of enrichment by randomly drawing 1000 SNP sets matched for different parameters: 1) MAF, 2) dTSS, 3) number of LD partners ($r2 > 0.8$). Surprisingly, matching null SNPs only on MAF and dTSS resulted in $p<0.001$ in 100% of instances. We observed that only by additionally matching on LD partners we were able to achieve appropriate type 1 error rates. As an alternative, we also defined null distributions by shifting DHS annotations locally by a random value between 5kb to +5kb. Using this approach, we observed close to the expected (5%) false positive rate at $p<0.05$ within coding (9%), intronic (11%), 5' UTR (4%), 3' UTR (10%), and intergenic regions (7%); but we had high power to detect DHS enrichment for promoter catalogs (95%). Conclusion: SNP enrichment strategies can be upwardly biased to detect false associations. We present two strategies to address this: 1) match SNPs stringently on the dTSS, MAF and the number of LD partners or 2) shift annotations locally to define null distributions. It is critical that, as investigators assess whether trait associated SNPs are relevant to specific annotations, these approaches are used to avoid dramatically inflated statistics.

1830T

dbVÖR: An open source database system for managing phenotype and genotype information for complex trait studies. *R.V. Baron[1], Y.P. Conley[2], M.B. Gorin[3], D.E. Weeks[1,4]*. 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Health Promotion and Development, School of Nursing, University of Pittsburgh, Pittsburgh, PA, USA; 3) Department of Ophthalmology, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California, USA; Jules Stein Eye Institute, Los Angeles, California, USA; 4) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

In genetic studies of complex traits, accurate data management is vitally important, yet often challenging. As technological advances permit genotyping at an ever increasing numbers of markers, handling such large scale data in a reasonable amount of time requires clever computational approaches. When samples are genotyped at the same marker multiple times, a consensus genotype for use during the analyses needs to be decided upon. Data cleaning will require samples or marker ranges to be discarded or re-measured. To address these issues, we have developed a portable open source database system, built using Python and MySQL, named dbVOR, after Vör, an inquiring Norse goddess of wisdom from whom nothing can be concealed. To handle large amounts of genome-wide genotype data, instead of storing genotypes individually, one by one, these data are split into chunks, which are then stored in blocks in the database. dbVOR also can store experiments done with small numbers of markers in a conventional way, an individual genotype at a time. To resolve multiple genotypes of samples, we generate agreement matrices displaying the genotype concordance, and either can output the consensus genotype if all genotypes agree, or the user can specify which genotype is more trustworthy and to be used. dbVOR is run from the command line, controlled by a configuration file. dbVOR has facilities for importing data in Illumina and Affymetrix and tabular formats, for storing build-specific genetic and physical maps, and for handling marker and person aliases (e.g., to help resolve multiple different ID systems). dbVOR outputs in a variety of formats, including PLINK binary format and Mega2 annotated format. It also supports filtering of families, individuals, chromosomes, chromosome ranges, markers and traits, so a desired subset of the data can easily be extracted. Our age-related maculopathy exome chip data has 247,519 SNPs stored in blocks on 1,058 people. It took 470 seconds (s) and 3.22 GB of memory on a 3.33 GHz Core 2 Mac to export 25,175 SNPs on chr. 1 to a binary PLINK file. There are 39 SNPs in both the blocked and conventional data: extracting from blocked only took 10 s, conventional 75 s, and extracting from both and resolving conflicts took 100 s. dbVOR is freely available from our http://watson.hgen.pitt.edu/register web site. This work was supported by NIH grants R01 EY009859 (PI: Gorin), R01 GM076667 (PI: Weeks), and ARRA supplement R01 EY009859-S14 (PI: Gorin).

1831F

Mega2: enhanced data-handling for facilitating genetic linkage and association analyses. *C.P. Kollar[1], R.V. Baron[1], N. Mukhopadhyay[2], D.E. Weeks[1,3]*. 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 3) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

It is common in a genetic study of a complex disease to use a variety of different analysis programs. Invariably, this will require reformatting the data into the precise input format required by each of the analysis programs used. Our Mega2 software seeks to facilitate this process by automating common data reformatting tasks, thereby markedly reducing the chance of data reformatting errors, making data setup much less error-prone, and saving the user the time of writing, debugging, and maintaining data conversion scripts. We have recently extended the capabilities of Mega2 in a number of ways. In addition to accepting LINKAGE-format input files, it now accepts PLINK-format files, both text-based and compact binary formats, as input. Mega2 is also more efficient than it was previously, enabling it to handle larger data sets and to perform its conversion operations faster. While continuing to support conversion to commonly used formats like Merlin, Mendel, SimWalk2, and SOLAR, Mega2 has now been extended to support data conversion to more analysis formats, including PLINK, Cranefoot, IQLS, FBAT, MORGAN, BEAGLE, Eigenstrat, and Structure. For some output options, Mega2 supports the generation of high-quality plots of the results using our nplplot R package, as well as generation of custom track files for use within the UCSC genome browser. It has also been extended to support organisms other than humans. Internally, Mega2 is now written in C++, and the use of object-oriented programming techniques has greatly simplified the process of adding support for new analysis programs. Mega2 is open source and is freely available, along with extensive documentation and a 'quick-start' tutorial, from our http://watson.hgen.pitt.edu/register web site. This work was supported by NIH grant R01 GM076667 (PI: Weeks). Earlier contributions to our initial code base were made by Lee Almasy, Mark Schroeder, and William P. Mulvihill.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging:: Machine learning techniques for quality control for 100,000 subjects genotyped on the Affymetrix® Axiom® system. *M. Kvale[1], S. Hesselson[1], T. Hoffmann[1], D.K. Ranatunga[2], J. Gollub[3], T. Webster[3], Y. Zhan[3], Y. Lu[3], G. Mei[3], L. Walter[2], D. Ludwig[2], B. Dispensa[1], C. Schaefer[2], P.Y. Kwok[1], N. Risch[1].* 1) Inst Human Genetics, Univ California, San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Affymetrix Inc., Santa Clara, CA.

The Research Program on Genes, Environment and Health (RPGEH) has assayed genotypes on at least 670,000+ SNPs for each of 100,000 subjects to deliver a clean, consistent dataset for use for use in research on genetic influences on a broad variety of health conditions. The number of subjects created challenges for both calling genotypes and for ensuring the highest possible quality across the whole dataset. In this presentation, we describe novel applications of machine learning to better assess sample and SNP assay quality. To determine SNP quality in the Axiom® genotyping assay, it is necessary to go beyond the confidence measures provided by the BRLMM-P genotyping engine. The gold standard for assessing SNP quality is manual inspection of fluorescent intensity profiles and genotype statistics of the population. The 100,000 samples were genotyped in 58 separate sets of samples that lead to more than 42 million intensity profiles and associated genotype inferences; manual assessment of these would take an impractically long time. To leverage the utility of manual assessment over all the genotypings, we created a support vector machine (SVM) classifier based on geometric and statistical measures of the intensity profiles, confidence distributions, and genotype statistics and trained it using manually graded SNPs. Optimization of the SVM hyperparameters was performed using cross-validation and an adaptive multigrid search. The resulting SVM classified SNP quality at a level comparable with manual grading and showed typical classification accuracy of 98-99%, with disagreements happening mainly in the marginal quality cases. A significant source of poor genotype calls came from SNP locations in which double deletions (a copy number of zero) produced a null cluster not accounted for by BRLMM-P. The SVM classifier was adapted to detect the presence of null clusters and allow for recovery of these copy number variants. An SVM classifier was also created to aid in gender identification of assayed samples. Gender inference from the assay was invaluable in detecting sample and plate mix-ups. Because of wide variance in X and Y intensities and potential large chromosomal deletions, a simple threshold test is not sufficient. An SVM was trained against survey gender to look for problem misclassifications. Of more than 100,000 samples, several hundred misclassifications were detected and removed from the dataset.

1833T

FBAP: A pipeline for family-based quality control of pedigree structures and dense genetic marker data. *A.Q. Nato[1], N.H. Chapman[1], C.Y.K. Cheung[2], Z. Brkanac[3], E.M. Wijsman[1,2,4].* 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 4) Department of Genome Sciences, University of Washington, Seattle, WA.

Inheritance vectors (IVs) specify the flow of founder alleles of each non-founder in a pedigree making them useful as a foundation for statistical genetic analyses, such as linkage analysis, association scans, and next-generation sequencing studies. Stringent quality control (QC) procedures for pedigrees ranging from small up to very large pedigrees and for genotype data of increasing resolution (multiallelic linkage marker panels, dense diallelic SNP marker panels, and high-throughput sequence data) are essential for accurate family-based analyses. We develop a family-based analysis pipeline (FBAP) that implements QC checks on genetic data of diverse breadth and depth, samples IVs based on validated pedigree structures and cleaned genotype data, and formats data for family-based analyses such as linkage analysis, association analysis, or imputation from sequence data. FBAP first identifies relationship/pedigree errors through the comparison of pairwise kinship coefficients based on pedigree structure vs. empirical kinship coefficients estimated using genotype data. Marker genetic locations (Kosambi) and physical positions are taken from the Rutgers Map and subsequently converted to their corresponding positions based on the Haldane function. An initial marker subpanel is selected from the dense panels by screening SNPs through LD-based SNP pruning, and by setting a minimum intermarker distance of 0.5 cM. Additional subpanels are obtained using different starting markers. The IVs for each initial subpanel are sampled by gl_auto of the MORGAN package conditional on validated pedigree structures, marker map, allele frequencies, and genotype data. Using each initial subpanel, Mendelian-consistent errors of remaining markers that are not on this subpanel are detected by GIGI, which flags markers with possible errors. This process is performed on each subpanel to ultimately generate a final framework panel (composed of cleaned markers) and its corresponding sampled IVs. FBAP therefore allows researchers to select markers without Mendelian consistent or inconsistent errors, sample IVs based on validated data, and subsequently perform different types of family-based analyses.

1834F

Comparing a few SNP calling algorithms using low-coverage sequencing data. *X. Yu[1], S. Sun[1,2].* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Cancer Center, Case Western Reserve University, Cleveland, OH.

Several single nucleotide polymorphism (SNP) calling programs have been developed to identify novel SNPs and mutations in next generation sequencing (NGS) data. However, low sequencing coverage presents challenges to accurate SNP calling. Moreover, commonly used SNP callers usually include several metrics for each potential SNP in their output files. These metrics are highly correlated in complex patterns, making it extremely difficult to select SNPs to do any further experimental validation. To compare the performance of SNP callers in a low coverage sequencing dataset, we first compare the SNP calling results generated from four algorithms, SOAPsnp, Atlas-SNP2, samtools, and GATK, without any post-output filtering. We have a few findings. First, we find that SOAPsnp calls more SNPs than other algorithms since it has little internal filtering criteria. However, Atlas-SNP2 reports the least number of SNPs since it has stringent internal filtering criteria. Second, using several cutoff values for the sequencing coverage of called SNPs, we find that filtering the SNPs with a higher coverage threshold improves the agreement among the four algorithms. Third, we explore the values of a few key metrics in each algorithm, and use them as post-output filtering criteria to maximize the agreement of SNP findings among algorithms. Our exploratory results show that high coverage regions or bases tend to have high calling qualities. We recommend the users to employ more than one SNP calling algorithm, and use coverage and calling quality as filtering criteria for reliable SNP identification.

1835W

Influence of low level contamination on variant calling and filtration of NGS data and its quality control. *H. Ling, K. Hetrick, E. Pugh, J. Romm, K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. In NGS labs, cross sample DNA contamination can be one of the major causes of genotyping errors and false positives. Contamination may be present in source DNA, introduced during library preparation or cross-talk during PCR amplification. To better understand its influence on data quality and QC data, we investigated 1) at what level variant calls start to be affected by contamination, 2) whether variant calling can be corrected by down-sampling alternate alleles to a fixed value or by providing an estimated contamination level, and 3) the upper limit of contamination at which the correction will still work properly to eliminate the influence. We chose a set of high quality samples and manually constructed contamination by proportionally merging BAM files from subjects with varying levels and types of combination (related/unrelated, ethnicities, 2-/3-way) at pre-determined level. Both contaminated and non-contaminated samples were called together by Unified Genotyper. A number of QC metrics (reproducibility, concordance and sensitivity to array data) were employed to evaluate the presence of contamination and quality of variant calls. VerifyBamID was used to estimate contamination levels to see how accurate the estimation is and the performance of down-sampling in correcting variant calls by feeding the estimated contamination level to caller. The contamination level was well estimated by VerifyBamID despite some variation across different types of contamination. Without any effort of correction, variant calls start to be affected when contamination reaches 3%. Down-sampling was effective in correcting moderate contamination when an accurate estimate of contamination level was provided during variant calling. However, when contamination level reached 10% or higher, down-sampling to remove contamination did not work as well and significant numbers of errors remained in the variant calls. Application and integration of VerifyBamID with variant calling allows us to detect contamination at early stages and significantly improves calling accuracy.

1836T

Handling high-dimensional genetics data using multilevel dimensionality reduction algorithms in genetic association studies. *K. Cho[1, 2], D.R. Gagnon[1, 3], H. Wu[1, 4].* 1) Massachusetts Veterans Epidemiology Research and Information Center; VA Boston Healthcare System, Boston, MA; 2) Division of Aging, Department of Medicine, Brigham and Women's Hospital/Harvard Medical School, Boston, MA; 3) Boston University School of Public Health, Boston, MA; 4) Computer Science and Networking, Wentworth Institute of Technology; Boston, MA.

In recent years with advancing genotyping and sequencing technologies, there are more genetic data available than one can thoroughly analyze with existing tools and methods. This has become one of the analytical challenges in the initial phases of big scale genetic studies. In whole-genome or genome-wide exploration of novel associations, without a priori knowledge of specific regions or genes of interest, researchers rely on the available techniques and methods that perform association tests based on a way of summarization or assuming independence. In addition, traditional statistical procedures present eminent challenges in using these data, where the number of parameters p is scalably larger than number of observations n. These limitations may compromise the level of false positive results and power to conduct studies with acceptable level of confidence. One of the ways to reduce the impact of these limitations is to first perform a data dimension reduction process and then evaluate the resulting panels of markers. We propose several algorithms using traditional PCA, PCA incorporating heritability, LASSO, and combinations of these to evaluate the impact of type one error. Using the Genetic Analysis Workshop 18 simulated data, we apply the proposed algorithms on selected null regions of chromosome 3 with regards to the diastolic blood pressure phenotype. Then we use SKAT as the evaluation tool to perform association analysis using the resulting panels from each algorithm. We then systematically compare type I error rates among different algorithms with respect to the baseline panel. Our preliminary work using a subset of 2000 SNPs (1723 polymorphic SNPs) in unrelated samples, shows a substantial reduction of the markers through applying proposed algorithms. Among these, the PCA-only algorithm resulted in 47 components comprised of 363 unique SNPs and PCA followed by LASSO algorithm resulted in a set of 135 SNPs. Using the LASSO-only and LASSO followed by PCA, there were 110 and 109 SNPs (32 components) left in the resulting panels, respectively. We are also investigating PCA incorporating heritability approaches using the family datasets. As the amount and dimensionality of the network of genomics data is only escalating in the coming years, a timely, robust and practical analytical pipeline through multilevel dimensionality reduction techniques provides an efficient approach for the initial screening tool.

Genotype imputation in the era of next-generation sequencing. *G. Pistis[1,2,3], E. Porcu[1,2,3], C. Sidore[3], F. Danjou[3], M. Steri[3], A. Mulas[3], M. Zoledziewska[3], F. Busonero[3], F. Reinier[4], R. Atzeni[4], M. Lobina[3], R. Pilu[4], M. Marcelli[4], B. Tarrier[5], H.M. Kang[1], A. Angius[3,4], C.M. Jones[4], D. Schlessinger[6], F. Cucca[2,3], G. Abecasis[1], S. Sanna[3].* 1) University of Michigan, School of Public Health, Ann Arbor, MI, 48109; 2) Università degli Studi di Sassari, Dipartimento Scienze Biomediche, Sassari, 07100, Italy; 3) Istituto di Ricerca Genetica e Biomedica-CNR, Monserrato (CA), 09042, Italy; 4) Center for Advanced Studies, Research and Development in Sardinia - CRS4, Pula, Italy; 5) DNA Sequencing Core, University of Michigan, Ann Arbor, MI, USA; 6) Laboratory of Genetics, NIA, Baltimore, MD, USA.

Genotype imputation is an essential tool to infer missing and untyped genotypes in genetic studies. Nevertheless, the performance of genotype imputation on rare (MAF <0.5%) and low frequency variants (MAF <1% and >0.5%) is still an unexplored field, and several important issues must be specifically addressed: choice of reference panel, quality of input genotypes/haplotypes and imputation quality for less common variants. Recently, we completed whole genome sequencing of 2,120 Sardinians using a low-pass approach (average 4x coverage) as well as genotyping of 6,600 individuals enrolled in the SardiNIA project, using four different Illumina Beadchip arrays: OmniExpress, Cardio-MetaboChip, ImmunoChip and ExomeChip. We used combinations of the first three arrays to perform genotype imputation using Sardinian sequencing data (SardSeq) as population-specific reference panel, and used the fourth array to evaluate accuracy as squared Pearson correlation R2 between dosages and the real genotypes. We also performed imputation using two 1000 Genomes Project (1000G) reference panels (ALL and EUR datasets). We observed that the use of SardSeq boosted imputation accuracy compared to the other external reference panels generated from geographically distant populations, with differences highly dependent on the particular genotype array used. For example Cardio-MetaboChip provided a more accurate imputation when using the SardSeq panel (mean R2 0.7) compared to 1000G panels (mean R2 0.3). The benefit was even more striking for low frequency and rare variants when imputation was performed based on the OmniExpress array: the mean R2 were, for the first type of variants, 0.91, 0.57 and 0.52 when using SardSeq, 1000G-ALL and 1000G-EUR reference panels, and 0.69, 0.40 and 0.35 for the second. Furthermore, we found that the imputation accuracy using the SardSeq panel on Europeans was on average similar to that reached using 1000G panels on the Sardinian population, for any combination of the same arrays, in both real and simulated datasets. Interestingly, a combined panel of SardSeq and 1000G haplotypes was more beneficial in Europeans than in Sardinians. Our results suggest that using a population-specific reference panel rather than public references (especially for different ancestral or geographically distant populations) yielded better imputation quality and, particularly for less common imputed variants, might reduce false positive signals in association analyses.

1838W

Impact of Quality Control on the Heritability Analyses for Qualitative Traits. *J. Liu[1,3,4], T. Hoffmann[1,3], E. Jorgenson[5], J. Witte[1,2,3,4].* 1) Department of Epidemiology & Biostatistics; 2) Department of Urology; 3) Institute for Human Genetics; 4) Diller Family Cancer Center, University of California, San Francisco; 5) Kaiser Permanente Northern California Division of Research, Oakland, CA.

While a single SNP accounts for only a small fraction of the genetic variation in complex traits, recent work has shown that a substantial heritability of complex quantitative traits can be explained by considering all SNPs simultaneously from genome-wide association studies. This approach has been extended for evaluating the chip heritability of qualitative disease traits. However, analyzing disease traits requires more rigorous quality control than for quantitative heritability~or for a conventional GWAS~because slight case-control differences can be magnified into false evidence of heritability. In this study, we investigate various factors that may affect the assessment of disease heritability, and give a detailed quality control framework for accurately estimating heritability. Using two GWAS of prostate cancer, we show that leaving out key steps can vastly over- or under-estimate heritability. In a GWAS of European Americans, the naïve prostate cancer heritability is an unreasonable 68%, whereas the 'cleaned' heritability is 59%. In a GWAS of African Americans, the naïve heritability is 22%, and the cleaned heritability is 32%. The key factors that lead to over and underestimates are (1) SNPs fail Hardy-Weinberg Equilibrium test and (2) individuals with genome-wide similarities greater than 0.025. Both of the 'cleaned' estimates are in line with what one would expect from previous heritability estimates for prostate cancer. These findings emphasize the need to use more stringent quality control criteria for evaluating chip-heritability in disease traits than one might expect based on heritability for quantitative traits or GWAS.

1839T

Visualization software for the efficient review of alternate genotype calls. *Z. Xu, N. Pankratz.* University of Minnesota, Minneapolis, MN.

The Illumina HumanExome BeadChip (the 'exome chip') has unique challenges over traditional GWAS arrays, as rare variants are often not clustered well using the default GenomeStudio GenCall/GenCall2 algorithms. New algorithms have been developed to address this, such as zCall and optiCall, however no known software can visually compare genotype calls from different algorithms overlaid on raw intensity data in an integrated and efficient manner. We have developed platform-independent Java software to plot a marker's probe intensities for all individuals and to color-code any user-defined variable (e.g., gender, study, DNA source, genotyping batch, in addition to the genotype itself) thus allowing investigators to look for batch effects, detect if a SNP association is due to artifact, or to see if rare variants are being called accurately. We have also implemented an annotation system whereby the user can tag a marker (e.g., 'unusable', 'copy number variant', 'pseudo-autosomal chrY marker', 'extra heterozygote clusters', 'okay') using a single key stroke or mouse click which can also auto-advance to the next questionable marker. Lists of questionable markers can be generated automatically using over a dozen criteria, including low call rate, excess/low heterozygosity, mean theta values deviating from expected, etc. In addition, alternate genotype calls can be imported and customizable colors/symbols can be used to denote points that are discordant for the various calling algorithms (e.g., samples called as missing by GenCall and as heterozygotes by zCall could be orange triangles). The user can then use the software to draw a square around these points and set them to what the user believes to be the proper genotype call. Once this is done for a series of markers, the reclustered data can be exported into the user's preferred format (e.g., PLINK). The software is highly responsive in loading (<1s) and advancing markers (instantly), and when applied to exome chip data for 7676 individuals from the Minnesota Twin Family Study, all 24,898 flagged markers could be reviewed and recalled by one technician over the course of four days. The ability to plot disparate genotype calls and to recluster them is not known to be available in any existing software, commercial or otherwise. This software is publicly available as free and open source and will allow researchers to triage, annotate, and recall markers from any array as quickly and as efficiently as possible.

PhenoMan: Phenotypic data exploration, selection, management and quality control for association studies of rare and common variants. *B. Li, G. Wang, S.M. Leal.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Next generation sequencing and other high-throughput technology advances have promoted great interest in detecting associations between complex traits and genetic variants. Phenotype selection, quality control (QC) and control of confounders are crucial and can have a great impact on the ability to detect associations. Although there are available programs to perform association analyses, e.g. PLINK, they cannot be used for comprehensive management and QC of phenotype data. To address this need PhenoMan was developed to 1.) select individuals based upon multiple phenotype criteria, 2.) replace missing covariate data, 3.) remove duplicates samples and individuals who are related, belong to another population or have incorrect sex specification, 4.) recode primary traits and covariates, 5.) transform and visualize quantitative traits, 6.) remove or windsorize outliers, 7.) select covariates for analysis, 8.) create residuals and 9.) provide summary statistics. A report is generated for each data set in order that the same protocol can be used to ensure consistency and harmonization between analyses: PhenoMan is a user friendly interactive program that integrates data exploration, management and QC using a unified platform. Proper QC of phenotypes before proceeding to association analyses is critical to ensure control of type I and II errors, reliable effect estimates and consistent results between studies. PhenoMan is highly beneficial for preparation of case, control and quantitative trait data for association studies using new data sets as well as those obtained from public repositories. The PhenoMan program and documentation are available at https://code.google.com/phenoman.

Forensic Inference via a Genome Parade. *Y. Chen[1,2], R. Xia[1,2], F.A. San Lucas[4,2], S. Vattathil[3,2], P. Scheet[1,2,3,4].* 1) Division of Biostatistics, School of Public Health, The University of Texas Health Science Center at Houston, TX; 2) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX; 3) Program in Human and Molecular Genetics, The University of Texas at Houston Graduate School of Biomedical Sciences; 4) Program in Biomathematics and Biostatistics, The University of Texas at Houston Graduate School of Biomedical Sciences.

Contamination of DNA may present problems or clues in studies using high-throughput next-generation sequencing data. Methods such as ContEst (Cibulskis et al, 2011, Bioinf., 27:2601) and ContaminationDetection (Jun et al, 2012, AJHG, 91:839) have been shown to provide accurate estimates of contamination levels using complementary microarray data to look for deviations from expected allele-specific read counts. Here we present a statistical model that incorporates the dependence of these population allele frequencies, or linkage disequilibrium (LD), to improve component identification when encountering mixtures of two diploid genomes in next-generation sequencing data. Our method, which we call Genome Parade, uses a hidden Markov model similar to fastPHASE (Scheet & Stephens, 2006, AJHG, 78:629) to accommodate dependence of alleles potentially from a contaminator's DNA, essentially presenting pairs of haplotypes 'in turn' from a model for genetic variation in front of the observed data for comparison (analogous to an 'identity parade'). Using simulated and real data, we explore certain forensic applications, as existing methods offer limited power to identify the genotypes of a contaminating individual. For example, compared with an approach that ignores LD, our method increases the squared correlation between estimated genotypes and true genotypes of the contaminating individual from .57 to .82 in a scenario of 2% contamination and sequencing depth of 100. This is essentially an application of low-coverage LD-based imputation in the unusually difficult setting where we are interested in the rare source of DNA in a mixture. This may be useful when attempting to identify a contaminating individual in a subtle mixture of DNA, when plausible candidates are not readily available, or to aid in reducing a search space for brute-force methods that use large databases. In a related application, Genome Parade may be useful when indeed there exists a suspected source of contamination but when the alternatives do not come from an identifiable list. In such cases, the probability of the data may be easily calculated for the suspected source, but to quantify this evidence a comparison must be made to haplotypes drawn from the general population. Finally, incorporation of LD may aid in quantifying contamination in applications of targeted sequencing, since ignoring the dependence in the data indicates a false sense of precision when data are limited.

1842T

Discovery and replication of genetic interactions for quantitative lipid traits. *E.R. Holzinger[1], M. Farrall[5], F. Drenos[7], C.B. Moore[3], I.B.C. Lipid Working Group[8], S. Setia[4], H. Watkins[5], F.W. Asselbergs[6], B.J. Keating[2], M.D. Ritchie[4].* 1) National Institutes of Health, National Human Genome Research Institute, Inherited Disease Research Branch, Baltimore, MD; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, University of Pennsylvania, Philadelphia, PA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 4) Center for Systems Genomics, The Pennsylvania State University, University Park, PA 16870; 5) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 6) Department of Cardiology, Division of Heart and Lungs, University Medical Center Utrecht, 3508 GA Utrecht, The Netherlands; 7) Centre for Cardiovascular Genetics, Institute of Cardiovascular Science, Faculty of Population Health Sciences, University College London, London, UK; 8) IBC Lipid Working Group.

The genetic etiology of human lipid quantitative traits may be further elucidated by considering interactions between variants. In this study, we perform a genome-wide interaction study (GWIS) for four different lipid traits - low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), total cholesterol (TC), and triglycerides (TG). Our analysis consisted of a discovery phase using individuals from five different cohorts (ARIC, CARIDA, CHS, FHS, and MESA; n~14,000) and a replication phase in a subset of the PROCARDIS cohort (n~6400). Currently, there is no gold standard for performing a powerful GWIS. Due to the computational and multiple testing burden of exhaustively testing all pairwise interactions, filters are often applied before interaction testing. In this analysis, we used two different filters: 1. Main effects filter (MEF) - exhaustively test for pairwise interactions between SNPs that pass a main effect threshold of $p<0.001$. 2. Biological filter (BF)- SNP-SNP models generated with prior biological evidence supporting a potential interaction using Biofilter 2.0. We tested interactions using a linear regression model with a multiplicative interaction term for the two model SNPs. We selected SNP pairs from the discovery analysis with interaction $p<0.001$ and identified all SNP-SNP models that represent the same signal based on LD. We then tested these models in the replication dataset. We corrected for the number of interaction signals tested in the replication phase using a Bonferroni correction (MEF: $p < 0.0003$; BF: $p<0.002$). In the MEF analysis, 15 interaction signals replicated for HDL-C, 4 for LDL-C, and 12 for TG. No models replicated for TC. For the BF analysis, the TG trait analysis resulted in 4 interaction signals that replicated. No interactions replicated for the other lipid traits. Interestingly, the same SNP-SNP interaction replicated in both the MEF and BF analyses for TG (rs1263173 and rs12225230; $p=4.8\times10^{-5}$). Currently, more replication efforts are being conducted in other independent datasets to further assess these results. In this study, we identify potential interaction signals that may be contributing to the genetic etiology of various lipid traits. We also developed a pipeline for performing a computationally efficient interaction analysis. Future work will investigate the molecular mechanisms that may underlie statistically validated interactions.

1843F

Association analysis of gene-environment interactions in lipid profile using exome sequence data. *Z. He, G. Wang, S. Leal.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Virtually all common diseases are a result of the complex interplay of genetic and environmental factors. Among the environmental factors, cigarette smoking is a well-established environmental risk factor contributing to multiple complex phenotypes, for example lipid profile which includes plasma high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C), and triglycerides levels. However, little is understood about the potential interactions between genetic variations and smoking that are associated with lipid profile, mainly because the lower statistical power to detect an interaction than detecting a main effect. A number of methods have been developed to enhance the power of detecting gene-environment interaction. Among these methods, set-based approaches along with correlation-based screening have been shown to have superior performances, by aggregating signals within a set and reducing the multiple-testing burden in genome-wide gene-environment interaction studies. Set-based methods include a number of recently proposed rare variant association methods, for example the burden tests and variance component tests. In this study the relative performance of each of these methods was evaluated using simulated data under a wide range of scenarios. We also applied these approaches to analyze potential gene-environmental interactions that are associated with lipid profile, using sequencing data from NHLBI-ESP (Exome Sequence Project). Additional information about the interactions between gene and cigarette smoking that are associated lipid profile may yield secure insights into its role in cardiovascular disease.

1844W

Meta-analysis identifies gene-by-environment interactions as demonstrated in a study of 4,965 mice. *E. Kang[1], B. Han[2,3,4], N. Furlotte[1], J. Joo[5], D. Shih[6], R. Davis[6], A. Lusis[6,7], E. Eskin[1,7].* 1) Department of Computer Science, University of California, Los Angeles, CA, USA; 2) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA, USA; 3) Partners HealthCare Center for Personalized Genetic Medicine, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 5) Interdepartmental Program in Bioinformatics, University of California Los Angeles, CA, USA; 6) Department of Medicine, University of California, Los Angeles, CA, USA; 7) Department of Human Genetics, University of California, Los Angeles, CA, USA.

Identifying environmentally specific genetic effects is a key challenge in understanding the structure of complex traits. Model organisms play a crucial role in the identification of gene-by-environment interactions, as a result of the unique ability to observe genetically similar individuals across multiple distinct environments. A large number of model organism studies with varying environmental conditions measure the same traits. For example, knockout or diet-controlled studies are often used to examine plasma cholesterol levels in mice. These studies when examined in aggregate provide an opportunity to identify genomic loci bearing environment-dependent effects. However, straightforward application of traditional methodologies to aggregate datasets suffers from several problems. First, environmental conditions are often variable and do not fit the standard univariate model for interactions. Additionally, applying a multivariate model results in increased degrees of freedom and low statistical power. In this paper, we propose a meta-analytic approach based on a random effects model to identify loci involved in gene-by-environment interactions by jointly analyzing multiple studies with varying environmental conditions. Our approach is motivated by the observation that methods for discovering gene-by-environment interactions are closely related to random effect models for meta-analysis. We show that the interactions can be interpreted as heterogeneity and can be detected without utilizing the traditional uni- or multi-variate models for discovery of gene-by-environment interactions. We apply our method to combine 17 mouse-studies containing a total of 4,965 animals. Using these studies, we identify 26 significant loci involved in plasma HDL cholesterol levels. Among these, 23 loci are previously confirmed to have an effect on HDL cholesterol or closely related lipid levels in the blood, while 3 loci are novel. Several of these loci show significant evidence of gene-by-environment interactions including a locus on chromosome 8 showing strong evidence of sex by knockout-driven LDL-level interaction, which simultaneously affects HDL cholesterol levels. A great advantage of our approach is that due to a various design strategy of combined study, it provides significantly higher power and improved resolution for identification of the underlying genes.

1845T

GMDR: A conceptual framework for detection of multifactor interactions underlying complex traits. *X. Lou.* Dept Biostatistics, Univ Alabama Birmingham, Birmingham, AL.

Biological outcomes are governed by interacting networks consisting of multiple genetic and environmental factors that jointly act in often unpredictable ways. Determining multifactor interactions underlying complex traits is the primary topic of interest in recent genetics studies but presents enormous statistical and mathematical challenges. The computationally efficient multifactor dimensionality reduction (MDR) approach, originally for a case-control study, has recently emerged as a promising tool for meeting these challenges. On the other hand, complex traits are expressed in various forms such as categorical, ordinal, continuous, count and time-to-event and have different data generation mechanisms that cannot be appropriately modeled by a dichotomous model; the subjects in a study may be recruited according to its own analytical goals, research strategies and resources available, not only unrelated individuals from a homogeneous population. Although several modifications and extensions of MDR have in part addressed the practical problems, they are still limited in statistical analyses of diverse phenotypes, multivariate phenotypes and correlated observations, correcting for potential population stratification, and unifying both unrelated and family samples into a more powerful analysis. I propose here a comprehensive conceptual framework, referred as to generalized MDR (GMDR), for a systematic extension of MDR. The proposed approach is quite versatile, not only allowing for covariate adjustment, being suitable for the analysis of almost any trait type, e.g., binary, count, continuous, polytomous, ordinal, time-to-onset, multivariate and others, as well as combinations of those, but also being applicable to various study designs including homogeneous and/or admixed unrelated-subject and family as well as mixtures of them. The proposed GMDR offers an important addition to the arsenal of analytical tools for identifying nonlinear multifactor interactions and unraveling the genetic architecture of complex biological traits. (This study is being supported by NIH grant DA025095.).

1846F

Novel statistical framework for gene-environment interaction. *A.R. Stefanescu, X. Wen.* Biostatistics, University of Michigan, Ann Arbor, MI.

Investigations by Voorman, et al. (2011), Zuk, et al. (2011), and Wen and Stephens (2011) have shown that model misspecification in the context of gene-environment interaction can lead to an array of serious analytical issues, including missing heritability and inflated type I error. Firstly, we demonstrate through simulation the detrimental effects of ignoring gene-environment interaction in cases when interaction is known to be present. Secondly, we address the weaknesses of the naïve model that ignores interaction by comparing it to a traditional interaction model and also proposing a more robust subgroup analysis framework. Finally, we intend to explore the potential applications of the new method by integrating tissue-specific eQTLs into GWAS analyses of complex traits.

Our preliminary results showed that when error variance was held constant and genetic effect size was varied by environmental category in simulated data sets, ignoring interaction explained little of the observed variance, while the interaction models explained a much greater proportion of observed variance as heterogeneity of genetic effect increased. Of the two interaction models, the subgroup analysis performed the best, showing consistently higher estimated heritability values than the traditional interaction model, regardless of levels of heterogeneity. Furthermore, when we allowed phenotype variance to differ by environmental category (a common phenomenon observed at the cellular level), the interaction models also performed substantially better than the model ignoring interaction. Of the two interaction models, the subgroup analysis performed the best. This result comes as no surprise since the traditional interaction model assumes constant error variance across environmental conditions.

The novel subgroup analysis structure is immediately applicable to studies in which the environment variable is discrete, such as in different tissue types (NIH GTEx Project, for example) and in threshold exposures. We further intend to generalize this model to the continuous environment case. The generalized model would be applicable to studies that use biomarkers such as hormone levels as environment variables.

1847W

Accounting for population structure in gene-by-environment interactions in genome-wide association studies using mixed models. *J. Sul[1], W. Yang[1], E. Kostem[1], N. Furlotte[1], D. He[1], E. Eskin[1,2].* 1) Computer Sci, Univ California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, California, USA.

Genome-wide association studies (GWASs) attempt to identify genetic variants associated with complex traits by collecting a set of unrelated individuals. If individuals are related or from different populations, a phenomenon called population structure may cause spurious associations. GWASs on model organisms such as inbred mouse strains that are highly diverse in genetic background are readily susceptible to population structure. Several methods have been proposed to address this problem, and although GWASs have identified numerous variants associated with many traits using the methods, those variants explain only a small fraction of trait heritability.

Among several contributions that may account for a significant fraction of heritability, one is gene-by-environment interactions (GEIs). Discovering GEIs can provide insight into disease pathways, an understanding of the effect of environmental factors in disease, better risk prediction and personalized therapies. GEIs are often discovered in model organisms because of possibility to manipulate different environments.

In this paper, we first show analytically that for the same reasons that population structure causes spurious associations of genetic variants, it also causes spurious GEIs. We then use both simulation and inbred mouse strains termed Hybrid Mouse Diversity Panel (HMDP) to observe spurious GEIs. HMDP consists of 100 classical inbred and recombinant inbred (RI) strains, and they are genotyped through high density SNP typing. We analyze their lipid phenotypes, and the environment is a thioglycollate injection to recruit macrophages. We observe that test statistics for GEIs are inflated across most phenotypes, leading to spurious GEIs. Lastly, we propose a method to account for population structure for GEIs using mixed models. It has been shown that mixed models effectively control population structure on effects of genetic variants. We show that directly applying mixed models to GEIs, however, does not control population structure on GEIs because current mixed models are designed to control inflation of genetic effects. We extend mixed models to control population structure on both genetic and GEIs effects and show that our method removes the inflation of test statistics on simulation and the HDMP dataset.

1848T

Improved detection of variants with main or interaction effects using a robust location-scale testing framework. *D. Soave[1,2], A.D. Paterson[2,1], L.J. Strug[2,1], L. Sun[1,3].* 1) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 2) Research Institute, The Hospital for Sick Children, Toronto, Canada; 3) Department of Statistical Sciences, University of Toronto, Toronto, Canada.

The most common approach in genetic association studies is to test for phenotypic mean (location) differences between genotypes. Complex genetic etiologies such as GxG and GxE interactions can result in phenotypic variance (scale) differences between genotypes for a SNP of interest. Formally modeling GxG and GxE effects can detect these interactions, but may not be practical due to issues such as multiple hypothesis testing or missing information concerning interacting exposures. As an alternative, Levene's test for equality of variance has been proposed (Pare et al., 2010). Not surprisingly, when the distribution of a quantitative trait per genotype differs mostly in variance, this scale-test has better power, but it is not robust for detection of differences in location. More recently, Aschard et. al. (2013) proposed a distributional test that compares the percentiles of phenotypic values between genotypes. It has the advantage of detecting either mean or variance differences, or both. While this approach comprehensively evaluates the phenotypic distribution between genotypes, the sample size required to differentiate distributions is much larger than for detecting mean or variance differences. Furthermore, the full information contained in a (approximate) normally distributed trait is well captured by the mean and variance. We propose a joint location-scale testing framework. We consider a direct likelihood approach that tests the null hypothesis of equal mean and equal variance between genotypes. We compare findings with alternative Fisher and minimum p-value methods that combine evidence from the complementary individual location and scale tests. The combined methods are more robust to model assumptions, and they allow for flexibility with the specific individual tests chosen. Extensive simulation studies confirm that the proposed location-scale testing framework is powerful for detection of differences in location or scale or both. Furthermore, in most of the simulation scenarios considered by Aschard et. al. (2013), the proposed method is equally or more powerful than the distributional test. Application to a candidate gene modifier study of cystic fibrosis and a genome-wide association study of type 1 diabetes complications show that the new testing framework preserves the priority of previously identified top ranked variants while pointing to new candidates.

1849F

Improved detection of genetic exposures with unspecified effect modifiers. *T.L. Edwards[1], C. Li[2].* 1) Department of Medicine, Vanderbilt University, Nashville, TN; 2) Department of Biostatistics, Vanderbilt University, Nashville, TN.

Complex phenotypes often result from interplay of multiple genetic and environmental factors. Association analyses can gain power by modeling interaction effects when they exist. However, existing methods require explicit specification of effect modifiers, and exhaustive pairwise scans of SNPs introduce well known computational, statistical, and logistical challenges. Knowledge of the loci that are contextually related to traits through effect modifiers may be crucial for understanding genetic relationships with factors such as lifestyle, race, and drug treatment effects. For continuous phenotypes, we propose a single-locus association method that accounts for interaction through modeling both marginal mean and variance as linear functions of genotype. We base this approach on the observation that when effect modification occurs, the difference between conditional means of the dependent variable at each level of the effect modifier varies by genotype, and that this influences the conditional variance for each genotype. We derive marginal mean and variance as functions of genotype and show that the marginal variance is a quadratic function of both genotype and strength of effect modification under commonly used interaction models. Using simulations we compare our method with a test of marginal genotypic effect on the mean with constant variance and with a method recently proposed by Aschard et al. (Genetic Epidemiology, 2013). The results show our method controls type I error rate and significantly improves power over both alternatives. For example, under one scenario, our method had 68% power at the GWAS significance level $p<5e-8$, while linear model had 39% and that of Aschard et al. had 45%; under another scenario, our method had 91% power versus 78% and 83% for the alternatives. This new method will help detect genes that affect phenotypes mostly through interactions with effect modifiers and may help explain some missing heritability for many complex phenotypes. This method could be applied to standing collections of genetic data to discover novel associations without the need for collecting and scanning candidate environmental effect modifiers, or the difficulty of coordinating pairwise SNP scans for consortium studies.

1850W

Genome Wide Interaction Study of Dengue Shock Syndrome.
L. GRANGE[1,2], J.F. BUREAU[1], S. SAKUNTABHAI[1,3]. 1) Functional Genetics of Infectious Diseases, Institut PASTEUR, PARIS, FRANCE; 2) Université PARIS Diderot, Paris VII, FRANCE; 3) Department of Medicine, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Although Genome-Wide Association Studies (GWAS) have been successful in identifying more than 500 single nucleotide polymorphisms (SNPs) associated with a broad range of diseases, these SNPs explain only a part of the genetic component of these diseases. Up to now, these GWAS have proceeded by testing one SNP at a time. Thus, only SNPs with a marginal effect have been detected, while other ones that act primarily through a complex mechanism involving interactions with other genetic variants and environmental factors have yet to be discovered. The identification of these interactions is very challenging and powerful statistical methods for conducting genome-wide interactions studies (GWIS) are needed. We compared power and false discovery rate among existing programs for detecting genetic interactions using simulation datasets with different genetic interaction models. Because of their respective low false discovery rate and high power, we chose to use Plink to perform exhaustive epistasis search on real data and Model-Based Multifactor Dimensionality Reduction (MBMDR) to validate the best signals obtained. Using the previously reported GWAS dataset of dengue shock syndrome (Khor ***et al.***, *Nature Genetics*, 2011), we performed an exhaustive epistasis search, using Plink's fast-epistasis mode, on 481 344 quality controlled SNPs and identified 2 couples of regions that contributed repeatedly to the best hits of this study. 3 SNPs located in the same region on chromosome 1 (between positions 77,814,710 and 78,041,795 - Reference Genome Build 36.3) gave strong interaction signals (*P* values < 10E-10) with 3 closely located SNPs on chromosome 18 (between positions 55,425,493 and 55,461,588). Similarly, 2 SNPs from the same region on chromosome 2 (between positions 124,921,887 and 124,962,562) interacted with 6 SNPs on chromosome 7 (between positions 26,688,535 and 26,863,964) (*P* values < 10E-10).Interestingly enough, these SNPs had no marginal effects (*P*>0.4 in GWAS). We used MBMDR on 200 SNP extracts from these regions to validate the significance of the interactive signals. Pairs from chromosomes 1 and 18 turned out not to be significant with MBMDR but pairs from chromosomes 2 and 7 reached p values of 10E-4 which is the lowest one can expect from the 10,000 permutations we ran. These preliminary results support a pure epistatic effect between *CNTNAP5* gene on chromosome 2 and *SKAP2* gene on chromosome 7. Replication and functional analysis are on the way.

Gene-Gene Interaction Detection Using a Two-stage Model.
Z. Wang[1], J. Sul[1], S. Snir[2], J. Lozano[3], E. Eskin[1]. 1) Department of Computer Science, Univ California, Los Angeles, Los Angeles, CA; 2) Department of Evolutionary and Environmental Biology, University of Haifa, Israel; 3) Department of Computer Science and Artificial Intelligence, University of the Basque Country, Donostia, Spain.

Genome wide association study (GWAS) has been used extensively to discover genetic variations associated with traits. Many studies have reported associations between a single nucleotide polymorphism (SNP) and traits. However, recent GWAS results show that complex traits are influenced by multiple SNPs and it is likely that these SNPs interact. To detect the interaction between SNPs, we need to perform a pairwise association test between a trait and a pair of SNPs. A brute force approach which calculates the association statistics between a trait and all pairs of SNPs is infeasible because of the large number of SNPs collected in current GWAS studies. We propose a two-stage model to reduce the number of tests needed while maintaining similar power to the brute force approach. In the first stage, our method performs the single marker test on all SNPs and selects a subset of SNPs that achieve a certain significance threshold. In the second stage, we perform a pairwise association test between traits and pairs of the SNPs selected from the first stage. We applied our approach to the Northern Finland Birth Cohort data and achieved 30 times speedup while maintaining 99% of the power of the brute force approach.

Long range phasing using consistency graphs of identity by descent.
I. Pe'er, H.R. Shokri, P.F. Palamara. Dept Computer Sci, Columbia University, New York, NY.

Long range haplotype phasing of heterozygous genotype calls had been proposed by considering segments of identity by descent to homozygous individuals. We hereby extend this framework theoretically by defining a special graph structure across a genomewide-typed or sequenced cohort. Formally, each segment of identity by descent is defined by a pair of typed individuals i,j and a genomic interval $(l..r)$. We define a graph G_i for each individual whose nodes are the segments $[(i,j),(l..r)]$ incident on individual i. Nodes $[(i,j),(l..r)]$ and $[(i,k),(l'..r')]$ are linked by an edge if their corresponding segments overlap $l'<r$ and $l<r'$. Such edges are weighted according to the consistency of the footprints of these segments along the genomes of individuals j and k, defined as log probability of their genotypes being identical by descent along the intersecting interval $(\max(l,l'),\min(r,r'))$. Maximum-likelihood phasing of i into her two parental haplotypes is equivalent to finding the maximum cut in G_i. This framework allows handling alleles of various frequencies, incorporating sequencing/genotyping errors, while properly weighting interval length and missing data. Computationally, we observe that G_i is an interval graph, for which the Max-Cut problem is fixed-parameter-tractable, i.e. polynomial given a bound on the clique number of G_i, using a dynamic program that progresses along the maximal cliques in G_i along the genome. This implies a polynomial solution for maximum-likelihood phasing of i. Practically, when G_i has large cliques, we observe that such cliques mean highly redundant phasing information, that we therefore omit. We further speedup performance by observing that most segments of identity by descent longer than a length threshold are only slightly longer than their defining cutoff. This means G_i is approximately a unit interval graph, where the Max-Cut problem admits a linear-time solution. To phase the entire cohort, we iterate phasing of each G_i, updating the information regarding identity-by-descent segments after phasing so that $[(i,j),(l..r)]$ is probabilistically assigned to the possible phases of i. When sufficiently many segments are available, these iterations quickly converge to the correct phasing.

Levinson[2], D. Koller[1,10], S.B. Montgomery[10,11]. 1) Computer Science, Stanford University, Stanford, CA; 2) Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA; 3) Department of Psychiatry, University of Iowa Hospitals & Clinics, Iowa City, IA; 4) 4 Department of Psychiatry, Columbia University and New York State Psychiatric Institute, New York, NY; 5) Illumina, Inc., La Jolla, CA; 6) Personalis, Inc., Menlo Park, CA; 7) Biomedical Genomics Center, University of Minnesota, Minneapolis, MN; 8) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 9) Centrillion Biosciences, Inc., Palo Alto, CA; 10) Department of Pathology, Stanford University, Stanford, CA; 11) Department of Genetics, Stanford University, Stanford, CA.

Environmental and behavioral factors including substance use have significant impact on public health and individual risk of many common diseases, but the cellular basis for such effects is not fully understood. Through sequencing RNA from primary tissue (whole blood) of 922 living individuals, we explore the transcriptional correlates of common environmental factors. The DGN cohort was interviewed extensively to record medical, behavioral, and environmental variables, offering an opportunity to study their effects on the cell at a large scale. We observe broad transcriptional changes correlated with time of day, substance use, and medication, including changes in pathways relevant to disease risk. Notably, differences are apparent not only in gene expression levels, but also in quantitative measures of alternative splicing. Further, by integrating genetic information into this analysis, we can explore the combined regulatory impact of genotype and environment, including GxE interactions affecting diverse transcriptional traits. In addition to evaluating environment-specific quantitative trait loci (eQTL), RNA-sequencing offers an additional avenue for exploring GxE interactions through a novel method to evaluate differential allele-specific expression (ASE). By employing Bayesian methods to identify the most likely environmental and technical covariates responsible for variation in gene expression, we have identified both differential expression and splicing, along with a number of cases where the effect of a regulatory variant appears to be modulated by specific environmental factors. For example, genes inferred to respond to smoking include pathways related to beta-cell regulation and diabetes. These data and analyses offer a window into the complex response of the cell to behavior and environmental factors that carry significant health consequences.

Within-gene interactions in GWAS identifies novel susceptibility loci - The WTCCC data revisited. *N. Sharaf Eldin[1], Q. Liu[1], S. Jabbari[1], L. Wang[2], C. Franco-Villalobos[1], S. Mahasirimongkol[3], H. Yanai[3, 4], L.J. Martin[1], K. Tokunaga[3], Y. Yasui[1].* 1) School of Public Health, University of Alberta, Edmonton, Alberta, Canada; 2) College of Agriculture & Biotechnology, Zhejiang University, China; 3) Department of Human Genetics, School of International Health, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Fukujuji Hospital, Japan Anti-Tuberculosis Association, Kiyose, Japan.

Genome-wide association studies (GWAS) examine single nucleotide polymorphisms (SNPs) associated with disease risk. A Standard single-SNP analysis, however, ignores combined effects of multiple SNPs; and SNP-set interactions remain largely unexplored at the genome-wide level. Here we show how exploring interactions of all SNPs within each gene can identify appreciable numbers of novel susceptibility loci. We re-analyzed six diseases in The Wellcome-Trust-Case-Control-Consortium (WTCCC) data: bipolar disorder (BD), coronary artery disease (CAD), hypertension (HT), rheumatoid arthritis (RA), type 2 diabetes (T2D), and type 1 diabetes (T1D). We considered two forms of SNP-set interactions: SNP intersection and SNP union. SNP-set interactions within each gene were assessed using logic regression. The number of genes showing strong evidence of association was: 88 for BD, 81 for CAD, 88 for HT, 161 for RA, 78 for T2D and 192 for T1D. All strong single-SNP signals of WTCCC and around 80% of recent GWAS meta-analyses signals were confirmed. In addition, strong evidence emerged implicating a large number of new discoveries supported by apparent biologically plausible links to disease. Top significant genes were: *CBLN4* with BD, *P2RX4* with CAD, *BBOX1* with HT, *STAG3L4* with RA, and *RHOJ* with T2D. Novel disease susceptibility loci with biologically plausible links to the six diseases were detected in our interaction analysis. This emphasizes the importance of considering higher order SNP-set interactions in addition to the standard single-SNP analysis in GWAS.

Applications of Hidden Markov Models with Conditional Emission Probabilities to Identify Regions of Identity-By-Descent in Whole-Exome Sequencing Data. *M. Kimmel[1,2], S. Hicks[1], S.E. Plon[3].* 1) Department of Statistics, Rice University, Houston, TX; 2) Department of Bioengineering, Rice University, Houston, TX; 3) Departments of Pediatrics and Human and Molecular Genetics, Baylor College of Medicine, Houston, TX.

Identifying regions of identity-by-descent (IBD) using the observed identity-by-state (IBS) status is an effective approach in identifying disease-causing mutations in Mendelian disorders. A previously developed inhomogenous first-order hidden Markov model (HMM) was applied to genotype data produced from whole-exome sequencing (WES) data to identify chromosomal regions of IBD in siblings with an autosomal recessive disorder [Bioinformatics 27: 829-836, 2011]. Our approach redefines the observed and hidden state space from a binary status to the true IBD and IBS status and uses inhomogeneous transition probabilities to account for position, distance and sex-specific recombination rates. To improve prediction accuracy, we extend the HMM to incorporate conditional emission probabilities and show these conditional emission probabilities vary as a function of the minor allele frequency. This analysis suggests minor allele frequency should be included in the determination of IBD regions when using WES data. We evaluate the HMMs using simulated human WES data and real datasets to identify regions of IBD. Using the known IBD status from the simulated families, we compare the root mean squared error (RMSE) from each model averaged over a set of 100 simulated families. We show a first-order HMM with conditional emission probabilities using the redefined hidden IBD status has smaller root mean squared error (RMSE = 0.17) compared to the first-order HMM previously developed (RMSE = 0.22). Our IBD model which incorporates minor allele frequency provides researchers a tool to filter large portions of the exome more accurately when searching for the causal variant(s) associated with Mendelian disease. Supported by CPRIT grant RP101089, NCI grant CA155767, NCI T32 training grant CA096520 and NCN (Poland) grant 519579938.

Cryptic relatedness in epidemiologic collections accessed for genetic association studies. *J. Malinowski[1], R. Goodloe[1], K. Brown-Gentry[1], D.C. Crawford[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Dept. of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Over the last few years, epidemiologic collections have been a major resource for genotype-phenotype studies of complex disease given their large sample size, racial/ethnic diversity, and breadth and depth of phenotypes, traits and exposures. A major disadvantage of these collections is they often survey households and communities without collecting extensive pedigree data. Failure to account for substantial relatedness can lead to inflated estimates and spurious associations. To examine the extent of cryptic relatedness in an epidemiologic collection, we accessed the Third National Health and Nutrition Examination Survey (NHANES III), a population-based survey with DNA performed from 1991-1994 (n=7,159). Genome-wide genetic data is not available in NHANES III; though hundreds of SNPs genotyped in a variety of candidate genes are available for analysis. We performed identity-by-descent (IBD) estimates in three subpopulations of NHANES III: Hispanic (MEX, n=2073), non-Hispanic white (NHW, n=2631), and non-Hispanic black (NHB, n=2108) using PLINK to identify potential familial relationships from presumed unrelated subjects. After quality control, we calculated IBD with 784 SNPs in MEX, 721 SNPs in NHW, and 691 SNPs in NHB. In MEX, we identified two potential identical twin relationships ($z_2 \geq 0.90$, π-hat>0.95), 312 potential parent/child relationships ($z_1 \geq 0.95$, $0.48<\pi$-hat<0.53), and 98 potential full-sibling relationships ($0.40<z_1<0.60$, $0.15<z_0/z_2<0.35$, $0.40<\pi$-hat<0.60). In NHW we did not observe any potential identical twin relationships, however, we did observe 1833 potential parent/child relationships ($z_1 \geq >0.95$, $0.48<\pi$-hat<0.50) and 18 full-sibling relationships ($0.40<z_1<0.60$ and $0.15<z_0/z_2<0.35$, $0.40<\pi$-hat<0.60). We identified two potential identical twin relationships in NHB ($z_2 \geq 0.93$, π-hat>0.95), 376 potential parent/child relationships ($z_1 \geq 0.95$, $0.48<\pi$-hat<0.52), and 44 potential full-sibling relationships ($0.40<z_1<0.60$, $0.15<z_0/z_2<0.35$, $0.40<\pi$-hat<0.60). We did not observe any 1st degree cousin relationships ($0.70<z_0<0.80$, $0.20<z_1<0.30$) in any of the three subpopulations. We identified numerous potential 2nd degree relationships ($0.45<z_0/z_1<0.55$, $0.23<\pi$-hat<0.27) such as half-siblings, grandparent/grandchild, and uncle/nephew in each of the three subpopulations, though PLINK was unable to discriminate among these relationships. Despite the lack of genome-wide data, our results suggest substantial cryptic relatedness in this epidemiologic collection.

1857T

IBDLD-3: A fast and parallelized software package for IBD estimation from genomic data. *L. Han, M. Abney.* Human genetics, University of Chicago, Chicago, IL.

The estimation of identity by descent (IBD) from genomic data has gained much interest recently as a tool for a variety of genetic analyses. Here we present a new implementation of our IBD estimation method that is a dramatic improvement in both speed and accuracy over our original software package. Computation time is substantially reduced due to, in part, the use of OpenMP to parallelize execution over many processors or cores. We have also implemented methodological improvements in our hidden Markov model based approach both for estimating the parameters of the model and in the computation of posterior IBD probabilities that result in both higher accuracy in the estimates and computational speed-ups. These improvements apply for both the case where pedigree information is available and when it is not. Our simulation studies show that IBDLD3 is much more accurate at estimating the true IBD sharing than the original implementation with reduced noise giving substantially improved performance at both point-wise estimates of IBD and in the detection of segments. IBDLD3 is robust to genotype and pedigree error, or other forms of misspecified relationships, and is computationally fast enough to estimate all possible IBD sharing states at every SNP from a high-density genotyping array for hundreds of thousands of pairs of individuals. The open source C++ software package IBDLD v3.1 is freely available to be downloaded.

Combinatorial Conflicting Homozygosity (CCH) enables the rapid identification of genetic linkage in the presence of multiple phenocopies. *A.P. Levine[1], T.M. Connor[1], D.D. Oygar[2], G.H. Neild[1], P.H. Maxwell[3], A.W. Segal[1], D.P. Gale[1].* 1) Division of Medicine, University College London, London, United Kingdom; 2) Nicosia State Hospital, Burhan Nalbantoglu General Hospital, Nicosia, North Cyprus; 3) School of Clinical Medicine, Cambridge University, Cambridge, United Kingdom.

The analysis of multiplex kindreds has been successfully used to identify rare disease-linked variants; however genome-wide linkage analysis of such pedigrees can fail to identify linked loci in the presence of phenocopies, as can occur where the phenotype is either non-specific or incompletely ascertained. To overcome these challenges, we developed a method based on the principle of conflicting homozygosity (CH) in which runs above a certain length of consecutive biallelic markers containing no occurrences of homozygosity for both major and minor alleles across a set of affected individuals are inferred to result from identical by descent (IBD) inheritance. An equivalent approach was described by Leibon et al. and Thomas et al. (2008), referred to as Shared Genomic Segment Analysis. We add a combinatorial feature to our method, packaged in a Python software program, in which the analysis is automatically repeated on all subsets of affected individuals. To characterise the parameter thresholds that define a locus as one likely inherited IBD, we analysed subsets of unrelated HapMap individuals. Gene-dropping simulations in pedigrees defined the sensitivity and specificity of our approach. We applied our program to a large family in which microscopic haematuria, proteinuria or renal impairment segregated as an autosomal dominant trait in 17 members. The proband was wild type for a panel of candidate mutations. Linkage analysis (which took >3 days) failed to identify one or more loci with suggestive or significant linkage. Consistent with this, CH analysis of all 17 affecteds (which took <2 seconds) demonstrated no loci shared IBD. We hypothesised the presence of one or more phenocopies and sequentially analysed all possible combinations of subsets of progressively decreasing size of the 17 affected individuals. Analysis of all 12,376 combinations of 11 of the 17 affecteds (which took ~7 hours running serially) identified three loci, one of which contained the gene *COL4A3*, mutations in which are known to cause familial kidney disease. Sequencing identified the previously described pathogenic G871C mutation in all 11 affecteds carrying the haplotype, no unaffected individuals and none of the six affecteds who did not share the linked haplotype (including the proband). We propose that combinatorial CH can be used to identify loci shared IBD in the presence of phenocopies and may be of value in gene hunting.

1859W

Investigating the Importance of Disparate Genetic Influences across African and European Descent Populations. *T. de Candia[1,2], M.C. Keller[1,2].* 1) Psychology & Neuroscience Dept, University of Colorado, Boulder, CO; 2) Institute for Behavioral Genetics, University of Colorado, Boulder, CO.

The degree to which genetic influences overlap across ethnicity has been a matter of contention. Besides the possibility that causal variants (CVs) differ between ethnicities, traits may be differentially predicted by genes due to different SNP-CV linkage disequilibrium (LD) patterns as well as artifactual differences in plates or genotyping procedures. To systematically investigate the factors that can affect genetic correlations tagged by SNPs between ethnic populations, we simulated CVs in 10849 African descent (AD) and 10007 Europen descent (ED) genotypes from four datasets (ARIC, WHI, MESA, CARDIA). A random set of 2,000 SNPs that passed quality control procedures and that were largely independent of each other were chosen as CVs for each ethnicity. For each CV, we constructed a continuous phenotype with a heritability of 0.5, and used a bivariate mixed linear model (Lee et al, 2012) to estimate the heritabilities and correlation tagged by nearby SNPs. We then explored the extent to which LD and CV allele frequencies, as well as differences in these parameters across ethnicity, predicted these parameters. Across CVs, heritabilities were underestimated for both ADs (0.40, sd=0.11) and EDs (0.44, sd=0.12), and as expected, this appeared to be be explained by incomplete LD ($r2=.33$ in ADs and .17 in EDs, $p < 1.55e-06$). We found that the mean genetic correlation was 0.94, only slightly lower than its expected value of 1. Controlling for minor allele frequencies differences, differences in LD patterns across ethnicities lowered genetic correlations ($r=-0.25$, $p < 2e-16$). On the other hand, controlling for LD pattern differences, allele frequency differences did not predict differences in genetic correlations ($r=-0.01$, $p > 0.05$). Our findings suggest that genetic correlations will be high between ethnic groups when CVs are the same, despite differences between ethnic groups in SNP LD patterns and MAFs. Thus, low genetic correlations between ethnic groups might suggest different causal variants are influencing the phenotypes and/or technical aspects of the design artificially reduce genetic correlations. Of the two factors investigated here, differences in LD patterns across ethnicities appeared to have a greater influence on SNP-correlations than did differences in MAFs. We discuss the implications of these findings on genetic correlations we observe for height and BMI.

1860T

Employing Identity by Descent to Inform Rare Variation in Gene Based Tests. *D.S. Park, C. Gignoux, L. Fejerman, D.G. Torgerson, D. Hu, S. Huntsman, C.S. Eng, E.G. Burchard, E. Ziv, N. Zaitlen.* University of California San Francisco, San Francisco, CA.

Genetic variants genotyped by commercial genotyping platforms capture approximately half of the estimated heritability of the dozens of complex human phenotypes examined to date (Visscher et al. 2012). Rare variants may make up a substantial fraction of the missing heritability (Manolio et al. 2009). Recent advances in sequencing technologies have enabled deeper exploration of rare genetic variants and their role in disease susceptibility than was previously possible with array based genotyping (Eichler et al. 2010). Although sequencing costs are likely to continue to fall, the resources to achieve the sample sizes necessary to perform a well-powered rare variant analyses can be prohibitive (Liu et al. 2013). In this work, we examine the use of segments of pairwise identity by descent (IBD) computed from array based genotype data to serve as a proxy for rare variants, preventing the need for expensive sequencing and permitting rare variant analyses of existing data sets. Our assumption is that the majority of rare variants have occurred recently and therefore exist on the same IBD background. We apply existing methods (B. L. Browning and Browning 2011) (Gusev et al. 2009) to identify segments of IBD and a clustering approach to group individuals with pairwise IBD status commensurate with an untyped rare variant (Gusev et al. 2011). However, instead of testing clusters for association directly, we turn each cluster into a 'pseudo-SNP' which represents an untyped rare variant. Since traditional single-variant tests tend to be inadequately powered to detect associations with rare variants, various gene-based tests have been proposed to examine the combined effects of rare variants. We test genes for association using SKAT in combination with our IBD based pseudo-SNPs (Wu et al. 2011). We applied our method to two Latino cohorts, one consisting of asthmatics from the GALA cohort (Burchard et al. 2004) (Kumar et al. 2013) and the other consisting of breast cancer cases (Fejerman et al. 2008). We examine in detail the underlying assumption of our method by determining the fraction of rare variants captured as pseudo-SNPs in several exome and whole genome sequencing data sets.

1861F

Computationally-efficient long-range phasing with very large datasets. *M.J. Barber[1], R.E. Curtis[2], K. Noto[1], Y. Wang[1], J.M. Granka[1], N.M. Myres[2], J.K. Byrnes[1], C.A. Ball[1], K.G. Chahine[2].* 1) Ancestry.com, San Francisco, CA; 2) Ancestry.com, Provo, UT.

While computationally intensive, phasing a large set of genotypes (i.e. > 100,000 samples) into probable haplotypes presents the opportunity to leverage sample size to increase phasing accuracy for each and every sample. Phasing switch error rate can be greatly minimized when using genotypes with a specified parent-offspring relationship, but such datasets are not universally available. Recent advances in methodology have utilized the large number of identity-by-descent segments (IBD-SEGs) between a sample and the rest of the samples in the dataset to improve phasing accuracy. These 'long-ranged' phasing approaches use an IBD-SEG to help phase the matched IBD region. At AncestryDNA, we are applying the principle of long-range phasing to very large (and growing) datasets of genotyping data. Our approach assembles high-confidence IBD-SEGs to form an explicit surrogate parent for each sample. The assembly of an explicit surrogate parent is computationally efficient: the only requirement is assessing each IBD-SEG for quality separately, rather than performing a joint analysis. Given an explicit surrogate parent, phasing and IBD-SEGs can then be updated. Our approach has the added advantage of enabling updates to the phase estimates of full or partial genotypes when new high-quality IBD-SEGs are identified, as is common in constantly growing databases such as AncestryDNA's. We test the accuracy of our approach using simulated genotyping datasets and thousands of confirmed parent-offspring relationships from the AncestryDNA database. Our novel approach aims to efficiently and accurately phase large numbers of samples in a way that could be relevant and widely practical for a variety of applications, including datasets from genome-wide association studies that are being generated by the genetics community.

1862W

IBD Mapping of Autism Microarray Data. *G. Povysil, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria.

Identity by descent (IBD) between two individuals means that their alleles are identical because they were inherited from a common ancestor. This information can be used via IBD mapping to increase the power of association analysis by grouping single nucleotide variants (SNVs) based on IBD. The basic principle of IBD mapping is to look for segments of DNA that are shared identical by descent more often among cases than controls.

HapFABIA is a biclustering algorithm that was originally designed to extract short IBD segments that are present in multiple individuals from large sequencing data using only rare variants. In this setting we used HapFABIA on SNP microarray data from the Autism Genetics Resource Exchange (AGRE) to look for IBD segments that are shared more often by cases than controls.

We found several IBD segments that were almost exclusively shared by cases. Some of these map to genes that have been previously associated with autism. Further analyses are needed to confirm or dismiss these results.

1863T

Individual Perspective Measures of Population Structure. *X. Zheng, B. Weir.* Department of Biostatistics, University of Washington at Seattle, Seattle, WA.

The methods of principal component analysis (PCA) and hierarchical clustering on individual genotypic data have been widely used to detect population structure in genome-wide association studies. The principal component axes often represent perpendicular gradients in geographic space, and we provide an interpretation of PCA based on relatedness measures, which are described by the probability that sets of genes are identical-by-descent (IBD). An approximately linear transformation between the projection of individuals onto the principal components and allele admixture fractions assuming two or more ancestral populations is revealed. Furthermore, a measure of individual dissimilarity based on the coancestry coefficient was proposed for hierarchical clustering. Compared to other dissimilarity measures (such like identical-by-state methods), its expected value is directly related to the kinship coefficient without being confounded by allele frequency, and it is a moment estimator and suited for large-scale GWAS data. Both PCA and hierarchical clustering were applied to HapMap Phase II and III data. The population admixture proportions inferred by PCA are consistent with what HAPMIX and ADMIXTURE estimate. Hierarchical clustering successfully separates Chinese and Japanese samples in HapMap Phase II data based on their coancestry coefficients. Finally, a combination of PCA and hierarchical cluster analysis should help us better understand population structure for isolated and admixed populations.

1864F

Model-free Estimation of IBD Sharing Probabilities in Admixed Populations. *M. Conomos.* University of Washington Department of Biostatistics, Box 357232, Seattle, WA 98195.

A large number of genetic studies involve samples from structured populations, including those with ancestry admixture. Estimating measures of relatedness such as kinship coefficients and identity by descent (i.b.d.) sharing probabilities in these samples is a challenge. Commonly used relatedness estimators, such as those implemented in PLINK, the genetic relationship matrix (GRM), and the EM algorithm, assume population homogeneity and are biased in the presence of population structure. The REAP method (Thornton et al., 2012) addresses relatedness estimation in admixed populations by utilizing individual specific allele frequencies. In order to estimate individual specific allele frequencies, however, REAP relies on estimates of admixture proportions and ancestral allele frequencies from likelihood based methods such as ADMIXTURE (Alexander et al., 2009) or FRAPPE (Tang et al., 2005). As a consequence, REAP is inherently sensitive to mis-specification of model assumptions in these methods; mis-specification of the number of ancestral populations represented in the sample, or insufficient reference samples from them, may lead to inaccurate admixture proportions and/or biased allele frequency estimates. We propose a model-free method of estimating i.b.d. sharing probabilities using principal components without the requirement of external reference samples. We accomplish this through the use of a modified GRM, similar to that in REAP, along with an analogous novel estimator for the probability of sharing two alleles i.b.d. that relies on an alternative coding of genotype values. We demonstrate the utility of our method by estimating i.b.d. sharing probabilities of more than 12,000 African Americans and Hispanics from the Women's Health Initiative study.

1865W

Homozygosity mapping combined with linkage analysis in human families in the age of high-density DNA variants. *J. Ott[1,2], Y. Li[3], E. Engle[4], S. Shaaban[5].* 1) Institute of Psychology CAS, Beijing, Beijing, China; 2) Ott Lab, Rockefeller University, New York; 3) School of Statistics, Shanxi University of Finance & Economics, Taiyuan, Shanxi, China; 4) Departments of Neurology, Medicine, and Ophthalmology, Harvard Medical School, Howard Hughes Medical Institute, Boston, MA; 5) Department of Neurology, Harvard Medical School, Dubai Harvard Foundation for Medical Research, Boston, MA.

Exome sequence data are often obtained in small human families. Extracting SNPs from variant (vcf) files allows for linkage analysis but power is often low. Also, multipoint linkage analysis tends to be problematic due to correlations among closely spaced SNPs. Here we propose a modern, new approach: (1) At each SNP, only one lod score (at $\vartheta = 0.0001$) is calculated. (2) With SNPs being in chromosomal order, a run of positive lod scores (ROL) is defined as a set of contiguous SNPs all with lod scores > 0.01, delimited by SNPs with lod scores $\leq$ 0.01 or a chromosome end. ROLs are analogous to runs of homozygosity (ROH) in homozygosity mapping in unrelated individuals but are more realistic as they take into account allele frequencies and family relationships. (3) For two families with a given disease, we focus on long ROLs (eg. > 500 kb) and count the number N of ROLs between the two families that overlap by k base pairs, eg. $k = 1000$ bp. (4) We approximate the null distribution of N by computer simulation by randomly placing observed ROLs on chromosomes so as to obtain a p-value associated with N. We applied our new method to two 2-generation families with comitant strabismus, each with 1 or 2 affected children and two related parents. Traditional linkage analysis furnished max. lod scores < 2 (genome-wide p >> 0.05). Focusing on the 80 longest ROLs in each family, our approach identified $N = 17$ ROLs overlapping by at least 1 bp ($p = 0.1319$), and $N = 16$ ROLs overlapping by at least 1 Mb ($p = 0.0027$). Thus, this approach finds strong genome-wide significance where traditional linkage analysis is unsuccessful, and at the same time allows replicating linkage results in a second family, with both families being of only modest size. As negative controls, (1) we applied our method to two families with very different diseases, with resulting p-values >> 0.50; (2) also, when our eye disease families are analyzed under no linkage then no single overlap is observed. ROLs significantly overlapping between two families presumably harbor common susceptibility variants. Thus, by design, this procedure takes into account multiple disease genes, possibly located on different chromosomes. Our new method is expected to be more powerful for recessive than dominant acting variants but this is not a serious shortcoming as most mutations are recessive.

1866T

A statistical approach for variant calling using pedigree information and phase informative reads. *K. Kojima, N. Nariai, T. Mimori, M. Takahashi, Y. Yamaguchi-Kabata, Y. Sato, M. Nagasaki.* Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi Japan.

Variant detection from genome-wide sequencing data is essential for the analysis of disease causing mutations and elucidation of disease mechanisms. However, variant calling in low coverage regions is difficult due to sequence read errors and mapping errors. Hence, variant calling approaches that are robust to low coverage data are demanded. We propose a new variant calling approach that considers pedigree information and haplotyping based on sequence reads spanning two or more heterozygous positions termed phase informative reads. In our approach, genotyping and haplotyping by the assignment of each read to a haplotype based on phase informative reads are simultaneously performed. Therefore, positions with low evidence for heterozygosity are rescued by phase informative reads, and such rescued positions contribute to haplotyping in a synergistic way. In addition, pedigree information supports more accurate haplotyping as well as genotyping, especially in low coverage regions. Since undesirable influence from homozygous positions to the read assignment prevents accurate haplotyping, we introduce latent variables that determine zygosity at each position, and avoid the influence from homozygous positions by using the latent variables. In performance evaluation with a parent-offspring trio sequencing data,our approach outperformed existing approaches in accuracy on the agreement with SNP array genotyping results. Also, performance analysis considering distance between variants showed that the use of phase informative reads is effective for the accurate variant estimation, and further performance improvement is expected with longer sequencing data.

Mathematical model explains gender differences in intelligence by variation in mating preferences. *M. Nagel.* Molec Gen, Ctr Nephrology, Weisswasser, Germany.

Gender differences in variance in intelligence measures is a contentious issue. While some investigators insist that males show greater variance than females, other fervently disagree. By our study we show that at least part of the controversy may be explained by cultural and social differences in mating behavior. Though previous work already mentioned the tremendous effect that mating preferences can have, it did not include such possibilities into their models. The mathematical model proposed by this study allows to evaluate changes in variance in respect to mating preferences. The model presumes that most of the alleles determining human intelligence are located on the X chromosome. The model works no matter whether those effects on intelligence are positive or negative. Therefore this assumption is~given the considerable number of known X-linked intellectual deficiencies~quite plausible. The model follows the mathematical technique of folding two probability functions. The probability mass function of cognitive (dis)abilities, which is binomial, and the hypothetical probability density function of mating preferences, which can define any probability distribution, however skewed. The model predicts that with improved mating precision~that is partners mate more precisely in the same range of intelligence~the long disputed greater variance in intelligence measures among male individuals vanishes and becomes equal to that of women. It can be hypothesized that recent social-economical changes had exactly that effect. It can be further hypothesized, that the same effect has implications for the evolution of human intelligence.

1868W

Accounting for model structure uncertainty when predicting intervention effects from observational data. *M. Rantalainen, C.C. Holmes.* Dept Statistics, Univ Oxford, Oxford, United Kingdom.

Prediction of the consequences of intervention effects, such as gene knockdowns, from observational data is of central interest in biomedical sciences. Experimental perturbations are expensive and sometimes impossible due to ethical consideration. This motivates the development of statistical and causal methods to prioritize between experiments. Graphical models together with intervention calculus provide a formal framework for predicting bounds on intervention effects from observational data but only when the underlying graphical model is known. Recently developed methods have shown how the graph itself can be inferred from data, with the limitation that only bounds on the causal effects can be estimated (Maathuis, M. H. et al., Estimating high-dimensional intervention effects from observational data. Annals of statistics, 2009). These methods have been shown to outperform (non-causal) statistical methods in terms of predicting intervention effects, and have also been validated through perturbation experiments. These methods are, however, based on accurate inference of the equivalence class of a Directed Acyclical Graph (DAG) from data. Here we present an extension to previously reported methods that allow for uncertainty in the inferred DAG, combining ideas from the area of causal inference with a Bayesian treatment of the structure of the graphical model. Our objective is to properly account for the uncertainty associated with the structure of the graphical model that is inferred from molecular profiling data. The proposed method utilises Markov Chain Monte Carlo sampling over orders combined with Bayesian model averaging to approximate the posterior of intervention effects. We report simulation results that demonstrate under realistic conditions the proposed methods have considerable advantages over existing methods, as well as results from applications to real omics data in the context of cardiovascular disease.

1869T

A variance-component based approach to pathway analysis in expression data. *E.E. Quillen, V.P. Diego, E. Drigalenko, M.P. Johnson, J.W. MacCluer, T.D. Dyer, E.K. Moses, M.C. Mahaney, J.E. Curran, H.H.H. Göring, L. Almasy, J. Blangero.* Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

The application of pathway and gene-set based analyses to high throughput data is increasingly common and represents an effort to understand underlying biology where single-gene or single-marker analyses have failed. Many such analyses rely on the a priori identification of genes associated with the trait of interest. In contrast, this variance-component based approach creates a distance matrix between individuals based on the covariance in expression of genes within each pathway. Previously generated mRNA data from 1240 Mexican-American participants in the San Antonio Family Heart Study was considered in relation to circulating HDL levels. Previous single-gene and over-representation analyses of HDL in this sample identified one gene and four associated pathways. Transcript levels were ascertained from total RNA isolated from lymphocytes and analyzed with the Illumina Sentrix Human Whole Genome (WG-6) Series I BeadChips. All probes were standardized by z-scoring within individuals. 16,681 probes were detectable above baseline levels in the majority of individuals, have non-zero heritability, and can be annotated using ReMOAT mapping. Expression levels for genes composing 228 pathways drawn from the Kyoto Encyclopedia of Genes and Genomes (KEGG) database were adjusted for age and sex before inverse normalizing. For each pathway, the normalized values were used to construct matrices of Malhanobis distances between each pair of individuals in R. Using SOLAR, a polygenic null model of HDL level was generated including sex and age as covariates. A model including each distance matrix in turn was compared to the null model to determine if the pathway is significantly associated with HDL. A final model was constructed by iteratively including each of the associated pathway matrices, in order of magnitude of effect, and removing matrices that do not explain additional variation, likely due to overlap in genes between the pathways. This method has a number of advantages when compared to single transcript and pathway over-representation analyses, including the ability to estimate the proportion of variation explained by each pathway and all pathways combined, as well as the logistical advantage of only calculating the distance matrices once for each mRNA data set regardless of the number of phenotypes. Most importantly, this method allows for the simultaneous consideration of multiple pathways to determine if they represent independent associations.

1870F

Genetic pathways enriched with type 1 diabetes suggest novel causal genes for type 1 diabetes. *M. Evangelou, D.J. Smith, O.S. Burren, N.M. Walker, J.A. Todd, C. Wallace.* JDRF/WT Diabetes and Inflammation Laboratory , Department of Medical Genetics, Cambridge Institute for Medical Research, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom.

Pathway analysis can complement single-SNP analysis in exploring genomewide association (GWA) data to identify disease associated genes. We applied a gene-based competitive pathway analysis to previously published type 1 diabetes (T1D) GWA data covering a total of 5,916 T1D cases and 7,338 controls, all of white European origin. After mapping each SNP to a unique gene according to distance, we explored three different statistics that summarize the association of each gene (the minimum single SNP p-value, the mean -log p value, and the Fisher's product statistic) and two methods for summarizing the association across genes in a pathway (Fisher's product method and the adaptive rank truncated product method).

Of 314 BioCarta and 1,272 Reactome pathways, 30 and 101, respectively, were associated using at least one statistic, and just five (three BioCarta and two Reactome) were associated using all six statistics. The BioCarta pathways were 'IL-2 receptor beta chain in T-cell activation', 'Antigen dependent B-cell activation' and 'The Co-stimulatory signal during T-cell activation' and the Reactome pathways were 'GRB7 events in ERBB2 signaling' and 'Regulation of IFNG signaling'. This echoes much that is known about the etiology of type 1 diabetes.

We identified SNPs with small GWAS *p*-values near genes in associated pathways that have not been reported as associated with T1D. The genes *FASLG, RAF1* and *SOCS1* were identified as potential novel gene risks of T1D. The *FALSG* is associated with Celiac disease but has not reported as associated with T1D, whereas the *SOCS1* gene is associated with a number of autoimmune diseases including T1D. The *RAF1* gene has not been reported as associated with T1D or with any other autoimmune disease. SNPs near these three genes are currently being genotyped in a replication cohort. Such replication will prove the utility of pathway analysis not only for identifying pathways of interest, but for using this information to alter our prior belief of association and thus identify novel disease associated SNPs that do not reach stringent genomewide significance levels.

1871W

A Powerful Statistical Method for Genetic Pathway Analysis. *N. Liu, Q. Yan, N. Yi.* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Genetic pathway represents certain biological mechanisms of diseases. Pathway analysis takes into account the biologically pathway-gene-marker hierarchical structure, while traditional analysis strategy for genome-wide association studies (GWAS) usually focuses on single marker analysis. Therefore pathway analysis may potentially complement single-marker analysis and provide additional insights for the genetic architecture of complex diseases, thus may lead to higher statistical power and more biologically meaningful interpretation. In this work, we proposed a new method for genetic pathway analysis. It is based on kernel machine testing and adaptive rank truncated product test. The genotype data of 2000 subjects from WTCCC Type I Diabetes were used for simulation studies. We compared the performance of our new method and several other methods. The preliminary results show that the new method has the highest power while maintaining correct Type I error rate in most of the scenarios we considered.

1872T

A supervised dimension reduction approach for pathway-based analysis in Genome-wide association study. *Z. Wei[1], J. Li[2], W. Wang[1], H. Hakonarson[2].* 1) New Jersey Institute of Technology, Newark, NJ; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Pathway-based gene set enrichment analysis (GSEA) has been routinely conducted as a complementary approach for conventional single-SNP based association tests in genome wide association study (GWAS). Since the first simple extension from the GSEA for microarray gene expression data years ago, methodology research is undergoing rapid development for improving GSEA in GWAS. Quite a few new methods have been proposed. One common strategy is to utilize dimension reduction technique, hoping to improve power by reducing the unnecessary large degree of freedom. However, most of existing methods are unsupervised approaches, namely, not exploiting trait information, when reducing dimensionality. Here we employ a supervised strategy by applying the ridge regularized Kernel Sliced Inverse Regression (KSIR) to achieve dimension reduction. Not only can KSIR exploit trait information, but also it is capable of capturing non-linear effects by flexibly employing various non-linear kernel functions. Using simulation studies, we show that the KSIR method outperforms conventional unsupervised competing methods in terms of causal pathway ranking and the statistical power. We also demonstrate the superior performance of KSIR in analysis of a real dataset, the WTCCC Ulcerative Colitis dataset consisting of 1762 cases and 3773 controls as the discovery cohort, and 591 cases and 1639 controls as the replication cohort. We identify several immune and non-immune pathways relevant to Ulcerative Colitis, including some novel ones that may be worthy of further investigation for their roles in the development of Ulcerative Colitis.

1873F

Rank-based analysis of transcriptome data reveals biologically relevant atopic dermatitis genes and pathways. *TB. Mersha[1], D. Ghosh[2], GK. Hershey[1], JA. Bernstein[2].* 1) Division of Asthma Research, Cincinnati Children's Hospital Medical Center, University of Cincinnati, Cincinnati, OH; 2) Immunology and Allergy, Department of Internal Medicine, University of Cincinnati, Cincinnati, OH.

Atopic Dermatitis (AD), a chronically relapsing inflammatory disorder of the skin, affects an estimated 15 to 30% of children and 2 to 10% of adults. While the exact causes of AD are not fully understood, genetic differences may also be responsible for AD susceptibility. Several independent groups have identified differentially expressed genes (DEGs) between healthy versus AD patients using microarray technology. However, there is little overlap in the DEG lists reported by different groups due to variation from random noise, biological and experimental differences, as well as differences in the extraction and handling of RNA samples. Therefore, a statistical rank-based analysis is necessary to identify a set of genes that are consistently dysregulated among multiple independent microarray studies. We obtained AD-related expression data from the GEO dataset (http://www.ncbi.nlm.nih.gov/geo/; accessed in March 2013) using 'human [organism] AND Atopic dermatitis' search terms. In this study we focused on six datasets after eliminating data obtained from non-human/ex-vivo cell-culture experiments. We, then, screened genes differentially expressed between skin samples from AD and healthy control subjects using classical t-test and p-values of <0.05 as significant threshold. We identified differentially expressed genes (with fold change >=1.5) consistently up/down-regulated in at least 5 out of 6 datasets and ranked them according to their average fold changes. The associations of particular gene across studies may represent a true association with AD and should be given highest priority. We identified 24 DEGs, out of which 8 were found to be consistently upregulated, while 16 genes were consistently downregulated in all the datasets analyzed. Top upregulated genes were KRT16 (related to Keratinocyte production) and LTF (related to the expression of lactoferritin, as anti-microbial protein), while the top down-regulated genes were LOR (loricrine), LCE2B (late cornified envelop 2B), FLG (fillaggrin) genes- mostly related to skin barrier function. Pathway analysis revealed that the DEGs are related to epidermal development or inflammatory pathways. Thus, rank-based analysis of publicly available data indicates biologically relevant genes and pathways thus providing mechanistic clues to observed gene expression patterns in AD.

1874W

Novel Top Down Dissection of Complex Traits Based on Germline Signatures. *H.K. Im[1], N.J. Cox[2].* 1) Department of Health Studies, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

Genome-wide association studies and more recently whole genome/exome sequencing studies have identified thousands of genetic variants reproducibly associated with many complex diseases and traits. However, by and large the biological mechanisms underlying these discoveries are still lacking. In addition, it is becoming increasingly clear that a large number of variants with modest effect sizes are contributing a substantial proportion of the total heritability of complex traits. Thus methods that aggregate variants into biologically meaningful units and integrate functional and regulatory evidence are dearly needed. Several gene-based approaches have emerged in order to address this problem. We propose to go a step further with a top down systems level approach that dissects the anatomy of complex traits in terms of higher level biological processes and components. For this purpose, we are in the process of developing a catalog of germline signatures (GSigDB) using cellular, animal, and bioinformatic models as well as clinical and non-clinical human data. These signatures allow testing novel hypothesis regarding disease etiology, pleiotropy among traits, to name a few. These signatures are stored as optimal weights to be applied to whole genome data and generate polygenic scores or predictions of endophenotypes. The weights are computed integrating data from existing large scale meta analysis and regulatory and functional information. For example, for the insulin resistance signature we use the effect sizes from the meta analysis of ~50K individuals published by the MAGIC consortium. We applied our approach to the 7 diseases from Wellcome Trust Consortium. We found that both insulin resistance (p=0.0029) and beta cell function (p=0.053) have similar effect sizes on the risk to type 2 diabetes. Interestingly, we also found that type 1 diabetes risk shows a significant association with insulin resistance (p=0.054) and beta cell function (p=0.040) with similar effect sizes. BMI was not significantly associated with type I diabetes, as expected. For the 5 other diseases there was no significant association with insulin resistance or beta cell function except for a negative association between Crohn's disease and insulin resistance (p=0.0057) . This finding is intriguing but needs to be replicated in an independent dataset. In conclusion, our top down approach allows us to ask high level biological questions and generate new mechanistic hypothesis.

1875T

A systems-biology approach to identify and prioritize sub-networks of functionally-related genes for Alzheimer's disease and subsequent in vivo validation of candidate genes using a *C. elegans* model of Aβ toxicity. *S. Mukherjee[1], M. Kaeberlein[2], J. Kauwe[3], A. Naj[4], P. Crane[1], Alzheimer's Disease Genetics Consortium.* 1) Department of Medicine, University of Washington, Seattle, WA; 2) Department of Pathology, University of Washington, Seattle, WA; 3) Departments of Biology and Neuroscience, Brigham Young University; 4) Perelman School of Medicine, University of Pennsylvania.

Background: Recent genome-wide association studies (GWAS) have identified around 20 variants as late-onset Alzheimer's disease (LOAD) susceptibility loci in whites. In addition to these single loci tests, it is important to detect and understand combined effects of multiple associated genes on LOAD. We performed a preliminary network analysis incorporating human protein-protein interaction database from BioGRID to the HapMap2-imputed combined ADGC data set. Post-GWAS, this helps researchers to prioritize functionally related genes and networks that are of the highest biological relevance underlying the pathogenesis of LOAD. Methods: We combined HapMap2-imputed data sets from 15 studies after performing strict quality control. We performed a case-control association for LOAD adjusting for population sub-structure and study sites on a set of 19,692 unrelated individuals using PLINK and those results were used to perform a gene-wide analysis using VEGAS. The gene-wide association results were then integrated into the human protein-protein interaction network using a dense module searching (DMS) method to identify candidate genes or sub-networks for LOAD. We then attempted to functionally validate candidate genes from this network in vivo using a transgenic *C. elegans* model of $A\beta_{1-42}$ toxicity. Results: The network analysis identified several of the known LOAD risk loci as well as other genes such as *LPL, HSF1, EGFR STAT5B,* and *UBC* to be strongly associated with LOAD. RNAi knockdown of the *C. elegans* orthologs of *HSF1 (hsf-1)* or *UBC (ubq-1 or ubq-2)* significantly accelerated the age-associated onset of $A\beta_{1-42}$ toxicity. Conclusions: We were able to identify a set of significant modules and candidate genes, including some well-studied genes not detected in the single-marker analysis of GWA studies for LOAD, and to demonstrate a role for two of these genes as modifiers of Aβ toxicity in *C. elegans*. This approach provides complementary data to a GWAS of a complex disease phenotype by incorporating biological knowledge derived from protein-protein interactions and allows for initial functional validation *in vivo*. Further functional enrichment analysis is needed to determine whether these novel loci may provide targets for interventions to ameliorate LOAD.

1876F

Hierarchical learning of regulatory networks from RNA-sequencing of 35 human tissues. *E. Pierson, S. Mostafavi, A. Battle, D. Koller, The GTEx Consortium.* Stanford University.

Understanding the regulatory interactions between genes, and identifying those interactions that are shared across human tissues and those that are specific to each tissue, is essential for understanding regulatory mechanisms that govern similarities and differences between tissues and can help reveal tissue-specific responses to environmental or genetic perturbations. The GTEx project, with RNAseq data from more than 1,000 samples across 35 human tissues, provides an opportunity for such analysis. Here, we utilize the GTEx dataset to learn regulatory networks across these 35 tissues, where each network captures interactions between genes in a particular tissue. To do so, we present a method that makes use of a tissue hierarchy, enabling us to learn such networks even for tissues with very few samples. Our method consists of two components. First, we derive a tissue hierarchy that reflects the relationships between tissues based on expression data using hierarchical clustering, and is shown to be consistent with tissue lineage relationships. We then develop a fast algorithm that uses this hierarchy to learn sparse regulatory networks in each tissue, using a L2-regularization penalty to enforce the fact that tissues nearby in the hierarchy should have similar networks. This regularization increases accuracy by allowing for transfer learning from tissues for which we have many samples to tissues for which we have few. We show, using cross validation on three different gene sets, that this algorithm learns networks more accurately than either learning a single network for all tissues or learning a network for each tissue independently. We discuss the broad applicability of this algorithm to any set of hierarchically related networks, such as those from phylogenetic or cancer datasets. We further validate the accuracy of our learned networks by comparison to four external databases: COEXPRESdb, TS-CoExp, previously identified transcription factors, and Gene Ontology. Finally, we analyze hubs and clusters in the learned networks to identify conserved and distinct patterns across tissues. We find that tissue-specific transcription factors have fewer connections in our networks than the average gene, and that general transcription factors have more, along with network connectivity consistent with shared and tissue-specific functional relationships.

1877W

Seasonal changes in gene expression represent cell type composition in whole blood. *M. Neeleman[1], S. de Jong[2], J.J. Luykx[1,3], M.J. ten Berg[4], E. Strengman[5], H.H. ten Breeijen[6,7], L.C. Stijvers[4], J.E. Buizer-Voskamp[1], S.C. Bakker[1], R.S. Kahn[1], S. Horvath[8,9], W.W. van Solinge[4], R.A. Ophoff[2,8].* 1) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, Utrecht, The Netherlands; 2) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA, USA; 3) Department of Psychiatry, ZNA hospitals, Antwerp, Belgium; 4) Department of Clinical Chemistry & Haematology, Division of Laboratories & Pharmacy, University Medical Center Utrecht, Utrecht, The Netherlands; 5) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 6) Department of Pharmacoepidemiology and Clinical Pharmacology, Utrecht Institute for Pharmaceutical Sciences; Faculty of Science, Utrecht University, The Netherlands; 7) Department of Clinical Pharmacy, University Medical Center Utrecht, The Netherlands; 8) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California 90095, USA; 9) Department of Biostatistics, School of Public Health, University of California, Los Angeles, California 90095, USA.

Seasonal patterns in behavior and biological parameters are widespread. Here, we examined seasonal changes in whole blood gene expression profiles of 233 healthy subjects. Using weighted gene co-expression network analysis, we identified three co-expression modules showing circannual patterns. Enrichment analysis suggested that this signal stems primarily from red blood cells and blood platelets. Indeed, a large clinical database with 51,142 observations of blood cell counts over three years confirmed a corresponding seasonal pattern of counts of red blood cells, reticulocytes and platelets. We found no direct evidence that these changes are linked to genes known to be key players in regulating immune function or circadian rhythm. It is likely, however, that these seasonal changes in cell counts and gene expression profiles in whole blood represent biological and clinical relevant phenomena. Moreover, our findings highlight possible confounding factors relevant to the study of gene expression profiles in subjects collected at geographical locations with disparaging seasonality patterns.

1878T

Imputation Performance of ~4,000 genomes from the UK10K Project. *J. Huang[1], B. Howie[2], J. Marchini[3] on behalf of the UK10K Cohorts Consortium.* 1) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Department of Human Genetics, University of Chicago, Chicago, Illinois, USA; 3) Department of Statistics, University of Oxford, Oxford, UK.

Imputation from reference haplotypes has proved instrumental to the success of genome-wide association studies. Imputation based on whole-genome sequencing (WGS) data is expected to further increase the utility of this approach to variants of lower minor allele frequency (MAF). To date, the 1000 Genomes project has made publically available data for a set of 1,092 genomes (4X) for individuals of multiple ethnicities. The UK10K Cohorts project has now generated a dataset of 3,781 genomes (6X), aiming to exhaustively characterize genetic variation down to 0.1% MAF in the British population.

We compared the UK10K reference panel with the 1000 genomes panel alone and the two combined. The combination of two WGS reference panels was carried out using a new functionality in IMPUTE2. We generated two pseudo-Illumina 610k bead chip datasets as imputation targets by sub-sampling WGS data from: (1) 10% samples of the UK10K project; (2) four European samples from Complete Genomics (80X). The imputation quality was measured by Pearson correlation coefficient (r^2) between the imputed genotype dosage and the masked sequences. For each of the above six scenarios (three reference panels, two SNP-arrays), we run two further analyses: (1) re-phasing the WGS data using a new algorithm implemented in SHAPEIT v2; (2) varying the -k_hap parameter in IMPUTE2 that controls the number of haplotypes used to impute each sample (500 vs. all haplotypes).

Using 3,781 UK10K genomes significantly improved imputation quality for variants with MAF between 0.1% and 5%. Increasing the number of haplotypes sampled and re-phasing the WGS reference panel provided further improvement. Adding 1000 Genomes data to UK10K data increased the number of variants imputed but not imputation accuracy. For variants with MAF of 0.1%, 0.5%, 1%, 2%, 5% respectively, the mean r^2 for using the optimal approach (two reference panels, rephased, all haplotypes sampled) is 0.531, 0.634, 0.709, 0.771, 0.856, compared to 0.253, 0.338, 0.511, 0.634, 0.780 by using the standard approach (1000 Genomes data alone, phased as-is, 500 haplotypes sampled).

In summary, we demonstrated improved imputation for European samples by using UK10K data and a new strategy to re-phasing and combining WGS reference panels.

1879F

Next generation sequencing and its application in clinical practice. *E. Klee[1], P.A. Decker[1], N. Jia[1], S.K. McDonnell[1], S.N. Thibodeau[2], M. de Andrade[1]*. 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Next generation sequencing technologies have rapidly advanced to the point that patient-specific whole-genome sequencing may soon be as routine as X-rays and cholesterol testing. However, the challenge in interpreting the vast amount of data generated by genomic sequencing and effectively using it to guide decisions about an individual's health care is significant. As part of Mayo Clinic's Center of Individualized Medicine we are developing a pipeline to analyze whole exome sequencing (WES) of small to large pedigrees and provide insights in genetic disease. In this abstract we focus on the challenge of SNV/SNP selection necessary to perform identity by descent (IBD) analysis for validating the correct relatedness between relatives. For SNV selection we selected samples with genotype data from both WES and SNP chip arrays to select sets of informative markers based on minor allele frequency and linkage disequilibrium. We used the maximum likelihood method available in PLINK and the maximum likelihood method available in PREST for IBD analysis and applied, them to pedigrees of different size. To determine possible bias in the computed IBD, we varied the number of related subjects, the type of relationship and number of variants used in the analysis. We observed that the IBD calculation in PREST is not as susceptible to biased results for close relationship as in PLINK , and including a sample of unrelated subjects helps stabilize the IBD calculation in PLINK and PREST.

1880W

A Weighted U statistic for Genetic Association Analyses of Sequencing Data. *C. Wei[1], M. Li[2], Z. He[3], Q. Lu[1]*. 1) Department of Epidemiology and Biostatistics, Michigan State University, East Lansing, MI; 2) Division of Biostatistics, Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, Arkansas; 3) Department of Biostatistics, University of Michigan, Ann Arbor, Michigan.

Despite the recent success of genome-wide association studies, a large proportion of genetic variants predisposing to complex diseases remain uncovered. Evidence from genetic studies and evolutionary theory has suggested rare variants could play an important role in the biological pathways of complex diseases. The advance of next generation sequencing technology facilitate the generation of massive amount of genetic variants and offers great opportunity to investigate the role of millions rare variants in the genetic etiology of complex disease. Nevertheless, great challenge has also been posed to statistical analyses of high-dimensional sequencing data. The association analyses based on traditional statistical methods endure substantial power loss because of low frequency of genetic variants and extremely high dimensionality of the data. We therefore developed a weighted U statistic for high-dimensional association analysis of next-generation sequencing data. Based on the non-parametric U statistic, our method makes no assumption of the underlying disease model and can be applied to various types of phenotypes (e.g., binary and continuous phenotypes). Through simulation studies and an empirical study, we found our method outperformed a commonly used SKAT method when the underlying assumption is violated (e.g., the phenotype follows a heavily skewed distribution) and attained comparable performance to SKAT when underlying assumption is satisfied. In an empirical study of Dallas Heart Study (DHS) sequencing data, our method was also able to detect the association of ANGPTL 4 with very low density lipoprotein cholesterol.

1881T

Accurate Genotype Calling with Contaminated Sequencing Data. *M. Flickinger, G. Jun, G.R. Abecasis, M. Boehnke, H.M. Kang.* Department of Biostatistics and Center for Statistical Genetics, School of Public Health, University of Michigan, Ann Arbor, MI.

Advances in next-generation sequencing have enabled a wide range of large-scale genetic studies. While the quality of the sequence data is generally improving, protocols are not perfect and inevitably sampling handling errors may occur. One common error is sample contamination through the mixing of two or more samples. We previously developed methods to detect contaminated samples (Jun et al. AJHG 91:839-848, 2013), so that these could be flagged and dropped from analysis. Here we describe new mixture-model-based methods to account for contamination in the genotype likelihoods which result in genotype calls for contaminated samples with accuracy approaching that for uncontaminated samples. To explore the operating characteristics of our method, we simulated contamination in silico by mixing reads from pairs of 198 European 1000 Genomes Project BAM files for whom both high-depth (50-150x) exome and low-depth (4-6x) whole genome sequencing data were available. We then compared the resulting calls to the available Omni 2.5M and Exomechip genotype arrays to evaluate success. In our first experiment, we constructed samples with an 85:15 mix corresponding to 15% contamination. In the high-depth exome data, the overall genotype discordance with the Exomechip decreased from 3.6% to 0.9% by modeling the contamination, compared to 0.3% for datasets with no contamination. For the low-depth data, we used our method to model contamination in the genotype likelihoods and then Beagle for linkage-disequilibrium-aware calling. Here we saw a drop in discordance with the Omni array data from 9.3% to 3.5% compared to 1.1% with no contamination. Furthermore, the false positive and false negative rate (% of incorrect and missed non-reference alleles) were also reduced by >50% for both high- and low-depth data. When the identity of the contaminating sample is known, our approach can incorporate this information resulting in further improvement: reducing discordance for high-depth data to 0.7%, approaching the 0.3% discordance observed when analyzing uncontaminated samples. In conclusion, our methods provide an effective alternative to expensive re-sequencing for accurately genotyping low to moderately contaminated samples.

1882F

A Rare Variant Selection Algorithm to Locate Susceptible Rare Variant from Sequencing Data. *S. Wang, H. Sun*. Dept Biostatistics, Columbia Univ, New York, NY.

Current association methods for sequencing data have been focused on aggregating rare variants across a gene or a genetic region due to the fact that analyzing individual rare variants is underpowered. To identify which rare variants in a gene or a genetic region out of all variants are associated with the outcomes is a natural next step. Here we propose a forward variable selection-based algorithm that is able to identify the locations of potentially susceptible rare variants that are associated with the outcomes with sequencing data. More specifically, we test associations of variants individually in the first step to select the most outcome-related variant that has the maximum test statistic. In step 2, weighted linear combinations of two variants with the selected variant from Step 1 and all other variants one by one are generated and tested to select the most outcome-related two-variant combination. Note that the most outcome-related variant selected in Step 1 could be either risk or protective. In Step 2, we also consider the combination of potentially protective variants through flipping of the variant coding. Similar to a forward variable selection, we keep adding one variant in each step until the test statistic of the linear combination of the combined variants is no longer increasing, and the combined variants are consider as the best combination of potentially causal variants. We evaluated the selection performance of the proposed algorithm through simulation studies where different effect sizes, sample sizes and directions of the effects of the individual rare variants were considered. The results demonstrated that the proposed algorithm is able to select subsets with most of the outcome related rare variants in all simulation scenarios considered. The proposed method was also applied to sequence data on the ANGPTL gene family from the Dallas Heart Study (DHS). The proposed method was implemented in an R package RVsel which will be freely downloaded at http://www.columbia.edu/~sw2206.

Functional Linear Model with both Functional Response and Functional Predictors for Genetic Studies of Temporal Quantitative Trait with both GWAS and Next-Generation Sequencing Data. *D. Lee, C. Hanis, M. Xiong.* University of Texas School of Public Health, Houston, TX., US.

Traditional quantitative genetics has primarily studied traits that are measured at a specified location or time. The traits are investigated as isolated and static variables. However, in real biologic world, many quantitative traits change over time. These quantitative traits are repeatedly measured as functions of time or complete curves. In other words, these traits are observed either as continuous random functions, or on a dense grid. It is now well documented that next-generation sequencing (NGS) can generate several millions or even dozens of millions of genetic variation data. As a consequence, these genetic variation data are so densely distributed across the genome that the genetic variation can be modeled as a function of genomic location. In summary, random functions appear as either responses or predictors, or both. Although the current widely used statistical methods for QTL analysis are based on multivariate analysis, the standard multivariate statistical analysis often fails with functional data. To overcome the limitations of the traditional QTL analysis, we propose to use functional linear model in which a trait curve is modeled as a response function, the genetic variation in a genomic region or gene is modeled as a functional predictor, and the genetic effects are modeled as a function of both time and genomic position for genetic analysis of a temporal quantitative trait with both GWAS and NGS data. By intensive simulations, we demonstrate that the functional linear model for genetic studies of the temporal quantitative traits has the correct type 1 error rates and much higher power to detect association than the current methods. The proposed method is applied to Starr County Sleep Studies where oxygen saturation of 767 individuals with 795,736 SNPs were measured for 380 minutes on average.

Weighted combination of truncated P-values for rare causal variants detection. *W.Y. Lin[1], X.Y. Lou[2], G. Gao[3], N. Liu[2].* 1) Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan; 2) Department of Biostatistics, University of Alabama at Birmingham, Birmingham, Alabama; 3) Department of Biostatistics, Virginia Commonwealth University, Richmond, Virginia.

With the development of next-generation sequencing technology, there is a great demand for powerful methods to detect rare causal variants (minor allele frequencies (MAFs) < 1%). Testing for each variant site individually is known to be underpowered, and many methods have been proposed to test for the association of a chromosomal region containing multiple variant sites with phenotypes. However, this pooling strategy inevitably leads to the inclusion of a large proportion of neutral variants, which may compromise power. Here, we have proposed a T-sigma-MidP method that combines per-site P-values with weights based on MAFs. Before combination, we first imposed a truncation threshold upon the per-site P-values to guard against noise caused by the inclusion of neutral variants. Simulations have shown that T-sigma-MidP outperforms competing tests in the majority of simulation settings. We applied T-sigma-MidP to the Dallas Heart Study data set, and obtained more significant results in testing for the association of the ANGPTL4 gene with triglyceride and very-low-density lipoprotein. The proposed T-sigma-MidP method is recommended for the easiness of its implementation, its satisfactory power to detect rare causal variants (population MAF < 1%) and/or uncommon causal variants (1% < population MAF < 3%), and its robustness to noise from neutral variants.

1885F

Detecting Genomic Clustering of Risk Variants from Sequence Data: Cases vs. Controls. *JP. Sinnwell[1], DJ. Schaid[1], SK. McDonnell[1], SN. Thibodeau[2].* 1) Dept Biostatistics, Mayo Clinic, Rochester, MN; 2) Dept. Lab Med Path, Mayo Clinic, Rochester, MN.

As the ability to measure dense genetic markers approaches the limit of the DNA sequence itself, taking advantage of possible clustering of genetic variants in, and around, a gene would benefit genetic association analyses, and likely provide biological insights. The greatest benefit might be realized when multiple rare variants cluster in a functional region. Several statistical tests have been developed, one of which is based on the popular Kulldorff scan statistic for spatial clustering of disease. We extended another popular spatial clustering method - Tango's statistic - to genomic sequence data. An advantage of Tango's method is that it is rapid to compute, and when single test statistic is computed, its distribution is well approximated by a scaled chi-square distribution, making computation of p-values very rapid. We compared the Type-I error rates and power of several clustering statistics, as well as the omnibus sequence kernel association test (SKAT). Our results showed that the Ionita-Laza version of Kulldorff's scan statistic had the greatest power over a range of clustering scenarios. Although our version of Tango's statistic, which we call 'Kernel Distance' statistic, had slightly less power than the scan statistic, its rapid computation time makes it an appealing competitor to the scan statistic.

1886W

GEE-based kernel association test in family based sequencing studies. *X. WANG[1,2], S. Lee[1], T. Cai[1], T.W. Yu[3], C.A. Walsh[3], X. Lin[1].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 2) Graduate Program in Public Health, Stony Brook University, Stony Brook, NY; 3) Division of Genetics, Children's Hospital Boston, Boston, MA.

Family-based designs in sequencing studies provide opportunities to detect genetic variants that complement studies of unrelated individuals. By exploiting co-segregation and Mendelian inheritance information, family based designs are more efficient at prioritizing casual variants, and which can improve genotyping error check and imputation of variants in unsequenced samples. In this study, we consider testing the effect of a SNP/SNV set in family studies. Specifically, we propose a Generalized Estimating Equations (GEE)-based kernel association test, a variance component-based testing method, to test for the association between a phenotype and multiple variants in a SNV set jointly using family samples. The proposed approach allows for both continuous and discrete traits, where the correlation among family members is taken into account through the use of an empirical covariance estimator. We derive the theoretical distribution of the proposed statistic under the null and develop analytical methods to calculate the p-values. We also propose an efficient resampling method for correcting for small sample size bias in family studies. The proposed method allows for easily incorporating covariates and SNP-SNP interactions. Simulation studies show that the proposed method properly controls for type-I error rates under both random and ascertained sampling schemes in family studies. We demonstrate through simulation studies that our approach has superior performance for association mapping compared to the single marker based minimum p-value GEE test for a SNP set effect over a wide range of scenarios. We illustrate the application of the proposed method using data from an exome sequencing study of autism.

1887T

Comparisons of the power functions and asymptotic relative efficiencies of empirical genetic relationship kernels in heritability and association testing. *V.P. Diego[1], M. Almeida[1], J. Peralta[1,2], T.D. Dyer[1], J.W. Kent, Jr.[1], J.T. Williams[1], L. Almasy[1], H.H.H. Göring[1], R. Duggirala[1], J. Blangero[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX, USA; 2) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, WA, Australia.

Empirical genetic relationship kernels (GRKs) have spurred on the development of powerful statistical genetic methods. Using the genome partitioning method, empirical GRKs can be used to estimate heritabilities based on the set of genes underlying specific metabolic pathways. Under our novel eigensimplification approach to likelihood analysis of variance component (VC) models, we have shown in theory how empirical GRKs can be used for rapid and efficient association analysis in samples of large extended families, where the speed of the analysis is commensurate with that for the same sample size of unrelated individuals. However, there are several competing GRK algorithms in the literature, and it is not obvious which of these is optimal for a given study design. To address this issue we studied the statistical properties of GRKs estimated over sequence data for 959 individuals from Genetic Analysis Workshop 18 by six well-known algorithms in relation to heritability and association testing. Named after their software packages, the six GRK algorithms are PLINK, GCTA, KING-homogeneous, KING-robust, REAP, and LDAK. The eigensimplification approach, which is based on a spectral representation of the likelihood, gives elegant expressions for the expected likelihood ratio test statistic (*ELRT*). For heritability, the *ELRT* is: $-\Sigma \ln[1+h^2(\lambda_{gi}-1)]$, where h^2 and λ_{gi} are the heritability and additive genetic eigenvalues, and the summation is taken over n individuals. For association, we have: $-n\ln(1-h^2_q)+\Sigma\ln[1+h^2_t(\lambda_{gi}-1)]-\Sigma\ln[1+h^2_r(\lambda_{gi}-1)]=$ *ELRT* [h^2_q>0:unrelateds]-(*ELRT* [h^2_t>0:pedigrees]-*ELRT* [h^2_r>0:pedigrees]), where h^2_t, h^2_q and h^2_r are the total, quantitative trait locus and residual heritabilities, respectively. Power analyses are made relatively easy because the *ELRT* well approximates the noncentrality parameter (NCP) in likelihood-based power functions. Moreover, precisely because the *ELRT* measures the NCP it can be used for asymptotic relative efficiency (ARE) analysis using the Pitman ARE. We discuss our results in terms of the observed relationships between study design and GRK. We also found that since certain GRK algorithms may produce GRKs that are not positive semidefinite (PSD), it is important to exercise care in this regard. If a GRK is non-PSD, then procedures to either constrain such kernels to be PSD or to correct them in the sense of making them PSD must be employed.

1888F

A DNA variant caller adapted to assess mitochondrial DNA variation in lymphocytes from 2,000 Sardinians. *J. Ding[1], C. Sidore[2,3], O. Meirelles[1], M.K. Wing[2], F. Busonero[3], R. Nagaraja[1], F. Cucca[3], G.R. Abecasis[2], D. Schlessinger[1].* 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 3) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Monserrato, Cagliari, Italy.

The degree to which mitochondrial DNA (mtDNA) varies heritably and somatically has been much discussed, but has not been systematically analyzed on a population basis. Further, accumulation of mutations in mitochondrial DNA has been suggested to play an important role in aging. To approach such an analysis of mtDNA variation, genotype calling and analytic programs developed for nuclear DNA must be modified, because each cell has 100-10,000 mtDNA copies that can vary at any site (i.e., heteroplasmy). We have developed an algorithm that is adapted to identify variants in mtDNA; it incorporates the sequencing error rate at each base in likelihood calculations and is flexible to allow for different allele fractions at a variant site across individuals. Our analysis procedure is also adapted to the circular mitochondrial genome, a key difference from the linear chromosomes assumed by most read mapping algorithms.

We assess homoplasmies and heteroplasmies in mtDNA sequences of lymphocytes from ~2,000 SardiNIA Project participants. The distribution of the number of homoplasmies per individual is bimodal, with an average value of 22. The number of heteroplasmies with a minor allele fraction threshold of 4% varies considerably among individuals, with most individuals displaying 3 or less heteroplasmies, but some showing considerably more. The overall heteroplasmy increases with age, but the slope is small, yielding an average increase of ~1 heteroplasmy between ages 20 and 80. As expected, mothers and their children share essentially all homoplasmies but a lesser proportion of heteroplasmies. Overall, it is clear that mitochondrial variants do accumulate in lymphocyte populations as a function of age, but the extent of accumulation remains hard to assess accurately because many variants are on par with sequencing error rate. Currently, attempts are being made to increase resolving power by using higher sequence coverage and by studying individuals from families.

The results to date provide information about mtDNA haplogroups and the inheritance of homo- and heteroplasmies in Sardinia. The algorithm can be further extended in several ways: for example, to study mtDNA from cloned normal cells in greater depth, and to investigate the nuclear DNA variability in cancer cells.

Understanding the limits of pooled next-generation sequencing to identify causal modifier variants in Cystic Fibrosis. *J. Gong[1], F. Lin[2], T. Chiang[1], K. Keenan[3], M. Miller[1], D. Soave[1,4], W. Li[1,4], L. Sun[4,5], J. Rommens[2,6], L. Strug[1,4].* 1) Program in Child Health Evaluative Sciences, the Hospital for Sick Children, Toronto, ON, Canada; 2) Program in Genetics and Genome Biology, the Hospital for Sick Children, Toronto, Ontario, Canada; 3) Program in Physiology and Experimental Medicine, the Hospital for Sick Children, Toronto, Ontario, Canada; 4) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 5) Department of Statistical Sciences, University of Toronto, Toronto, Ontario, Canada; 6) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Modifier genes contribute to variability in morbidity across multiple organs affected in cystic fibrosis (CF). SLC26A9, SLC9A3 and SLC6A14, were shown to contribute to CF intestinal obstruction (MI) in a hypothesis driven GWAS (Sun et al, (2012) Nat Genet 44:562-9). PCR-enriched overlapping segments of the three genes from 200 CF individuals, 100 with MI (cases), were sequenced using pooled next-generation methods (pNGS) by deCODE genetics. We sought to (1) identify variants for follow-up genotyping in a larger sample; and (2) determine whether pNGS can provide reliable association findings. We performed quality control on the FastQ reads followed by read alignment, variant call and filtration. For each variant, we estimated minor allele frequency (MAF) for cases and controls, using a pNGS-specific method (Wang et al, (2010) Genet Epidemiol, 34:492-501). We compared these estimates to those from genotype data on the same set of individuals. We then compared three association methods for pNGS data: simulation-based method (Wang et al, ibid), Fisher's exact test, and a permutation approach. Finally, we performed Sanger sequencing (SS) in one region of SLC6A14 selected by the association results to assess the reliability of our findings. For 54 common SNPs in both the pNGS and array-based genotype data, we found a high correlation between the estimated MAFs (ρ=0.95 for cases and 0.93 for controls). Comparison of the association methods showed no consistent rankings across the variants, although one region in intron 6 of SLC6A14 was highlighted by all three methods. Some of the sequencing variants in this region were in high LD with imputed SNPs, but in general this region was poorly imputed. pNGS identified all the variants detected by SS in this region. However, the local MAF estimates from both pNGS and imputation differed substantially from that provided by SS, resulting in discrepant association interpretation. Our experience suggested that pNGS is reliable for variant detection. Its estimation of MAF was reasonable on average, but a sub-gene region was observed where the MAF estimates (and thus association results) differed substantially from values obtained from SS. The discrepancies were functions of region-specific qualities of the sequence data and genetic architecture, neither of which can be known a priori. There was no general agreement among the tested pNGS association methods, limiting the usage of pNGS data for reliable association testing.

1890T

Accurate local ancestry inference in exome sequenced admixed individuals using off target sequence reads. *Y. Hu[1,2], C. Willer[3], X. Zhan[2], H. Kang[2], G. Abecasis[2].* 1) Integrative Biology, University of California, Berkeley, CA, 94720, US; 2) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, 48109, US; 3) Department of Human Genetics, University of Michigan, School of Medicine, Ann Arbor, MI, 48109, US.

Estimates of the ancestry of specific chromosomal regions in admixed individuals are useful for studies of human evolutionary history and in disease gene mapping. Previously, this ancestry inference relied on high quality genotypes from genome-wide association study (GWAS) arrays. These high quality genotypes are not always available when samples are exome-sequenced, the strategy of choice for many ongoing genetic studies. Here we show that off-target reads generated during exome sequencing experiments can be combined with on-target reads to accurately estimate the ancestry of each chromosomal segment in an admixed individual. To reconstruct local ancestry, our method SEQMIX models aligned bases directly instead of relying on hard genotype calls. We evaluate the accuracy of our method through simulations and analysis of samples sequenced by the 1,000 Genomes Project and the NHLBI Grand Opportunity Exome Sequencing Project. In African-Americans, we show local ancestry estimates derived using our method are very similar to those derived using Illumina's Omni 2.5M genotyping array, and much improved in relation to estimates that use only exome genotypes and ignore off-target sequencing reads. Software implementing this method, SEQMIX, can be applied to analysis of human population history or for disease gene mapping studies in admixed individuals.

1891F

Flexible and robust methods for rare-variant testing of quantitative traits in pedigrees. *Y. Jiang[1,2], K.N. Conneely[1,2], M.P. Epstein[1,2].* 1) Department of Biostatistics and Bioinformatics, Rollins School of Public Health, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

Rare-variant sequencing studies are increasingly popular strategies for investigating the missing heritability of complex human traits. Although a series of statistical methods have been developed to analyze rare variants, the majority of tests are restricted to case-control and population-based study designs. Few statistical methods have been developed to analyze rare variants in family-based studies. As more and more resequencing studies employ family-based designs to overcome potential bias caused by population stratification and to study cosegregation patterns of causal variants, the development of powerful methods for family-based analyses of rare variants is needed. With this in mind, we propose a rare-variant association test for quantitative traits in families that uses a kernel framework. Within a region of interest, the model partitions a family member's genotype at a rare variant into a within-family component (robust to population stratification but sensitive to genotype error) and an orthogonal between-family component (sensitive to population stratification but less sensitive to genotype error). For large-scale sequence data, our approach first constructs a kernel test using the between-family component as a screening tool to identify top hits. We then follow up these top hits using a kernel test based on the robust and independent within-family component. Unlike other methods, which assume that all variants in the tested region have the same direction of effect on the phenotype, our method remains powerful when causal variants in the test region may have differing direction of effect. Our method can also accommodate covariates and is flexible in that it can still perform well under partial missingness of parental genotypes. Finally, our method has the practical benefit of permitting efficient calculation of p-values based on asymptotics rather than requiring computationally-expensive permutations, which enables practical application to genome-wide data. Using simulated data, we have already shown that our method can avoid inflated false positive rates caused by population stratification. We will also use simulated data to explore power and further apply our method to the Sardinia sequencing dataset available through dbGaP for illustration purposes.

1892W

Study designs for next-generation sequencing: some empirical evidence. *P. Marjoram, D.G. Conti, M. Salomon, D.C. Thomas.* Dept Preventive Med, Univ Southern California, Los Angeles, CA.

GWAS aims to find SNPs associated with phenotypes of interest. Since detected SNPs are likely to be in linkage disequilibrium with the truly causal SNP, rather than being causal themselves, a common follow-up study will be to sequence an area around one or more regions containing such SNPs. Multiple non-trivial questions arise: What regions should we chose? How wide should those regions be? How deep should the coverage be? What study design should we use: two-phase case-control (Schaid et al., Genet Epidemiol 2013;37: 229-38.), family-based (Xu & Zhi, AJHG 2012;90:1028-45), etc.? How do we best analyze the resulting data? We will describe our efforts as part of NIH's "GWASeq" consortium, which aims to provide the empirical data that will allow the community to answer these questions. Our component of the consortium focuses on data from the Colorectal Cancer Family Registry (C-CFR) (Newcomb et al., CEBP 2007;16: 2331-43). We have sequenced around 4000 samples from the C-CFR, across 10 regions, at more than 50X coverage. Our data is a mixture of population-based and pedigree-based samples. We will describe the study, the data that results from it, and the conclusions that can be drawn regarding design of such studies in future and the implications regarding so-called "missing heritability.".

1893T

Are base qualities necessary in the context of high coverage sequencing? *M.W. Snyder, J. Shendure.* Genome Sciences, University of Washington, Seattle, WA.

Base quality scores from next-generation sequencing instruments are used in a variety of data processing steps. Some aligners use quality scores to guide read placement on a reference. During variant discovery and variant calling, probabilistic and likelihood-based models may make use of quality scores in genotype inference. Downstream, post-processing steps often include filtering variants on the basis of base quality score metrics. However, the storage and use of these quality scores has associated costs. First, intermediate file sizes are significantly increased: for reads in the FASTQ format, the stored base qualities nearly double the overall size of each file. These same qualities may then be propagated forward to SAM or BAM format, where file size is again inflated by the presence of base quality information. Additionally, the use of base qualities during likelihood calculations, read placement, or variant filtering imposes a computational penalty on data processing pipelines. Conventional wisdom suggests that these costs are justified by the concomitant increase in genotype accuracy to which they give rise. Here, we challenge the validity of this assumption in the context of very high coverage datasets generated on modern sequencing instruments. We attempt to use the counting statistics naturally arising from high coverage sequencing as surrogates for base qualities, and investigate the impact on genotype accuracy of processing sequencing data that has been stripped of base quality scores. To wit, we perform alignment, variant discovery, and genotyping without base quality scores, using a combination of conventional and custom software tools, and compare our results to variant calls from existing data analysis pipelines and gold standard genotypes. We apply our approach to a family trio (NA12877, NA12878, and NA12882) sequenced to 200X coverage on an Illumina HiSeq 2000 system and for whom gold standard genotypes are available from orthogonal methods. In preliminary investigations, we achieve approximately 99% non-reference genotype concordance with array-based genotypes. We downsample the original reads and evaluate genotype accuracy as a function of mean coverage. We additionally describe the cost savings in terms of reduced computational time and smaller storage footprint achieved through the application of this approach.

1894F

A UNIFIED SEQUENCE KERNEL ASSOCIATION TEST ALLOWING FOR ADMIXED SUBJECTS WITH ARBITRAY RELATEDNESS. *W. Ouyang[1,2], H. Deng[1,2], H. Qin[1,2].* 1) Department of Biostatistics and Bioinformatics Tulane University School of Public Health and Tropical Medicine.1440 Canal Street, New Orleans, LA 70112; 2) Center for Bioinformatics and Genomics, Tulane University School of Public Health and Tropical Medicine, 1440 Canal Street,New Orleans, LA 70112.

Rare genetic variants may potentially contribute to more missing heritability complex human diseases. Over the recent years, next generation sequencing studies (NGSs) have been conducted to provide more comprehensive and accurate description of rare and common variants, and a number of statistical methods have been developed for identifying sequence associations. Current prominent sequence association methods assume homogeneity and/or un-relatedness of study subjects. Such assumptions could be severely violated in the samples from admixed populations, e.g., African Americans and Hispanic Americans. Population stratification and cryptic relatedness are two important confounders in genetic association studies in admixed populations. In this paper, we have developed a unified sequence association test (AdmSKAT) to allow for the NGS data of admixed subjects with arbitrary pedigree structure and diverse directions of effect of genetic variants on phenotype. Our AdmSKAT approach extends the conventional population based sequence kernel association test (SKAT) and family-based SKAT by jointly modeling population stratification, relatedness and local ancestry-by-genotype interaction to ensure type I error control and to improve statistical power. We simulated extensive sequence data of admixed families for method comparisons. Under the null of no sequence association, our AdmSKAT and FamSKAT controlled type I error rates, whereas naïve application of the conventional SKAT and FLM lead to inflated type I error rates. Our AdmSKAT were more powerful than the FamSKAT when applied to all the simulated scenarios of admixed families. AdmSKAT has higher power than competing method in many different scenarios.We then apply our AdmSKAT to analyze the real and simulated sequence data on hypertension of Mexicans from GAW18.

Phasing and imputation of 12,000 1x coverage whole genome sequenced Chinese women. *W. Kretzschmar[1], J. Flint[1], J. Marchini[2], CONVERGE Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom.

The CONVERGE study of Major Depression has collected low-coverage (1x) sequencing data on 12,000 Chinese women. This study is one of the largest whole-genome sequencing studies currently underway. To accurately infer genotypes in these samples, LD-based genotype refinement methods are needed. However, the study size makes this a challenging proposition. We have investigated several computationally tractable strategies for calling genotypes. Current MCMC schemes for phasing and genotype calling do not explicitly encapsulate the local IBD structure between individuals. We have investigated new adaptive MCMC schemes to sample haplotypes and genotypes that underlie each sample that try to learn details about local haplotype sharing as the MCMC sampler evolves. We have also investigated whether current methods can be made to produce acceptable results within practical time frames.

We have applied these methods to genotype likelihoods at ~14 million 1000 Genomes Project Phase 1 (TGPP1) SNPs polymorphic in TGPP1 Asians. We were able to infer genotypes in the whole CONVERGE cohort at a computational cost equivalent to ~2,000 CPU days on a single core of a current Intel processor. We have measured the accuracy of our imputed genotypes using external validation genotypes on 16 individuals typed on the genome-wide Illumina Zhonghua-8 SNP chip with 890,371 SNPs. We find that the mean imputation r^2 at MAFs <0.5%, 0.5-1%, 1-2%, 2-5%, and >5% are 0.21, 0.57, 0.70, 0.82, and 0.92. Overall, these results illustrate the feasibility and accuracy of using very low-coverage sequencing in large studies.

1896T

Construction of an accurate haplotype reference panel that incorporates multi-allelic variants from sequencing data. *A. Menelaou[1], S.L. Pulit[1], L.C. Francioli[1], J. Marchini[2], P.I.W. de Bakker[1], Genome of the Netherlands consortium.* 1) Department of Biomedical Genetics, University Medical Centre Utrecht, Utrecht, Netherlands; 2) Department of Statistics, University of Oxford, United Kingdom.

Next-generation sequencing allows in-depth characterization of human polymorphism. Although imputation from sequencing panels can increase the effective coverage of GWAS, the imputation quality (and therefore power to discover novel loci) is dependent on accurately phased haplotypes, especially for lower-frequency variation. Furthermore, as the focus shifts increasingly beyond common biallelic SNPs, it is also necessary to incorporate multi-allelic variants into such panels.

To investigate the added value of sequencing trios for the construction of an imputation panel, we analyzed the Genome of the Netherlands (GoNL) Project data, which includes 250 parent-offspring trios sequenced at 14x using Illumina HiSeq. We constructed the haplotypes using MVNcall, a genotype calling and phasing method that accounts jointly for LD structure, sequencing information, and family relationships. We evaluated the imputation quality in 81 independent samples with Dutch ancestry sequenced with Complete Genomics (CG), where we obtained an aggregate imputation accuracy (r^2) of 0.63 for SNPs with frequency <0.5%. For those SNPs, we observed a 16% increase in accuracy when we phased the trios (0.63) jointly versus phasing only the (unrelated) parents (0.47), highlighting the impact of trio-based phasing. In the same Dutch samples, imputation accuracy for lower frequency variants <10% was increased for GoNL as compared to 1000 Genomes Phase 1 (1KG) panel.In independent CEU and TSI samples from 1KG with CG data, imputation quality with GoNL was better than that with 1KG-CEU and equivalent to that with 1KG-TSI, at the same sample size. A combined GoNL+1KG panel achieves the highest imputation accuracy (0.70 for SNPs with frequency <0.5%), motivating the creation of a worldwide sequencing-based panel.In parallel, we have extended MVNcall to handle imputation of multi-allelic variants including SNPs, indels, structural variants and microsatellites. Because MVNcall determines phase for each site independently onto an accurate pre-phased haplotype scaffold, there are several advantages to other existing methods. First, the imputation of nearby sites is not affected by the presence of complex variants (that are inherently more difficult to impute). Second, there is a considerable computational efficiency gain by considering all variants independently. We have applied MVNcall in STRs detected by 1KG Phase 3, and multi-allelic SNPs and indels discovered in GoNL.

Modeling gene expression and rare sequence variation to identify genes and subnetworks underlying autism risk. *L. Liu[1], J. Lei[1], S. Sanders[2], J. Willsey[2], Y. Kou[3,4], L. Klei[5], C. Lu[1], X. He[6], A. Ma'ayan[4], J. Noonan[2], N. Sestan[7], J. Buxbaum[3,4,8,9], M. State[2,10,11,12], B. Devlin[5], K. Roeder[1,6].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA; 2) Department of Genetics, Yale University School of Medicine, New Haven, Connecticut, USA; 3) Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 4) Department of Psychiatry, Icahn School of Medicine at Mount Sinai , New York, New York, USA; 5) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA; 6) Ray and Stephanie Lane Center for Computational Biology, Carnegie Mellon University,Pittsburgh, Pennsylvania, USA; 7) Department of Neurobiology and Kavli Institute for Neuroscience, Yale University School of Medicine, New Haven, Connecticut 06510, USA; 8) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 9) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 10) Program on Neurogenetics, Yale University School of Medicine, New Haven, Connecticut, USA; 11) Child Study Center, Yale University School of Medicine, New Haven, USA; 12) Department of Psychiatry, Yale University School of Medicine, New Haven, USA.

Rare variants, especially de novo loss of function (LoF) mutations, have proven effective at identifying genes affecting risk for autism spectrum disorders (ASD). When a de novo LoF mutation falls in a gene, and more than one ASD proband carries such a mutation, the gene is likely to be a risk gene. Based on the rate of de novo mutations in ASD probands versus their siblings, we infer that roughly half of the genes with LoF mutations observed only once per gene in the combined sample affect risk. To extract more information from Whole Exome Sequence (WES) data, He et al. develop a statistical model that integrates data from family and case-control studies to infer the likelihood a gene affects risk for ASD; this model, called TADA for Transmission And De novo Association, summarizes genetic evidence a gene affects risk for ASD. Still, given the limited WES data, can we garner more information regarding ASD risk? Relative to genes with strong genetic support for involvement in ASD, we hypothesize that genes expressed at the same developmental period and region of the brain, and with highly correlated expression, would themselves be more likely to affect risk for ASD because they are functionally interrelated. To find these sub-networks of co-expressed genes we jointly model two kinds of data: gene co-expression in specific brain regions and periods of development; and the TADA analysis of rare variants from recent sequencing studies; both from published studies. We model the ensemble data as a Hidden Markov Random Field (HMRF), with the graph structure determined by gene co-expression. An HMRF model is a natural framework for the interrelationships amongst nodes of a network and to combine such interrelationships with node-specific observations: gene identity, its expression, its associated genetic data, and whether it affects risk for ASD (yes/no), which will be estimated. The HMRF models the dependency in the network, which is inherent in the correlation of a gene's state, ASD risk gene or not, with its near neighbors states. The statistical analysis identifies over a hundred genes that plausibly affect risk, a large fraction of which are not known to affect risk for ASD. For those that are not novel, many were implicated on the basis of the statistical model, not the strength of the genetic evidence alone. A third of the genes with a single LoF de novo mutation were implicated. These results expand our understanding of the neurobiology of ASD.

Gene-based Generalized Functional Linear Models for Case-Control Association Studies. *R. Fan[1], Y. Wang[1], L. Lobach[2].* 1) Biostatistics and Bioinformatics Branch, Division of Epidemiology, Statistics and Prevention Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Rockville, MD 20852; 2) he Memory and Aging Center, Uunversity of California, San Francisco, CA 94158.

Functional generalized linear models are developed for testing associations between dichotomous traits and multiple genetic variants in a genetic region. Although the observed genetic marker data are discrete, we view them as realizations of continuous genetic variant functions. We believe that the genetic variant functions have intrinsic functional structure. By using modern state-of-art functional data analysis technique, the observed high dimension genetic variant data are used to estimate the genetic variant functions based on B-spline or Fourier basis functions or functional principal component decompositions. Then, the estimated genetic variant functions are used in the logistic models to connect to phenotype adjusted for covariates. Both fixed and mixed effect functional generalized linear models are built to test the association between dichotomous traits and genetic variants adjusting for covariates. After extensive simulation analysis, it is shown that the Rao's efficient score tests or global score tests of the proposed fixed effect models have similar power as optimal sequence kernel association test (SKAT-O) for two scenarios: (1) the causal variants are all rare; (2) the causal variants are both rare and common. The proposed test statistics generate accurate type I errors in simulation studies. The methods can be used in both gene-based genome-wide/exome-wide association studies or candidate gene analysis.

1899T

Functional Linear Models for Association Analysis of Quantitative Traits. *Y. Wang[1], R. Fan[1], J.L. Mills[2], A.F. Wilson[3], J.E. Bailey-Wilson[3], M.M. Xiong[4].* 1) Biostatistics and Bioinformatics Branch, Division of Epidemiology, Statistics and Prevention Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Rockville, MD; 2) Epidemiology Branch, Division of Epidemiology, Statistics and Prevention Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Rockville, MD; 3) Inherited Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Human Genetics Center, University of Texas - Houston \ P.O. Box 20334, Houston, TX.

Functional linear models are developed in this paper for testing associations between quantitative traits and genetic variants, which can be rare variants or common variants or the combination of the two. By treating multiple genetic variants of an individual in a human population as a realization of a stochastic process, the genome of an individual in a chromosome region is a continuum of sequence data rather than discrete observations. The genome of an individual is viewed as a stochastic function which contains both linkage and linkage disequilibrium (LD) information of the genetic markers. By using techniques of functional data analysis, both fixed and mixed effect functional linear models are built to test the association between quantitative traits and genetic variants adjusting for covariates. After extensive simulation analysis, it is shown that the F-distributed tests of the proposed fixed effect models have higher power than that of sequence kernel association test (SKAT) for three scenarios: (1) the causal variants are all rare; (2) the causal variants are both rare and common; and (3) the causal variants are common. The superior performance of the fixed effect functional linear models is most likely due to its optimal utilization both genetic linkage and LD information of multiple genetic variants in a genome and similarity among different individuals, while SKAT only models the similarities and pairwise LD but does not model linkage and higher order LD information sufficiently. In addition, the proposed fixed effect models generate accurate type I errors in simulation studies. We also show that the functional kernel score tests of mixed effect models are preferable in candidate gene analysis and small sample problems. The methods are applied to analyze three biochemical traits in data from the Trinity Students Study.

1900F

Pooled Whole Exome Sequencing as a Strategy for Establishing Population Mutation Profiles. *E. Rinella[1], K. Upadhyay[2], C. Oddoux[3], H. Ostrer[2].* 1) New York University Medical Center, New York, NY; 2) Albert Einstein College of Medicine, Bronx, NY; 3) Montefiore Medical Center, Bronx, NY.

While the cost of next-generation sequencing continues to decline, it can still be prohibitive to conduct large cohort studies. One strategy that we propose is to pool individual samples prior to library preparation thereby significantly reducing per sample sequencing costs. We created a pool from 200 Ashkenazi Jewish (AJ) women and submitted two identical aliquots of the pool for whole exome sequencing. Preliminary analysis of the two 200-Pool aliquots shows an average read depth (RD) of 122x and 116x for 200-PoolA and 200-PoolB, respectively, yielding a total of 59,010 on-target variants. The allele counts were combined for the 2 aliquots and frequencies were compared to array data for 1574 SNPs previously genotyped for the individuals in this pool, revealing an accuracy of r2=0.90 at an on-target RD <100x and r2=0.98 at RD ≥100x. The 59,010 variants were also filtered against the Online Mendelian Inheritance in Man (OMIM) database yielding 278 (0.47%) mutations, of which 61 of the OMIM variants were classified as pathogenic mutations. Among the mutations previously described in this population were those for hereditary hemochromatosis (HFE p.H63D), Factor V Leiden (F5 p.R534Q), and Canavan disease (ASPA p.Y231X). Among the newly identified conditions for which mutations were identified were autosomal recessive hypoparathyroidism (PTH p.R83X), Fletcher factor deficiency (KLKB1 p.S143N), autosomal dominant deafness (MYO1A p.G662E), Warfarin sensitivity (CYP2C9 p.I359L), trimethylaminuria (FMO3 p.V257M), hyperglycinuria (SLC6A20 p.T199M), atransferrinemia (TF p.P589S), and autosomal recessive renal tubular acidosis (ATP6V0A4 p.M580T). Pooled exome sequencing provides a cost effective method for establishing population mutation profiles, such as the profile developed here for the Ashkenazi Jewish population, and if linear will be an important reference for specific disease association studies.

1901W

A hidden Markov random field approach to modeling genetic association based on graphs derived from gene expression. *J. Lei[1], L. Liu[1], B. Devlin[2], K. Roeder[1].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA;; 2) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA;.

Gene-based association testing problems involve tens of thousands of hypothesis tests and it is well known that traditional family-wise error rate control will be too conservative for large multiple testing problems. Standard false discovery rate (FDR) control procedure improves power, but because this approach focuses solely on the p-values of individual hypotheses, this approach too can have suboptimal power by ignoring correlations between individual hypotheses. When substantial prior knowledge is available, however, power can be increased if the prior information and the data can be modeled appropriately. We propose a hierarchical hidden Markov random field (HMRF) model for gene-based association using a graph built from gene expression data. The prior information from the network can be applied to improve the power and reduce false discovery under the realistic assumption that a test for a given gene should depend on data from neighboring genes in the network. The parameters of the HMRF model determine the spatial clustering of the gene-based association statistics. By applying iterative conditional modes (ICM), the HMRF model parameters can be estimated efficiently. The multiple testing is then carried out under an empirical Bayes framework by controlling the local false discovery rate (lFDR). To further increase flexibility and computation efficiency, we propose a hierarchical approach that focuses on subnetworks of co-expressed genes, which vary in structure from loosely netted gene modules to very tightly clustered genes sets. Data from simulations and from an autism study of rare variants demonstrate that our proposed approach is much more powerful than the single feature analysis. Our procedure is computationally feasible with provable performance and optimality guarantees under realistic assumptions. The proposed method can be applied to a wide variety of multiple hypothesis and feature selection problems.

1902T

A New Statistical Method for Identifying Differentially Methylated Regions in Complex Diseases. *P. Liu[1,2], C. Chen[1,2], X. Hua[1,2], Y. Lu[1,2], M. Liang[1].* 1) Department of Physiology, Medical College of Winconsin, Milwaukee, WI; 2) Cancer Center, Medical College of Winconsin, Milwaukee, WI.

DNA methylation is an important epigenetic modification that regulates transcriptional expression in complex diseases, such as cancer. It occurs when a methyl group becomes covalently attached to the 5-carbon position of a cytosine residue at a ‘CpG’ site. Of particular interest are CpG sites located in CpG islands which are clusters of CpG sites showing dynamic variations of methylation levels and often colocalized with *cis* regulatory elements such as gene promoters. Increased DNA methylation in CpG islands within or close to gene promoters is typically associated with transcriptional repression or gene silencing. Genomic segments with enriched 5-Methylcytosine marks can be mapped to single-base resolution using next-generation sequencing. Such high-throughput base-resolution methylation data have unique features and hence require the development of new analytic approaches. These important features include dependence of methylation among CpG sites within a CpG island and the influence of depth of sequence coverage on measuring methylation rate at CpG sites. Here, we proposed a new statistical method for identifying differentially methylated CpG regions from base-resolution methylation sequencing Data. Our approach accounts for correlation structures among CpG sites and incorporates depth of sequence coverage as weights for measuring methylation rate in CpG sites. We evaluated the performance of our new approach and compare it to other tests including the most commonly-used t-test and Fisher’s exact through a wide range of simulations. The simulation results show that regular tests for analyzing methylation sequencing data dramatically inflate type I error rates in the presence of physical proximity of CpG sites. While our new method is a valid test and gains statistical powers when weighting methylation rate by depth of sequence coverage. To demonstrate its utility, we applied it to the analysis of methylation sequencing data from non-small cell lung cancers and revealed novel methylation patterns in lung cancer.

1903F

A nonparametric model for haplotypes in population bottlenecks. *L.T. Elliott[1], Y.W. Teh[2].* 1) Gatsby Computational Neuroscience Unit, University College London, London, UK; 2) Department of Statistics, University of Oxford, Oxford, UK.

Clustering methods based on hidden Markov models are useful for approximating the haplotype structure of genetic sequence data that have undergone a recent population bottleneck or admixture. In these models (such as fastPHASE, IMPUTE2 and BEAGLE), latent cluster indicators can specify the genetic founder or component from an admixed population from which a loci on a given sequence originates. In this work we present BNPPHASE (Bayesian nonparametric Phase), a nonparametric model of haplotype structure based on a hierarchical Dirichlet process hidden Markov model (HDP-HMM). Bayesian nonparametric models handle latent variable domains with unbounded dimensionality and in BNPPHASE the number of genetic founders is unknown but inferred concurrently with the rest of the model without a separate model selection phase. BNPPHASE describes genetic sequences in which the proportions describing the distribution of each one of an unknown number of genetic founders varies along the chromosome reflecting ancestral recombination events. BNPPHASE advances previous work in nonparametric genetic models by providing nonhomogeneous cluster proportions and by identifying haplotypes across loci through the use of the recently proposed 'sticky' HDP-HMM leading to more efficient inference and to posteriors that more closely resemble the genetic process. The popular fastPHASE model can be seen as a finite truncation of BNPPHASE. The BNPPHASE model can be described by a generative process in which the cluster indicators for each sequence either remain the same from one loci to the next or, with a probability given by a recombination rate, are updated according to local Dirichlet processes that are linked together using a standard hierarchical Dirichlet process model. In a series of experiments involving phased data simulated from a population bottleneck with K ancestral genetic founders, we hold out data and compare the imputation accuracy of BNPPHASE with that of its finite truncations. We show that the flexibility of BNPPHASE, which stems from its nonparametric nature, allows BNPPHASE to achieve higher imputation accuracy even after the capacity of a given finite model is exhausted. Furthermore, we show that BNPPHASE can be used to estimate the number of genetic founders in a sample and that it can discover situations in which the total number of ancestral genetic founders changes along the chromosome due to selection or genetic drift.

1904W

Using network methodology to infer population substructure. *D. Prokopenko[1], C. Lange[1,2,3,4], J. Hecker[1], P. Costa[1], E.K. Silverman[3], H. Loehlein Fier[1].* 1) Institute of Genomic Mathematics, University of Bonn, Bonn, Germany; 2) Department of Biostatistics, Harvard School of Public Health, Boston, United States; 3) Channing Laboratory, Brigham and Women's Hospital, Boston, United States; 4) German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany.

One of the main caveats of association studies is the possible affection by bias due to population stratification. Existing methods rely on model-based approaches like structure (Pritchard et al. 2000) and ADMIXTURE(Alexander et al. 2009) or on principal component analysis like EIGENSTRAT(-Price et al. 2006, Patterson et al. 2006).

Here we describe the problem of population substructure from the graph-theoretical point of view. We group the sequenced individuals into triads, which depict the relational structure, utilizing a similarity measure, i.e. covariance matrix. We then merge the triads into a network. We apply community detection algorithms in order to identify homogeneous subgroups or communities, which can further be incorporated as covariates into a logistic regression. We apply our method to populations from different continents in the 1000 Genomes Project and evaluate the type 1 error based on the empirical p-values. Our simulation results suggest that the network approach provides a more precise information of population structure than existing methods.

1905T

eqtl-tools: a toolset for scalable eQTL mapping. *A. Di Narzo[1,2], K. Hao[1,2].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Institute of Genomic and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY.

Motivation: Expression Quantitative Trait Loci (eQTL) mapping on modern datasets requires the evaluation of a massive number of correlations. Current tools are either too slow or have hard limits on the input/output data formats and memory requirements. They also lack the flexibility to accommodate sex chromosomes or nonparametric models. Implementation: eqtl-tools is a set of command line utilities for fast and comprehensive eQTL mapping which uses plain text, tab-delimited tables as the main data format, allows for easy control of memory usage, and handles missing data consistently. Conclusions: eqtl-tools significantly lowers the amount of RAM necessary to perform eQTL analysis, while incurring in moderate speed penalty w.r.t. the best alternative solution to date. It handles chromosome X and facilitates integration into custom data analysis pipelines. It also allows more sophisticated modeling, e.g. nonparametric methods, and calibrates empirical false discovery rate (FDR) through permutation. Availability: The package is easy to deploy, self-documenting, and released under the GPL-v3 license on eqtl-tools.googlecode.com. Contact: antonio.dinarzo@mssm.edu.

1906F

Trans-ethnic fine mapping of cis eQTLs across eight ancestry groups.
C. Grace[1], J.C. Whittaker[2], J. Huxley-Jones[2], A.P. Morris[1]. 1) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, Oxfordshire, United Kingdom; 2) GlaxoSmithKline, Medicines Research Centre, Gunnels Wood Road, Stevenage, UK.

Trans-ethnic meta-analysis can increase power to detect expression quantitative trait loci (eQTLs) and improve fine-mapping. We considered lymphoblastoid cell line expression in Phase 3 HapMap populations from multiple ancestry groups: CEPH (CEU, European), Chinese (CHB, East Asian), Gujarati Indians (GIH, South Asian), Japanese (JPT, East Asian), Luhya (LWK, African), Mexican (MEX, Hispanic), Maasai (MKK, African) and Yoruba (YRI, African). Genotypes were available for all samples and were used as a scaffold for imputation with the Phase 1 1000 Genomes panel (June 2011). We tested for association with expression of 1639 probes within each study for cis eQTLs (1Mb upstream and downstream of gene), and then combined studies via trans-ethnic meta-analysis implemented in MANTRA, a Bayesian approach which allows for heterogeneity in allelic effects between groups. We first combined studies within the same ancestral group: African (LWK, MKK, YRI), East Asian (CHB, JPT) and European, South Asian and Hispanic (CEU, GIH, MEX). Subsequently, we combined the 'ancestry-specific' association statistics across ethnicities. With this data, we aimed to evaluate the improvement in discovery and fine-mapping of eQTLs through trans-ethnic meta-analysis and 1000 Genomes imputation. After imputation, the lead SNP at 1,629 probes achieved genome-wide significance (log10 BF > 6), compared with 1,591 for HapMap genotypes alone. An improvement in the strength of the association at the lead SNPs was observed after imputation for 1,239 probes. Probe ILMN_10409_6860670 (chr10:105156223; HGNC: USMG5; up-regulated during skeletal muscle growth 5) has the greatest increase in association signal after imputation. The lead typed SNP is rs7831 (log10 BF = 132), whilst the lead imputed SNP is 10-105161778 (log10 BF = 250). To determine which ancestry groups are most informative for fine-mapping, we defined 99% credible sets of imputed and HapMap SNPs that are most likely to contain the causal variant. As expected, the African group has the lowest median credible set size (44 SNPs, 154 Kb), followed by the European, South Asian and Hispanic group (82 SNPs, 227 Kb) and East Asian group (105 SNPS, 318 Kb). Combining all ancestral groups leads to further improvements in resolution (median 99% credible set size of 8 SNPs over 19 Kb). This study has demonstrated that trans-ethnic meta-analysis and imputation provides a powerful means for discovery and fine-mapping of eQTLs.

1907W

Statistical methods for the analysis of gene expression in single-family studies for genetic and complex disease.
S. Merella[1], P. Brambilla[3], F. Martinelli Bonesch[3], E. Stupka[1], P. Provero[1,2]. 1) Center for Translational Genomics and Bioinformatics, San Raffaele Scientific Institute,Milan,Italy; 2) Dept of Molecular Biotechnology and Health Sciences, University of Turin, Turin, Italy; 3) The Laboratory of Genetic of Neurological Complex Disorders, INSPE & Division of neuroscience, San Raffaele Scientific Institute,Milan,Italy.

Multiplex families are a powerful tool to investigate heritability in complex diseases to investigate genetic components of the disease. Heritability can be investigated not only through genetic approaches (SNP genotyping or re-sequencing) but also using gene expression analysis. There are specific challenges in working with gene expression data. Each family can present different genetic makeup producing heterogenous gene expression across families. Previous approaches developed for multiplex families were focused on identifying significant genes across multiple families. Moreover in each family there will be a strong genetic component of gene expression from which the disease effect needs to be distinguished and identified. We developed a statistical method for the analysis of gene expression data on single-family studies to minimize the problem in interpreting these data, and in particular to disentangle of genetic effects from other factors affecting gene expression, such as pathological status and environmental exposure. We combined the information obtained from the Ornstein-Uhlenbeck (OU) and Phylogenetically Independent Contrasts (PIC) models, that have been previously applied to describe evolutionary process. In this work the two models have been transferred to a context in which the quantitative trait has different values in diseased and healthy individuals. The models are defined on trees derived from family pedigrees to explicitly model the inheritance of gene expression and thus to identify those genes that are affected by the disease status. In order to validate the method and verify the sensitivity and specificity of the test, simulated datasets were generated starting from a family pedigree in order to take into accounts the genetic component and the disease status of every gene for every individual. We also used a real dataset from a family pedigree of a multiplex family with 4 multiple sclerosis affected individuals. The results obtained on simulated datasets reports that the two models provide increased sensitivity with respect to traditional gene expression analysis approaches (t-test within LIMMA). The analysis of the MS affected family also identified genes and pathways associated with the disease.

1908T

Probabilistic Phase Concordance For Enhanced Detection Of Somatic Allelic Imbalance.
C.M. Hahn[1,3], S. Vattathil[2,3], P. Scheet[1,2,3]. 1) Biomathematics and Biostatistics Program, The University of Texas Graduate School of Biomedical Sciences, Houston, TX 77030, USA; 2) Human & Molecular Genetics Program, The University of Texas Graduate School of Biomedical Sciences, Houston, TX 77030, USA; 3) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX 77030, USA.

DNA microarrays have been successful for interrogating somatically acquired chromosomal aberrations, such as deletions, duplications, and copy-neutral LOH, often using paired tumor and normal samples. However, studies of tumor genomes in settings of high levels of normal DNA contamination, or for complex mixtures of multiple clones, require computational methods sensitive enough to detect subtle allelic imbalance (AI). For this purpose, Vattathil & Scheet (2013, Gen Res 23:152) introduced hapLOH, a method that incorporated haplotype information by calculation of a phase concordance between the B allele frequencies (BAFs) and the estimated haplotypes. This method improved power by taking into account the dependence in the direction of the BAF shifts. However, it ignored two pieces of information that should aid identification of AI, namely the magnitude of the BAF shifts (dispersion about an expected value) and knowledge about haplotype accuracy (i.e., marker pairs with poorly estimated haplotypes should be downweighted). We now introduce an extension to hapLOH that accommodates these features by combining the original output with BAF values and possible haplotype reconstructions to define a probabilistic phase concordance and further refine AI detection. We accommodate the magnitudes and direction of BAF shifts by taking the density of a pair of observed BAFs as a mixture of 4 bivariate normal distributions. The probabilistic concordance can then be used to test specific regions of interest and designate emission probabilities in a hidden Markov model. We identify regions of increased dispersion in the BAFs of SNP data from various simulated and real mixtures of tumor and normal DNA, as regions of allelic imbalance and their characteristics are indicative of tumor aberration types found within such mixtures. We anticipate this extension will harness the power obtained from considering the complete distribution of BAFs while retaining the speed of hapLOH. Further applications could aid time-course monitoring of subtle changes in tumor profiles or response to therapy.

1909F

Conducting Large-Scale Imputation Studies on the Cloud.
S. Buyske[1,4], K. Vahi[2], E. Deelman[2], U. Peters[3], T.C. Matise[4]. 1) Statistics & Biostatistics, Rutgers Univ, Piscataway, NJ; 2) Information Sciences Institute, University of Southern California, Marina del Rey, CA; 3) Public Health Sciences, Fred Hutchinson Cancer Research Center (FHCRC), Seattle, WA; 4) Department of Genetics, Rutgers University, Piscataway, NJ.

The PAGE (Population Architecture using Genomics and Epidemiology) study has genotyped 70K individuals on the gene-centric 196K SNP Metabochip. Imputation on a PAGE sub-study, using Mach-Admix with the 1000 Genomes Project full panel, has 700+ computational tasks and requires 35 days/1K subjects on a moderately fast workstation. Since managing these computations by hand is impractical and much of the computation is parallelizable, we constructed a computational workflow.

The fastest imputation tasks complete in seconds while the slowest take 12+ hours and require 7+ GB of RAM. The computational needs of such a workflow can strain typical resources, yet campus clusters often lack high-memory machines. Commercial computational clouds, however, offer a range of compute instances optimized for different use cases. We structured the imputation steps as a computational workflow and provisioned resources from the Amazon Web Services to support the application execution. Pegasus Workflow Management System (Pegasus WMS) is used to manage the workflow on Amazon EC2. Pegasus WMS represents the workflow of an application in an abstract form, agnostic of the resources available and the location of data and executables. It compiles workflows into executable form by querying catalogs. The executable workflow can be executed on remote and distributed resources such as remote clusters and clouds. When errors occur, Pegasus tries to recover by retrying tasks, by retrying the entire workflow, by providing workflow-level checkpointing, by re-mapping portions of the workflow, by trying alternative data sources for staging data, and, when all else fails, by providing a rescue workflow detailing only the work that still remains. We defined an imputation workflow in Pegasus and have applied it to two different sub-studies of PAGE. We will use this approach on 18 additional sub-studies. For the current runs, we provisioned 20 m2.xlarge EC2 instances with 2 cores each and 17 GB of memory. We configured a Condor pool on these resources and used Pegasus to map the workflow onto these instances and run the workflows. Imputation from the Metabochip on our first 2 substudies showed 32 to 36 hours/1K subjects of EC2 run time with a serial time equivalent of 34+ days/1K subjects. There were 5 failures caused by transient S3 access issues from within the EC2 cloud. Pegasus automatically recovered by retrying the failed jobs.

1910W

SKAT Admix: extending the SKAT method for rare variant association to admixed populations. *A.E. Byrnes[1], M.C. Wu[1], M. Li[2], Y. Li[1,3,4].* 1) Biostatistics, University North Carolina, Chapel HIll, NC; 2) Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia Pennsylvania; 3) Genetics, University of North Carolina, Chapel Hill, NC; 4) Computer Science, University of North Carolina, Chapel Hill, NC.

The Sequence Kernel Association Test (SKAT), first proposed in 2011, was designed to measure association between a set of genetic variants (including rare variants) and complex genetic traits quickly and efficiently. Here, we expand the SKAT methodology for use in admixed populations by first predicting the ancestry for each individual, at each locus, by utilizing additional sequencing data from each of the parent populations. We then apply the SKAT methodology to minor alleles likely to be inherited from each parent population separately, resulting in a SKAT statistic for each parental population. For example, in the case of African Americans, we conduct one SKAT test for those markers of European ancestry and one for those of African ancestry. To evaluate this method, we present a series simulations intended to mimic large sequencing studies of a quantitative trait in African Americans. In our simulations, the chosen variants are only causal if they originate from one of the parental populations, either African or European. We also examine different numbers of causal variants and directions of association. We find that SKAT Admix has increased power to find association compared to SKAT alone in most cases. In addition, the SKAT method has been proven to preserve type I error without requiring permutation. In our simulations, SKAT Admix also preserves Type I error for variants of both African and European ancestry. Data from the 1000 Genomes Project suggest that many more rare variants are population specific, as compared to common variants. It has also been suggested that rare variants show stronger patterns of stratification than common variants. For these reasons, we suggest a test that attempts to separate genomic data based on the predicted population of origin for admixed data.

1911T

The visualization of probabilistic results from consumer genetic testing for ethnicity at AncestryDNA. *R.E. Curtis, K.H. Freestone, M.J. Barber, J.M. Callaway, K. Noto, Y. Wang, C.A. Ball, K.G. Chahine.* AncestryDNA, Provo, US.

An important, but often overlooked, challenge in consumer genetics is the design of engaging and informative data visualization strategies that help consumers understand and fully appreciate the results of their genetic tests. Successful data visualizations that allow accurate and meaningful interpretation of consumer genetic test results must (1) help consumers overcome erroneous preconceptions or assumptions, (2) bridge gaps in the genetics education of consumers and (3) communicate the uncertainty associated with probabilistic predictions to consumers who may not have a strong understanding of statistics. Conveying uncertainty associated with predictions is crucial because many aspects of genetic science rely on probabilistic theory, including identity by descent (i.e., cousin matching), admixture predictions (i.e., ethnicity), and relative disease risk. If the stochastic nature of genetic algorithms is not properly conveyed in the visualization, naïve users often will either whole-heartedly accept the results as ground truth or dismiss them altogether. At AncestryDNA, we have considered this problem in the context of admixture prediction based on autosomal SNP testing. Over the past year, we have delivered over 125,000 admixture predictions to consumers across the US and conducted multiple surveys to assess our customer's satisfaction with and comprehension of those predictions. User surveys revealed several areas for improvement: some consumers had incorrect assumptions about the test; many consumers were confused about genetic concepts and most consumers were unable to understand the probabilistic nature of the predictions. In response to our consumer reactions, we have developed new visualization tools that attempt to address the types of shortcoming described above and to create consumer-friendly approaches to describe statistical concepts such as confidence intervals, sensitivity, positive predictive value, and standard deviations. As part of the natural life cycle of iterative consumer-facing improvements, we survey and evaluate our user interfaces using systematic questionnaires and focus groups to judge which tools most effectively convey the concept of genetics and probabilistic theory to a largely naïve consumer population. We will present our findings based on the conviction that the principles we have applied in our iterative development, testing and refinement of user experiences can also extend to other aspects of consumer genetics.

1912F

Next Generation of Genotype Imputation Methods. *S. Das, G.R. Abecasis.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Genotype imputation is a key step in the analysis of human genetic studies as it facilitates in increasing power of gene mapping, enables combination of results across different studies and accelerates fine-mapping efforts. Imputation works by finding the shared haplotype segments between the sample individuals typed on a commercial array and a reference panel of more densely typed individuals (e.g. The International HapMap Project, The 1000 Genomes Project etc.). Advances in high-throughput sequencing technologies have resulted in rapid increase in the size of these publicly available data-sets. Using these as reference panels would soon result in prohibitive computational costs. We introduce a strategy called 'state space reduction' which reduces the description of short genomic regions to the number of distinct haplotypes rather than the total number of haplotypes. The existing formulas have been refined to work with only these distinct haplotypes in a series of short genomic regions which covers the whole genome. The proposed algorithm maintains the accuracy of the current methods while reducing the computational costs. We also formulate a recursive algorithm to find the optimal structure/design of such genomic regions.

1913W

SECA: SNP effect concordance analysis using genome-wide association summary results. *D. Nyholt.* Neurogenetics Lab, QIMR, Brisbane, QLD, Australia.

Epidemiological and clinical studies indicate many human complex disorders co-occur within an individual, while family and twin studies suggest correlations in familial and genetic liabilities. To date, over 1350 genome-wide association studies (GWAS) have been performed to identify common single nucleotide polymorphisms (SNPs), associated with 830 phenotypes (disease endpoints or quantitative traits). A surprising finding of GWAS is that many loci show pleiotropic effects by being associated with more than one distinct phenotype. Indeed, a study of 1380 genes and 1687 SNPs listed in the NHGRI Catalog of Published GWAS (February 4, 2011) found 16.9% of genes and 4.6% of SNPs show pleiotropic effects (Sivakumaran et al. 2011). Identifying and taking advantage of polygenic overlap across phenotypes can improve detection of genetic risk factors, because when risk is correlated across phenotypes, pooled analyses will be better powered than individual-disorder analyses.

To facilitate the discovery of pleiotropic effects and examine polygenic risk shared across two phenotypes, I have developed a user-friendly web-based application called SECA to perform SNP effect concordance analysis. SECA takes two input files of GWAS summary results, each containing: i) SNP rsID, ii) effect allele (EA), iii) non-effect allele (NEA), iv) p-value from association test, and v) regression coefficient (beta), odds ratio, or z-score for the EA relative to the NEA. SECA first aligns the SNP effects across the two GWAS summary results (dataset1 and dataset2), and extracts a subset of independent SNPs (randomly or prioritized by p-values in dataset1) via linkage disequilibrium clumping. Next, SECA tests for enrichment of overlapping (pleiotropic) SNPs and whether the effect directions are concordant across the datasets via binomial, Fisher's, and false discovery rate statistical tests of dataset2 SNPs, after conditioning on association results in dataset1. SECA also prepares Q-Q, true discovery rate and bar plots to visualize enrichment and polygenic overlap.

Using publicly available GWAS summary data, SECA corroborates recent results from the *Cross-Disorder Group of the Psychiatric Genomics Consortium* (Lancet 2013 381:1371-9), finding significant polygenic overlap between bipolar disorder, major depressive disorder, schizophrenia and autism spectrum disorder, but not with attention deficit-hyperactivity disorder.

1914T

Testing Hardy-Weinberg Equilibrium of Multi-allelic Markers: Computational R code for Implementing MCMC algorithm via a Markov Base. *M. Rao, S. Venkatesan.* Environmental Hlth, Univ Cincinnati, Cincinnati, OH.

The goal of the presentation is to test Hardy-Weinberg Equilibrium for Multi-allelic markers a la Fisher. The test involves looking at all possible genotype data sets with the same allele frequencies. This collection of data sets could be humongous. If this is the case, Fisher's exact test cannot be implemented. We have developed a Markov base to negotiate the collection. We can then implement a Markov Chain Monte Carlo Simulation Algorithm exploiting the Markov Base to carry out the Fisher's exact test. An R code will be presented to complete the computations. The code will be run on some examples.

1915F

Relative performance and application of gene- and pathway-level methods for genome-wide association studies. *G.L. Wojcik, W.H. Kao, P. Duggal.* Department of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.

Background: Genome-wide association studies (GWAS) have identified more than 10,000 associated SNPs with 840 traits. Despite this success, there still remains the problem of 'missing heritability' for most traits. One contributing factor may be the result of examining one marker at a time as opposed to a group of markers that are biologically meaningful in aggregate. To address this problem, a variety of gene- and pathway-level methods were developed to identify putative biologically relevant associations. Markers are put into either gene-level units or pathways as designated in databases such as Gene Ontology (GO). A simulation was conducted to systematically assess the performance of gene- and pathway-level methods. **Methods**: Using genetic data from the Wellcome Trust Case Control Consortium (WTCCC), case-control status was simulated based on an additive polygenic model where cases have more risk alleles. A total of 20 pathways and 226 genes were selected from GO biological processes. We evaluated 20 methods (e.g. VEGAS, MAGENTA, GATES, HYST, SRT, Fishers, etc.) based on their sensitivity, specificity, type I and type II error. The influences of gene and pathway size, number of causal single nucleotide polymorphisms (SNPs) in each gene/pathway, and effect size were assessed. Simulations using two sample sizes were examined: traditionally underpowered (n=250 cases, 250 controls) and larger (n=2250 cases, 2250 controls). **Results**: Despite low overall sensitivity (20-60%), specificity was high (89-100%) with low type I error (0.1-6%). Classical methods, not developed to handle linkage disequilibrium, have higher sensitivity, but higher type I error. Newer methods that directly estimate correlation structures were underpowered to detect genes with smaller effect sizes, but type I error was low. All methods were able to detect genes that would have been ignored in a traditional GWAS. Pathway-level methods' performance was dependent upon database annotation. Gene-level methods can rely on annotation from standardized databases but pathway-level methods use a heterogeneous pool. **Conclusions**: The interpretation of gene- and pathway-level methods is dependent upon their specific, inherent assumptions and the resources they rely on. Low type I error and high specificity increase confidence in the identified genes and pathways, despite low sensitivity. Gene- and pathway-level methods may provide valuable insight into the 'missing heritability' of traits.

1916W

Using Gentrain and Z-Call to Identify Problematic SNPs in Rare Variant Genotype Calling. *J. Romm, I. McMullen, M. Jewell, J. Zhang, E. Pugh, KF. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality Next-Gen Sequencing (NGS), Genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. Many commercially available genotyping arrays (HumanExome, HumanOmni2.5, HumanOmni5 and all Illumina 'plus exome' arrays) contain SNP content that enables users to assay low minor allele frequency (MAF) variants (<1%). In order to accurately call these low MAF SNPs, CIDR first clusters a project's data using GenomeStudio version 2011.1, Genotyping Module version 1.9.4, GenTrain Version 1.0. We then use a series of filters based on GenomeStudio/Gentrain metrics (call rate, cluster separation, etc.) and flag SNPs that have likely clustering or calling errors for manual review and adjustment of clusters. In addition to these filters, we use Z-Call (Goldstein, et al, Bioinformatics, 2012) to detect SNPs where Gentrain has called a SNP completely homozygous and Z-Call detects a heterozygote cluster. SNPs flagged with Z-Call are manually reviewed and clusters are modified or the SNP is dropped. This method works well for a breadth of project sizes. Project 1, 95 total samples, had 317 SNPs flagged and 31 were dropped after manual review. Project 2, 284 total samples, had 389 SNPs flagged and 110 were dropped after manual review. Project 3, 4,079 total samples had 223 SNPs flagged and 88 were dropped after manual review.

1917T

Accurate and rapid genetic analysis of genomic data under mixed model with multiple variance components. *H.M. Kang, S. Yang.* Biostatistics Dept, Univ Michigan, Ann Arbor, Ann Arbor, MI.

Ultra-high dimensional genetic analysis of genomic data, such as expression quantitative loci (eQTL) mapping, becomes increasing important to unravel the regulatory mechanisms of genetic variation causing molecular phenotypic changes. Analysis of high-throughput sequencing data dramatically increased the hypothesis space and the computational burden. At the same time, the inherent confounding factors such as batch effects or population structure requires us to apply sophisticated statistical models such as mixed models, which even more increase the computational costs compared to simple linear models. Here we demonstrate an accurate and computationally efficient procedure for genetic association analysis with high dimensional expression data under linear mixed models with multiple variance components, at a computational cost comparable to the simple linear model. Our methods have three important advantages over existing methods. First, the computational complexity of our method is linear to the number of samples, markers, and genes, similar to the GRAMMA-Gamma method (Svishcheva et. al. 2012). However, our method does not rely on the simplifying assumption of constant inflation factor across the genome. Instead, it accurately incorporates marker-specific inflation factor (Kang et. al. 2010) without sacrificing the computational complexity. Second, our method robustly deconvolutes the variance component attributed by the technical batch effects from the variance component attributed by the hidden sample structure using an importance sampling approach. As a result, our method robustly controls Type I error for each phenotype while avoiding overcorrection due to misspecified correlation structure between samples. Third, our method achieves linear time estimation of variance component parameters for multiple variance components by utilizing multiple sets of precomputed singular vectors. As a result, the computational cost of our method across n samples, m markers, and g genes becomes $O(ngm)$ when n is smaller than g and m, which is the same to the time complexity of simple linear model. Our method is being implemented into the widely used EPACTS (Efficient and Parallel Association Container Toolbox for Sequence data) software package, with many utilities and visualization supports for eQTL analysis. We expect that the EPACTS-eQTL will be an extremely useful software package to unravel the causal regulatory mechanism from DNA and mRNA sequencing data.

1918F

Detecting genetic heterogeneity in complex diseases with a weighted U statistic. *Q. Lu[1], C. Wei[1], R.C. Elston[2].* 1) Dept of Epidemiology and Biostatistics, Michigan State University, East Lansing, MI; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio.

For most complex diseases, a large proportion of the genetic variants remain undiscovered. While current research interests have shifted toward uncovering rare variants, gene-gene/gene-environment interactions, and structural variations, the impact of genetic heterogeneity in human diseases has been largely overlooked. Converging evidence suggests that diseases with the same or similar clinical manifestations could have different underlying genetic etiologies. Most of the existing analytical approaches assume the disease under investigation has a homogeneous genetic cause and could, therefore, have low power if the disease undergoes heterogeneous biological pathways. In this paper, we propose a statistical approach, a heterogeneity weighted U (HWU) approach, for high-dimensional association analysis taking genetic heterogeneity into account. HWU can be applied to various types of traits (e.g., binary and continuous), and is designed for detecting heterogeneous genetic effects. Through simulations, we compared HWU with a non-heterogeneity weighted U (NHWU) and the conventional generalized linear model (GLM). The results showed that HWU has substantial gain in power compared to NHWU and GLM in the presence of genetic heterogeneity, while retaining a performance similar to that of NHWU and GLM when the effects are homogeneous. Using HWU, we conducted a genome-wide analysis to study genetic heterogeneity in nicotine dependence. The genome-wide analysis of nearly one million SNPs from the Study of Addiction: Genetics and Environments (SAGE) took 5.8 hours, identifying heterogeneous effects of two new genes (i.e., CYP39A1 and VDAC3) on nicotine dependence.

1919W

Efficient and Accurate Population-Scale KIR Typing from SNP Chip Data. *S. Leslie[1, 2], D. Vukcevic[1], J. Traherne[3, 4], S. Naess[5], M. Lathrop[6, 7], T.H. Karlsen[5], M. Moffatt[8], W. Cookson[8], J. Trowsdale[3, 4], G. McVean[9], S. Sawcer[10].* 1) Statistical Genetics, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 2) Department of Mathematics and Statistics, The University of Melbourne, Parkville, Victoria, Australia; 3) Cambridge Institute for Medical Research, University of Cambridge, UK; 4) Department of Pathology, University of Cambridge, UK; 5) Research Institute of Internal Medicine, Department of Cancer Medicine, Surgery and Transplantation, Oslo University Hospital Rikshospitalet, Oslo, Norway; 6) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 7) Fondation Jean Dausset - CEPH, Paris, France; 8) National Heart and Lung Institute, Imperial College London, UK; 9) Wellcome Trust Centre for Human Genetics, Oxford, UK; 10) Department of Clinical Neurosciences, University of Cambridge, UK.

KIR (killer immunoglobulin-like receptor) genes are of great interest in regard to resistance to viruses, autoimmune disease, reproductive conditions and cancer. Like HLA, they are highly polymorphic and some KIR molecules interact with HLA class I. Better understanding genetic associations of KIR with disease requires accurate typing of both HLA and KIR variants. KIR exhibit copy number variation (CNV) and haplotypes may comprise from 4 to 15 or more genes. This kind of diversity makes KIR typing expensive and time consuming. Thus to date KIR has been understudied. SNP imputation for other SNPs is now routine, and performs extremely well, and SNP-based imputation for HLA is very good and becoming more widely used, but currently there are no imputation methods for KIR. To address this we have developed a high-throughput, accurate statistical imputation methodology for KIR typing using SNP variation data. We use a reference data set of approximately 600 haplotypes of European descent typed at 305 SNP loci covering 400kb in the vicinity of the KIR genes. These SNPs were typed on Immunochip. We fit a statistical model to these SNPs that enables us to impute KIR alleles from SNP variation alone. Validation experiments, using cross-validation and in a separate group of individuals, show accuracy for typing KIR gene copy number is at least 95% for the overwhelming majority of KIR genes, with better that 90% accuracy for the rest. Despite the relatively small reference database our results provide strong proof of principle that accurate imputation of KIR from SNPs is feasible. Experience with other loci (e.g. HLA) indicates that accuracy is likely to improve dramatically with increased reference panel size, and that imputation is likely to perform well for non-European populations provided good reference data is available. Our results show that accurate and efficient typing of KIR genes from SNP-chip data is possible. This is a novel approach that will make KIR data available to large cohort studies using SNP chips, meaning that disease association with KIR can be directly studied for the first time. This will facilitate significant insights into the role of KIR in human disease.

PSEUDOMARKER 2.0: efficient computation of likelihoods using NOMAD. *A. Schaffer[1], E.M. Gertz[1], T. Hiekkalinna[2], S. Le Digabel[3], C. Audet[3], J.D. Terwilliger[2,4,5].* 1) National Center for Biotechnology Information, NIH, Bethesda, MD; 2) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, FINLAND; 3) GERAD and Départment de Mathématiques et de Génie Industriel, École Polytechnique de Montréal, Montréal, CANADA; 4) Department of Psychiatry, Department of Genetics and Development, and Columbia Genome Center, Columbia University, New York, NY, USA; 5) Division of Medical Genetics, New York State Psychiatric Institute, New York, NY USA.

PSEUDOMARKER [Hiekkalinna et al. Hum Hered 2011; 71:256-266] is a software package that tests for significant relationships between a putative trait-predisposing locus and genotypes at a series of markers, such as microsatellites or single nucleotide polymorphisms (SNPs). Typically, such packages either test for cosegregation of markers with a putative trait-predisposing locus within families (genetic linkage), or test for differences in marker genotype frequencies between unrelated cases and controls (linkage disequilibrium, LD). With PSEUDOMARKER, one can jointly analyze linkage and LD, or LD conditional on linkage, using pedigree relationships among individuals and singleton individuals. PSEUDOMARKER version 1 maximizes several likelihood functions using a generalized pattern search (GPS) algorithm [Dennis and Torczon, SIAM J Optim 1991; 1:448-474] implemented in a custom version of the ILINK [Cottingham et al. Am J Hum Genet 1993; 53:252-263] program. The running time of PSEUDOMARKER depends on the number of times the optimization algorithm evaluates a likelihood function. We modified ILINK substantially to use the software package NOMAD [Le Digabel ACM Trans Math Softw 2011; 37:1-15] to maximize likelihoods instead of GPS, resulting in generally comparable or better optima with many fewer evaluations of the likelihood functions. Out of 288 tests, NOMAD reported a log likelihood more than 0.005 better than that found by GPS 68 times, while GPS was at least 0.005 better only 7 times. On 12 datasets with multiple tests per set, the number of likelihood evaluations in PSEUDOMARKER version 2.0 is reduced by a multiplicative factor of at least 2 on each dataset and reduced by a factor of more than 7 on the best test set, as compared to version 1. PSEUDOMARKER is available from http://www.helsinki.fi/~tsjuntun/pseudomarker.

1921F

MMAP: a comprehensive mixed model program for analysis of pedigree and population data. *J. O'Connell.* Div Endo/Diabetes/Nutrition, Univ Maryland, Baltimore, MD.

The application of mixed models for genetic analysis has seen a sharp increase the last several years. The power and flexibility of the mixed model has been applied to both population and pedigree data, to both single SNP and multi-SNP data as random and fixed effects, to gene expression and general omics data, to both estimation and prediction of genetic risk, to mapping both common and rare variants, and to understanding the genetic architecture of complex traits. Kernel machine methods, kriging, and non-parametric regression can be cast into the mixed model framework to take advantage of available machinery. The basic ingredients in the mixed model are covariance matrices that measure similarity between subjects based on genetic data.

MMAP is an optimized and flexible mixed model analysis platform that incorporates a wide range of covariance structures such as additive, dominance, epistasis, maternal and imprinting using pedigree and/or genotype data and also allows users to define their own covariance structures. Likelihood calculations use multi-threaded optimized matrix libraries to handle multiple random effects. MMAP can import data from a variety of imputation programs to avoid data manipulation and IBS/IBD programs to build covariance structures.

MMAP uses a fast low-memory method to calculate additive and dominant genetic covariance structures using SNP data, which can be quite challenging for large data sets. For polygenic SNP analysis MMAP can store SNP-covariance products to reduce the complexity subsequent analyses with the same subjects to linear regression, independent of phenotype or covariates.

We present results in both animal and human data. We show that the genetic architecture of complex traits can include significant non-additive variance such as dominance in milk traits estimated in 35,000 Holstein cows and in blood pressure in 3500 Amish subjects. We show that including sources of non-additive variance in estimating SNP effects can improve predictive ability. We also present a detailed comparison between pedigree and genomic estimates of heritability in the Amish to measure missing heritability.

1922W

SALAD: A software suite for admixture linkage analysis and discovery.
R. Johnson[1, 2], *G. Nelson*[1], *C. Winkler*[3]. 1) BSP CCR Genetics Core, Frederick National Laboratory, SAIC Frederick, Inc, Frederick, MD; 2) Chaire Bioinformatique, Conservatoire National des Arts et Mètiers, Paris, France; 3) Basic Research Laboratory, Frederick National Laboratory, SAIC Frederick, Inc, Frederick, MD.

The importance of accounting for population structure in genetic studies and the power of admixed populations has long been recognized. Technological advances over the last decade have made it possible to sample and analyze these populations for regions of admixture linkage disequilibrium associated with clinical outcomes. Admixture linkage analysis remains a powerful, important tool in genetic studies, and many good software packages exist to aid the researcher. Multiple software packages requiring disparate data formats are required to fully analyze and prepare all but the simplest admixture linkage models. The Suite for Admixture Linkage Analysis and Discovery (SALAD) was developed to bring together tools for admixture linkage studies from study design to manuscript preparation. The backbone of SALAD, local and global ancestry inference, is done using a Hidden Markov Model similar to other admixture linkage software. These ancestry estimates can be further analyzed in a flexible modeling framework, allowing the user to model clinical outcomes as a function of global and local ancestry in addition to relevant covariates, using the appropriate generalized linear model. The case-only locus-genome statistic implemented in ANCESTRYMAP (Patterson et. al. 2004) is also included, as well as basic locus-genome statistics for other data types (e.g. continuous or survival). This can be generalized to compare any two user defined models based on Bayes factors. Also included in SALAD are tools for ancestry informative marker panel discovery, reading and writing data in common formats, GWAS data analysis and various publication quality graphics functions. Power and accuracy of SALAD is tested using simulated data, and relevant comparisons with similar software packages are made.

1923T

Local Ancestry Inference for Whole Genome Sequence Data.
B. Maples[1,2], *S. Gravel*[3], *E. Kenny*[4,5,6,7], *C. Bustamante*[1]. 1) Genetics, Stanford University, Stanford, CA; 2) Biomedical Informatics, Stanford University, Stanford, CA; 3) Human Genetics, McGill University, Montreal H3A 1B1, Canada; 4) Genetics and Genome Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Statistical Genetics, Icahn School of Medicine at Mount Sinai, New York, NY; 6) Charles Bronfman Institute of Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 7) Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sanai, New York, NY.

Local ancestry inference is an important step in the genetic analysis of fully sequenced human genomes. Current methods can only detect continental-level ancestry (i.e., European vs. African vs. Asian) accurately even when using millions of markers. Here, we present RFMix, a powerful discriminative modeling approach that is faster (~30X) and more accurate than existing methods. We accomplish this by using a conditional random field (CRF) parameterized by random forests trained on reference panels. RFMix is capable of learning from the admixed samples themselves to boost performance and autocorrect phasing errors. RFMix shows high sensitivity and specificity in simulated Hispanic/Latinos, African Americans, and admixed Europeans, Africans, and Asians. Finally, we demonstrate that African Americans in HapMap contain modest (but non-zero) levels of Native American ancestry (~0.4%).

1924F

Estimating Sample Size and Power for Nested Cohort Studies.
R. Hoffmann. QHS, Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Objective: Because of the rarity of certain diseases, the high cost of gene sequencing and the high cost of obtaining gene expression data the sample size and power of a nested cohort study needs to be obtained when <u>all</u> the cases, but only <u>some</u> of the non-diseased are sampled.

Methods: A nested cohort study may sample all the cases in each cohort, but only some of the controls from each cohort. Obtaining estimates of Relative Risk (RR) or the expression ratio involves choosing the correct sample from the non-diseased from both cohorts. The statistical power was determined separately for matched, stratified (using a stratified random sample) and unmatched (using a simple random sample) non-diseased. The power was determined using simulated data with both rare variant and common variants making up a complex disease structure. Rare variants are defined as alleles that have <0.5 percent, < 1 percent or less than 5 percent prevalence. The disease structure is patterned on either (1) a disease structure that has a few well-defined candidate genes, as well as a disease structure that potentially involves as many as 5000 potential locations. Stratification ranged from no stratification to stratification that is related to the disease to stratification that is unrelated to the disease.

Results: A sample of matched non-diseased to the diseased is found to have the least power and the highest probability of a false discovery. A stratified random sample had high power and a substantially lower probability of false discovery. An unmatched sample was found to have substantially higher power, but a higher probability of false discoveries if substantial stratification is present and not related to the disease system. Continuous expression data had higher power, but otherwise showed the same pattern with respect to sample selection of the non-diseased.

Impact of measurement error on testing genetic association with quantitative traits.
J. Liao[1,2], *X. Li*[2,3], *T.Y. Wong*[1,2,4], *J.J. Wang*[5], *C.C. Khor*[1,6], *E.S. Tai*[4,7,8], *T. Aung*[1,2], *Y.Y. Teo*[3,4], *C.Y. Cheng*[1,2,4,8]. 1) Department of Ophthalmology, National University of Singapore and National University Health System, Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore, Singapore; 3) Department of Statistics and Applied Probability, National University of Singapore, Singapore, Singapore; 4) Saw Swee Hock School of Public Health, National University Health System, National University of Singapore, Singapore, Singapore; 5) Centre for Vision Research, University of Sydney, Sydney, Australia; 6) Division of Human Genetics, Genome Institute of Singapore, Singapore, Singapore; 7) Department of Medicine, National University of Singapore and National University Health System, Singapore, Singapore; 8) Duke-NUS Graduate Medical School, Singapore, Singapore.

Background: Ignoring measurement error of a phenotypic trait will lead to underestimation of the standard error and hence reduce the power to detect genetic associations. We examined the impact of sample size, allele frequency and effect size in the presence of measurement error for quantitative traits.

Methods: The statistical power to detect genetic association by comparing phenotype mean and variability was investigated analytically. The non-centrality parameter for a non-central F distribution was derived and verified using simulation study. We obtained equivalent formulas for the cost of phenotype measurement error while maintaining equal power. Effects of differences in measurements were examined in a genome-wide association study (GWAS) of two grading scales for cataract and a replication study of genetic variants influencing blood pressure with multiple measurements.

Results: The mean absolute difference between the analytic power and simulation power for comparison of phenotypic means and variances were less than 0.005, and the absolute difference did not exceed 0.02. To maintain the same power, a one standard deviation (SD) in measurement error of a standard normal distributed trait required a one-fold increase in sample size for comparison of means, and a three-fold increase in sample size for comparison of variances. GWAS results revealed almost no overlap in the significant SNPs ($p < 10^{-5}$) for the two cataract grading scales. Genetic variant rs1458038 associated with blood pressure was replicated in averaged blood pressure measurements but not in single blood pressure measurement due to larger measurement error.

Conclusions: We have developed a framework for researchers to quantify power or to calculate sample size in the presence of measurement error, which will be applicable to studies of phenotypes in which the measurement is highly variable.

1926T

Slicing the Genome: A New Approach to Association in Complex, Longitudinal Diseases. *A. Musolf[1], D. Londono[1], A.Q. Nato, Jr.[2], P. Vuistiner[3], C.A. Wise[4,5,6], L. Yu[1,7], S.J. Finch[8], P. Bovet[9], M. Bochud[3], T.C. Matise[1], D. Gordon[1].* 1) Department of Genetics, Rutgers University, Piscataway, NJ, USA; 2) Division of Medical Genetics, University of Washington, Seattle, WA, USA; 3) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 4) Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, TX, USA; 5) Department of Orthopedic Surgery, Texas Scottish Rite Hospital for Children, TX, USA; 6) Department of Orthopaedic Surgery, University of Texas Southwestern Medical Center, Dallas, TX, USA; 7) Center of Alcohol Studies, Rutgers University Piscataway, NJ, USA; 8) Department of Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY, USA; 9) Unit for Prevention and Control of Cardiovascular Disease, Section of Non Communicable Diseases, Ministry of Health and Social Services, Seychelles.

We previously published a method that tests for association between a longitudinal phenotype and genetic variants. The method uses growth mixture models (GMM) to determine longitudinal trajectory curves. The Bayesian posterior probability (BPP) of belonging to a specific curve, an outcome variable from the GMM, is used as a quantitative phenotype in association analyses. Though the method proves to be powerful for a single causal variant under multiple inheritance scenarios, power significantly decreases when more than one causal variant is considered. Here, we present a new method designed to detect multiple causal SNPs associated with longitudinal phenotypes in both family and population studies. The method also allows for the incorporation of covariates. This novel method retains several ideas from our first method, however instead of performing individual association tests with each SNP, we slice the genome into non-overlapping blocks of 50 SNPs (which we term a "mega-locus") and obtain a significance value on each mega-locus. This is accomplished via the SumStat method, developed by Jurg Ott and colleagues. As SumStat works for population studies only, we use a modified procedure (TDT-HET) to test for family-based association. We consider various scenarios in our simulations, including four causal variants located within a single mega-locus and eight causal variants spread between two mega-loci on different chromosomes. We also introduce environmental covariates. Our data set is highly stratified to ensure robustness in the presence of population stratification. P-values for each mega-locus on each data set are computed. To adjust for multiple testing, the final p-values are combined via Fisher's method (per mega-locus) and by the false discovery rate (FDR). We report that our simulations: 1) appear to maintain the proper type I error and 2) have greater than empirical 75% power for most simulations. These results suggest that our method can detect multiple causal SNPs located in multiple regions across the genome. We believe that this method will be useful to researchers who are studying complex diseases with longitudinal phenotypes. It allows for potentially high power for association of causal loci with disease progression phenotypes for both population and family studies, even in the presence of confounding elements such as population stratification and environmental variables.

1927F

Use of Electronic Medical Records to Measure Phenotypic Heritability. *S. Hebbring[1], Z. Ye[2], M. He[1,2], J. Mayer[2], S. Schrodi[1], M. Brilliant[1].* 1) Center for Human Genetics, Marshfield Clinic, Marshfield, WI; 2) Bioinformatics Research Center, Marshfield Clinic, Marshfield, WI.

A priority of the NIH is to understand the genetic etiology of common and rare diseases so that genetics may be used in 'personalized medicine.' All diseases are the result of a combination of environmental and/or genetic factors. Conducting genetic/genomic studies is difficult without evidence of a strong genetic component by heritability measurements. Heritability can be measured in a variety of family structures including twins and extended families. A particular challenge in conducing heritability estimates is identifying appropriate families with available phenotypic information. To address this challenge, and to demonstrate proof-of-principle that electronic medical records (EMRs) can be used to efficiently characterize disease heritability, we estimated the heritability of muscular dystrophy (MD) in a Marshfield Clinic patient cohort (Personalized Medicine Research Project, PMRP) with available family structure data (4,475 families) all linked to patient EMRs. MD was chosen as a positive control because of its well characterized genetic etiology and has a well-defined ICD9 code (359.1) easily extractable from the EMR. In this population, 6 out of 18 MD cases were familial in nature. The broad sense heritability estimated for MD using the EMR was 0.63 (SE 0.16), and closely matched expected estimates. To further follow-up on the use of EMRs to characterize the potential genetic contribution of human disease, we established a Marshfield Clinic twin cohort (15,802 twin pairs) and again ascertained MD diagnosis using the EMR. In the twin cohort, there was an enrichment for disease concordance in twins (4 affected pairs out of 17 individuals, p=1.59E-8). These results, both from extended and twin families, demonstrate proof-of-principle that the EMR may be a powerful and efficient tool when doing studies of heritability even in the absence of existing genetic/genomic data.

Optimal Strategies for Identifying Disease Associated Singletons. *S. Rashkin, G. Jun, G. Abecasis.* Center Statistical Genetics, Univ Michigan, Ann Arbor, MI.

Rare functional variants are hypothesized to explain much of the heritability of common, complex diseases. These variants are generally missing from genotyping array based studies and understanding their role in disease requires sequencing. Singletons, the rarest of these variants, can only be detected with high power by deep sequencing, which remains expensive. At lower depth, costs can be greatly reduced, enabling sampling sizes to increase, but many singleton variants will be missed. Here, we examine the balance between power to detect rare variants at different sequencing depths and sample sizes, so as to maximize power and minimize cost for studies that explore the role of singleton variants in human disease.

We used a simulated multisample caller to calculate power of singleton discovery based on different read depths (2-50x), sample sizes (20-5000), and error rates (0.001-0.01). While all three factors influence power, read depth appears to have the largest effect. At 10x coverage, power to detect a singleton variant is greater than 0.75 for all combinations of sample sizes and error rates examined. At 20x coverage, power exceeds 0.95, regardless of sample size and error rate. We validated our simulation by down-sampling deeply sequenced exome samples and assessing our ability to detect previously called singletons.

While we are interested in our ability to detect singletons, it is also important to study how this affects association results. We approximated the power of an association test using analytical computations that considered sample size, population frequency of singletons, relative risk for carriers, prevalence of disease, and read depth. Analysis of association study power allows for determination of the ideal sample size and read depth to use in studying singletons under a variety of conditions. Changes in sample size, relative risk, or frequency of singletons have a large effect on power: increasing frequency of singletons or relative risk allows for smaller sample sizes to attain high power. For a fixed sample size, at lower depth (<10X), increasing coverage increases power; as depth increases (typically beyond >15-20X), power remains relatively constant. Thus, our results suggest that studies of the contribution of rare variants to human disease will be optimally powered at coverage of ~10X and that coverage should only be increased when such an increase does not require a decrease in sample size.

1929T

Response Dependent Sampling Designs And Analysis In Studies With Rare Variants. *L. Sun[1,2], A. Derkach[2], J.F. Lawless[3,1].* 1) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 2) Department of Statistical Sciences, University of Toronto, Toronto, ON, Canada; 3) Department of Statistics and Actuarial Science, University of Waterloo, Waterloo ON, Canada.

Rare variants play an important role in studies of complex human diseases and traits, and next generation sequencing technology provides rich data for analysis. This recent focus on rare variants has produced a significant number of sequencing studies as well as a large number of association tests. However, theoretical and empirical results have shown that in order to achieve high power large sample sizes are needed. Compared to random sampling, it has been shown that response-selective sampling designs can greatly improve the power of association studies with common variants and recently, rare variants. We extend the range of tests for multiple rare variants and show how adjustments to existing tests can increase power. We also investigate sampling strategies where random samples are taken from the tails of the response distribution and there may also be stratification on covariates. Through theoretical calculations and extensive simulations, we investigate what designs and testing approaches are efficient and robust across various genetic models.

1930F

Quantitative-trait-dependent sampling designs for genetic association analysis of a rare variant score. *Y.E. Yilmaz[1, 2, 4], J.F. Lawless[2, 3], S.B. Bull[1, 2]*. 1) Samuel Lunenfeld Research Institute, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) Department of Statistics and Actuarial Science, University of Waterloo, Waterloo, Ontario, Canada; 4) Department of Mathematics and Statistics, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

For rare variant analysis related to a quantitative trait (QT), selection of individuals for sequencing according to their QT value can improve cost-efficiency. We consider QT-dependent two-phase sampling designs for regression analysis of a QT on a rare variant score obtained by aggregating rare genetic variants in a specified functional unit. In the first phase, we obtain trait values for all individuals in a cohort; in the second phase, we obtain genetic sequence data for a subset of individuals selected according to their trait values. Under stratified sampling, individuals in strata defined by high or low trait values can be selected with a higher fraction than those with an intermediate trait value. Under extreme-trait sampling, only individuals with high or low traits values are selected. In such trait-dependent sampling designs, inference based on standard linear regression methods that treat the QT as the dependent variable, ignoring the selection, may be misleading. We review the key features of two well-known methods for analysis under two-phase designs: likelihood-based inference for response-biased samples and inverse probability weighting (IPW) based on estimating equations, and describe analytic and simulation-based approaches to compare various sampling designs according to the number and size of strata, and the allocation of the phase 2 sample to the specified strata, as well as the distribution of the rare variant score and associated effect size. The relative efficiency of alternative designs depends on the method of analysis. Under a stratified sampling design, and assuming a linear relationship between the trait and rare variant score with normally distributed error term, likelihood inference favours extreme-trait-selection whereas IPW analysis requires non-zero sampling fractions in all strata and can be sensitive to sparsely sampled strata. Based on evaluation of type I error and power of a likelihood ratio test of rare variant association by simulation, we recommend likelihood-based design and analysis for both extreme-trait and more general stratified sampling, with the choice between them based on considerations of robustness as well as relative efficiency.

1931W

Caveats of extreme sampling strategies for resequencing studies. *H. Qin[1], W. Ouywang[1], S. Cao[1,2], T. Yang[1], Y.-P. Wang[1,2], H.-W. Deng[1]*. 1) Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, 1440 Canal Street, New Orleans, LA 70112, USA; 2) Department of Biomedical Engineering, Tulane University, 534 Lindy Boggs Building, New Orleans, LA 70118, USA.

Selective sampling strategies are crucial to enrich causal rare genetic variants for cost-effective next-generation resequencing studies. One widely employed selective sampling strategy is extreme phenotype sampling - sampling individuals with extreme phenotypes. It seems to be a common sense that extreme phenotype sampling can enrich the presence of causal rare genetic variants compared to random sampling. An intuitive alternative of extreme phenotype sampling is extreme residual sampling - sampling individuals with extreme residuals after adjusting for covariates (e.g., identified genetic variants, population structure surrogates, and environmental factors) from phenotypes. In this paper, we mathematically modeled the causal architecture among phenotype, target genetic variants, and covariates. Under the causal architecture, we analytically investigated the probabilities of the three sampling strategies to detect target genetic variants. We proved the following results: Extreme phenotype sampling is inferior to random sampling when covariates are negatively correlated with target genetic variant. Extreme residual sampling is superior to random sampling; but it is inferior to extreme phenotype sampling if covariates are positively correlated to target genetic variant and target genetic effect is mild. Typical examples are reported for illustrations. In conclusion, no sampling strategy can uniformly dominate all the others under all circumstances. For a resequencing study, the 'optimal' sampling strategy depends on the underlying causal architecture among phenotype, target genetic variants, and covariates.

1932T

Identifying potential cancer vaccine targets with high-throughput sequencing. *E. Aronesty[1,2], K. Robasky[2], W.D. Jones[2,3]*. 1) Bioinformatics, Johns Hopkins University, Washington, DC; 2) Expression Analysis a Quintiles Company, Durham, NC; 3) Department of Pathology and Laboratory Medicine, University of North Carolina School of Medicine, Chapel Hill, NC.

Since the HPV vaccine was introduced to prevent cervical cancer, other vaccine targets remain elusive. Here, we use RNA-Seq to detect viral homologs in tumor sample expression data obtained from TCGA. We compare with normal tissue expression obtained from GTEX data sets, and to 'paired-normal' from blood samples where available. We have inspected RNA sequence of for breast, liver, cervical, ovarian, prostate, colon, lung, and brain cancers, and found that the overall viral presence is higher in cancer tissue compared to uninfected patient tissue. We present a method for producing a virome, removing low-complexity reads, counting viral presence by genus, as well as two methods for comparing counts between patient tissue and GTEX reference tissue. Finally, we assemble contigs for statistically significant viruses, and annotate results in a manner sufficient for vaccine target identification.

1933F

A Dynamic Model for Classification of Gene Regulation with RNA-seq Data. *L. Li, M. Xiong*. University of Texas School of Public Health.

Characterizing gene regulation and capturing its feature will provide valuable information for understanding biological process. Variation in gene expression underlies many biological processes and holds a key to unraveling mechanism of gene regulation. However, the gene expression measured by microarray provides limited information to reveal the features of gene regulation. The rapidly developed NGS technologies have been becoming the platform of choice for gene expression profiling. RNA-seq for expression profiling offers comprehensive picture of transcriptome and has made a number of significant qualitative and quantitative improvements on gene expression analysis and provides multiple layers of resolutions and transcriptome complexity:the expression at exon, SNP, and positional level; splicing; post-transcriptional RNA editing across the entire gene; isoform and allele-specific expression. To unravel the features of gene transcription, we propose to use differential equation to model the observed number of reads across the gene. We view the number of reads or expression level at each position as a function of the genomic position and view the transcription process as a dynamic process of transcription along the genome. Instead of taking derivative of expression level with respective the time, we calculate derivative of the expression level with respect to genomic position. We use a second order differential equation to model the dynamics of transcription process along the genome. Iterative principal differential analysis is used to estimate the coefficients in ODE by specifying the ODE as the data-driven penalty in the B-spline smoothing. We iterate between curve smoothing and ODE estimation until convergence occurs. The proposed methods are applied to ovarian cancer RNA-seq data with 412 tumor samples from TCGA dataset. We study the stability and transient response of transcriptional process for each gene using its fitted differential equation. These dynamic features of the gene transcription can reveal various alternative splicing, alternative start and end of transcription, and isoforms. Based on the dynamic features of gene transcriptional process we use the coefficients of ODE to classify the gene transcription into four categories. Our results will provide valuable information for understanding the mechanism of gene regulation and unraveling disease process. These results may also open a new way to find drug target and disease treatments.

1934W

Telomere Length in Circulating Leukocytes Is Associated with Lung Function and Disease. *E. Albrecht[1], E. Sillanpää[2], S. Karrasch[3], A. Couto Alves[4], V. Codd[5,6], I. Hovatta[7,8], J.L. Clinical and experimental studies suggest the involvement of premature aging in COPD. Using an epidemiological approach we studied whether accelerated aging indicated by reduced telomere length, as a marker of biological age, is associated with COPD and asthma, and whether intrinsic age-related processes contribute to the inter-individual variability of lung function. Our meta-analysis of 14 studies included >1,000 COPD cases with >15,000 controls, >2,500 asthma cases with >28,000 controls, and the spirometric indices forced expiratory volume in one second (FEV1), forced vital capacity (FVC), and their ratio FEV1/FVC in >13,000 individuals. Associations were tested by linear regression, adjusting for age, sex, and smoking status. We observed negative associations between telomere length and COPD as well as asthma, with stronger effects in women compared to men. The analysis of spirometric indices showed positive associations between telomere length and all investigated spirometric measures. The associations were weaker in apparently healthy subjects compared to COPD or asthma patients. Our results indicate that lung function may reflect biological aging primarily due to intrinsic processes which are likely to be aggravated in lung diseases. Shortened telomeres in COPD and asthma suggest that induced aging is involved in the pathogenesis of these diseases.

1935T

How much does family history information add to other risk factors when predicting a patient's risk of colorectal cancer? *L. Jonah[1], B.K. Potter[1], J. Little[1,2], J.C. Carroll[3], Q. Hasanaj[1], J. Allanson[4], D. Castle[5], B.J. Wilson[1], CIHR Emerging Team in Genomics in Screening.* 1) Department of Epidemiology & Community Medicine, University of Ottawa, ON, Canada; 2) Canada Research Chair in Human Genome Epidemiology; 3) Family Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 4) Department of Pediatrics, University of Ottawa, ON, Canada; 5) ESRC Innogen Centre, University of Edinburgh, Edinburgh, UK.

Background: Positive family history (FH) is associated with risk of many common complex diseases. Most clinical guidelines include FH in assessing disease risk. However, the evidence base to inform the routine use of FH in primary care is largely lacking. The 2009 NIH State-of-the-Science Panel on Family History and Improving Health concluded that, for FH to be established as an evidence-based tool, there is a need to evaluate its predictive ability and prognostic value in combination with traditional risk factors. Published research suggests that FH might offer statistically significant improvements to disease risk classification, but clinical utility still needs to be evaluated. We report the findings of a study of colorectal cancer (CRC) risk prediction, in which the impact on clinical decisions of adding FH to other risk factor information is provisionally evaluated. **Objectives**: To assess the incremental improvement in individual CRC risk prediction which is gained by adding FH to other clinical information recommended in risk models, and its potential impact on patient classification and management. **Methods**: This is a secondary cross-sectional analysis of data from the Assessment of Risk of Colon Tumors in Canada Study, a case control study. The dataset contains information on a range of risk factors as well as FH. We used a risk assessment model developed by Freedman et al (2009) to select variables (diet, NSAID use, physical activity, etc) for univariate and logistic regression analyses. We developed three models: Model 1 included non-FH covariates; Model 2 added FH to Model 1; and Model 3 incorporated a broader range of risk factors available in the dataset, including FH. For each model, the predictive/discriminatory ability was evaluated using ROC curves. **Results**: We present the three models, their accompanying ROC curves, and the Δarea under the curve achieved by adding FH and other variables to the base risk model. We also present the results of reclassification analyses which clarify how individuals shift between risk strata under the three models, including alterations in false positives and/or false negative rates. We comment on the likely clinical implications of risk reclassification, and offer recommendations for future research to clarify the thresholds for cost-utility analyses. These analyses offer a framework for the practical assessment of genomic information in clinical and patient decision-making.

1936F

Population based study of permanent teeth agenesis in Japanese. *J. Machida[1], T. Nishiyama[2], S. Yamaguchi[5], M. Kimura[3], A. Shibata[3], T. Tatematsu[3], Y. Abe[1], S. Makino[1], H. Miyachi[3], K. Shimozato[3], Y. Tokita[4].* 1) Oral and maxillofacial surgery, Toyota Memorial Hospital, Toyota, Aichi, Japan; 2) Public health, Aichi Medical School, Nagakute, Aichi, Japan; 3) Maxillofacial Surgery, School of dentistry, Aichi-Gakuin University, Nagoya, Japan; 4) Perinatology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan; 5) Oral and Maxillofacial Surgery, Aichi Children's Health and Medical Center.

Tooth agenesis is one of the most common congenital anomalies in humans and it is characterized by developmental absence of teeth. Clinical and epidemiologic studies of defined geographic populations can serve as a means of establishing data for genetic counseling and as a first step in identification of causes. In this study, we carried out clinical and epidemiologic studies at Aichi Prefecture, Japan. Four thousand eighty eight medical records of 15 year old school children from west Mikawa area were reviewed and prevalence rates calculated. In addition, medical and dental records of 71 unrelated patients with tooth agenesis of Aichi-Gakuin University were reviewed to obtain sibling recurrence risk. The prevalence of hypodontia with absence of one to five missing permanent teeth, excluding third molars and oligodontia with absence of more than six permanent teeth were 6.84%(95% CI: 6.06%; 7.68%) and 0.13%(95% CI: 0.04%; 0.30%), respectively. Sibling recurrence ratio in absence of one, two, three to five, and six or more teeth were 0.245% (95% CI: 0.138%; 0.383%), 0.250% (95% CI: 0.073%; 0.524%), and 0.222% (95% CI: 0.064%; 0.476%), and 0.438% (95% CI: 0.264%; 0.623%), respectively. This suggests severe phenotype, oligodontia fitted with an autosomal dominant inheritance, whereas mild phenotype, hypodontia is most compatible with an autosomal dominant trait with incomplete penetrance and/or polygenic inheritance. Our findings on the intra oral distribution of agenesis of permanent teeth in children may help us better understand the etiology of agenesis.

1937W

Population Architecture using Genomics and Epidemiology (PAGE): The association of trans-ethnic genetic variation with glucose and insulin levels in PAGE. *S.A. Rosse[1], C.S. Carlson[1], D. Crawford[4], J. Haessler[1], C.A. Haiman[6], T. Matise[5], K.E. North[2,3], J. Pankow[7], N. Pankratz[8], U. Peters[1], A. Young[1], C. Kooperberg[1].* 1) Public Health Genetics, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC; 3) Department of Epidemiology, School of Public Health, University of North Carolina, Chapel Hill, NC; 4) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 5) Department of Genetics, Rutgers University, Piscataway, NJ; 6) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 7) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 8) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN.

Type 2 Diabetes Mellitus (T2DM) has an increasing burden of morbidity and mortality worldwide, particularly in populations of non-European descent. Although Genome-Wide Association Studies (GWAS) have established numerous loci associated with diabetes-related glycemic traits, the subsequent identification of causal variants remains a considerable challenge. Leveraging differences in local linkage disequilibrium (LD) structure between genetically diverse populations is a powerful method to narrow candidate region. To explore the generalization of susceptibility loci for fasting glucose (FG) and fasting insulin (FI) we fine-mapped 17 previously identified loci by investigating a total of 12,227 variants genotyped on the MetaboChip in individuals without diabetes from the PAGE study. A previous analysis demonstrated that exploring European GWAS loci in African Americans is a powerful approach to identify likely functional candidate(s) and secondary signals for FG and FI within PAGE. In this analysis we expand upon previous work to investigate the generalization of European GWAS loci and search for novel SNP effects for FG and ln(FI) across multiple ethnicities in a total of 21,002 Hispanic, 8140 Asian, 3500 Hawaiian and 11,795 African American individuals. Association between SNPs and trait was evaluated using linear regression for FG and logistic regression for ln(FI) under an additive genetic model (adjusted for age, sex, BMI, diabetes status, and principal components). Each ethnicity and study was first analyzed separately. Meta-analysis was conducted on results across studies within each ethnicity and with all ethnicities combined. In our preliminary analysis we attempted to fine-map 17 European GWAS loci by genotyping an average of 720 SNPs per region in 3,215 Hispanic women from Women's Health Initiative. Using a Bonferroni adjusted threshold, we detected one significant SNP (rs116132956, β=1.29 mmol/L, p=6.12×10^{-5}) in the *DGKB* region previously identified in AA and EA. Although the direction of effect was the same across populations, the most extreme p-values were at three statistically independent SNPs for AA, HA, and EA suggesting fine mapping of functional variants at the *DGKB* locus. A deeper understanding of the genetic influences across populations on glucose and insulin levels will provide insight into the underlying biology of T2DM that could have important implications for the development of therapeutic targets and prevention strategies.

1938T

Estimating genetic correlations between traits from summary statistics. *H.K. Finucane[1], S. Lindstrom[2], A.L. Price[2].* 1) MIT, Cambridge, MA; 2) Harvard School of Public Health, Boston, MA.

Estimating genetic correlation, a measure of the shared genetic origin of two traits, is a problem of high interest (Lee et al. 2012 Nat Genet). Here, we present a method to estimate genome-wide genetic correlations from GWAS summary statistics, which are much more widely available than raw genotype data. We focus on the genetic correlation of genotyped SNPs, as in Lee et al. 2012. Our method is applicable to either quantitative or case-control traits, and includes corrections for cryptic relatedness between samples, and for linkage disequilibrium (LD) between SNPs. For a fixed set of SNPs, let b and b' be vectors of normalized SNP effect sizes for two phenotypes. The genetic correlation between these two phenotypes is defined as r = E[bb']/(Var(b)Var(b'))^(1/2). We estimate E[bb'] by using the estimated effect sizes (i.e. summary statistics) and applying a correction for LD. We estimate Var(b) and Var(b') by using the estimated effect sizes and applying corrections for sampling noise, LD, and cryptic relatedness. Our derivations quantify the impact of both cryptic relatedness and LD on average chi-square statistics, extending the derivation of Yang et al. 2011 Eur J Hum Genet for strictly unrelated samples with LD. Theory and simulations show that the estimates of E[bb'], Var(b) and Var(b') are unbiased, and the resulting estimate of genetic correlation is consistent. Under the infinitesimal model in which true effect sizes are normally distributed, this estimator of genetic correlation is the maximum likelihood estimator. The corrections for LD and cryptic relatedness are based on a reference panel of raw genotypes from the same population, but we evaluate the method's robustness to mismatched reference panels. We validate the method using data from the Wellcome Trust Case Control Consortium, and apply the method to estimate the genetic correlation between mammographic density and breast cancer using summary statistics from over 50,000 samples.

1939F

Derivation of a genome-wide significance threshold for African populations. *M.D. Fortune[1,2], I. Tachmazidou[1], E. Zeggini[1].* 1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) Department of Applied Mathematics and Theoretical Physics, Cambridge, UK.

Genome-wide association studies examine common variation across the genome for association with complex traits of interest. Significance is declared at the widely-accepted threshold of p<5.0E-08. This has been derived from the total number of effective common variant (minor allele frequency (MAF) >0.05) tests in European populations and has been based on HapMap data. As the GWAS field is shifting to the study of more structured and heterogeneous populations, for example of African descent, a new statistical significance level has to be defined. Lower levels of linkage disequilibrium between common variants may necessitate a more stringent threshold. In addition, the availability of sequence data further empowers the assessment of the effective number of independent tests, as common variation has been comprehensively assayed. Many methods exist which exploit the correlation structure, either haplotypic or genotypic, between the variants. We have implemented several of these on two African datasets, Luhya in Webuye, Kenya (LWK) and Yoruba in Ibadan, Nigeria (YRI) , from the 1000 Genomes Project (sequence data, phase I integrated public data release), in order to estimate the effective number of tests for common genetic variation (MAF over 1 or 5%) in African populations. For comparison we also used the Utah residents (CEPH) with Northern and Western European ancestry CEU dataset from the same source. Using the haplotypic correlation coefficients, as proposed by Moskvina and Schmidt resulted in an estimate of 3.0E-8 for the European dataset, and 1.15E-8 for the African datasets at MAF over 5%. The same algorithm at MAF over 1% gave an estimate of 1.5E-8 for the European dataset, 7.0E-9 for LWK and 4.4E-9 for YRI. This reflects the greater genetic variation in present day sub-Saharan African populations.

1940W

Mediating genetic effects using twin data. *A. Ulgen[1], W. Li[2], J. Hjelmborg[3].* 1) Faculty of Medicine, Eastern Mediterranean University, Famagusta, TRNC, Mersin-10-Turkey; 2) Robert S Boas Center for Genomics and Human Genetics, Feinstein Institute for Medical Research, North Shore LIJ Health System, Manhasset, New York, United States of America; 3) Department of Biostatistics, Institute of Public Health, University of Southern Denmark, Odense, Denmark.

We apply a genetic modeling via simulation to twin data for obesity and cancer related measurements. For obesity, we use both BMI and other quantities derived from BMI to measure the weight growth. More specifically, the log(BMI) at baseline is regressed over other factors: ln(BMI_ij)= beta_i + alpha_i *j +gamma*age_i+epsilon_ij, for individual I and timepoint j (time since the baseline, in years). The alpha_i is then the log-weight growth rate (Hjelmborg et al. Obesity, 16(4), 2008). For cancer data, we use phenotypes available in the registry. We follow the genetic modeling of twin data proposed by (Dite et al. and Stone et al; Cancer Epidemiol Biomarkers Prev; 17(12), 2008 and 17(12), 2012, respectively.) In this modeling, the phenotype of a twin in a twin pair is regressed over both twins' co-variates. If the two twins in a twin pair are labeled as 1 and 2, Y denotes phenotype and X covariate, then E(Y)= alpha + beta_1 X_1 +beta_2 X_2. It was shown that by varying a covariate experimentally, the expected value of the phenotype measure would change.In our analysis, we assume a bivariate normal distribution for both (Y1,Y2) and (X1,X2). We treat phenotype measurements such as BMI, growth rate, at the baseline time as X, and that at the later time as Y. This approach would incorporate measurements at two points along a time course, thus enhance the power to detect the genetic component. We also introduce a random effects model for the stratification effects.

1941T

Detecting recent coevolution through ancestry association on different chromosomes in African-Americans. *H. Wang[1], Y. Choi[2], X. Wang[3], B. Tayo[4], U. Brockel[5], C. Hanis[6], S. Kardia[7], S. Redline[8], R. Cooper[4], N. Risch[9], H. Tang[2], X. Zhu[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Biostatistics, Harvard, Boston, MA; 4) Department of Public Health Science, Loyola University Medical Center, Maywood, IL; 5) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 6) Department of Epidemiology, Human Genetics and Environmental Sciences, University of Texas Health Science Center at Houston, Houston, TX; 7) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 8) Department of Medicine, Harvard Medical School, Boston, MA, USA; 9) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA.

Genetic coevolution could be maintained through compensatory mutations over evolutionary history. Recent studies have found evidence of coevolution between physically unlinked genes and loci. We hypothesized that recent allelic coevolution could be detected by examining simultaneous or complementary transmission of ancestry alleles in different genomic regions. This hypothesis can be tested in recently admixed populations such as African Americans. We analyzed the correlations of local ancestry across the genome in 20,097 African Americans sampled from three different study cohorts: CARe, WHI, and FBPP. The ancestral proportions were estimated using HAPMIX and SABER+. Inverse-variance weighted meta-analysis approach was used to combine results from the three study cohorts. Our analysis revealed 79 pairs of genetic regions on different chromosomes which are significantly correlated (p-value < 10-9 in meta-analysis), suggesting possible evidence of coevolution. Several of these regions contain genes previously demonstrate to be under selection such as SLC30A9 and ASPM.

Investigating bias due to population stratification in pharmacogenetic studies. *X. Chen, C. Molony, C. Zhang, H. Zhou.* Informatics and Analysis, Merck , Boston, MA.

It is well known that bias will be introduced in population-based association studies in the presence of population stratification (PS). Failing to control for PS might lead to identification of spurious association signals from ancestry-informative markers, rather than the causal disease loci. However, the impact and magnitude of this confounding by ethnicity remain unclear in the context of pharmacogenetic studies (PGx), where genome-wide associations studies (GWAS) are applied retrospectively on a subset of population from Phase II/III randomized clinical trials to discover genetic biomarkers associated with drug responses. Through using a simulation study design, we systemically investigated the type I error rates and bias in the estimates caused by PS in PGx. Various population substructures and treatment response models were generated to evaluate the bias in main genetic effects and the interactions between gene and treatment effects. Simulation results indicated that it is crucial to perform association analyses within each genetically homogeneous population even in well conducted randomized clinical trials. Otherwise false positive results due to differences in drug response rates across ethnicities were likely to be observed. With respect to the Phase II clinical trials conducted in a mixed population (e.g. African American), the bias due to PS appeared limited when differences of drug response rates among ethnicities are small to moderate. We also demonstrated that applying standard statistical approaches of adjusting ancestral histories can effectively provide unbiased estimations of main genetic effects and genetic by treatment interaction effects in PGx for identifying predictive biomarkers of drug response , while maintaining valid false-positive rates.

Validation of an ancestry estimation analysis method using a comparison of FRAPPE and STRUCTURE. *J.J. Bryan[1], K. Tang[1], R. Kittles[2], C.L. Mouritsen[1].* 1) Sorenson Genomics, 2495 South West Temple Salt Lake City, UT. 84115; 2) University of Chicago 5841 South Maryland Avenue AMB W601 MC6091 Chicago, IL 60637.

An analytical test method for estimating genetic ancestry has been developed wherein 190 Ancestral Informative markers (AIMS) are genotyped and compared to reference populations. This study was performed to ascertain the test's ability to accurately estimate admixture. Ancestry estimation was performed for 44 unrelated, self-declared 'African American' (ASW) samples from the HAPMAP3 dataset using a genome-wide dense marker set (~860k SNPs) to establish the 'true' genetic affinities to 5 reference populations (European, East Asian, India Subcontinent, Indigenous America, and Sub-Saharan Africa). The same set of 44 samples was analyzed again, using the 190 AIMs in our test. For the 190 AIMs, two different statistical programs were independently employed, FRAPPE and STRUCTURE, both recognized for their validity in this type of comparative analysis. Each sample analysis was performed 50x, with a permutation procedure to account for the variability in the reference sample panels. The genetic affinities were thus estimated with well defined confidence intervals. The ancestry estimation results with the 190 AIMs were then compared to that of the high density ~860k set and then to each other. The results showed that our ancestry tests with either method corresponded very well to the data from the ~860k estimations; and strong consistency was also observed between the FRAPPE and STRUCTURE programs. More than 90% of the samples having a comparative r-squared value greater than 0.92 between the two programs. The overall difference between results obtained using FRAPPE and STRUCTURE were minimal, with an average difference between the corresponding ancestry percentages less than 0.2%. These data were further validated using an additional 144 self-declared 'African American' samples, with near equivalent results.

The search for a method that utilizes biological information to predict human's place of origin has occupied scientists for millennia. Modern biogeography methods are accurate to 700 km in Europe but are highly inaccurate elsewhere, particularly in Southeast Asia and Oceania. The accuracy of these methods is bound by the choice of genotyping arrays, the size and quality of the reference dataset, and principal component (PC)-based algorithms. To overcome the first two obstacles, we designed GenoChip, a dedicated genotyping array for genetic anthropology with an unprecedented number of ~12,000 Y-chromosomal and ~3,300 mtDNA SNPs and over 130,000 autosomal and X-chromosomal SNPs carefully chosen to study ancestry without any known health, medical, or phenotypic relevance. We also 615 individuals from 54 worldwide populations collected as part of the Genographic Project and the 1000 Genomes Project. To overcome the last impediment, we developed an admixture-based Geographic Population Structure (GPS) method that infers the biogeography of worldwide individuals down to their village of origin. GPS's accuracy was demonstrated on three data sets: worldwide populations, Southeast Asians and Oceanians, and Sardinians (Italy) using 40,000-130,000 GenoChip markers. GPS correctly placed 80%; of worldwide individuals within their country of origin with an accuracy of 87%; for Asians and Oceanians. Applied to over 200 Sardinians villagers of both sexes, GPS placed a quarter of them within their villages and most of the remaining within 50 km of their villages, allowing us to identify the demographic processes that shaped the Sardinian society. These findings are significantly more accurate than PCA-based approaches. We further demonstrate two GPS applications in tracing the poorly understood biogeographical origin of the Druze and North American (CEU) populations. Our findings demonstrate the potential of the GenoChip array for genetic anthropology. Moreover, the accuracy and power of GPS underscore the promise of admixture-based methods to biogeography and has important ramifications for genetic ancestry testing, forensic and medical sciences, and genetic privacy.

AdmixKJump: Identifying population structure in recently diverged groups. *T. O'Connor*[1,2,3]. 1) Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, Maryland; 2) Division of Endocrinology, Diabetes, and Nutrition, Department of Medicine, University of Maryland School of Medicine, Baltimore, Maryland; 3) Department of Genome Sciences, University of Washington, Seattle, Washington.

Correctly identifying population structure is important both to understand population history and to mitigate the potential for confounding in association analyses. Statistically, recent population divisions can be difficult to recognize, as there has not been substantial time for the groups to differentiate. Objective methods to identify recent population divisions are needed. ADMIXTURE has developed a cross-validation approach to select the correct number of K (i.e. clusters or putative populations), but how this statistic performs on recent population divisions with realistic simulations has yet to be evaluated. Also, alternative approaches from the informatics and statistical literature may be better suited to recent demographic events. I have implemented a new metric for admixture analysis, AdmixKJump, and compared it with the performance of the cross-validation statistic. I use a coalescent simulation framework based on parameters estimated from the Exome Sequencing Project to generate whole genome sequences with multiple populations. I vary the split time between populations to evaluate how accurate each method is in identifying the correct number of clusters over 50 replicates. With a sample size (n) of 50 for each of two populations, the admixture parameters themselves have almost no error at ~6KYA (ie ~1K years prior to the expansion). The cross-validation metric gains 100% power at about 14KYA, whereas AdmixKJump reaches 100% accuracy at 10KYA. I also find that the new measure has more power with smaller sample sizes (testing n=10, 20, ..., 50), for instance n=30 is 100% at 12KYA for AdmixKJump. I then apply the new metric to the results of the Great Apes Project and 1000 Genomes Project. I find comparable results to the cross-validation approach, emphasizing the narrow improvement window of AdmixKJump and the need for future improvements to fully capture the population structure in these data sets. In conclusion, I have developed a new objective approach to identifying population structure, which has more power than previous methods, especially with recent demographic events.

Distribution of genetic ancestry and candidate disease allele frequencies in Puerto Rico. *Y. Afanador*[1], *I. Rivera*[1], *W. Guiblet*[1], *LGDS. Consortium*[1], *M. Yeager*[2], *V. Washington*[3], *J.C. Martinez-Cruzado*[1], *T. Oleksyk*[1]. 1) Biology, University of Puerto Rico, Mayaguez Campus, Mayaguez, PR; 2) Frederick National Laboratory for Cancer Research, Frederick, MD; 3) Biology, University of Puerto Rico, Rio Piedras Campus, San Juan, PR.

In modern human populations, sensitivity to complex diseases is often determined by past demographic events, selection, and admixture. Puerto Ricans are an excellent model to understand this relationship as they acquired characteristics from three ancestral origins: African, European, and Native American. We are using a geographically distributed random sample of reference from each of the 78 municipalities of Puerto Rico collected by undergraduate students from a NSF funded educational curriculum, the Local Genome Diversity Studies (LGDS). This study provides estimates for individual ancestry proportions across the island. Different admixture contributions carry different disease alleles that can account for prevalence of diseases that are on the top of the list of death causes in the Island: diabetes, kidney disease, heart disease, and cancer. Candidate genes for these diseases are being studied for their association with ancestry as well as the disease occurrence in the general population compared to the patients. For example, preliminary analysis of candidate gene polymorphisms for the end stage kidney disease (ESKD) patients from the island showed significant differences in frequencies of some disease-relevant variants, specifically in the NPHS2, ATF6, and ENPP1 genes when compared with the reference population, and the geographical distribution of the risk alleles shows a pattern consistent with the history of admixture across the island. These results demonstrate the importance of history and geography of admixture to the pubic health and personalized medicine decisions. Funding for this study came in part from NSF grant: DUE 1044714 TUES: Integration of Research and Undergraduate Education: Local Genome Diversity Studies in Puerto Rico.

Allelic Frequency Determination of Asthma-Related Single Nucleotide Polymorphisms and the Relation of Genetic Admixture in Asthma disease Prevalence among Puerto Ricans. *I. Rivera*[1], *Y. Afanador*[1], *C. Garcia*[1], *W. Guiblet*[1], *E. Suárez*[2], *J.C. Martinez-Cruzado*[1], *T.K. Oleksyk*[1], *Local Genome Diversity Studies.* 1) Biology Dept, University of Puerto Rico, Mayaguez Campus, Mayaguez, PR; 2) Biology Dept, University of Puerto Rico, Ponce Campus, Ponce PR.

Asthma is one of the most recognized complex human disorders characterized by an airway obstruction due to an exacerbated immune response. Currently, asthma is estimated to affect more than 235 million people worldwide with an annual cost of around $115 billion. In Puerto Rico asthma prevalence has been estimated to be 15% from 2000-2007, reaching an alarming 20% in 2003, making Puerto Ricans one of the populations with the highest asthma prevalence worldwide. Since asthma is more frequently seen in populations from African descent (around 12-14% Afro-Americans) and Puerto Ricans share on average 21% African ancestry, it has been suggested that an admixture factor might be involved. In order to evaluate this hypothesis, two sets of samples were collected: 1) a set of asthma-diagnosed patients; and 2) a systematically collected random sample set of individuals representing all 78 municipalities of the island: the Local Genome Diversity Studies cohort (LGDS). We assayed the allelic frequency of candidate asthma-related single nucleotide polymorphisms (SNPs) in patients and compared them to the general population reference samples from the LGDS cohort. In order to evaluate an additional admixture component that might contribute to asthma occurrence, we further analyzed the admixture proportions of African, European and Native American ancestry using a panel of ancestry informative markers (AIMs). Our results help validate previous studies in genetically diverse Hispanic populations, and indicate the potential for novel ancestry-related candidate gene polymorphisms that correlate with asthma occurrence in Puerto Rican population. Funding for this study came in part from NSF grant: **DUE 1044714** *TUES*: *Integration of Research and Undergraduate Education: Local Genome Diversity Studies in Puerto Rico* .

Evidence for interaction of population-specific EFHC1 alleles with genetic ancestry in juvenile myoclonic epilepsy. *R.L. Subaran*[1], *J.M. Conte*[2], *W.C.L. Sterart*[1], *D.A.G. Greenberg*[1]. 1) Research Institute, Columbus, OH. Nationwide Children's Hospital; 2) Columbia University, New York, NY. Mailman School of Public Health.

Missense mutations in the EFHC1 gene have been reported to cause juvenile myoclonic epilepsy (JME) with high penetrance in patients reporting Hispanic ancestry. However, observations from other studies call into question the magnitude and scope of this effect. To help probe the relationship of EFHC1 to JME, we examine the frequency of these mutations in a group of Hispanics identified in New York City and in participants from non-Hispanic populations. We screened 117 healthy controls (60 Hispanic, 57 non-Hispanic of various ethnicities) for EFHC1 mutations purported to cause JME in Hispanics. To search for novel pathogenic mutations, we sequenced the exons of EFHC1 in a newly ascertained group of Hispanic JME patients. We compared our findings to the frequencies found in 1KGP. The EFHC1 coding mutations we found in our patients were also found in our controls except for a novel splice-donor mutation carried by a single JME patient. Of the five coding mutations previously reported to cause JME with high-penetrance, we found three at appreciable frequencies in our non-Hispanic controls and in the non-Hispanic participants of the 1KGP. In general, EFHC1 coding mutations are not a major cause of JME in Hispanics. However, ascertaining specific Hispanic subpopulations on the basis of JME causes enrichment of EFHC1 alleles seen otherwise only in non-Hispanic populations, suggesting a hypersensitivity to disruption of EFHC1 in these Hispanic subpopulations. Importantly, our findings help shed light on the nature of this effect on a common disorder in a historically understudied population.

1949W

Genomic scans for haplotypes of Denisova and Neanderthal ancestry in modern human populations. *F.L. Mendez, M.F. Hammer.* University of Arizona, Tucson, AZ., USA.

Evidence of archaic introgression into modern humans has accumulated in recent years. While most efforts to characterize the introgression process have relied on genome averages, only a small number of introgressive haplotypes have been shown to have an archaic origin after rejection of the alternative hypothesis of incomplete lineage sorting. Accurate identification of introgressive haplotypes is crucial both to characterize potentially functional consequences of archaic admixture and to quantify more precisely the genomic impact of archaic introgression. We perform two independent genomic scans for haplotypes of Denisova and of Neanderthal origin in a geographically diverse sample of complete genome sequences. These scans are based on the local sharing of polymorphisms and linkage disequilibrium, respectively. The analysis of concordance between the methods is then used to estimate the power and to compare demographic inference when performed using either all the data or just the genomic regions with no evidence of introgression. Moreover, we evaluate the extent to which Denisova haplotypes are observed in non-Melanesian populations, and investigate whether the presence of such haplotypes is better explained by their persistence in the population since introgression or by more recent gene flow from Melanesians.

1950T

Admixture Estimation in a Founder Population. *Y. Banda[1], M. Kvale[1], T. Hoffmann[1], S. Hesselson[1], H. Tang[3], D. Ranatunga[2], L. Walter[2], C. Schaefer[2], P. Kwok[1], N. Risch[1].* 1) Institute Human Genetics, University California San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California, Division of Research, Oakland, CA; 3) Department of Genetics, Stanford University, Stanford, CA.

Admixture between previously diverged populations yields patterns of genetic variation that can aid in understanding migrations and natural selection. An understanding of individual admixture (IA) is also important when conducting association studies in admixed populations. However, genetic drift, in combination with shallow allele frequency differences between ancestral populations, can make admixture estimation by the usual methods challenging. We have, therefore, developed a simple but robust method for ancestry estimation using a linear model to estimate allele frequencies in the admixed individual or sample as a function of ancestral allele frequencies. The model works well because it allows for random fluctuation in the observed allele frequencies from the expected frequencies based on the admixture estimation. We present results involving 3,366 Ashkenazi Jews (AJ) who are part of the Kaiser Permanente Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort and genotyped at 674,000 SNPs, and compare them to the results of identical analyses for 2,768 GERA African Americans (AA). For the analysis of the AJ, we included surrogate Middle Eastern, Italian, French, Russian, and Caucasus subgroups to represent the ancestral populations. For the African Americans, we used surrogate Africans and Northern Europeans as ancestors. For the AJ, we estimated mean ancestral proportions of 0.380, 0.305, 0.113, 0.041 and 0.148 for Middle Eastern, Italian, French, Russian and Caucasus ancestry, respectively. For the African Americans, we obtained estimated means of 0.745 and 0.248 for African and European ancestry, respectively. We also noted considerably less variation in the individual admixture proportions for the AJ (s.d. = .02 to .05) compared to the AA (s.d.= .15), consistent with an older age of admixture for the former. From the linear model regression analysis on the entire population, we also obtain estimates of goodness of fit by r2. For the analysis of AJ, the r2 was 0.977; for the analysis of the AA, the r2 was 0.994, suggesting that genetic drift has played a more prominent role in determining the AJ allele frequencies. This was confirmed by examination of the distribution of differences for the observed versus predicted allele frequencies. As compared to the African Americans, the AJ differences were significantly larger, and presented some outliers which may have been the target of selection (e.g. in the HLA region on chromosome 6p).
