American Society of Human Genetics 63rd Annual Meeting
October 22–26, 2013 Boston

POSTER ABSTRACTS

The program and abstract/poster board number next to each listing is followed by a **W** (Wednesday), or **T** (Thursday), or **F** (Friday) to indicate the day on which authors must be present at their poster boards. Posters will remain on the boards for all three days (Wednesday through Friday).

Session Topic/Title	*Abstract/Poster Board Numbers Start #*	*End #*
Epigenetics	412	511
Genome Structure, Variation and Function	512	694
Pharmacogenetics	695	743
Complex Traits and Polygenic Disorders	744	1180
Psychiatric Genetics, Neurogenetics and Neurodegeneration	1181	1430
Bioinformatics and Genomic Technology	1431	1693
Statistical Genetics and Genetic Epidemiology	1694	1942
Evolutionary and Population Genetics	1943	2105
Cardiovascular Genetics	2106	2260
Therapy for Genetic Disorders	2261	2312
Metabolic Disorders	2313	2406
Genetics/Genomics Education	2407	2424
Ethical, Legal, Social and Policy Issues in Genetics	2425	2476
Genetic Counseling	2477	2500
Health Services Research	2501	2521
Clinical Genetic Testing	2522	2639
Clinical Genetics and Dysmorphology	2640	2816
Prenatal, Perinatal and Reproductive Genetics	2817	2884
Molecular Basis of Mendelian Disorders	2885	3160
Development	3161	3187
Cytogenetics	3188	3257
Cancer Genetics	3258	3507

Posters should remain on the board for all three days (Wednesday through Friday)

POSTER AUTHOR SCHEDULE

The program and abstract/poster board number next to each listing is followed by a **W** (Wednesday), **T** (Thursday), or **F** (Friday) to indicate the day on which authors must be present at their poster boards. Refer to the schedule below for presentation times and for the poster mounting/removal schedule. **Posters should remain on the boards for all three days.**

Wednesday

10:00 am–10:30 am	Authors place posters on boards
10:00 am–6:00 pm	Posters open for viewing
10:30 am–12:30 pm	**Poster Session I (W)**
	10:30 am–11:30 am (*odd poster board numbers; author must be present*)
	11:30 am–12:30 pm (*even poster board numbers; author must be present*)

Thursday

10:00 am–4:30 pm	Posters open for viewing
10:30 am–12:30 pm	**Poster Session II (T)**
	10:30 am–11:30 am (*odd poster board numbers; author must be present*)
	11:30 am–12:30 pm (*even poster board numbers; author must be present*)

Friday

10:00 am–2:00 pm	Posters open for viewing
10:30 am–12:30 pm	**Poster Session III (F)**
	10:30 am–11:30 am (*odd poster board numbers; author must be present*)
	11:30 am–12:30 pm (*even poster board numbers; author must be present*)
2:00 pm–2:30 pm	**Authors must remove posters**
2:30 pm	Exhibit Hall and Posters closed

Quality Control and Data Normalisation in large Illumina Infinium HumanMethylation450 Datasets. *A. Drong[1], B. Lehne[2], M. Loh[2,3], C. Blancher[1], M.-R. Jarvelin[2,3,4,5], C.M. Lindgren[1], P. Elliott[2,4], M.I. McCarthy[1,6], J.S. Kooner[7], J.C. Chambers[2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Epidemiology and Biostatistics, Imperial College London, London, United Kingdom; 3) 3Institute of Health Sciences, University of Oulu, Oulu, Finland; 4) 4MRC-HPA Centre for Environment and Health, Imperial College London, London, United Kingdom; 5) National Institute of Health and Welfare, University of Oulu, Oulu, Finland; 6) Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 7) National Heart and Lung Institute, Imperial College London, London, United Kingdom.

Objectives: We aimed to develop methodology for epigenome-wide association studies (EWAS) of DNA methylation. This includes assessments and optimisation of current approaches for data preprocessing for use on large-scale datasets (N>2,000). Methods: The EpiMigrant DNA methylation data set was generated using the Illumina HM450 platform and includes baseline DNA samples of non-diabetic South Asians (N=2,687), approximately half of whom went on to develop diabetes. Of these samples, 36 were measured in duplicate to constitute the replication subset. We filtered methylation scores by a Bonferroni-corrected detection p-value, cutoff, instead of the default value of p<0.05. As a metric of performance, we used the count of false methylation calls on the Y chromosome in females. To test whether results were valid for autosomal markers, we compared the autosomal per-marker call rate to the rate of outliers (beta > 1.5 inter-quartile range). We then assessed two different methods for normalisation of methylation scores across arrays using the probe- wise correlation between duplicates in the technical replication dataset: QN1, quantile normalisation on Beta values, separated by probe type and colour channel into three categories and QN2, quantile normalisation on intensity values, further separated by methylated or unmethylated targets into six categories. Results:. We find that using the Bonferroni-corrected threshold (p<10-16 in our dataset) reduces the number of false methylation calls on the Y chromosome in females. Remaining intensity signals can be explained by probes cross-hybridizing to autosomal regions. For autosomal markers, using a lower detection p-value cutoff decreases the outlier rate, while only filtering 0.4% of markers. We find that before normalisation, only 9.9% of markers show high correlation (r>=0.8) between the two duplicates. QN1 increases this proportion to 10.6%, while QN 2 leads to 21.8% of probes reproducing (r>=0.8). The remaining high percentage of weakly performing probes can be explained by experimental variation exceeding inter-individual variation in methylation. These invariant markers are also unlikely to give rise to an association signal. Conclusion: We conclude that any analysis of large-scale EWAS data should be based on probes filtered for a Bonferroni-corrected detection p-value. To further increase data quality, we recommend separate quantile normalisation on intensities of the six different probe categories.

413F

Integrating genotype, methylome, chromatin states and disease state in a cohort of 750 individuals. *M.L. Eaton[1], G. Srivastava[2], A. Kundaje[1], L.B. Chibnik[2], B.T. Keenan[2], J. Ernst[3], D. Bennett[4], B. Bernstein[5], P. DeJager[2], M. Kellis[1].* 1) CSAIL, MIT, Cambridge, MA; 2) Neurosciences Institute, Brigham & Women's Hospital, Boston, MA; 3) UCLA, Los Angeles, CA; 4) Rush University Medical Center, Chicago, IL; 5) Massachusetts General Hospital, Boston, MA.

While the methodological framework for relating genotype to disease has been well established through the development of genome-wide association studies, the incorporation of intermediate molecular phenotypes such as DNA methylation and histone modifications into disease studies remains largely unexplored. Using a cohort of 750 individuals, half of whom were diagnosed with Alzheimer's Disease (AD), we sought to address the relationship between genotype, methylation status, chromatin state, and disease. Our first challenge was to nullify DNA methylation variability not attributable to genotype or AD, as several covariates confound this relationship including gender, batch and cell type tissue heterogeneity. We used methods including ICA and non-negative least squares to computationally remove this variation. We were then able to discover ~55K CpG probes with detectable genotype associations in cis (~12% of the array). These CpGs are preferentially located in enhancers and underrepresented in promoters based on a chromatin map generated by chromHMM on 7 histone marks of a matched brain region, suggesting distinct regulatory architectures. In associating DNA methylation changes with Alzheimer's disease, we found a pervasive signal of small effect size, robustly enriched for distal enhancer regions. Moreover, by linking the distal enhancers to the genes they regulate by correlating chromatin with gene expression, we found robust concentrations of associated CpGs in certain neuron- and signaling-specific gene pathways. Interestingly, disease-associated CpGs were enriched for meQTLs of weak effect but depleted for meQTLs of strong effect even after permutation, arguing further for a model of many loci of weak effect contributing overall to a disease onset burden. Overall, our results suggest that global regulatory changes are associated with complex disease, and suggest a general methodology for integration of genetic and epigenetic variation in the context of human disease.

414T

Epigenome-wide DNA methylation study reveals hypermethylated collagen genes and suggests a role for TGFβ in osteoarthritis. *M.A. Jeffries[1,2], J.A. James[2], A.H. Sawalha[3].* 1) Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Arthritis & Immunology, OMRF, Oklahoma City, OK; 3) Rheumatology, University of Michigan, Ann Arbor, MI.

Background: Osteoarthritis (OA) is the leading cause of chronic disability in the U.S., affecting 40% of individuals over the age of 70 and costing $128 billion annually in the US alone. Late-stage OA chondrocytes exhibit a host of gene transcription changes leading to upregulation of enzymes that contribute to cartilage breakdown. Herein, we characterize epigenome-wide DNA methylation changes in osteoarthritic compared to healthy cartilage from the same joints. Methods: Articular cartilage tissue from 12 OA femoral heads was dissected from affected and normal areas, frozen in liquid nitrogen, and DNA extracted. Following sodium bisulfite-treatment, DNA methylation was quantified at >485,000 CpG sites across the genome using Illumina HumanMethylation450 arrays. CpG sites with an absolute methylation difference between OA and normal cartilage ($\Delta\beta$) $\geq$ 15%, and P <0.01 after correction for multiple testing using a false discovery rate of 5%, were considered significant and used for analysis. Results: We found 442 differentially methylated CpG sites: 260 hypo- and 182 hypermethylated. Overrepresented gene sets included 'Connective tissue disorder' (n=53, p=4.73E-6 to 7.36E-3), 'Developmental disorder' (n=44, p=4.73E−6 to 7.36E−3), and 'Skeletal & muscular disorder' (n=59, p=4.73E−6 to 7.36E−3). Interesting DM in OA include hypermethylation of COL11A2, which functions to maintain spacing and diameter of type II collagen and is mutated in patients with Stickler syndrome and OSMED. Additionally, we found hypermethylation of COL6A2, hypomethylation of the fibrillar collagen gene COL1A1, and hypermethylation of COL18A1. Hypermethylation was also noted within the WNT pathway coreceptor LRP5, associated with OA in mice and is a susceptibility gene for OA in humans. Hypomethylation was found in the transcription factor RUNX1. Upstream regulator analysis identified significant association of TGFβ1 with 44 differentially methylated genes. Finally, canonical pathway analysis identified enrichment of several pathways, most prominently the ERK signaling pathway among differentially methylated genes (p=1.51E−4). Conclusions: We detected methylation changes in multiple collagen genes in OA. Our data suggest an epigenetic basis for defective collagen production in OA. Furthermore, we found evidence for epigenetic dysregulation of WNT signaling, and enrichment of genes associated with TGFβ- and ERK-pathway signaling, both are enticing targets for OA.

415F

Genome-wide profiling of DNA from blood reveals regions differently methylated in osteoarthritis patients. *G. Zhai, E. Aref Eshghi, H. Zhang, G. Martin, A. Furey, R. Green, G. Sun, P. Rahman.* Discipline of Genetics, Fac Med, Memorial Univ Newfoundland, St John's, NL, Canada.

Background: Osteoarthritis (OA) represents the most common form of arthritis and has substantial clinical and economic impact. Although recent studies have identified numerous genetic loci associated with OA, many of the risk factors for OA remain unexplained. We hypothesize that epigenetic mechanisms are responsible for the missing heritability in OA and tested our hypothesis using an epigenome-wide association approach. Methods: A total of 17 patients having knee- or hip-joint replacement due to primary OA and 24 healthy controls participated in this study. DNA was extracted from blood. DNA methylation profiling was performed using the Illumina Infinium HumanMethylation 450k chip, which measures about 480,000 different CpG sites covering 96% of RefSeq genes. It provides comprehensive gene region coverage, targeting multiple sites including the promoter, 5' UTR, 1st exon, gene body and 3' UTR. The methylation level at each CpG site was measured by β values varying from 0 (no methylation) to 1 (100% methylation). The significance level was defined as $p < 1.3 \times 10{-}7$, after Bonferroni correction for multiple testing. Results: We found 539 individual CpG sites significantly associated with OA, with a mean difference in methylation level of >10%. Among them, 516 were hypermethylated and 23 were hypomethylated in OA patients. These individual CpG sites represent 322 independent gene regions. Although methylation patterns may be tissue specific, 15 of the CpG regions that we identified were recently found to also be differentially methylated in articular chondrocytes from OA patients (Ann Rheum Dis 2013 Mar 16). Conclusion: We demonstrate that DNA methylation pattern in blood permit differ between OA patients and healthy controls. This may be valuable for identifying those at high risk for OA and the development of effective treatment for OA.

Diurnal Rhythms of Clock Gene DNA Methylation and their Relationship to Rhythms of Clock Gene Expression in the Human Cerebral Cortex.
A.S. Lim[1], G.P. Srivastava[2,3], L. Yu[4], A.S. Buchman[4], J.A. Schneider[4], A.J. Myers[5], D.A. Bennett[4], P.L. De Jager[2,3]. 1) Division of Neurology, Sunnybrook Health Sciences Centre, University of Toronto, Toronto, Ontario, Canada; 2) Department of Neurology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, IL; 5) Department of Psychiatry, University of Miami, Miami, FL.

BACKGROUND: The mammalian circadian clock is regulated by a highly conserved series of 'clock' genes participating in a near 24-h transcription-translation negative feedback loop. Recent work in Neurospora has suggested that rhythms of DNA methylation in or near clock genes may play a role in regulating the core circadian clock. However, whether such rhythms are also present in human tissues, and how they relate to clock gene expression, is uncertain. METHODS: We quantified DNA methylation at 128 CpG sites in or near 6 canonical clock genes - PER2, PER3, CRY1, CRY2, ARNTL, and CLOCK - using Illumina Infinium HumanMethylation450 microarray data from dorsolateral prefrontal cortex samples from 753 deceased individuals in 2 cohort studies of older individuals, the Religious Orders Study and the Rush Memory and Aging Project. We quantified transcript abundance for these genes using Illumina Human HT-12 Expression microarray data from a subset of 490 of these individuals. Transcript abundance and methylation level at each CpG site was parameterized as a function of time of death using cosine curves. RESULTS: Significant daily rhythms of methylation were seen in 63/128 CpG sites ($p<0.05$), and in the expression of PER2 ($p=3.1\times10^{-4}$), PER3 ($p=2.5\times10^{-4}$), CRY1 ($p=7.0\times10^{-4}$), ARNTL ($p=5.9\times10^{-5}$), and CLOCK ($p=7.3\times10^{-3}$) with the timings of peak transcript abundance mirroring those seen in other diurnal mammals. The timing of the nadir of methylation was site specific. For rhythmic CpG sites within the gene body, the timing of the nadir of methylation clustered between 16:00 and 22:00, irrespective of the timing of transcript abundance. However, for sites upstream of the promoter region and in the 5'UTR, the timing of the nadir of methylation was roughly in-phase with the timing of peak abundance of the corresponding transcript showing temporal correlation between hypomethylation and expression. Finally, significant sex differences were seen, with transcript abundance peaking later in men than in women for all 5 rhythmic clock genes, and the nadir of methylation occurring later in men than in women for 22 of the 63 rhythmic CpG sites. CONCLUSIONS: There are site-specific diurnal rhythms of DNA methylation in and near canonical clock genes, with characteristic site-specific phase relationships to transcript abundance and to global circadian rhythms. Rhythms of DNA methylation may play a role in the regulation of the circadian clock in human cerebral cortex.

DNA methylation analysis of human neuronal and non-neuronal cells at the base pair resolution.
J. Ueda[1], M. Bundo[2], F. Sunaga[2], M. Nishioka[2,3], E. Hashimoto[4], W. Ukai[4], T. Saito[4], K. Kasai[3], K. Iwamoto[2], T. Kato[1]. 1) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute, Wako, Japan; 2) Department of Molecular Psychiatry, Graduate School of Medicine, The University of Tokyo,Tokyo, Japan; 3) Department of Neuropsychiatry, Graduate School of Medicine, The University of Tokyo, , Tokyo, Japan; 4) Department of Neuropsychiatry, School of Medicine, Sapporo Medical University, Sapporo, JAPAN.

Epigenome information such as DNA methylation and histone modification in the human brain cells reflects their developmental history, neuronal activity, and environmental exposures. Studying the epigenetic modifications in the brain cells is critical to understanding of the role of the genome in brain functions, as well as the pathophysiology of psychiatric disorders. We have previously revealed distinctive DNA methylation patterns of neuronal and non-neuronal cells, those were derived by neuronal marker-based nuclei sorting technique, with promoter-wide tiling arrays. Here we extended our DNA methylation study at the base pair resolution using whole genome-bisulfite sequencing (WGBS). Neuronal and non-neuronal genomic DNA derived from a postmortem prefrontal cortex of subject with no neuropsychiatric disorders was used for bisulfite modification. We obtained 939 and 784 million paired-end reads from sequencing of neuronal and non-neuronal cells, respectively. After mapping with Bismark software, average coverage on CpG sites were 23X for neuronal cells and 17X for non-neuronal cells. Gene Ontology analysis of differentially methylated CpGs between neurons and non-neurons revealed that hyper-methylated genes in neurons compared to non-neurons were enriched to the GTPase and signal transduction-related terms. Strikingly, hypo-methylated genes in neurons compared to non-neurons were enriched to the synapse-related terms. In addition, by comparing DNA methylation data obtained from different platforms including tiling array, reduced representation bisulfite sequencing (RRBS), Illumina HumanMethylation450, and WGBS, we identified characteristics and advantage of each platform.

418T

Methylation of Leukocyte DNA and Ovarian Cancer: Relationship with Disease Status and Outcome.
B. Fridley[1], S. Armasu[2], M. Cicek[2], K. Kalli[2], M. Larson[2], D. Koestler[3], D. Rider[2], V. Shridhar[2], J. Olson[2], J. Cunningham[2], E. Goode[2]. 1) University of Kansas Medical Center, Kansas City, KS, USA; 2) Mayo Clinic, Rochester, MN, USA; 3) Dartmouth College, Lebanon, NH, USA.

We hypothesize that DNA methylation (DNAm) in leukocytes of epithelial ovarian cancer (EOC) cases and controls may differ and that, among cases, this DNAm may vary by disease outcome. Thus, we performed case-control and survival analyses using 336 EOC cases and 398 controls (3 experimental batches) with blood-based DNAm assayed with the Illumina Infinium HumanMethylation27 or 450 BeadChips. To limit spurious results, we limited analysis to CpG probes measured on both arrays, and we removed non-specific probes and probes associated with distributions of white blood cell types. The association of the DNAm levels for 24,520 CpG sites with disease status and overall survival (OS) was completed using linear and Cox-proportional hazards models. Meta-analysis across three batches was completed using a random effect meta-analysis. The top association between DNAm and case-control status was observed for CpG cg04834572 near DUSP13 ($p=1.6\times10^{-14}$, individual batch p range from 2.1×10^{-4} to 1.1×10^{-6}). The top pathway enriched, based on Fisher's Exact test, was the telomerase signaling ($p=1.24\times10^{-3}$). This pathway and variants in TERT have been found to be associated with the development of many cancers, including EOC. TERT has an extensive role in the maintenance of functional telomeres which are important in the protection of chromosomes from DNA damage. The top CpG sites associated with OS were: cg10276549 near GABRE ($p = 5.8\times10^{-5}$); cg06171242 near ACOT13 and TTRAP ($p=4.4\times10^{-4}$); and cg14360897 near RNF167 and SLC25A11 ($p=5.9\times10^{-4}$). The most enriched pathways were: relaxin signaling ($p=7.09\times10^{-5}$) and CXCR4 signaling ($p=1.25\times10^{-4}$) and IL-8 signaling ($p=3.05\times10^{-4}$), all containing GNB1, GNA12, and PIK3R4. GNA12 has been found to be associated with response to platinum/taxane combination therapy, while PIK3R4 is a member of the phosphoinositide 3-kinases family which is involved in multiple cell functions, including proliferation and cell survival. Via a CpG-by-CpG approach accounting for CpGs known to correlate with white blood cell types, we identified genes with differential DNAm signals by EOC disease status and OS. Although pre-treatment case samples were used, a study limitation is the lack of prediagnostic blood samples for EOC. Thus, we are unable to conclude that the CpGs are involved in disease etiology. Future research is needed to functionally determine the biological and epigenetic relevance of the detected CpG sites associated with EOC status and OS.

419F

The combination of genome wide screening and DNA methylation in the determination of bio-marker discovery in ovarian and breast cancer.
M. Poulin, A. Meyer, L. Yan. EpigenDx, Hopkinton, MA.

The association of genetic abnormalities and specific cancers is leading to an increasing number of bio-markers that can be used for early detection of cancers, determination of treatment protocols and predicted prognoses. Additionally, the methylation state of an increasing number of genes is also producing possible predictive bio-markers for specific cancers and stages of cancer as well. To this end, we have analyzed both breast and ovarian cancers and their normal adjacent tissue using both DNA methylation analysis and genome wide array screening for LOH and copy number variations. The combination of these two methods has yielded several groupings of markers that are cancer specific as well as showing specificity for the specific tumor type. We will present the results of the combination of the genome wide analysis and DNA methylation results that may be used in combination to produce potential biomarkers for these two cancer types.

420T

Independent contribution of epigenetic modifications within lipoprotein metabolism genes to plasma lipid profile variability. *S.P. Guay[1,2], D. Brisson[2,3], B. Lamarche[4], D. Gaudet[2,3], L. Bouchard[1,2].* 1) Department of Biochemistry, Université de Sherbrooke, Sherbrooke, Qc, Canada; 2) ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Saguenay, Qc, Canada; 3) Department of Medicine, Université de Montréal, Montréal, Qc, Canada; 4) Institute of Nutrition and Functional Foods, Université Laval, Québec, Qc, Canada.

Background: Inheritance plays a central role in the determination of plasma levels of lipids by explaining up to 60% of the interindividual variability. However, the gene polymorphisms identified so far explain less than 25% of the heritability of plasma lipid levels. Recent studies suggest that epigenetic modifications (DNA methylation), a non-traditional hereditary factor, could explain a significant proportion of the missing heritability of complex traits, such as plasma lipid levels. **Objective:** To assess whether the DNA methylation of key genes of the lipoprotein metabolism is associated with changes in fasting plasma lipid levels (high-density lipoprotein cholesterol (HDL C), low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG)) in patients with familial hypercholesterolemia (FH) carrying the same *LDLR* mutation (p.W66R). **Methods/Results:** In the current study, 98 untreated FH patients (61 men and 37 women) were recruited. Blood DNA methylation levels were measured at the *ABCA1*, *ABCG1*, *CETP*, *LCAT*, *LDLR*, *LIPC*, *LPL*, *PLTP* and *SCARB1* gene loci using bisulfite pyrosequencing. Partial Pearson's correlation analysis showed that DNA methylation levels at the *ABCA1*, *ABCG1*, *CETP*, *LIPC*, *LPL* and *PLTP* gene loci were significantly associated with HDL-C, LDL-C and/or TG levels in a sex-specific manner in FH (all p<0.05). Multivariate linear regression models showed that conventional predictors of the plasma lipid profile (age, anthropometric measurements, blood pressure and fasting glucose levels) explained 33.7% of HDL-C, 17.5% of LDL-C and 26.1% of TG level variability in men (all p<0.001), and 11.4% of HDL-C, 10.7% of LDL-C and 29.3% of TG level variability in women (all p<0.02). When epivariants were added to the statistical models, the variance explained by the combination of conventional and epigenetic factors was found to be increased for both sexes (49.9% for HDL-C, 38.2% for LDL-C and 33.0% for TG levels in men (all p<0.001), and 16.8% for HDL-C, 16.9% for LDL-C and 41.8% for TG levels in women (all p<0.02)). Together, these epivariants independently explained up to 15.8% of HDL-C, 24.0% of LDL-C and 17.4% of TG level variability in FH (all p<0.02). **Conclusion:** These results suggest that epigenetic perturbations of key lipoprotein metabolism genes are associated with fasting HDL-C, LDL-C and TG levels and might contribute to explain the interindividual variability as well as the missing heritability of plasma lipid levels among FH subjects.

421F

Abberant CpG island methylation of Caspase-3 gene in Uterine Leiomyomas. *S. Vaidya[1,2], K. Prabhakar Rao[2], Q. Hasan[1,2], N.A. Shaik[3].* 1) Genetics, Kamineni Hospitals, Hyderabad, Hyderabad, India; 2) Department Of Genetics,Osmania University, Hyderabad,india; 3) Department of Genetic Medicine & Princess Al-Jawhara Al-Brahim Centre of Excellence in Research of Hereditary Disorders (PACER-HD).

Uterine Leiomyomas are one of the commonly seen benign growths of reproductive-age group women. These tumors are often associated with excessive bleeding, pelvic pain, infertility, and pregnancy complications in affected women. Role of hormones, genes and environmental factors highlights the multifactorial nature of these complex tumors. Although, numerous genetic alterations are closely associated with the pathogenesis of uterine leiomayomas, the underlying DNA methylation patterns have not been extensively studied in developing these reccurent tumors. Hence, to investigate if epigenetic factors could explain the significant deviations in apoptosis mechanisms, we have examined the methylation status of key apoptotic factors such as Bcl2 and Caspase-3 genes in the pathogenesis of leiomyomas collected from 200 uterine hysterectomies. Using Methylation Specific Restriction Assay, methylation status of P2 promoter region (–1001 to –690) of BCL2 gene and intronic CpG island of Caspase-3 genes were determined for both Leiomyoma and matched myometrium tissues. There were 22 CpG sites in the 312 bp fragment of Bcl2 and 10 CpG sites in the 174 bp Caspase-3 amplicons we have analyzed. Our results have showed that Caspase-3 intronic CpG island is hypomethylated by 2.6 folds in leiomyomas against adjacent myometrium tissues [P = 0.006; OR 2.629 ,95 % CI (1.290 - 5.398)], whereas, Bcl2 gene showed no changes in its methylation pattern [P = 1.000 ; OR 1.000,95 % CI (0.537 - 1.864]. The present data indicate the upregulation of Caspase-3 expression in fibroids suggesting dysregulated apoptotic process in these solid tumors. Furthermore, DNA methylation changes may not be playing a role for overexpression of Bcl2, which is known factor in the development of resistance to apoptosis in UL.

422T

DNA methylation profiling of preeclamptic placentas reveals distinct subgroups. *S.L. Wilson[1,2], J.D. Blair[1,2], C.W. Hanna[1,2], P. von Dadelszen[2,4], S. Langlois[1], D.E. McFadden[2,3], W.P. Robinson[1,2].* 1) Department of Medical Genetics, The University of British Columbia. Vancouver, BC,CA; 2) Child and Family Research Institute. 950W 28th Ave. V5Z 4H4, Vancouver, BC,CA; 3) Department of Pathology, The University of British Columbia. Vancouver,BC,CA; 4) Department of Obstetrics and Gynecology, The University of British Columbia. Vancouver,BC,CA.

Preeclampsia is a leading cause of maternal and perinatal death worldwide, complicating 2-8% of pregnancies. Early-onset preeclampsia (EOPET) arising prior to 34 weeks gestation tends to be more severe and associated with greater placental changes, as compared to late-onset preeclampsia (LOPET) arising after 34 weeks gestation. Intrauterine growth restriction (IUGR) often occurs conjunctively with preeclampsia and it has been suggested that normotensive IUGR (nIUGR) may be caused by similar placental malfunction. Recently, we showed extensive DNA methylation differences in EOPET placentas in comparison to controls. We hypothesized that some DNA methylation changes associated with EOPET placentas may overlap with LOPET and nIUGR associated placentas, but that these groups will also show unique signatures indicating distinct etiologies. The Illumina Infinium HumanMethylation450 BeadChip was used to investigate DNA methylation at greater than 485,000 CpG sites in chorionic villi from placentas associated with EOPET (N=20), LOPET (N=19), normotensive IUGR (N=15) and gestational-age and sex matched controls (N=47). Principal component analysis showed a major effect of gestational age, however, EOPET placentas also clustered distinctly from controls. Interestingly, the LOPET samples with conjunctive IUGR (N=11) clustered separately from those without IUGR (N= 8), the latter of which overlapped controls. The nIUGR group also clustered with the controls. When considering each subgroup compared to gestational-age and sex matched controls separately with a false discovery rate <5% and DNA methylation difference of >5% EOPET showed widespread DNA methylation changes. Fewer significant changes were noted in LOPET with IUGR. CpGs in 102 genes including ECE1 and CYP1A2 were found to be differentially methylated. No significantly different CpGs were identified when comparing nIUGR or LOPET without IUGR to controls. This study provides evidence that EOPET, LOPET, nIUGR, and compound LOPET & IUGR associated placentas have distinct molecular profiles. Further investigation into the differential methylation patterns between EOPET,LOPET, nIUGR and compound LOPET & IUGR may give insight to molecular pathogeneses resulting in preeclampsia and other placental disorders.

MATRIX MODULATES DNA METHYLATION IN HUMAN BLADDER SMOOTH MUSCLE CELLS (BSMC). *K.J. Aitken[1], J.X. Jiang[2], C. Sotiropolous[2], S. Pu[1], T. Kirwan[1], D.J. Bagli[1,2,3].* 1) Sickkids Hospital, Toronto, Ontario, Canada; 2) Department of Physiology, University of Toronto, Toronto, Ontario, Canada; 3) Department of Surgery, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada.

Extracellular matrix changes are often crucial inciting events for fibroproliferative disease. Epigenetic changes, specifically DNA methylation, are critical factors underlying differentiated phenotypes of smooth muscle and fibroblasts. We examined the dependency of matrix-induced fibroproliferation and SMC phenotype on DNA methyltransferases. The cooperativity of matrix with growth factors, hypoxia and strain was also examined. Primary rat visceral SMC of early passage (0-2) were plated on native collagen or damaged/heat-denatured collagen. Hypoxia was induced with 3% O_2, 5% CO_2 and 95% N_2 over 48 hours. Inhibitors were applied 2-3 hours after cells were plated on matrix, or immediately before hypoxia. Cells were fixed and stained for DNMT3A and α-smooth muscle actin or smooth muscle myosin heavy chain. Western blotting and QPCR were also used to examine DNMT expression on the two matrix environments. Illumina 450K array of CpG sites was performed on bisulfite converted DNA from smooth muscle cells on damaged matrix vs native collagen. Differences in beta values were considered significant after correction for multiple testing by benjamini hochberg analysis, p<0.05. An *a priori* analysis of sites proximal to SMC-related genes was performed using t-test and benjamini hochberg analyses. Damaged matrix up regulates DNMT3A nuclear localization and expression, and influences differentiation in BSMCs exposed to denatured matrix +/– hypoxia. Analysis of DNA methylation signatures showed that matrix caused significant DNA methylation alterations in a discrete number of 14 CpG sites proximal to 12 genes related to SMC differentiation. Matrix has a profound effect on the regulation of SMC phenotype, which is associated with altered expression, localization of DNMTs and discrete changes DNA methylation.

424T

Dose-dependent effect of *in utero* smoking on DNA methylation among Latino children in a methylome-wide association study. *S.S. Oh[1], D. Hu[1], C.R. Gignoux[1], J.M. Galanter[1], S. Huntsman[1], D. Torgerson[1], C. Eng[1], L.A. Roth[1], A. Davis[2], H.J. Farber[3], P.C. Avila[4], E. Brigino-Buenaventura[5], M.A. LeNoir[6], K. Meade[2], D. Serebrisky[7], L.N. Borrell[8], W. Rodríguez-Cintrón[9], R. Kumar[10], J.R. Rodríguez-Santana[11], F. Lurmann[12], E. Burchard[1].* 1) UC San Francisco, San Francisco, CA; 2) Children's Hospital and Research Center Oakland, Oakland, CA; 3) Baylor College of Medicine and Texas Children's Hospital, Houston, TX; 4) Feinberg School of Medicine, Northwestern University, Chicago, IL; 5) Kaiser Permanente-Vallejo Medical Center, Vallejo, CA; 6) Bay Area Pediatrics, Oakland, CA; 7) Jacobi Medical Center, Bronx, NY; 8) City University of New York, Bronx, NY; 9) Veterans Caribbean Health System, San Juan, Puerto Rico; 10) The Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL; 11) Centro de Neumologia Pediatrica, San Juan, Puerto Rico; 12) Sonoma Technology, Petaluma, CA.

It is known that *in utero* smoke exposure leads to changes in DNA methylation of specific genomic regions (CpG loci). However, the extent to which DNA methylation is affected by the amount of exposure is unknown. We hypothesized that DNA methylation patterns vary by the 'dose' of *in utero* smoking. To investigate the association of DNA methylation with *in utero* smoking, we conducted a methylome-wide association study (MeWAS) on 528 Latino children from the GALA II Study, a nation-wide case-control study of Latino children with and without asthma. Methylation status at >480,000 CpG loci was assessed using the Infinium HumanMethylation450 BeadChip. We used robust linear regression to test the association between CpG methylation and the number of trimesters that children were exposed to *in utero* smoking, adjusting for sex, age, ethnicity, asthma status, plate, position, and the first 10 principal components of variation within our data set.

The most significant differentially methylated locus in our MeWAS was in the first exon of *FAM83A*. For each trimester a mother smoked during pregnancy, her child had 2% less methylation ($p = 4.9E{-}7$; $FDR < 0.05$). Two additional suggestive loci include *ABL2* (1.2% less methylation per trimester, $p = 3.2E{-}6$; $FDR < 0.10$) and WNT3A (0.5% less methylation per trimester, $p = 4.4E{-}6$; $FDR < 0.10$). All three genes are involved in pathways known to be disrupted by tobacco smoke exposure. *FAM83A* is expressed in the lung, and *in vitro* studies have found it to be upregulated in bronchial epithelial cells following exposure to tobacco smoke. ABL2 functions in cytoskeletal rearrangements, and WNT3A is a key regulator of cell fate and patterning during embryogenesis.

In a MeWAS assessing the dose-response effect of *in utero* tobacco smoking, we found that *in utero* smoking was associated with altered methylation at three biologically relevant loci. Furthermore, we found that the degree of methylation was dose-dependent. Smoking during pregnancy is particularly insidious not only for harming the developing fetus but also for its effects manifested in later life. Our findings underscore the importance of tobacco prevention, control, and cessation efforts.

425F

DNA methylation profiling implicates several genes in type 2 diabetes. *M.A. Carless, H. Kulkarni, M.C. Mahaney, H.H.H. Goring, L. Almasy, A.G. Comuzzie, J. Blangero.* Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

Type 2 diabetes (T2D) is a global epidemic, becoming increasingly prevalent due to a rising incidence of obesity caused primarily by poor diet and lack of physical activity. The incidence of T2D is particularly high in Mexican Americans and although the disease is known to be genetically regulated, implicated loci explain only a small portion of the genetic liability. Epigenetic regulation, such as DNA methylation, is a novel mechanism that may lead to gene dysfunction and disease development. Using Illumina HumanMethylation450 BeadChips, we performed genome-wide DNA methylation profiling of >450,000 CpG sites in peripheral blood cells from 859 Mexican Americans from ~40 large pedigrees. In total, 20% of individuals were diagnosed with T2D and all individuals had fasting glucose measures available. Normalized DNA methylation data underwent analysis using SOLAR to test for heritability of each CpG site, and for association with T2D status and fasting glucose (in non-diabetic samples only). We used the Bonferroni method to correct for multiple comparisons. Approximately 24% of CpG sites were found to be significantly heritable (mean $h^2=0.433$, $p<1.06\times10^{-7}$). We identified 12 statistically significant associations between DNA methylation levels and T2D ($p<1.04\times10^{-7}$). The top association was for a CpG site in the *TXNIP* gene ($p=5.57\times10^{-18}$). Txnip is known to modulate glucose metabolism and insulin sensitivity, likely playing a role in T2D and possibly contributing to the therapeutic action of metformin. We also identified a significant association between diabetes and *ABCG1* ($p=5.45\times10^{-12}$), which has been implicated in reverse cholesterol transport, insulin secretion and glucose tolerance. Significant associations between DNA methylation and T2D status were also seen in other genes previously implicated in diabetes, including *CPT1A* ($p=5.92\times10^{-10}$) and *DHCR24* ($p=7.66\times10^{-9}$), as well as in potentially novel genes. Most of these genes were also at least nominally significantly associated with fasting glucose in the non-diabetic portion of our dataset (n=683). Our study has identified a number of genes that show DNA methylation changes associated with T2D in a Mexican American population. We are currently conducting pyrosequencing studies to validate these findings. We show here that DNA methylation profiling is a powerful means to identify genes involved in T2D, which may ultimately aid in the development of targeted therapeutics for diabetic treatment.

426T

Methylation analysis of CpG islands in the *TYR* and *P* genes: correlation with gene expression. *X. Wang[1], L. DSOUZA[1], H. HE[1], C. ANTOLIK[1], Q. ZHANG[1,2].* 1) OGVFB, NEI/NIH, Bethesda, MD; 2) Department of Immunology, Capital Medical University, Beijing, China.

Oculocutaneous albinism types 1 and 2 (OCA1 & OCA2) are autosomal recessive disorders of melanin biosynthesis characterized by hypopigmentation of hair, skin and eyes. OCA1 is caused by mutations in the gene that encodes tyrosinase (TYR; 11q14-q21). OCA2 is caused by mutations in the gene that encodes the P protein (OCA2; 15q11.2-q12). Mutations in these genes have been detected in a majority of OCA patients, but a small proportion do not have any detectable mutations or have only one identifiable mutation despite sequencing all the coding regions of the gene. Epigenetic phenomena have demonstrated roles in the regulation of gene expression. However, the role of DNA methylation in the development of OCA is not known. Three melanoma cell lines (A375, SK-28, and MNT1) and a retinal pigment epithelium cell line (ARPE-19) were previously found to contain different levels of pigmentation and gene expression. The A375 cell line has no TYR and P gene expression and pigmentation. The SK-28 cell line has no pigmentation but TYR and P gene expression. The MNT1 cell line has both TYR and P gene expression as well as pigmentation, and the ARPE-19 cell line has pigmentation and TYR gene expression but no P gene expression. We hypothesized that the DNA methylation status in the candidate CpG islands around promoter regions of the TYR and P genes may play a role in the regulation of gene expression. Therefore, we analyzed TYR and P gene CpG methylation status by bisulphite sequencing of genomic DNA from these cell lines. We found CpG sites to be hypermethylated in TYR in the A375, SK-28 and ARPE-19 cell lines. In contrast, those CpG sites were hypomethylated in the MNT1 cell line. Furthermore, we found that only the A375 cell line was hypermethylated (all the CpG sites were methylated) for the P gene CpG island, and the rest of the cell lines had a hypomethylated CpG island (all the CG sites were unmethylated). Corresponding mRNA levels were also correlated by qRT-PCR. Further analysis should lead to a better understanding of the role of methylation in the regulation of TYR and P gene expression.

427F

The Role of Brain DNA Methylation in the Pathology of Alzheimer's Disease: Evidence of an Interaction Effect. *PL. De Jager[1, 2, 3], G. Srivastava[1, 2, 3], ML. Eaton[3, 4], L. Yu[5], A. Meissner[3, 6], JA. Schneider[5], M. Kellis[3, 4], DA. Bennett[5], LB. Chibnik[1, 2, 3].* 1) Institute for the Neurosciences, Departments of Neurology & Psychiatry, Brigham & Women's Hospital, Boston, MA; 2) Department of Neurology, Harvard Medical School, Boston, MA; 3) Broad Institute of MIT and Harvard, Cambridge, MA; 4) Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, MA; 5) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, IL; 6) Department of Stem Cell and Regenerative Biology, Harvard Stem Cell Institute, Harvard University, Cambridge, MA.

The DNA methylome captures the transcriptional potential of a cell or tissue. Differential methylation of validated Alzheimer's disease (AD) loci could influence their effect; however where methylation falls along the disease pathway is unclear. We examine four causal models to assess the role of methylation on the pathology of AD. We utilized data from two longitudinal cohorts, the Religious Order Study and Rush Memory and Aging Project. DNA methylation profiles were generated in samples of dorsolateral prefrontal cortex using Illumina HumanMet450K beadset. We analyzed CpG sites within 25 kb of 11 validated AD susceptibility genes. The outcomes of interest were a measure of neuritic plaque (NP) accumulation and pathologic diagnosis of AD. First, independent associations between CpGs and outcomes were assessed using linear (NP) and logistic (AD) regression. The four hypothesized models are: (1) CpG mediated association, (2) reverse causality, (3) independent associations and (4) SNP by CpG interaction. Both (1) and (2) were assessed using mediation analyses and (4) was assessed for multiplicative interaction followed by stratified analyses. Correction for multiple testing was done using the Benjamini-Hochberg method. A total of 719 subjects were included in the analyses. Nine CpGs across 5 genes (*BIN1* (3), *CLU* (2), *MS4A6A* (2), *ABCA7* (1) and *APOE* (1)) were associated with the outcomes. Together they explain 13.1% of the variability of NP and 14.8% of AD. No gene region showed evidence for either model (1) or (2), however *APOE* showed evidence of (3) with 1 CpG associated with the outcomes but not the APOE haplotype. Most interestingly, a strong interaction effect was seen with the *CR1* in 3 CpGs at the 5' end of the gene, cg10021878 ($p_{interaction}$ = 4.5E−5, 1.3E−4), cg00175709 ($p_{interaction}$ = 0.003, 0.01) and cg05922028 ($p_{interaction}$ = 0.004, 0.04) for NP and AD respectively. Among those with the risk allele rs6656401$^{AT/AA}$ there is an inverse association between methylation and outcome, indicating more methylation is associated with less NP and decreased odds of AD, whereas those with rs6656401^{TT} more methylation is associated with more NP and increased odds of AD. Less significant interactions were also seen in *BIN1*, *ABCA7* and *PICALM*. These observations suggest that, within known AD susceptibility genes, methylation is related to pathologic processes associated with AD and may play a role in influencing gene expression from susceptibility loci.

Array-based assay detects genome-wide 5-methylcytosine and 5-hydroxymethlycytosine in non-human primates and mice. *R.S. Alisch[1], P. Chopra[2], L.A. Papale[1], A.T.J. White[1], A. Hatch[1], P.H. Roseboom[1], M. Brown[1], S.T. Warren[2].* 1) Psychiatry, Univ. of Wisconsin School of Medicine - Madison, Madison, WI; 2) Human Genetics, Biochemistry, and Pediatrics, Emory University School of Medicine, Atlanta, GA.

Murine and non-human primates (e.g. rhesus monkeys) represent excellent model systems to study human health and disease conditions, especially in the brain. However, use of these model systems for genomic profiling studies is limited because most array-based tools have only been developed to survey the human genome. Here we present the optimization of a widely used human DNA methylation array, designed to detect 5-methylcytosine (5-mC), and show that non-human data generated using the optimized array reproducibly distinguishes tissue types within and between chimpanzee, rhesus, and mouse, with correlations near the human DNA level ($R^2 > 0.99$). While using this assay to conduct a genome-wide methylation analysis of rhesus placental and fetal tissues reveals 6,102 differentially methylated loci with pathways analysis significantly overrepresented for developmental processes, restricting the analysis to oncogenes and tumor suppressors genes finds 125 differentially methylated loci, suggesting that rhesus placental tissue carries a cancer epigenetic signature. Further optimization of the assay to detect 5-hydroxymethylcytosine (5-hmC) finds highly reproducible 5-hmC levels within human, rhesus, and mouse brain tissue that is species-specific with a hierarchical abundance among the three species (human > rhesus >> mouse). Together, these data show that this array-based methylation assay is generalizable to all mammals for the detection of both 5-mC and 5-hmC, greatly improving the utility of mammalian model systems to study the role of epigenetics in human health, disease, and evolution.

429F

Airborne Particulate Matter Exposure Modifies the Canonical MAP-Kinase Pathway: From Methylomic Analysis to Biological Implications. *J.J. Carmona[1,2,3,4], T. Sofer[4,5], L. Cantone[6], B. Coull[5], A. Maity[7], J. Schwartz[1,2,3], X. Lin[4,5], A. Baccarelli[1,2,3,4,8,9].* 1) Laboratory of Environmental Epigenetics, Department of Environmental Health, Harvard School of Public Health, Boston, MA, USA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA, USA; 3) Exposure, Epidemiology, & Risk Program, Department of Environmental Health, Harvard School of Public Health, Boston, MA, USA; 4) Program in Quantitative Genomics, Harvard School of Public Health, Boston, MA, USA; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 6) Department of Clinical Sciences and Community Health, Università degli Studi di Milano, Milan, IT; 7) Department of Statistics, North Carolina State University, Raleigh, NC, USA; 8) Dana-Farber/Harvard Cancer Center, Boston, MA, USA; 9) Harvard/Massachusetts General Hospital Center on Genomics, Vulnerable Populations, and Health Disparities, Boston, MA, USA.

Background: Exposure to air particulate matter with an aerodynamic diameter < 2.5 m (PM2.5) is known to elevate blood markers of inflammation and increase cardiopulmonary morbidity and mortality. Major components of PM2.5 are Black Carbon (BC) due to traffic and sulfate from coal-burning power plants. DNA methylation is known to be sensitive to environmental toxins and to mediate environmental effects on clinical outcomes via regulation of gene expression. We hypothesize that exposure to air pollution components affects DNA methylation in blood leukocytes, in genes from inflammatory pathways. Methods: 141 males from the Normative Aging Study (NAS), residing in the Boston area, were selected. Leukocyte DNA samples were hybridized to the RefSeq 385K Promoter tiling array (Roche NimbleGen, Madison, WI) representing the promoter regions of all well-characterized genes in the RefSeq database, as well as all of the UCSC-annotated CpG islands. Sample immunoprecipitation, labeling, hybridization and data extraction were performed according to standard procedures optimized by Roche-NimbleGen. Air pollution components, BC and sulfate, were measured with a sensor located on the roof of the Countway Library at the Harvard Longwood Campus. 30-days moving average values of BC and sulfate were calculated for each participant at his clinical visit date. Sulfate measures were available for 92 of the individuals. Genes associated with the MAP-kinase and NFkB signaling pathways were identified using the BIOCARTA website. Forward stepwise Canonical Correlation Analysis was applied to identify specific genes in the pathways associated with the exposures, and p-values were calculated using a permutation test. Analysis for the effect of BC on the MAPK pathway was adjusted for age and sulfate exposure, and similarly for other pathways/exposures. Results: The MAPK pathway consists of 84 genes. Our analysis identified 10 genes whose methylation was associated with BC exposure, adjusted for sulfate and age (p-value 0.01). The association analysis between sulfate and methylation in this pathway suggested 9 genes, but was not statistically significant (p-value 0.086), which is possibly due to low power. There was no evidence of association between air pollution and methylation in the NFkB pathway. Conclusion: The effects of air pollution may influence inflammatory outcomes via MAPK gene methylation. These results will be validated in a larger subset of men from the NAS cohort.

430T

Epigenomic fetal programming: identifying genomic sites differentially methylated after exposure to maternal gestational diabetes and responsive to its treatment. *A.A. Houde[1,2], S.M. Ruchat[1,2], C. Allard[3], P. Perron[2,3], J.P. Baillargeon[3], J. St-Pierre[2,4], D. Gaudet[2,5], D. Brisson[2], M.F. Hivert[3,6,7], L. Bouchard[1,2].* 1) Department of Biochemistry, Université de Sherbrooke, Sherbrooke, QC, Canada; 2) ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Saguenay, QC, Canada; 3) Department of Medicine, Université de Sherbrooke, Sherbrooke, QC, Canada; 4) Department of Pediatrics, Chicoutimi Hospital, Saguenay, QC, Canada; 5) Department of Medicine, Université de Montréal, Montréal, QC, Canada; 6) Department of Population Medicine, Harvard Pilgrim Health Care Institute, Boston, MA; 7) Massachusetts General Hospital, Boston, MA.

Background: *In utero* exposition to gestational diabetes mellitus (GDM) is associated with increased lifelong susceptibility to obesity and metabolic disorders for the offspring. Recent evidences showed that epigenetic modifications may be involved in the metabolic health programming of the newborn exposed to GDM. Nevertheless, whether the treatment of GDM women (diet or diet+insulin) has an impact on DNA methylation levels has not been established. **Hypothesis:** DNA methylation at specific gene locus in placenta and cord blood is affected by exposure to GDM and its treatment. **Methods:** Placenta and cord blood samples were obtained from 43 women: 14 with normoglycemia (NGT) and 29 with GDM treated with diet (n=16, GDM-D) or diet+insulin (n=13, GDM-I). GDM was diagnosed between weeks 24-28 of pregnancy according to WHO criteria. DNA methylation was assessed at >485 000 CpG sites using the Infinitum HumanMethylation450 BeadArray. DNA methylation differences between the 3 groups were determined using ANCOVAs (adjustment for infant sex, gestational age, maternal BMI at 1st trimester of pregnancy and history of GDM (P_{adj})) and significance of pairwise comparisons was verified with Tukey's test. **Results:** Women were on average 29 years old. GDM-I women were slightly overweight at 1st trimester (BMI=27.1 kg/m^2) in comparison to GDM-D and NGT (23.9 and 24.6 kg/m^2) (P=0.05). In placenta exposed to GDM, lower levels of methylation were observed at *TOX2* ($P=6.8\times10^{-7}$; $P_{adj}=1.2\times10^{-6}$) and *DPP6* ($P=8.8\times10^{-6}$; $P_{adj}=1.9\times10^{-5}$) compared to NGT-exposed placenta. At *PLB1* locus, lower methylation levels were observed in placenta from GDM-D women (77.5% in NGT vs 73.6% in GDM-D; ANCOVA $P_{adj}=9.6\times10^{-6}$), whereas levels from GDM-I (78.2%) were similar to those from women with NGT. Similarly, in cord blood, we observed that CpG sites near *GNASAS* ($P_{adj}=8.5\times10^{-5}$) and *MYH7B* ($P_{adj}=4.5\times10^{-5}$) were differentially methylated in offspring from GDM-D mothers and were similar in NGT and GDM-I groups suggesting that insulin treatment offsets the impact of GDM exposure at these loci. In cord blood, methylation levels at *STC2* were lower in offspring from mother with GDM, treated either with diet or insulin ($P_{adj}=4.0\times10^{-5}$). **Conclusion:** Our results suggest that exposure to GDM or its treatment may influence DNA methylation at specific locus in the placenta and cord blood. The choice of clinical management of GDM may therefore have long lasting effect on the offspring's epigenome and metabolic health.

431F

Convergence of genetic, epigenetic and environmental factors on CpG-SNPs associated with human disorders: implications for transcriptional regulation in human brain. *D.R. Sarkisyan, I. Bazov, M.M.H. Taqi, H. Watanabe, O. Kononenko, V. Tashbulatov, T. Yakovleva, G. Bakalkin.* Pharmaceutical Biosciences, Uppsala University, Uppsala, Sweden.

Interaction between the genome, epigenome and environment is critical for the development of complex disorders. Expression of the genome may be influenced by the environment by shaping epigenetic mechanisms. At CpG-SNP sites, the genetic factors such as SNPs converge with environmentally-influenced epigenetic marks such as CpG dinucleotides, sites for cytosine methylation. The average occurrence rate of SNPs at a CpG site is 10-fold higher than the overall SNP occurrence rate, thus CpG-SNPs are overrepresented in the human genome (Xie et al., 2009). CpG dinucleotides are 7-fold more abundant at SNP sites than expected (Tomso and Bell, 2003). Correlation analysis identified allele specific methylation (ASM) on 30% heterozygous SNPs, and found that up to 88% of ASM regions are dependent on the presence of CpG-SNPs (Kerkel et al., 2008; Shoemaker et al., 2010). Some CpG-SNPs may be associated with a disease, and alterations of their methylation under environmental influences may be a critical factor affecting gene expression and contributing to disease vulnerability. Such CpG-SNPs may be located within DNAse I hypersensitivity sites (DHSs) and targeted by generic and sequence-specific regulatory factors (RF). The CpG-SNP hypothesis received support in recent studies by us and others (John et al., 2011; Kaminsky et al., 2011; Martin-Trujillo et al., 2011; Reynard et al., 2011; Taqi et al., 2011; Ursini et al., 2011). We address this hypothesis by comparing abundance of CpG-SNPs and non-CpG SNPs at DHSs and binding places for 161 RFs in a panel of 91 cell lines (ENCODE releases 1-3). We compared SNPs associated with alcohol dependence, behavioral disorders, neurodegenerative disorders, and the rest of SNPs implicated by NHGRI GWAS Catalog. As a model gene we analyzed methylation of CpG-SNPs in prodynorphin (PDYN), coding for opioid dynorphin peptides. Three PDYN CpG-SNPs were significantly associated with alcohol dependence and differentially methylated in human brain. In the brain of alcoholics, methylation of the C allele of SNP rs2235749 (3'-UTR; C>T; C is non-risk variant) was increased (P<0.001) and positively correlated with PDYN mRNA and dynorphin peptides (P<0.05). A DNA-binding factor that differentially targets the T, risk allele, and the methylated and unmethylated C allele of this SNP, was identified. This findings support CpG-SNP hypothesis. Supported by Swedish FAS, VR and FORMAS. Tissues were received from the NSWTRC, University of Sydney.

432T

Methylation analysis in tongue tissue of BWS patients identifies the (epi)genetic cause in 3 patients with normal methylation levels of H19 and KCNQ1OT1 in blood. *M. Alders[1], S.M. Maas[2], D.M. Kadouch[3], K. van der Lip[1], H.J. Bliek[1], C.M.A.M. van der Horst[4], M.M.A.M. Mannens[1].* 1) Clinical Genetics, Academic Medical Center , Amsterdam, Netherlands; 2) Paediatrics, Academic Medical Center, Amsterdam, The Netherlands; 3) Dermatology, Academic Medical Center, Amsterdam, The Netherlands; 4) Plastic and Reconstructive Surgery, Academic Medical Center, Amsterdam.

Beckwith Wiedemann Syndrome (BWS) is caused by aberrant imprinting of genes in the chromosome 11p15 region. A molecular cause for BWS is found in approximately 80% of patients while 20% remains unexplained. We analyzed the imprinting status of H19 and KCNQ1OT1 in resected tongue tissue of 11 BWS patients, three of which had normal methylation levels in blood. In 8 patients with known methylation defects in blood (6 isolated KCNQ1OT1 hypomethylation, 2 UPD), the same defects were detected in tongue. The methylation levels of H19 in tongue were comparable to those found in blood. The methylation levels of KCNQ1OT1 were relatively higher in tongue than in blood in most patients. In all three patients with normal methylation levels in blood aberrant methylation patterns were found in tongue tissue. In two patients a UPD was detected and the third case had hypermethylation of H19. This result shows that tissue specific mosaic (epi)genetic changes, not present in blood, is the underlying defect in at least a subset of BWS patients without a molecular diagnosis after standard genetic testing.

433F

An Integrated epigenomic-transcriptomic-genetic analysis of schizophrenia brain identifies novel molecular pathways to disease. *J. Mill[1,2], R. Pidsley[2], J. Viana[1], A. Jeffries[2], C. Wong[2], C. Troakes[2], L. Schalkwyk[2].* 1) Exeter University, Exeter, Devon, United Kingdom; 2) Institute of Psychiatry, King's College London, London, United Kingdom.

Schizophrenia (SZ) is a common psychiatric disorder characterized by the presence of psychotic symptoms and altered cognition. Although SZ is highly heritable, the molecular etiology of the disease is largely unknown. In addition to genetic and structural genomic variation, recent evidence supports a role for altered epigenomic and transcriptomic processes in disease pathogenesis. Frontal cortex and cerebellum tissue was obtained from 23 schizophrenia patients and 24 healthy controls. Genome-wide DNA methylation, expression and SNP profiling were performed using the Illumina Infinium Human Methylation450, HumanHT-12v4 Expression, HumanOmniExpress BeadChips respectively. Integrated multi-level analyses provide evidence of SZ-associated DNA methylation and gene expression changes at biologically relevant loci, including GABBR1, RASA3, C8A, NRN1, BNIP3, GAD1 and SERPINA3. Furthermore we identify cis-eQTLs and cis-mQTLs at SZ candidate genes nominated from published GWAS analyses, an increased burden of CNVs in patients with SZ, and a rare NRXN1 deletion in an SZ patient that is associated with altered DNA methylation. Together these results provide important insights into the biological mechanisms underlying SZ and highlight the value of taking an integrated '-omics' approach to complex disease.

434T

Whole Genome Bisulfite Sequencing of Cell Free DNA and its Cellular Contributors Links Placenta Hypomethylated Domains to Gene Deserts. *T. Jensen[1], S. Kim[1], C. Chin[1], Z. Zhu[1], T. Lu[1], C. Deciu[1], D. van den Boom[2], M. Ehrich[2].* 1) Research and Development, Sequenom Center for Molecular Medicine, San Diego, CA; 2) Research and Development, Sequenom, San Diego, CA.

Circulating cell free (ccf) DNA is useful for non-invasive diagnostic testing in prenatal health and oncology. In both cases, the nucleic acid of interest is the minority species and thus needs to be differentiated from the highly abundant ccf DNA background. DNA methylation can serve as a method for distinguishing these; however, this depends on an in depth knowledge of the DNA composition. Whole genome bisulfite sequencing (WGBS) was performed on a set of unmatched samples including ccf DNA from 8 non-pregnant (NP) female donors, genomic DNA from 7 buffy coat and 5 placenta samples, and ccf DNA from 7 pregnant females to gain a comprehensive understanding of the ccf DNA methylome in pregnant plasma. We first created a methylome map of ccf DNA from non-pregnant donors at single base resolution. Consistent with previous work in differentiated cell types, almost all cytosine methylation in NP ccf DNA samples occurred in the CpG context. We also found CpG cytosines within longer fragments were more likely to be methylated, linking DNA methylation and fragment size in ccf DNA. Next, we performed a series of pairwise comparative analyses to identify differentially methylated regions (DMRs). Comparison of the methylomes of placenta and NP ccf DNA enabled the detection of greater than 50000 DMRs, the majority resulting from placenta hypomethylation. We found that >90% of these DMRs were located outside of CpG islands and were often associated with distinct histone tail modifications. Further investigation of the identified DMRs revealed the presence of large domains exhibiting consistent hypomethylation in placenta samples relative to NP ccf DNA across millions of consecutive bases. We found these domains to occur primarily in CpG poor gene deserts. DMRs identified when comparing placenta to NP ccf DNA were recapitulated when comparing pregnant ccf DNA to NP ccf DNA, confirming the ability to detect differential methylation in ccf DNA mixtures. Overall, these data enabled the generation of methylome maps for each sample type at single base resolution, identified a link between local DNA methylation and ccf DNA fragment length, provided comprehensive lists of DMRs between sample groups, and uncovered the presence of megabase-size placenta hypomethylated domains. Furthermore, we anticipate these results to provide a foundation to which future studies based upon discriminatory DNA methylation for non-invasive testing can be compared.

DNA Methylation at CPT1A is Associated with Triglyceride Levels, BMI and WHR. *D.M. Absher[1], M.R. Irvin[2], S. Aslibekyan[2], J. Sha[2], L.L. Waite[1], D. Zhi[3], K. Stanton Thibeault[1], J. Ordovas[4], D.K. Arnett[2].* 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) Department of Epidemiology, University of Alabama, Birmingham, Birmingham, AL; 3) Department of Biostatistics, University of Alabama, Birmingham, Birmingham, AL; 4) Department of Epidemiology, Atherothrombosis and Imaging, Centro Nacional de Investigaciones Cardiovasculares, Madrid, Spain.

Epigenetic variation is thought to be a contributor to complex traits, and is likely to account for some of the missing heritability for phenotypes that have been incompletely explained by genetic variants. As the epigenome is dynamic and environmentally responsive, epigenetic modulators of dietary traits and responses are likely to be critically important to the development of cardiovascular disease and type-2 diabetes. We have undertaken an epigenetic analysis of GOLDN (Genetics of Lipid Lowering Drugs and Diet Network) study participants to identify DNA methylation patterns that contribute to lipid metabolic traits and related phenotypes. Using the Illumina Methylation450 array to measure DNA methylation at ~470,000 CpGs in CD4+ T-cells from 995 individuals in 183 families, we fit mixed effects regression models to identify CpGs where DNA methylation levels were strongly associated with baseline triglyceride levels (TG), body mass index (BMI), and waist-hip-ratio (WHR). We identified a CpG in the CPT1A (carnitine palmitoyltransferase 1A) gene that was significantly associated with all three traits ($p=6.9e{-28}$ for TG, $p=2.8e{-11}$ for BMI, and $p=4.7e{-11}$ for WHR), with ~2.4% of baseline TG variance explained by methylation at this locus. Given that CPT1A is an important regulator of fatty acid metabolism, we hypothesized that the impact of methylation on BMI and WHR would be mediated through its effects on TG. Regression models using TG as a covariate led to a reduced, but not eliminated, significance for BMI ($p=6.8e{-06}$) and WHR ($p=2.3e{-04}$), suggesting that CPT1A methylation has some effects on BMI and WHR that are independent of baseline TG. In addition to CPT1A, we also identified 7 other CpGs that achieved genome-wide significance with BMI exclusively, including CpGs near the CD38, AHRR and PGHDH genes. Furthermore, 1 additional CpG near RPS6KA2 was significantly associated with WHR.

DNA Methylation Profiling is Robust in Different Tissue Types and Reveals Distinct Patterns Across Rheumatoid Arthritis Samples and Phenotypes. *L.F. Barcellos[1], X. Shao[1], E. Elboudwarej[1], A. Baker[1], E. Sinclair[3], L.A. Criswell[2].* 1) Div Epidemiology-SPH, Univ California, Berkeley, Berkeley, CA; 2) Div Rheumatology, Dept Medicine, Univ California, San Francisco, CA; 3) The UCSF-GIVI CFAR Immunology Core, Univ California, San Francisco, CA.

Rheumatoid arthritis (RA) is a chronic inflammatory disease with potential to cause substantial disability, primarily due to the erosive and deforming process in joints. RA etiology is complex with contributions from genetic and non-genetic factors. Epigenetic changes such as altered patterns of DNA methylation (DNAm), are also present in RA. Our goal was twofold: (1) to establish a protocol for performing DNAm profiling of specific immune cell populations isolated from large numbers of samples that is cost and labor efficient, and both accurate and reproducible; (2) to characterize DNAm profiles in RA cases and controls across multiple cell types to identify similarities and differences relevant to disease status, phenotypes and pathogenesis. We generated genome-wide DNAm profiles using Illumina HumanMethylation450 BeadChips (n~22,000 genes, 459704 sites, post QC) in PBMCs, CD14+ monocytes, CD19+ B cells, and CD4+ memory and naïve T cells in 90 individuals (60 female cases and 30 controls) from the UCSF RA Cohort. We investigated the impact of sample storage conditions on: cell count, purity, DNA yields, quality and stability of DNAm profiles. The five outcomes were compared between cells isolated from PBMCs, stained and sorted by FACS on the same day of blood collection, and cells isolated from PBMCs, stained and stored overnight in buffer at 4°C and sorted the second day following collection; all from the same individual. Results show overnight storage did not impact the above outcomes. Background subtraction and beta-mixture quantile normalization was applied to all case and control data. Mean DNAm levels were highly correlated between all cell types in both cases and controls; however, CD4+ memory T cells differed more from CD14+ monocytes ($r<0.94$) DNAm levels within putative RA genes identified through GWAS (43 genes; 883 CpG sites) were similar between cases and controls; however, some differences were noted. Hypermethylation in RA case B cells compared to controls for HLA-DRB1, CCR6, AFF3 and TAGAP CpG sites was observed, whereas, PTPN22 CpG sites were hypomethylated; IRF5 was hypomethylated in case CD4 naïve T cells compared to controls. Visualization of CpG DNAm profiles using multidimensional scaling revealed separation between cell types; results also suggest age and clinical phenotypic associations with DNAm. Our results emphasize the cell specificity of DNAm, which has important implications for understanding human health and disease.

437F

Gene networks for social cognition in Williams syndrome. *L. Dai[1], R. Weiss[2], J.R. Korenberg[1].* 1) Center for Integrated Neuroscience and Human Behavior, Brain Institute, Department of Pediatrics, Univ. of Utah, Salt Lake City, UT; 2) Human Genetics, Univ. of Utah, Salt Lake City, UT.

Williams syndrome (WS), a neurodevelopmental disorder with hypersocial behavior, results from a deletion of ~ 28 genes on 7q11.23, that ultimately disturbs the neural circuitry involving oxytocin and vasopressin. Although cognitive deficits and social-emotional features are ultimately due to the deleted genes, the critical downstream pathways are unknown. Previous studies used rare WS genetic events, partial deletions seen in <2% of WS, to parse DNA contributions, implicating GTF2I and GTF2IRD1 in social behavior, and showing that perturbations of transcriptional networks (34 WS patients and 18 typical controls), implicate disturbed function at synapse and dendritic spine. Here we address the possible role of epigenetic mechanisms in WS using genome-wide analyses of DNA methylation. We employed the Illumina Infinium HumanMethylation450 array to query the methylation of ~500K CpG/non-CpG sites in whole genome using whole blood DNA from 7 WS and 5 parents. The results revealed striking epigenetic changes throughout the genome, with differences from controls in 15,987 methylation sites (p<0.05), corresponding to 7478 genes. 72% of the significant changed methylated sites are in CpG islands of which 67.1% are hypermethylated in WS. Hyper and hypomethylated sites coexist within single genes. Further, the data indicate differences with parental origin and gender: hyper-methylation in maternal deletions (74.6%) vs 25.4% in paternals. Methylation also varies with gender, hypermethylation seen more in males (78.6%) than in females (21.4%), suggesting that the subtle differences in WS genes dramatically alter the epigenetic landscape of the genome, largely through imprinting mechanisms but also related to gender. Preliminary evidence on GTF2I, previously associated with WS social behavior (Dai et al., 2009) and imprinted gene expression (Collette et al., 2009), suggests that methylation effects in WS may affect gene expression and possibly phenotype. Finally, similar to autism spectrum disorders, WS, FZD9 and Wnt signaling, indicated by Partek pathway enrichment analysis, may provide a common pathway of disorders of social behavior. Analyses of larger cohorts are in progress. These data indicate that genes in the WS region alter genome wide epigenetic mechanisms and result in widespread modification of methylation, strongly implicating these in the disturbed development and brain function seen in WS.

438T

Identification of CpG-SNPs Associated with Osteoporosis. *H. Shen[1], C. Qiu[1], L. Zhang[1,2], C. Xu[1], H.W. Deng[1,2].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 2) Center of Systematic Biomedical Research, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China.

Background Osteoporosis is an increasingly serious public health problem, affecting over 200 million people worldwide. Osteoporosis is mainly characterized by low bone mineral density (BMD), which is under strong genetic control. To date, over 50 BMD-associated loci have been identified, however, all these loci together account for no more than ~5% of BMD variation. In addition, despite the markers identified, specific functional variants are generally unknown. The introduction or disruption of CpG sites has been suggested as a potential mechanism through which some single nucleotide polymorphisms (SNPs) can affect gene function via epigenetics. To identify novel and/or potential functional variants which associated with osteoporosis, we conducted a meta-analysis of genome-wide association studies (GWAS) for BMD, specifically focusing on CpG-SNPs. Methods By leveraging the extensive catalog of common and rare genomic variants identified by the 1000 Genomes Project and our in-house pilot whole-genome high-coverage deep re-sequencing study of 44 Caucasians, we identified 2,197,763 CpG-SNPs throughout the human genome and imputed the genotypes for these CpG-SNPs in five cohorts with a total of 11,140 subjects. Meta-analysis was carried out by using the program METAL. Results Twenty CpG-SNPs in 6 genes, specifically, CCDC170, C7orf76, PTH2R, SHFM1, WNT4, and FAM3C, showed association with hip BMD at the genome-wide significance level (p<=5.0E−08). Moreover, we detected suggestive association (p<=1.0E−06) with hip BMD for additional 85 CpG-SNPs, which were distributed in 21 other genomic regions. Interestingly, most of the BMD-associated CpG-SNPs are mapped to candidate genes (e.g., ESR1, SOX6, WNT16, etc) that have been significantly associated with BMD in previous GWAS and/or have known functional roles in bone biology, suggesting SNP induced alterations of DNA methylation is likely to be an important mechanism mediating the genetic basis of osteoporosis. Conclusion In this study, we identified a number of SNPs that may contribute to BMD variation through altering DNA methylation levels of specific genes. These results provided novel insights into the genetic basis of osteoporosis, and highlighted the close connections between genetic and epigenetic mechanisms of complex diseases.

DNA Methylation in Six Cell and Tissue Types in Sjögren's Syndrome Reveals Distinct Patterns Across Samples and Clustering Based on Disease Status. *A.S. Baker[1], D. Quach, BS[1], H. Quach, BS[1], E. Elboudwarej, MPH[1], L.F. Barcellos, PhD, MPH[1], L.A. Criswell, MD, MPH[2].* 1) Genetic Epidemiology and Genomics Lab, School of Public Health, University of California, Berkeley, CA, USA; 2) Department of Rheumatology, School of Medicine, University of California, San Francisco San Francisco, CA, USA.

Sjögren’s Syndrome (SS) is a chronic, multisystem autoimmune disease characterized by progressive destruction of the exocrine glands, with subsequent mucosal and conjunctival dryness. Increasing evidence supports a role for DNA methylation status in autoimmune disease risk and severity. Our goal was to characterize methylation profiles in SS subjects and healthy controls across multiple cell and tissue types to identify similarities and differences relevant to disease status and pathogenesis. We generated genome-wide DNA methylation profiles using Illumina HumanMethylation450 BeadChips in minor salivary gland biopsy tissue, fresh and banked peripheral blood mononuclear cells (PBMC), CD14+ monocytes, CD19+ B cells, and CD4+ T cells in ten participants (five cases and five controls) from the Sjögren’s International Collaborative Clinical Alliance (SICCA; http://sicca.ucsf.edu/; N01 DE32636) repository. Additionally, we characterized full genome SNP profiles. Sorting of freshly collected blood samples was performed using MACS®technology. DNA yields for all cell and tissue types were high; all samples were background subtracted and normalized with beta-mixture quantile (BMIQ). Methylation of individual measured CpG sites was stable across the six cell types for ~240,000 CpGs (variance< 0.001); however, variance > 0.10 for ~900 CpGs. Mean methylation was calculated within each cell type for the 473,929 CpGs detected by the BeadChip. Mean methylation was highly correlated between all cell types in cases, controls, and in a combined data set (r2: 0.91 - 0.99) with the lowest correlation between salivary gland tissue and CD14+ monocytes and the highest correlation between fresh and banked PBMCs. Methylation levels within 17 putative SS genes identified with GWAS were similar between cases and controls; however, median methylation levels for BLK and TNFSF4 CpGs were 10%–18% less in cases compared to controls within salivary gland tissue. Data visualization of methylation profiles using Multi-Dimensional Scaling revealed distinct separation between cell types in addition to separation based on case status with the greatest separation by case status visible in CD19+ B cells and salivary gland tissue samples. Our results emphasize the cell and tissue specificity of DNA methylation. Additional research, including studies of gene expression for regions associated with disease risk or severity, will be required to fully define the role of DNA methylation in SS.

Epigenetics in cow's milk allergy: a Dutch epidemic. *P. Henneman[1], N.C.M. Petrus[2], A. Venema[1], M.M.A.M. Mannens[1], A.B. Sprikkelman[2].* 1) Clinical Genetics, , DNA-diagnositcs Laboratory, University of Amsterdam, Academic Medical Center, Amsterdam, Netherlands; 2) Pediatric Respiratory Medicine and Allergy, Emma Children’s Hospital, University of Amsterdam, Academic Medical Center, Amsterdam, The Netherlands.

Cow’s milk allergy (CMA) in Dutch infants is more prevalent (~10%) compared to infants from other countries in Europe (~2%). Children suffering from CMA have an increased risk on developing other allergic diseases in later life. Accumulating evidence suggests involvement of gut-microbiota and maturation of the immune-system in CMA. CMA is a complex disorder with an estimated heritability of 15%. Therefore early environmental factors are likely to be involved in CMA. It has been shown that epigenetic gene regulation can be altered by environmental factors. We aimed to detect epigenetic associations with the expression of CMA. We studied a sample of children from the Dutch EuroPrevall birth cohort study (N=20 CMA vs. N=20 controls), age and gender matched (50% girls). Inclusion criteria were based on questionnaires and challenge proven CMA. Bisulfite converted DNA (blood) was analyzed using the 450K infinium DNA-methylation array of Illumina®. Statistical analysis was performed in ‘R’ using IMA. Four groups were analyzed, combined, boys, girls and a subgroup of extremes. Subsequently, we performed pathway-analysis in ‘R’ using the global-test package. Methylation arrays were analyzed successfully. Associations with a P-value <2.6*10−4 were considered as potential candidates (pc), P-values < 2.6*10−6 were assumed significant. In the combined group we detected 13 pc-loci, in boys 15 pc-loci and 1 significant locus (ZNF281, P = 1.1E−06), in girls we detected 6 pc-loci and in the extremes 9 pc-loci. Eight pc-loci and the significant locus were found in both combined groups and males. Two loci overlapped between females and the combined group, suggesting robust association. Associations and pathway-analysis both detected involvement of chromatin-structure, epithelial maturation, intestinal function/absorption and immunological mechanisms. Although the limited statistical power is low in this small sample size study and the character of CMA is complex, we were able to detect plausible loci and pathways involved in chromatin remodeling, epithelial maturation, intestinal function and immunological anti-viral responses. Replication studies have to confirm our findings.

In this study we investigated the role of the epigenome, a possible mediator of environmental effects during development, in the pathogenesis of Autism Spectrum Disorders (ASDs). ASDs encompass a heterogeneous group of diseases characterized by impairments in communication and social interaction, and repetitive stereotyped behaviors. The prevalence of ASDs has increased dramatically, with current epidemiologic estimates citing a diagnosis in 1 out of every 90 individuals. Rates of ASD rise with parental age, with fathers older than 40 and mothers older than 35 each possessing greater independent risk of having a child with an ASD. Recent studies have helped further elucidate the genetic basis of ASDs, investigating the role of copy number, common, and rare variation in the disease. However, these findings explain only a fraction of ASD etiology.

We tested an homogeneous ectodermal cell type from individuals with ASD compared with typically developing (TD) controls born to mothers of ≥35 years, using a quantitative genome-wide DNA methylation assay. We show that DNA methylation patterns are dysregulated in individuals with ASD, performing a stringent analysis that accounted for confounding effects due to subject age, sex and ancestral haplotype, while also excluding mosaic aneuploidy and copy number variability in these subjects. Of note, the loci with altered DNA methylation were found at genes expressed in the brain, genes encoding protein products significantly enriched for interactions with those produced by known ASD-causing genes, representing a perturbation by epigenomic dysregulation of the same networks compromised by DNA mutational mechanisms.

The results indicate the presence of a mosaic subpopulation of epigenetically-dysregulated, ectodermally-derived cells in subjects with ASD. The epigenetic dysregulation observed in these ASD subjects born to older mothers may be associated with aging parental gametes, environmental influences during embryogenesis or could reflect mutations of the chromatin regulatory genes increasingly implicated in ASD. The results indicate that epigenetic dysregulatory mechanisms may complement and interact with DNA mutations in the pathogenesis of the disorder.

442T

Epigenetic and ecogenetic silencing of the FMR gene unrelated to CGG TNR expansion. *J. Kapalanga[1,3,4,5,6], Y. Said[3,7], D. Wong[2,3], A. Gandy[2,3], M. Moyo[5,6], N. Nkiru[4], A. Singh[3]*. 1) Dept Pediatrics, Genetics, Schulich School of Medicine, Western University/Grey Bruce Health Services, Owen Sound, ON, Canada; 2) Paediatrics, Dalhousie University, Halifax, NS Canada; 3) Summerside Medical Center, Summerside, PEI Canada; 4) Grey Bruce Health Services, Owen Sound, ON, Canada; 5) Cambridge Memorial Hospital, Cambridge, ON, Canada; 6) Pediatrics, McMaster University, Hamilton, ON, Canada; 7) Allergy and Pediatric Pulmonology King Fahad Specialist Hospital, Dammam,Saudi Arabia.

Expansions and hypermethylation of a CGG trinucleotide repeat (TNR) at the 5'untranslated region of the FMR1 gene results in transcriptional silencing of the gene. These molecular events have been established as the underlying cause of over 95% of patients with the Fragile-X syndrome (FXS). The commonest features of the FXS phenotype include intellectual disability, hyperactivity, impulsivity, a peculiar jovial speech, autistic features, macrocephaly, macrotia, and macroorchidism. In a behavioral and developmental pediatric practice it is common to see patients with the FXS phenotype but without molecular demonstration of the CGG TNR expansion in the abnormal range. In this study pediatric patients were ascertained through multicenter general, behavioral and developmental pediatrics clinics over a 10 year period. Patients were identified after presenting with a constellation of at least four common FXS phenotypic features including, intellectual disability, hyperactivity, autistic features, and distinctive craniofacial features. During the 10 year period 798 patients with the FXS phenotype, were tested for FXS by currently established molecular methods. Chromosomal studies were also done in all 798 patients. All patients were found to have CGG repeat size of 5 - 45 in their FMR1 gene and chromosomal studies were normal. Point mutations are rare (<1%) and would not be expected to be a significant cause of the FXS phenotype in these patients. These observations suggest that the FXS phenotype can occur unrelated to TNR expansion, chromosomal abnormalities or point mutations. It is conceivable that silencing of the FMR1 gene can occur by epigenetic mechanisms possibly modulated by ecogenetic factors even in the absence of CGG TNR expansion at the 5'untranslated region of the FMR1 gene. This implies that with a certain threshold of epigenetic and ecogenetic influences, silencing of a 'normal' FMR1 gene with repeat size of 5-45 can occur. It is also possible that epi-ecogenetic mechanisms interfere with production of a functional fragile X mental retardation protein (FMRP) by a putatively 'normal' FMR1 gene. We plan a comprehensive analysis of epigenetic influences on expression of the FMR1 gene with simultaneous assay of the FMRP. This could lead to an elucidation of the underlying etiopathogenic mechanisms that result in having the FXS phenotype unrelated to CGG TNR expansion.

Multiple methylation errors at imprinting control regions in patients with S-adenosylhomocysteine hydrolase (AHCY) deficiency.
U. Zechner[1], A. Fitzner[1], J. Knežević[2], M. Polović[2], N. El Hajj[3], E. Schneider[3], R. Belužić[2], S.H. Mudd[4], T. Haaf[3], O. Vugrek[2]. 1) Institute of Human Genetics, University Medical Center of the Johannes Gutenberg University Mainz, Mainz, Germany; 2) Division of Molecular Medicine, Institute Ruer Bošković, Zagreb, Croatia; 3) Institute of Human Genetics, University of Würzburg, Germany; 4) Laboratory of Molecular Biology, National Institute of Mental Health, Bethesda, MD.

S-adenosylhomocysteine hydrolase (AHCY) deficiency is a novel human disease, which was first discovered in Croatia in 2004. Main characteristics are psychomotor delay and severe myopathy (hypotonia, absent tendon reflexes and delayed myelination) from birth, associated with hypermethioninaemia, elevated serum creatine kinase levels and increased genome-wide DNA methylation. The prime function of AHCY is the efficient removal of S-adenosylhomocysteine (SAH), the by-product of transmethylation reactions. As SAH is one of the most potent methyltransferase (MT) inhibitors, its rapid removal is crucial to avoid product inhibition of MTs. Thus, AHCY plays a critical role in regulation of biological methylation processes. We set out to more specifically characterize DNA methylation changes in blood DNA samples of seven AHCY-deficient patients as well as HepG2 and HEK293 cell lines after shRNA-mediated knockdown of the AHCY gene by determining the DNA methylation levels at differentially methylated regions (DMRs) of seven imprinted genes (*MEST*, *NESPAS*, *SNRPN*, *LIT1*, *H19*, *GTL2* and *PEG3*) as well as Alu and LINE-1 repetitive elements. Analysis of the imprinted gene DMRs revealed abnormal methylation levels with moderate to strong hypermethylation at several DMRs in three of the seven patients and rather normal differential methylation patterns in the other four patients. The knockdown cell lines also exhibited methylation changes to different degrees at the analyzed DMRs. Methylation analysis of Alu and LINE-1 repetitive elements demonstrated no methylation abnormalities. Microarray-based experiments to analyze the complete DNA methylome of AHCY-deficient patients in comparison to normal individuals are in progress. The finding of hypermethylation in the patients' DNA samples is opposite to what is expected considering the inhibitory effect of SAH on MTs. As an explanation for this finding, it can be speculated that only some MTs are inhibited and, thus, leave excess substrate for other specific DNA MTs not sensitive to increased SAH levels and functioning properly. Our preliminary data indicate that AHCY deficiency may represent a good model disease for studying the biological consequences of multiple methylation errors in epigenetic research. Thus, findings from this study may make an important contribution to develop standard and high-throughput tools for the diagnosis of AHCY deficiency and other diseases associated with aberrant epigenetic modifications.

444T

DNA differential methylation is observed at BRCA1 promoter but not in 8q24.21 in cleft lip and palate.
L. Alvizi, G.S. Kobayashi, C.B.F. Silva, D.Y. Sunaga, D.F. Bueno, M.R.S. Passos-Bueno. Genetics and Evolutionary Biology, University of São Paulo, São Paulo, Sao Paulo, Brazil.

Purpose: DNA methylation is known to be a heritable regulatory mechanism in gene expression and influenced by both genetic and environmental factors. It is also known that impairment in gene methylation status may lead to gene expression dysregulation and thus disease. In this context, cleft lip and palate (CL/P) is a congenital craniofacial malformation with high incidence (1:700 live births) strongly determined by the genetic and environmental interplay in which epigenetic factors such as DNA methylation are very plausible factors in the malformation etiology. Aiming to investigate DNA methylation at specific sites to CL/P, we investigated whether BRCA1 , previously associated to CL/P (Kobayashi and Alvizi et al, 2013 PloS ONE), and 8q24.21 CL/P risk region were differentially methylated in CL/P samples in comparison to control samples. Methods: Bisulfite sequencing analysis for BRCA1 promoter was performed in a DNA sample set obtained from dental pulp stem cells (DPSC) of 18 CL/P and 12 controls and for 8q24 region in a DNA sample set from white blood cells DNA of 34 CL/P and 44 controls. A total of 300 clones for BRCA1 promoter and 780 clones for 8q24.21 were sequenced and analysis was performed using BISMA (Bisulfite Methylation Analysis - BPCD online tool). BRCA1 expression was also assessed by qRT-PCR in the DPSC sample. Results/Conclusions: Total BRCA1 promoter methylation was significantly higher (+1,4%) in the DPSC CL/P sample. Besides, BRCA1 promoter CpGs 1, 2 and 11 were the most hipermethylated in the CL/P sample (17.8%, 30.2% and 23.1%, respectively). As expected, BRCA1 expression was significantly reduced in comparison to controls (p=0.001). No evidence of differential methylation at the 8q24.21 cleft lip risk locus was found in the white blood cells DNA sample of CLP patients as compared to controls. Our results suggest that downregulation of BRCA1 in CL/P samples may be driven by increased BRCA1 promoter methylation and the causative factors in this hypermethylation should be next investigated. BRCA1 expression rescue by promoter demethylation is being conducted in DPSC CL/P samples. FAPESP/CNPq-MCT.

Widespread changes in DNA methylation at CpG island shores and distal regulatory regions in response to a bacterial infection.
L.B. Barreiro[1,2], A. Pacis[2,3], L. Tailleaux[4], V. Yotova[2], J.C. Grenier[2], R. Pique-Regi[6], K.D. Hansen[7], Y. Gilad[5]. 1) Department of Paediatrics, Faculty of Medicine, University of Montréal, Montréal, Canada; 2) Ste-Justine Hospital Research Centre, Montreal, Canada; 3) Department of Bioinformatics, Faculty of Medicine, University of Montréal, Montréal, Canada; 4) Unité de GénétiqueMycobactérienne, Pasteur Institute, Paris, France; 5) Department of Human Genetics, University of Chicago, Chicago, USA; 6) Department of Molecular Medicine and Genetics, Wayne State University, Detroit, USA; 7) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, USA.

DNA methylation is an essential epigenetic modification for gene regulation, development, and disease processes. Recent studies have reported the dynamic nature of DNA methylation in response to different environmental conditions in mammalian cells. To better understand the role of DNA methylation in immune responses to infection, we collected single-base pair resolution methylation profiles of dendritic cells (DCs) before and after infection with *Mycobacterium tuberculosis* (MTB), the causative agent of tuberculosis (TB). We identified 1695 differentially methylated regions (DMRs) genomewide that span 300 hundred base pairs on average. Our findings show that changes in methylation do not occur in CpG islands and promoters but rather in low CpG-density regions, namely in CpG shores and distal regulatory regions. By using DNAse hypersensitivity sites (DHS) data we show that DMRs are enriched among DHS, which are strong predictors of open chromatin and active regulatory regions. We also observed a significant overlap of DMRs with enhancer regions as well as regions bound by transcription factors of key importance in immune responses, such as NF-κB. Finally, we show that DMRs are enriched within close proximity of genes that were differentially expressed genes after MTB infection. Specifically, we show that 25% of the genes that change expression after infection also have a DMR in close proximity. Genes close to DMRs that are hypomethylated after MTB infection tend to be up-regulated upon infection, whereas genes close to hyper-methylated DMRs tend to decrease their expression levels. These findings suggest a mechanistic link between changes in DNA methylation and changes in gene expression after MTB infection. Importantly, our results suggest that methylation levels might be more dynamic than previously thought, particularly in response to an infectious agent.

446T

Acceleration of age-associated methylation patterns in peripheral blood of HIV-1-infected adults.
R.M. Baxter[1], T.M. Rickabaugh[2], M. Sehl[2], J.S. Sinsheimer[1], O. Martinez-Masa[3], S. Horvath[1], E. Vilain[1], B.D. Jamison[2]. 1) Human Genetics, UCLA, Los Angeles, CA; 2) Medicine, division of Hem./Onc., UCLA, Los Angeles, CA; 3) Medicine, divsion of OB & GYN, UCLA, Los Angeles, CA.

Young HIV-1-infected adults, even when successfully treated with antiretroviral therapy, are prone to diseases more commonly associated with older uninfected adults. In addition, HIV-1-infection has been shown to have additive, detrimental effects, with aging on both cell number and telomere length within peripheral lymphocytes suggesting that HIV-1-infection accelerates aging in these cells by at least 10 years. However, it remains unknown whether aging and HIV-1-infection exert these effects through similar, or disparate, mechanisms. As we had previously identified methylation patterns associated with aging in uninfected adults, we tested whether HIV-1-infection would induce methylation changes associated with aging. Utilizing Infinium methylation arrays, we evaluated methylation levels at more than 450,000 CpG sites in DNA isolated from peripheral blood mononuclear cells (PBMC) obtained from the Multicenter AIDS Cohort Study (MACS), a longitudinal study of HIV-1 infection. Samples were from young (20–24 years) and older adults (48–56 years). Each group consisted of 12 HIV-1-infected individuals and 12 age-matched uninfected controls. We examined the relationship between differential methylation across age and HIV-1 infection and found that CpG sites with a positive age correlation were often also hypermethylated in HIV-1 infected individuals. A smaller number of sites correlated with decreased methylation in both aging and HIV-1-infeciton. Weighted gene co-methylation network analysis (WGCNA) identified 11 modules in the data based on methylation levels. CpG sites within module 7 were significantly correlated with both age and HIV-1 status. Using this module we demonstrated that HIV-1 infection accelerated age-related methylation by about 13 years. Examination of the genes related to the CpGs in this module showed enrichment for polycomb group targets, genes such as *SOX1, SOX8, PENK, MYOD1*, and *NPTX2* that are known to be involved in cell renewal and aging. These data demonstrate that HIV-1 infection is associated with methylation patterns that are similar to those associated with aging in the general population. The acceleration of aging due to HIV-1 infection by 13 years fits well with other studies on the effects of HIV-1 in the immune system. Taken together these data suggest that HIV-1-infection does accelerate some aspects of aging and that general aging and HIV-1 related aging work through at least some common mechanisms.

Methylation QTLs often show opposite allelic directions when comparing different tissues. *M.J. Bonder[1], S. Kasela[2,3], K. Kirotar[3], M. Kals[2], M. Ivanov[4], A. Metspalu[2,3], M. Ingelman-Sundberg[4], C. Wijmenga[1], A. Zhernakova[1], L. Milani[2], L. Franke[1].* 1) Genetics, University Medical Center Groningen, Groningen, Groningen, Netherlands; 2) Estonian Genome Center, University of Tartu, Tartu, Estonia; 3) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 4) Section of Pharmacogenetics, Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden.

Introduction It is clear that many disease-associated genetic variants affect gene expression (eQTL mapping). However, this effect is often tissue specific. We recently observed that within the same individuals eQTLs can show opposite allelic directions when comparing different tissues (Fu et al, PLoS Genetics 2012, Fairfax et al, Nature Genetics 2012). Here we investigated whether the same phenomena can be observed when investigating the effects of genetic variants on methylation (meQTL mapping)

Material and Methods We collected genotype, expression and methylation data from 94 Swedish liver samples. This was combined with a set of 84 Dutch individuals for whom we collected genotype, expression and methylation from liver, saturated adipose tissue, visceral adipose tissue and muscle. We performed eQTL and mQTL mapping in each of these tissues.

Results In the liver data we identified 2,920 significant meQTL probes and 443 significant eQTL probes after stringent multiple testing correction (estimated false discovery rate = 0). When investigating the other three tissues, we found that around 80% of the meQTLs and around 50% of the eQTLs that were identified in the non-liver datasets were also present in liver. We then assessed whether these overlapping QTL signals had consistent allelic directions. For the eQTLs we did not identify probes which showed an opposite effects in liver as compared to the other tissues. However, we observed 14 unique methylation probes, which gave significant opposite allelic effects in liver as compared to the three other tissue types. As we did not observe any opposite allelic effects when comparing the meQTLs detected in the individual Swedish and Dutch liver samples, we believe the 14 probes with opposite allelic effects reflect true positive results.

Conclusion In this study we found that around 80% of the meQTLs are shared between different tissues, but we also identified a few meQTLs that showed completely opposite allelic effects when comparing different tissues. We thus conclude that careful selection of the tissue of interest is crucial when it comes to interpretation of both methylation and expression QTL results.

Predicting Prostate Cancer Progression through Gene Network Analysis of Methylation Data. *L. Briollais, K. Kron, B. Bapat, H. Ozcelik.* Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON, M5T 1L9, Canada.

Promoter and 5' end methylation regulation of tumour suppressor genes is a common feature of many cancers. Such occurrences often lead to the silencing of these key genes and thus they may contribute to the development of cancer, including prostate cancer. In order to identify methylation changes in prostate cancer progression, we performed a genome-wide analysis of DNA methylation using Agilent human CpG island arrays available on 20 patients (10 with Gleason score 6 and 10 with Gleason score 8). Our first set of analyses identified a large number of potential epigenetic biomarkers of prostate cancer progression, including various genes belonging to the Homeobox family. The second set of analyses aimed at constructing a gene network around the Homeobox genes and use this information as a predictive tool for prostate cancer progression. The different models found in the second stage of our analysis showed an excellent predictive ability and these models were further validated in an independent data set of methylation data as well as in a gene expression data set. We finally discuss various statistical approaches for gene network analysis including graphical models. Our conclusion is that gene network analysis can provide a very sensible and comprehensive framework for understanding the genetic basis of complex human diseases and for identifying individuals the more susceptible to disease progression.

Background and Objective: Methylation levels, which influence gene expression, can be influenced by environment and life style. Obesity, as a product of both nutritional environment and life style, could be related to methylation levels. Here we present preliminary findings from a pilot study examining DNA methylation patterns across the genome in young obese and lean male Samoans to identify epigenetic loci associated with obesity. Methods: DNA was extracted from whole peripheral blood from 46 obese (BMI >=32 & Abdominal Circumference >=92.5cm) and 46 lean (BMI <26 & Abdominal Circumference <92.5cm) in the age range 25–40 years. The blood was drawn while fasting the morning after the anthropometric measures were taken. We used methylumi and wateRmelon packages in R available through Bioconductor to analyze data from the 450K Human Methylation Array. The M-values (log2 of the methylation levels) were calculated, as these are preferred to beta values. The M-values were adjusted for chip and row batch effects using the ComBat package. Probe filtering was done to exclude any outlying samples and sites before computing the M-values. To identify differentially methylated positions between obese and lean males at each locus or probe, we used a moderated-t-test that adjusted for multiple testing using the Benjamini-Hochberg method (Limma package). Results: A total of 469,507 CpG loci across the genome in 92 individuals were investigated. A total of 91,805 probes emerged as differentially methylated in obese males when compared to lean males at an q-value threshold of 0.05; 3,454 of these had p-values less than the Bonferroni threshold of 1.06 × 10–7. The 3,454 top hits represent approximately 1,345 different regions, several of which have previously been associated with obesity. An additional data set of 92 individuals is being generated. Support: This work was supported by NIH R01 HL093093 (PI: Stephen McGarvey).

CHARGE syndrome (CHARGE) is a rare autosomal dominant genetic disorder, with an incidence of 1 in 8500–10000 births. Clinical diagnosis for CHARGE is based on non-random associations of the following congenital abnormalities: Coloboma of the eye, Heart defects, Atresia of the choanae, Retarded growth and development, Genital abnormalities, Ear abnormalities/deafness/vestibular disorder. In the majority of cases, CHARGE is the result of haploinsufficiency due to a nonsense, missense, or deletion in the gene encoding Chromodomain Helicase DNA-binding protein (CHD7). Targeted mutational studies in Drosophila (kismet) and mouse (Chd7) have found phenotypes similar to those found in human. In Drosophila reduced expression of kismet/CHD7 results in deficits in axonal pruning, guidance and extension as well as defects in memory and motor function. Normal mammalian growth and development depend on the correct epigenetic programming of the genome. Epigenetic patterns evolve across development utilizing mechanisms such as DNA methylation and covalent modifications of histone proteins. In Drosophila, kismet the ortholog of human CHD7 has been demonstrated to regulate the repressive histone H3 methylation mark of lysine 27. In human cell lines, CHD7 has been shown to bind to chromatin regions that are active as demonstrated by histone H3 lysine 4 methylation and DNAse1 hypersensitivity of these binding sites. CHD7 also interacts with RNA polymerase II, forming complexes that alter chromatin structure to facilitate access for transcriptional machinery. These epigenetic modifications of histone H3 are tightly linked to DNA methylation patterns. We hypothesized that specific DNA methylation alterations occur as a result of the heterozygous CHD7 mutations and could reveal critical downstream targets associated with CHARGE clinical features. We have analyzed cases with CHD7 mutations comparing their methylation alterations to age and sex-matched controls using the Illumina Inifinium Methylation450 BeadChip array. Data were analyzed using the IMA package in R and Genome Studio software from Illumina. We identified both gain and loss of methylation in genes that play a role in growth and neurodevelopment. The identification of these epigenetic modifications could lead to an improved understanding of the pathophysiology of CHARGE and the type of chromatin regions to which CHD proteins are recruited.

Contribution of DNA methylation to gene expression varies by tissue and age. *C. Chen[1,2], C. Zhang[1,2], L. Cheng[1,2], J. Badner[4], E. Gershon[4], J. Sweeney[5], J. Reilly[6], J. Bishop[1,3], C. Liu[1,2].* 1) Psychiatry, University of Illinois at Chicago, Chicago, IL; 2) Institute of Human Genetics, University of Illinois at Chicago, Chicago, IL; 3) Department of Pharmacy, University of Illinois at Chicago, Chicago, IL; 4) Department of Psychiatry and Behavioral Neuroscience, The University of Chicago, Chicago, IL; 5) Department of Psychiatry, University of Texas Southwestern, Medical Cetner, Dallas, TX; 6) Psychiatry, Northwestern University, Chicago, IL.

DNA methylation, as an epigenetic mark on CpG dinucleotides, was considered to simply block the binding of transcription factors in promoter region and repress gene expression. However, recent studies showed that DNA methylation functions vary with genomic context and tissues. We systematically evaluated correlations between expression of individual genes and DNA methylation at cis-regions in brain cerebellum (CB), prefrontal cortex (PFC), and blood and lymphatic endothelial cells (LEC). We found that less than 5% of the genes were significantly correlated with DNA methylation level within one specific tissue. Many other genes have their expression correlated with methylation by tissue types or across life span while their expressions have little variation within one tissue of limited age range. Positive correlations were observed in all tests. CpG sites from correlated pairs were more dynamic and tissue-specific in CpG-poor regions. Genes involved in age-dependent methylation regulation were enriched with brain development functions. CpG sites in promoter CpG Island (CGI) were more likely to be consistently unmethylated, and corresponding regulated genes were enriched for acetylation functions. These diverse correlations suggested complexity of the roles of DNA methylation in regulating gene expression. DNA methylation of most CpG sites may have been used to define spatiotemporal gene expression patterns, i.e., tissue and age variations, while much fewer CpG sites mediate variations of gene expression within tissue in human population for individual differences.

Effective adjustment of differential cell populations in epigenome-wide association studies. *J. Chen[1], J. Huang[2], L. Liang[1,2], X. Lin[1].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA.

Epigenome-wide association studies, which investigate an association between epigenetic variation and phenotypic variation, have attracted increasing attention recently, especially given the availability of the Infinium HumanMethylation450 BeadChip. Blood samples are routinely collected for measuring DNA methylation. However, blood is a mixture of different cell types, each with a unique methylation pattern. Differential cell populations between case and control samples can potentially confound the associations of interest. Several approaches have been proposed to estimate cell proportions and include them as covariates in a regression model. The effectiveness of this strategy depends on the quality and completeness of a reference panel of purified cell types, which are not always available. We propose to adjust for the confounding of cell mixtures using PCA (Principle Component Analysis), SVA (Surrogate Variable Analysis) and ISVA (Independent Surrogate Variable Analysis). Our proposed method is easily to be carried out and does not require a reference panel. By including the estimated principle components (PCs) or surrogate variables (SVs) in regression models, these methods correct the inflation of QQ-plots under the null due to cell mixture confounding and improve power when true signal presents. We demonstrate by simulation that the proposed methods can capture the cell proportions as low as 3% in presence of batch effects and population stratification, and ISVA is more efficient in capturing the proportions of rare cell types, while all methods perform similarly for dominant cell types. We further show that PCA but not SVA/ISVA breaks down when a large number of true signals are mixed with false signals due to confounding. We apply the methods to several 450K methylation data sets and find that the first few PC/SVs are sufficient to capture the proportions of dominant cell types - neutrophil and lymphocyte, while rare cell types such as eosinophil require more PC/SVs. Our results show that SVA/ISVA provide a convenient and effective approach to adjust for differential cell populations as well as other batch effects and population stratification in epigenome-wide association studies.

A specific DNA methylation signature associated with NSD1+/- mutations in Sotos syndrome reveals a significant genome-wide loss of DNA methylation (DNAm) targeting CGs in regulatory regions of key developmental genes. *S. Choufani[1], C. Cytrynbaum[2], A.L. Turinsky[3, 4], Y.A. Chen[1], D. Grafodatskaya[1], J. Xiang[1], M. Feigenberg[2], B.Y.H. Chung[5], D.J. Stavropoulos[6], R. Mendoza-Londono[2], D. Weksberg[1,2].* 1) Program in Genetics and Genome Biology, Hosp Sick Children, Toronto ON, Canada; 2) Div Clin & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 3) Molecular Structure & Function, Hosp Sick Children, Toronto, ON, Canada; 4) Centre for Computational Medicine, Hosp Sick Children, Toronto, ON, Canada; 5) Dept of Paediatrics & Adolescent Med, Li Ka Shing Faculty of Medicine, Hong Kong; 6) Paediatric Laboratory Medicine, Hosp Sick Children, Toronto, ON, Canada; 7) Dept. of Medical Genetics, UBC, Child and Family Research Institute, Vancouver, BC, Canada; 8) Our Lady's Hospital for Sick Children, Crumlin, Dublin 12, Ireland; 9) Department of Computer Science and Donnelly Centre, University of Toronto, Toronto, ON, Canada.

Sotos syndrome (SS) is characterized by somatic overgrowth and intellectual disability. Most SS cases (>75%) have mutations in NSD1 (nuclear receptor-binding SET domain protein 1). NSD1 binds near promoter elements and regulates transcription initiation and elongation via interactions with H3-K36Me and RNA polymerase II. To determine if NSD1 mutations impact stable epigenetic marks such as DNA methylation (DNAm), we compared DNAm in peripheral blood DNA from SS cases with NSD1 mutations (NSD1+/–; n=20) to controls (n=30) using the Illumina Infinium450methylation BeadChip. Differential DNAm analysis using non-parametric statistics (with correction for multiple testing) coupled with permutation analyses identified a surprisingly high number (n=2157) of differentially methylated (DM) CG sites (with >20% difference in DNAm) between SS and controls. These sites were distributed across the genome; 95% demonstrated loss of DNAm. Using unsupervised hierarchical clustering of the 2157 DM CG sites, all SS cases with NSD1 +/– clustered as a distinct group separate from controls. Moreover, DNAm at these sites clearly distinguished SS (NSD1+/–) from Weaver syndrome (EZH2+/-, n=5), another overgrowth syndrome which has considerable phenotypic overlap with SS. These results suggest that these DM CG sites constitute a DNAm signature that is specific for NSD1+/–. Also, the DNAm signature was successfully used to reclassify NSD1 variants of unknown significance (VUS) in six cases of SS into functionally damaging (n=1) and non-pathogenic (n=5) variants. The majority of these DM CGs mapped to enhancers and CpG island shores. Analysis of ChIP-seq data showed that NSD1+/– specific CG sites are associated with reduced H3K36me3 marks in both normal blood and embryonic stem cells. Also, Ingenuity analysis showed enrichment in neural and cellular development pathways (p<0.001). We then searched for binding motifs enriched in these NSD1+/– DNAm targets using MEME and JASPAR CORE database; SP1 was the most enriched with binding sites in 41% of the targets (NCOR= 0.62). This is the first report of an NSD1+/– specific DNAm signature in SS and that loss-of-function mutations in NSD1 can deregulate the intricate transcriptional balance of key developmental genes. Further elucidation of this signature will significantly impact our understanding of the molecular pathophysiology of SS and identify the specific molecular targets for NSD1 that govern its action in early development.

Comparison of methylation profiles in human blood and lung tissue identifies tissue specific CpG methylation sites. *D. Daley[1], K. Ushey[1], L. Akhabir[1], A. Saferali[1], S.M. Mah[2], A. Sandford[1], M.S. Kobor[2], P. Parè[1].* 1) James Hogg Research Center Department of Medicine University of British Columbia Vancouver, BC, Canada V6G 1Y6; 2) Department of Medical Genetics University of British Columbia Vancouver, BC, Canada V5Z 4H4.

We hypothesize that differences in methylation patterns between individuals may contribute to the etiology of asthma, COPD and other lung related traits. As the majority of genetic studies collect and maintain blood samples from study participants, blood is likely to be the most widely available resource for studies looking to investigate the relationship between phenotype and methylation status. Given our interest in pulmonary phenotypes, and the knowledge that methylation patterns are tissue specific we wanted to identify CpG sites that demonstrate tissue specific methylation (TSM) patterns between blood and lung tissues. **Methods:** To evaluate TSM we used 36 paired samples (blood and lung tissue from the same individual) and 22 lung only samples. Methylation of over 450 thousand CpG sites throughout the genome was evaluated using the Illumina Infinium HumanMethylation450K bead chip array. Methylation levels were assessed using beta values which range from 0 (no methylation) to 1 (complete methylation). Principal components were used to identify 3 samples which clustered differently, all 3 samples were noted to have low and/or poor quality DNA and were removed from subsequent analyses. Correlations between beta values were examined using principal components, heatmaps, and a mixture model of three distributions (unmethylated, variable methylation, complete methylation). **Results:** We identified 49,376 CpG sites with apparent tissue specific methylation. There are 31 CpG sites with extreme differences in methylation, at these sites there is complete methylation in lung tissue but no methylation in blood tissue. We further identified 4,541 CpG sites that are unmethylated in lung tissue, and demonstrate intermediate (variable) methylation patterns in blood tissue, 34,974 CpG sites with complete methylation in blood and intermediate levels of methylation in lung tissue and finally 9,830 sites where there is complete methylation in lung tissue and intermediate levels in blood tissue. Next we evaluated specific genes which have been associated in genome-wide association studies with lung related diseases. We noted good correlation between blood and lung methylation values at *ORMDL3* asthma locus but poor concordance at the Thymic Stromal Lymphopoietin (*TSLP*) locus. **Conclusion:** We have identified 49,376 CpG sites with tissue specific methyation, including CpG sites in the asthma gene *TSLP*.

455F

Hippocampal gene expression, miRNA expression and DNA methylation changes in a mouse model of Fetal Alcohol Spectrum Disorder (FASD). *E.J. Diehl, Bl. Laufer, SM. Singh.* Biology, Western University, London, Ontario, Canada.

Alcohol abuse during pregnancy can lead to a range of neurological abnormities termed Fetal Alcohol Spectrum Disorder (FASD). The mechanisms by which alcohol (ethanol) induces FASD are poorly understood; however, disruption of the regulation of genetic programs in the brain may be involved. We have previously developed a model to generate FASD-like mice showing characteristic learning and memory impairment. Furthermore, as young adults these mice show persistent changes in whole-brain gene expression. However, the mechanisms maintaining these long-term alterations remain unknown. Epigenetic phenomena are increasingly implicated in FASD; however, few studies have integrated multiple genome-wide epigenetic analyses in one study. Here, we examined global difference gene expression, DNA methylation, microRNA (miRNA), and histone methylation in the hippocampi of ethanol-exposed mice. We hypothesized that altered epigenetic mechanisms induce gene expression changes in the hippocampus which may underlie learning and memory impairment. Mouse pups were injected with saline or ethanol on postnatal days 4 and 7, the period equivalent to human trimester three. At 70 days of age, hippocami were isolated and used for gene and miRNA expression microarray, and methylated DNA immunoprecipitation & microarray (MeDIP-chip). ChIP-chip was used to assess changes in histone H3 lysine 4 trimethylation (H3K4me3) and histone H3 lysine 27 trimethylation (H3K27me3). Fifty nine genes were differentially expressed at p<0.05 and fold cut off 1.2. Ingenuity Pathway Analysis (IPA) identified the top affected biological pathway as ‘Free Radical Scavenging, Gene Expression, Dermatological Diseases and Conditions’ with 13/40 molecules affected. Five genes had gene expression and DNA methylation changes; one such gene was Mafg, downregulated by 1.21 fold. MAFG is a transcription factor involved in oxidative stress response. Two miRNAs which target Mafg, miR-130a and miR-200b were upregulated. Mafg may be downregulation as a result of miRNA and DNA methylation changes induced by ethanol. Ethanol is known to induce oxidative stress in the developing brain through a variety a mechanisms including reduction of antioxidant levels and increasing reactive oxygen species (ROS) production. Alteration in the epigenetic regulation of Mafg and other oxidative stress response genes may represent a novel point of interface between the epigenetic and oxidative stress mechanisms of FASD generation.

456T

Genome-wide DNA methylation profiles in fruit flies and the effect of huntingtin knockout. *S. Erdin[1], K. Dietz[1,2], A. Ragavendran[1], M.E. Talkowski[1,3,5], J.A. Walker[1,3], J.F. Gusella[1,4,5].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Louisiana State University Health Sciences Center, Shreveport, LA; 3) Department of Neurology, Harvard Medical School, Boston, MA; 4) Department of Genetics, Harvard Medical School, Boston, MA; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA.

The definitive presence of DNA methylation in Drosophila melanogaster has not yet been established and, if present, the epigenetic role at specific loci will need to be determined. We previously detected different DNA methylation levels in male and female wild type fruit flies using immunological methods with antibodies specific for 5'-Methylcystosine (5mC) and 5'-Hydroxymethlcystosine, suggesting genome-wide methylation is present. In this study, we hypothesized that (a) DNA methylation is present in the male and female adult flies, (b) the pattern of DNA methylation is gender-specific, and (c) the loss of huntingtin protein results in genome-wide differential methylation compared to wild-type flies. We conducted a methylated DNA immunoprecipitation (meDIP) sequencing experiment that profiles methylation patterns on a genome-wide scale based on enrichment using antibodies specific for 5mC. Extracting DNA from the adult fly's brain, we prepared eight sequencing libraries with 47.3 million 50 bp paired-end reads on average for each of wild-type and huntingtin-null male and female flies with 5mC and 5hmC specific antibodies and their counterparts with no antibodies for comparison. For analysis, we followed a computational protocol involving: quality filtering of reads by Sickle, sequence alignment to the fruit fly reference genome by BWA and subsequent filtering of alignments by SamTools. To identify peaks and differentially methylated regions and their annotation, we used standard tools specifically designed for meDIP-seq analysis, Medips and peak callers, MACS and Homer. Our preliminary results based on differentially methylated regions identified by Medips relying on edgeR's statistical analysis (FDR < 0.001) and methylation peaks identified by MACS (p-value < 1e−5) confirm the presence of global DNA methylation in the fly, reveals genome-wide gender-specific differences, and suggest differential methylation associated with loss of huntingtin. Replication of these findings and further downstream analyses are ongoing, but these data confirm the presence of methylated DNA sites in Drosophila melanogaster and suggest a significant role of huntingtin in epigenetic modification.

A novel method for identification and quantification of consistently differentially methylated genomic regions. *C. Fann[1], C.L. Hsiao[1], C.J. Chang[2].* 1) Epidemiology & Genetics, Inst Biomed Sci, Acad Sinica, Taipei, Taiwan; 2) Graduate Institute of Clinical Medical Science, Chang Gung University, Taoyuan, Taiwan.

Advances in biotechnology have resulted in large-scale studies of DNA methylation. A differentially methylated region (DMR) is a genomic region with multiple adjacent CpG sites that exhibit different methylation statuses among multiple samples. Many so-called 'supervised' methods have been established to identify DMRs between two or more comparison groups. Methods for the identification of DMRs without reference to phenotypic information are, however, less well studied. An alternative 'unsupervised' approach was proposed, in which DMRs in studied samples were identified with consideration of nature dependence structure of methylation measurements between neighboring probes from tiling arrays. Through simulation study, we investigated effects of dependencies between neighboring probes on determining DMRs where a lot of spurious signals would be produced if the methylation data were analyzed independently of the probe. In contrast, our newly proposed method could successfully correct for this effect with a well-controlled type I error and a comparable statistical power. Identification of DMRs in a population of samples is vital for understanding methylation variation within a dataset. By applying to two real datasets, we demonstrate that our method provides a more global picture of methylation variation either between groups or between individuals in a single screen.

Malignant pleural mesothelioma (MPM) is a rare and aggressive tumor strongly associated with asbestos exposure. Only 5–17% of individuals exposed to asbestos develop MPM, suggesting the involvement of other environmental, genetic and epigenetic risk factors. DNA methylation is an important mechanism of gene silencing in human malignancies. The relationship between aberrant DNA methylation and inflammation has been documented in many types of cancers, including MPM. Asbestos exposure may contribute to MPM onset through this relationship. We conducted an epigenome-wide scan to identify differentially methylated regions (DMR) in 40 MPM cases versus 40 controls, and in asbestos high-exposed versus low-exposed subjects. Methylation status was measured for about 470K CpG sites in DNA from whole blood, using the HumanMethylation450 BeadChip (Illumina, S. Diego, CA). Logistic regression analysis after adjustment for age, gender and center of recruitment showed no significant association with MPM of any single CpG methylation profile. However, a regional analysis showed multiple significant signals in several genomic regions. In particular, a significant decreased methylation (P<10−7) has been identified in asbestos exposed subjects compared with non-exposed for BLCAP (bladder cancer associated protein), a tumor suppressor gene, and NNAT (neuronatin), which was reported as overexpressed in non-small cell lung carcinoma, both of them located on opposite strands in the same locus on Chr20. No significant difference has been found between the overall cases and controls at the regional analysis. To verify if blood DNA could indeed be a proxy for MPM tissue, we compared the methylation profiles of DNA from whole blood and from corresponding MPM cell lines of 4 MPM cases. The methylation profiles at the BLCAP/NNAT locus proved to be comparable in DNA from blood or MPM cells. These results suggest that different DNA methylation profiles can be related to asbestos exposure induced tumorigenesis of MPM and that epigenetic changes are detectable also in blood DNA.

Epigenetic modification of the genome through methylation plays a key role in the regulation of diverse cellular processes. Changes in DNA methylation patterns have been associated with many complex diseases. Recent studies have found significant differences in the methylation patterns of peripheral blood between African Americans and non-Hispanic Whites. In this study, we leveraged estimates of genomic ancestry in 575 Latino children of multiple Latino ethnicities (Puerto Rican, Mexican, and other) enrolled in the GALA II study of childhood asthma to determine whether differences in global and local methylation patterns between ethnic groups could be explained by ancestry. We measured DNA methylation at ~450,000 markers using the Illumina Infinium HumanMethylation450 BeadChip. We used multidimensional scaling to determine global methylation patterns. Ethnicity was significantly associated with the sixth principal coordinate ($p < 2 \times 10{-}16$ for the overall effect of ethnicity on PC6 and for the comparison of Puerto Ricans to Mexicans). Native American ancestry, when added to the model, was also highly associated with the principal coordinate, and its inclusion in the model eliminated the significance of the association between ethnicity and the methylation pattern measured by PC6. We then performed an epigenome-wide association study between ethnicity and methylation at each site. There was a significant association between ethnicity and local methylation patterns at 1356 sites at a Bonferoni corrected significance level ($1.4 \times 10{-}7$). We performed a mediation analysis to determine the extent to which genomic ancestry mediated the effect of ethnicity on local methylation. Of the 316 methylation sites with a p-value less than $1 \times 10{-}10$, 40 (13%) were significantly mediated by Native American ancestry. The median proportion of the effect of ethnicity on methylation mediated by Native American ancestry was 66% across all sites. An epigenome-wide association study between Native American Ancestry and methylation found 309 sites with a Bonferoni corrected significance level of $1.4 \times 10{-}7$ or below. These findings have broad implications for the study of methylation patterns across populations and for disease association studies. There significant differences in methylation patterns between ethnic groups that are due to ancestry differences in those groups. These differences should be accounted for in performing epigenome wide disease association studies.

A fast and simple method for whole genome bisulfite sequencing library preparation from ultra-low DNA input: Pico-MethylSeq library preparation kit.
K. Giang, T. Chung, X. Sun, X. Jia. Zymo Research Corporation, Irvine, CA.

The distribution of 5-methylcytosine (5-mC) in DNA within the eukaryotic genome is known to greatly affect gene regulation and is currently a major topic of research. Studies on DNA methylation have been aided by advancements in bisulfite conversion and next-gen sequencing technologies which, when coupled, provide single-base resolution of 5-mC in the whole genome. Many whole-genome bisulfite sequencing (WGBS) library preparation protocols designed to analyze 5-mC distribution in the whole genome employ bisulfite to convert unmethylated cytosine bases to uracil after the library preparation and while these protocols produce reliable results, degradation of DNA is inherent to bisulfite conversion. As such, a large proportion of the adapterized library is fragmented and can no longer be amplified, which requires these protocols to call for large amounts of starting input DNA that is often times impossible to obtain. By rearranging the order of library preparation and bisulfite conversion, we developed a streamlined protocol that reveals whole-genome methylation patterns at single-base resolution. The work-flow leads with the degradation inherent to bisulfite conversion to randomly fragment the DNA prior to the library preparation, which allows the protocol to accommodate for pico-gram quantities of starting input, making it ideal for analysis in precious and limited samples. Comparisons of sequencing data from this WGBS library preparation method with the established Reduced Representation Bisulfite Sequencing method using human DNA showed a correlation coefficient of 0.95 for CpG sites with more than 10X coverage. With slight modifications, this protocol is versatile in its ability to prepare libraries for ChIP-seq and RNA-seq.

Evaluation of Illumina 450K Methylation Chip using Technical Replicates.
W. Guan[1], M. Bose[1], J.S. Pankow[1], E.W. Demerath[1], J. Bressler[2], M. Fornage[2], M. Grove[2], T. Mosley[3], C. Hicks[3], K. North[4], E. Boerwinkle[2]. 1) Univ of Minnesota, Minneapolis, MN; 2) Univ of Texas Health Sciences Ctr at Houston, Houston, TX; 3) Univ of Mississippi, Jackson, MS; 4) Univ of North Carolina-Chapel Hill, Chapel Hill, NC.

DNA methylation is a widely studied epigenetic mechanism that alterations in methylation patterns may be involved in the development of common diseases.. As part of the Atherosclerosis Risk in Communities (ARIC) Study, the Illumina Infinium HumanMethylation450 (HM450) BeadChip was used to measure DNA methylation in peripheral blood obtained from ~3000 African American participants. Over 480,000 cytosine-guanine (CpG) dinucleotide sites were surveyed on the HM450 BeadChip. For most of the CpG sites (>90%), we observed significant differences in methylation levels between samples on different plates and chips, largely due to technical error. To evaluate the impact of technical errors, we used 137 technical replicates included in the study. For each CpG site, we calculated an intraclass correlation coefficient (ICC) to compare variation of methylation levels within- and between-replicate pairs, ranging between 0 and 1. The median of observed ICC values is .30, with interquartile range (IQR) of .52 (.11-.63). We observed a relatively large proportion (7.7%) of assayed CpG sites with ICC of 0. The distribution of ICC was modeled as a mixture of censored or truncated normal and normal distributions, which was fitted using an EM algorithm. The CpG sites were clustered into zero-, low-, and high-reproducibility groups, according to the calculated posterior probabilities. The proportions of sites in the three groups are approximately 8%, 50%, and 42%, respectively. We then demonstrated the performance of proposed clustering on CpG sites on their associations with smoking status of samples in the ARIC study. Our results suggested that association at CpG sites with low reproducibility may be under-estimated given the impact of technical variation and needs to be interpreted carefully.

Edematous severe childhood malnutrition is associated with widespread DNA hypomethylation.
N.A. Hanchard[1,2], S. Howell[3], K. Marshall[3], X. Wang[1], T.E. Forrester[3], M.E. Reid[3], J.W. Belmont[1,2], C.A. McKenzie[3]. 1) USDA/ARS/Children's Nutrition Research Center, Baylor College of Medicine, 1100 Bates Ave, Houston, TX, 77030, USA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX, 77030, USA; 3) Tropical Metabolism Research Unit, Tropical Medicine Research Institute, University of the West Indies, Mona, Kingston 5, Jamaica.

Severe childhood malnutrition (SCM) is a major global health problem that contributes to more than two million childhood deaths worldwide each year. SCM occurs in two clinically distinct forms — the more severe edematous SCM (ESCM), and the milder non-edematous SCM (NESCM). The etiology of this clinical dichotomy is unclear; however, previous studies have observed differences between acutely-ill ESCM and NESCM patients in the flux of methyl-groups through the 1-carbon conversion of methionine to homocysteine. Because this reaction contributes significantly to the maintenance of CpG dinucleotide methylation during mitosis, we hypothesized that in high-turnover tissues, DNA methylation in ESCM patients might differ relative to NESCM patients. We used the Illumina Infinium HumanMethylation450 BeadChip array to evaluate methylation at ~485,000 genome-wide CpG sites in buccal DNA samples collected from Jamaican children recruited shortly after recovery from acute SCM, and Jamaican adults recruited 18 or more years after having SCM. After data normalization and quality control, linear regression models were used to determine CpG sites with differential methylation between ESCM and NESCM patients. Immediately post-SCM recovery, we found that samples from ESCM children (N=9) showed significant differential hypomethylation relative to NESCM (N=8) at 21,000 CpG sites genome-wide (false discovery rate, FDR, p<0.01), involving 1,461 genes with more than two significant probes. In pathway analyses, the top 1,000 differentially hypomethylated probes were 4-fold enriched for genes involved in GTPase regulator activity (FDR, $p<1 \times 10{-}3$). Conversely, there were no statistically significant differences in methylation between ESCM (N=10) and NESCM (N=14) individuals sampled as adults. Our results provide evidence for genome-wide differential DNA methylation in ESCM that is directly related to the nutritional insult, and provide a basis for larger studies to replicate our observations. Further, these results suggest that methylation may be a useful intermediate phenotype with which to probe possible genetic trait loci that could provide insight into why some children develop ESCM while others develop NESCM, despite similar environmental and dietary exposures.

463F

Epigenetic Alterations and an Increased Frequency of Micronuclei in Women With Fibromyalgia.
C. Jackson-Cook[1,2], V. Menzies[3], K.J. Archer[4], J. Brumelle[1], K.H. Jones[1,5], Q. Zhou[4], G. Gao[4], T.P. York[2], D.E. Lyon[3]. 1) Dept Pathology, VA Commonwealth Univ, Richmond, VA; 2) Dept Human & Molecular Genetics, Virginia Commonwealth Univ, Richmond, VA; 3) School of Nursing, VA Commonwealth Univ, Richmond, VA; 4) Dept Biostatistics, Va Commonwealth Univ, Richmond, Va; 5) NeoDiagnostix, Inc., Rockville, MD.

Fibromyalgia (FM) is a debilitating condition associated with multiple symptoms, including chronic, widespread pain; dyscognition; fatigue; sleep disturbances; and depression. These symptoms often culminate in decreased workplace productivity, increased health/disability costs, and compromises in the overall quality of life for people with FM. While the adverse health and economic impacts of FM have been well recognized, its etiology remains enigmatic. We hypothesized that FM is associated with the development of acquired somatic epigenetic and/or chromosomal alterations. To test this hypothesis we compared the frequency of spontaneously occurring micronuclei (MN) and genome-wide methylation patterns (Illumina 450K HumanMethylation Chip) in leukocytes of women with FM (N=10) to those seen in comparably aged healthy controls (N=42 [MN]; N=8 [methylation]). A 3.26-fold significantly increased mean frequency of MN ($\psi 2$ =45.552; df= 1; p=1.49×10−11) was observed in the patients with FM [mean=51.4, sd= 21.9] when compared to the controls [mean=15.8, sd=8.5]. Significant differences (N=69 sites) in methylation patterns were also observed between cases and controls (5% false discovery rate), with 91% of these differentially methylated regions (DMRs) being attributable to increased methylation values in the women with FM. The DMRs involved 15 significant biological function groups, including (but not limited to) genes involved in neuron differentiation, nervous system development, skeletal/organ system development, and chromatin compaction. Specific genes with a DMR(s) included the brain-derived neurotrophic factor (BDNF) gene (noted to play an important neuromodulatory role in pain transduction, learning and memory), as well as genes involved in muscle contraction (NR4A3; HDAC4; FEZ1; PRKG1), chromatin compaction (NAT15; HDAC4; UHRF1), and DNA damage or chromosomal segregation (SOD3; UHRF1; NAT15). In summary, these results support the role of epigenetic and acquired chromosomal alterations as a possible biological mechanism leading to or resulting from symptoms associated with FM. Ultimately, since epigenetic changes demonstrate plasticity, recognition of consistent epigenetic alterations associated with FM could provide a means for developing future therapeutic or intervention strategies to treat this debilitating condition.

Epigenome-wide methylation patterns across multiple fetal tissues.
A.C. Just[1], A.A. Baccarelli[1], R.J. Wright[2], H.H. Burris[3], G. Estrada[4], L. Schnaas[4], R.O. Wright[2]. 1) Harvard School of Public Health, Boston, MA, USA; 2) Icahn School of Medicine at Mount Sinai, NY, USA; 3) Department of Neonatology, Beth Israel Deaconess Medical Center, Division of Newborn Medicine, Children's Hospital Boston, Harvard Medical School, Boston, MA, USA; 4) National Institute of Perinatology, Mexico City, Mexico.

Rationale: Methylation is a common epigenetic mark with regulatory functions important for cell differentiation, normal development, and disease. Methylation is also responsive to environmental exposures. New tools enable measures of methylation with single-base resolution across the genome which can be utilized in large epidemiologic studies. A limitation however is that typically only surrogate tissues such as white blood cells have been studied. Human genomic methylation patterns in many potential target tissues have not yet been characterized. Objectives: To compare genomic methylation across multiple fetal tissues (cord blood, placenta, umbilical vein, umbilical artery) collected from the same individuals and identify similar and distinct patterns across samples. Methods: All four fetal tissues were collected for DNA extraction from participants (n=9, total tissue samples= 36) in Mexico City. Samples were run on the Illumina Human Methylation 450K beadchip and resulting % methylation values (betas) were adjusted with subset quantile normalization (Touliemat and Tost 2012). Methylation profiles were compared using multi-dimensional scaling and Pearson's correlation analysis using all probes passing QC as well as subsets defined based on genomic context. Measurements and Main Results: After initial quality control 428,055 CpG sites passed filtering for all 36 samples. Subsetting to autosomal probes, the largest Pearson's correlations between tissues, calculated for each participant, were for umbilical vein and umbilical artery (range 0.975 to 0.995) and the lowest for cord blood and placenta (range 0.796 to 0.834) with similar values when restricted to sites located in CpG islands. Conclusions: Correlation analysis demonstrates that DNA from umbilical vein and artery have more similar patterns of methylation than do cord blood versus placental DNA. In a larger cohort analysis currently underway (n = 130 participants), methylation measures in these fetal tissues will be related back to prenatal exposure to environmental stressors (e.g. lead, air pollution, psychosocial stress) and as mediators of associations between exposures and birth outcomes.

465F

Mapping the DNA unmethylome with mTAG, a novel method to investigate the epigenome.
V. Labrie[1], E. Kriukienė[2], T. Khare[1], G. Urbanaviěiūtė[2], A. Lapinaitė[2], K. Konceviěius[3], D. Li[4], T. Wang[4], S. Pai[1], C. Ptak[1], J. Gordeviěius[5], S.C. Wang[6], A. Petronis[1], S. Klimašauskas[2]. 1) The Krembil Family Epigenetics Laboratory, Centre for Addiction and Mental Health, Toronto, Canada; 2) Department of Biological DNA Modification, Institute of Biotechnology, Vilnius University, Vilnius, Lithuania; 3) Faculty of Mathematics and Informatics, Vilnius University, Vilnius, Lithuania; 4) Department of Genetics, Center for Genome Sciences and Systems Biology, Washington University School of Medicine, St. Louis, MO, U.S.A; 5) Institute of Mathematics and Informatics, Vilnius University, Vilnius, Lithuania; 6) Institute of Systems Biology and Bioinformatics, National Central University, Chungli, Taiwan.

DNA methylation is an epigenetic mechanism that contributes to the regulation of eukaryote genomes, and impacts normal phenotypic variation and disease risk in humans. We have developed a novel method to investigate DNA methylation, through the mapping of unmethylated regions of the genome. Our techniques known as DNA methyltransferase-direct transfer of activated groups (mTAG) uses covalent tagging of unmodified CpG sites, followed by affinity enrichment. The enriched unmodified DNA fraction is then analyzed with tiling microarrays or next-generation sequencing. Numerous control experiments and studies done with human genomic DNA from cultured cells and tissues demonstrate that the mTAG approach reveals unique cross-section through the complex epigenomic landscape, and offers high precision and robustness compared to existing affinity-based techniques. Overall, the mTAG technique is a valuable addition to the toolbox of epigenomic studies.

Functional data analysis for identifying differentially methylated regions.
M. LeBlanc[1,2], C. Page[2,3], A. Frigessi[2], B. Kulle Andreassen[1,2]. 1) Epi-Gen, Institute of Clinical Medicine, Akershus University Hospital, University of Oslo and Akershus University Hospital, Oslo, Norway; 2) Department of Biostatistics, University of Oslo, Oslo, Norway; 3) Department of Neurology, Institute of Clinical Medicine, University of Oslo, Oslo, Norway.

There is general agreement that methylation studies need to report results for differentially methylated regions (DMR). As such, methylation studies are well suited for the application of statistical methods that simultaneously analyze all available data for a given region of interest. One approach for this is functional data analysis (FDA), where statistics are calculated using functions describing the pattern of methylation over a defined region. In contrast, most methylation studies to date either use statistics based on single methylation probes or summarize single probe values within a region of interest with one value (e.g. maximum or mean). There are also methods using various smoothing methods, where the statistical approach operates with a summary measure based on the smoothed values (e.g. Jaffee 2012). We apply statistical methods based on FDA to methylation data. Using simulated data, we explore the utilities of FDA in the context of methylation and compare it to other methods used in the literature. In addition, we apply the proposed method to a recent dataset. The results encourage the use of FDA for methylation data in predefined regions of interest.

DNA methylation analysis of iPS cells using whole-genome bisulphite sequencing. *D. Lee[1,2], J. Shin[1], P. Tonge[4], M. Puri[4], A. Nagy[4,5], J. Seo[1,2,3].* 1) GMI, Seoul national university, Seoul, Seoul, South Korea; 2) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul 110-799, Korea;; 3) Macrogen Inc., Seoul 153-023, Korea;; 4) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario M5G 1X5, Canada; 5) Department of Molecular Genetics, University of Toronto, Toronto M5S 1A8, Canada.

Somatic cell reprogramming involves epigenetic remodeling of chromatin architecture including DNA methylation, conferring induced pluripotent stem cells (iPSCs) with characteristics similar to embryonic stem (ES) cells. However, it remains unclear how the epigenetic pattern changes during the reprogramming process and how it controls the messenger RNA expression. To address these questions, we utilized a secondary inducible reprogramming system developed in mouse using piggyBac-mediated transposition of the four reprogramming factors. Here we report whole-genome DNA methylation profiles at single-base resolution for mouse ES cells, secondary mouse embryonic fibroblast (MEF), secondary factor independent iPSCs induced from these MEFs, and cells undergoing reprogramming from Day 2 to 18, using whole genome bisulfite sequencing, along with comparative analysis of RNA expression and Histone modification (H3K4me3, H3K27me3, H3K36me3) using NGS. We clarified how the epigenetic change controls RNA expression and showed CpG methylation blocks the activation of core pluripotency genes. We defined 7990 differentially methylated regions (DMRs) in CpG context. Ectopic expression of reprogramming factors leads to a dynamic CpG methylation change from start of the process. Gain of CpG methylation occurs rapid and massive around PRCs (RING1, Suz12, EZH2) binding sites both in ESC like and aberrant direction. CpG methylation of transcription factor binding sites of 4 factors (Oct4, Sox2, Klf4, cMyc) or the factors activated early in reprogramming (Nanog) showed demethylation during high dox treatment, but only at the exact binding sites. However the samples became pluripotent showed demethylation in wide region around binding sites of all the core pluripotency factors, including Esrrb, Tcfcp2l1, and Zfx, We also observed that H3K4me3 and H3K27me3 are biased to regions showing low CpG methylation. These regions show dynamic change of both histone modifications and RNA expression. Thus, the regions with high CpG methylation are restricted to non-Histone modification and the genes having high CpG methylation promoters showed low expression. Our data provide evidence for how ectopic reprogramming factors affect CpG methylation in early stage of reprogramming and what is essential to gain pluripotency.

468T

Correlation and Null Hypothesis in Epigenome-wide Association Studies (EWAS). *B. Lehne[1], A. Drong[2], M. Loh[1], W. Zhang[1], W. Scott[1], M.R. Jarvelin[1,3,4,5], P. Elliott[1,3], M.I. McCarthy[2,6], J.S. Kooner[7], J.C. Chambers[1].* 1) Epidemiology and Biostatistics, Imperial College London, London, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) MRC-HPA Centre for Environment and Health, Imperial College London, London, United Kingdom; 4) Institute of Health Sciences, University of Oulu, Oulu, Finland; 5) National Institute of Health and Welfare, Oulu, Finland; 6) Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 7) National Heart and Lung Institute, Imperial College London, London, United Kingdom.

DNA methylation plays an important role in the regulation of gene expression and may be involved in the molecular mechanisms that lead to many human diseases. Currently multiple large-scale Epigenome-wide Association Studies (EWAS) are in progress to investigate the relationships between DNA methylation and phenotypic variation. In this work we analyse the p-value distribution that arises in an EWAS under no association, using permutation testing of Infinium 450K data for 2,660 individuals.

Under no association we observe a substantial deflation of test statistics (median genomic inflation factor λ_{median}=0.92). We demonstrate that this apparent deflation is caused by close correlation between methylation markers, even if these markers have entirely different genomic locations (mean pairwise correlation r_{mean}=0.23 for 1,000 randomly selected markers). This correlation structure substantially reduces the number of independent tests and affects the distribution of test statistics under the Null Hypothesis.

We identified multiple adjustments that reduce correlation between markers; Quantile Normalisation notably reduces correlation (r_{mean}=0.071) resulting in a reduction of statistical deflation (λ_{median}=0.968). Including technical confounding factors (bisulfite-batch, control probe intensities), biological confounding factors (gender, age, white-blood cells) and principal components (PC 1-5) as linear predictors in the regression model leads to a further reduction in correlation and statistical deflation. Together these adjustments remove the majority of correlation between markers (r_{mean}=0.018 for 1,000 randomly chosen markers) and re-establish the Null Hypothesis (λ_{median}= 1.003).

We conclude that correlation between markers is the consequence of biological and technical confounders, each of which affect the methylation status of multiple markers simultaneously. Correlation between markers affects the Null Hypothesis underlying an EWAS. Analysis of EWAS data is enhanced by careful adjustment for these confounding factors.

469F

Importance of Batch and White Blood Cell Subtypes Correction in Analysis of Illumina Infinium 450K Methylation Arrays. *M. Loh[1,2], B. Lehne[1], A. Drong[3], W. Scott[1], W. Zhang[1], M.-R. Jarvelin[1,2,4,5], P. Elliott[1,4], M.I. McCarthy[3,6], J.S. Kooner[7], J.C. Chambers[1].* 1) Epidemiology and Biostatistics, Imperial College London, London, United Kingdom; 2) Institute of Health Sciences, University of Oulu, Oulu, Finland; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 4) MRC-HPA Centre for Environment and Health, Imperial College London, London, United Kingdom; 5) National Institute of Health and Welfare, University of Oulu, Oulu, Finland; 6) Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 7) National Heart and Lung Institute, Imperial College London, London, United Kingdom.

DNA methylation plays a key role in regulation of gene expression. Dense microarrays such as the Infinium 450K are currently in use to investigate relationships between methylation and complex disease, however most studies are limited to analysis of DNA from heterogeneous cell populations such as peripheral blood. We explore the impact of batch effect and variation in white blood cell (WBC) subsets on methylation association signals in studies of peripheral blood, and evaluate strategies for correcting for technical and biological confounding. We measured methylation in DNA extracted from peripheral blood from 1,072 people with incident Type-2 diabetes (T2D; cases) and 1,615 controls using the 450K array. 36 DNA samples were analysed in duplicate. Measured WBC subsets (basophils, eosinophils, lymphocytes, monocytes and neutrophils) were available for all participants. In addition we estimated WBC subsets (B-cells, granulocytes, natural killer [NK], monocytes and T-cells [CD4+ and CD8+]) using the method proposed by Houseman *et al.* (2012). Regression analysis was used to quantify the associations between methylation and replicate or case-control status, and adjustment for technical and biological confounding. Amongst the duplicate samples, we observed strong association between replicate batch and methylation (genomic inflation factor λ=2.188). Adjustment for 24 different in-built control probes on the array reduces the degree of statistical inflation, with bisulfite conversion control showing the strongest effect (λ=1.292). Simultaneous correction for all control probes corrects for majority of the inflation (λ=1.098). In the case-control study, there was high concordance between measured and imputed WBC subsets. We found close association of WBC subsets with DNA methylation (λ=3.090). The association of methylation with T2D case-control status showed substantial departure from null expectation (λ=1.130). Adjustment for inferred WBC subsets displayed better reduction in inflation (λ=1.076) compared to measured values (λ=1.134). In particular, adjustment for NK cells (λ=1.108) and monocytes (λ=1.118) had the strongest effects. Epigenome-wide association studies of DNA methylation are confounded by technical and biological factors, including the distribution of cell subtypes. Corrections for batch via the use of control probes, as well as cell subtypes at least partially reduces confounding and statistical inflation in analysis of these complex data.

The effects of a therapeutic equivalent dose of olanzapine on genome-wide DNA methylation in hippocampus and cerebellum, in a rat model in vivo. *M.G. Melka[1], B.I. Laufer[1], P. McDonald[1], C.A. Castellani[1], N. Rajakumar[2], R. O'Reilly[2], S.M. Singh[1].* 1) Molecular Genetics Unit, Department of Biology; 2) Department of Psychiatry, University of Western Ontario, London, Ontario, Canada, N6A 5B7.

Background: The mechanism of action of olanzapine in treating schizophrenia is not clear. This research reports the effects of therapeutic equivalent treatment of olanzapine on DNA methylation in a rat model in vivo. Methods: Genome-wide DNA methylation was assessed using MeDIP-Chip analysis. All methylated DNA immunoprecipitation (MeDIP), sample labeling, hybridization, and processing were performed at Arraystar Inc. (Rockville, Maryland, USA). The identified gene promoters showing significant alterations to DNA methylation were then subjected to ingenuity pathway analysis (Ingenuity System Inc, CA, USA). Results: The results show that antipsychotic medications cause an increase in methylation in 1159, 1310 and 1329 genes and a decrease in methylation in 638, 567 and 533 genes in hippocampus, cerebellum and liver, respectively. Most genes affected are tissue-specific. Only 41 genes (~3%) affected showed an increase and no gene showed a decrease in methylation in all three tissues. Further, the two brain regions shared 127 (~10%) genes affected. Interestingly, the genes affected are enriched in pathways affecting dopamine signalling, molecular transport, nervous system development and functions in hippocampus; ephrin receptor signalling and synaptic long term potentiation in cerebellum; tissue morphology, cellular assembly and organization in liver. Also, the affected genes included those previously implicated in psychosis. Conclusions: The known functions of affected genes suggest that the observed epigenetic changes may underlie amelioration of symptoms as well as account for certain adverse effects including the metabolic syndrome. The results offer novel insight into the mechanisms of actions of olanzapine, in the understanding of therapeutic as well as side effects of antipsychotics.

Astrocytic abnormalities and global DNA methylation patterns in depression and suicide. *C. Nagy[1,2], M. Suderman[3,4], M. Szyf[4], N. Mechawar[1,2], C. Ernst[1,2], G. Turecki[1,2].* 1) Medicine, McGill University, Verdun, Quebec, Canada; 2) McGill Group for Suicide Studies, Douglas Mental Health University Institute; 3) McGill Centre for Bioinformatics; 4) Department of Pharmacology and Therapeutics.

Background: Astrocytes are central nervous system specific cells involved in numerous brain functions including the regulation of synaptic transmission and of immune function. There is mounting evidence suggesting astrocytic dysfunction in major depression and suicide. Objective: To identify gene-based changes associated with astrocytes and to determine if DNA methylation plays a role in these abnormalities. Design: MBD2-based methylome sequencing of cases with astrocytic abnormalities. Participants, setting, and main outcome measures: We first characterized prefrontal cortex samples from 121 individuals (76 who died by suicide and 45 sudden death healthy controls) for the astrocytic markers GFAP, ALDH1L1, SOX9, GLUL, SCL1A3, GJA1, and GJB6. A subset of 22 cases with consistently downregulated astrocytic markers was then compared to 17 matched controls using MBD2-sequencing followed by validation with high resolution melting and bisulfite Sanger sequencing. With these data, we generated a genome-wide methylation map unique to altered astrocyte-associated depressive psychopathology and suicide. Results: The map revealed regions of differential methylation between cases and controls, the majority of which displayed reductions in methylation levels in cases. A large number of our differentially methylated regions overlapped with known ENCODE identified regulatory elements. Conclusions: Taken together, our data indicate significant differences in methylation patterns specific to astrocytic dysfunction associated with depression and suicide, providing a potential framework for better understanding this phenotype.

472T

The effects of perinatal testosterone exposure on DNA methylation in the brain are late-emerging and dynamic. *T.C. Ngun[1,2], N.M. Ghahramani[1,2], P.Y. Chen[3], S. Krishnan[1,2], S. Muir[1,2], T. TeSlaa[3], L. Rubbi[3], A.P. Arnold[2,4], G.J. de Vries[5], N.G. Forger[5], M. Pelligrini[3], E. Vilain[1,2].* 1) Department of Human Genetics, David Geffen School of Medicine at University of California Los Angeles (UCLA), Los Angeles, CA, USA; 2) Laboratory of Neuroendocrinology of the Brain Research Institute, UCLA, Los Angeles, CA, USA; 3) Department of Molecular, Cellular, and Developmental Biology, UCLA, Los Angeles, CA, USA; 4) Department of Integrative Biology and Physiology, UCLA, Los Angeles, CA, USA; 5) Neuroscience Institute, Georgia State University, Atlanta, GA, USA.

Sexual differentiation of the rodent brain is driven mainly by the actions of gonadal hormones, primarily testosterone (T) and estradiol. Perinatal exposure to T can have long-lasting and irreversible consequences on brain anatomy. These have been termed organizational effects, and lead to masculinization of certain brain regions, including those that control sexually dimorphic traits. The molecular mechanisms underlying these effects are still poorly understood. We hypothesized that perinatal T exposure will affect DNA methylation patterns in two sexually dimorphic brain regions - the bed nucleus of the stria terminalis/preoptic area (BNST/POA) and the striatum - and that this exposure contributes to the establishment of sex differences in the methylome. We established the first genome-wide methylation profiles for males (XY), females (XX), and females treated with T at birth (XX+T) at two time points. The first was postnatal day 4 (PN4) (within the critical window for T's organizational effects) and the second was PN60 (adulthood), to evaluate the longer term effects of T. Our approach was validated by the finding that the majority of X chromosome CpG sites differing between XX and XY mice at PN60 were hypermethylated in XX animals in both regions of the brain, consistent with X chromosome inactivation. The short-term effect of T exposure was relatively modest: 45 genes were differentially methylated between XX and XX+T in the BNST/POA, while 68 genes were influenced by T in the striatum. However, by PN60, this number had grown dramatically. The number of T-influenced genes was 760 in the BNST/POA and 1377 in the striatum. The traditional view of brain organization is that organization by T is stable. Therefore our finding that only a few of the genes affected by T at PN4 were the same as those affected at PN60 in either region was unexpected. Methylation at sexually dimorphic CpG sites in XX+T was more masculinized at PN60 than PN4 in both regions. However, the masculinizing effect of T on the methylome was stronger in the striatum than in the BNST/POA. Taken together, these data suggest that the organizational effect of T on the brain methylome is late-emerging and dynamic. Our data also suggest that organization by T may occur via early programming on relatively few genes and that this small initial effect sets up the brain to respond in a particular fashion to later developmental events. Drs. Ngun and Ghahramani contributed equally to this work.

Genome-wide DNA Methylation Network Analysis for Osteoporosis Risk. *c. qiu[1], H. Shen[1], J. Li[1], H.W. Deng[1,2].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 2) Center of Systematic Biomedical Research, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China.

Background: Osteoporosis is a common disease mainly characterized by low bone mineral density (BMD) and increased risk of fractures. Peripheral blood monocytes (PBMs) may act as precursors of osteoclasts, the bone resorption cells, and also produce cytokines important for osteoclast activity, and thus represent major systemic target cells for bone metabolism. Alterations in DNA methylation has been implicated as a key regulatory mechanism in the etiology of human complex diseases. Recent studies suggested that DNA methylome is organized into modules of co-methylated features. In this study, we carried out a network analysis to construct modules of highly co-methylated gene promoters in PBMs and identify modules that are significantly associated with BMD. Methods: Genome-wide DNA methylation profiles were generated by MeDIP-seq in PBMs from 18 unrelated Caucasian postmenopausal females with extremely high (n=9) and low (n=9) hip BMDs. MeDIP-seq signals were normalized and quantified using the MEDIPS analysis package. By focusing on the promoter DNA methylation data, we applied a weighted correlation network analysis (WGCNA) to identify the co-methylation modules and summarize the methylation profiles of each module into a single representative eigengene value. The eigengene values of individual modules were compared between the high and low BMD groups to identify co-methylation modules associated with BMD. Results: We identified a total of 18 co-methylation modules, each ranging in size of 32-251 gene promoters. Specifically, the overall methylation level of module-18 was significantly higher in the low-BMD group (p=0.002). Gene ontology analysis suggested that module-18 was highly enriched for genes belonging to a number of interesting biological processes, such as 'cellular response to vitamin D' (p=1.75E−16), 'blood vessel endothelial cell migration' (p= 4.33E−12), and 'cellular response to mechanical stimulus' (p=2.07E−09). Interestingly, several of the module-18 genes (e.g., AQP9, ITGB1) have been associated with BMD variation through previous genome-wide association studies. Conclusions: Using system level network analysis, we reconstructed the promoter co-methylation network in PBMs and identified a co-methylation module that may mediate variation in risk to osteoporosis. Our results highlighted the advantages of using systems-level network analysis to add value to the traditional DNA methylation analysis.

Genome-wide placental DNA methylation analysis of severely growth-discordant monozygotic monochorionic twins reveals a novel epigenetic signature for IUGR. *M. Roifman[1], S. Choufani[2], S. Drewlo[3], S. Keating[4], J. Kingdom[5], R. Weksberg[1,2].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 2) Genetics and Genome Biology Program, Hospital for Sick Children Research Institute, University of Toronto, Toronto, Canada; 3) Research Centre for Women's and Infants' Health, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Canada; 4) Department of Laboratory Medicine and Pathology, Mount Sinai Hospital, University of Toronto, Toronto, Canada; 5) Maternal-Fetal Medicine Division, Department of Obstetrics and Gynecology, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

Background: Intrauterine growth restriction (IUGR) refers to reduced fetal growth in the context of placental insufficiency. IUGR is not only associated with perinatal morbidity and mortality, but has also been linked to adult-onset diseases, such as obesity, hypertension and diabetes, and thus poses a major health burden. Placental epigenetic dysregulation has been implicated in IUGR; however, clear pathophysiological mechanisms remain to be elucidated. Monozygotic monochorionic (MZ-MC) twins are particularly affected by IUGR in the setting of severe discordant growth with unequal placental share. Because MZ twins have the same genotype at conception, and a shared maternal environment, they provide a unique model for studying epigenetic regulation of the placenta (i.e. the non-shared environment). **Objective:** We compared genome-wide placental DNA methylation patterns of severely growth-discordant MZ-MC twins to identify novel candidate genes for IUGR in the context of unequal placental share. **Methods:** We studied 8 severely growth-discordant MZ-MC twin pairs, each with unequal placental share. Snap frozen placental samples were obtained at delivery from each twin. Placental pathology was histologically determined. We used the Infinium HumanMethylation450 BeadChip array platform to identify genomic regions exhibiting differential methylation in IUGR versus normal twins. **Results:** Our analysis of larger twins (n=8) versus smaller twins (n=8) identified 138 candidate genes with statistically significant ($p<0.05$) differential methylation (using a cutoff of 10% difference in DNA methylation). Across these 138 genes, the lower weight twins exhibit a distinctly different methylation signature compared to their higher weight counterparts. These genes, many linked to IUGR for the first time in this study, confer a variety of functions, including cellular development, signaling, angiogenesis, and lipid metabolism. Largest methylation differences between the two groups were found in the *DECR1*, *LEPR* and *SPG7* genes, implicating lipid metabolism and mitochondrial dysfunction as prominent pathophysiological mechanisms in this form of IUGR. **Conclusion:** We propose a novel epigenetic signature for IUGR in the context of unequal placental share in MZ-MC growth-discordant twins, highlighting lipid metabolism and mitochondrial dysfunction as major contributors, and suggesting an underlying mechanism for the fetal reprogramming associated with adult-onset diseases.

Deloukas[1], the MuTHER consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 4) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Churchill Hospital, Oxford, UK; 5) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 6) Department of Genetic Medicine and Development and Institute for Genetics and Genomics in Geneva, University of Geneva Medical School, Geneva, Switzerland; 7) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, UK; 8) Department of Medical Sciences, Molecular Medicine and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 9) Present address: Department of Human Genetics, McGill University, McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 10) Present address: Department of Haematology, Cambridge Institute for Medical Research, University of Cambridge, Cambridge, UK.

Epigenetic mechanisms, such as DNA methylation, are attractive candidate processes for explaining the interplay of genetic and environmental factors in complex traits. We explored the associations between genetics and epigenetics utilizing genome-wide DNA methylation profiles (Illumina HumanMethylation450) from skin (N=469) and adipose tissue (N=648) from female twins in the MuTHER study. We found that methylation levels were generally highly correlated between skin and adipose tissue from the same individual ($r_{s\ median}$=0.96); this dropped significantly if only the (10%) most variable sites were analysed ($r_{s\ median}$=0.78). For around 1% of CpG sites we observed marked differences in average methylation levels between the tissues (Δbeta>0.3). We found methylation variability to be suppressed in regions known to impact gene regulation such as promoters (adipose: P<1.E-5; skin: P<1.E-4). We then studied the degree of association between adipose DNA methylation and expression of nearby genes in this tissue, and of 13,532 genes we found 17% to have at least one significant association with a slight enrichment of negative correlations. Concordance in methylation for both adipose and skin tissue was greater between MZ twins than DZ twins, indicating genetic influences on DNA methylation. Narrow-sense heritability analysis showed evidence for DNA methylation being heritable (h^2_{mean} adipose=0.19; skin=0.13) and half of the heritable adipose CpG sites were associated with common variants (metQTLs) located in close proximity to the methylation site (FDR1%, median distance 12kb). Cross-tissue comparison revealed that the vast majority (63%) of adipose metQTLs could be replicated in skin (P<0.05 and same direction of effect; estimated proportion of significant tests π1=0.74). Our results show that there is widespread genetic regulation of CpG methylation in adipose and skin tissue. Integrating our adipose metQTL data with adipose reference epigenomes (H3K4me1 and H3K4me3) from the NIH Roadmap Epigenomics and the GWAS catalogue (NHGRI) revealed significant enrichment of metQTLs overlapping with metabolic disease loci in enhancer elements. Finally, we have been scanning cardiometabolic and skin related traits available in the MuTHER study for association to methylation changes. As expected we find strong tissue-phenotype dependency; for example, 3.5-fold more methylation sites in adipose tissue associated with body mass index than in skin (FDR1%).

476T

The Highs and Lows (of Methylation) in the Placental Epigenome. *V. Shridhar, P. Shaw, K. Bunce, T. Chu, D. Peters.* Obstetrics and Gynecology, University of Pittsburgh, Pittsburgh, PA.

Fetal health and development during gestation have long-term consequences upon the overall health of an individual. Regulation of fetal development is strongly influenced by gestational age-appropriate cues from the uterine environment. These cues often take the form of epigenetic marks at the feto-maternal interface on the placenta. There is increasing evidence that the placental epigenome has far-reaching effects on both prenatal and postnatal life of the fetus.

We generated the methylation profiles of 6 placental (from 3 male and 3 female fetuses) as well as 3 unmatched maternal blood cell samples, using Agilent Technology's SureSelect Methyl-seq targeted enrichment kits. We found that placental DNA is hypo-methylated, as compared to the maternal blood cell DNA, in accordance with previously published results. There were smaller-sized tracts in placental DNA that were methylated, compared with maternal DNA. We classified the placental epigenome into methylated (>80%) and unmethylated (<20%) domains. We correlated methylation levels of the genes within these domains to publically available expression level data from gestational-age matched placental tissue. At a gene level, there was a positive correlation between methylation and expression. Gene ontology groups that were over-represented in the methylated domains included embryonic morphogenesis, endopeptidase activity, cell fate commitment, organ development and regulation of apoptosis (p<0.05). Ontology groups over-represented in the unmethylated domains included metal ion homeostasis, GPCR activity and heterochromatin formation among others (p<0.004). There were some gender-related differences in placental methylation levels. Analysis is currently ongoing to better define these regions of high and low methylation as well as the physiological relevance of these methylation sites. Term placentas are being harvested to study the changes in epigenome over time. Additionally, we intend to extend this study for comparison of methylation profiles of placentas from pregnancies with complications, such as preeclampsia and pre-term labor.

We anticipate that these studies will yield novel insights into placental gene expression over the course of gestation and into the epigenetic mechanisms of preeclampsia and pre-term birth.

Whole-genome bisulfite sequencing (WGBS): A novel `post-bisulfite conversion' library construction method from low gDNA inputs. *R. Sooknanan, J. Hitchen, D. Gabel, V. Ruotti.* Epicentre® (an Illu1EPICENTRE Biotechnologies. LLC (an Illumina® company), Madison, WI, USA mina® company), Madison, WI.

Genome-wide analysis of 5-methylcytosine (5-mC) and 5-hydroxymethylcytosine (5-hmC) are possible with whole-genome bisulfite sequencing (WGBS), where unmethylated cytosine residues are converted to uracil. Further, with the use of T4 β-glucosyltransferase (T4-BGT) and Ten-eleven Translocation Gene Protein 1 (Tet1) enzymes, 5-hmC can be discriminated from 5-mC on a genome-wide basis. However, a major challenge in WGBS is the degradation of DNA that occurs during bisulfite conversion under conditions required for complete conversion. Typically, ~90% of input DNA is degraded and thus, is especially problematic with limited starting amounts of DNA. Additionally, regions that are rich in unmethylated cytosines are more sensitive to strand breaks. As a consequence, a majority of DNA fragments contained in di-tagged NGS DNA libraries treated with bisulfite 'post-library construction' can be rendered inactive due to strand breaks in the DNA sequence flanked by the adapter sequences. These mono-tagged templates are then excluded during library enrichment resulting in incomplete coverage and bias when performing whole genome bisulfite sequencing. Here, we describe a novel 'post-bisulfite conversion' library construction method for preparing NGS libraries from genomic DNA prior to the addition of the adapters. This 'post-bisulfite conversion' library construction method uses the untagged single-stranded DNA as template for the subsequent addition of adapter sequences required for NGS. Thus, single-stranded DNA fragments independent of size and position of strand breaks remain as viable templates for library construction, eliminating the loss of fragments and the selection bias associated with a 'post-library construction' bisulfite conversion strategy. This novel 'post-bisulfite conversion' library construction method exhibits increased sensitivity and efficiency and improved coverage required for WGBS for detecting 5-mC and 5-hmC marks.

478T

A novel sequencing method for genome-wide profiling of 5-hydroxymethylcytosine with single-base resolution. *D. Tan, H. Chung, X. Sun, X. Jia.* Zymo Research Corp., Irvine, CA.

5-hydroxymethylcytosine (5hmC) is an epigenetic mark abundant in embryo stem cells and brain tissues. The exact biological functions of 5hmC are still under close investigation although several lines of evidence have indicated it could be involved in active DNA demethylation. Meanwhile, extensive studies have been carried out to determine its genomic distribution. A number of approaches have been developed using either affinity based enrichment, such as hMeDIP, that rely on antibody and other specific binding proteins to target 5hmC, or modified bisulfite sequencing, namely oxidative bisulfite sequencing (OxBS) and TET assisted bisulfite sequencing (TAB-sequencing). However, all those methods have limitations which hamper their application. For example, affinity based methods lack single base resolution while modified bisulfite sequencing methods require efficient chemical or enzymatic oxidation which cannot be easily achieved or guaranteed. As an alternative, we have developed a novel genome-wide sequencing method that utilizes an enzyme based modification approach coupled with bisulfite-sequencing for detecting 5hmC. This methodology allows quantification of 5hmC levels with single CpG resolution and can also be employed for locus-specific assays. Using this method, we were able to map and quantify 5hmC sites at the genomic scale for several different biological samples. This novel method can determine the exact location and abundance of 5hmC, which will facilitate our understanding of 5hmC in regulating gene expression in different biological contexts.

The role of DNA methylation in B°AT1 transcriptional regulation along crypt-villus axis. *E. Tumer, T. Juelich, S. Broer.* Research School of Biology, The Australian National University, Canberra, Australia.

Hartnup disorder is an autosomal recessive disorder caused by mutations in the B°AT1 (Slc6a19) gene encoding the major transport system for neutral amino acids in the intestinal brush-border membrane. B°AT1 protein is expressed at the apical membrane of enterocytes in increasing amounts along the crypt-villus axis. Previously, we showed that HNF1a and HNF4a bind to the Slc6a19 promoter up-regulating transcription. Sox9, by contrast, suppressed the promoter activity induced by HNF1a and HNF4a. Sox9 is a transcription factor known to be involved in the differentiation of stem cells into mature enterocytes, and is highly expressed in the crypt region, but absent at the villus tip. Thus Sox9 expression could explain the gradient of B°AT1 in the intestine. However, despite HNF1a and HNF4a expression in the liver, B°AT1 is not expressed, while Sox9 is absent. As a result we considered DNA methylation as a mechanism to regulate B°AT1 expression. DNA methylation of a transcription factor binding sites can prevent transcription factor from binding to the DNA. Kikuchi et al (2010) suggested that HNF1a binding to the B°AT1 promoter could be prevented by methylation in the liver. However, they observed particular methylation in the liver at position -1080, which is 940 bp upstream of the HNF1a binding site. In this study we investigated the DNA methylation status of the B°AT1 promoter, using bisulfite sequencing. DNA methylation was determined in a 1.2 kb region upstream of the B°AT1 transcriptional start site in liver, kidney and crypt-villus preparations. From each experiment a minimum 10 independent clones were sequenced. Twenty CpG sites were analysed and found to be differentially methylated in the chosen tissues. We found that CpG dinucleotides around HNF1a, HNF4a and TATA binding sites were hypomethylated in the villus, whilst being hypermethylated in the crypt and in liver tissue. These results indicate that DNA methylation might play a role together with Sox9 in the repression of B°AT1 expression in the crypt, whereas in the liver cells DNA methylation itself might be sufficient. Kikuchi, R., S. Yagi, et al. (2010). "Genome-wide analysis of epigenetic signatures for kidney-specific transporters." Kidney international 78(6): 569–577.

Epigenome-wide differences in DNA methylation of autosomes in Klinefelter's Syndrome. *E.S. Wan[1], W. Qiu[1], J. Morrow[1], T.H. Beatty[2], J. Hetmanski[2], E.K. Silverman[1], D.L. DeMeo[1] on behalf of the COPDGene Investigators.* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Rationale: Klinefelter's Syndrome (47 XXY) affects approximately 1 in every 600 human male births and is associated with hypogonadism and impaired fertility, tall stature with eunuchoid proportions, and a variety of cognitive and behavioral disorders. The degree to which Klinefelter's (KF) subjects present with this clinical spectrum is highly variable and may suggest a role for epigenetics. While the role of DNA methylation in X-inactivation among KF subjects has been explored, differential methylation at autosomal sites has not previously been described.

Methods: All subjects were recruited from the COPDGene study, a multi-center, cross-sectional cohort of non-Hispanic white and African American current and former smokers with ≥10 pack-years of smoking. Six KF subjects were identified during genome-wide genotyping. Genome-wide DNA methylation data was obtained on 5 KF subjects (the 6th had insufficient DNA) and 105 male control subjects using the Illumina HumanMethylation450K Beadchip. Preprocessing, quantile normalization, and adjustment for batch effects were performed using *limma*, *minfi* (v 1.4.0) and *sva* (v 3.4.0) packages in R (release 2.15); all pre-processing and subsequent analyses were performed separately for Infinium I and Infinium II probe types. Empirical Bayes methods were used to test for differential methylation between KF subjects and controls at 470,326 autosomal CpG sites using linear models adjusted for age, race, and body mass index (BMI). A false-discovery rate of <0.05 was used to denote significance.

Results: There were no significant differences by race or current smoking status between KF subjects and controls; KF subjects were significantly younger and had a higher mean BMI than controls. 204 Infinium I sites and 275 Infinium II sites, including sites annotated to the G-protein coupled receptor 27 (*GPR27*) and Fas associated factor 1 (*FAF1*), met the *a priori* threshold for significance.

Conclusions: Differential methylation at non-imprinted autosomal CpG sites exists in Klinefelter's syndrome and may highlight novel loci associated with the clinical manifestations of the syndrome.

481F

Ascorbate is a possible cofactor for Tet proteins to hydroxylate 5mC to 5hmC. *G. Wang, E. Minor, K. Dickson, C. Gustafson, B. Court, J. Young.* Dr. John T. Macdonald Foundation Dept. of Human Genetics, Hussman Inst.for Human Genomics, Univ Miami, Miami, FL.

Ascorbate (vitamin C) is best known for its role in scurvy, in which the hydroxylation of collagen catalyzed by collagen hydroxylases is incomplete due to ascorbate deficiency. Recently, Tet (ten-eleven translocation) family dioxygenases (also known as Tet proteins) have been identified to hydroxylate 5-methylcytosine (5mC) to 5-hydroxymethylcytosine (5hmC) in DNA. Both Tet proteins and collagen hydroxylases belong to the iron and 2-oxoglutarate-dependent dioxygenase superfamily. These dioxygenases utilize Fe^{2+} as a cofactor, 2-oxoglutarate as a co-substrate, and some of them including collagen hydroxylases require ascorbate as another cofactor for full catalytic activity. We found that the content of 5hmC was extremely low in mouse embryonic fibroblasts (MEFs) cultured in ascorbate-free medium. Additions of ascorbate dose- and time-dependently enhanced the generation of 5hmC, without any effects on the expression of Tet genes. Treatment with another reducer glutathione (GSH) did not change the level of 5hmC. Further, blocking ascorbate entry into cells by phloretin and knocking down Tet1-3 expression by short interference RNAs (siRNA) significantly inhibited the effect of ascorbate on 5hmC. The effect of ascorbate on 5hmC generation appeared independent on iron uptake by cells or the production of 2-oxoglutarate. These results suggest that ascorbate enhances 5hmC generation, most likely by acting as a cofactor for Tet proteins to hydroxylate 5mC to 5hmC. Thus, we have uncovered a novel role for ascorbate in modulating the epigenetic control of genome activity.

482T

A new target enrichment system generating ultra-high complexity probe pools for targeted bisulfite sequencing. *J. Wendt[1], M. Suzuki[2], T. Richmond[1], N. Patterson[2], T. Millard[1], D. Green[1], R. Bannen[1], R. Selzer[1], T. Albert[1], J. Jeddeloh[1], J. Greally[2], D. Burgess[1].* 1) Roche NimbleGen Inc., Development and Technology Innovation Groups, Madison, WI; 2) Albert Einstein College of Medicine, Center for Epigenomics, Bronx, NY.

DNA methylation has been shown to have a role in a host of biological processes, including silencing of transposable elements, stem cell differentiation, embryonic development, genomic imprinting, and inflammation, as well as, many diseases, including cancer, cardiovascular disease, and neurologic diseases. Epigenetic modifications can also affect drug efficacy by modulating the expression of genes involved in the metabolism and distribution of drugs, as well as, the expression of drug targets, contributing to variability in drug responses among individuals. There are currently a number of tools to study DNA methylation status, either at a single locus level, using methods like methylation-specific PCR or MALDI-TOF-MS, or at a broader, genome-wide level, using DNA microarrays, reduced representation bisulfite sequencing (RRBS), or even whole genome shotgun bisulfite sequencing. The latter method is preferred by many researchers, as it provides DNA methylation status at base pair resolution and allows for the assessment of percent methylation at each position in the genome. However, it is expensive in terms of money and analysis to generate such data for the entire genome, when generally only a subset of the genome is of interest to most researchers. We describe a system for the targeted enrichment of bisulfite treated DNA, allowing researchers to focus on a subset of the genome for high resolution cytosine methylation analysis. Regions ranging in size from 10 kb to 75 Mb may be targeted, and multiple samples may be multiplexed and sequenced together to provide an inexpensive method of generating methylation data for a large number of samples in a high throughput fashion. Innovations that differentiate our system, including probe design, selection and manufacture, as well as optimization techniques to improve capture uniformity, will be highlighted.

Epigenome-wide association study of Autism Spectrum Disorder using Post-Mortem Brain Tissue. *C.C.Y. Wong[1], D.H. Geschwind[2,3,4], N. Parikshak[2], C. Troakes[5], J. Viana[6], D. Condliffe[1], T.G. Belgard[2], S. Prabhakar[7], J. Mill[1,6].* 1) King's College London, MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, De Crespigny Park, London, UK; 2) Center for Autism Research and Treatment, and Program in Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, CA, USA; 3) Department of Human Genetics, University of California, Los Angeles, CA, USA; 4) Program in Neurogenetics, Department of Neurology, University of California, Los Angeles, CA, USA; 5) King's College London, MRC Centre for Neurodegeneration Research, Institute of Psychiatry, De Crespigny Park, London, UK; 6) University of Exeter Medical School, Exeter University, St Luke's Campus, Exeter, UK; 7) Computational and Systems Biology, Genome Institute of Singapore, 60 Biopolis St, Singapore 138672, Singapore.

Autism Spectrum disorders (ASD) is a group of complex neurodevelopmental disorders characterized by considerable etiological heterogeneity. Although genetic variation in several dozen ASD genes has been implicated in the development of ASD, collectively accounting for 10-20% of ASD cases, there is emerging evidence to suggest a role for epigenetic variation in the disorder. In this study, we performed an epigenome-wide association study (EWAS) of ASD using a large collection of post-mortem brain tissue (n=139) obtained from four brain regions. DNA methylation was quantified using the Illumina Infinium 450K Human Methylation array in conjunction with an analysis pipeline developed by our group. We identified a number of significant disease-relevant differentially methylated regions (DMRs), including several located in the vicinity of genes previously implicated in psychiatric disorder. Pathway analysis of our top loci highlighted a significant enrichment of epigenetic disruption in biological networks and pathways relevant to disease and neurodevelopment. Overall, our data provide further evidence to support a role of differential DNA methylation in the etiology of ASD.

484T

Racial and Ethnic Variation in DNA Methylation of Human Peripheral Blood. *Y. Yang[1], R. Sebra[1], Y. Li[2], J.F. DeCoteau[3], I. Peter[1], S.A. Scott[1].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Anesthesiology, Xuzhou Medical Colleage, Xuzhou, Jiangsu, China; 3) Cancer Stem Cell Research Group, University of Saskatchewan, Saskatoon, SK, Canada.

Genome-wide DNA methylation profiles can differ between human cell types and tissues; however, little is known about CpG methylation variability between racial and ethnic populations. To determine if significant ethnic-specific CpG methylation differences exist in germline DNA, 60 African-American, Caucasian, Chinese, and Hispanic peripheral blood DNA samples from unrelated healthy adults were subjected to DNA methylation profiling using the HumanMethylation450 BeadChip (450K-array; Illumina). 450K-array probes that contained known single-nucleotide polymorphisms or mapped ambiguously to the human genome were removed, and batch effects controlled for by quantile normalization. To validate these data, selected samples were subjected to targeted genome-wide bisulfite sequencing (84 Mb; 24x average coverage; Agilent Technologies), which had high concordance with 450K-array methylation profiling (r=0.976). Unsupervised hierarchical clustering of 450K-array probes with high beta-value (β) standard deviation (SD>0.15) among all 60 samples suggested ethnic-specific methylation profiles for the four tested populations. Moreover, probes were tested for differential ethnic-specific methylation using the Kruskal-Wallis test and a population mean $|\Delta\beta|>0.15$, which identified 407 CpG methylation sites that were significantly differentially methylated between at least two of the four populations ($p<0.001$). Six selected regions subsequently were validated by third-generation bisulfite single-molecule real-time (SMRT®) sequencing of population-pooled ~500 bp amplicons (1123x average coverage; Pacific Biosciences), which confirmed ethnic-specific 450K-array probe and/or region methylation differences. Among the 407 identified ethnically variable CpG methylation sites (located in or near 265 genes), the majority were located outside of CpG islands and their methylation profiles were sufficient to accurately separate all four populations by principal component analysis. Although DNA methylation can change with age and be modulated by environmental stimuli, these data suggest that a small proportion of CpG sites in the human genome are epigenetically stable in peripheral blood mononuclear cells and can reflect racial and/or ethnic ancestry. Additionally, these data have important implications for epigenome-wide association studies of complex human diseases and suggest that further investigation on the mechanism of ethnically variable CpG methylation is warranted.

Gene based association analysis of brain DNA methylation with Alzheimer's disease pathology using random permutation. *L. Yu[1], G. Srivastava[2,3,4], L. Chibnik[2,3,4], M. Eaton[4,5], S. Leurgans[1], A. Meissner[4,6], P.L. De Jager[2,3,4], D.A. Bennett[1].* 1) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, IL; 2) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology & Psychiatry, Brigham and Women's Hospital, Boston, MA; 3) Harvard Medical School, Boston MA; 4) Broad Institute of MIT and Harvard, Cambridge, MA; 5) Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, MA; 6) Department of Stem Cell and Regenerative Biology, Harvard University, Harvard Stem Cell Institute, Boston, MA.

Background: Gene based analysis of DNA methylation serves as a useful tool to test the global hypothesis for regional association of CpGs with traits of interest. In order to minimize the inflation of Type I error, the correlations between CpGs must be considered. However, the correlation structure of CpGs has not been fully understood. We propose a permutation based method to evaluate methylation associations by gene regions controlling for correlations among CpGs. Methods: We analyzed gene based associations of brain DNA methylation at 11 validated AD loci, *APOE*, *CR1*, *BIN1*, *CD33*, *CLU*, *ABCA7*, *CD2AP*, *PICALM*, *EPHA1*, *MS4A6A* and *MS4A4A*, with the pathologic diagnosis of Alzheimer's Disease (AD). We utilized data from two ongoing longitudinal cohort studies of aging and dementia, the Religious Orders Study (ROS) and the Memory and Aging Project (MAP). Genome wide methylation profiles were generated from dorsolateral prefrontal cortex tissue samples using Illumina HumanMethylation450 beadset. We first applied logistic regression models with AD diagnosis according to NIA Reagan criteria as the binary outcome, and examined the associations of individual CpGs at each of the 11 loci. Next, for each locus we combined the significance values of individual CpGs using the truncated product method; and the observed statistics were tested against corresponding empirical null distributions derived by random permutation of the phenotype to obtain one methylation p-value per gene. Results: 719 ROS and MAP individuals were included in the analysis. An average age at death was 88 years (SD=6.6 years), 63.4% were females and 60.1% met criteria for pathologic AD. The most significant genes for the association of DNA methylation with AD were *ABCA7* (p<10-6) and *BIN1* (p=8.4×10-5). Similar associations were nominally significant for *CLU* (p=0.036) and *MS4A6A* (p=0.054). Little evidence of association of DNA methylation with AD was seen with the remaining AD loci. Conclusion: These findings suggest that gene based disease associations can be driven by genomic and epigenetic mechanisms. Gene based association analysis using random permutation helps to investigate regional association while accounting for the internal structure of genetic markers.

Down-regulated microRNA-199a-3p induces aberrant DNA methylation in testicular cancer by directly targeting DNMT3A. *B. Chen, S. Gu, Y.K. Suen, L. Li, W.Y. Chan.* School of Biomedical Sciences, the Chinese University of Hong Kong, Shatin,, N.T.,, Hong Kong.

It was previously demonstrated that miR-199a was downregulated in testicular germ cell tumor (TGCT) probably caused by hypermethylation of its promoter. Further studies found that re-expression of miR-199a in testicular tumor cells (NT2) led to suppression of cell growth, cell migration, invasion and tumor metastasis. More detailed analyses showed that these properties of miR-199a could be assigned to miR-199a-5p, one of its two derivatives. The biological role of the other derivatives, miR-199a-3p in TGCT, remains largely uncharacterized. In this report we identified DNA (cytosine-5)-methyltransferase 3A (DNMT3A), the de novo methyltransferase, as a target of miR-199a-3p. We demonstrated that after transient transfection of miR-199a-3p into NT2 cells, DNMT3A expression (especially the DNMT3A gene isoform 2, DNMT3A2) was significantly decreased at mRNA and protein levels. The dual luciferase reporter assay results showed that miR-199a-3p significantly reduced the luciferase activity in NT2 cells when co-transfected with miR-199a-3p and Luc-DNMT3A construct harboring the potential binding site for miR-199a-3p. In clinical samples, DNMT3A2 was significantly overexpressed in malignant testicular tumor tissues, and the expression of DNMT3A2 was inversely correlated with the expression of miR-199a-3p. However, DNMT3A expression did not negatively regulate miR-199a expression in NT2 cells. Further characterization of miR-199a-3p revealed that it negatively regulated DNA methylation partly through targeting DNMT3A. Overexpression of miR-199a-3p restored the expression of APC and MGMT tumor-suppressor genes in NT2 cells via affecting DNA methylation of their promoter regions. Our studies demonstrated the deregulation of miR-199a-3p expression in TGCT may provide novel insights into the mechanism of TGCT carcinogenesis and suggested a potentially therapeutic use of synthetic miR-199a-3p oligonucleotides as effective hypomethylating compounds in the treatment of TGCT.

The utility of DNA extracted from saliva for methylation studies of psychiatric traits. *A.K. Smith[1,3], V. Kilaru[1], T. Klengel[2], K.B. Mercer[3], K.N. Conneely[3,4], K.J. Ressler[1], E.B. Binder[1,2].* 1) Psychiatry & Behavioral Sciences, Emory University, Atlanta, GA; 2) Max Planck Institute of Psychiatry, Munich, Germany; 3) Genetics and Molecular Biology Program, Emory University, Atlanta, GA; 4) Human Genetics, Emory University, Atlanta, GA.

DNA methylation has become increasingly recognized in the etiology of psychiatric disorders. Because brain tissue is not accessible in living humans, epigenetic studies are often conducted in blood, but few are conducted in children because even a blood draw may be too invasive. Saliva is readily collectable, but the proportion of epithelial cells and leukocytes varies between individuals and represents a significant confound. This study will evaluate whether DNA isolated from saliva is comparable to DNA from blood for outcomes relevant to psychopathology; because of the wealth of adult and animal data, child abuse will be used as an example. Saliva and blood samples were collected from 64 African American participants in the Grady Trauma Project, each of which completed the Childhood Trauma Questionnaire to assess abuse. DNA methylation was interrogated with the HumanMethylation450 BeadChip. The proportion of epithelial cells in saliva and specific leukocyte types in blood were estimated. We examined the association of each CpG site with child abuse using linear models that adjusted confounding factors such as age, sex, race, batch effects and cellular heterogeneity. Similar models were used to test whether DNA methylation levels in saliva predicted those of blood. For all analyses, the FDR was controlled at 5 percent. Hierarchical clustering segregated blood samples from saliva samples. Overall, DNA methylation of only ~10 percent of CpG sites from saliva predicted that of blood. While no individual CpG site remained associated with child abuse after adjustment for multiple testing, the test statistics for analyses of saliva and blood were moderately correlated (r=.21). We evaluated CpG sites in 11 genes that were reported as differentially methylated in the blood of those with a history of child abuse. The majority of those genes contained CpG sites whose saliva methylation levels were highly predictive of those in blood ($p<1\times10^{-7}$) though certain areas of the gene (i.e. promoters) were more likely to contain such sites. These results have applications for longitudinal and biomarker studies as well as large-scale DNA methylation studies of childhood psychiatric disorders. DNA derived from saliva may be informative for research questions that can be assessed in blood, though only a small fraction of CpG sites can be considered correlated. Tissue-specific differences seem more prominent than those related to shared genetic or environmental factors.

Rapid DNA Methylation Analysis of the FXN gene in Friedreich ataxia cells and tissues. *S. Al-Mahdawi, C. Sandi, M.A. Pook.* Biosciences, Brunel University, Uxbridge, United Kingdom.

Friedreich ataxia (FRDA) is caused by a homozygous GAA repeat expansion mutation within intron 1 of the FXN gene, leading to reduced expression of frataxin protein. Evidence suggests that the mutation induces epigenetic changes and heterochromatin formation, thereby impeding gene transcription. Thus, studies using FRDA lymphocytes and lymphoblastoid cell lines have detected increased DNA methylation of specific CpG sites upstream of the GAA repeat, together with histone acetylation and methylation changes in regions flanking the GAA repeat. We have previously reported DNA methylation changes in FRDA brain, cerebellum and heart tissues, which are the primary affected systems of the disorder. Bisulfite sequence analysis of the FXN flanking GAA regions revealed a shift in the FRDA DNA methylation profile, with upstream CpG sites becoming consistently hypermethylated and downstream CpG sites becoming consistently hypomethylated. However, bisulfite sequencing is a time-consuming procedure. Therefore, we have now developed specific 'methylscreen' restriction enzyme digestion and qPCR-based protocols to more rapidly quantify DNA methylation at four of the upstream CpG sites. Analysis of human cerebellum and heart tissue samples was used to validate the technique by comparison with previous bisulfite sequencing results. Increased DNA methylation in both FRDA cerebellum and heart tissue samples compared with unaffected control samples was confirmed at all 4 CpG sites. Increased DNA methylation at all four CpG sites in the upstream GAA repeat region was also confirmed in human FRDA fibroblast cells, which have not previously been characterized. The levels of DNA methylation at two CpG sites in the upstream GAA repeat region, together with transgenic FXN mRNA levels and frataxin expression levels were determined in Y47R control and YG8R FRDA mouse fibroblasts, neural stem cells (NSCs) and neuronal/glial differentiated NSCs. In all three cell types, there is increased DNA methylation in YG8R FRDA cells compared with Y47R control cells, which is associated in all cases with decreased FXN mRNA and frataxin protein expression in YG8R FRDA cells compared with Y47R control cells. These methylscreen protocols will allow the rapid detection of DNA methylation changes at the FXN locus in FRDA cells and tissues subsequent to epigenetic-based therapeutic testing.

Systematic classification of common disease-associated regulatory DNA variations by their epigenomic relationship. *M. Dozmorov, C. Giles, J. Wren.* Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK.

Background: The success of genome-wide association studies (GWASs) in finding causative genomic variants for Mendelian phenotypes is contrasted with their inability to accurately elucidate complex patterns and biological roles of mutations underlying non-Mendelian inheritance. Our motivation was to find common epigenomic elements enriched with sets of disease-specific SNPs, and to systematically classify the diseases by their epigenomic background. Methods: Human disease-specific sets of SNPs were extracted from the UCSC GWAS catalog. We used our method, GenomeRunner (http://sourceforge.net/projects/genomerunner/) to test them for statistically significant associations with epigenomic data extracted from the UCSC genome database. Disease-specific epigenomic associations were compared with random associations, obtained by testing random sets of SNPs sampled from the GWAS catalog. P-values of enriched associations were calculated using Fisher's exact test, and corrected for multiple testing using Benjamini-Hochberg procedure. Results: 212 disease and 363 trait/phenotype associated sets of SNPs were tested for associations with >4,000 genome annotation data. We identified that diseases/traits of similar origin (immunological, neurological, metabolic) tend to act within similar epigenomic context, and can be distinguished by their epigenomic associations. Our results suggest that alterations of specific epigenomic regulators may underlie disease susceptibility, paving a road for future epigenomic drug design and therapeutic targets. Conclusion: The vast and growing amount of genome annotation data contains enormous potential to interpret sets of disease-associated mutations within a common, unifying theme of epigenomic regulators. Considering these themes will empower us to interpret the results of GWASs in terms of unifying mechanisms, complementing SNP-gene-pathway approaches. Conversely, similarities and differences in epigenomic context of disease- and trait-associated SNPs provide a new means to classify phenotypes and understand their common epigenomic denominators.

Integrated epigenetic analysis of APOBEC gene family in breast cancer. *Y. Zhang, R. Delahanty, W. Zheng, J. Long.* Division of Epidemiology, Department of Medicine, Vanderbilt University Medical Center, Nashville, Tennessee.

The APOBEC gene family was initially reported to play critical roles in virus restriction. We recently found that a common germline deletion in the *APOBEC3B* gene was strongly associated with breast cancer risk. It has been reported that the *APOBEC3B* gene may play a significant role in C-to-T mutations in breast cancer. However, it remain unknown how *APOBEC3* family genes are regulated. In this study, we aimed at determining epigenetic profile of activation and inactivation of APOBEC family members in breast cancer cell lines through large-scale integrated analyses. All data were downloaded from the GEO/ENCODE databases. RNA-seq data were available from 12 cell lines, including three estrogen receptor negative (ER-), eight estrogen receptor positive (ER+) breast cancer cell lines as well as one normal breast epithelia cell line. Data of epigenetic markers based on ChIP-seq, including H3K4me3, H3K27ac, H3K4me1, H3K36me3, H3K9me3 and H3K27me3, were available from both ER+; and ER- breast cancer cell lines. DNA methyl-seq data were obtained only in one ER- cell line. RNA-seq data showed that among *APOBEC* genes, the *APOBEC3B* gene was the only one showing up-regulation compared with normal breast cell lines. Other APOBEC members, including *APOBEC1*, *APOBEC2*, *APOBEC3A*, *APOBEC3D*, *APOBEC3F*, *APOBEC3G*, *APOBEC3H*, *APOBEC4* and *AID* were either not expressed or down-regulated in breast cancer cell lines with an exception of the constantly high expression of the APOBEC3C gene observed in ER- breast cancer cell lines but down-regulation in ER+; breast cancer cell lines. Activated epigenetic markers, including H3K4me3 and H3K27ac and H3K36me3, were observed in the *APOBEC3B* gene, in both ER+; and ER- breast cancer cell lines. The activated markers H3K4me3 and H3K36me3 were also observed in the *APOBEC3C* gene in the ER- cell lines. Except the *APOBEC3B* and *APOBEC3C* genes, all other *APOBEC* family members showed DNA hyper-methylation at their promoters in the ER- cell line, which may contribute to their no expression or down-regulation. In conclusion, our integrated epigenetic analysis showed that both histone modification and DNA methylation may regulate gene expression patterns in APOBEC family members in breast cancer cell lines.

Role of CTCF in epigenetic regulation of 4qD4Z4 macrosatellite repeat. *J. Lim[1], J.M. Moore[1], N.A. Rabaia[1], Y.D. Krom[2], S.J. Tapscott[1,3], S.M. van der Maarel[2], G.N. Filippova[1].* 1) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 3) Department of Neurology, University of Washington, Seattle, WA.

Facioscapulohumeral muscular dystrophy (FSHD) is caused by incomplete repression of the D4Z4 macrosatellite repeat array on the disease-permissive chromosome 4q that results in aberrant expression of DUX4, the candidate FSHD gene imbedded within the D4Z4 repeat. Loss of repressive chromatin modifications at the D4Z4 array in FSHD has been reported to be associated with increased binding of the chromatin insulator protein CTCF (Zeng, et al., 2009 and Ottaviani, et al., 2009). However, due to repetitive nature of the D4Z4 array, there is very limited information available on CTCF binding at this region. Here we characterize CTCF binding at the 4q35 D4Z4 locus and identify several CTCF binding sites within each D4Z4 repeat unit with two sites located at the boundary with the proximal p13E-11 sequence as well as a cluster of five CTCF sites at the distal D4Z4/pLAM region flanking the pLAM polyadenylation site that is critical for generation of polyadenylated DUX4 transcripts. Moreover, one of the CTCF binding sites at the pLAM region shows FHSD-related haplotype-specific binding. We confirm that CTCF binds to the D4Z4 repeats in both FSHD1 and FSHD2 muscle cells but not in controls. Consistent with the role of CTCF in protection of genes from epigenetic silencing, we observe a significant loss of both histone H3K9 trimethylation and DNA methylation at CTCF binding sites at D4Z4 in FSHD cells in comparison to controls. Depletion of CTCF results in increase of histone H3K9 methylation at the D4Z4 and reduction of the DUX4 transcripts levels in FSHD myoblasts. Our findings suggest that CTCF binding at the D4Z4 locus in FSHD may interfere with the setting and/or maintenance of repressive epigenetic marks and result in inappropriate DUX4 transcription.

492T

Subtelomeric deletions exert telomere position effects on nearby genes. *J. Gerfen, H.M. Mason-Suares, M.K. Rudd.* Department of Human Genetics, Emory University, Atlanta, GA.

Copy number variations (CNVs) are a major cause of autism, intellectual disability, and birth defects. In some cases, loss or gain of genes within the CNV can explain clinical features in affected individuals. However, many pathogenic CNVs are associated with patient phenotypes without pinpointing the gene(s) involved. Position effect, where genes nearby but outside the CNV have altered expression, is another process that could be involved in disease etiology. In particular, telomere position effect (TPE) is a well-described epigenetic process in model systems where genes are silenced by proximity to a heterochromatic telomere. We measured TPE in lymphoblastoid cell lines derived from patients with pathogenic subtelomeric deletions using ChIP-chip and RNA-seq followed by targeted analysis with qPCR and next-generation sequencing of PCR amplicons. Analysis of four different subtelomeric deletions demonstrated a variety of chromatin and expression changes in genes adjacent to deletions. In one 5.5-Mb deletion of the short arm of chromosome 4 we detected an ~400-kb region enriched in histone three lysine nine trimethylation, a marker of heterochromatin, directly adjacent to the chromosome breakpoint. RNA-seq analysis of *EVC*, a gene ~150-kb from the breakpoint and within the region of heterochromatin, revealed allele-specific skewing of expression. We found that one allele accounts for 80% of the transcripts, suggesting that the *EVC* locus on the other chromosome is at least partially silenced. Other genes outside the region of heterochromatin were expressed at similar levels from both alleles. Silencing of *EVC* may be responsible for the atrial septal defect in this patient. Heterozygous mutations of *EVC* have been reported in a family with single atria, and recessive mutations lead to Ellis-van Creveld syndrome, which includes structural defects of the atria. These data support our hypothesis that heterochromatin originating from a new telomere can silence genes adjacent to a subtelomeric deletion. Other deletions in our study showed weaker TPE. We are currently characterizing additional chromatin modifications associated with human TPE and measuring the distance of TPE spreading in other CNVs. Our experiments are the first to demonstrate TPE from a native human telomere. These data will elucidate the role of CNV position effects in disease and may reveal new genes involved in patient phenotypes.

493F

Chromatin state characterization of GWAS results of different neuropsychiatric traits is suggestive of brain-specific as well as non-neuronal origins of disease. *R.A. Ophoff[1], J. Ernst[2].* 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, California; 2) Depts of Biological Chemistry and Computer Science, UCLA, Los Angeles, California.

The Psychiatric Genomics Consortium (PGC) has been instrumental in GWAS of neuropsychiatric traits. GWAS results of the different disease groups have been encouraging with partly overlapping findings between the disorders. A significant proportion of GWAS identified disease variants localize outside known genic regions but within regulatory elements as described through genome-wide functional data as generated by the ENCODE project. As part of our effort to better understand the PGC GWAS findings at the functional level we set out to study the chromatin state of the top SNP findings for bipolar disorder, schizophrenia and major depressive disorder. We obtained the PGC GWAS results of the different disorders and generated a clumped ranked list of independent SNPs based on association signal and removing any SNPs in LD. The ranked list of SNPs was compared with chromatin state maps defined by NIH Epigenomics Roadmap Consortium based on applying ChromHMM to multiple histone modifications mapped across 90 samples covering a wide range of different primary cell types. We focused the comparison on a canonical enhancer state, associated with high cell type specificity, to assess whether biologically relevant cell types were preferentially associated with GWAS prioritized SNPs. We computed the significance of the overlap of the number of GWAS SNPs overlapping the enhancer state using a binomial distribution where the probability of overlap was based on the frequency of the enhancer state among all SNPs in the clumped ranked list. Instead of focusing on one specific cutoff in the GWAS ranked list, we compared the overlap at each position within the top several thousand and ranked the cell types based on the most significant p-value obtained at any cutoff. We observed enrichment of GWAS signal highlighting neuronal-derived cell types for bipolar disorder and schizophrenia. However, ChromHMM analysis of the GWAS data of major depressive disorder completely lacked evidence of involvement of neuronal cell types. Schizophrenia and bipolar disorder share a substantial genetic risk, which may explain our findings of enrichment for neuronal cells, even though our results may indicate different classes of neuronal cells to be involved. The lack of enrichment of neuronal cells for GWAS of major depressive disorders could imply a non-neuronal origin for the disease.

494T

Histone H2A variants: one family, different roles in the human genome. *M.Y. Tolstorukov[1,2], J.A. Goldman[1], C. Gilbert[3], V. Ogryzko[3], N. Volfovsky[4], R.M. Stephens[4], R.E. Kingston[1], P.J. Park[5].* 1) Department of Molecular Biology, Massachusetts General Hospital, Boston, MA; 2) Division of Genetics, Brigham and Women's Hospital, Boston, Massachusetts, USA; 3) Oncogenese, Differenciation et Transduction du Signal, Institut Andre Lwoff, Villejuif, France; 4) Advanced Biomedical Computing Center, SAIC-Frederick, NCI, Frederick, MD, USA; 5) Center for Biomedical Informatics, Harvard Medical School, Boston, MA.

Readout of genomic information is controlled and modulated by chromatin structure, which at the basic level is represented by the DNA wrapped around the histone core. Although chromatin structure in human cells has been extensively investigated in recent years, the biological role and genomic distribution of the replacement histone variants remain poorly understood. Using publicly available and newly generated data, we focus on the variants of histone H2A, one of the most diverse histone families. In particular, we produced genome-wide profiles of the variants H2A.Z, macroH2A and H2A.Bbd using HeLa cell lines that stably express affinity-tagged versions of the corresponding histones. We report that nucleosomes bearing variant H2A.Bbd protect less DNA and are enriched inside actively transcribed genes. This is in contrast to macroH2A nucleosomes, which are enriched in repressed genes. At the same time, H2A.Bbd and macroH2A are not mutually exclusive and a detectable fraction of the genome is enriched for both variants. To further investigate the role of the recently discovered variant H2A.Bbd we preformed a comparative analysis of the transcription products in the cells where H2A.Bbd was depleted with shRNA and in control. This analysis showed that the H2A.Bbd depletion results in the 'net' down-regulation of gene expression and in the disruption of mRNA splicing pathways. Thus, our analysis suggests that H2A.Bbd may be involved in the formation of a specific chromatin structure that facilitates transcription elongation and initial mRNA processing. We also observe that specific chromatin organization involving histone variants may affect the level of conservation of the underlying DNA sequence. For instance, we report that the loci preferentially occupied by the nucleosomes bearing H2A.Z variant as well as such histone modifications as H3K4me3 show decreased frequency of SNPs as compared to the loci associated with 'bulk' nucleosomes. Taken together, our results demonstrate that H2A variants play highly specialized roles in human chromatin and that their distribution is evolutionary conserved.

495F

Spread of repressive chromatin from the expanded GAA trinucleotide repeat mutation contributes to gene silencing in Friedreich ataxia. *Y.K. Chutake[1], S.I. Bidichandani[1, 2].* 1) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Department of Biochemistry & Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Friedreich ataxia (FRDA) is a neurodegenerative disease caused by an expanded GAA trinucleotide repeat (TNR) in intron 1 of the *FXN* gene. Reduction in levels of *FXN* mRNA and subsequently the mitochondrial protein, frataxin, has been attributed to the expanded TNR. The expanded GAA TNR interferes with transcriptional elongation via at least two mechanisms: formation of one or more abnormal DNA structures, and by formation of repressive chromatin. Together these result repeat length dependent transcriptional deficiency downstream of the GAA TNR. However, consistent with the expanded GAA TNR being a source of position effect variegation in mammalian cells, we demonstrate via mononucleosomal chromatin immunoprecipitation that the repressive chromatin spreads upstream from the GAA TNR thus encompassing the transcription start site and promoter of the *FXN* gene. Indeed, Nucleosome Occupancy and Methylome sequencing (NOMe-seq) experiments revealed reduced accessibility via tight nucleosomal occupancy in the vicinity of the transcriptional start site in FRDA cells versus controls. The spread of repressive chromatin is associated with reduced binding of the chromatin insulator protein CTCF and Myc, which are known regulators of *FXN* gene transcription. Indeed, FRDA patients show a deficiency of transcription, reduced occupancy of RNA pol II, and reduced H2A.Z upstream of the expanded GAA TNR, indicating that a less permissive transcriptional landscape extends far upstream from the expanded GAA TNR. Therapeutic strategies for FRDA would have to effectively target the repressive chromatin spanning a larger region of the *FXN* gene than previously recognized.

496T

Complex molecular findings in 11p15-associated Imprinting Disorders require a broadening of testing strategies. *M. Begemann, S. Spengler, L. Soellner, T. Eggermann.* RWTH Aachen, Aachen, Germany.

The chromosomal region 11p15 is one key player in molecular processes regulated by genomic imprinting. Genomic as well as epigenetic disturbances affecting the two imprinting control regions (ICRs) 11p15 are associated either with Silver-Russell syndrome (SRS) or Beckwith-Wiedemann syndrome (BWS): SRS patients carry ICR1 hypomethylation, maternal 11p15 duplications or uniparental disomies (UPD), whereas the opposite alterations are characteristic for BWS. In the last years, a growing number of patients suffering from imprinting disorders (IDs) has been reported showing a hypomethylation at the two ICRs in 11p15 as well as at further imprinted loci on other chromosomes. The molecular basis of these multilocus methylation defects (MLMDs) is widely unknown, however an interaction between trans-localized imprinted genes via a so-called Imprinted Gene Network (IGN) has been suggested. Cases with other types of molecular disturbances than aberrant methylation (e.g. uniparental disomy (UPD), chromosomal imbalances) support this IGN concept. The complex molecular alterations as well as the overlapping and sometimes ambiguous clinical findings in ID patients often make the decision for a specific ID test difficult. As aforementioned, the 11p15 loci are consistently affected in all ID patients with more complex alterations, but the pattern of affected loci is nearly unpredictable. We therefore suggest to implement molecular tests in routine ID diagnostics which allow the detection of a broad range of (epi)mutation types (epimutations, UPDs, chromosomal imbalances) and cover the currently known ID loci. The need to apply multilocus tests (methylation-specific MLPA, SNuPE) is corroborated by our experience from routine diagnostics in more than 650 patients referred as SRS or BWS: (a) Multilocus tests increase the detection rates as the tests ascertain numerous loci. Thereby the chance to identify even slight mosaic hypomethylation patterns is growing. (b) Patients with unusual phenotypes and unexpected molecular alterations will be detected. (c) The testing of rare imprinting disorders becomes more efficient and quality of molecular diagnosis increases. (d) The tests identify MLMDs. In future, the detailed characterization of clinical and molecular findings in ID patients will help us to decipher the complex regulation of imprinting as the basis of an individualized therapeutic management in IDs.

497F

Allelespecific analysis of putative imprinted gene network members in human. *D. Prawitt[1], F. Bohne[1], D. Langer[1], U. Martiné[1], K. Oexle[2], B.U. Zabel[3], T. Enklaar[1].* 1) Molecular Genetics Lab, Center for Pediatrics and Adolescent Medicine, Univ. Medical Center, Mainz, Germany; 2) Institute of Human Genetics, Technical University, Munich, Germany; 3) Center for Pediatrics and Adolescent Medicine, University Medical Center, Freiburg, Germany.

The two imprinting disorders Beckwith-Wiedemann syndrome (BWS) and Silver-Russell syndrome (SRS) present with marked intrauterine and postnatal overgrowth (BWS) or growth retardation (SRS). Molecular defects are heterogeneously associated and are mainly due to epigenetic changes in imprinting control regions (ICR) of the 11p15.5 region. ICR1 regulates the monoallelic expression of *IGF2* and *H19 in cis*. A subgroup of SRS and BWS patients present with epigenetic alterations of other chromosomal regions, arguing for a functional dependence of the affected imprinted genes. To date the molecular mechanisms of the ICR1 effects are incompletely defined and their analysis often has to be performed using genetically engineered model organisms. The description of a network of imprinted genes (IGN) in mice raised the possibility to improve the comprehension of multilocus imprinting defects in humans and depicts candidate genes involved in associated clinical symptoms. The presented work offers an unusual mechanistic insight into ICR1-driven regulation of imprinted genes in human cells. By utilizing unique fibroblasts with paternal (BWS) or maternal (SRS) uniparental disomy 11p15, we uncovered a set of transcriptionally co-regulated imprinted genes on different chromosomes. According to findings for murine orthologues the genes can be part of an IGN involved in regulating developmental growth.

498T

The allelic expression of Gnas is affected by mutations in Mecp2 and maternal strain. *H. Stitik[1,2], R.D. O'Connor[1,2], A. Kumar[2], N.C. Schanen[1,2].* 1) Department of Biological Sciences, University of Delaware, Newark, DE 19716, USA; 2) Nemours Biomedical Research, Alfred I duPont Hospital for Children, Wilmington, DE 19803, USA.

The GNAS gene encodes the G protein stimulatory alpha subunit of (Gsα) and shows tissue specific monoallelic expression that is regulated through a methylation-dependent process. To determine whether the Methyl CpG Binding Protein 2 (MeCP2) was involved in regulation of imprinting of the Gnas transcript, we examined allelic expression of Gnas in tissues from male progeny of an outcross between C57Bl/6J females, wild type or heterozygous for a null allele for Mecp2 (Mecp2tm1.1Bird/J), and Mus castaneus (CAST) males. Using a strain specific polymorphism, we determined the parental origin of the Gnas transcript in tissues at postnatal days 3 (P3) and 28 (P28). In keeping with previous reports, our control cross showed a preference for maternal expression of Gnas in tissues that are imprinted. However, unexpectedly, we found that allelic expression of Gnas was altered in both wildtype and mutant progeny of the Mecp2+/- mothers, showing preferential paternal expression of the Gnas transcript in a number of tissues. Furthermore, we observed both a loss as well as a gain of imprinting at P3 in the kidney and calvaria, respectively. Since a strain effect has been reported in other imprinted loci, we sought to determine whether the strains used in this outcross could be affecting the expression of Gnas by performing a reciprocal cross between CAST female X C57Bl/6J male mice. These studies revealed expression patterns consistent the previous wildtype outcross with the exception of the spleen, which showed preferential expression of the C57Bl/6J allele. Additionally, we examined the differentially methylated region (DMR) in exon 1A that is responsible for controlling expression of Gnas using sodium bisulfite conversion and sequencing analysis to determine if there was a developmental shift in methylation in wild type C57Bl/6J mice. In all tissues examined, methylation increased significantly from P3 to P28. These studies suggest a transgenerational effect of maternal Mecp2 genotype on imprinting of Gnas in mice that occurs in a tissue specific manner and demonstrate epigenetic regulatory processes are impacted by strain and age.

499F

Exploring the role of NLRP7 in reprogramming of CpG methylation in the oocyte and early embryo. *S. Mahadevan[1,2,3], S. Wen[2,4], Y. Wooi[2,3], Z. Liu[3,5], M. Kyba[6], B. Sadikovic[4,7], I. Van den Veyver[1,2,3,4].* 1) Interdepartmental Program in Translational Biology and Molecular Medicine, Baylor College of Medicine, Houston, TX; 2) Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 3) Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital, Houston, TX,; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics (Neurology), Baylor College of Medicine, Houston, TX; 6) Lillehei Heart Institute and Department of Pediatrics, University of Minnesota, Minneapolis, MN; 7) Department of Pathology and Laboratory Medicine, McMaster University, Hamilton, ON, Canada.

Maternal effect mutations in NLRP7 cause recurrent, biparental hydatidiform moles (BiHM), a trophoblastic disease characterized by loss of imprinting at maternally imprinted loci. The existing paradigm suggests a loss of methylation at maternally imprinted loci, while studies from our group in hESC revealed a global, genome wide shift in methylation dynamics causing us to further investigate the extent to which loss of NLRP7 affects the cellular epigenetic state. We had previously shown that NLRP7 physically interacts with the transcription regulator YY1. ChIP-qPCR of YY1 in HEK293 cells with overexpression of NLRP7 revealed an increased occupancy of YY1 at imprinted loci such as PEG3 and SNRPN. This increased occupancy of YY1 at its target sites is not caused by an upregulation in YY1 expression or intra-cellular redistribution within the cell. Fortuitously, it was also observed that NLRP7, which was previously thought to be entirely cytoplasmic in localization, was capable of migration into the nucleus. Given that YY1 is also nuclear in localization, NLRP7's presence in the nucleus likely contributes to the observed differences in YY1 occupancy at its target sites. Computational interrogation of the protein sequence of NLRP7 revealed a putative bipartite nuclear localization sequence (NLS). In the absence of NLRP7's ability to localize within the nucleus, it will be informative to assess whether YY1 occupancy at its target sites is also affected. This information is not only valuable from the perspective of understanding NLRP7 function but is suggestive of NLRP7's potential of being a novel YY1 cofactor. The observation that the loss of methylation at maternally imprinted loci is caused by a maternal loss of NLRP7 argues in favor of a role for this protein in the oocyte and / or early embryo in the process of imprint acquisition and/or maintenance. A systematic interrogation of proteins with known roles in imprint acquisition and/or maintenance revealed physical interaction of NLRP7 with CG Binding Protein 1 (CGBP / CFP1). Given that distinct domains of CFP1 function as mediators of crosstalk between histone and DNA methylation, current efforts are focused on delineating which domains of CFP1 interact with NLRP7. The overall scope of this project is to gain insight into the roles of these proteins in the reprogramming of CpG methylation in the oocyte to embryo transition.

Epigenetic effects of the endocrine disruptor phthalate: influence of the genetic background. *A. Paoloni-Giacobino[1,2], Ch. Stouder[1], E. Somm[3].* 1) Department of Genetic Medicine and Development, Geneva University Medical School, Geneva, Switzerland; 2) Swiss Center for Applied Human Toxicology, Geneva, Switzerland; 3) Department of Pediatrics, Geneva University Medical School, Geneva, Switzerland.

Di-(2-ethylhexyl)phtalate (DEHP) is a plasticizer with endocrine disrupting properties found ubiquitously in the environment. The aim of the present study was to evaluate the possible deleterious effects of DHEP administration in pregnant mice, on imprinted genes in the offspring. Mice of 2 different genetic backgrounds (C57BL/6 and FVB/N) were chosen and treated with DHEP during the time of embryo sex determination. Potential effects of DHEP on the methylation of the differentially methylated domains (DMDs) of 4 paternally expressed genes, Snrpn, Peg1, Peg3 and Igf2r and of 3 maternally expressed genes, H19, Gtl and Igf2 were investigated. The degrees of methylation of the imprinted genes were analysed in the sperm as well as in the liver and skeletal muscle. In parallel, the mRNA expressions of Snrpn, Peg3, Igf2r in these same tissues were studied to assess the link between the imprinted gene methylation and expression. In the sperm DEHP did not affect the degree of methylation of the paternally expressed genes except that of Igf2r in the C57BL/6 mice but induced decreases in the degree of methylation of all the maternally expressed genes in the C57BL/6 mice whereas it had no effect on these same genes in the FVB/N mice. In the liver, DEHP induced ubiquitous effects, potentially representing a relaxation of the monoallelic methylation pattern, in all or in 6 out 7 of the imprinted genes tested in C57BL/6 and FVB/N mice, respectively. In the muscle, 5 out of 7 and 3 out of 7 imprinted genes were affected by DEHP in the C57BL/6 and FVB/N mice, respectively. Eventually, the mRNA expressions in the sperm, liver and muscle of 2 imprinted genes, Snrpn and Peg3 were increased by DEHP in FVB/N mice, in the absence of any change of DMD methylations. In conclusion, DEHP has an effect on sperm DNA methylations that seems to be dependent on the genetic background. The direct effects of DEHP on somatic cells affect practically all imprinted genes studied, especially in the liver. The effects of DEHP on gene expressions are either direct or mediated by epigenetic effects other than DNA methylation.

Establishing induced pluripotent stem cell-derived neurons as an appropriate cellular model for studying mechanisms of myoclonus-dystonia. *K. Freimann, A. Westenberger, P. Seibler, A. Weissbach, N. Brueggemann, K. Lohmann, C. Klein, A. Gruenewald.* Institute of Neurogenetics, University of Luebeck, Luebeck, Germany.

Myoclonus-dystonia (M-D) is a movement disorder presenting with a combination of dystonic features and brief myoclonic jerks. Mutations in the *epsilon sarcoglycan* (*SGCE*) gene have been found to cause this autosomal dominantly inherited disorder. Due to maternal imprinting the penetrance of M-D is reduced. *SGCE* encodes one ubiquitously expressed and one brain-specific isoform of a membrane-associated glycoprotein. In order to understand the molecular mechanisms leading to M-D it is important to develop a cellular model that recapitulates the conditions (including the presence of methylation - imprinting) in neuronal cells of patients. To establish whether induced pluripotent stem cell (iPSC)-derived neurons are such an appropriate model, we compared the imprinting status of *SGCE* in fibroblasts, iPSCs, and iPSC-derived neurons of one *SGCE* mutation carrier and two healthy controls. To distinguish between methylated and unmethylated sequences, we treated DNA extracted from these cells with bisulfite. Furthermore, we analyzed the presence of the two different *SGCE* isoforms by direct sequencing of cDNA reversely transcribed from mRNA extracted from fibroblasts and iPSC-derived neurons of one control. Upon bisulfite treatment, differential methylation of the *SGCE* promoter was detected in fibroblasts, iPSCs, and iPSC-derived neurons of two controls and one M-D patient, resembling the methylation status previously shown for lymphoblast-derived DNA. Sequencing revealed that fibroblasts express only the ubiquitously present *SGCE* isoform, whereas iPSC-derived neurons express the ubiquitous isoform as well as the brain-specific *SGCE* isoform. These findings suggest that the process of reprogramming of fibroblasts to iPSCs and further differentiation of iPSCs into neurons does not alter the imprinting status of *SGCE* in these cells. Additionally, the finding of the brain-specific *SGCE* isoform in iPSC-derived neurons, that was not detected in non-neuronal cells taken from patients (i.e. fibroblasts), suggests that splicing of *SGCE* changes in a tissue-specific manner when patient-derived fibroblasts are transformed into neurons. Thus, neurons derived from iPSCs of *SGCE* mutation-carrying patients can be considered not only a biologically relevant but also functionally adequate cellular model for studying molecular mechanisms leading to M-D.

Full resolution DNA methylome analysis in multiple tissues from twins. *S. Busche[1,2], M. Caron[2], T. Kwan[2], V. Forgettta[1,3], B. Ge[2], S. Westfall[2], J. Qi[1,2], M-M. Simon[2], J.T Bell[4], . MuTHERConsortium[4,5], . UK10KConsortium[4,5], J.B. Richards[1,3,4], G. Bourque[1,2], M. Lathrop[1,2], P. Deloukas[5], T.D Spector[4], T. Pastinen[1,2], E. Grundberg[1,2].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) Lady Davis Institute for Medical Research, Jewish General Hospital, McGill University, Montreal, Quebec, Canada; 4) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 5) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Numerous population studies applying methylome analyses by the Illumina450K array are on-going, but no comprehensive or unbiased analysis of CpG variation at the population level has been carried out to date. Using adipose tissue (AT) and whole-blood (WB) from monozygotic (MZ) and dizygotic (DZ) twins of the well characterized MuTHER/TwinsUK cohort (e.g. dense phenotype, 450K and WGS data available) we aim to unravel the impact of stochastic, environmental, and genetic factors underlying methylation (mCpG) variation and the impact on disease susceptibility using whole genome bisulfite sequencing (WGBS). So far, we have analyzed 26 AT and 21 WB samples (6 MZ pairs, 5 DZ pairs, 7 singletons) generating a total of 1.97 Tbp sequence at on average 6.5-fold coverage for AT and 9.7-fold for WB samples. Totally, we identified 21M and 24M CpG sites in AT and WB with an average methylation level of 85%. CpG values detected by WGBS at > 4-fold coverage were highly concordant with overlapping Illumina 450K data (Pearson's r = 0.93-0.95) but only <1% of global mCpG variation is accessible through the 450K array. Pairwise comparisons of MZs (<20% vs. >80% methylated) allowed us to identify the proportion of mCpG variation that is of environmental origin, which corresponded to on average 0.03% in AT and 0.015% in WB. Similar comparisons of DZs and unrelated yielded a ~5- and ~10-fold increase. Sequence variants at the CpG site appeared to underlie most non-environmental mCpG, and thorough variant removal reduced this increase to ~2-fold. Further analysis of environmental driven differentially methylated regions (eDMRs; ≥ 3 consecutive CpGs within 500 bp and ΔmCpG>40%) using MZs revealed on average 90 eDMRs per tissue and pair with no overlap across tissue, highlighting tissue-specificity with likely correlation with phenotypic discordance. We also studied tissue-specific DMRs (tDMRs) and found AT-specific, hypomethylated tDMRs to be highly enriched (17-fold) in human adipocyte enhancer elements (H3K4me1, NIH Roadmap Epigenomics Project). Finally, the existence of WGS (UK10K project) will allow us to define the largest allele-specific methylation (ASM) dataset in multiple tissues, including random, parent-of-origin and sequence-dependent effects. Preliminary data indicates ASM effects accounting for 1% of all CpGs, where a minor proportion (3.4%) corresponds to known imprinted loci with the remaining effect most likely being due to sequence-dependent ASM effects.

503F

Epigenome-wide association study on identical twins discordant for birth weight. *Q. Tan[1], M. Frost[2], L. Christiansen[1].* 1) University of Southern Denmark, Odense, Denmark; 2) Odense University Hospital.

Epidemiological evidences have shown that early life exposure to adverse environment, e.g. bad nutrition, and stress during pregnancy of mother which usually resulting in low birth weight, could have long-term health consequences including metabolic disorders, diabetes, hypertension, and even mental diseases in adult life. Epigenetics is a molecular mechanism that explains the acquired changes or modification in gene function independent of DNA sequence variation with DNA methylation as one of several epigenetic mechanisms most intensely studied. In order to examine if low birth weight induces persistent epigenetic modification detectable at adult ages, we performed a genome-wide DNA methylation profiling in peripheral blood of 150 pairs of identical Danish twins discordant for birth weight using the Illumina Infinium HumanMethylation450 BeadChip featuring 485,000 CpG sites across the genome. After quality control and data preprocessing using free R package minfi, data were analysed by a mixed effects model including fixed effect variables such as birth weight difference, age and sex of twin pairs; random effect variables such as batch, well, and sample position on the array, etc. Statistical analysis revealed 12 probes with p value<1e-05, among them 1 probe with p value<1e-06. Biological pathway analysis using these probes showed no significant functional cluster involved. In conclusion, our analysis suggests that discordant birth weight in identical twins is not associated with measured DNA methylation level at adult ages. Similar studies on tissues other than peripheral blood are required in order to re-confirm and generalize our conclusion.

504T

Identification of a differentially methylated locus in monozygotic twins discordant for esophageal atresia. *L. Boutaud de la Combe[1], A. Pelet[1], C. Bole[2], J. Tost[3], W. Carpentier[4], N. Cagnard[2], R. Smigiel[5], V. Rousseau[6], F. Gaudrin[7], J. Amiel[1], S. Lyonnet[1].* 1) INSERM U781,Université Paris Descartes-Sorbonne Paris Cité, Institut Imagine, Paris 15, Paris, France; 2) Plateforme de génomique et de bioinformatique, Université Paris Descartes-Sorbonne Paris Cité, Institut Imagine, Paris 15, Paris, France; 3) Centre National de Génotypage CEA - Institut de Génomique 2 rue Gaston Crémieux CP5721 91057 Evry Cedex France; 4) Plateforme P3S,UPMC Pitié Salpétrière 91 Blv de l'Hôpital 75013 Paris France; 5) Genetics Department Wroclaw Medical University Marcinkowskiego 1 PL 50-368 Wroclaw, Poland; 6) Service de Chirurgie Viscérale Pédiatrique Hôpital Necker 149 rue de Sèvres 75743 Paris Cedex 15, France; 7) AFAO 56 rue Cécile 94700 Maisons-Alfort France.

Until recently monozygotic twins were considered to be genetically identical. However the increasing description of monozygotic twins discordant for a phenotype leads us to change our point of view. Numerous causes can explain the discordance between twins. In addition to environmental causes, genomic and epigenomic modifications can occur in only one of the sibs, such as mosaic mutations, post-zygotic alterations and DNA methylation. In order to understand the molecular bases of isolated esophageal atresia, we are studying monozygotic twins discordant for this serious and frequent congenital malformation. Our work aims at finding the origin of the esophageal atresia that occurs in only one child of each twin pair. We decided to investigate two hypotheses: genomic and epigenomic. Eight twin pairs were studied; one twin of each pair has esophageal atresia with or without other congenital abnormalities (such as anomalies of the heart or kidney). All the pregnancies were the result of natural conception and the parents were not consanguineous. Twins were raised together and the children are 2 to 7 years of age. Thus, we assume that environmental differences are negligible. Genomic and epigenomic hypothesis were tested searching first for copy number variations (CNVs) in the twins DNA and then for methylation differences between the child suffering from esophageal atresia and his healthy co-twin. No CNVs were found, however, using a cytosine microarray (Illumina Infinium HumanMethylation450 BeadChip) we have compared 450,000 CpG loci and have found a modification of methylation ($p < 0.05$) at a locus that could explain the phenotypical discordance between twins. This locus shows both a hypermethylation in the promoter and a hypomethylation in the gene body in the affected sibs compared to healthy co-twins. We predict that it could modify the expression of this gene.

505F

An epigenome-wide association study using monozygotic twins identifies putative loci associated with osteoporotic phenotypes. *V. Forgetta[1], W. Kirsten[2], P. Deloukas[2], T. Spector[2], J. Bell[2], JB. Richards[1].* 1) Epidemiology and Biostatistics, McGill University, Montreal, Quebec, Canada; 2) Department of Twin Research, King's College London, London, United Kingdom.

Aim: To identify epigenetic loci associated with bone mineral density (BMD) phenotypes using monozygotic (MZ) twin data from EpiTwin (http://www.epitwin.eu/), a TwinsUK project (http://www.twinsuk.ac.uk/). **Methods:** As part of the EpiTwin project, a total of 172 TwinsUK samples were assayed using the Illumina 27k methylation kit, including 33 pairs of MZ twins, 43 pairs of dizygotic twins and 20 unrelated individuals. For the 33 pairs of MZ twins, we tested the Spearman correlation of the difference in methylation between each sib-pair to the difference in phenotype for total forearm (FA), total hip (TH) or total spine (SP) BMD. The phenotypes were standardized, adjusting for age, sex, weight (for total hip only), chip id, chip position, and chip batch. The phenotype value closest to the DNA extraction date was used. The significance threshold for the correlation test was set to $1\times10{-}4$. **Results:** Of the 33 pairs of MZ twins, 23 pairs had phenotype values for total forearm, hip and spine BMD. The methylation difference of a total of 7 genes had significant Spearman correlation ($p < 1\times10{-}4$) with differences in BMD phenotypes; 3 for TH (NTRK3, VSTM1 and ZNF438), 3 for FA (PIGC, PKP1, CBG), and 2 for SP (CBG and SLC6A11). The most significant correlation was obtained for corticosteroid-binding globulin (CBG) using the total forearm BMD phenotype (p-value $5.46\times10\text{-}6$), and was also significant, albeit to a lesser extent, for total spine BMD (p-value $1.67\times10\text{-}5$). The correlation for CGB is highly linear and positively correlated, where a positive difference in methylation leads to a positive difference in BMD phenotype between MZ sib-pairs. **Discussion:** This epigenome wide study has identified 7 putative loci correlated with BMD phenotypes. Among these loci is corticosteroid-binding globulin, a gene known to influence corticosteroid hormone levels, which in turn strongly influence bone physiology. Further validation is underway shortly, including replication of findings using a larger cohort of twins and unrelated individuals using the Illumina 450k methylation kit.

506T

Analysis of the epigenetic interplay between DNA methylation, histone modifications and gene expression in monozygotic twins discordant for psoriasis identified dysregulated disease-associated genes. *R. Lyle[1,2], K. Gervin[1,2], G.D. Gilfillan[1,2], M. Hammerø[1], H.S. Hjorthaug[1], A.O. Olsen[2,3], T. Hughes[1], J.R. Harris[4], D.E. Undlien[1,2].* 1) Med Gen, Oslo Univ Hosp Ulleval, Oslo, Norway; 2) University of Oslo, Oslo, Norway; 3) Department of Dermatology, Oslo University Hospital, Oslo, Norway; 4) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway.

Psoriasis is a common, chronic inflammatory immune-mediated disease, which affects mainly the skin, but also the joints. The worldwide prevalence is reported to range between 1–11.8% depending on ethnicity and geographical area. Psoriasis has a strong genetic component with an estimated heritability of 66%. However, additional genetic, environmental and/or epigenetic factors are thought to be important, as concordance rates among MZ twins are only 35–72%. There is an increasing belief that epigenetic variants could explain some of the missing heritability in psoriasis. The aim of this study is to identify epigenetically dysregulated genes which contribute to the development of psoriasis. We performed comprehensive high-throughput bisulfite sequencing (RRBS), ChIP-seq and RNA-seq in CD4+ cells isolated from 20 MZ twin pairs discordant for psoriasis and explored DNA methylation at ~2 million CpG sites, histone modifications (H3K4me3 and H3K27me3) and gene expression, respectively. This approach enables an integrated analysis of the epigenetic interplay between DNA methylation, histone modifications and gene expression and identification of disease-associated epigenetic patterns and dysregulated genes. Preliminary findings identify potential susceptibility genes and point towards pathways containing epigenetically dysregulated genes in psoriasis. To our knowledge, this is the first study that attempts to systematically integrate DNA methylation, histone modifications and gene expression in MZ twins discordant for psoriasis in order to reveal and understand the epigenetic component in this disease.

507F

Genome wide DNA methylation profiling of monozygotic twins discordant for trisomy 21. *M.R SAILANI[1,2], F. Santoni[1], A. Letourneau[1,2], P. Makrythanasis[1], C. Borel[1], M. Guipponi[1], C. Gehrig[1], A. Vannier[1], S.E Antonarakis[1,2,3].* 1) Genetic MEDICINE and DEVELOPMENT, University of Geneva, Geneva, Geneva, Switzerland; 2) National Center of Competence in Research Frontiers in Genetics, University of Geneva, Switzerland; 3) iGE3 institute of Genetics and Genomics of Geneva, Switzerland.

DNA methylation is essential in mammalian development and has an effect on gene expression. We have hypothesized that methylation differences induced by trisomy 21 (T21) contribute to the phenotypic characteristics and heterogeneity in T21. In order to determine the methylation differences in T21 without the interference of the genomic variation, we have used fetal fibroblasts from monozygotic twins discordant for T21. We also used fibroblasts from monozygotic twins concordant for T21, normal monozygotic twins without T21, and unrelated normal and T21 individuals as controls. We applied Reduced Representation Bisulfite Sequencing (RRBS) to generate nucleotide resolution of DNA methylation based on high throughput sequencing (HiSeq 2X-100bp, One sample per lane) between each pair of twins. CpGs with at least 10X read coverage in two technical replicates were selected for the subsequent analysis. An initial analysis of MZ twins discordant for T21 identified 28,526 differentially methylated C nucleotides out of 1,589,507 interrogated nucleotides (DMCs) (FDR<0.001 and at least 50% methylation difference per C). The KEGG gene ontology analysis of genes harboring these DMCs, showed an enrichment for calcium signaling (FDR 3.1×10^{-7}), axon guidance (FDR 7.4×10^{-7}), and focal adhesion (FDR 5.1×10^{-5}) pathways. This preliminary study of methylation differences in monozygotic twins discordant for genomic abnormalities is a promising approach to understand the molecular pathophysiology of aneuploidies.

508T

DNA methylation analysis of the human X chromosome in multiple tissues. *A. Cotton[1,2], M. Jones[1,3], C. Chen[3,4], W. Wasserman[1,3], M. Kobor[1,3], C. Brown[1,2].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Molecular Epigenetics Group, Life Sciences Institute, Vancouver, BC, Canada; 3) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, University of British Columbia, Vancouver, BC, Canada; 4) Graduate Program in Bioinformatics, University of British Columbia, Vancouver, BC, Canada.

46, XX human females undergo X-chromosome inactivation (XCI) to achieve dosage compensation with 46, XY males. While the majority of X-linked genes are subject to XCI, over 15% of genes escape from XCI and are expressed from both the active X chromosome and the mostly silent inactive X chromosome. Previous studies have demonstrated that DNA methylation (DNAm) can be used to predict the XCI status of genes with CpG island promoters. Of the nearly 1800 X-linked islands on the Illumina Infinium HumanMethylation450 array, over half overlap a transcription start site and can be used to predict the XCI status of a gene. We examined X-linked DNAm in over 700 samples from human buccal cells, blood, brain and lung which allowed assessment of 331 genes for which no XCI status was previously known. The examination of over 50 individuals with matched tissue samples provided evidence for tissue-specific XCI. In agreement with previous reports, a subset of genes without island promoters demonstrated DNAm typical of an island associated with an XCI status. The sequence of subject genes was compared to escape genes to determine how sequence might influence the spread of XCI . A third of probes were located more than 1kb from a transcription start site but were used to examine DNAm within and between genes. Gene body DNAm levels were examined comparing genes features such as exons and introns in an effort to further our understanding on the complex relationship between DNAm and gene expression. Of the over 1500 probes found between genes, nearly 1000 were found in islands not associated with a gene. The vast majority of these islands demonstrated DNAm levels similar to that of subject genes. These non-promoter islands were divided into those enhancers predicted from the ENCODE projects to determine if DNAm associated with X-linked enhancers was unique. Non-island CpGs, including those in repetitive elements, were found to have significantly more DNAm in males compared to females suggesting hypermethylation on the active X. Many diseases occur at different rates in males and females. For most X-linked genes, XCI achieves dosage compensation between males and females however when a gene escapes from XCI females theoretically have a higher gene dose which may in turn contribute to difference in disease susceptibility. In addition to importance in modulating disease, the study of XCI provides new insights into epigenetics gene regulation and nuclear compartmentalization.

509F

Toward understanding the higher-order chromatin organization at the human inactive X chromosome. *E. Darrow, B. Chadwick.* Biological Science, Florida State University, Tallahassee, FL.

X-chromosome inactivation is the mammalian form of dosage compensation that balances X-linked gene expression between the sexes. This is achieved by repackaging the chosen inactive X chromosome (Xi) into facultative heterochromatin that ultimately shuts down most gene expression from the chromosome. The Xi is organized into two, non-overlapping types of heterochromatin, that at metaphase occupy multiple alternating chromatin bands, giving rise to a characteristic striped appearance. At interphase, heterochromatin of the same type aggregates together resulting in two distinct heterochromatin territories. Euchromatic marks are largely absent from the Xi with the exception of several specific regions that at metaphase reside at the intersection between the two heterochromatin types. We have determined the identity of the underlying DNA sequences for three of these euchromatin signals, and each consists of large tandem-repeat DNA, that are Xi-specific DNaseI hypersensitive sites and are bound by the epigenetic organizer protein, CCCTC-binding factor (CTCF). At interphase, these DNA sequences make Xi-specific, very long-range interactions that are significantly reduced when CTCF levels are depleted. Considering their location at the heterochromatin boundary and their frequent multi-megabase interactions, we propose that these repeats represent folding elements that contribute to the formation and maintenance of the Xi chromosome territory. To assess their role as chromosome folding elements we have developed active pairs of transcription activator-like effector nucleases (TALENs) that are capable of directly excising the two largest tandem repeats. These tools are being used to investigate whether these tandem repeats contribute to the three-dimensional conformation and maintenance of chromosome territories on the Xi.

The p.V37I Exclusive Genotype Of GJB2: A Genetic Risk-Indicator of Postnatal Permanent Childhood Hearing Impairment. *l. li[1,2], J. Lu[1,2], Z. Tao[2,3], Q. Huang[1,2], Y. Chai[1,2], X. Li[1,2], Z. Huang[1,2], Y. Li[1,2], M. Xiang[1,2], J. Yang[1,2], G. Yao[4], Y. Wang[4], T. Yang[1,2], H. Wu[1,2].* 1) Xinhua Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China; 2) Ear Institute, Shanghai Jiaotong University, Shanghai, China; 3) Shanghai Children's Medical Center, Shanghai, China; 4) Shanghai Child Health Care Institute, Shanghai, China.

Background: Postnatal permanent childhood hearing impairment (PCHI) is frequent (0.25‰–0.99‰) and difficult to detect in the early stage, which may impede the speech, language and cognitive development of affected children. Genetic tests of common variants associated with postnatal PCHI in newborns may provide an efficient way to identify those at risk. We hypothesized that the p.V37I exclusive genotype of GJB2, a prevalent genetic variant in East Asians, is associated with postnatal PCHI and therefore serves as a genetic risk-indicator. Methods and Findings: We sequenced the GJB2 gene in a cohort of 45 Chinese subjects with postnatal PCHI, 1516 ethnically-matched control newborns with various newborn hearing screen (NHS) results, and 173 newborns who failed the NHS but passed the referral hearing diagnosis. The p.V37I exclusive genotype of GJB2 is present in a substantial percentage (20%) and is strongly associated with postnatal PCHI ($P = 1.4\times10{-}10$). The prevalence of this genotype also increases significantly in normal-hearing newborns who failed at least one NHS ($P = 0.024$ for those who failed only the initial NHS; $P = 1.7\times10{-}8$ for those who failed both the initial and the repeat NHS). Conclusion: The p.V37I exclusive genotype of GJB2 causes subclinical hearing impairment at birth and increases risk for postnatal PCHI. Genetic testing of GJB2 in East Asian newborns who fail at least one NHS will facilitate prompt detection and intervention of postnatal PCHI.

Up-Regulates of angiogenesis-associated MicroRNAs in placenta from women with a low flow-mediated vasodilation. *L.M. RODRIGUEZ, A.F. DUQUE, A. SANCHEZ, A.C. AGUILAR, A. CASTILLO.* UNIVERSIDAD DEL VALLE, CALLE 4B 36-00, CALI - COLOMBIA.

Purpose: microRNAs profiling have emerged as a molecular tool to understand epigenetic regulation process and a possible impact in diseases prognosis or complications, such as in future mother at gestational period, during which endothelial function changes may be involved in differential expression profile of microRNAs associated with angiogenesis in placental vascularization. Methods: we evaluated FMD (flow-mediated vasodilation) during the first and third trimester of pregnancy in eleven primigravidae singletons as a vascular functional biomarker. Besides, at the delivery we took a placental sample to evaluate the microRNA expression associated with angiogenic pathway using miScript miRNA PCR array (Qiagen). Mann-Whitney and t-Student test, with p-value <0.05 were use to statistical analysis. Results: we found four upregulated miRNAs: hsa-miR-16 (p-valor: 0.044941), hsa-miR-130a (p-valor: 0.037793), hsa-miR-132 (p-valor: 0.045386) and hsa-miR-296 (p-valor: 0.043906) at women group that showed a negative change in FMD. Three of them (hsa-miR-130a, 132 and 296) are pro-angiogenic with a possible implication in a placental blood vessel increasing production and a decrease blood flow compensatory mechanism. Conclusion: Thereby, the impact in the microRNAs identification in the maternal-fetal health is important to prevent possible problem associated to placental vascularization.

512W

ChIP-seq ascertained occupancy of MEF2C, a GWAS-implicated osteoporosis locus, points to an inflammation-mediated role in bone density determination. *S.F.A. Grant[1,2], S. Deliard[1], F. Zhu[3], Q. Xia[1], A.D. Wells[4], K.D. Hankenson[3], M.E. Johnson[1].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) School of Veterinary Medicine, University of Pennsylvania, Philadelphia, PA; 4) Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA.

Genome-wide association studies (GWAS) have demonstrated that genetic variation at the *MEF2C* (MADS box transcription enhancer factor 2, polypeptide C) locus is robustly associated with bone mineral density (BMD), primarily at the femoral neck. MEF2C is a transcription factor known to operate via the Wnt signaling pathway. Our hypothesis was that MEF2C regulates the expression of a set of molecular pathways critical to skeletal function. Drawing on our laboratory and bioinformatic experience with ChIP-seq, we analyzed ChIP-seq data for MEF2C available via the ENCODE project to gain insight in to its global genomic binding pattern. We aligned the ChIP-seq data generated for GM12878 (an established lymphoblastoid cell line). Using HOMER, a total of 17,611 binding sites corresponding to 8,118 known genes were observed. We then performed a pathway analysis of the gene list using Ingenuity. At 5kb, the gene list yielded 'EIF2 Signaling' as the most significant annotation, with a P-value of 5.01×10^{-26}. Moving further out, this category remained the top pathway at 50kb and 100kb, then dropped to just second place at 500kb and beyond by 'Molecular Mechanisms of Cancer'. Also consistently high on these lists at all distances was 'B Cell Receptor Signaling' and 'T Cell Receptor Signaling', plus at 50kb and beyond 'RANK Signaling in Osteoclasts' was a consistent feature and resonates with the main general finding from GWAS of bone density. We also observed that MEF2C binding sites were significantly enriched primarily near inflammation associated genes identified from GWAS; indeed, a similar enrichment for inflammation genes has been reported previously using a similar approach for the vitamin D receptor, an established key regulator of bone turnover. These results represent the first ever reported ChIP-seq derived genome wide map of MEF2C binding. Our analyses point to known connective tissue and skeletal processes but also provide novel insights in to networks involved in skeletal regulation. The fact that a specific GWAS category is enriched points to a possible role of inflammation through which it impacts BMD.

Enhancer activity patterns across 100 epigenomes reveal novel human disease associations. *W. Meuleman, L.D. Ward, A. Kundaje, M. Kellis, the Roadmap Epigenomics Program.* MIT, Cambridge, MA.

The NIH Roadmap Epigenomics Program has generated a large resource of epigenomic marks including histone modification patterns in both primary human tissues and human cell lines, with the goal of creating global reference maps of regulatory elements and study their biological roles. We have used these datasets to generate chromatin state maps by learning combinations of histone modification patterns indicative of different functional classes. The chromatin state annotations reveal ~500,000 active and poised enhancer regions, and ~120,000 active and poised promoter regions across cell types, as well as strongly and weakly transcribed regions, repressed regions, and heterochromatic regions. We use these epigenomic maps to cluster regulatory regions into 55 enhancer modules and 70 promoter modules of coordinated activity across cell types. We find that the vast majority of enhancers and promoters are cell type restricted, and highly enriched in developmental processes. Surprisingly, only a small percentage of promoter regions are constitutively active, suggesting a higher similarity between enhancer and promoter regions than previously recognized. The identified enhancer and promoter modules were found to be associated with distinct GO categories among neighboring genes, which reflected their cell-restricted activity patterns. Because these activity patterns provide information about developmental dynamics beyond single-tissue annotations, we asked whether they provided additional insights into the noncoding genetic architecture of diseases and the strength of selective pressures on different regulatory programs. We first tested SNPs from the NHGRI GWAS catalog against individual cells' enhancer maps, revealing enhancer enrichments with a high degree of tissue specificity, such as adult liver enhancer SNPs associated with total cholesterol and adipose and pancreatic islet enhancer SNPs associated with fasting glucose levels. Interestingly, when we instead used enhancers clustered by activity, in some cases GWAS SNP enrichments were discovered for activity signatures and not for individual tissues; for example, coronary heart disease associated SNPs are enriched for a type of enhancer active in many non-immune tissues and enriched for proximal gene GO annotations of substrate adhesion-dependent cell spreading, apoptotic cell clearance, and response to fluid shear stress.

514F

Human-specific cytogenetic structures support the emergence of new regulatory elements. *G. Giannuzzi, A. Reymond.* Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

Human and chimpanzee genomes are 98.8% identical within comparable sequence. They however differ structurally in nine pericentric inversions, one fusion that originated human chromosome 2 (HSA2), content of their heterochromatin, and localization of segmental duplications. The possible functional consequences of these cytogenetic and structural differences are not fully understood and their possible involvement in speciation remains unclear. We analyzed the genome-wide distribution of histone modifications that decorate transcription start sites with human-specific enrichment compared to chimpanzee and macaque. We show that these histone modifications are not randomly distributed in the human genome, indeed they preferentially map to genomic regions with a human-specific organization, like subtelomeric, pericentromeric, and segmentally duplicated areas. Likewise, loci exclusive to the human lineage, such as the HSA2 fusion point and its ancestral pericentromeric region and the breakpoints of the HSA1 and HSA18 pericentromeric inversions, significantly accumulated human-specific transcription start sites. We find a similar enrichment of chimpanzee-specific H3K4me3 peaks in subtelomeric and segmentally duplicated regions of the chimpanzee genome, revealing a common propensity of new cytogenetic structure in acquiring potential novel transcription start sites. These concentrations of species-specific transcription start sites in genome structure unique to one species are not limited to a single tissue as we uncovered them in prefrontal cortex, neuronal cells, and lymphoblastoid cell line. Our findings support the existence of an evolutionary role of chromosomal rearrangements and allow inferring causality, i.e. chromatin reconfiguration follows genome reorganization. They suggest that evolutionary novelties derived from structural changes should be investigated not only for novel transcripts and gene expression differences but also for epigenetic and regulatory changes.

515W

Architectural proteins modulate the higher order chromatin structure of the *CFTR* locus. *N. Gosalia[1,2], A. Harris[1,2].* 1) Human Molecular Genetics Program, Ann and Robert H. Lurie Children's Hospital of Chicago Research Center, Chicago, IL; 2) Department of Pediatrics, Northwestern University, Feinberg School of Medicine, Chicago, IL.

Cystic fibrosis is an autosomal, recessive disease that results from mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, which encodes a chloride ion channel with a complex expression pattern. Tissue-specific *CFTR* expression is regulated by multiple *cis*-acting elements, including intronic enhancers, which interact with the promoter. The mechanisms that organize higher order chromatin structure to establish and maintain gene expression are not fully understood; however, data suggest they may involve CTCF and cohesin. These factors have important roles in the three-dimensional organization of loci and at insulators, which are critical barriers for preventing inappropriate activation or repression of genes. At the *CFTR* locus, depletion of CTCF or the cohesin component, RAD21, increases gene expression. ChIP for CTCF and the cohesin components, RAD21 and SMC1, after CTCF or RAD21 knockdown shows loss of all three factors at several sites across the region and retained occupancy at others. To determine if loss of CTCF and/or RAD21 altered the higher order organization of *CFTR*, quantitative chromosome conformation capture (q3C) was used. After RAD21 depletion, q3C data show partial loss of interactions across the locus between the gene promoter, known enhancers such as the one in intron 11, and CTCF/cohesin binding sites. In contrast, after CTCF knockdown no changes in enhancer-promoter interactions are observed, however, interactions between the -20.9kb insulator element and CTCF/cohesin binding elements 3' to *CFTR* are suppressed. These data suggest that though cohesin and CTCF are critical for some aspects of the chromatin organization at the locus they are not the major components of the complex that loops distal enhancers to the promoter. Moreover, the increase in *CFTR* expression after knockdown also suggests that CTCF and cohesin may inhibit *CFTR* expression by recruiting repressive complexes to the locus. Identifying these repressive factors may facilitate therapies to alleviate cystic fibrosis disease severity by increasing the levels of *CFTR* transcript and CFTR protein.

516T

Impact of three-dimensional organization of chromatin on long-range enhancers. *A. Pankov, J. Song.* Institute for Human Genetics, UCSF, San Francisco, CA.

In order to fully understand how genes and regulatory regions are organized and coordinated for transcriptional regulation, it is not sufficient to only consider the genomic locations of regulatory sites. In fact, the three-dimensional chromatin interactions have been shown to regulate transcriptional and epigenetic states demonstrating that long-range chromatin interactions act as a mechanism to regulate many important genes. Currently, methods to identify such long-range relationships have been technically challenging. High-throughput approaches such as DNase-Seq, ChIP-Seq, and Hi-C methods have been previously used to study the influence of long-range enhancers on regulating transcription, but these either have low resolution for human samples (Hi-C) or lack the important connectivity information to investigate how regulatory elements interact with their distal target gene promoters (ChIP-seq and DNase-seq). Through the use of ENCODE Chromatin Interaction Analysis Paired-End Tag sequencing (ChIA-PET) data as a high-resolution, cost-effective alternative, we are able to determine robust distal interactions and analyze their role in transcriptional regulation. As part of this project, we first remove background noise present in the data from the complexity of chromatin structures in nuclear space and the nature of proximity ligation. This involves creating an appropriate model for read counts to reduce the influence of confounding factors in the data; identifying the genomic location of regulatory elements; and removing random interactions between two regions as ones that occur infrequently relative to the overall signal of the two regions. Then, by modeling the data as a graph with regulatory sites as nodes and number of interactions as edge weights, we are able to use graph partitioning techniques to find densely connected substructures known as interaction hubs. Finally, we annotate each interaction hub with transcriptional information and match each node with its regulatory function through other ENCODE assays. By labeling each node, we are able to analyze how different structural and regulatory motifs contribute to transcriptional regulation. Through our findings, we are able to determine the functionally and three-dimensionally important structures that regulate gene transcription.

517F

Genetic determinants of population-level variation of chromatin modifications. *H. Kilpinen[1,2], S.M. Waszak[3], A.R. Gschwind[2,4], S.K. Raghav[3], R.M. Witwicki[4], A. Orioli[4], M. Wiederkehr[4], N. Panousis[1,2], N. Hernandez[4], A. Reymond[4], B. Deplancke[3], E.T. Dermitzakis[1,2].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Institute of Bioengineering, School of Life Sciences, Swiss Federal Institute of Technology, Lausanne, Switzerland; 4) Center for Integrative Genomics, Faculty of Biology and Medicine, University of Lausanne, Lausanne, Switzerland.

The study of gene regulation through intermediate cellular phenotypes has lead to the identification of genomic loci that associate with quantitative changes in gene expression levels in human populations. While such regulatory variation is extremely widespread, it has been challenging to pinpoint the exact molecular processes that are affected by these variants before differential gene expression is manifested. To address this, we mapped quantitative trait loci (QTL) for genome-wide RNA polymerase II and PU.1 binding, as well as levels of histone modifications H3K4me1, H3K4me3, and H3K27ac in 52 unrelated individuals from the 1000 Genomes project. Chromatin immunoprecipitations of all assays were produced from a single growth of lymphoblastoid cell lines and sequenced to a high coverage (median > 48M high quality reads per individual). We identified between 591 and 2096 independent peaks with a cis-QTL for each assay at a false discovery rate of <5% (50 kb window centered on each peak), representing 2-4% of peaks genome-wide. Extending the window to 100 kb resulted in ~16% increase in the number of detected QTL peaks. The majority of variants affected only a single peak, and we observed on average 3-4-fold enrichment of the identified QTL at known expression QTL, as well as significant overlap of QTL among the different chromatin assays. We are currently exploring the biological properties and interactions of the identified chromatin QTL with the aim of understanding the regulatory mechanisms through which differential gene expression is achieved, as well as the proportion of gene expression variation in the population that can be explained by quantitative changes in chromatin and transcription factor binding.

518W

Molecular analyses of *cis*-interactions of the *SOX9* promoter with its sex determining long-range regulators using chromatin conformation capture-on-chip (4C). *P. Stankiewicz[1,2], M. Smyk[2], P. Szafranski[1].* 1) Dept. of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland.

Evolutionary conserved transcription factor *SOX9* is essential for development of testes and differentiation of chondrocytes. Heterozygous point mutations and genomic deletions involving *SOX9* lead to the skeletal malformation campomelic dysplasia (CD) often associated with male-to-female sex reversal. Chromosomal rearrangements with breakpoints mapping in the protein-gene desert regions up to 1.3 Mb both 5' and 3' to *SOX9* and likely disrupting *cis*-regulatory elements, have been described in patients with usually milder forms of CD. Breakpoint clustering 5̀ to *SOX9* allowed to define four non-overlapping intervals associated with different phenotypes: Pierre Robin sequence (~1.06-1.23 Mb), acampomelic CD (~789-932 kb), sex reversal (~517-595 kb), and moderate to severe CD (~50-375 kb). In addition, a different phenotype consistent with Cooks syndrome (brachydactyly-anonychia) has been reported as associated with genomic duplications ~1.2 Mb 5' to *SOX9*. We found that these regions overlap four gene clusters encoding long non-coding RNAs (lncRNAs): TCONS_00025479, TCONS_00025148, TCONS_00025195, and TCONS_00026151, suggesting that similar to other developmental genes, lncRNAs might contribute to long-range regulation of *SOX9* expression. The sex reversal region (RevSex) was proposed to harbor a putative testis-specific and sex determining enhancer. The other sex determining interval was mapped to a gene desert >1.3 Mb downstream to *SOX9*. We performed chromatin conformation capture-on-chip (4C) analysis in Sertoli cells and lymphoblasts to verify the already proposed long-range interactions and to identify potential novel regulatory elements responsible for sex reversal in patients with CD. We identified several novel *cis*-interacting regions both up- and downstream to *SOX9* with some of them overlapping lncRNAs preferentially expressed in testes. Our data further support the role of the two previously proposed regulatory regions in the control of *SOX9* expression during sex determination and point at lncRNAs as likely mediators of some of these interactions.

519T

Identification of genetic variants that affect histone modifications in human cells. *G. McVicker[1,2], B. van de Geijn[1,3], J.F. Degner[1,3], C.E. Cain[1], N.E. Banovich[1], N. Lewellen[2], M. Myrthil[2], Y. Gilad[1], J.K. Pritchard[1,2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Howard Hughes Medical Institute, University of Chicago, Chicago, IL; 3) Committee on Genetics, Genomics and Systems Biology, University of Chicago, Chicago, IL.

Histone modifications are important markers of function and chromatin state, yet the DNA elements that direct them to specific locations in the genome are poorly understood. Here we use the genetic variation in Yoruba lymphoblastoid cell lines as a natural experiment to identify genetic differences that affect histone marks and to better understand their relationship with transcriptional regulation. Across the genome, we identified hundreds of quantitative trait loci that impact histone modification or RNA polymerase (PolII) occupancy. In many cases the same variant is associated with quantitative changes in multiple histone marks and PolII, as well as in DNaseI sensitivity and nucleosome positioning, indicating that these molecular phenotypes often share a single underlying genetic cause. We find that polymorphisms in many transcription factor binding sites cause differences in local histone modification and identify specific transcription factors whose binding leads to histone modification in lymphoblastoid cells. Finally, we find that variants that impact chromatin at distal regulatory sites frequently also direct changes in chromatin and gene expression at associated promoters. In summary, the class of variants identified here generate coordinated changes in chromatin both locally and sometimes at distant locations, frequently drive changes in gene expression, and likely play an important role in the genetics of complex traits.

520F

Lethal lung developmental disorder due to a novel deep intronic deletion. *P. Szafranski[1], Y. Yang[1], M.U. Nelson[2], M.J. Bizzarro[2], R. Morotti[3], C. Langston[4], P. Stankiewicz[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Pediatrics; 3) Dept. of Pathology, Yale University School of Medicine, New Haven, CT; 4) Dept. of Pathology, Texas Children's Hospital, Houston, TX.

FOXF1 encodes a forkhead transcription factor mediating hedgehog signaling in tissues of mesodermal origin, primarily in endothelia and mesenchyme of the developing lungs and intestines. Haploinsufficiency of *FOXF1* causes an autosomal dominant neonatally lethal lung disorder, Alveolar Capillary Dysplasia with Misalignment of Pulmonary Veins (ACDMPV). We identified a 0.8 kb deletion within the single 1.4 kb intron of *FOXF1* in a deceased newborn with histopathologically verified ACDMPV. The deletion arose *de novo* on the maternal copy of chromosome 16q, supporting the notion that *FOXF1* is partially paternally imprinted in human lungs. It did not compromise the major splice sites and *FOXF1* splicing pattern was only moderately affected. However, the deletion reduced the level of *FOXF1* mRNA in the peripheral lung tissue by almost 40%. We found that the *FOXF1* intron exhibits transcriptional enhancer activity, and the deletion removed the major binding sites for CTCF and CEBPB, the key regulators of chromatin architecture and transcription. Interestingly, our *in vitro* reporter assay analyses suggest that the deletion not only disabled the enhancer but possibly transformed it into a transcriptional suppressor. Currently used diagnostic assays such as chromosomal microarray analysis or whole-exome sequencing do not detect deep intronic copy-number variation or simple nucleotide variation, thus underestimating their pathogenic significance. Our data further emphasize the importance of testing of the non-protein coding regions in the human genome.

521W

Rare Recurrent Homozygous Deletions in a Large Population Reveals High Penetrance Loss of Function Variants Underlying Rare Strong Phenotypes. *J. Glessner[1,2], J. Li[1], B. Chang[1], K. Thomas[1], R. Golhar[1], X. Chang[1], Y. Guo[1], D. Li[1], N. Abdel-Magid[1], C. Kao[1], Y. Li[1], J. Bradfield[1], C. Kim[1], C. Hou[1], F. Mentch[1], H. Qiu[1], C. Cardinale[1], M. Garris[1], L. Vazquez[1], D. Abrams[1], G. Otieno[1], T. Wang[1], R. Pellegrino da Silva[1], R. Chiavacci[1], J. Connolly[1], B. Keating[1,2], P. Sleiman[1], S. Grant[1,2], H. Hakonarson[1,2].* 1) The Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA; 2) Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, 19104, USA.

We analyzed Illumina SNP microarray data for 68,028 high quality uniformly processed samples and called homozygous deletions (HZDs) using PennCNV with an intersection set of 520,017 SNPs. 263 homozygous deletion CNVRs were detected in multiple unrelated individuals. 146 directly overlapped gene exons. 57 show significant enrichment for a disease state. 631 HZDs were specific to one patient, of which 414 overlapped exons. Chip version, ethnicity population/evolutionary genetics, and sample sources (projects) were all data complexities explored for further insight into the genesis of the HZDs and to control for bias. HZDs are the most confident of all copy number states due to the strong drop in relative intensity (log r ratio) coupled to a uniformly random genotype (b allele frequency). Using a multi-normal curve fitting approach, all HZDs were confirmed. This high confidence calling and population based CNV quality assessment allows for a very small number of SNPs and length lower detection limit. HZDs closely parallel the extensive work in gene knockout studies to study phenotypes and allow for recapitulation of the phenotype in humans by naturally arising variations observed in our study. From a clinical perspective, HZDs provide the strongest possible genetic variant in complete ablation of a gene's function and may help to diagnose rare constellations of symptoms for early intervention. For example, we uncovered a HZD overlapping NF1 exclusively in an individual with multiple clinical features suggesting neurofibromatosis without the formal clinical diagnosis until now. Another child had HZD in PARK2, currently asymptomatic. By further evaluating deletions as an allelic genotype (CN=0->1 1, CN=1->1 2, other->2 2), we were able to detect deletions significantly deviating from Hardy-Weinberg equilibrium by lack of heterozygous deletions suggesting embryonic lethality of the heterozygous deletion variant a specific loci. ParseCNV and Plink were used for population analysis and association of the CNV calls. This large scale association of homozygous deletions to clinical phenotypes represents a major advancement in leveraging genomic variants in direct clinical application and my guide direction of effects for future therapeutic interventions.

522T

Identification of copy number variants (CNVs) using computational algorithms and array CGH technologies. *P.S. Samarakoon[1,2], H.S. Sorte[1,2], B.E. Kristiansen[2], T. Skodje[2], A. Stray-Pedersen[2], O.K. Rodningen[2], R. Lyle[2].* 1) Department of Medical Genetics, University of Oslo, Oslo, Norway; 2) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway.

With advances in next generation sequencing technologies and genomic capture techniques, exome sequencing has become a cost effective approach for mutation detection in genetic diseases. However, computational CNV prediction algorithms using exome sequence data exhibit limitations due to the low sensitivity and specificity in predicting small CNVs (covering 1-4 exons). Additionally, Comparative Genomic Hybridization based microarrays (aCGH) used for genome wide high-resolution CNV detection also show restrictions in exonic CNV detection due to the low scoring probes over GC rich regions. Therefore, the goal of the research project was to develop a protocol to detect exonic CNVs (including 1-4 exons), combining computational algorithms and custom aCGH. In this study, we predicted CNVs of 30 exomes obtained from 1000 genomes project using seven computational programs, including an in-house developed algorithm. CNV calling of the proposed algorithm relies on GC% based read depth normalization followed by generation of the best-matched reference dataset for target exome. In parallel to the computational prediction, CNVs were also identified by using aCGH, which was designed to capture exonic regions in 1000 genomes exome and Gencode v.15. Next, true CNVs were identified by comparing computational predictions to the aCGH results. Results of each computational program showed a significant variation in predicted CNV counts (ranging 0-2500). Due to the drastic variation in resulted CNV counts, intersection operations were performed to identify CNVs predicted by multiple programs. As intersection operation showed a direct effect in decreasing the number of predicted CNVs to 0-250 from 0-2500, this was used as a filter for our CNV pipeline. Finally, CNVs resulted from complete protocol (true CNVs), which were not reported in database of genomic variants (DGV) were identified as novel CNVs. Application of the complete protocol on 9 individuals presented 77 novel CNVs including 26 that cover single exons. Additionally, protocol was then implemented on primary immunodeficiencies (PIDDs) patients at Oslo University Hospital and predicted PIDD causing CNVs from the computational approach were validated using the custom array. Thus, identifying PIDD causing CNVs while demonstrating the capability in detecting shorter exonic CNVs proved clinical importance of the proposed protocol.

523F

Genomic characterization and copy number analysis of human induced pluripotent stem cells (iPSCs) from 22q11.2 deletion syndrome patients. *C. Purmann[1,2], S. Pasca[3], H. Gai[3], A. Krawisz[3], X. Zhu[1,2], J. Rapoport[4], J. Berstein[5], J. Hallmayer[1], R. Dolmetsch[3], A.E. Urban[1,2].* 1) Department of Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Neurobiology, Stanford University, Stanford, CA; 4) National Institutes of Health, Child Psychiatry Branch, NIMH, Bethesda, MD; 5) Department of Pediatrics, Stanford University School of Medicine, Stanford, CA.

The 22q11.2 deletion syndrome, also known as DiGeorge Syndrome or Velocardiofacial Syndrome (VCFS), is a common genomic disorder in humans. The clinical phenotype is variable, but includes most notably neurodevelopmental abnormalities, craniofacial and cardiovascular malformations, as well as immune deficiencies. It is thought that large CNVs present critical aberrations during early brain development that manifest in childhood or later in life. The lack of understanding how exactly these CNVs exert their influence on a molecular level is exacerbated in neurogenetic diseases where it is difficult to access the relevant human tissues for detailed molecular studies. One very promising avenue around this obstacle comes from the recent development of induced pluripotent stem cells (iPSCs) whereby skin cells from patients can be reprogrammed into pluripotent stem cells which can then be differentiated into neuronal cells for controlled molecular study. Here, we report the genomic characterization of a panel of iPSCs from seven 22q11.2 deletion patients and seven matched controls. Multiple iPSC lines were created from each proband, and between one and three lines per proband were analyzed using SNP arrays, for a total of 26 iPSC lines analyzed. We used the new Illumina HumanOmni5Exome array which interrogates more than 4.5 million loci genome-wide. The resulting data can be used to detect duplications and deletions with high accuracy. For each iPSC line derived from a patient, we determined the exact extent of the main deletion. We also determined for all lines the overall complement of CNVs and SNPs, including in a small subset of the lines a few additional, smaller CNVs that would have been missed with karyotype analysis, but that are large enough that they should be taken into consideration while using the iPSCs as a model system. The iPSCs are showing full differentiation potential along the neuronal trajectory. For a subset of the iPSCs, we used RNA-Seq analysis and detected gene expression changes in a large number of the genes within the deletion region. These iPSC lines will be a highly valuable resource for the analysis of this important microdeletion syndrome, as well as in general for the elucidation of molecular effects of large copy number aberrations on the genomic control of cellular differentiation and functioning. Furthermore our analysis highlights that high-resolution genome analysis in iPSC based model systems should be standard practice.

524W

Common CNVs of Innate Immune Response Genes Defensin DEFA1/A3 And Complement C4A Are Medium Effect-Size Risk Factors for Human Autism Spectrum Disorders (ASD). *H. Wang[1,2], K. Linter[1], E. Hansen[1], B. Zhou[1], YL. Wu[1], K. Jones[1], A. Schwaderer[2], D. Hains[2], CY. Yu[1], G. Herman[1].* 1) Center for Molecular and Human Genetics the Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, Ohio 43205; 2) Center for Translation Research the Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, Ohio 43205.

Products of innate immune response genes are not only crucial in the defense against infections, but are also needed in nerve pruning during the formation of synapses in the central nervous system. Many innate immune response genes are characterized by frequent, inter-individual gene copy number variations (common CNVs). The role of common CNVs for immune-related genes in the pathogenesis of ASD is unknown. Our objective is to determine common CNVs of innate immune response genes for antimicrobial peptides α-defensins DEFA1 and DEFA3, and complement C4A and C4B in genetic risks of ASD. Our study population included 185 ASD patients (90.3% White, 9.7% other races) and >500 race-matched healthy controls from Ohio. Of the White ASD patients, 84% were male and 16% were female; the mean age (±SD) at disease diagnosis was 3.3±1.8 years old. Continuous CNVs for defensins DEFA1/A3 and complement C4 were determined by TaqI genomic restriction fragment length polymorphisms (RFLPs) for all control samples. The relative quantities of DEFA1 and DEFA3 were interrogated by 'hot-stop' PCR and HaeIII-RFLP, and those of C4A and C4B were elucidated by PshAI-PvuII RFLP. The CNV-defined samples facilitated development of sensitive TaqMan-based qPCR amplicons to decipher CNVs for DEFA1/A3 and C4A/C4B in ASD. The copy number for DEFA1/A3 in a diploid genome of White subjects varies from 4 to >15; and for C4, 2 to >6. The mean copy number (±SD) of DEFA1/A3 in ASD is 6.37±1.24, compared to 6.85±1.81 in controls (p=0.0013). On average, ASD patients have 0.5 copy of DEFA1/A3 less than healthy subjects. In particular, there is a marked decrease in the frequency of the high copy-number groups of (≥9 copies) in ASD (4.2% versus 13.0%; p=0.0006). The odds ratio (95% CI) for low copy number of DEFA1/A3 in ASD is 3.39 (1.52-7.56). DEFA1 and DEFA3 proteins differ by the A65D polymorphism. The absence of D65 (i.e., homozygous deficiency of DEFA3) has a frequency of 10.8% in ASD, compared to 18.1% in controls [OR=1.81 (1.02-3.21); p=0.035], suggesting the presence of DEFA3 is a risk factor for ASD. For complement C4, we observed a significantly lower copy number of C4A (ASD=1.93±0.74; controls= 2.10±0.76; p=0.008) but not C4B in ASD. The odds ratio for homozygous and heterozygous deficiency of C4A in ASD is 1.52 (1.02-2.29). In summary, common CNVs for defensins DEFA1/A3 and complement C4A are novel, medium effect-size genetic risk factors in White ASD.

525T

***TM4SF20* ancestral deletion and susceptibility to a pediatric disorder of early language delay and cerebral white matter hyperintensities.**

White matter hyperintensities (WMH) of the brain are important markers of aging and small vessel disease. WMH are rare in healthy children and, when observed, often occur with comorbid neuroinflammatory or vasculitic processes. Utilizing 180k oligonucleotide-based, exon-focused array-comparative genomic hybridization in 15,493 children, we identified a 4-kb deletion co-segregating with WMH (penetrance ~70%) and early childhood language delay in multiple families, predominantly from Southeast Asia. The 15 unrelated carrier children, mostly of Vietnamese, Thai, Burmese, Filipino, Indonesian, and Micronesian descent were referred for the evaluation of early language delay, autism spectrum disorders, and/or brain imaging abnormalities. Formal speech and language assessment showed significant discrepancies between verbal and non-verbal skills in the deletion carriers. The premature brain aging phenotype with punctate to multifocal WMH was also observed in ~70% of young carrier parents. The complex 4-kb deletion in 2q36.3 removes the penultimate exon 3 of *TM4SF20*, a gene encoding a transmembrane protein of unknown function. Minigene analysis showed that the resultant net loss of an exon introduces a premature stop codon, which, in turn, leads to the generation of a stable protein that fails to target to the plasma membrane and accumulates in the cytoplasm. This deletion was found to be present in 46/2,018 (2.3%) umbilical cord blood samples from Vietnamese Kinh infants, indicating an allele frequency of about 1%, embedded in a common ancestral haplotype. Our study highlights the importance of understanding population-specific low-frequency highly penetrant alleles, and points to a likely toxic mechanism of TM4SF20 truncation that accounts for a strong effect on disease susceptibility related to familial early language delay and autism spectrum disorders in the Southeast Asian pediatric population.

The use of MLPA-based strategy for discrete copy number genotyping of complex multi-allelic CNVs.
P. Kozlowski, M. Marcinkowska-Swojak. ECBiG, Poznan University of Technology, Poznan, Poland.

Copy number variation has recently been recognized as an important type of genetic variation that modifies human phenotypes. Copy number variants (CNVs) are being increasingly associated with various human phenotypes and diseases. However, the lack of an appropriate method that allows fast, inexpensive and, most importantly, accurate CNVs genotyping significantly hampers CNVs analysis. This limitation especially affects the analysis of multi-allelic CNVs that frequently modify various phenotypes. We present a multiplex ligation-dependent probe amplification (MLPA)-based strategy for multiplex and individual copy number genotyping of both simple bi-allelic and complex multi-allelic CNVs. We used this strategy for discrete genotyping of thee extensively studied CNVs, including: CNV-CCL3L1, CNV-DEFB and CNV-UGT2B17, which have been associated with risk of HIV infection, psoriasis and osteoporosis, respectively. Our experiments confirmed the high reproducibility and accuracy of the obtained genotyping results. Acknowledgements: NCN grant 2011/01/B/NZ5/02773.

Co-evolutionary relationship between chemokines and chemokine receptor: An evolutionary perspective.
C. Tsui[1], Y. Hung[1], D. Liu[3], D. Chen[2]. 1) La Sierra University, Riverside, CA; 2) Dept Pathology, University of California, Irvine; 3) Center for Stem Cell and Translational Medicine, School of Life Sciences, Anhui University.

Chemokine are a family of small cytokines with the ability to induce chemotaxis in nearby responsive cells. The diversity of chemokine ligands and their receptors are generated via segmental duplication as evidence by genomic positions. Specifically, their genomic positions are tightly clustered within few genomic loci with evidence of segmental duplications. Here, we attempt to decipher the evolutionary history of chemokine receptors and their ligands by conduct cross species sequence analysis at the level of transcript sequences as well as the genomic sequences. Specifically, 27 annotated human chemokine receptor sequences as well as 35 annotated human chemokine ligand sequences are mapped to 24 available mammalian genomes. Reciprocal best hit alignments are obtained to generate a list of putative paralogous chemokine gene from each respective species. Each of these putative gene sequences are then used to determine potential orthologous gene within the respective genome. Using this method, we deduced generation of chemokine and its receptors diversity at various point in the mammalian evolution. In addition, there are clusters of chemokine receptors showing a reduction in the paralogous genes. The generation, as well as, the reduction of gene diversity likely hint the differences in evolutionary pressure each respective species face.

High-resolution analysis of DNA copy number variations in Systemic Lupus Erythematosus patients.
F.B. Barbosa[1], M. Simioni[2], E.A. Donadi[3], V.L. Gil-da-Silva-Lopes[2], A.L. Simões[1]. 1) Department of Genetics, School of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, SP, Brazil; 2) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas (UNICAMP), Campinas, SP, Brazil; 3) Division of Clinical Immunology, Department of Medicine, School of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, SP, Brazil.

Advances in molecular-based techniques for DNA investigation enabled the detection of an important type of genomic variation named copy number variations (CNVs). CNVs are defined as genomic segments, usually greater than 1 kilobase (kb) in size, ranging in copy number when compared to a reference genome. They can contribute to risk variability among individuals in complex diseases etiology. Systemic Lupus Erythematosus (SLE) is an autoimmune disease with strong genetic component characterized by chronic inflammation and autoantibodies production. To date, several loci have been associated with SLE pathogenesis by genome-wide association studies (GWAS). However, there are few analyses about CNVs in SLE patients. The purpose of this study was to determine the role of CNVs in 23 SLE patients. To screen the CNVs, high-resolution array Genomic Hybridization Assay was performed using the Affymetrix® CytoScan™ HD platform. To calculate copy numbers, the data were normalized to baseline reference intensities using 366 samples (270 HapMap samples and 96 healthy normal individuals). Data was analyzed by *Chromosome Analysis Suite v.1.2.2* (ChAS) software, which includes the Hidden Markov Model (HMM) algorithm used to determine the copy number states. At total, 406 CNVs were identified (CNV average number per patient was 18), distributed across all chromosomes, except Y. Deletions were more frequent than duplications, 311 and 95, respectively. CNV profile showed 269 CNVs were overlapped by genes, 152 unique CNVs and 59 CNV regions (CNVRs). From all, 39 CNVs detected have not been described in the main database of healthy subjects, the Database of Genomic Variants (DGV). Nine of these have not been described in any structural variants databases. CNVs were found in ten genes previously related with autoimmunity: deletion-type CNVs in *STAT4*, *HLA-DPB2*, *CFHR4*, *CFHR5*, *SNTG1*, *IL3RA*, *UGT2B15*, *ADAM3A* and duplication-type CNVs in *MECP2* and *KIAA1267*. This is the first report of CNVs in these genes in SLE patients. The identification of CNV in SLE suggests a possible contribution of these variations to development of autoimmunity or the onset of the disease. This is consistent with the observed overlap between CNVs and genes implicated in the development of autoimmunity. The action of these genes in determining SLE or any other autoimmune disease should be investigated in future studies. Support: FAEPA, CAPES and FAPESP.

Duplication-Normal-Duplication Rearrangements in Human Genomic Disorders. *C.R. Beck[1], P. Liu[1], J.R. Lupski[1,2,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Inverted repeats are prevalent in the human genome, and are often implicated in genomic rearrangements such as inversions (see Human Molecular Genetics 2013 Mar 15 and Human Mutation 2013 Jan;34(1):210–20). Although copy number neutral events are plentiful between normal human genomes, inverted repeats may also play a role in the duplication of genomic locations that include dosage sensitive genes, leading to disease. Recently, duplication-triplication-duplication (DUP-TRP/INV-DUP) structures mediated by inverted low copy repeats (LCRs) have been described for both the *MeCP2* and the *PLP1* loci. Analysis of array data has also identified duplication-normal-duplication (DUP-NML-DUP) structures in multiple different patient cohorts. These structures can also be mediated by inverted repeat sequences, either through inversion and duplication or through complex mechanisms. To date, we have compiled 18 patients with DUP-NML-DUP rearrangements detectable by high-density array comparative genomic hybridization (aCGH). Discerning the breakpoint sequences and locations for a number of these patients has implicated both inverted LCRs and inverted *Alu* elements in the formation of these rearrangements. Interestingly, we have found that *Alu*-mediated inversion can precede tandem duplication in one patient family, and are investigating the frequencies of similar inversions in normal individuals. This implicates a potential two-step process in the generation of seemingly complex rearrangements, wherein a structural rearrangement that is copy number neutral can be present at least one generation before a non-recurrent tandem duplication leading to disease in a patient. This finding broadens the scope of the inverted repeat sequences important to genomic rearrangements and increases our understanding of how the use of a reference sequence to assess complexities in patient cohorts can confound analysis.

High Resolution Copy Number Variation Analysis using Droplet Digital PCR. *J. Berman, J. Regan, N. Heredia, D. Skvortsov, N. Klitgord, S. Tzonev, E. Hefner.* Bio-Rad Digital Biology Center, Pleasanton, CA.

Copy number variations (CNVs) from single-gene to segmental duplications are increasingly recognized as critically dynamic features of the human genome. Altered copy number status is associated with several disease states, including autism spectrum disorder, schizophrenia, and multiple cancers. Technological hurdles have historically limited meaningful interrogation of copy number status. SNP-based microarrays, aCGH, and qPCR typically lack the sensitivity and fine quantitative discrimination required for resolution of higher copy number states. This is particularly true for copy number evaluation in heterogeneous samples, like somatic mosaicism or tumor biopsies, where only a small fraction of cells might have copy number alterations. Droplet digital PCR (ddPCR) enables accurate and reproducible copy number determination using a simple, cost-effective workflow amenable to high throughput. Using single-well ddPCR, consecutive copy number states can be distinguished between samples of 5 and 6 copy number at 95% confidence levels. Here we use validated Bio-Rad ddPCR CNV assays to discriminate copy number status of multiple genes with low to high copy number states. The evaluation of higher-order oncogene amplifications, such as MYC, MET, and FGFR2, will be demonstrated in FFPE and cell line matrices. The ability to resolve a 5% difference (1.05-fold) in copy number will be demonstrated using mosaic or admixed samples heterogeneous for copy number status. This has immediate implications for researchers interested in reproducibly resolving somatic mosaicism, tumor heterogeneity, or other applications where fine quantitative discrimination is essential.

Accurate measurement of C4 gene copy number variation by chip-based digital PCR. *C. Chen, D. Do, K. Li, D. Keys.* Genetic Applications R & D, Life Technologies, 180 Oyster Point Blvd., South San Francisco, CA 94080.

The fourth component of human complement (C4) is an essential factor of the innate immunity. The C4 gene is represented as two isoforms, C4A and C4B, in the genome. Its copy number varies in human individuals. Lower copy number variation (CNV) of the C4 gene has been implicated with various diseases in human. Here, we have evaluated both chip-based digital PCR (dPCR) and conventional qPCR for measuring the copy numbers of C4 genes in human DNA samples from Coriell and patient samples. There is a high concordance in C4 copy numbers between two methods. However, dPCR offers a better precision which enables to measure a smaller change in DNA copy numbers for up to 8 copies. qPCR can determine the DNA copy numbers for 0- 4 copies. The chip-based dPCR system can accurately measure DNA copy numbers for at least 6 copies. Of 251 patients and 253 healthy controls examined, there is a strong association of the low C4A copy number with primary sclerosing xholangitis (PSC).

Copy number variants associated with the risk of systemic lupus erythematosus: Design a lupus risk prediction system. *Y. Chung, S. Jung, J. Kim, S. Yim.* Integrated Res Ctr Genome Polymorphism, Catholic Univ Korea,Sch Medicine, Seoul, South Korea.

Copy number variation (CNV) is one of the major components of human genetic variations and it is thought to contribute to inter-individual differences in diverse phenotypes. Several CNVs have been identified to be associated with systemic lupus erythematosus (SLE) mostly by the target gene approach. However, genome-wide feature of CNVs and their roles in the risk of SLE remain unknown. We aimed to discover SLE-associated CNVs in Korean women. In this study, we performed genome-wide assessments of CNVs and replicated the significant candidate variants in 946 SLE cases and 702 controls. We found that three deletion-type CNVRs in 1q25.1, 8q23.3, and 10q21.3 were significantly associated with SLE. Of the three candidates, CNVRs in 1q25.1 (RABGAP1L) and 10q21.3 were successfully replicated (OR=1.30, P=0.038 and OR=1.90, P=3.6×10−5, respectively) and the associations were confirmed again by deletion-typing PCR. The CNVR in C4 gene, which showed a potential association in the discovery stage, was included in the replication analysis and found to be significantly associated with the risk of SLE (OR=1.88, P=0.01). Through deletion-typing PCR, the exact sizes and breakpoint sequences of the deletions were defined. Individuals with the deletions in all three loci (RABGAP1L, 10q21.3 and C4) had a much higher risk than those without any deletions in all three loci (OR=5.52, P=3.9×10−4) (Kim et al., Arthritis Rheum 2013 65:1055-63). Based on these findings, we develop a multiplex CNV analysis system for predicting the risk of SLE using MLPA-CE-SSCP method. This system contains six CNV targets including the three CNV loci described above. Here we present the efficacy of our MLPA-CE-SSCP based lupus risk prediction system.

533W

Genome-wide CNV association study of primary caries. *K.T. Cuenco[1], M. Lee[1], X. Zheng[1], E. Feingold[1], D.E. Weeks[1], R.J. Weyant[1], R.J. Crout[2], D.W. McNeil[2], M.L. Marazita[1].* 1) Univ Pittsburgh, Pittsburgh, PA; 2) West Virginia Univ, Morgantown, WV.

Background/Objective: Dental caries is a common childhood disease and highly heritable (30% to 60%) even after adjustments for shared environment. The heritability of primary tooth caries is estimated to be 59%. Genetic risk factors for dental caries in children have been investigated through the NIH Gene, Environment Association Studies Consortium (GENEVA) genome-wide association study (GWAS). Past GENEVA GWAS analyses of primary caries have not considered the contribution of genetic effects from copy number variation (CNV). A more comprehensive investigation of these genetic variants is needed. We attempt a genome-wide CNV association study to identify CNVs correlated with childhood dental caries using existing GWAS data. Methods: Participants were drawn from caries populations collected through University of Pittsburgh, Iowa Fluoride Study, and Iowa Head Start Study. Caries status and demographics were obtained from GENEVA children (n = 1245; ages 3–12 years). Subjects self-reported as Caucasian. Primary caries status was defined as decay and filling teeth (DFT) score ≥ 1 [n = 584] vs DFT = 0 [n=661]. These subjects were included in the GENEVA genotyping runs on a Illumina 610-Quad platform. Marker calls were generated by the Center for Inherited Disease Research and used for CNV calling. We used CNV calls generated using the GC model wave adjustment procedure in PennCNV software. Poor-quality samples are filtered out if the log R ratio standard deviation was greater than 0.3. A CNV call was considered acceptable if the call was based on > 3 consecutive markers. CNVs with copy number <2 were defined as deletions. Copy number >2 were defined as duplications. Caries association analyses focused on autosomes only, and adjusted for DNA sample source and age. Additional existing CNV probes were analyzed for association with caries. Results: We are currently assessing which CNVs associate with primary caries. Any CNVs that correlated with primary caries may give insight into additional genetic targets to pursue. Support: DE018903, DE014899, DE09551, DE12101, DE020127.

Copy number variation profiling of patients with Oesophageal Atresia and VACTERL. *A. deKlein[1], E. Brosens[1, 2], H.P. Zaveri[3], E. de Jong[1, 2], D.A. Scott[3, 4], D. Tibboel[2].* 1) Clinical Gen, Erasmus MC, Rotterdam, Netherlands; 2) Pediatric Surgery, Erasmus Medical Centre - Sophia Children's Hospital, Rotterdam, Netherlands; 3) Molecular & Human Genetics , Baylor College of Medicine, Houston, Texas, USA; 4) Molecular Physiology & Biophysics, Baylor College of Medicine, Houston, Texas, USA.

Esophageal Atresia (EA) with or without Tracheal-Esophageal Fistula (TEF) are common congenital anomalies whose cause is unknown in over 90% of affected patients. EA/TEF can be present either as an isolated defect or in association with other developmental defects: e.g. as one of the core features of the VACTERL (Vertebral, Anal, Cardiac, TEF, Renal and Limb anomalies) association. The hypothesis that genetic defects contribute to both EA/TEF and VACTERL etiology is supported by the fact that EA/TEF is a variable feature of several known monogenetic syndromes. Among these possible defects are Copy Number Variations (CNVs). As de novo CNVs can help to identify causal genes or affected biological pathways, the recurrence of unique and rare inherited CNVs may, in combination with other factors, predispose for the development of EA/TEF and other features of the VACTERL association. We therefore profiled 255 affected individuals with SNP-arrays. All had one or more large CNV, most of them were known polymorphisms. We observed six unique loci with a de novo CNV: 4p15, 4q35, 5q11, 6q23, 7p22 and 8q13. We also identified over 300 inherited CNVs which were either absent or uncommon in published control cohorts and our in-house database. Interestingly, 45 of these inherited variants were recurrent in our patient cohort. Ingenuity Pathway Analysis revealed enrichment of several biological functions including embryonic and digestive tract development. Using our genome-wide approach we identified several loci that may impact biological pathways disturbed in EA/TEF or VACTERL association patients.

Human Endogenous Retroviral Elements (HERVs) Mediate Multiple Large Deletions and Reciprocal Duplications Suggestive of NAHR. *P. Dittwald[1, 2, 6], I.M. Campbell[3, 6], A. Shuvarikov[4], C.R. Beck[3], P. Hixson[3], T. Gambin[3], C.A. Shaw[3], A. Gambin[2, 5], J.A. Rosenfeld[4], P. Stankiewicz[3].* 1) College of Inter-Faculty Individual Studies in Mathematics and Natural Sciences, University of Warsaw, Warsaw, Poland; 2) Institute of Informatics, University of Warsaw, Warsaw, Poland; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA; 5) Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland; 6) Equal contribution.

The vast majority of recurrent deletions, duplications, inversions, and translocations, resulting in genomic disorders or variation, are mediated by nonallelic homologous recombination (NAHR) between low-copy repeats (LCRs) or segmental duplications distributed throughout the human genome. However, recurrent genomic rearrangements are also mediated by non-LCR structures: AT-rich cruciforms [e.g. t(11;22)] and human endogenous retroviruses (HERVs) [AZFa deletions in Yq12 and t(4;18)]. Most recently, using chromosomal microarray analysis, we identified nine de novo, identically-sized 3.3 Mb deletions in 3q13.2q13.31, which were likely mediated by NAHR between two directly oriented HERV elements 4,954 and 5,684 bp in length sharing 4,839 bp of 95.71% DNA sequence identity. We hypothesized that other HERV pairs throughout the human genome may serve as substrates for NAHR and lead to genomic instability. Based on the HERV properties at the 3q13.2q13.31 and Yq12 loci, we developed features of HERV elements mediating NAHR. We identified 204 HERV pairs matching our criteria and thus potentially predisposing ~ 11.8% of the human genome to HERV-mediated recurrent rearrangements. Cross-referencing these predicted susceptibility regions with copy-number variants (CNVs) in our chromosomal microarray databases revealed deletions and apparently reciprocal duplications, ranging in size between 189 kb and 1.36 Mb and mapping to LCR-free chromosomal regions 1q41, 2p12 (two loci), and 11q24.3 in nine unrelated patients. DNA sequencing of long-range PCR-amplified junction fragments showed that all CNVs had different breakpoints mapping within HERVs 5,711–6,136 bp in size and sharing stretches of 93-95% DNA sequence identity with their partner. The presence of HERV-mediated deletions and reciprocal duplications indicates NAHR as a causative mechanism, even though the length and the sequence homology of the HERV elements are less than that currently thought to be required for NAHR. Our data demonstrate an underappreciated role of HERV elements in human genome instability. We propose that in addition to HERVs, other repetitive elements such as LINEs may also be responsible for the formation of recurrent CNVs via NAHR.

536W

A comprehensive high resolution map of copy number variants shows unique disease risks in a consanguineous Arab population. *K. Fakhro[1], J.L. Rodriguez-Flores[2], N. Yousri[1], A. Robay[1], J.G. Mezey[2,3], R.G. Crystal[2].* 1) Department of Genetic Medicine, Weill Cornell Medical College - Qatar, Doha, Qatar; 2) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY; 3) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Genetic studies in Arab populations suffer a lack of databases containing population-level background genetic variation, making it difficult to assess the impact of newly discovered mutations in Arab patient cohorts. We present here the first comprehensive copy-number variation (CNV) map of 108 native Qataris, comprising individuals from all 3 Arab subpopulations (Q1 - Bedouin, Q2 - Persian and Q3 - African). We used QuantiSNP and CNVPartition to make CNV calls from Illumina 2M SNP array data (mean call rate >99.8%) [1624 high quality CNV Regions (CNVRs) - 1201 deletions, 423 duplications; mean size 49.9 kb; range 59 bp-1.97 Mb; total coverage 21 Mb]. Of 1624 CNVRs, 445 affected 2209 unique genes, including 78 severe Mendelian disease genes. Of interest, 459 of 1624 CNVs (28%) were novel to Qataris; 91 of these affected 243 genes, including 14 severe OMIM genes. In order to also assess CNVs below the detection resolution of arrays, we used CNV calls from whole genome sequencing (WGS) data (>50X coverage) in the same 108 individuals. 400,239 CNVs were detected (average >3,800/individual; size range 50bp-1.2Mb) affecting >246Mb of genomic content - the majority of which were non-genic (>80%) and novel to Qataris (52%). Surprisingly, only a minority (~30%) of array-CNVRs overlapped WGS-derived CNVRs; thus, despite a >10-fold increase in number of CNVRs called, WGS-algorithms may still miss a significant number of potentially real, large CNVRs in a population. In total, CNVRs in this population affected >9000 unique genes, with ontological enrichment of >10 KEGG pathways relevant to public health (e.g., cancer, cardiovascular function, type II diabetes) and 78 severe Mendelian disease genes (e.g., ciliary disorders, mental retardation, and congenital defects). The distribution of CNVs was skewed across the three major subpopulations, with a higher number of CNVs as well as a larger percentage of the genome affected per individual in Q1 *vs* Q2 or Q3. Together, this data suggests that CNVs could be important to public health of the Qatari population, that public databases lack a significant amount of CNVs from understudied global populations, and that SNP-array CNVs may still be useful rather than redundant if the aim is to comprehensively uncover all CNVRs within a population.

537T

Post-zygotic Structural Changes in the Nuclear Genome of Human Blood Cells. *L.A. Forsberg[1], C. Rasi[1], D. Absher[2], L. Lannfelt[3], A. Morris[4], C. Lindgren[4], E. Ingelsson[5], L. Lind[6], D. Dumanski[1].* 1) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL, USA; 3) Department of Public Health and Caring Sciences, Division of Molecular Geriatrics, Uppsala University, Uppsala, Sweden; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN, United Kingdom; 5) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 6) Department of Medical Sciences and Science for Life Laboratory, Uppsala University.

Post-zygotic, acquired with age mutations in normal cells represent an understudied aspect of genome biology. Human post-zygotic mosaicism has been studied in embryos, aborted fetuses, children with developmental defects and in cancer. However, little is still known about the type and frequency of acquired genetic aberrations in normal cells from subjects in the general population, especially from larger cohorts that are well stratified by age. Our recent analyses suggest that such mosaicism is surprisingly common, with the highest estimate of 3.5% for elderly/old subjects being affected by various large-scale aberrations. Our analyses are now extended to include 1153 elderly men from a Swedish population-based cohort ULSAM (Uppsala Longitudinal Study of Adult Men) that has been followed clinically for more than 40 years. We aim to i) better describe to frequency and genomic distribution of acquired structural genetic variants in normally aging subjects, ii) further investigate longitudinally collected samples and describe how the frequencies of variant-clones varies with time within individuals and their relation to onset of disease, iii) to determine which cellular sub-compartments of blood usually display different types of genetic structural aberrations and to find phenotypic correlations. So far, peripheral blood sampled at ages ranging from 70.7-83.6 years has been analyzed using the Illumina 2.5MHumanOmni-chip with strict selection of genotyping quality. The size thresholds for scoring the structural variants were 250 kb for gains and 10 kb for deletions and CNNLOH. Next generation whole genome sequencing was used for validation. Remarkably, at least one structural change was observed in 42.7% of the genotyped men with gains being the most common type. These results illustrate the high frequency and importance of post-zygotic mosaicism in normal cells, which should be studied further for associations with various diseases.

538F

Creating a haplotype map for multi-allelic forms of copy number variation in humans. *R. Handsaker[1,2], S. McCarroll[1,2].* 1) Harvard Medical School, Department of Genetics, Boston MA; 2) Broad Institute, Program in Medical and Population Genetics, Cambridge, MA.

An important need in human genetics is to begin to understand multi-allelic copy number variants (mCNVs) - polymorphisms involving genomic segments that segregate in 4, 10, 20 or more different potential copy-number levels in human populations, generally due to tandem or dispersed duplications. Such variants have been refractory to almost all earlier molecular technologies and have therefore not been understood at the levels of alleles, allele frequencies, and haplotypes.

To accurately measure the copy number of mCNV loci using whole-genome sequence data, we first developed new computational approaches building upon Genome STRiP (Handsaker, 2011), a method for discovering and genotyping deletion polymorphisms. Extending our approach to high copy-number and mCNVs, we have ascertained over 10,000 CNVs (including 1600 mCNVs) in 849 individuals using low-coverage (4x) sequencing data from Phase 1 of the 1000 Genomes Project and we have made precise measurements of integer copy number in each individual. Using intensity data from SNP arrays, we estimate the false discovery rate of these CNVs to be less than 5%. The subset of these CNVs that were 'genotypeable' in an earlier, array based study (Conrad et al.) show genotype concordance greater than 99% with our results.

To understand how CNV alleles relate to SNPs and haplotypes, we needed to determine not just diploid copy number in each individual, but the contribution of each chromosome and haplotype to diploid copy number. We developed an approach that combines accurate copy number measurements with dense SNP data, building upon innovations in the Beagle software, to infer CNV alleles, phase them with nearby SNPs, and utilize haplotypes to predict the copy-number contribution of each chromosome in each individual. This work has allowed us to begin to evaluate the limits of genotype imputation for multi-allelic, recurrently mutating forms of copy number variation. We describe new ways to phase and impute the states of multi-allelic, high-copy-number CNVs, and their application to GWAS data. We find that these methods are highly successful at many mCNV loci, including loci with many common alleles.

Digital Droplet PCR (ddPCR) has recently emerged as an ultra-sensitive method of analyzing specific nucleic acid sequences in a complex mixture of sequence fragments. We have developed an approach to employ this technology platform to detect and quantify human genomic somatic mosaic Copy Number Variants (CNVs) that are present in as little as .01% of the native cell population. This unprecedented degree of sensitivity was enabled by the novel approach of 'junction probe placement.' In this we used fluorescent probes that uniquely bind to the junction sequences of mosaic CNVs. The result is a binary fluorescent readout for each ddPCR reaction droplet, each of which contains only picograms of genomic DNA, yielding high sensitivity while maintaining a low false positive rate. Using this method we were able to confirm and quantitate a previously unreported abundance of somatic genome variation, being present in the form of mosaic lineage-manifested CNVs (LM-CNVs) in human fibroblast tissue. We defined the term LM-CNV to describe CNVs detected by genome-wide analyses in an iPSC line but not in the fibroblast culture from which the given iPSC line was derived -- without making a statement as to the nature of the CNV-forming event.These LM-CNVs had become unmasked in iPSC lines derived in a clonal fashion from the fibroblast tissue of origin. The LM-CNVs had originally been detected by low-coverage whole-genome sequencing in 7 fibroblast samples and 20 corresponding induced pluripotent stem cell lines obtained from two families [Abyzov et al., Nature. 2012 Dec 20;492(7429):438–42]. We found that on average an iPSC line has two LM-CNVs. After detecting LM-CNVs by sequencing based analysis in the iPSC lines we investigated the masked, mosaic presence of the same CNVs in the fibroblast tissue of origin. Using standard PCR across the predicted sequence breakpoints we determined that more than half of the LM-CNVs detected in iPSC lines were already present as low allele frequency, mosaic somatic CNVs in the fibroblasts and that up to 40% of fibroblast cells carry such medium-sized to large somatic CNVs. We then used ddPCR and custom designed junction placement probes to determine the degree of mosaicism of the LM-CNVs. We found that in the samples analyzed the range of mosaicism for LM-CNVs was from 0.3%–14% allelic frequency.

Copy number variation studies by single cell sequencing. *J. He[1], P. Liu[2], Y. Man[3].* 1) Department of Biology, South University of Science and Technology of China, Shenzhen, guangdong, China; 2) Department of Chemistry Boston University, Boston, MA 02215; 3) Department of Biology Boston University, Boston, MA 02215.

Studying complex biological systems such as a tumor, a developing embryo, or a brain often involves understanding the behavior and heterogeneity of the individual cells that constitute the system and their interactions. Genomic analysis by single cell sequencing has provided important insights; however current single cell amplification methods and the bioinformatics tools are at the early developing stage. In particular, current single cell sequencing technology has strong amplification bias which makes the CNV analysis challenging. We have therefore been working to optimize methods for CNV analysis of single cells. We performed comprehensive comparisons of MALBAC, GenomePlex WGA4 and MDA methods for single cell amplification. We also developed CNV detecting bioinformatics tools that are good for single cells sequencing data with amplification bias and relatively low coverage. We will describe the application of single cell sequencing in profiling CNVs in neurons. There is a major unanswered question in neuroscience that whether there exists genomic variation between individual neurons of the brain. This variation may contribute to functional diversity or to an unexplained burden of neurological disease. To address this question, we developed a method to amplify genome of single neurons from rat. Single-neuron sequencing allows systematic assessment of genomic diversity in normal brain and shed light into understanding the role of copy number variations in recognition and memory.

Measurement of Cyclin D1 copy number variation at the single cell level using droplet digital PCR. *E. Hefner, Y. Jouvenot, N. Klitgord, K. Hamby.* Bio-Rad Laboratories, Pleasanton, CA.

Amplification of the oncogene CCND1 is linked to poor prognosis in a variety of cancers including melanoma. Accurate copy number variation (CNV) measurement at the single cell level could shed light on the spectrum of CCND1 amplifications within the tumor and ultimately refine prognosis. Current methods for single cell CNV include qPCR, sequencing and array CGH. All of these methods require targeted or whole genome enrichment strategies followed by discrete sample measurements. However, the pre-amplification solution creates a different set of issues including increased cost, time and most importantly the potential for skewed results due to bias in the enrichment procedure. Here, we present a method for determining CCND1 copy number state in single cells without the need for pre-amplification. Samples containing subpopulations of cells with various levels of CCND1 amplification were subjected to single cell ddPCR and the results compared to bulk PCR measurements. The results clearly demonstrate the resolving power of ddPCR for the detection of CCND1 copy number state at the single cell level.

Comparison of copy number variation (CNV) calling performance in large numbers of technical replicate SNP array data using three different, widely-used CNV calling algorithms. *A. Hofmann[1], S. Herms[1,2], F. Degenhardt[1], T.W. Mühleisen[3], M.M. Nöthen[1], S. Cichon[1,2,3], P. Hoffmann[1,2,3].* 1) Institute of Human Genetics Department of Genomics Life & Brain Center University of Bonn; 2) Genomics Research Group Division of Medical Genetics University hospital Basel; 3) Institute of Neuroscience and Medicine Genomic Imaging Research Center Juelich.

Copy number variants (CNVs) have been shown to explain part of the heritability in various multifactorial diseases. Many of these findings are derived from SNP-array data generated in the course of large genome-wide association studies (GWAS). This is not without challenges, however: SNP-arrays contain an ever increasing density of probes which results in a decreased signal-to-noise ratio. The latter causes problems for automated CNV calling algorithms and is a major cause for the unambiguous calling of smaller (<350kbp) and/or low frequency CNVs. Recent studies have therefore focused on the much more reliable calling of larger CNVs (number of consecutive marker or length) and often considering the easier to detect deletion events only. This study compares the performance and differences in CNV calling using three widely-used CNV calling algorithms: CNVPartition, QuantiSNP2 (v2.2), and PennCNV. As SNP array data a large number of technical replicates (n>500) all genotyped at the University of Bonn on Illumina's HumanOmniExpress- and HumanOmni1M arrays were used. We observed an unexpectedly high fluctuation in the prediction of cnv events throughout the three algorithms. All gave comparable findings for larger findings (> 1Mbp) but suffered to give consensus results for smaller variants. Since the replicates were typed on the same array type, this allowed to evaluate effects of the chemistry or the operator in the lab. Results will be shown and based on that parameters will be presented that allow for a better evaluation of the quality of CNV callings from SNP array data.

543T

Ultraconserved Elements: often disrupted in disease-specific copy number variation, almost never involved in benign CNVs. *R.B. McCole, C.Y. Fonseka, C.-T. Wu.* Department of Genetics, Harvard Medical School, Boston, MA.

Ultraconserved elements (UCEs) are genomic regions showing exceptionally strong and unexplained levels of DNA sequence conservation between related species. We have hypothesized that UCEs function as 'copy counters,' helping genomes to maintain exactly the correct number of chromosomes and the right amount of genetic information. This model predicts that perturbations in the copy number of UCEs will be highly deleterious to the cell and, ultimately, to the individual. Early tests of the model examined the co-occurrence (overlap) of UCEs with copy number variants (CNVs) and segmental duplications (SDs) in the human genome. These studies demonstrated that the profiles of human CNVs and SDs are highly depleted for UCEs, thereby lending support to our model. We have now extended these studies to address the following questions: How quickly do UCEs become depleted from the profiles of CNVs? When does this depletion occur? Does it require one or more rounds of human reproduction? Using new sets of UCEs and the most recent datasets of CNVs, we find that depletion is rapid and does not necessarily involve passage through the germline. We also find that depletion is absent from CNVs that arise specifically in cancer, suggesting that while UCEs are refractory to deletion or duplication in healthy cells, in the disease state they are often disrupted, which may be an important but hitherto overlooked aspect of cancer initiation or progression.

Copy Number Variation Analysis for Whole-Exome and Targeted Sequencing using NextGENe® Software Version 2.3.4. *J. McGuigan, J. Wu, C.S. Liu.* SoftGenetics, LLC., State College, PA.

NextGENe version 2.3.4 includes a sophisticated new algorithm for copy-number variation (CNV) detection from a wide variety of projects, including whole-exome and targeted sequencing panels. This algorithm is based on fitting a beta-binomial model to the coverage ratio. This fitting process results in the amount of noise in the data being measured automatically. The confidence of CNV calls is adjusted based on the amount of noise.

Regions are defined for the aligned data in a 'sample' project and a 'control' project. Whole-exome sequencing can use CDS locations, while targeted sequencing can define regions as the location of amplicons. Each region has a total RPKM coverage (sample plus control) and a coverage ratio (sample divided by total). The fitted equation returns a 'dispersion' value for any level of coverage and this value is used to generate beta-binomial distributions for 3 cases- heterozygous deletion, normal (no CNV), and heterozygous insertion (increased copy number). Normalized likelihoods are calculated from these distributions and used in a Hidden Markov Model (HMM) to make the final CNV calls. Each call is given a phred-scaled probability score for insertion and deletion.

The final report contains the calls, quality scores, annotation, and analysis results (dispersion values and likelihoods). Results can also be viewed in graphical form, showing the coverage ratio and call for each region. In this analysis both whole-exome and targeted sequencing data was analyzed.

545W

Identification of deleterious CNVs in a low SES African American Population. *K.B. Mercer[1], L.M. Almli[1], K.J. Ressler[2], J.G. Mulle[1].* 1) Department of Psychiatry, Emory School of Medicine, Atlanta, GA; 2) Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA.

Genome-wide association studies (GWAS) and copy number variant (CNV) discovery have become the standard approaches in attempts to identify genetic variants that result in heritable disorders. The discovery of CNVs has advanced our understanding of genetic variants associated with disorders such as autism and schizophrenia, and will continue to reveal variants that are responsible for yet unknown genetic risk. However, most surveys of CNVs have utilized self-selected case-control populations rather than population-based samples, which may lead to study bias and flawed estimates of CNV prevalence. In the current study, we aim to estimate the prevalence of CNVs associated with genomic disorders in an underserved, impoverished, at-risk African American population. Methods: The Grady Trauma Project is actively recruiting study participants from Grady Memorial Hospital, (Atlanta, GA) which offers healthcare to low income individuals. Study participants are recruited from waiting rooms of either primary care or OB/GYN offices. Willing participants are asked to donate DNA to be used in genetic studies, and to complete questionnaires assessing demographics, trauma exposure and various health outcomes, particularly those related to Depression and PTSD. We used Illumina Omni-Quad genome-wide array data (1M SNPs) derived from 2,927 unrelated African Americans and the PennCNV detection program to identify large CNVs (>100kb) that have previously been found to significantly associate with disease risk. We compared the frequency of disease associated CNVs ($p<0.05$) reported by Cooper et al in Nature Genetics 2011 (healthy controls only) to the frequency of these CNVs in our study sample cohort. Results: We find an unusually high prevalence of genomic-disorder associated CNVs: 2% of this population carries at least 1 CNV associated with a genomic disorder (n = 64), compared with 1% of controls (n = 88 out of 8,329; p-value =1.971e-06). The odds ratio (2.22; 95% CI: 1.59-3.10) reveals an increased risk of deleterious CNVs in this population. Notably, we find 2 previously undiagnosed individuals with the 22q11.2 (VCFS) deletion, and 2 individuals with the RCAD (renal cysts and diabetes disorder; 17q12) deletion. This Z fold excess implies that this population may be underserved and undertreated with respect to detection of genomic disorders.

Determining the utility of MitoExome targeted array CGH in the diagnosis of OXPHOS disorders. *H.S. Mountford[1,2], E.J. Tucker[1], A.G. Compton[1,2], N.J. Lake[1,2], S.G. Hershman[3,4,5], S.E. Calvo[3,4,5], V.K. Mootha[3,4,5], D.R. Thorburn[1,2,6].* 1) Murdoch Childrens Research Institute, Royal Children's Hospital, Flemington Road, Parkville, VIC, 3052, Australia; 2) Department of Paediatrics, University of Melbourne, Melbourne, VIC, 3052, Australia; 3) Center for Human Genetic Research and Department of Molecular Biology, Massachusetts General Hospital, 185 Cambridge Street, Sixth Floor, Boston, MA 02114, USA; 4) Department of Systems Biology, Harvard Medical School, 200 Longwood Avenue, Boston, MA 02115, USA; 5) Broad Institute of Harvard and Massachusetts Institute of Technology, 7 Cambridge Centre, Cambridge, MA 02141, USA; 6) Victorian Clinical Genetics Services, Royal Children's Hospital, Flemington Road, Parkville, 3052, Australia.

Mitochondrial oxidative phosphorylation (OXPHOS) disorders are the most common inborn error of metabolism, affecting at least 1 in 5000 live births. OXPHOS diseases are notoriously difficult to diagnose, as they show extreme clinical and genetic heterogeneity, comprising over 150 monogenic disorders with many more 'disease genes' yet to be discovered. For about 50% of patients and families, the genetic basis of their OXPHOS disorder remains elusive. Previously, we developed a targeted DNA capture and massively parallel sequencing method to detect variants within the mitochondrial genome and exons of 1034 nuclear genes encoding the mitochondrial proteome or MitoExome [1]. Our MitoExome study investigated 45 unrelated Australasian patients with an enzyme and clinical diagnosis of an OXPHOS disorder, none of whom had a previous molecular diagnosis. Our studies have now provided a molecular diagnosis in 15 of these patients with mutations in 11 mitochondrial OXPHOS-related disease genes [1, 2] and identified variants in another 5 candidate genes (9 patients) we now regard as new disease genes. The remaining 21 patients (~46%) had no recessive-type likely pathogenic mutations identified. To further investigate these unsolved patients we designed a Roche NimbleGen 12x135 CGH array to target the MitoExome genes. The design covered all 14,053 exons; 51,380 probes falling within an exon and at 50bp intervals; 63,937 probes falling within introns at 900bp intervals; and 22,285 probes designed at 3,600bp intervals designed upstream, downstream and across each MitoExome gene to form a 'backbone'. Currently, we have applied this technology to 12 patients and identified an average of 4.1 novel copy number changes per patient; 2.4 duplications and 1.6 deletions. Current investigations aim to validate copy number changes found in these patients by long-range PCR before investigating the pathogenicity of these alterations in patient tissue and fibroblast cell lines. To date, at least 2 appear to contain pathogenic copy number changes. Our study is investigating the utility of using a combination of MPS and aCGH to enable a greater diagnostic yield than targeted or Exome MPS approaches alone would enable. The sensitivity and specificity of the CGH array make it very useful to follow up patients without a molecular diagnosis from MPS. 1.S. E. Calvo et al., Sci Transl Med 4, 118ra10 (2012) 2.E. J. Tucker et al., Cell Metab 14, 428 (2011).

547F

European-specific selection at the CCL3L1 locus. *H.T. NGUYEN[1, 2], T.R. MERRIMAN[1], M.A. BLACK[1].* 1) Biochemistry Department, University of Otago, 710 Cumberland street, Dunedin 9016, New Zealand; 2) Mathematics and Statistics Department, University of Otago, 710 Cumberland street, Dunedin 9016, New Zealand.

Infectious disease has been a prominent selective agent in Europe for over one thousand years. The chemokine CCL3L1 binds to the CCR5 receptor, and a 32-bp-deletion mutant (delta32) of CCR5 confers resistance against human immunodeficiency virus (HIV) infection. CCL3L1 copy number (CN) variation has been associated with rheumatoid arthritis and susceptibility to HIV infection, supporting the hypothesis that genetic variants in CCL3L1-CCR5 have previously been subject to selection. We therefore examined selection at the CCL3L1 locus in East Asian, West African, European and American populations using 3 megabases of 1000 Genomes Project data in this region. Two tests based on extended haplotype homozygosity were applied: Integrated Haplotype Score (iHS) and Cross Population Extended Haplotype Homozygosity (RSB). The strongest iHS-signal values were seen in the European population between CCL4 and CCL3L3. Selection specific to European was supported by the RSB signal between European and the three other populations. We then measured CCL3L1 gene CN and identified tag-SNPs for CCL3L1 CN using a newly-developed tool, CNVrd2, in order to identify the relationship between CCL3L1 CN and the selected haplotype identified from the iHS and RHB tests. This haplotype was common in individuals with CN=2, but less common in other groups ($p = 0.00045$, 61%, 34% and 45.6% in CN=2, CN<2 and CN>2 sample sets respectively). Another haplotype was identified specifically for CN<2 ($p = 1.68e{-}08$, $r = -0.3$) and tag-SNPs for deletion (CN<2) were identified only in European (maximum $r2 = 0.42$, $p < 0.05$). We conclude that there is evidence of selective pressure specific to populations of European ancestry, consistent with a role for the CCL3L1 locus in resistance to infectious disease in Europe.

548W

Integration of copy number and structural variation across families can provide unique insight into disease pathology: *Osteogenesis Imperfecta* and Autism cases explored. *A. O'Hara, L. Culot, S. Verma, Z. Che, S. Shams.* BioDiscovery Inc., Hawthorne, CA.

Rapid identification of candidate genomic aberrations responsible for disease phenotype is important in both research and clinical settings. Increasingly, structural variant information must also be combined with sequencing data in order to uncover pathogenic events and then be further resolved through comparison with related genomes. Here we explore two constitutional cases, *Osteogenesis Imperfecta* in a proband with consanguineous parents, explained through comparison with sibling, and an autism case with a suspected *de novo SHANK2* deletion and family trio data. An approach that can integrate structural and sequence variation across related samples will be presented.

549T

SMN1 and SMN2 conversion rates and their influence on the identification of spinal muscular atrophy carriers. *J. Regan, T. Legler, D. Shelton, D. Maar, K. Hamby.* Bio-Rad Laboratories, Pleasanton, CA.

Spinal muscular atrophy (SMA) is the second leading cause of death in children behind cystic fibrosis, affecting 1 in 6000 newborns. SMA is an autosomal recessive disease attributed to deleted or mutated survival motor neuron gene 1 (SMN1). This gene is located within a 500 kb region that is copied and inverted to the centromeric side of SMN1. The copied SMN gene is called SMN2 and it has a single nucleotide change from SMN1 that causes alternative splicing of transcripts, which leads to a less stable protein than protein derived from full-length SMN1 transcripts. The repetitive nature of the inverted region makes it prone to homologous recombination and copy number variation. Individuals with no functional copies of SMN1 due to deletion or mutation have SMA, the severity of which is determined by the number of SMN2 genes. Accurately quantifying the number of SMN1 and SMN2 genes is difficult as just a single nucleotide difference distinguishes the two genes. Afflicted individuals with just 1 - 2 copies of SMN2 have onset of muscle weakness within months of birth followed by death before the age of two, whereas individuals with higher numbers of SMN2 can have symptom onset after the third decade of life and no shortened life expectancy. Histone deacetylases activate SMN transcription, but the window for applying therapies to newborn babies is very small as >95% of motor neurons are lost within 6 months. The promise of reducing the severity of the disease enhances the importance of early diagnosis and intervention before irreversible motor neuron damage occurs. The autosomal recessive nature of the disease provides the possibility that through careful screening the incidence of the disease could be significantly reduced. Traditional carriers (1,0) can be identified using qPCR, however this methodology fails to identify carriers that have cis-configured copies of SMN1 (2,0). Here, we use droplet digital PCR (ddPCR) to accurately quantify the number of SMN1 and SMN2 genes in 384 HapMap samples from four different ethnic backgrounds. Furthermore, we employ digital linkage analysis to determine the frequency of SMN1-to-SMN2 conversion and vice versa. This information is useful for understanding the factors that influence the frequency of carriers, which is estimated to be 1/50. Lastly, we explore the possibility and limitations of using linkage analysis for identifying cis-configured carriers, which are missed by all other methodologies.

550F

Frequency of gene usage and copy number variation within the rearranged Immunoglobin Heavy-Chain Variable locus based on immune repertoire sequencing. *M.J. Rieder[1], D. Williamson[1], A. Sherwood[1], R. Emerson[1], C. Desmarais[1], M. Chung[1], H. Robins[1,2], C. Carlson[1,2].* 1) Adaptive Biotechnologies, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

The human adaptive immune system is composed of both B and T cells that undergo somatic recombination at specific loci to create rearrangements of Variable (V), Diversity (D) and Joining (J) gene segments. For the B-cell immunoglobin receptor heavy-chain (IGH), the CDR3 regions are defined by the VDJ gene segments and nucleotide insertions/deletions at these junctions that create the vast sequence diversity of the IGH repertoire. Characterizing the germline DNA in these regions is impeded by the high sequence similarity between gene segments, mutation and copy-number variation (i.e. large insertions/deletions). Currently, there is a fundamental lack of information about the baseline IGH immune repertoire V gene usage and diversity within healthy human controls. To provide an estimate of this, we sequenced functionally recombined gene segments to infer the underlying gene structure. From a set of 132 healthy controls we sorted C19+/CD27+ B-cells from whole blood and amplified genomic DNA using a highly multiplexed PCR assay that targeted the rearranged IGH receptor locus. Following DNA sequencing and data processing to assign V, D and J gene families and names, we examined the usage frequency of IGHV gene segments across all individuals. We found that of the 98 V gene segments only 56 (57%) were used at a frequency > 0.1%, and ~10 showed little to no usage (present in <1% of individuals). This data also allowed us to identify two IGHV genes currently annotated as orphons (pseudogenes assigned to an alternate chromosomal location) that had unambiguous functional usage (IGHV4/OR15-8; IGHV3/OR16-09) and therefore must reside at the IGH locus on chromosome 14. Finally, by taking this functional approach we were able to screen all V gene segments for germline copy-number variation (e.g. large insertion/deletion events encompassing individual genes) by looking for an excess of deletion events or modal changes in gene usage. We confirmed that existence of 12 of 15 previously identified deleted IGHV gene segments. Strong deletion evidence was observed for an additional six IGHV genes (IGHV3-NL1, IGHV3-33, IGHV1-24, IGHV4-04, IGHV3-41, IGHV3-35) and ten with highly likely germline deletion events. These data suggest that functional immune profiling of rearranged immune receptors provides a more robust method of identifying individual structural variation and provides insight into the immune repertoire of healthy controls.

551W

Copy Number Variants near SLC2A9 are Associated with Hyperuricemia. *R.B. Scharpf[1], L. Mireles[2], E. Halper-Stromberg[3], A. Tin[2], A. Chakravarti[4], E. Boerwinkle[5], J. Coresh[2], W.H.L. Kao[2].* 1) Oncology, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 3) Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 5) IMM Center for Human Genetics, University of Texas School of Public Health, Houston, Texas.

Hyperuricemia is associated with multiple diseases, including gout, cardiovascular disease, and renal disease. Serum urate is highly heritable suggesting a strong genetic component, yet genome-wide association studies of single nucleotide polymorphisms (SNPs) and serum uric acid concentrations explain only a small fraction of the heritability. Whether common copy number variants (CNVs) contribute to uric acid levels is not known. Here, we use high-throughput genotyping arrays to assess DNA copy number on a genome-wide scale among 9,738 individuals of European ancestry who participated in the Atherosclerosis Risk in Communities (ARIC) study. Loss of DNA copy number at genomic coordinates 10,002,252-10,009,766bp on chromosome 4p16.1 is associated with a 5.39 percent increase of uric acid concentrations among women (95% CI: 4.32-6.47, p = 4.4e−24) and a 1.39 percent increase among men (95% CI: 0.30-2.49, p = 0.012). The CNV locus is approximately 200kb from several SNPs in the urate transporter SLC2A9 that have been previously associated with uric acid concentrations in ARIC, including SNP rs7675964. Among women with the same rs7675964 genotype, loss of copy number is associated with a 3.01 percentage increase (95% CI: 1.96-4.07) of uric acid concentrations (p = 4.84e-33). In addition to variation of DNA sequence, loss of DNA copy number may contribute to the genetic predisposition of serum uric acid concentrations, particularly among women, explaining some of the missing heritability from standard genome-wide analyses with SNPs.

552T

Comprehensive comparison of copy number variations detection using Illumina Omni 2.5M and Affymetrix CytoScan® arrays. *C. TANG[1,2], E. WONG[1], H. GUI[1], S. CHERNY[1,4], P. SHAM[1,2,4,5], P. TAM[3,5], M. GARCIA-BARCELÓ[3,5].* 1) Department of Psychiatry; 2) Centre for Genomic Sciences; 3) Department of Surgery; 4) State Key Laboratory of Brain and Cognitive Sciences; 5) Centre for Reproduction, Development and Growth, the University of Hong Kong, Pokfulam, Hong Kong.

Structural variation has been recognized as a genetic risk factor contributing to human diseases, and in particular, congenital disorders. Smaller scale copy number variations (CNVs) have also been linked to a number of neurodevelopmental phenotypes, including intellectual disability as well as autism spectrum disorders. The precise detection of CNVs is therefore necessary for understanding disease pathogenesis. Recently, the new generation of SNP-based arrays, Affymetrix CytoScan® and Illumina Omni 2.5M offer an unique opportunity for improved discovery of CNVs with their special design. We explored the performance of these new platforms by genotyping in duplicate on each platform, 4 samples from patients diagnosed with a congenital disease. Performance of the CNV calling was assessed on the basis of sensitivity and specificity, both within and across platforms using various CNV detection software. Similar to previous generations of SNP-based genotyping arrays, the concordance of CNVs was found to be moderate and dependent on the calling software. In general, Cytoscan offered higher sensitivity whereas more specific calls were achieved using Omni. To conclude, multiple CNV calling methods should be employed for reliable CNV calling.

553F

Characterisation of the *RNU2* CNV, a bulky neighbour for *BRCA1*. *C. Tessereau[1, 2], N. Monnet[1], M. Imbert[1], M. Buisson[1], L. Barjhoux[1], C. Cuenin[7], C. Schluth-Bolard[3, 4], D. Sanlaville[3, 4], Z. Herceg[7], E. Conseiller[2], M. Ceppi[2], L. Duret[5], OM. Sinilnikova[1, 6], S. Mazoyer[1].* 1) Genetics of Breast Cancer, Cancer Research Center of Lyon, CNRS UMR5286/Inserm U1052/Université Lyon 1, Lyon, France; 2) Genomic Vision, Bagneux, France; 3) Service de Génétique, Laboratoire de Cytogénétique Constitutionnelle, Centre de Biologie et de Pathologie Est, Hospices Civils de Lyon, France; 4) INSERM U1028, CNRS UMR5292, Université Claude Bernard Lyon 1, Equipe TIGER, 69000 Lyon, France; 5) Laboratoire de Biométrie et Biologie Evolutive, Université de Lyon, Université Lyon 1, CNRS, INRIA, UMR5558, Villeurbanne, France; 6) Unité Mixte de Génétique Constitutionnelle des Cancers Fréquents, Hospices Civils de Lyon, Centre Léon Bérard, Lyon, France; 7) Epigenetics Team, Molecular Carcinogenesis and Biomarkers Group, International Agency for Research on Cancer, F-69008, Lyon, France.

The question of the implication of multiallelic CNVs in complex traits remains largely open as most of them cannot be genotyped by array technology. In this work, we focused on the *RNU2* locus, a variable number of tandem repeats that contains the gene coding for the snRNA U2, an essential element of the splicing machinery. *RNU2* was shown many years ago to reside close to the breast cancer susceptibility gene *BRCA1* but is still missing from the latest human genome assembly and cannot therefore be investigated by recent genomic approaches. Using unassembled contigs, we precisely located *RNU2* within the chromosome 17 reference assembly, 124 kb telomeric of *BRCA1*. By FISH analyses on combed DNA (Molecular Combing), we determined more precisely the exact allelic number of repeats than with the previously used Pulse Field Gel Electrophoresis technique and found a range of 6-82 and a level of heterozygosity of 98% in 41 individuals. We used the 1,000 Genome Project data for analysing the variability of this macrosatellite by mapping sequence with unlocalized human genomic contigs and confirmed its high degree of polymorphism suggesting that depth-of-coverage calculation is a very useful tool for accurate multi-allelic CNV characterization. We found 24 frequent SNPs within the *RNU2* basic unit, and the genotype data for 1,106 individuals confirmed previous results showing a concerted evolution of this CNV. Thanks to our precise location, we were able to confirm that the *RNU2* array is within the *BRCA1* linkage disequilibrium block, which allowed us to study the *RNU2* array transmission over a large number of generations. A surprising resulting observation is that a highly variable locus can nevertheless be highly stable. Given the high level of polymorphism of this locus, we also measured the expression of U2 snRNA by qRT-PCR in 16 individuals carrying 36 to 110 repeats. Although the U2 level varied up to 6.6 times between individuals, it is not linked to the *RNU2* CNV copy number. By pyrosequencing, we found a higher level of methylation of the *RNU2* gene enhancer sequences in individuals with the highest copy number, suggesting that methylation could be involved in dosage compensation. These findings extend our knowledge of a recently neglected CNV that could be valuable for evaluating the potential role of structural variations in disease due to its location next to a major cancer susceptibility gene.

554W

Testing rare coding deletions identified using dense exome chip array data for contribution to type 2 diabetes. *M. Thurner[1], A. Mahajan[1], N. Robertson[1], A. Kumar[1], W. Rayner[1], F. Karpe[2], C. Palmer[3], T. Spector[4], M. McCarthy[1], K. Gaulton[1], GoT2D consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, UK; 3) Diabetes Research Centre, Biomedical Research Institute, University of Dundee, Ninewells Hospital, Dundee, UK; 4) Department of Twin Research, King's College London, London, UK.

Loss of function (LoF) of gene activity is a major contributor to phenotypic variability and contributes to both Mendelian and complex disease. The extent to which LoF events might influence susceptibility to type 2 diabetes (T2D), however, is currently unknown. In particular, partial or complete deletions of coding sequence leading to gene LoF have not been explored on a large scale. We thus investigated exonic deletions that could be discovered using the Illumnia HumanExome SNP array (consisting of >240,000 primarily exonic variants). We developed an analytical pipeline for deletion discovery from this array that applies several existing structural variant calling algorithms (PennCNV and QuantiSNP) and merges the resulting calls together to produce one set of calls per sample. We first applied this pipeline to exome chip data from 650 samples whole genome sequenced as part of the GoT2D project and for which genome-wide SV calls have been made using GenomeSTRIP. After filtering merged calls using strict quality thresholds removing samples with large variability and periodicity in signal intensity we detected 20 deletions. 15 of 20 calls (75%) were also detected in low pass sequencing with 100% specificity in genotyping at all but one call. We then applied the same procedure to exome chip data for 11,686 UK T2D case and control samples. A total of 208 deletions were identified 100% of which were low frequency (MAF <0.01) and 48% (100) were singletons. We tested these 208 variants for individual association to T2D at each single SV, and identified large deletions on chromosome 7 overlapping *RARRES2*, *REPIN1*, *LRRC61*, *C7orf29* and *ZNF775* (66,394bp, P=3.0×10−5) and on chromosome 15 overlapping *TSPAN3* and *PSTPIP1* (37,580bp ,P= 1.1×10−4) with significant T2D association after correction for multiple testing. Both are present in the Database of Genomic Variants (DGV), supportive of these being true deletion events. We further characterized 26 and 101 very rare deletions (allele count < 10) present only in cases and controls, respectively, and identified several in potential genes of interest such as *SLC30A8*. These results strongly suggest dense exome arrays can accurately identify gene deletions that can be assessed for contribution to disease. Continued refinement to calling and analysis procedures, coupled with validation and deeper phenotypic investigation of specific deletions of interest, will help clarify the role of coding deletions in T2D susceptibility.

Multiplex emulsion haplotype fusion PCR to determine haplotypes at structurally complex regions. *J. Tyson, H.A. Black, J.A.L. Armour.* School of Life Sciences, University of Nottingham, Nottingham, United Kingdom.

Current human genome sequencing studies produce a vast amount of data that is generally phase insensitive. The importance of haplotypes is well documented, yet the reconstruction of maternal and paternal haplotypes over distances longer than a few kilobases is not trivial. Despite the progress made in both statistical and experimental determination of phase, problems remain in assembling (and reconstructing linear haplotypes in) regions of structural variation. Copy number variable regions (CNVRs), such as the *DEFA1A3* locus on chromosome 8p23.1, pose a particular challenge with respect to the determination of haplotypes. Regions with multiple copies of a highly similar sequence tend to be collapsed into a single copy on the genome assembly. As is the case for many CNVRs, multiple levels of complexity exist at the *DEFA1A3* region in the form of copy number variation, gene identity and sequence variation and, as such, determination of the true sequence haplotype in these regions is problematic. For many CNVRs, whilst the diploid copy number can be straightforwardly measured, haplotype copy number and positional information regarding the order of genes with the phase of SNPs either side of the CNVR is often overlooked. We have developed a multiplex emulsion haplotype fusion PCR (EHFPCR) approach to determine structural haplotypes and provide positional information about the location of the genes and associated sequence variants across the *DEFA1A3* CNVR. Amplicons of up to 1kb in length were designed both centromeric and telomeric to the CNVR, to fuse to amplicons within the CNVR. EHFPCRs were carried out in a multiplex reaction, with allele-specific PCR and sequencing used to detect the phase. Integration of sequence data led to the construction of a structural haplotype of approximately 59kb across the *DEFA1A3* CNVR in HapMap individuals, in which the relative positions of different gene sequence variants were defined. The spatial arrangement of genes within any CNVR is valuable in studying the relationship between gene copy number and gene expression, and the relationship between haplotype structure and expression. This work has enabled the reconstruction of haplotypes across the *DEFA1A3* CNVR, providing a more complete view of the haplotype structures at this locus. In addition, EHFPCR is applicable to other regions of the genome, when a more focused approach to assembling haplotypes may be required.

556F

Study of 455 molecularly unsolved LWD and ISS cases: identification of two deletions and the first duplication upstream of SHOX. *H. Verdin[1], L. Borms[1], E. Debals[1], B. D'haene[1], G. Matthijs[2], E. Maris[3], S. Depoorter[4], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Center for Human Genetics, University of Leuven, Leuven, Belgium; 3) Department of Pediatrics, Ghent University Hospital, Ghent, Belgium; 4) Department of Pediatrics, AZ Sint-Jan, Bruges, Belgium.

Short stature homeobox-containing gene (*SHOX*) is located in the telomeric pseudo-autosomal region (PAR1) on the short arms of the X- and Y-chromosome. This PAR1 region also contains seven enhancer elements, three located upstream and four downstream of *SHOX*. A heterozygous defect of *SHOX* or its enhancer elements can lead to Léri-Weill dyschondrosteosis (LWD) or idiopathic short stature (ISS). LWD is a dominant skeletal malformation syndrome characterised by disproportionate short stature, mesomelic limb shortening and the Madelung deformity. ISS is defined as a height below -2 SDS in the absence of known causative disorders. Mutations in *SHOX* or its downstream enhancer elements are found in 50 to 100 % of LWD cases, and in about 2 % of ISS cases. Only recently, the first upstream deletion in a patient with ISS has been described encompassing two of the three upstream enhancer elements. The objective of this study is to assess the contribution of upstream copy-number variations in a large population of molecularly unsolved LWD- and ISS-patients who have been pre-screened for *SHOX* and the downstream PAR1-region. The copy number of the three upstream (CNE-5, CNE-3 and CNE-2) enhancer elements was assessed for 455 patients using real-time quantitative polymerase chain reaction (qPCR) with in-house developed assays for each enhancer element. In 424 patients a normal copy-number was found for the three enhancers. An upstream deletion was found in two ISS patients. In the first patient a deletion of CNE-3 and CNE-2 was found while in the second patient CNE-5 and CNE-3 were deleted. Interestingly, the recently published upstream deletion comprises CNE-5 and CNE-3 which means that the shortest region of overlap for these three deletions only includes CNE-3. Even more remarkable is that we also found a duplication encompassing CNE-5, CNE-3 and CNE-2 in a patient with ISS. These observations therefore point to a possible crucial rule for CNE-3 as enhancer element in the regulation of *SHOX*. In the past, another upstream deletion of *SHOX* comprising the three enhancer elements has been described in a family with brachymesomelic dysplasia and Peters anomaly of the eyes. As our patients do not present with this severe phenotype it remains to be determined why a deletion of the same enhancer elements leads to a different phenotype. In conclusion, we report two upstream deletions and the first upstream duplication in ISS patients.

557W

Diversity of the human LILRB3/A6 locus encoding a myeloid inhibitory and activating receptor pair. *N. Vince[1,2], A. Bashirova[1,2], R. Apps[1], Y. Mochalova[3], X. Yu[2], M. Carrington[1,2].* 1) Cancer and Inflammation Program, Laboratory of Experimental Immunology, SAIC-Frederick, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Ragon Institute of MGH, MIT and Harvard, Boston, MA; 3) University of Maryland, Baltimore County, Baltimore, MD.

Leukocyte Ig-like receptor B3 (LILRB3) and LILRA6 represent a pair of inhibitory/activating receptors with identical extracellular domains and unknown ligands. LILRB3 can mediate inhibitory signaling via ITIMs in its cytoplasmic tail whereas LILRA6 can signal through association with an activating adaptor molecule, FcRγ, which bears a cytoplasmic tail with an ITAM. The receptors are encoded by two highly polymorphic neighboring genes within the Leukocyte Receptor Complex (LRC) on human chromosome 19. Here we report that the two genes display similar levels of single nucleotide polymorphisms with the majority of polymorphic sites being identical. In addition, the *LILRA6* gene exhibits copy number variation (CNV) whereas *LILRB3* does not. A screen of healthy Caucasians indicated that 32% of the subjects possessed more than 2 copies of *LILRA6*, whereas 4% have only one copy of the gene per diploid genome. Analysis of mRNA expression in the major fractions of PBMCs showed that *LILRA6* is primarily expressed in monocytes, similarly to *LILRB3*, and its expression level correlates with copy number of the gene. We suggest that the *LILRA6* CNV may influence the level of the activating receptor on the cell surface, potentially affecting signaling upon LILRB3/A6 ligation.

558T

Highly variable tandem repeat genes: hotspots for primate evolution and human disease susceptibility. *C.T. Watson[1,2], D. Ho[2], M. Brahmachary[2], A. Guimatre[2], C. Borel[2], P. Warburton[2], A.J. Sharp[2].* 1) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Tandemly repeated (TR) genes can exhibit extreme variation in copy number and account for a significant portion of sequence variation between individuals, populations, and species. Targeted studies of TR genes have implicated roles for specific loci in adaptation and human disease risk; however, due to their multi-copy and structurally complex nature, TR gene polymorphisms are poorly captured by genome-wide technologies, and as a result remain understudied. Using a basic computational approach, we identified >180 RefSeq genes in the human genome with >1 copy at a non-overlapping interval on the same chromosome. These genes were enriched in poorly assembled regions, 33% mapping within 50 Kbp of an assembly gap, compared to only 1.6% of all RefSeq genes. To assess the extent of TR gene copy number variation in humans and related species, we designed custom locus-specific Nanostring assays for digital genotyping of copy number at each TR gene in 165 HapMap individuals (YRI;CHB;CEU) and five non-human primate (NHP) species. Secondary probes designed for several loci confirmed the precision of our assays, revealing high concordance in copy number estimates between probes (R^2>0.75). From this screen, we found that the majority of TR genes (~70%) were copy number variable in humans. Inter-individual variation was as high as 5-10 fold, and many genes exhibited significant stratification between populations (V_{st}>0.2). Similarly, we observed a high degree of variation within NHPs, and in many instances, the degree of copy number polymorphism showed species-specific patterns; for example, *REXO1L2P* has 100-250 copies in humans, whereas greater than 900 copies were observed in Gorilla. In contrast, the *GAGE* gene was in single copy in NHPs, but ranged between 15-60 copies in humans. Furthermore, TR genes had significantly higher rates of non-synonymous amino acid changes (P=3.3×10^{-7}). We also uncovered features of TR genes that are important in the context of human disease, in particular, most show very low levels of linkage disequilibrium with flanking SNPs, with only 2 TR genes tagged by neighboring SNPs at r^2≥0.8. Together, these findings demonstrate that previous GWAS have had limited power to assess the impact of TR gene variation in disease susceptibility. To address these shortcomings, we are currently screening 26 of the most polymorphic TR genes in populations with various autoimmune diseases for which a majority of disease variance remains uncharacterized.

559F

Detection of CNV gains and losses with Affymetrix® Axiom® arrays. *T. Webster, H. Zuzan, J. Gollub, J. Schmidt, A. Roter.* Algorithms & Data Analysis, Affymetrix, Santa Clara, CA.

Copy number variations (CNVs) polymorphisms are common in phenotypically normal individuals and some have been shown to increase risk for human diseases, for example schizophrenia and other neuropsychiatric disorders. The ability to detect single nucleotide polymorphisms (SNPs) as well as copy number variation in the same genome screen is efficient and advantageous. We show that Affymetrix® Axiom® arrays, designed to detect genome-wide associations with SNPs and InDels, also detect copy number variations. The CNV detection method computes log2(ratios) for each marker, where for each marker site the sum of allele intensities from an individual is normalized by the intensity produced by taking the average of several genomes from phenotypically normal individuals, assumed to represent the normal copy number state. While genotypes are determined by analyzing a large set of samples at a single location, achieving an accuracies of greater than 99.5%, CNVs are evaluated from the same data set by analyzing a contiguous set of markers along the genome in a single sample. The method was applied to whole genome data from a set of HapMap individuals. We present evidence of CNV gains and losses in HapMap individuals that were genotyped with Axiom® arrays and by literature evidence and established CNV detection technologies, such as the Affymetrix CytoScan® HD microarray.

560W

Fusion genes resulting from complex duplications in chromosome Xq28. *L.W. Zuccherato[1], B. Alleva[1], C.M.B. Carvalho[1], J.R. Lupski[1,2,3].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Changes in gene dosage likely are responsible for many genomic disorders. However, advances in technology are revealing that complex genomic rearrangements (CGRs) can lead to the formation of new genes that have potential effects in the disease phenotype. Chromosomal rearrangements can be produced by recombination and replication mechanisms and can convey diverse phenotypic effects. Gene fusions have been observed in somatic alterations such as cancer, and despite the importance of these fusion genes, the underlying mechanism(s) that result in their formation in constitutional chromosome alterations and other rearrangements are poorly understood. Data from the breakpoint junction sequencing of two individuals carrying duplications involving the Xq28 region enabled us to predict a complex pattern of rearrangements that include the fusion of exons from genes *F8/CSAG1* and *BCAP31/TEX28*. RT-PCR experiments confirmed the expression of the new fusion genes in transformed lymphoblastoid cell lines from these patients. The rearrangement found in the *F8/CSAG1* produced an inversion of the 5'UTR of the *F8* gene, leading to a transcript in the same orientation as transcript *CSAG1*. Moreover, the newly expressed *F8/CSAG1* transcripts included a partial sequence of ERVL-MaLR intronic repetitive element. This provides evidence that the 'exonization' of repetitive elements can occur in the formation of a fusion gene and may be triggered by changing the genomic context in which a gene is transcribed. Future experiments will address the functional relevance of these changes at the protein level and the further impacts of structural variation on patient phenotypes. Thus, complex rearrangements mediated by the replication mechanism FoSTeS/MMBIR may contribute to exon shuffling processes and diversify the repertoire of expressed transcripts, and therefore CGRs may have a role in the evolution of both individual genes as well as the human genome.

561T

Mapping of a human genome with a single molecule nanochannel array platform for genome-wide structural variation analysis and de novo sequence assembly of next-generation sequence reads. *Y.Y.Y. Lai[1], A.C.Y. Mak[1], E.T. Lam[2], J. Silbert[3], T.P. Kwok[4], J.W. Li[4], A.K.Y. Leung[4], J.J.K. Wu[5], A.K.Y. Yim[4], A. Poon[1], C. Chu[1], C. Lin[1], M. Requa[2], A. Hastie[2], T. Anantharaman[2], H. VanSteenhouse[2], H. Dai[2], F. Trintchouk[2], M. Saghbini[2], M. Austin[2], K. Haden[2], H. Cao[2], S.M. Yiu[5], K.Y. Yip[4], T.F. Chan[4], M. Xiao[3], P.Y. Kwok[1].* 1) University of California, San Francisco, San Francisco, CA, United States; 2) BioNano Genomics, San Diego, CA, United States; 3) Drexel University, Philadelphia, PA, United States; 4) Chinese University of Hong Kong, Shatin, Hong Kong; 5) University of Hong Kong, Hong Kong, Hong Kong.

Genetic variation results in human population diversity and differential disease susceptibility. Different methods, such as quantitative PCR, array comparative genomic hybridization (aCGH), Sanger or next-generation sequencing have been used for identification of these polymorphic loci, however they have either low sensitivity in repetitive regions, are too labor-intensive and time consuming, or do not provide positional information about the structural variants. To overcome the above disadvantages from current methods, we use a single-molecule mapping approach to identify structural variation as well as to provide scaffolds for de novo assembly of a diploid human genome, NA12878, from 'short reads' sequences. Genome mapping utilizes highly parallel nanochannel arrays in which thousands of very long single DNA molecules are linearized and imaged. This novel approach is automated on the Irys System, which can scan the entire genome rapidly to generate physical maps that provide a more comprehensive view of the genome. NA12878, the daughter in a CEPH-CEU trio, was used as this sample has been genotyped and sequenced extensively as part of the International HapMap and 1000 Genomes Projects. We nicked and fluorescently labeled DNA fragments, size ranging from 100 kb - 500 kb, at Nt. BspQI (GCTCTTCN/) sites. To date, we generated over 50X coverage data and constructed de novo assembled genome maps that cover more than 90% of the genome using an automated assembly pipeline. We identified many structural variants (indels) including those previously known in this sample. Overall, this genome mapping approach is simple and can be performed in any modern molecular genetics laboratory.

562F

CNP imputation using 1000 Genome Project data as reference panel and intensity based analysis of copy number variation in African Americans.

Copy number variants (CNVs) are important source of variation in the human genome, but can be challenging to assay directly with current chip-based genotyping methods used for genome-wide association studies (GWAS). Therefore, there is a need to improve our ability to assess this class of variation. The release of Phase I of the 1000 Genomes Project (1KGP) has catalogued a large number of both SNPs and CNVs. One of the major uses of the SNP data has been imputation of genotypes at locations not directly genotyped in GWAS conducted on conventional SNP array. Because common copy number polymorphisms (CNPs) are often in linkage disequilibrium with neighboring SNPs, it is possible to impute common CNPs using SNP data. We evaluated the feasibility of imputation of 1KGP deletion CNVs in a large panel of 1845 African Americans from Jackson Heart Study (JHS) within CARe (Candidate Gene Association Resource) project. We used the IKGP Phase 1 data as a reference panel, and cross-validated imputation with directly called CNPs, comparing imputed genotypes with those directly measured on the array using Birdsuite software (Canary for known common CNPs and Birdseye for rare CNVs). We evaluated several metrics for imputation. First, reachability: how many actual 1KGP CNVs for a known sample (CEU HapMap) were imputed. Second, stability: how often a CNV was assigned the same copy number across 24 sample replicates. Third, accuracy of CNP imputation in JHS samples. The reachability analysis showed that imputation had highest, and Canary intermediate, and Birdseye the lowest reachability. The stability analysis showed that the imputation was the most stable among the 24 replicates, with almost 100% stability. The accuracy analysis showed that CNPs were imputed with accuracy similar to that of SNPs at MAF≥0.05, with less accuracy at MAF<0.05 (dosage r^2 of 0.65 vs. 0.8 with beagle r^2>0.4). Moving forward, we are cataloguing CNVs in the full CARe data set, comprising more than 8000 African American individuals from the Atherosclerosis Risk in Communities (ARIC) study, Cleveland Family Study, Coronary Artery Risk Development in Young Adults (CARDIA) study, JHS, and the Multi-Ethnic Study of Atherosclerosis (MESA). We will also generate a large catalogue of directly typed CNV genotypes in African Americans who also have SNP genotype data. This catalogue will be useful for imputation in west African-ancestry samples and for testing association to phenotypes.

563W

Haplotype imbalance reveals subtle genomic mosaicism in blood and cell line samples.
S. Vattathil[1,2], X. Xiao[2], P. Scheet[2,1]. 1) Human and Molecular Genetics Program, The University of Texas at Houston Graduate School of Biomedical Sciences; 2) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston.

Genomic mosaicism resulting from proliferation of somatically-mutated cells is known to occur in ostensibly normal individuals, however the prevalence and consequences of mosaicism remain unknown. The challenge is that, since somatic mosaicism is infrequent in the population and clonal mutations may be rare within any mosaic individual, methods must be both efficient enough to apply to many samples and sensitive enough to detect minor cell populations. Recent large-scale analyses (Laurie ***et al.***, *Nat Gen* **44**:642; Jacobs ***et al.***, *Nat Gen* **44**:651) have used SNP microarray data to detect somatic mosaicism and outline its relationship to age and cancer incidence, but acknowledge limited power of detection due to difficulties created by noisy data, especially when the clonal population is small. We have previously described a method for combining individual haplotype estimates and B allele frequencies from SNP microarrays to localize allelic imbalance existing in minor cell populations. The advantage of the haplotype-based approach is that it is more robust to stochastic noise inherent to array data, and therefore more sensitive to mutations existing in very low proportions (<10%) of the sampled cells. We are applying the method to a large set of publicly available samples collected by the GENEVA Consortium. Preliminary results from 4,121 blood and blood-derived cell line samples genotyped on the Illumina Human1M microarray identify 1003 mosaic events, including recurrent somatic variation on chromosome 22q in 0.2% (7/2,801) of blood samples and 11.7% (155/1,320) of cell line samples that corresponds to recent findings of recurrent deletion in the region but indicates higher recurrence rate than previously reported. While these events have strong phase concordance signal from our method, some of them may have been missed in other analyses because stringent filtering was required to compensate for low noise tolerance of the detection methods used.

564T

Genome-wide bioinformatic analysis demonstrates distinct *Alu* elements predispose specific loci to pathogenic structural rearrangements.
I.M. Campbell[1], C.R. Beck[1], P.M. Boone[1], C.A. Shaw[1], J.R. Lupski[1,2,3]. 1) Molecular & Human Genetics, Baylor College Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Although the genomic features associated with large recurrent copy number variations (CNVs) of the human genome are well studied, the sequence characteristics that predispose to smaller rearrangements remain poorly understood. *Alu* elements are non-autonomous retrotransposons that have accumulated during primate evolution to make up approximately 8% of the reference human genome. *Alu*s are associated with genome instability and are enriched at the breakpoints of genomic deletions and duplications. A distinct subset of generally small CNVs are mediated by directly-oriented *Alu* elements aligned at the CNV breakpoints. Such CNVs are a frequent cause of some human diseases, including inactivating mutations of LDLR, SPAST and VHL. Although the *Alu* elements present at the breakpoints of these CNVs are aligned, they are much shorter and less similar than low-copy repeats that mediate non-allelic homologous recombination. Thus, the mechanism and genomic features that promote this type of CNV remain largely unknown. We hypothesized that sequence features and distribution of *Alu* elements predispose some loci to *Alu-Alu* mediated CNVs. To test this, we analyzed *Alu* elements participating in such CNVs using breakpoints determined in our laboratory at the SPAST locus as well as from the literature. We determined that elements participating in *Alu-Alu* CNVs are longer, have more conserved Pol III binding sites, have longer poly-A tails, and are richer in GC content than the genome wide average. Analyses suggest these differences cannot be explained by element length alone. We applied knowledge of the characteristics of *Alu*s that participate in CNVs genome wide to identify loci with large numbers of directly oriented exon-flanking pairs matching the characteristics of *Alu-Alu* mediated CNVs. We cross-referenced this list of loci with potentially clinically relevant CNVs identified in over 25,000 patients from our diagnostic laboratory. We discovered a significant enrichment in small (<250 kb) genomic deletions involving the genes with the largest numbers of these distinct *Alu-Alu* pairs. Notably, a number of the genes identified as both enriched in the distinct *Alu-Alu* pairs and with small CNVs in our database were previously reported to undergo *Alu-Alu* recombination. These data help define repetitive elements participating in copy number variation, elucidate mechanisms underlying these rearrangements, and may allow prediction of disease causing CNVs at a genomic level.

565F

Comprehensive analysis of polymorphic numt insertions in Human and Primate populations. *G. Dayama[1], S.B. Emery[2], J.M. Kidd[1,2], R.E. Mills[1,2].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

The transfer of mitochondrial genetic material into the nuclear genomes of eukaryotes is a well-established phenomenon. Many studies over the past decade have utilized reference genome sequences of numerous species to characterize its prevalence and also its role in human diseases. The recent advancement of high throughput sequencing technologies has enabled the interrogation of genomic variation from whole genome sequence data at a much finer scale, resulting in high quality maps of SNP, INDEL, and copy number variation. In contrast, there has been little focus on the diversity of nuclear mitochondrial insertions (numts) in human populations. To address this deficiency, we have developed an approach to discover and genotype previously undiscovered numt insertions using whole genome, paired-end sequencing data. We have identified more than 150 novel sites of numt insertions by applying our method to over a thousand individuals in twenty populations from the 1000 Genomes Project and other datasets. This expands our current knowledge of existing numt locations in the human genome by 20% and represents a substantial increase from the 14 polymorphic numt loci previously reported. Over 90% of the newly identified numts were found in less than 1% of the samples we examined to date, suggesting that they occur infrequently in nature or have been rapidly removed by purifying selection. We further extended our analysis to the whole genomes of over sixty non-human primates belonging to four genera and collectively examined these variants for biases in sequence context at insertion sites and their potential for functional effects. We believe this research will help clarify to what extent that numts play a role in hominoid diversification and phenotypic variability.

566W

An Estimate of Effective Population Size from Individuals of Various Populations. *H.R. Johnston IV.* Department of Biostatistics, Rollins School of Public Health, Emory University, Atlanta, GA.

The advent of whole genome sequencing has allowed for population genetic analyses, previously only theory, to be applied to the data they were designed for. In particular, genome sequences from multiple populations across the globe allow for inferences to be made about historical population events. Utilizing a method originally proposed by RC Griffiths(1), and later leveraged by Johnston and Cutler(2), the effective population size of the population an individual is drawn from can be calculated. In this approach, the heterozygous SNPs of an individual, being a natural sample of size two, are binned over short distances, with the resultant distribution used to infer effective population size. Individuals from different populations are then compared to determine whether any patterns in effective population size can be discerned. Preliminary data, based on a single individual per population, shows that the effective population size for an African population is 8000, while a European population is 7625, a Chinese population is 6004 and a Korean population is 5362. These results need to be fleshed out using multiple individuals to limit the inherent error in these estimates, but the current result is as expected. The effective population size in African population is larger than those of other populations. A next step will involve analyzing sequences of individuals within multiple different populations from each continent, allowing for a finer analysis of demographic history. 1.Griffiths R (1981) Neutral two-locus multiple allele models with recombination. Genome Wide Associated Variants in Migraine Susceptibility: A Replication Study from North India. *B. Mittal[1], J. Ghosh[1], S. Pradhan[2].* 1) Genetics, SGPGI, Lucknow, UP, India; 2) Neurology, SGPGI, Lucknow, UP, India.

Objective: Genome wide association studies (GWAS) have identified various migraine susceptibility variants. We aim to replicate five GWAS associated polymorphisms (rs1835740, LRP1 rs11172113, TRPM8 rs10166942, PRDM16 rs2651899 and TGFBR2 rs7640453) in North Indian population. Furthermore, we checked the SNPs in strong linkage disequilibrium (LD) with the selected variants. We also undertook to predict the functional effect (in silico) of the variants. Design: The study included 340 migraineurs and 200 controls. Genotyping was performed by PCR-RFLP, ARMS PCR and Taqman. Logistic regression was used for association analysis. LD plot was prepared using genotyping data retreived from ENCODE and HapMart. Functional effect was predicted by F-SNP and FastSNP. Results: We did not observe any significant effect of the variant genotype or allele of the first migraine GWAS associated marker, rs1835740. However, significance was observed in case of heterozygous genotype for total migraineurs and in few subgroups: migraine without aura (MO) and females. We suggest potential protective effect of LRP1 rs11172113 polymorphism in migraine susceptibility especially in males. A marginal association was observed for TRPM8 rs10166942 variant in total as well as female migraineurs. PRDM16 rs2651899 variant genotype and allele showed a protective effect on migraine and MO susceptibility On the other hand, TGFBR2 rs7640543 variant did not have significant influence on migraine susceptibility in North Indian population. Most of the selected SNPs (except LRP1 rs11172113) and some of the SNPs in strong LD were predicted to affect transcriptional regulation. Functional effect of LRP1 rs11172113 could not be found but SNP in strong LD with it was found to affect transcription factor binding sites. Conclusion: We present the first replication study of GWAS associated polymorphisms in a population other than European.

568F

Truncating mutations in protocadherin 15 exon 33 which encodes the cytoplasmic domain are unlikely to be disease-causing. *C.L. Perreault-Micale, N. Chennagiri, C.J. Kennedy, A. Frieden, D. Neitzel, N. Faulker, S. Hallam, V. Greger.* Good Start Genetics®, Inc., Cambridge, MA, USA.

The protocadherin 15 gene (PCDH15) encodes a calcium-dependent cell adhesion protein important in mechanosensory transduction. Loss of function mutations in PCDH15 cause Usher syndrome type 1F, an autosomal recessive disease characterized by profound congenital hearing loss, vestibular dysfunction and retinitis pigmentosa. Usher syndrome 1F is one of the disorders that show increased incidence in the Ashkenazi Jewish (AJ) population, with the founder mutation R245X accounting for 75% of alleles. In order to determine the mutation spectrum in a pan-ethnic population, we sequenced the coding region and intron-exon borders of PCDH15 using next generation DNA sequencing technology in 8456 individuals referred by IVF clinics across the US. All mutations were confirmed using Sanger sequencing. We identified 5 carriers of 3 previously described pathogenic mutations (R245X, R643X, and R929X). We also found 11 novel truncating variants in 28 individuals. The novel mutation R1106X is located in exon 25 (transcript variant C, NM_033056.3), upstream from the most 3' known pathogenic variant (c.4257delA) in exon 32 and is predicted to be pathogenic since loss of this region of PCDH15 has already been associated with disease. The remaining 10 novel truncating mutations are clustered in exon 33, which encodes most of the C-terminal cytoplasmic domain. One of those variants, c.4831_4834dupAACA, was observed 16 times. 12 carriers of this duplication were self-reported African Americans (out of a total of 599 tested), resulting in a minor allele frequency of 1% in this population. The high incidence of truncating variants observed in exon 33 in our population indicates that exon 33 variants are unlikely to cause the severe phenotype associated with Usher syndrome type 1F. PCDH15 has a large number of transcript variants, with at least 3 alternate exons coding for the cytoplasmic domain. The truncating exon 33 variants are probably tolerated because differentially spliced cytoplasmic domain isoforms can function redundantly. It is widely accepted that truncating variants disrupt gene function, and thus are expected to be disease-causing in genes underlying recessive (loss of function) disorders. However, this example provides an exception to this rule. Deep sequencing of pan-ethnic populations has enabled us to address these key assumptions regarding the functional effects of some PCDH15 truncating mutations.

Rapid Genome Wide Mapping at Single Molecule Level Using Nano-Channel Array for Structural Variation Analysis and *De Novo* Assembly.
H.C. Cao[1], A.H. Hastie[1], E.L. Lam[1], H.D. Dai[1], T.A. Anantharaman[1], M.X. Xiao[3], P-Y.K. Kwok[2]. 1) BioNano Genomics Inc, San Diego, CA; 2) UCSF, San Francisco, CA; 3) Drexel University, Philadelphia, PA.

Despite continued cost reduction in raw base generation, improvement in base-calling accuracy, and recent advances in read length, complete *de novo* assembly with accurate genome wide structural variant (SV) analysis of an individual large complex genome remains expensive and challenging. In particular, many disease relevant SVs up to hundreds of kilobases long in the human genome are severely underestimated due to a lack of effective tools. We present a rapid genome-wide analysis method based on new NanoChannel Array technology (IrysTM System) that temporarily confines and linearizes extremely long DNA molecules for direct image analysis at tens of gigabases per run. This high-throughput platform automates the imaging of genomic DNA hundreds to thousands of kilobases in length at single-molecule level, retaining long-range haplotypes. High-resolution genome maps assembled *de novo* via unique sequence motif labeling preserves native large and small structural variation information (especially highly repetitive regions), which are intractable with current short read NGS platforms. This information is collected independently of sequencing methods and is very valuable to identify structural variants as well as to validate and finish sequencing assemblies. Here we report the complete *de novo* assembly and analysis of complex regions and whole genomes of several human samples (including a cancer genome) with this approach. Unlike inference from mate-pair library sequencing approaches, hundreds of large structural variants were uncovered without apparent bias (e.g., size or insertion vs deletion) due to its more direct visualization and measurement. We have corrected errors in previous assemblies, spanned and sized many of the remaining gaps, identified known and novel structural variants and phased haplotype blocks, including in the highly variable complex regions related to human immune system functions. We have also discovered abundant previously unknown highly complex large repetitive patterns (greater than 2kb and inverted) spanning large regions of genome and pinpointed foreign genomic components inserted within the host human genome, important for understanding disease and oncogenesis. Widespread use of this technology will continue to enable new genome discoveries, expand our view of genome architecture, and improve understanding of functional regions.

570T

Describing translocations using HGVS sequence variation nomenclature, suggested extensions. *P. Taschner, J. den Dunnen.* Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands.

Translocation breakpoints are traditionally described using ISCN nomenclature based on chromosomal banding patterns (1). Due to the limited number of translocation breakpoint sequences identified the sequence variation nomenclature guidelines of Human Genome Variation Society (HGVS, http://www.hgvs.org/mutnomen), which are mainly focused on simple variants, did not require specific rules for detailed description of genetic rearrangements. This changed with the introduction of new technologies allowing rapid discovery of breakpoint sequences from complex structural rearrangements including translocations. The description of such complex variants challenges the existing guidelines. Here, we suggest extending the HGVS nomenclature guidelines to facilitate unambiguous description of translocations and their breakpoints. A main feature of the description is that the precise chromosomal breakpoint can be derived easily. The suggested format should provide sufficient flexibility and consistency limiting alternative interpretations and ambiguous descriptions. The new translocation rules can be combined with those proposed previously for complex changes, which included: i) nesting to support description of changes within inversions and duplications, ii) composite changes to support concatenation of inserted sequences (2). We have applied the rules in practice by describing all translocation breakpoints involving the DMD gene (see DMD gene variant database, http://www.lovd.nl/DMD). The specifications should allow easy implementation in sequence variant nomenclature checkers (e.g. Mutalyzer, https://Mutalyzer.nl). We are planning to extend the functionality of Mutalyzer to incorporate the latest version of the HGVS sequence variation nomenclature guidelines as part of the development of curational tools for gene variant databases (Locus-Specific DataBases, LSDBs). We believe that the HGVS translocation description format is easier to understand and more effective in practice than the equivalent descriptions in the VCF4.1 format, which was designed to describe variant data from next generation sequencing experiments (3). 1) ISCN (2013). 2013. Common variation in the Melanocortin 4 Receptor gene (MC4R) is associated with increased food intake and obesity in American Indians.
Y.L. Muller, R.L Hanson, M. Thearle, D. Hoffman, B. Gene, K. Huang, S. Kobes, S. Votruba, J. Krakoff, W.C. Knowler, C. Bogardus, L.J. Baier. Diabetes Molecular Genetics Section, National Institutes of Health, Phoenix, AZ.

We previously identified 10 rare non-synonymous mutations in the Melanocortin 4 Receptor (MC4R) gene by sequencing 7900 American Indians living in the Gila River Indian Community of Arizona, where most of the residents are of Pima Indian heritage. The overall prevalence of MC4R functional coding mutations in this population was 2.4%. In the current study, we investigate whether common non-coding variants in MC4R could also contribute to risk of obesity in American Indians. Single nucleotide polymorphisms (SNPs; N=63) spanning a ~414 kb region encompassing MC4R were genotyped in 5880 American Indians who had longitudinal measures of body mass index (BMI). Most of these individuals had a measure of maximum BMI from a non-diabetic exam during childhood (maximum z-score, age and sex adjusted, between ages of 5 and 20 years) and had a measure of maximum BMI from a non-diabetic exam during adulthood (maximum BMI after the age of 15 years). A subset of these individuals had been studied as inpatients in our Clinical Research Center and had measures of body composition as assessed by dual x-ray absorptiometry (N=415) and ad libitum food intake measured over 3 days by an automated vending machine system (N= 203). A promoter variant (rs8097783) with a risk allele frequency (RAF) of 0.48 was associated with BMI in childhood (p=0.01 for age and sex adjusted Z score) and adulthood (p=0.0007, adjusted for age, sex, birth year and heritage). Another promoter SNP (rs1187299; RAF= 0.94) was also associated with BMI in childhood (adjusted p=0.005) and adulthood (adjusted p=0.06), where the risk allele was further associated with a higher percentage of body fat (p=0.01, adjusted for age, sex and family membership) and an increase of 640 kcal/day in total food intake (p= 0.003, adjusted for age, sex, percent body fat, family membership and heritage). The rs11872992 promoter variant was predicted to cause a loss of function by the Ingenuity Variant Analysis. *In vitro* luciferase assay of rs11872992 found that the risk allele had a modest decrease in promoter activity (p=0.005). We conclude that both common and rare variation in MC4R can influence food intake and contribute to risk of childhood and adulthood obesity in American Indians.

572W

Next-generation sequencing of complete mitochondrial genomes of Slovenian Lebers's Hereditary Optic Neuropathy patients revealed one novel mutation and several probable synergistic variants. *D. Glavac[1], M. Tajnik[1], M. Jarc-Vidmar[2], M. Hawlina[2].* 1) Department of Molecular Genetics, Faculty of Medicine, University of Ljubljana, Korytkova 2, SI-1000 Ljubljana; 2) Eye Hospital, University Medical Centre, Grabloviěeva 46, SI-1000 Ljubljana.

Purpose. Leber hereditary optic neuropathy (LHON) is maternally inherited eye disorder. It results from point mutations in highly polymorphic mitochondrial DNA (mtDNA). Although the LHON in the majority of the patients is a result of one of the three most common mutations, in some cases the genetic background is not clear. We investigated nine Slovenian patients diagnosed with LHON, from which only two were positive for one of the most common mutations. In order to find novel pathogenic variants, we performed deep sequencing of whole mtDNA. Methods. DNA of nine LHON patients and 2 controls was extracted from whole blood samples. Patients were first screened for most common LHON mutations using Sanger sequencing. In addition, for 6 patients and 2 controls we performed whole mtDNA amplification and deep sequencing using Ion Torrent technology. Results. Two patients were positive for T14484C and G3460A mutations. In the other patients, whole mtDNA deep sequencing detected novel homo and heteroplasmic variations. We identified 25 non-synonymous and 36 synonymous substitutions in mtDNA protein-coding regions. Their impact on protein structure and function was determined using bioinformatic prediction tools. We found 16 novel non-synonymous LHON-associated variants, from which 11 were homoplasmic and 5 were heteroplasmic. Two patients had significant visual improvement, one with concomitant improvement of VEP amplitudes. Conclusions. In early stage of LHON, before optic disc pallor develops, VEP P100 was abnormal in all, while PERG N95 was attenuated only in some patients. The prevalence of most common LHON mutations in the Slovenian patients is lower than in other parts in Europe. Using deep sequencing approach, we identified new potentially pathogenic mtDNA variations in Slovenian LHON patients, which do not harbour one of the three most common mutations.

573T

Genetic diversity in black South Africans from Soweto. *M. Ramsay[1, 2], S. Hazelhurst[3], Y. Li[4], M. Waldvogel[4], J. Eichenberger[4], S.A. Norris[5], M. Govind[5], M. Tikly[6], C. Hon[4], K.J. Johnson[4], N. Hartmann[4], F. Staedtler[4], A. May[1, 2].* 1) Division of Human Genetics, University of the Witwatersrand, Faculty of Health Sciences, Johannesburg, South Africa; 2) National Health Laboratory Service, Johannesburg, South Africa; 3) Wits Bioinformatics, University of the Witwatersrand, Johannesburg, South Africa; 4) Novartis Institutes for Biomedical Research (NIBR), Human Genetics and Genomics, Basel, Switzerland or Cambridge, MA, USA; 5) MRC/Wits Developmental Pathways for Health Research Unit, Department of Paediatrics, School of Clinical Medicine, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa; 6) Division of Rheumatology, Chris Hani Baragwanath Hospital and the School of Clinical Medicine, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Background: Due to the unparalleled genetic diversity of its peoples, Africa is attracting growing research attention. Several African populations have been assessed in global initiatives such as the International HapMap and 1000 Genomes Projects. Notably excluded, however, is the southern Africa region, which is inhabited predominantly by south eastern-Bantu speakers, currently suffering under the dual burden of infectious and non-communicable diseases. Limited reference data for these individuals hampers medical research and prevents thorough understanding of the underlying population substructure. Here, we present the most detailed exploration, to date, of genetic diversity in 94 unrelated south eastern Bantu-speaking South Africans, resident in urban Soweto (Johannesburg). Results: Participants were typed for ~4.3 million SNPs using the Illumina Omni5 beadchip. PCA and ADMIXTURE plots were used to compare the observed variation with that seen in selected populations worldwide. Results indicated that Sowetans, and other south eastern Bantu-speakers, are a clearly distinct group from other African populations previously investigated, reflecting a unique genetic history with small, but significant contributions from diverse sources. To assess the suitability of our sample as representative of all Sowetans, we compared our results to a larger control and case sample selected for a rheumatoid arthritis study. The control group showed good clustering with our sample, but among the cases were individuals who demonstrated notable admixture of possible clinical relevance. Conclusions: Our data represent a suitable reference set for south eastern Bantu-speakers, on par with a HapMap type reference population, and constitute a prelude to the Southern African Human Genome Programme.

574F

The African Genome Variation Project Phase II: Detailed characterisation of genetic variation in Sub-Saharan Africa. *D. Gurdasani[1,2], T. Carstensen[1,2], African Genome Variation Project Phase II Investigators.* 1) Public Health & Primary Care, Univ Cambridge, Cambridgeshire, United Kingdom; 2) Wellcome Trust Sanger Inst, Cambridge, Cambridgeshire, United Kingdom.

Background: The African Genome Variation Project (AGVP) is an international collaboration that aims to produce a comprehensive catalogue of human genetic variation in Sub-Saharan Africa (SSA) in order to extend our understanding of population history, genetic diversity among populations in SSA, as well as provide a global resource to help design, implement and interpret genomic studies in SSA. Phase 1 of the AGVP involved genotyping of 100 unrelated individuals from each of 16 ethno-linguistic groups from SSA with the 2.5 million (M) Illumina genotype arrays. Here, we present preliminary data from phase II of the AGVP. This project specifically aims to extend AGVP phase I by whole genome sequencing (WGS) of 2000 individuals from genetically diverse populations within Africa in order to develop a resource that provides a comprehensive catalogue of genetic variation in SSA along with core phenotypes accessible to the global scientific community. Methods: AGV phase II has completed low coverage (4x) WGS of 3 geographically distinct populations from Ethiopia, South Africa and Uganda. By October 2013, we aim to extend sequencing to include 1000 individuals from distinct populations including Khoe-San groups in Namibia. WGS was carried out using Illumina Hiseq 2000. Read alignment, recalibration and genotype calling was carried out using GATK best practice recommendations. Results: We identified 19M, 19.2M and 18.8M variants across the whole genome among Baganda (100 samples), Ethiopia (120 samples) and Zulu (100 samples) population groups. Of these, 10%, 18.1% and 9% of variants were novel, respectively. Consistent with previous literature, non-synonymous variants were enriched in the lower allele frequency spectrum, with the ratio of non-synonymous to synonymous SNPs being reversed, indicating enrichment for functional variants. The overlap of variants between populations was modest, with 9.5%, 19.4%, and 11% of variants being private in these populations, respectively. Genetic differentiation measured by Fst was high among populations (mean pairwise Fst= 0.036), with differentiation being greatest between Ethiopian and other populations (Fst=0.05). Conclusions: We identified a large number of novel and potentially functional rare variants among the 3 populations sequenced, with a high proportion of private variants in each population. These findings argue for more detailed characterisation of genetic variation in SSA populations using WGS approaches.

575W

The completion of the 1000 Genomes Project. *A. Auton, The 1000 Genomes Project Consortium.* Albert Einstein College of Medicine, Bronx, NY.

The 1000 Genomes Project has expanded the scope of known human genomic variation through the detection or validation of over 40 million SNPs, indels, and larger structural variants. As such, it is expected that over 95% of variants with an allele frequency of at least 1% within the human population will have been characterized by the project. In the final phase of the project, data have been collected from an additional 12 populations, with a particular expansion in sampling from populations with African or South Asian ancestry. In total, low coverage (~5X) whole genome sequence data have been combined with high coverage (~80X) exome data for over 2,500 individuals from 26 global populations.

Through these efforts, nearly all the short sequence variants detected in a typical human genome sequenced today will have been previously identified. To demonstrate the utility of the 1000 Genomes resource, we have obtained deep whole genome sequence data from 138 diverse trios, allowing direct comparison of the high and low depth sequencing approaches, as well as investigation of integrated calling methods. We show that even for high coverage genomes, utilizing 1000 Genomes data can improve the accuracy of detected variation and aid downstream interpretation.

In addition, the project has also been working towards ascertaining additional types of variation. While earlier phases of the project focused on simple types of genetic variation in easily accessible parts of the genome, the final phase is using novel analytic methods to identify more complex types of variation such as multi-allelic polymorphisms, complex structural variants, and short tandem repeats (STRs). By integrating multiple detection approaches that leverage information from read mapping, locally reassembly, and full-scale de novo assembly, we are able to generate a more complete picture of human genetic variation.

576T

Quality control metrics for whole-exome sequence data analysis and detailed genetic variation from 6,000 disease participants within the UK10K project. *J. Floyd on behalf of the UK10K Consortium: exomes.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The UK10K project is a large-scale next generation sequencing project that has sequenced nearly 4,000 low-coverage whole genomes (6x depth) and over 5,000 high-coverage whole exomes (50x depth). Very few projects of this magnitude have been undertaken to date. Therefore, detailed characterization of the developed quality control (QC) and variation observed with comparison to other large resources such as the 1000 Genomes Project and the NHLBI EVS is of benefit to the broader community. Genome-wide association studies have previously demonstrated the importance of high quality data prior to analysis and these issues are even more likely to influence analysis of next-generation sequence data. The sample-level QC undertaken included identifying sample contamination (~3% of samples sequenced), cryptic population relatedness (0–3% depending on subgroup), genuine familial (but sometimes inaccurately reported) relatedness, and ethnic outliers (0–4% depending on subgroup). To detect possible effects of changing sequencing chemistry and/or variant calling we also report metrics such as the Ti/Tv ratio for SNVs and 3n/non-3n ratio for indels, mean depth and mean number of variants by minor allele frequency bins. After sample QC, 5233 samples remained for analysis. Ethnic outliers and related samples were removed or controlled for within the analyses. For instance, non-UK families were intentionally gathered and analyzed for some of the rare diseases. On average, nearly 70,000 variants passed variant QC per sample of which ~98% were SNVs. Variant QC included VQSR and a per-subject variant filter based on genotype quality. After sample and variant QC, we report a list of highly mutable genes where we see a higher than expected number of novel variants after controlling for gene length across several case phenotypes and sub groups within UK10K and NHLBI. We also evaluated the differences in multi- and single-sample variant calling and their respective abilities to accurately call singleton variants. The majority (~90%) of SNVs called and passed by single-sample are also called and passed by multi-sample with high genotype concordance (>99.5%). We are currently pursuing a validation of a subset of these variants using Sequenom plexes to estimate the proportion of variants missed by single or multi-sample calling alone. The QC steps and evaluations described here provide important information to the exome-sequencing community as ever more sequencing efforts proceed.

577F

Detailed annotated whole genome sequences of a Tibetan Trio family revealed high-altitude genetics and demographic insights. *M. He[1], A. Asan[1], X. Jin[1], E. Huerta-Sanchez[2], R. Wang[3], Z. Cuo[4], Y. Shan[1], Y. Shi[1], M. Yang[2], X. Xie[1], K. Harris[2], D. Cao[1], I. Song[1], J. Zhao[1], Z. Su[1], J. Zhang[1], Y. Chang[1], C. Yu[1], H. Huasang[1], J. Luosang[1], X. Yi[1], Y. Liang[1], R. Nielsen[2], Jun. Wang[1], W. Wang[1], Jian. Wang[1].* 1) BGI-ShenZhen, Shenzhen, Guangdong, China; 2) Statistics and Integrative Biology, UC Berkeley, Berkeley, CA; 3) Naqu local Peoplès Hospital, Lhasa, China; 4) The Second People's Hospital of the Tibet Autonomous Region, Naqu, China.

Unlike most other population groups in the world, the Tibetan population is unique in that it thrives at altitudes higher than 4000 meters, having experienced extreme cold and extreme altitude conditions for many generations. Understanding how Tibetans are adapted on a genetic level to live in low oxygen environments may elucidate the molecular pathways underlying the negative health effects of oxygen deprivation. Thus, the whole-genome sequences of the Tibetan trio will be a useful resource because these genomes will (1) contribute to the diversity of whole-genomes that have been sequenced, (2) be a good reference for studies on identifying the genetic basis of high altitude adaptation, (3) aid studies of gene-environment interactions for those disease variants and (4) be valuable for understanding human genetic history and demography. Here, we sequenced and analyzed the first whole genomes of a Tibetan trio family (father-mother-son). We identify 3,947,651 SNVs, 730,709 InDel and 3,480 structure variants from the two genomes(dad and mom), including 278,689 novel variants (7.06%) might be specific to the Tibetan population, and measured their relevance for individual health, high altitude adaptation and demographic history. We also inferred the effective population sizes of the Tibetan population from the two diploid genomes(dad and mom) of the trio and indicated Tibetans split from Han around 22,000 years ago. This is inconsistent with previous exome based estimation, partly caused by few recombination events were left in present sequence more recently than 20,000 years ago. We found a very rare variants (low frequency in other population) from moms disease prediction may be associated with her high-altitude heart disease. The discovery of a large proportion of population specific variants and the other insights we obtained in the study demonstrate the necessity of population-scale whole genome sequencing for genetic health profiling and more accurate demographic inference of the Tibetan population in the future.

578W

Genetic Structure and Diversity of 38 Singapore Indians from Deep whole-genome sequencing. *L.P. Wong, H.T. Ong, K.H. Lai, W.Y. Saw, X. Liu, E.P.N. Pillai, Y.Y. Teo.* Saw Swee Hock School of Public Health, National University of Singapore, 10 Kent Ridge Crescent, Singapore 119260.

Deep whole genome sequencing across multiple samples provides an opportunity to elucidate the genetic structure and diversity of a population at finer resolution. We conducted deep sequencing of 38 cosmopolitan Indians in Singapore to understand the genetic structure of Asian Indians which is unique in relation to its historical background and genetic admixture. Genetic diversity of Asian Indians is a powerful avenue to establish disease loci map. Furthermore, this population which contributes close to one fifth of the world's population is absent in the Phase 1 release of the 1000 Genomes project. Therefore, our aim of sequencing 38 Asian Indians is to analyze their genetic structure and fully characterize their genetic profiles. On top of that, the formal study of their genetic diversity would reveal many implications in medical research and serve as an invaluable resource. Given the availability of whole genome sequences of archaic hominin genomes (Denisovan and Neanderthal) and 15 other populations across the globe, we examined the relationship of modern human genomes with archaic hominin genomes. The genetic makeup of our samples was more closely related to Southern Indians than Northern Indians. We then demonstrated that 38 Indian genomes has high genetic sharing with Denisovan, evidence of potential admixture between Denisovan and modern humans who are ancestors to Asian Indians. Moreover, we discovered genetic ancestry of mitochondrion and Y chromosome that deviates from the autosomes.

579T

Detection of variations and their frequencies of the *CCR5* gene and its promoter region in Japanese and Okinawan population by NGS analysis using pooled DNAs. *T. Kaname[1], K. Yanagi[1], M. Higa[1], S. Song[2], K. Naritomi[1].* 1) Dept Med Gen, Univ Ryukyus, Nishihara, Japan; 2) Roche Diagnostics K.K., Tokyo, Japan.

Discoveries of the GWAS based on common SNPs could explain 2-15% of heritable variation in disease risk. It was speculated that there are considerable 'missing heritability' existing. Since rare variations would be next resources to elucidate such 'missing heritability', it is important to find novel rare variations in a targeted region in a population. We developed a method for survey analysis of low frequent variations in a targeted region in a specific population by next-generation sequencing (NGS) analysis using pooled DNAs.

Here, we show an example to trace variations and to estimate each frequency in the *CCR5* gene including promoter region in 100 Japanese and 100 Okinawan people. Genomic DNAs of 100 individuals were mixed in equal amount or genomic DNA in each individual was used to amplify CCR5 genomic region by LA-PCR. Then, pooled targeted region of CCR5 for 100 individuals was analysed using a NGS platform, GS Junior (Roche). After mapping reads to the reference, SNPs and indels were called and the frequency was estimated by count rate of the reads. Next, we confirmed each variation and calculated each frequency in the population by PCR-RFLP, allele specific PCR or direct sequencing in each individual.

Allelic frequency estimated by the NGS analysis using pooled DNAs almost correlated the real frequency calculated by the individual analysis. Finally, eight novel variations including non-synonymous substitution were found in 200 individuals. For sensitivity to low allelic frequency, 0.5% of allele in the population could be detected at least.

580F

Functional characterization of rare variants in human Dopamine receptor D4 gene by genotype - phenotype correlations. *A. MichealRaj[1], N. Jatana[2], Md. Jafurulla[3], L. Narayanan[2], A. Chattopadhyay[3], B.K. Thelma[1].* 1) Department of Genetics, University of Delhi South Campus, New Delhi, Delhi, India; 2) Bioinformatics Center, Sri Venkateswara College, New Delhi, India; 3) Membrane and Receptor Biology Group, Centre for Cellular & Molecular Biology, Hyderabad, India.

Objective: Rapid population growth and weak purifying selection in human populations have been suggested to be causal for the origin of rare variants, many of which could be deleterious and have a major effect of relevance to disease risk. Several rare variants have been reported in dopamine receptor D4 (DRD4) gene, belonging to the GPCR family and associated with many neuropsychiatric conditions. DRD4 is also an important drug target in antipsychotic medication. Therefore, the aim of this study was to identify rare variants of therapeutic relevance in *DRD4* using a combination of in silico and in vitro tools. **Methods:** Cells stably expressing the cDNAs of four non-synonymous coding rare variants of *DRD4* (rs1800443, V194G; rs4991150, R237L; rs3889692, A281P; rs34662058, S284G) were generated independently. Ligand binding using [3H]spiperone, G-protein mediated signal transduction (Inhibition of forskolin stimulated adenylate cyclase acivity and phosphorylation of extra cellular receptor kinase) and molecular dynamics-simulation studies were performed and analysed to identify functionally important variants. **Results:** Of the four variants, A281P and S284G ensued to be functionally similar to wild type (WT). V194G variant protein was not able to inhibit forskolin stimulated adenylate cyclase activity and also failed to phosphorylate the extra cellular receptor kinase due to its insensitive nature towards both dopamine and quinpirole. Further, ligand binding studies showed significant reduction in binding affinity (Kd = 2.16 nM; p<0.001) and total number of binding sites (~66%; p<0.001) compared to WT. Potency of dopamine and quinpirole reduced to ~ 6-fold (p<0.01) and 3 fold (p<0.01) respectively with R237L when compared to WT protein and ligand binding studies showed reduction only in total number of binding sites (~40%; p<0.01). Ligand docking studies with these two variants revealed that binding of both dopamine (agonist) and spiperone (antagonist) with V194G variant seems to be superficial due to the structural rearrangement while variant R237L was structurally similar to WT. **Conclusion:** Valine (at V194G) and arginine (at R237L) residues seem to be important for the activity of DRD4.V194G variant seems to be structurally altered and thus rendered non-functional while R237L seems to be functionally active but with altered expression level. This novel finding is of potential value for lead molecule development for dopamine dysregulated disorders.

Determining the properties of loss-of-function variation in candidate essential human genes. *A.R. Rao, S.F. Nelson, E. Vilain, W.W. Grody, H. Lee.* David Geffen School of Medicine, University of California, Los Angeles, CA.

Rare genetic variants that severely disrupt protein-coding genes are known as loss-of-function (LoF) variants, and they are of considerable scientific and clinical interest, due to their presumed high probability of being deleterious and having a causal role in severe Mendelian disorders. A previous study surveying exomic variation in imputed low-coverage data and seven high-coverage exomes has estimated that a typical human genome contains approximately 100 genuine LoF variants with ~20 genes completely inactivated. We replicated this study using clinically generated, high-coverage (~100X mean coverage) exome data from over 200 individuals. In addition, we surveyed the frequency of individuals that are heterozygous or homozygous for LoF variants (nonsense mutations, splice site disrupting SNVs, frameshift indels, or larger deletions) in each gene, with further analysis on 1088 candidate 'essential' genes: orthologs of mouse (Mus musculus) genes with lethal knockout phenotypes. Only high-quality variants with a frequency of less than 1% based on publicly available exome data were considered. An individual genome contains ~280 candidate high quality LoF variants after initial filtering, and 1.4% of genes harbor LoF variants, on average. The proportion of genes mutated is not significantly different for essential versus non-essential genes, but the properties of LoF variants in the two categories differ. Nonsense mutations in essential genes are biased in their location and tend to be close to the start or the end of protein transcripts relative to nonsense mutations observed in non-essential gene list. Additionally, ~15% of the frameshift mutations found in non-essential genes affect all known transcripts of a gene. In contrast, this value is ~0 in essential genes. Thus, inspection of the genomic context of LoF variants is an important aspect of variant pathogenicity filtering of rare SNVs. In conclusion, the distribution of LoF variants in genes may suggest which regions of the studied genes are non-essential, or whether protein products may be rescued by alternative splicing, alternate pathways or redundant genes. Importantly, a measure of the expected LoF variation in a gene enables the estimation of the probability that a gene is causal for a severe Mendelian disorder, if a novel mutation were to be observed in that gene, and incorporating this information during variant interpretation would have a great impact on clinical sequencing practice.

Functional assessment of genetic variants associated with Lp(a) levels on chromosome 6q25-26. *K. Chen[1], W. Lu[1], Y. Cheng[1,2], K. Ma[1], G.S. Gerhard[3], C.D. Still[3], X. Chu[3], R. Yang[1], A. Gorden[1], M.J. Quon[1], B.D. Mitchell[1], A.R. Shuldiner[1,2], M. Fu[1].* 1) University of Maryland School of Medicine, Baltimore, MD; 2) Veterans Affairs Maryland Health Care System, Baltimore, MD; 3) Geisinger Obesity Institute, Geisinger Clinic, Danville. PA.

An increased level of lipoprotein(a) [Lp(a)] is a risk factor for atherosclerosis and aortic valve calcification. Through a genome-wide association study for Lp(a) in 1200 Old Order Amish subjects, we identified 137 common variants ($P = 5 \times 10^{-8}$ to 3.91×10^{-19}) spanning ~5.3 Mb region on chromosome 6q25-26 that were within or flanking 26 genes including *LPA*. To further investigate the effect of *LPA* variants on Lp(a) levels, we sequenced 40 exons, all intron-exon boundaries and 2 kb of the promoter region of the *LPA* gene in 24 Amish subjects. We identified 23 variants including 6 missense variants in exons 26, 32, 37, 39 and 40. Among these, two rare variants (rs3798220, MAF=0.009; rs10455872, MAF=0.022) showed the most significant associations with Lp(a) levels (P value: 1.07×10^{-14}; 1.85×10^{-12} respectively). We also measured copy numbers of kringle IV-2 (KIV-2), a known variant associated with Lp(a) levels, using qPCR. The number KIV-2 was significantly associated with Lp(a) levels ($P = 2.28 \times 10^{-9}$). Conditional analyses revealed that rs3798220 and rs10455872 were associated with Lp(a) levels independent of one another, and KIV-2 numbers were partially dependent on the two SNPs. Finally, we performed conditional analysis of SNPs on chromosome 6q25-26 region adjusted for the three variants in LPA gene. The magnitude of the association in the region of 6q25-q26 with Lp(a) levels was largely reduced (the most significant $P = 3.01 \times 10^{-6}$). To investigate the function of rs3798220 and rs10455872, we examined LPA gene expression by Quantitative PCR (qPCR) in 70 liver samples according to genotypes, matched by age and gender. LPA mRNA levels were significantly higher in carriers than noncarriers of rs10455872 (P=0.0002). We didn't detect any difference in LPA mRNA levels between rs3798220 carriers and noncarriers (p>0.05). These findings suggest rs10455872 within *LPA* may play a key role influence mRNA levels of *LPA* (transcription of stability), while rs3798220 may influence Lp(a) levels through effects on translation or protein stability. Further studies are underway to precisely elucidate the complex genetic architecture and regulation of Lp(a) and the role of genetic variation as a risk factor for cardiovascular diseases.

583F

Identification of nine mutations in the COL1A1 gene in Czech patients with osteogenesis imperfecta. *L. Šormová[1], I. Fialkowski[2], W. Van Hul[2], G. Mortier[2], I. Maík[3], I. Mazura[1].* 1) Charles University in Prague, 1st Medical Faculty, Prague, Czech Republic; 2) Antwerp University and University Hospital, Centre for Medical Genetics, Antwerp, Belgium; 3) Ambulant Centre for Defects of Locomotor Apparatus, Prague, Czech Republic.

Type I collagen is an abundant protein in connective tissues, especially in bone. The type I collagen molecule is a heterotrimer composed of two copies of the alpha 1(I) procollagen chain (encoded by the COL1A1 gene) and one copy of the alpha 2(I) procollagen chain (encoded by the COL1A2 gene). With this study we aimed to identify the genetic defect in a series of Czech patients with osteogenesis imperfecta (OI) (types IA, II/III, III, IVA and IVB). We elected to restrict the study to the analysis of the COL1A1 gene since 60% of OI mutations are present in this gene. We used gDNA isolated from whole peripheral blood. This research is the first study of the whole coding sequence of the COL1A1 gene of Czech patients affected by OI. The obtained genomic data were analysed using the Ensembl database. Unreported DNA variations in the coding and intronic consensus sequences were checked using the PC program Alamut (algorithms SpliceSiteFinder, MaxEntScan, NNSPLICE, GeneSplicer and Human Splicing Finder). We were able to identify the causal mutation in eight patients diagnosed with OI. In three cases with OI IA, we identified nonsense mutations p.Tyr47X at exon 2 (light blue sclera, mild bone deformities, joint hyperlaxity), p.Arg131X at exon 5 (shortened upper body segment, slightly barrel chest) and p.Glut1341X at exon 50 (blue sclera, light bone deformities, barrel chest, higher fractures frequency). In two patients we observed heterozygosity for a missense mutation p.Cys61Phe at exon 2 (OI type III - bone deformities, osteoporosis, barrel chest) and p.Pro1186Ala at exon 48 (OI type IA - blue sclera, mild bone deformities, lower BMD). In the latter patient also a heterozygous nonsense mutation p.Arg415X was found at exon 19. Changes of noncoding sequences were identified in three cases: c.1057-1G>T (intron 16, OI type IA/IVA - blue sclera, hearing loss, bone deformities, osteoporosis), c.1300-1G>A (intron 19, unclassified OI type, clinical data currently not completed), c.1353+38C>G (intron 20, OI type IA - blue sclera, face asymmetry, joint hyperlaxity, bone deformities, osteoporosis).

Findings from the third Critical Assessment of Genome Interpretation, CAGI 2013, a community experiment to evaluate phenotype prediction. *S.E. Brenner[1], D. Barsky[1], J. Moult[2], CAGI Participants.* 1) University of California, Berkeley, CA; 2) IBBR, University of Maryland, Rockville, MD.

The Critical Assessment of Genome Interpretation (CAGI, 'k-jē) is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. In the experiment, participants are provided genetic variants and make predictions of resulting phenotype. These predictions are evaluated against experimental characterizations by independent assessors. A long-term goal for CAGI is to improve the accuracy of phenotype and disease predictions in clinical settings.

The third CAGI experiment (2012 - 2013) consisted of ten diverse challenges. At time of abstract submission, assessment was underway and results will be known in July 2013. CAGI deliberately extends challenges from previous years, with the continuity allowing measurement of progress. For example, in the second CAGI, in a challenge to predict Crohn's disease from exomes, one group was able to identify 80% of affected individuals before the first false positive healthy person. In the third CAGI experiment, this challenge used an improved dataset, and several groups performed remarkably well, with one group achieving a ROC AUC of 0.94 in initial assessment. Another expanded challenge involved using Personal Genome Project genome data to predict phenotypes and match health records; this year, several groups were able to successfully map some genomes.

In the expanded challenge to predict benign versus deleterious variants in DNA double-strand break repair MRN genes~Rad50 (from last year), Mre11, and Nbs1~as determined by those that appear in a breast cancer case versus healthy control, predictions show how methods differ sharply in their effectiveness even amongst proteins in the same complex. A new challenge this year was to use exomes from families with lipid metabolism disorders, Familial Combined Hyperlipidemia (FCH) and Hypoalphalipoproteinemia (HA), to predict lipid profiles and a causative variant. Assessment of this challenge revealed a twist wherein real-world data differed sharply from theoretical models.

Other CAGI challenges include predicting: cancer impact of BRCA variants; splicing impact of p53 gene variants; and cell proliferation impact of p16 variants. Complete information about CAGI may be found at http://genomeinterpretation.org.

Whole genome sequencing of rhesus macaques reveals substantial functional variation and justifies a `reverse genetics' approach to identify new models of human disease. *M. Raveendran[1], D. Rio Deiros[1], G.L. Fawcett[1,2], Z. Johnson[3], N.H. Kalin[4], R.W. Wiseman[5], B. Ferguson[6], E. Vallender[7], S. Kanthaswamy[8], H. Doddapaneni[1], S. Jhangiani[1], D.M. Muzny[1,2], R.A. Gibbs[1,2], J. Rogers[1,2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Yerkes National Primate Research Center, Emory University, Atlanta, GA; 4) HealthEmotions Research Institute and Dept. of Psychiatry, University of Wisconsin, Madison, WI; 5) Wisconsin National Primate Research Center, Madison, WI; 6) Oregon National Primate Research Center, Oregon Health & Science Univ., Beaverton, OR; 7) New England Primate Research Center, Harvard Medical School, Southborough, MA; 8) California National Primate Research Center, University of California-Davis, Davis, CA.

Rhesus macaques (Macaca mulatta) are the most widely used nonhuman primates in biomedical research, serving as models in multiple areas, including infectious disease, neurobiology, endocrinology and metabolic diseases among others. Traditionally, macaque models of human disease were developed through expensive surveys to identify animals with appropriate phenotypes. To explore an alternative strategy, we generated whole genome sequences (25x coverage) for 51 unrelated Indian-origin rhesus macaques from five NIH primate research centers. Identification of potentially functional genetic variation in this species will create novel opportunities to study targeted genetic models of specific disease mechanisms or genetic pathways in animals much more similar to humans than rodents or other mammalian model organisms. Sequence reads (100bp, paired-end) were mapped to the rhesus genome assembly (rhemac2) using BWA, and variation called using SAMtools mpileup. Variant calls were filtered with a minimum q-score of 20, and only variants observed in two or more animals were retained. This identified >27.3 million SNPs (9.5 SNPs per kb) and >4.2 million small indels (1.5 indels per kb), more variation than would be expected in a similar sized survey of humans. Variants were annotated using ENSEMBL to identify those with possible functional effects. We found 48,485 non-synonymous variants, 756 stop codons gained or lost, 2,901 frameshift indels in coding genes, 1,753 codon insertions or deletions, and other annotation classes. The list of genes affected includes many known or suspected to influence risk of human disease. Using the same read data but less stringent filtering (not requiring that variants be observed in 2 animals) yields a total variant count of >37 million. The allele frequency spectrum for this distribution is heavily weighted to low frequency variation, similar to humans. More than 95% of this total variant list has minor allele frequency <0.25 and more than 45% have MAF <0.05. We will report results concerning coding and noncoding variation in rhesus macaques and discuss the significance of this reverse genetics approach. These results show that a significant amount of potentially functional variation is segregating in macaque research colonies, and opens new opportunities for analysis of specific phenotypic effects of functional mutations in genes known or suspected to influence human disease.

586F

Expression Minigenes Reveal the Limitations of Algorithms Predicting the Consequences of Putative Splice Site Mutations. *N. Sharma[1], P. Sosnay[1,2], A. Franca[1], C. Douville[3], A. Ramalho[4], L.B. Gottschalk[1], K.R. Siklosi[1], M. Amaral[4], R. Karchin[3], G.R. Cutting[1,5].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Biomedical Engineering, Institute for Computational Medicine, Johns Hopkins University, Baltimore, MD; 4) University of Lisboa, Faculty of Sciences, BioFIG - Centre for Biodiversity, Functional and Integrative Genomics, Lisboa, Portugal; 5) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Splice sites flanking each exon direct the generation of mature mRNA from heteronuclear RNA. Algorithms that utilize sequence conservation in splice sites provide reasonably accurate predictions as to whether DNA variants will affect the splicing process; however, the ability of algorithms to predict expression of full-length, truncated or no protein is untested. This is a critical issue as the nature and relative abundance of synthesized protein is generally the major determinant of the clinical phenotype caused by a mutation. To address this issue, we developed a novel expression minigene (EMG) system containing flanking intron sequence (~200bp) from multiple adjacent exons cloned into a full-length cDNA in a mammalian expression vector. Presence of the CMV promoter and EMG enables RNA splicing and translation to be tested concurrently. As a proof of concept, two EMGs including introns 11 and 12 and introns 14 to18 of the CFTR gene were created. Splicing was analyzed by RT-PCR followed by Sanger sequencing and protein translation by Western blot in two cell lines: Human Embryonic Kidney (HEK) 293 cells and CF Bronchial Epithelial (CFBE41o-) cells. A normal pattern of RNA splicing and robust protein translation was confirmed for the two wild-type EMGs. Five mutations associated with cystic fibrosis (c.1585-1G>A, c.1585-2A>G, c.1585-3T>G, c.1585-8G>A, c.1585-9T>A) were introduced into intron 11, three mutations (c.2657+3delG, c.2657+5G>A, c.2657+2_2657+3insA) into intron 16, one in intron 18 (c.2988+1G>A) and one in exon 18 (c.2988G>A). Loss of protein synthesis was observed for 9 of the 10 mutations due to nonsense mediated mRNA decay caused by a frameshift or an in-frame premature stop codon introduced by aberrant splicing. One mutation (c.2657+2_2657+3insA) generated fully processed CFTR protein. We compared our results with two currently available algorithms (ASSEDA and HSF) used to predict the transcript isoforms resulting from these mutations. Overall, HSF correctly predicted the aberrant transcript isoforms for half of the mutations while ASSEDA correctly predicted the abnormal splicing patterns for 2 of the 10 mutations. Neither of these programs predicted whether protein would be synthesized. Despite the limitations of current algorithms, experimental data generated by EMGs should enable the generation of algorithms that accurately predict the effect of splicing mutations upon protein production.

587W

Linear Decay of Retrotransposon Antisense Bias across Genes is Contingent upon Tissue Specificity. *S. Linker[1], D. Hedges[2].* 1) HIHG, University of Miami, Miami, FL; 2) Division of Human Genetics, The Ohio State University, Columbus, Ohio.

Retrotransposons (RT), which make up approximately half of the human genome, are gaining attention due to new techniques which allow polymorphic RT insertions to be identified from next-generation sequencing data. The ability to move forward and infer the effects of these polymorphisms will require a substantial increase in the understanding of the various effects that retrotransposons have on a coincident gene. Previous work in this area has highlighted the non-uniform distribution of retrotransposons across the genome leading researchers to propose that there may be local effects that modify their retention in various genomic contexts. Our work furthers this effort by determining predictable trends of retrotransposon accumulation as well as through identifying links between the presence of retrotransposons and gene expression. Our primary findings show that retrotransposons which are in the antisense orientation with respect to a gene, exhibit a linear decay in frequency across the length of the gene. Conversely, retrotransposons in the sense orientation maintain a low-level frequency independent of location within a gene. This linear trend of antisense RTs is inversely correlated with exon frequency, which we show has a linear increase in frequency across the length of most genes. Interestingly, this correlation is dependent upon the gene type (ie: housekeeping versus tissue-specific). Moreover, we have found that transcription factor binding motifs which are contained within RTs also exhibit a pattern of accumulation in certain regions of the gene. We used retrotransposons which are polymorphic in the human population to determine the potential for effect on expression of these inserts. Indeed we identified a subset of polymorphic RTs that were significantly correlated with altered gene expression after correction with FDR. These findings begin to map out predictable variables for the retention of RTs in the genome, and may aid researchers in inferring the effects of novel polymorphic RTs on local gene expression.

588T

Nicotine causes genome-wide microsatellite instability in normal epithelial cells. *J. Bavarva, L. McIver, T. Hongseok, H. Garner.* Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA.

Background: Nicotine has been associated with cancer development. However, there is no direct evidence of nicotine on genome-wide instability, including microsatellites, a highly unstable component of the genome. We hypothesized that nicotine can cause genome-wide microsatellite variability that can have significant biological consequences. Methods: We used a combined approach of customized microsatellite specific aCGH and low coverage whole genome sequencing to quantitate the microsatellites variability in MCF-10A normal human breast epithelial cells upon stressful exposure of nicotine. Results: Our customized microsatellite specific oligonucleotide array quantitates the content of microsatellites including all-possible repeats (1- to 7-mer) in a genome wide scale, which provides us an ability to quantitate microsatellites changes in mass. Global microsatellites content (GMC) exhibited hyper variability (17.8%) upon nicotine exposure. GC rich microsatellites showed a slight bias as they tend to loose GMC (54%) more than AT rich (46%) under nicotine stress. Effects were dose dependent and a stress recovery test indicated that GMC instability did not revert upon removal of stress. We next analyzed effect of oxidative stress on genome-wide microsatellites and discovered that pure oxidative stress is a very powerful microsatellite instability inducer (30.9%). The possible mechanism of nicotine induced microsatellite variability may therefore be linked to nicotine's ability to cause oxidative stress. Next, we used unbiased next-generation sequencing to perform low coverage whole genome sequencing of nicotine stressed cells and controls, and to re-validate our array based findings. We discovered that 10,502 microsatellite loci vary between nicotine stressed and control cells. We cross-examined all significant microsatellite motif families that were revealed through aCGH analysis and found general agreement between WGS and aCGH findings. We identified five variable microsatellite loci in coding regions (MOG, RPL14, ALLC, FAM157B and MAGEF1) and number of the loci upstream of coding sequences that may possibly influence the gene transcription and regulation. Conclusion: The results indicate that nicotine induces genome-wide microsatellite changes, may promote genomic instability and inhibit DNA-damage repair through oxidative stress that can facilitate cancer genesis.

589F

Probing genes for hyperphagia in rare-obesity related disorders. *M.G. Butler[1], J.D. Marshall[2], J. Rethmeyer[1], K. Wang[1], A.M. Manzardo[1].* 1) Psychiatry & Behavioral Sciences, University of Kansas Medical Center, Kansas City, KS; 2) The Jackson Laboratory, Bar Harbor, ME.

Hyperphagia and obesity are key features of several rare genetic obesity-related disorders including Prader-Willi syndrome (PWS) and Alström syndrome (ALMS). A better understanding of genetic causes through the study of obesity-related disorders should provide a more comprehensive picture of mechanisms that control food intake and energy balance related to the development of obesity. Comparison of gene expression patterns associated with rare mutations should provide insight into commonly disturbed gene pathways involved in appetite control and body weight regulation with application to obesity in the general population. We compared coding and non-coding gene expression in PWS, ALMS and nonsyndromic obesity relative to non-obese adult male controls using both lymphoblasts and brain tissue with the Affymetrix Human Exon 1.0 ST and GeneChip miRNA 2.0 arrays from total RNA isolated from PWS (N=7 males; mean age = 25yr; mean BMI=39), ALMS (N=6 males; mean age = 30yr; mean BMI=42), obese (N= 7 males; mean age = 32yr; mean BMI=51) and non-obese (N=7 males; mean age = 26yr; mean BMI=22) controls. In relationship to lymphoblasts from non-obese males, we found disturbances with 231 genes up-regulated in ALMS but no genes up-regulated in the obese or PWS males (FDR ≤ 0.2, fold ≥ 1.5). Of 124 down-regulated genes in ALMS, only the metallothionein gene (involved in heavy metal toxicity and oxidative stress) was significantly down-regulated in common with obese males (FDR ≤ 0.2, fold ≤ -1.5). Only SNRPN was down-regulated in PWS. Fifty-two miRNAs were up-regulated in lymphoblasts from ALMS and four were in common with obese but none with PWS (FDR ≤ 0.05, fold ≥ 2.0). Four separate target genes (EFR3B, CSF2RB, CDX5R1, TBC1D8) were significantly down-regulated in association with five up-regulated miRNAs (miR339-5p, miR-92a-1*, miR-93*, miR-25*, miR-92b-1*) in ALMS. Six separate target genes (CD68, MXI1, FAM102A, TP53INP1, MYO1D, ZRANB1) were significantly down-regulated in association with seven disturbed miRNAs (miR-93*, miR-373*, miR-29b-2*, miR-30c-1*, miR27a*, miR27b*, miR-149). Up-regulated genes in ALMS impacted development, cell cycle and transcription while down-regulated genes were involved with metabolic processes, immune responses and cell signaling transduction. Similar disruption of gene expression was found in brain tissue. The high number of gene disturbances observed may reflect the broad, multi-organ involvement of ALMS pathophysiology.

High sensitivity, single-cell expression analysis with the QX100 Droplet Digital PCR system. *G. Karlin-Neumann, S. Wang, Y. Jouvenot, E. Heffner.* Digital Biology Center, Bio-Rad Laboratories, Pleasanton, CA.

Over the last decade, it has become increasingly evident that gene expression profiles can vary from cell to cell, even within an apparently homogenous population. The analysis of this heterogeneity has become a focus of interest in various fields of biology, especially in stem cell research. The main obstacles to analysis of gene expression at the single-cell level are the low amount of starting material and the low abundance of many transcripts of interest. This requires a high level of confidence in results obtained from unique samples, making it difficult to be done accurately by traditional quantification methods such as qPCR. Droplet digital PCR (ddPCR™) provides absolute quantification of individual molecules with high precision, and without the requirement for standard curves or pre-amplification steps. Using Bio-Rad's QX100 ddPCR system, we developed a method that measures single-cell gene expression in multiplexed assays with high sensitivity and reproducibility, thus enabling us to simultaneously analyze expression of different targets in cDNA from the same cell. In order to perform this, we carefully evaluated various cell lysis and cDNA synthesis methods and developed a protocol with flow-sorted Jurkat cells that is fully compatible with ddPCR, easy to use and capable of analyzing gene expression in single cells without pre-amplification. We show that high, medium and low abundance transcripts (< 20 copies/cell) can be reproducibly measured with ddPCR. We further used this protocol to measure cell cycle-specific genes and revealed distinctive gene expression patterns in populations of single cells. This method allows us to easily and quickly measure the expression of multiple genes of interest in single cells, minimizing the stochastic effect of sampling and empowering us to accurately and sensitively detect and quantify low-expressing genes in single cells.

591T

Individual variation in the rate of retrotransposition in iPS cells and its effect on genomic instability with regard to medical utility. *T.T. Doucet[1,2], C. Smith[1,2,4], A. Ewing[3], K. Burns[1,5], L. Cheng[1,4], H.H. Kazazian[1].* 1) Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD USA; 2) Pre-doctoral training program in Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA; 3) Center for Biomolecular Science and Engineering, University of California at Santa Cruz, Santa Cruz, California 95064, USA; 4) Stem Cell Program, Institute for Cell Engineering, Division of Hematology, Department of Medicine, The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 5) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA.

Genomic instability can be caused by repetitive sequences in the human genome (retrotransposons) that can copy and paste themselves into new sites. We seek to understand how retrotransposition plays a role in genomic instability during the reprogramming process as well as the differentiation process. For iPS cells to be utilized as a medical treatment, their genomes must be stable. We are evaluating iPS and parental cell lines, the cells from which the iPS cells were derived, from three individuals utilizing next generation sequencing, RT qPCR, and immunohistochemistry. To ensure we find all the putative somatic insertions in the iPS lines, we have used a LINE-1 enrichment technique, L1-seq, prior to next generation sequencing. To validate putative somatic insertions in the iPS cells, we will use site specific PCR, a LINE-1 specific primer and a genome specific primer designed for each individual insertion, and Sanger sequencing. The presence of LINE-1 mRNA and LINE-1 associated proteins such as ORF1p and ORF2p are positive indicators of retrotransposon activity. Using the RNA isolated from both the parental lines and the iPS lines we have demonstrated an ~17-fold increase in LINE-1 RNA in the iPS lines evaluated compared to the expression in the parental lines. We have also seen ORF1 protein expression in the iPS cells, which is not present in the parental cells. To evaluate the differences in the rate of retrotransposition between individuals' iPS lines, we will utilize the retrotransposition assay in cell culture in which a full length LINE-1 is transfected into the cells and the rate of retrotransposition is characterized based on the protein expression of GFP using FACS. In the future, we will differentiate the iPS cells into several types of cells such as neuronal precursor cells and gastrointestinal cells to determine whether or not the differentiation process induces retrotransposition as well. By evaluating the rate of retrotransposition in iPS cells and their differentiated counterparts from several individuals, we hope to characterize retrotransposition to determine whether or not iPS cells derived from patients are sufficiently stable to be utilized as a medical therapy.

592F

High-resolution mapping of break locations in human common fragile sites FRA3B, FRA7H, and FRAXB. *C.L. Kaminski, W. Fitzsimmons, K. Dziuba, A. Layer, A.M. Casper.* Department of Biology, Eastern Michigan University, Ypsilanti, MI.

Common fragile sites are chromosomal loci that tend to break when DNA replication is partially impeded. These sites were first identified in humans and orthologs were later identified in many other mammals; the yeast Saccharomyces cerevisiae also contains loci susceptible to break formation under replication stress. Fragile site breaks can result in chromosomal alterations that drive early tumorogeneisis. For example, deletions at FRA3B and FRA16D cause loss of function at the tumor suppressor genes FHIT and WWOX, respectively, and FRA7G instability drives amplification of the MET oncogene. Several hypotheses have been proposed to explain the mechanism leading to breaks at fragile sites. One hypothesis proposes that a lack of origins in fragile site regions leads to incomplete replication when replication is slowed, causing breaks in un-replicated regions during anaphase. A second hypothesis proposes that fragile sites contain AT-rich sequences that are considered to be flexible and prone to forming secondary structures during replication, which can cause further replication stalling and replication fork collapse. We are evaluating these hypotheses using yeast artificial chromosomes (YACs) containing inserts of human DNA from fragile sites FRA3B, FRA7H, and FRAXB. The YAC insert sizes are 1.3 Mb, 730 Kb, and 362 Kb, respectively. We have placed yeast under replication stress, caused by low levels of polymerase alpha, to induce fragile site breaks. We have mapped 30 break locations in each YAC to a 6 Kb resolution. In all three YACs, there is a hotspot for breaks near the distal end of the human DNA fragile site insert. We found that 60% of FRA3B breaks are clustered within a 54 Kb hotspot, 60% of FRA7H breaks are within a 45 Kb hotspot, and 60% of FRAXB breaks are within a 55 Kb hotspot. We analyzed break locations in FRA3B and FRA7H relative to the locations of flexible AT-rich sequences and potential origins. There is no significant association between fragile site break locations and the AT-rich sequence locations. However, the average distance from break locations to potential origins is significantly larger than expected from the distribution of control, non-break areas ($p<0.01$). Analyses of break locations in FRAXB are in progress. These data support the origin-related hypothesis for fragile site breaks. To further test this hypothesis, we are generating a YAC with an additional replication origin inserted near the break hotspot in FRA3B.

Functional characterization of DcR3 in EBV transformed cell lines from IBD patients of different allelic background and role in disease pathogenesis. *R. Pandey[1], C. Cardinale[1], K. Kachelries[2], S.F.A. Grant[1,3], R. Baldassano[2,3], H. Hakonarson[1,3].* 1) Centre for Applied Genomics, Children's Hospital Of Philadelphia, Philadelphia, PA; 2) Division of Gastroenterology, Hepatology and Nutrition, Children's Hospital of Philadelphia; 3) Department of Pediatrics, Perelman School of Medicine at the University of Pennsylvania.

Aim: Decoy receptor3 (DcR3), member of the TNFR superfamily is a soluble receptor for FasL and plays significant role in immune suppression and tumor progression by neutralizing the FasL mediated apoptosis signal. Here we investigate the possible immuno-modulation mediated by DcR3 and NF-κB in EBV transformed control and patient derived cell lines with and without risk variants in the TNF Receptor Superfamily 6B gene, TNFRSF6B captured by the tagging SNP, rs2315008. **Methods:** Expression of DcR3 and its kinetics were examined by immunoblot analysis in whole cell lysates from EBV transformed control and patient derived cell lines of different genotype background for rs2315008 (AA, AT, TT). DcR3 induced rapid activation of nuclear factor κB (NF-κB) monitored by immnunoblot analysis of IkBα. Expression pattern of NF-κB complexes and kinetics in non-secretors, control and patient-derived EBV transformed cell lines was examined by immunoblot analysis in whole cell lysates, cytoplasmic and nuclear extracts. DcR3 knockdown was performed using specific DcR3 siRNA. Cell proliferation and cell death was measured by MMT assay. Caspase8, caspase9, caspase3, and Bcl2 expression were analyzed by western blots. **Results:** EBV transformed cell lines derived from IBD patients harboring risk variants in TNFRSF6B (A allele) exhibit differential pattern of DcR3 expression and NF-κB activation kinetics in comparison with wild type. siRNA mediated knockdown post 24hrs of nucleofection results in decreased DcR3 expression, increased cell death and decreased cell proliferation, effects that were also genotype-dependent. **Conclusion:** EBV cell lines from IBD patients harboring risk variants in the TNFRSF6B gene exhibit differential pattern of DcR3 expression and NF-κB activation. We propose that pathogenic inflammation in CD may be in part be the result of non-canonical developmental signals impinging on a NF-κB signaling module with an altered homeostasis of IκB proteins. Therefore, therapeutic intervention targeting the NF-κB activation pathways represents a promising opportunity for future therapy of IBD.

Functional characterization of the role that components of the retrograde transport machinery play in early HIV events. *S. Liu[1, 2, 4], M. Dominska[1, 2, 4], D.M. Dykxhoorn[1, 2, 3, 4].* 1) John P. Hussman Institute for Human Genomics; 2) Dr. John T. Macdonald Foundation Department of Human Genetics; 3) Department of Microbiology and Immunology; 4) University of Miami MIller School of Medicine, Miami, FL.

Human Immunodeficiency Virus (HIV) is a highly lethal lentivirus which is responsible for a tremendous amount of suffering and death in the United States and throughout the world. By attacking the host's immune system, HIV leaves the infected individual susceptible to a wide variety of opportunistic infections. HIV, like all viruses, relies on host cell factors for successful infection, replication and release of progeny virus. Large-scale functional genomic screens have identified a wide variety of novel host factors whose silencing inhibited viral replication in cultured cells. A more detailed examination of these HIV-dependency factors (HDFs) showed a significant enrichment for factors involved in the trans-Golgi network (TGN), a pathway which had not been previously implicated in early events in HIV replication. To examine the role that the TGN-HDFs play in the HIV-1 life cycle, cells silenced for the appropriate HDF were subjected to biochemical and cell biological analysis. The Conserved Oligomeric Golgi (COG) complex is a heteromer complex that functions as a tethering factor in concert with the Rab-family GTPase (RAB1) and the t-SNARE syntaxin 5 to facilitate the recruitment, interaction and fusion of membranes from early or late endosomes to the trans-golgi network (TGN). Our results show that the targeted silencing of components of the COG complex each impaired HIV-1 replication, as measured by intracellular p24 staining. These results suggested that the impairment in HIV-1 replication in these silenced cells occurred prior to gag translation. Analysis of the different forms of the HIV-1 genome showed that the defect in HIV-1 replication occurred prior to late RT product formation. This inhibition of HIV-1 is dependent on the HIV-1 envelope glycoprotein since viral particles pseudotyped with the vesicular stomatitis virus glycoprotein (VSVg) were unaffected. The identification of a novel role for HDFs in early events in the HIV-1 life cycle could suggest potential novel therapeutic approaches for the inhibition of viral transmission and replication.

ïDifferential Gene Expression in Granulosa Cells from Polycystic Ovary Syndrome Patients with and without Insulin Resistance: Identification of Susceptibility Gene Sets through Network Analysis. *S. KAUR[1], KJ. ARCHER[2], MG. DEVI[3], A. KRIPLANI[4], JF. STRAUSS[5], R. SINGH[1].* 1) ZOOLOGY, UNIVERSITY OF DELHI, DELHI, India; 2) Department of Biostatistics, Virginia Commonwealth University, Richmond, Virginia; 3) Gouri Hospitals, Delhi 110007, India; 4) Department of Obstetrics and Gynecology, All India Institute of Medical Sciences, New Delhi 110029, India; 5) Department of Obstetrics and Gynecology, Virginia Commonwealth University, Richmond, Virginia.

Context: Polycystic ovary syndrome (PCOS) is a heterogeneous, genetically complex, endocrine disorder of uncertain etiology in women. Objective: Our aim was to compare the gene expression profiles in stimulated granulosa cells of PCOS women with and without insulin resistance vs. matched controls. Research Design and Methods: This study included 12 normal ovulatory women (controls), 12 women with PCOS without evidence for insulin resistance (PCOS non-IR), and 16 women with insulin resistance (PCOS-IR) undergoing in vitro fertilization. Granulosa cell gene expression profiling was accomplished using Affymetrix Human Genome-U133 arrays. Differentially expressed genes were classified according to gene ontology using ingenuity pathway analysis tools. Microarray results for selected genes were confirmed by real-time quantitative PCR. Results: A total of 211 genes were differentially expressed in PCOS non-IR and PCOS-IR granulosa cells (fold change1.5; P0.001) vs. matched controls. Diabetes mellitus and inflammation genes were significantly increased in PCOS-IR patients. Real-time quantitative PCR confirmed higher expression of NCF2 (2.13-fold), TCF7L2 (1.92-fold), and SERPINA1 (5.35-fold). Increased expression of inflammation genes ITGAX (3.68-fold) and TAB2 (1.86-fold) was confirmed in PCOS non-IR. Different cardiometabolic disease genes were differentially expressed in the two groups. Decreased expression of CAV1 (3.58-fold) in PCOS non-IR and SPARC (1.88-fold) in PCOS-IR was confirmed. Differential expression of genes involved in TGF- signaling (IGF2R, increased; and HAS2, decreased), and oxidative stress (TXNIP, increased) was confirmed in both groups. Conclusions: Microarray analysis demonstrated differential expression of genes linked to diabetes mellitus, inflammation, cardiovascular diseases, and infertility in the granulosa cells of PCOS women with and without insulin resistance. Because these dysregulated genes are also involved in oxidative stress, lipid metabolism, and insulin signaling, we hypothesize that these genes may be involved in follicular growth arrest and metabolic disorders associated with the different phenotypes of PCOS.

596W

Insulin-Induced Kinase Signaling Contributes to Individual Differences in Response to Insulin. *I.X. Wang[2], V.G. Cheung[1,2].* 1) Howard Hughes Medical Institute; 2) Genetics/Pediatrics, Univ Pennsylvania, Philadelphia, PA.

Individual differences in sensitivity to insulin underlie diseases such as diabetes and influence cell growth and cancer susceptibility. Insulin mediates cellular functions by triggering signal transduction pathways that lead to subsequent changes in gene expression. In this study, we focused on individual variation in signal transduction. Even though signaling is the first step in cellular response to nutritional demands, individual variability in insulin-induced activation of signaling pathways is poorly understood. To address this, we exposed primary skin cells from normal individuals to insulin and measured phosphorylation of kinases. We found extensive individual variation in insulin-induced activation of key signaling factors, including ERK whose induction differs by more than 20-fold among our subjects. By genetic analysis, we identified DNA variants that influence signaling response and downstream changes in gene expression and cell proliferation. The effect of variation in kinase activation on gene expression is substantial; for example, differences in ERK activation contribute to about 16 to 44% of individual variation in insulin-induced changes in gene expression. To better understand the relationship between the signaling proteins and their target genes, we took advantage of the variability and constructed networks which identify the connections within the signaling pathways and the extensive crosstalk between signaling regulators and their target genes. In this presentation, I will describe our results that demonstrate how signal transduction is an important contributor to insulin sensitivity, therefore offer kinase modulators as promising therapeutics for diseases characterized by insulin resistance.

Relationship between mitochondrial DNA mutations and aging. Estimation of age at death. *S. C. Zapico, D.H. Ubelaker.* Anthropology, Smithsonian NMNH MRC 112, Washington, DC.

According to the aging theory presented by Harman, the production of free radicals rises with age and plays a key role in the degenerative processes of senescence. This oxidative stress increase could be the origin of cellular molecule damage. Particularly, the highest levels of oxidative stress are generated in the mitochondria due to the Electron Transport Chain (ETC). This oxidative stress increase induces accumulation of nonrepaired lesions in mitochondrial DNA (mtDNA). There are some studies that point out the relationship between mtDNA mutations and age in different tissues. These studies are potentially interesting for forensic identification because they can help to improve the estimation of age at death. Since teeth are the hardest tissue of human body, and one of the most abundant types of biological remains available in forensic cases, the present study aims to evaluate the mutations in mtDNA from dentin and pulp and their relation with the age. 30 healthy erupted third molars were extracted for valid clinical reasons from individuals from the Northwestern region of Spain aged 20 to 70. DNA was isolated from the dentin and pulp of each molar. We used specific primers of Hypervariable region 2 (HV2) of the mitochondrial D-loop to assess the mutations in each type of tissue by PCR. We found a decrease in the amplification of this region with age in dentin and variations in pulp. In order to quantify the amplification, we used Q-PCR and found the same results. There was an age-dependent decrease in the gene HV2 copy number in dentin. Using regression analysis, a negative significant linear correlation was found between mtDNA amplification and age in dentin. In contrast, we have not found a correlation between mtDNA amplification and age in pulp. The reason of this variation is the projection of the odontoblastic processes from pulp cells to dentin, which have numerous mitochondrias. As a result, the majority of oxidative stress is generated in the dentin, inducing mutations in mtDNA that are possible to relate to age. The findings from this research provide a new quantitative tool for the estimation of age at death that, in combination with traditional age markers, could improve identification accuracy in forensic cases. Future research may be able to expand on these results, using different types of teeth, analyzing different populations and extending the age range.

Genome-wide analysis identifies heat shock induced gene and chromatin regulatory protein network in Saccharomyces cerevisiae. *R. Li[1], M.D. Ritchie[2].* 1) Bioinformatics and Genomics, The Pennsylvania State University, State College, PA; 2) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, The Pennsylvania State University, State College, PA.

In Saccharomyces cerevisiae, hundreds of different proteins are involved in transcription regulation, yet much of the regulation mechanisms remain largely unknown. Previous studies have gained insights into transcription regulation from studying the protein factor binding responses induced by heat shock on cells; however, they were limited in scale. Recently, a comprehensive study of almost all DNA binding proteins, chromatin regulators, general transcription proteins, and elongation regulators in Saccharomyces generated ~200 proteins' genome-wide binding levels using ChIP-chip assays in normal and heat shock conditions. Basic statistical approaches have been used to identify important proteins that exhibit the highest fold changes in DNA binding levels between the two conditions. However, this approach can only interrogate individual proteins and it fails to uncover any potential interactions among the proteins involved in gene regulation. Thus we applied ATHENA (the Analysis Tool for Heritable and Environmental Network Associations), which is a software package for modeling the underlying interaction relationships between protein factors using a machine-learning technique, grammatical evolutionary neural networks (GENN). This proof-of-concept in yeast is the first evaluation of ATHENA for epigenetic data. Our model identified important protein factors that could differentiate the two conditions with 80–95% accuracy based on their genome-wide binding levels. Our top models consisted of approximately 10 protein factors selected from ~200 factors based on how well they can distinguish genes under normal condition or genes under heat shock condition when interacting with other protein factors. We replicated several protein factors known to be involved in heat-shock or stress related responses and we also identified a few novel factors, especially at the gene terminator regions. The network models showed that the protein factors exhibited non-additive relationships, indicating the presence of interactions among the protein factors. We also uncovered different regulation networks at the gene promoter regions and gene terminator regions, which shows that different sets of factors were affected by heat shock at distinctive biological locations. This machine learning approach demonstrates the ability to uncover interactions in protein binding data with high accuracy and it has the potential to be extended to any type of genomics data.

Human neuropathy target esterase rescues SWS Drosophila neurodegeneration. *N.D. Hein[1], A.K. Sujkowski[2], A.M. Taylor[1], R.J. Tabano[1], A. Harrell[1], S. Rainier[1], R.J. Wessell[2], J.K. Fink[1,3].* 1) Neurology, University of Michigan, Ann Arbor, MI; 2) Internal Medicine, University of Michigan, Ann Arbor, MI; 3) Geriatric Research Education and Clinical Center, Ann Arbor Veterans Affairs Medical Center.

Neuropathy target esterase (NTE) is a membrane phospholipase A2 with cAMP-dependent protein kinase (PKA) regulatory activity. NTE inhibition by organophosphorous (OP) compounds leads to chronic OP-induced delayed neuropathy. NTE mutations cause autosomal recessive motor neuron disease (NTE-MND), a form of hereditary spastic paraplegia (SPG39).

Drosophila Swiss cheese (SWS) shares 39% protein sequence identity with human NTE (hNTE). Drosophila SWS mutants exhibit progressive locomotor impairment, early lethality, and vacuolar degeneration and glial hyperwrapping in brain. SWS^5 has mutation G648R. SWS Drosophila neurodegeneration can be rescued by wildtype sws or wildtype murine NTE transgenes.

We examined the ability of wildtype hNTE to ameliorate the SWS neurogenerative phenotype. Flies transgenic for RU486-inducible elav-GAL4 (generated by A. Sujkowski) were crossed with transgenic UAS-NTE^{wt} flies; and progeny crossed with SWS^5 flies (generously provided by Dr. Doris Kretzchmar, Oregon Science & Health Univ.) and control flies to create flies with RU486-inducible, neuron-specific $hNTE^{wt}$ expression. Flies were maintained at 29°C and locomotor ability assessed at day 10 in a run-to-exhaustion protocol using iterative negative geotaxis (Tinkerhess et al, 2012). NTE protein (western blot), PKA activity, and NTE activity (phenyl valerate substrate) were assessed using published methods.

Western blot analysis confirmed the presence of hNTE protein in flies expressing wildtype hNTE (RU486-induced SWS^5, $elav^{GAL4\text{-}hNTE}$ and Berlin $K^{elavGAL4\text{-}hNTE}$ control flies). Locomotor activity of SWS^5 flies was approx. half that of wildtype flies. In contrast, SWS^5 flies expressing wildtype NTE (RU486-induced $SWS^{5/elavGAL4\ hNTE}$) had locomotor ability that was very similar to control flies. Histopathology studies of SWS^5, $SWS^{5/elavGAL4\ hNTE}$, and control flies is in progress.

Conclusion. These studies demonstrate the capacity of hNTE to functionally compensate for the SWS^5 Drosophila neurodegenerative phenotype. Together with the previously reported correction of SWS mutant phenotype by mNTE, these studies underscore the functional homology between mammalian NTE and SWS proteins. This *in vivo* assay of hNTE functional activity can be used to evaluate the functional significance of identified hNTE variants, including those in NTE-MND subjects.

Microbiomic profiles and clinicopathologic outcome markers in oropharyngeal cancers. *P. Funchain[1], G. Bebek[1,3], K. Bennett[1], F. Niazi[1], N. Fowler[4], B. Burkey[4], C. Eng[1,2].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Department of Genetics and CASE Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH; 3) Case Center for Proteomics and Bioinformatics Case Western Reserve University, Cleveland, OH; 4) Head and Neck Institute, Cleveland Clinic, Cleveland, OH.

Recent studies of the human microbiome suggest that non-human genetic material from the spectrum of commensal microorganisms which inhabit the human body, otherwise known as the human microbiome, provide a large contribution to human health and disease. In particular, investigations of the aerodigestive tract implicate the importance of the microbiome to immune-related disease such as inflammatory bowel disease and in cancers including gastric, colon and pancreas. Here, we hypothesize that microbiomes differ between tumor and adjacent normal tissue in persons with head and neck squamous cell carcinoma (HNSCC), and propose a relation to epigenetic modifications in inflammation- and HNSCC-associated genes. Matched tumor and adjacent normal fresh frozen tissue specimens were collected from 55 prospectively enrolled HNSCC patients. Metagenomic profiles were obtained by Sanger sequencing of 16S rDNA PCR products. Methylation status of four genes previously linked to HNSCC or inflammation (MDR1, IL8, RARB, TGFBR2) was assessed in 49 samples. Principle component analysis was used to identify bacterial subpopulations significantly associated with HNSCC and relevant clinical variables. In this cohort, median age is 62, male:female ratio is 3:2, 16% are HPV+. We find that microbial populations can separate tumors by tobacco ($p<0.005$) but not alcohol ($p>0.6$) status. Specific bacterial subpopulations, including Spirochaetes and Bacillales, significantly associate with HNSCC over normal tissue ($p<0.01$). MDR1 promoter methylation is seen in tumor samples but not in normal oral mucosa (22/49 vs 0/49), and associates with specific microbiomic subpopulations including Enterobacteriaceae and Tenericutes. Importantly, bacterial profiles are independent of HPV status. We conclude that the microbiomes of normal and tumor tissue in persons with HNSCC differ. Preliminary analysis suggests specific bacterial subgroups associate with specific clinicopathologic features, which suggesting a role for metagenomics in HNSCC as a novel area of investigation for diagnosis, prognostication, and therapeutic targeting.

Metagenomic diagnosis of culture-negative infective endocarditis. *A. IMAI[1], Y. ASANO[1], S. NAKAMURA[2], K. GOTOH[2], D. MOTOOKA[2], Y. SAKATA[1], T. IIDA[2], T. HORII[2], S. TAKASHIMA[1].* 1) Department of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, Osaka, Japan; 2) Department of Genome Informatics, Research Institute for Microbial Diseases, Osaka University, Suita, Osaka, Japan.

Infective endocarditis (IE) is still a lethal disease and detecting causative microorganisms is essential for choosing an optimal antibiotic and effective dosing periods. However, culture-negative IE is frequently observed, especially among cases that included premedication with antimicrobial agents. Conventional valve culture has disadvantages that it has low sensitivity and can detect only viable and target microorganisms with the culture medium currently available. Recently, the metagenomic approach using next generation sequencing (NGS) technology emerged as a comprehensive method for exploring causative agents of infectious diseases without prior culture .Therefore, we assessed the viability of metagenomic analyses to detect causative microorganisms in resected valves from IE patients who had underwent valve replacement surgery. We studied two representative cases, each of which is a patient with culture-positive IE and culture-negative IE, respectively. After the operation of a valve replacement therapy for IE we assessed causative bacteria in the resected valve both by cultivation survey and by metagenomic sequencing approach. The former case was affected with IE of the native aortic valve. The blood culture at the primary hospital was positive and negative at the time of referral to our hospital with antibiotic pretreatment. After the operation the resected valve culture was positive for the same bacteria species as detected in the previous hospital. By defining this patient as the case with culture-positive IE, we applied metagenomic approach to detect bacterial genome fragments with genome DNA extracted from the resected valve. Using BLAST search, the dominant parts in bacteria-derived sequences were mapped on the genomes of candidate bacterial species. The latter case was also affected with IE of the native aortic valve. There was no medical record of any cultivation test in previous hospital. Both the blood and valve cultures were negative at our hospital, assumed to be due to oral antibiotic treatment prior to admission. Metagenomic data of the resected valve showed S. sanguinis as a causative bacterium confirmed by Gram-staining in pathological specimen, in which Gram-positive cocci were identified in the valve tissue. In conclusion, comprehensive metagenomic approach using NGS could detect causative organisms in culture-negative IE case.

602W

Exome Capture from Saliva Produces High Quality Genomic and Metagenomic Data. *D. Bobo[1], T. Sharpton[4], P. Norman[5], M. Carpenter[3], M. Sikora[3], C. Gignoux[6], N. Gorgani[5], M. Guadalupe[7], K. Pollard[4,8], P. Parham[5], M. Feldman[9], J. Wall[8], C. Bustamante[3], J. Kidd[2], B. Henn[1].* 1) Ecology & Evolution, Stony Brook University, Stony Brook, NY; 2) Departments of Human Genetics, and Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Department of Genetics, Stanford University, Stanford, CA 94305; 4) The J. David Gladstone Institutes, University of California, San Francisco, San Francisco CA, 94158; 5) Department of Structural Biology, Stanford University, Stanford CA 94305; 6) University of California, San Francisco, CA, 94158; 7) Agilent Technologies, Genomics Division, Cedar Creek, TX 78612; 8) Institute for Human Genetics, and the Departments of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco CA, 94143; 9) Department of Biological Sciences, Stanford University, Stanford CA 94305.

Targeted capture of genomic regions reduces sequencing cost while generating higher coverage by allowing biomedical researchers to focus on specific loci of interest, such as exons. Targeted capture also has the potential to facilitate the generation of genomic data from DNA collected via saliva or buccal cells. DNA samples derived from these cell types tend to have a lower human DNA yield, may be degraded from age and/or have contamination from bacterial or other ambient oral flora. However, thousands of samples have been previously collected from these tissue types, and saliva collection has the advantage that it is a non-invasive form of collection, appropriate for a wide variety of research. We demonstrate successful enrichment and sequencing of 15 South African KhoeSan exomes with samples initially derived from saliva. The expanded exome dataset enable us to make several novel discoveries. First, the KhoeSan hunter-gatherers exhibit extremely high levels of genetic diversity in comparison to other individuals of African ancestry. Second, we discover and independently verify twenty previously unknown KIR alleles using methods we developed to accurately map and call the highly polymorphic HLA and KIR loci from exome capture data. Finally, we show that capture of saliva-derived DNA yields sufficient non-human sequences to characterize oral microbial communities, including detection of bacteria linked to oral disease (e.g. Prevotella melaninogenica). Metagenomic profiles obtained from exome-capture results are similar to those obtained from direct sequencing of saliva derived DNA, indicating that metagenomic analysis of saliva derived samples holds promise for future metagenomic studies as a 'free' addition to human exome sequencing.

Host genetic control of the human gut microbiome. *J.K. Goodrich[1,2], R. Blekhman[2,3], O. Koren[1,2], A.C. Poole[1,2], M. Beaumont[4], J.T. Bell[4], T.D. Spector[4], A.G. Clark[2], R.E. Ley[1,2].* 1) Dept of Microbiology, Cornell University, Ithaca, NY, USA; 2) Dept of Molecular Biology & Genetics, Cornell University, Ithaca, NY, USA; 3) Dept of Neurology & Neuroscience, Weill Cornell Medical College, New York, NY USA; 4) Dept of Twin Research & Genetic Epidemiology, King's College, London, U.K.

The gut microbiome differs markedly among individuals and is increasingly viewed as a risk factor in chronic diseases such as obesity, inflammatory bowel disease, and diabetes. The composition of the gut microbiome is a target for emerging therapies, which require an understanding of the factors shaping the microbiome, including host lifestyle, physiology, health, and their interactions. Importantly, the role of host genotype in modulating microbiota composition remains to be elucidated. In animal models, host gene deletions often shift microbiota composition, and genetic mapping has linked specific loci with gut microbial abundances. Similar studies are lacking in humans, however, recent twin-based studies comparing microbiota of monozygotic (MZ) and dizygotic (DZ) twin pairs failed to detect a genotype effect, possibly due to small sample sizes. Here, we characterized the faecal microbiota of 572 genotyped adults, including 114 MZ twin pairs and 159 DZ twin pairs. We determined the degree to which the microbial tree is heritable using the classical ACE twin model, which partitions the total variance of a phenotype into additive genetic effects (A), common environment (C), and unique environment (E). We identified components of the gut microbiota that have moderate heritability such as members of the families Ruminococcaceae, Lachnospiraceae, and Catabacteriaceae. We validated these findings by applying this approach to recently published data from two smaller scale studies of US twins. Furthermore, abundances of some bacteria are associated with specific genetic variants implicated in inflammatory bowel disease. Our results indicate that while the composition of an individual's microbiota is largely influenced by environmental factors, host genetics also plays an appreciable role for specific bacterial taxa. This report highlights the importance of understanding the effects of host genetics on the microbiome, and how host-microbe interactions can influence an individual's susceptibility to disease.

604F

Temporal variation in human gut microbiome composition in the Hutterites. *E.R. Davenport[1], O. Mizrahi-Man[1], K. Michelini[1], L.B. Barreiro[2], C. Ober[1], Y. Gilad[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Sainte Justine Hospital Research Centre Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, QC, Canada.

The bacterial composition of the human fecal microbiome is influenced by several environmental factors. Diet is believed to be one of the most important determinants, however, the extent to which dietary fluctuations alter the gut microbiome over time is unknown, both within an individual and between individuals. In this study, we examined the relationship between seasonal variation in produce consumption and variation in gut microbiome composition. To do so, we sampled stool and collected dietary survey information for 60 individuals of a founder population, the Hutterites, during both summer and winter months. These individuals live and eat communally; therefore many environmental factors - including diet - are similar across individuals. Additionally, menus are remarkably stable throughout the year, with the exception that fresh produce is primarily served during the summer and autumn months, allowing us to examine the association of produce availability to gut microbiome composition. We observed that although there is stability in the composition of the gut microbiome within individuals over time, there are also consistent and significant population-wide shifts in microbiome composition between seasons. Seasonal differences were detected in both (i) the abundance of particular taxa (FDR <0.05), including highly abundant phyla Bacteroidetes and Firmicutes, and (ii) gut microbiome diversity (by Shannon diversity; P = 0.001). Seasonal dietary differences in produce consumption likely explain, at least in part, the seasonal compositional shifts observed in the gut microbiota. For example, high levels of fresh produce consumed during the summer, containing complex starch and fiber, might explain our observations of increased abundance of Bacteroidetes in summer, a phyla containing complex carbohydrate digesters, and decreased levels of Actinobacteria, which have previously been negatively correlated to fiber content in food questionnaires. In conclusion, our observations demonstrate the plastic nature of the human gut microbiome in response to variation in diet.

Using blood-born miRNA profiles and machine-learning techniques to predict inflammatory phenotypes. *M. Huebenthal[1], G. Hemmrich-Stanisak[1], Z.G. Du[1], S. Nikolaus[2], S. Zeissig[2], S. Schreiber[1,2], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University of Kiel, Kiel, Germany; 2) Department of Internal Medicine, University Hospital Schleswig-Holstein, Kiel, Germany.

With accuracies ranging from 80% to 90% invasive methods such as ileocolonoscopy are still the standard for diagnosis of the complex diseases Crohn's disease (CD) and ulcerative colitis (UC). For these two major subphenotypes of inflammatory bowel disease (IBD) differences in miRNA expression can be shown. In this study we detected specific miRNA signatures, which allow stable distinction between the different phenotypes and therefore non-invasive prediction of patients' disease states. Based on 142 whole blood samples (62 CD, 64 UC and 16 healthy controls) expression profiles of 1733 miRNAs were determined using Small RNA sequencing (Illumina HiSeq2000). Classification and biomarker selection was performed using different types of Support Vector Machines and Recursive Feature Elimination, respectively. After model assessment based on manifold hold-out sampling sets of 107 miRNAs for CD and 48 miRNAs for UC were determined to distinguish between cases and healthy controls with estimated balanced accuracies of 87% and 94%. With balanced accuracy of 97% the distinction of IBD cases from healthy controls based on 93 miRNAs performed comparably well. Resulting in a balanced accuracy of 63%, 129 miRNAs were necessary to discriminate between CD and UC. In combination with the models constructed the reported sets of putative biomarkers allow for solving binary as well as multinomial classification tasks arising from the diagnosis of IBD. Our preliminary evaluation already yields to very high accuracies and is therefore of potential relevance for clinical application.

606T

Transcriptional profiling of lncRNAs reveals important biological roles in psoriasis. *L. Tsoi[1], M. Iyer[2], P. Stuart[3], T. Tejasvi[3], B. Li[4], J. Ding[5], J. Gudjonsson[3], H. Kang[1], R. Nair[3], A. Chinnaiyan[2], G. Abecasis[1], J. Elder[3].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Michigan Center for Translational Pathology, University of Michigan, Ann Arbor, MI; 3) Dermatology, University of Michigan, Ann Arbor, MI; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 5) Laboratory of Genetics, National Institute on Aging, Baltimore, MD.

Psoriasis is an inflammatory disease of skin and joints affecting 0.1–2% of the world's population. Previous studies have identified crucial immune and epidermal-differentiation genes that are differentially expressed in the lesional skin of psoriatic patients. However, most of these studies assayed only protein-coding genes. The functional importance of long non-coding RNA (lncRNAs), which are known to play a role in human disease, is yet to be determined for psoriasis. In this study, we applied a computational approach and stringent filtering to predict novel lncRNAs in our RNAseq data comprised of 92 psoriatic and 82 normal skin samples, and we characterized the expression patterns of the identified lncRNAs to infer their biological functions. We identified 7,145 known lncRNAs, and further predicted 319 novel ones, yielding on average genomic density of 2.5 expressed lncRNAs per Mb. Although the proportions of differentially expressed genes for protein-coding and known lncRNAs were similar (18%), over 60% of our novel lncRNAs were differentially expressed. This result suggests the novel lncRNAs identified here have a skin-specific expression pattern and function. Notably, the transcript with the most significant correlation between expression levels and disease severity as assessed by the local psoriasis area and severity index (PASI) is a lncRNA. We used co-expression analysis to infer the biological functions of lncRNAs, and the most enriched functions include immune response ($p=2\times10^{-7}$) and cytokine interactions ($p=6\times10^{-9}$). Our results also indicate significant enrichment ($p=5\times10^{-3}$) of novel lncRNAs in the epidermal differentiation complex on chromosome 1q21. The characterization of expression signatures for lncRNAs provided by this study suggests an important role for these transcripts in disease ethiology.

Deciphering and exploiting transcriptome-wide microRNA binding profiles in human brain. *R.L. Boudreau[1], P. Jiang[1], B.L. Gilmore[1], R.M. Spengler[1], R. Tirabassi[2], J.A. Nelson[2], C.A. Ross[3], Y. Xing[1], B.L. Davidson[1].* 1) University of Iowa College of Medicine, Iowa City, IA; 2) Oregon Health & Sciences University, Beaverton, OR; 3) Johns Hopkins University School of Medicine, Baltimore, MD.

The orchestration of brain function requires complex gene regulatory networks, which in part, are modulated by microRNAs (miRNAs). These non-coding RNAs associate with Argonaute (Ago) proteins to direct post-transcriptional gene suppression by binding to 3' untranslated regions (3'-UTRs), and growing evidence suggests that even slight aberrations in miRNA activities may alter synaptic function. To better understand how miRNAs contribute to human-specialized brain processes and neurological phenotypes, identifying their targets is of paramount importance. Here, we address the latter by profiling Ago2:RNA interactions using crosslinking immunoprecipitation coupled with high-throughput sequencing (CLIP-seq) to generate the first transcriptome-wide map of miRNA binding sites in human brain. We uncovered ~7000 stringent Ago2 binding sites which are highly enriched for conserved sequences corresponding to abundant brain miRNAs. This dataset points to functional miRNA:target pairs across more than 3000 genes and represents a valuable resource for accelerating our understanding of miRNA function in the central nervous system. We explored this interactome for clinically-relevant miRNA binding sites and identified numerous disease-associated targets for miR-137, a miRNA implicated in schizophrenia. In addition, we discovered miRNA binding sites overlapping single nucleotide polymorphisms linked to common and rare neuropsychiatric conditions, including Parkinson's and Alzheimer's. These findings provide clues which may facilitate the translation of genetic studies of complex neuropsychiatric diseases into novel or refined pathogenic mechanisms and therapeutics. Overall, this work lays the foundation for translating this methodology to characterize the diverse landscapes of miRNA:target interactions throughout sub-anatomical brain structures and across normal and diseased tissues.

Association of non-coding SNPs with decreased levels of miR-9 and alcoholism. *A. Pietrzykowski[1,2], Y. Wang[1], O. Anees[1], E. Mead[1], N. Kinstlinger[1], L. Tejeda[1], A. Hot[1].* 1) Animal Sciences, Rutgers University, New Brunswick, NJ; 2) Genetics, Rutgers University, New Brunswick, NJ.

Alcoholism has strong genetic underpinnings. The focus on protein-coding genes has only partially revealed the genetic basis of this complex, multigenic disorder. There is increasing recent evidence that microRNAs (miRNAs) play a key role in alcoholism and other types of addiction. miRNAs are produced by non-coding genes, whose products are small RNA molecules with a powerful role as master regulators of mRNA and protein expression. Many miRNAs can simultaneously control the expression of several genes. Our previous results using rodent models indicated that a particular miRNA, miR-9, is regulated by alcohol and has an essential role in the development of molecular tolerance to this drug. Here, we seek to determine an association of single nucleotide polymorphisms (SNPs) in the regions regulating miR-9 expression in alcoholism using human samples. miR-9 is encoded by three distinct genes, with each gene located within a larger host gene. Thus, six different promoters can control expression of mature miR-9. We used the UCSC Genome Browser to determine the length of each promoter (4 to 6 kb) and perform SNP discovery in all 6 regions. We used 282 alcoholic samples from the Collaborative Studies on Genetics of Alcoholism (COGA) collection, and 255 non-alcoholic controls from the NIMH control collection. Nested PCR and direct sequencing of PCR products were performed on each sample. GWAS-derived ancestry informative markers were used to correct for ancestry. Association, allele frequency, odds ratio, heterozygosity and Hardy-Weinberg equilibrium were determined for all samples. MAPPER2 or MatInspector were used to test the effects of SNPs on transcription factor binding. We established the presence of 142 SNPs in 2 categories: known SNPs (present in dbSNP) and new SNPs. 8 known SNPs independently have strong and significant association with alcoholism (they are a topic of a sister abstract submitted to the World Congress of Psychiatric Genetics). Interestingly, some of the rare new SNPs encode the same type of polymorphism, and can potentially change the binding of the same transcription factor. When analyzed as a group they have an association with alcoholism and could have a significant impact on miR-9 expression. Our results reveal the presence of alcoholism-associated SNPs in non-coding regions of the human genome important for miR-9 function. These findings identify novel genetic underpinnings and molecular mechanisms of the development of alcoholism.

609T

De novo discovery of distant regulatory elements by enhancer RNA expression. *H. Wu[1], A. Nord[1], J. Akiyama[1], M. Shoukry[1], V. Afzal[1], E. Rubin[1,2], L. Pennacchio[1,2], A. Visel[1,2].* 1) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, CA; 2) DOE Joint Genome Institute, Walnut Creek, CA.

Enhancer DNA elements can be actively transcribed to produce short and long transcripts, named enhancer RNAs or eRNAs. Recently, several groups showed that expression of eRNAs appears to correlate with enhancer activity in cell lines. However, whether this is true and can be used to identify tissue-specific in vivo enhancers remain unknown. Here we have investigated the expression dynamics of eRNAs in mouse embryonic tissues (E11.5), heart and limb. We show that active enhancers are transcribed in vivo, and there is global correlation between eRNA expression and tissue-specific enhancer activity. Both p300-dependent and -independent enhancers are marked by eRNA expression. By investigating the expression pattern of eRNA, it shows that the regulatory effects of enhancers are not limited to the nearest genes and the transcription of eRNA tend to be coordinated with their potential target genes. Taken together, this pilot study demonstrated that tissue-specific eRNA expression can be used as a novel method for in vivo enhancer predictions; the transcription of eRNAs and their targets may share common regulatory mechanisms.

MicroRNA regulation in the inner ear and link to deafness. *K. Avraham[1], A. Rudnicki[1], K. Ushakov[1], O. Isakov[2], N. Shomron[2].* 1) Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 2) Department of Cell and Developmental Biology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Mutations in microRNAs (miRNAs) have been discovered to lead to deafness in both humans and mice. miRNAs play a critical role in the development and regulation of sensory systems, including the inner ear, which is responsible for hearing and balance in mammals. Mutations are associated with human hearing impairment (Mencia et al. *Nat Genet* 2009). The study of miRNAs in humans, however, has been hampered by the unavailability of inner ear RNA from human subjects, making the mouse an invaluable model for studying miRNAs in the inner ear. For example, removal of Dicer using the *Cre-loxP* recombination system, driven by a Pou4f3 hair cell-specific promoter, led to depletion of hair cell miRNAs and resulted in complete deafness by one month of age (Friedman et al. *PNAS* 2009). To further dissect the function of miRNAs in the mammalian inner ear, we performed RNA-Seq on RNA isolated from mouse inner ear sensory epithelia. qRT-PCR confirmed the expression of these miRNAs and *in situ* hybridization was used to identify their spatial expression in the mouse inner ear. We used bioinformatics software to predict the targets of these miRNAs and verified them by *in vitro* over-expression and luciferase assays. A total of 7,732,589 and 8,452,794 small RNAs were found in the cochlear and vestibular samples, respectively. These included miRNAs, snoRNAs, transfer RNAs and ribosomal RNAs. Reads were aligned to the mature *Mus musculus* miRNA database (http://www.mirbase.org). miRDeep2 was used for novel microRNA prediction. We chose miRNAs for further study with a seed region that is conserved between mouse and humans and with high expression in the inner ear. One example is a miRNA gene that is included in the intron of the gene *Tectb*, which is expressed in the mouse inner ear and is associated with deafness. The gene produces two mature miRNAs, 5p and 3p, and the human orthologues of this miRNA, hsa-miR-6715a-3p and hsa-miR-6715a-5p, were previously identified in a study on miRNAs and piRNAs in the human epididymis (Li et al. *Gene* 2012). Temporal and spatial expression revealed expression in the cochlear and vestibular sensory epithelia, and spiral and vestibular ganglia. Arhgap12 was found to be a target of miR-6715a-3p, a protein of the RhoGAP family, implicating this miRNA-target pair in cell adhesion, inner ear morphogenesis and actin reorganization. Interactions between inner ear miRNAs and targets will shed light on the role RNA regulation plays in the mammalian ear.

611W

Integrated microRNA and mRNA signature associated with the transition from the locally confined to the metastasized renal cell carcinoma. *J. Billaud[1], Z. Wotschofsky[2,3], K. Jung[2,3], H. Meyer[2,4].* 1) Ingenuity Systems, Redwood City, CA; 2) Department of Urology, Charité - Universitätmedizin Berlin, Berlin, Germany; 3) Berlin Institute for Urologic Research, Berlin, Germany; 4) Institute of Physiology, Charité - Universitätmedizin Berlin, Berlin, Germany.

MicroRNAs (miRNAs) are endogenous small non-coding RNAs that regulate gene expression by interfering translation or stability of target transcripts. One miRNA can interact with several hundred mRNAs, while one mRNA can be regulated by several miRNAs. This interplay between miRNA and their mRNA has been proposed as an important process in cancer development and progression. We have investigated molecular networks impacted by predicted mRNA targets of differentially expressed miRNAs in patients with clear cell renal cell carcinoma (ccRCC) diagnosed with or without metastasis. miRNA and mRNA microarray expression profiles derived from primary clear cell renal cell carcinomas from patients with (in total 16 samples) or without diagnosed metastasis (in total 22 samples) were used to identify anti-correlated miRNA-mRNA interaction in ccRCC. For this purpose, Ingenuity pathway analysis microRNA Target Filter, which enables prioritization of experimentally validated and predicted mRNA targets was used. By applying an expression pairing tool, the analysis was focused on targets exhibiting altered expression in our analysis, finding miRNAs and their target genes with opposite or same expression. The resulting identified interactions were revalidated by RT-qPCR in another cohort of RCC patients. The predicted miRNA-mRNA interactions were also tested by functional analyses using miRNA knock-down and over expression experiments in renal cancer cell lines. Among the significantly differentially expressed miRNAs, we have identified 3 miRNAs (miR-146a, miR-128a and miR-17-5p) that were upregulated in primary tumors from patients without metastasis and down regulated in primary tumors from patients with metastasis. We have further identified the mRNA targets which expression were inversely correlated to these 3 miRNAs, and have been previously experimentally demonstrated in cancer setting in humans. Specifically we showed that BRAC1, MCM10, CDKN3, UHRF1, IL8 were downregulated and targeted by miR-146a-5p. The relation between these identified target genes and miRNA-146a was validated in cell culture experiments. In conclusion, we have identified novel target genes of dysregulated miRNA which are involved in the transition from primary RCC without metastases into tumors generating distant metastasis.

612T

Global Patterns of miRNA Variation and Population-specific Differentiation Based on Whole Genome Sequence Data. *R.A. Rawlings-Goss, S. Tishkoff.* Genetics, University of Pennsylvania, Philadelphia, PA.

MicroRNAs (miRNA) are evolutionarily conserved regulators of protein expression, and are responsible for controlling transcription of up to 60% of expressed genes. For this reason, miRNA profiling strategies are increasingly under clinical trial as biomarkers for complex diseases such as cancer and diabetes. Despite the important role of miRNA in disease, normal miRNA functional variation among different ethnic groups remains an open question, specifically in under-sampled populations such as ethnically and geographically diverse Africans. Here, we examine worldwide variation in miRNA genes by analyzing whole genome sequencing (60x coverage) in a panel of 69 unrelated individuals from 14 different ethnic groups. We include diverse African groups, not yet included in HapMap or 1000 genomes datasets, in an effort to identify novel human variation within miRNAs, as well as population-differentiated miRNA variants. We identified 198 novel variants within miRNAs, not present in dbSNP, with 29 novel variants located in the highly conserved seed sequence of mature miRNA. Additionally, between our African and non-African samples we observe highly population differentiated miRNA (PD-miRNA) variants, suggestive of global differences in miRNA landscape. Seven of the highly differentiated PD-miRNA are currently associated with disease (including several forms of cancer). Taken together, we outline PD-miRNA variants that could be acting individually or in combination to alter expression of tumor sensitive genes and hypothesize that this variation is contributing in part to the observed ethnic disparities seen in some forms of cancer.

Evaluation and identification of master regulatory microRNAs on protein levels. *A.L. Stark[1], R.J. Hause, Jr[2, 3, 4], R.B. Jones[2, 3, 4], M.E. Dolan[1].* 1) Dept of Medicine, Univ Chicago, Chicago, IL; 2) Committee on Genetics, Genomics, and Systems Biology, Univ Chicago, Chicago, IL; 3) Ben May Institute for Cancer Research, Univ Chicago, Chicago, IL; 4) Institute for Genomic and Systems Biology, Univ Chicago, Chicago, IL.

To elucidate a clearer understanding of the mechanisms involved in the cellular dynamics of regulation of gene expression, there has been considerable focus on studying its relationship to genetics, epigenetics, and microRNA. Many studies have focused on the relationship between miRNA and mRNA expression; thus, we sought to expand the regulatory understanding of the role of miRNA by evaluating its relationship to protein expression levels. We quantified 220 miRNAs and 441 protein isoforms across 68 LCLs derived from Yoruba cell lines from Ibadan, Nigeria. Two miRNAs, mir768-3p and mir29c, correlated with STAT3 protein expression with a Bonferroni-corrected $p < 0.05$. These relationships were not predicted bioinformatically or at the mRNA level. We then evaluated all miRNAs for the number of protein levels correlated with each miRNA. Using permutation analysis, each miRNA was found to be associated with more protein levels than would be expected by chance. This enrichment was robust independent of the significance level of the protein-miRNA relationship ($p < 0.05$, $p < 0.01$, $p < 0.005$). We identified two master regulatory miRNAs whose expression levels were associated with greater than ten other proteins at $p < 0.001$: mir125a-5p and mir768-3p. Expression of mir768-3p was significantly associated ($p < 0.01$) with response to five different chemotherapeutic agents (cisplatin, carboplatin, cytarabine, etoposide, and daunorubicin). Mir125a-5p has been widely implicated in the literature for its involvement in many complex processes, including carcinogenesis, inflammation, and metabolism. Our work annotates protein levels that may be regulated by microRNA. Further study of the role of microRNAs in protein expression will lead to a better understanding of dynamic cellular processes and pharmacologic phenotypes.

614W

Study of microRNAs regulated by hypoxia in cells latently infected by Kaposi's sarcoma-associated virus. *C. Viollet-Djelassi[1,2], D. Davis[2], C. Camps[1], M. Reczko[3], F. Pezzella[1], R. Yarchoan[2], I. Ragoussis[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) HIV and AIDS Malignancy Branch, Center for Cancer Research, National Cancer Institute, National Institute of Health, Bethesda, MD; 3) BSRC Al. Fleming, Vari, Athens, Greece.

Kaposi's sarcoma-associated herpesvirus (KSHV) infection, especially when combined with immunodeficiency, can lead to cancers such as Kaposi's sarcoma (KS), primary effusion lymphoma or multicentric Castleman's disease. KS is a highly vascular tumour, and KSHV genes have been shown to be induced by hypoxia and in turn to activate hypoxia-inducible factors, indicating a role of hypoxia in the KSHV life cycle. Additionally, virus-encoded microRNAs (miRNAs) have been increasingly recognised as contributors to viral cancer pathogenesis. Investigating their role in KSHV-related diseases is therefore of interest. We hypothesise that hypoxia and/or KSHV infection will alter cellular and viral miRNA levels that play a role in cancer progression and viral pathogenesis. To address this, we compared miRNA expression profiles of KSHV infected cells and non-infected cells under hypoxia and normoxia using Illumina small RNA and total RNA deep sequencing. In infected endothelial cells, we found that 112 mature human miRNAs and 4 viral miRNAs are differentially expressed in hypoxia compared to normoxia. In particular, hsa-miR-663b was the most down-regulated miRNA in hypoxia (>>32-fold), while hsa-miR-210 was one of the most up-regulated (7.275-fold) and its increases in 1% O_2 were further validated by qRT-PCR in different KSHV-positive cell lines (B-cells BCBL1 and endothelial cells SLKK). Interestingly, KSHV-miR-K12-3-3p, a known promoter of KSHV latency, was also significantly down-regulated in hypoxic infected cells (2.129-fold). Furthermore, the expression patterns of total RNA and miRNAs were analysed using Ingenuity Pathway Analysis (IPA). Canonical pathways including glycolysis, atherosclerosis signalling and coagulation system were found differentially regulated by hypoxia compared to normoxia in endothelial SLKK cells. The effect of the host derived and virus derived miRNAs on the expression patterns of both host and virus RNAs is being elucidated through integrated analysis in order to identify targets. The target mRNAs and respective proteins are being investigated in relation to KSHV-associated diseases and the hypoxic pathway. The outcomes of the present study will aid our understanding of how KSHV uses the host RNA silencing machinery to its advantage and provides clues as to how this intersects with the use of the cell's response to hypoxia. This research was supported by the Wellcome Trust and the Intramural Research Program of the NIH, NCI.

Functional Assessment of snoRNA derived microRNAs in Prader-Willi Syndrome. *V. Williamson, M. Mamdani, G. McMichael, V. Vladimirov.* Psychiatry, Virginia InstPsychiatric & Behavioral Genetics, Richmond, VA.

Prader-Willi Syndrome (PWS) is a neurodevelopmental disorder, characterized by hyperphagia, obesity and self-inflicting behaviors such as skin-picking, temper tantrums and impulsivity. Approximately, 70% of subjects with PWS carry a deletion on chromosome 15 (q11.1-11.3) containing a small nucleolar RNA (snoRNA) cluster, HBII-85. Recently, snoRNA were shown as a source for other small non-coding (ncRNAs) molecules, called microRNA (miRNA). MiRNAs were shown to have important neurodevelopmental properties through their ability to control gene expression. Our hypothesis is that HBII-85 affects PWS development through HBII-85 derived miRNAs and that deletion of this region in PWS eliminates miRNAs integral to proper neuronal functioning. Sequence analysis of the region surrounding the HBII-85 cluster (HBII-85-12, -16, -17, -18, -19, -21, -22) in publically available deep sequencing datasets suggests that multiple miRNAs are possible and expressed at consistently higher levels in specific cell lines such as HL60 cells. Further, target prediction using an intersection of the programs PITA, MiRanda, and TargetScan from a custom database (N = 349) for these HBII-85 "snomiRs" yielded 41 potential gene targets. The database included genes previously implicated in PWS studies as well as those identified through ontology terms neuronal or brain development. When compared to predictions generated using an non PWS related cancer database (N = 487) we see statistically significant enrichment (16% vs. 8.4%, df = 1; $p = 0.003$, $\psi 2$-test, two tailed). Additionally the predicted targets of two non-PWS, non-cancer miRNAs, hsa-mir-132 and -137 demonstrate no statistically significant enrichment of targets in either database (9.7% vs. 10.8%, df = 1, $p = 0.32$, $\psi 2$-test, two tailed). Luciferase (luc) and RNA immunoprecipitation analyses of the proposed relationship between these likely miRNA candidates and their gene targets is on-going. If successful, this study demonstrates a decidedly new view of the disorder and presents the possibility for new therapies in the future.

The olfactory neuroepithelium (ONE) represents a site where neural stem cells (NSC) can be obtained, as well as being very accessible. These cells can be cultured by neurosphere assay, forming spherical clusters of multipotent and progenitor cells in suspension with the ability to differentiate. These features make it a model for studying neural molecular and cellular processes. The ability of these cells to maintain an undifferentiated state and their capacity to differentiate requires that the cell can modify its expression, therefore depending on epigenetic mechanisms modulating molecules that promote the multipotentiality and that suppress cell differentiation. One such mechanism depends on microRNAs, small molecules of non-coding RNAs with roles in the regulation of expression. Its functions are both, neural lineage determination and in adult neural tissue functions. Obtaining human NSCs is a powerful tool to investigate neural processes. With this in mind, we cultured ONE cells from nasal swabs from 4 healthy volunteers. Neural marker expression was determined by by immunofluorescence. Subsequently a miRNA expression assay was performed with plates TLDA A y B of applied V 2.0. Cq values equal or greater than 36 were discarted. We assessed the expression level according to the DCt method, normalizing with the global mean and forming groups according to the mean plus / minus 1 or 2 standard deviations. Finally, we performed an in silico analysis looking for possible nervous system pathways in which expression of microRNAs are involved. We analyzed a total of 667 microRNAs. 246 microRNAs were expressed in at least 3 of the 4 samples. According to the expression level, 56 miRNAs had very high expression (23%), 23 high (9%), 66 medium (27%), 34 low (14%) and 67 very low (28%). Some of the microRNAs with higher expression are miR-222, miR-200c, miR-191, miR-30a *, miR-30e *, miR-484, miR-146a, miR-378, miR-24 miR-574-3p. Some miRNAs are already described with roles in neurogenesis as miR-184, miR-132 family members' miR-200c, and miR-30, among others. As for the expressed miRNAs possible role, predictions point to a possible involvement in neurodevelopmental pathways as well as in neural pathologies.

LncRNAs regulation in insulin resistance of the adipose tissue. *M. Pradas-Juni[1,2], X. Bofill[4], F. Hanzu[2,3], C. Fillat[4], R. Gomis[1,2,3], E. Fernandez-Rebollo[1,2].* 1) Diabetes and Obesity Research Laboratory, IDIBAPS, Barcelona, Spain; 2) Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Diseases (CIBERDEM), Barcelona, Spain; 3) Endocrinology Unit, Hospital Clínic de Barcelona, Barcelona, Spain; 4) Gene Therapy and Cancer, IDIBAPS, Barcelona, Spain.

The non-coding RNAs (ncRNAs) have been largely underestimated but lately are being recognized as essential regulators of translational regulation and other processes. The ncRNAs are aberrantly expressed in a variety of human diseases; and thus demonstrating potential roles in cellular development and metabolism. NcRNAs are classified into two major classes based on transcript size: small and long ncRNAs (lncRNAs). LncRNAs are mRNA-like transcripts longer than 200 nucleotides, lacking significant open reading frames, generally are transcribed by RNA polymerase II and are emerging as key regulators playing a major biological role in epigenetics, alternative splicing and even as regulators of mRNA decay. On the other hand, type 2 diabetes mellitus (T2DM) is the most common metabolic disorder in the world and obesity, meaning visceral adiposity, is the core problem. T2DM is characterized by hyperglycemia and impaired insulin action and/or secretion. The main role of obesity in T2DM is due to the visceral adipose tissue (VAT) insulin resistance. Based on this information we hypothesize that lncRNAs are key regulators in the insulin resistance of the VAT in T2DM. Aim: Characterize the lncRNAs and their 'co-regulated' mRNAs involved in insulin resistance of VAT. Methods: VAT from 8 obese and 8 obese with T2DM patients was used for RNA isolation to perform human lncRNA microarray V2.0 (Arraystar), which is designed for the global profiling of human lncRNAs (33,945) and protein-coding transcripts (30,215 mRNAs). To identify the highly correlated mRNA and lncRNA pairs, coding-non-coding gene co-expression network analysis (CNC) was performed. Results: First analysis identified 1,859 upregulated and 286 downregulated lncRNAs, and 1,136 upregulated and 238 downregulated mRNAs in T2DM obese patients compared to the obese controls (Fold Change ≥ 2.0, P-value ≤ 0.05). Specificity was increased by reducing the P-value (≤ 0.01) and obtaining 215 CNCs, and taking into account the lncRNA genomic localization in respect to mRNA, we obtained 40 CNCs. Finally these 40 CNCs were confirmed by qRT-PCR in three groups (n=4/group): obese, obese with T2DM and lean. This last filter shows that 9 CNCs are clearly deregulated in adipocytes from obese patients with T2DM. We are currently performing loss and gain-of-function approaches in human visceral adipocyte cell lines to understand the 9 CNCs function in adipogenesis and increased insulin resistance in the T2DM obese patients.

618T

Characterization of piRNA genomic distribution and expression variation in human individuals. *J. Xing[1,2], H. Ha[1,2], J. Song[1,3], S. Wang[1,2], K.C. Chen[1,3].* 1) Dept of Genetics; 2) Human Genetic Institute of New Jersey; 3) BioMaPS Institute for Quantitative Biology; Rutgers, The State University of New Jersey, Piscataway, NJ.

Piwi-interacting RNAs (piRNAs) are a class of recently discovered small non-coding RNAs whose best known function is to repress mobile element activity in animal germlines. To date, virtually all piRNA studies have been conducted in model organisms and little is known about piRNA diversity, target specificity and the mechanism of mobile element regulation in humans. In this study, we performed high-throughput piRNA sequencing in three human testis samples and generated over 50 million putative piRNA reads. Using this data, we characterized the piRNA cluster distribution across the human genome and measured the extent of piRNA expression variation among the three samples. Overall we identified ~10,000 piRNA clusters in the human genome. The piRNA clusters range from 1kb to 276kb in size and occupy ~3% of the genome. PiRNA clusters within genes are enriched in the 3' UTR region, consistent with previous findings in mouse. To examine the role of piRNAs in mobile element regulation, we determined the piRNA mapping density in the consensus sequence of Alu and L1 elements, the most abundant mobile elements in the human genome. We found that piRNAs preferentially mapped to specific motifs in the consensus of these mobile elements, and some piRNA mapping peaks show sequence/position patterns consistent with the ping-pong mechanism. In addition, we showed that human piRNA clusters show smaller variation in their expression level among human individuals than in Drosophila. Our study provide a comprehensive characterization of piRNA diversity and their interaction with genes and mobile elements in humans.

619F

Alternative splicing of MAP/microtubule affinity-regulating kinase 4 (MARK4) in glioma: search for involvement of Polypyrimidine-tract binding protein (PTB). *L. Fontana, D. Rovina, C. Novielli, I. Magnani, L. Larizza.* Medical Genetics, Department of Health Sciences, Università degli Studi di Milano, Milan, Italy.

MARK4 is a Ser-Thr kinase that phosphorylates MAPs taking part in the regulation of microtubule dynamics involved in cell cycle control. The MARK4 gene encodes two alternatively spliced isoforms: the canonical MARK4S, featuring 18 exons, and the alternative MARK4L, derived from skipping of exon 16. In glioma we pointed out an imbalance between the MARK4 isoforms with decreased MARK4S expression associated with overexpression of MARK4L. A high L/S ratio also characterizes human glioblastoma-derived stem cells and mouse neural stem cells and appears proportional to cellular de-differentiation and tumor grade. Since the deregulation of MARK4 expression in glioma is not due to mutations or copy number loss/gain, we hinted that alterations in alternative splicing (AS) may be at the origin of the observed MARK4 isoforms imbalance. It's well known that specific splice variants are commonly enriched in cancers as a consequence of splicing factors up-regulation. In glioma, in particular, overexpression of PTB, a key component in regulating neural stem cells proliferation and differentiation, drives an oncogenic splicing switch favoring isoforms, like MARK4L, derived from exon skipping. Bioinformatic analysis of the MARK4 sequence by SFMap software revealed three putative PTB binding sites in both introns flanking exon 16. A functional role of these sites is suggested by the high conservation in mouse, as confirmed by CLUSTAL W alignment, and by the surrounding polypyrimidine rich context, required for PTB activity. Western blot analysis showed a significant overexpression of PTB in our astrocytoma and glioblastoma samples, that correlates with MARK4L expression. Deletion of the last 80 nt of MARK4 IVS15 foster exon 16 inclusion in a splicing minigene system, revealing the presence of a functional intronic splicing silencer (ISS) in this region. However, mutagenesis of the predicted PTB binding site contained in the deletion does not affect minigene splicing, suggesting that PTB may bind to a non canonical ISS. Sequential deletions and mRNA-protein immunoprecipitation are in progress to validate the involvement of PTB in MARK4 AS. Our data suggest that PTB overexpression in glioma may favor MARK4L expression causing the observed imbalance between the two isoforms. The identification of the splicing factors involved in MARK4 AS appears essential to understand the basis of the imbalance observed in gliomas and to identify underlying oncogenic pathways.

A Synonymous Change, p.Gly16Gly in MECP2 Exon 1, Causes a Cryptic Splice Event in a Rett Syndrome Patient. *T.I. Sheikh[1,2], J. Vincent[1,2].* 1) Institute of Medical Sciences, University of Toronto, Toronto ON Canada; 2) Center of Addiction and Mental Health, Toronto ON Canada.

Background: Mutations in MECP2 are the main cause of Rett Syndrome. To date, no pathogenic synonymous MECP2 mutation has yet been identified. Here, we investigated a de novo synonymous variant c.48C>T (p.Gly16Gly) identified in a girl displaying a possible typical RTT phenotype. Methods: In silico analyses to predict effects of sequence on mRNA splicing were employed, followed by sequencing and quantification of lymphocyte mRNAs from the subject for splice variants MECP2_E1 and MECP2_E2. Results: Analysis of mRNA confirmed predictions that this synonymous mutation activates a splice-donor site at an early position in exon 1, leading to a deletion (r.[=, 48_63del]), codon frameshift and premature stop codon (p.Glu17Lysfs*16) for MECP2_E1. For MECP2_E2, the same premature splice site is used, but as this is located in the 5'untranslated region, no effect on the amino acid sequence is predicted. Quantitative analysis specific to this cryptic splice variant also revealed a significant decrease in the quantity of the correct MECP2_E1 transcript, which therefore suggests that this is the etiologically significant mutation in this patient. Conclusion: These findings suggest that synonymous variants of MECP2 as well as other known disease genes~and de novo variants in particular~ should be re-evaluated for potential effects on splicing.

Role of RNA Editing in ER Stress Response. *A. Richards[1], I. Wang[2], V. Cheung[2,3,4].* 1) Cell and Molecular Biology Graduate Program, University of Pennsylvania, Philadelphia, PA 19104, USA; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA 19104, USA; 3) Howard Hughes Medical Institute, Chevy Chase, MD 20815, USA; 4) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA 19104, USA.

Adenosine Deaminase Acting on RNA (ADAR) deaminates adenosine to inosine in double-stranded RNA. There are thousands of adenosine to inosine editing events in human cells. While some editing sites, such as those in ion channels, including the AMPA receptor, have been well studied, the role of RNA editing in a more general cellular context is less well understood. In this project, we aim to understand how RNA editing of genes involved in the endoplasmic reticulum (ER) and the Golgi affects their functions, particularly in ER stress response.

We have identified ~1,000 human genes edited by ADAR, as confirmed by a decrease in editing levels following ADAR knock-down. Among them, 108 are genes localized to the endoplasmic reticulum and the Golgi body. To study these editing events, we sequenced the mRNA and corresponding DNA from B-cells of 10 individuals. We found about 710 editing sites within these 108 ADAR target genes; on average, there are 6 editing sites and a range of one to 54 sites per gene. The editing levels vary across individuals. For example, the editing level of a site in the 3' UTR of *EIF2AK2* varies by greater than 4-fold across individuals (range 13%-57%). In addition, the editing levels differ at different sites. To study if editing levels change following cellular stress, we treated B-cells of 10 individuals with tunicamycin to induce ER stress. We then sequenced the DNA and mRNA of these cells before and at 2 and 8 hours following ER stress. About 275 of the 710 editing sites in ER and Golgi genes show an increase in editing level of >1.5-fold following ER stress. Editing level changes following ER stress also show individual variability. For example, the editing level of a site in the 3' UTR of *VHL* increases 1.8- to 7-fold across individuals following ER stress. Over 60% of ADAR editing sites in the ER and Golgi genes are located in the 3' UTR. Therefore, we aimed to determine if RNA editing influences gene expression to affect ER stress response. We used luciferase reporter constructs with the edited sequence of 3' UTRs and found that regions of various 3' UTRs can repress or enhance reporter gene expression.

In this presentation, we will illustrate the features of RNA editing in ER and Golgi genes. We will, further, describe how RNA editing levels respond to ER stress and how editing, in turn, may impact ER stress response.

Understanding translational regulation using RNA-Seq of Ribosome Protected mRNA fragments. *J. Pease[1], S. Kuersten[1], P. De Araujo[2], D. Vo[2], S. Burs[2], M. Qiao[2], A. Radek[1], E. Bahrami[3], P. Uren[3], A. Smith[3], L. Penalva[2].* 1) Epicentre, Madison, WI; 2) University of Texas Health Science Centre at San Antonio, San Antonio, TX; 3) University of Southern California, Los Angeles, CA.

Musashi1 (Msi1) is an evolutionarily conserved RNA-binding protein that has been implicated in a variety of cellular processes such as stem cell maintenance, nervous system development, and tumorigenesis. Msi1 is highly expressed in many cancers including glioblastoma, and is emerging as a potential therapeutic target in both regenerative medicine and cancer. Our goal is to better understand the regulatory role of Msi1 by identifying the RNAs targeted by Msi1 at the level of translation. Our approach is to use high-throughput RNA sequencing (RNA-Seq) to compare total mRNA to the Ribosome Protected mRNA Fragments (RPF) in order to provide quantitative analysis of translationally active mRNAs versus repressed pools of mRNAs present at a particular time or condition. Consequently, we developed a simplified method for preparing RNA-Seq libraries from Ribosome Protected fragments. A small hairpin (sh) RNA was used to knock down Msi1 activity in the glioblastoma cell line U251. RNA-Seq libraries were prepared from the ribosome protected fragments of control and shMsi1-treated cells and sequenced on the Illumina platform. Our results show RNA-Seq of ribosome protected fragments offers a viable approach to understanding the translational regulation role of Msi1.

Integrator Complex Subunit 8 mutation associated with cortical and cerebellar malformations results in disruption of the Integrator complex and spliceosomal defects. *G.M. Mancini[1], R. Oegema[1], D. Baillat[4], R. Schot[1], D. Heijsman[2], L. van Unen[1], S. Kheradmand Kia[1], J. Hoogeboom[1], A. Kremer[2], F.W. Verheijen[1], P. van der Spek[2], R.M. Hofstra[1], E. Wagner[4], M. Fornerod[3].* 1) Clin Genetics Erasmus Med Ctr, 3000CA Rotterdam, Netherlands; 2) Bioinformatics Erasmus Med Ctr, 3000CA Rotterdam, Netherlands; 3) Biochemistry Erasmus Med Ctr, 3000 CA Rotterdam, Netherlands; 4) Biochemistry and Molecular Biology, University of Texas Medical School, TX 77030 Houston, USA.

The Integrator Complex is responsible for the 3'-end processing of the spliceosomal U snRNAs. Maturation of these snRNAs is essential for the proper function of the major/minor spliceosome. Although there is accumulating evidence that the complex is necessary for normal vertebrate development, no association with human disease has been reported yet. Three siblings presented with severe intellectual disability, cerebellar hypoplasia and periventricular nodular heterotopia (PNH) of unknown cause. Using whole genome sequencing (Complete Genomics), and filtering for recessive inheritance, we discovered co-segregating compound heterozygous mutations in Integrator Complex Subunit 8 (INTS8) in the three sibs. Quantitative RT-PCR showed 2-fold decreased INTS8 RNA levels and lower levels of the catalytic subunits INTS4, INTS9 and INTS11 were observed in patient fibroblasts by western blot, indicating that the integrity of the complex is disrupted. Quantitative RT-PCR analysis uncovered significantly misprocessed levels of U1, U2 and U4. Pathway analysis (DAVID and IPA) of expression data (Affymetrix U133 expression arrays and Gene Chip 1.0 ST exon arrays) of RNA extracted from patient fibroblasts showed abnormal expression of genes required for mRNA splicing and posttranscriptional modification. Expression data of (developing) human brain structures (Allen Brain Atlas) show that expression of INTS8 peaks prenatally, especially in the ganglionic eminences, (sub)ventricular zone and hindbrain, similar to the developmental expression in mouse embryo (Emage database). Interestingly, these areas, from which neuronal precursors migrate to the cortex, are compatible with the regions affected by PNH and cerebellar hypoplasia in the patients. We propose that dysfunction of the Integrator Complex, possibly through snRNA misprocessing and spliceosomal defects, leads to severely disrupted brain development in humans.

624T

Predicting the impact of non-coding genetic variants on complex traits. *F. Luca, G. Moyerbrailean, R. Pique-Regi.* Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI.

Genome-wide association studies (GWAS) have been instrumental to identify a large number of genetic variants associated with complex traits. However, risk variants tend to fall in non-coding regions and likely affect gene regulatory mechanisms that are not yet well defined. Projects such as ENCODE have generated comprehensive catalogs of tissue-specific regulatory regions, but it is not clear how these are affected by a sequence change. Identification and functional characterization of variants in regulatory elements is a crucial step in understanding phenotypic expression in complex traits. To identify genetic variants that can potentially disrupt binding in a specific tissue, we developed a novel extension of the CENTIPEDE model that builds a new sequence motif model. First, we applied the CENTIPEDE approach to identify DNase-seq footprints where access to the DNA is blocked by a bound factor. Then, we calculated tissue-specific binding probabilities and how they change in the presence of a genetic variant. We used this approach across 280 cell-types from the ENCODE project, and then computed allele-specific binding (ASB) probabilities for all known variants (from the 1000Genomes project) overlapping motifs. We annotated >8.7 million sequence variants in footprints. For >5.6 million of these variants we predicted >2-fold difference in binding affinity. Among these predicted functional variants, 1,972 were associated with a complex trait from the NHGRI GWAS catalog. For example, we identified 6 independent variants predicted to disrupt binding of DEAF1, a factor involved in maintaining peripheral immune tolerance (in lymphnodes) and in cell proliferation. Of these variants, one is associated with Kawasaki Disease and is predicted to disrupt binding in lymphoblast and 3 are associated with different types of cancer. We then validated a subset of our predictions using ASB on heterozygous SNPs for six cell-types. 75% of the heterozygous SNPs with significant ASB are concordant with the predictions. These results represent one of the most extensive catalogs of tissue-specific regulatory sequences and genetic variants. We anticipate that this resource will be useful to annotate GWAS loci for many diseases and complex traits by providing new advantages in three key aspects: i) single base pair resolution, ii) tissue-specificity for more than 200 tissues, and importantly iii) a suggested molecular mechanism beyond physical annotation.

Mutation profiling of exonic-enhancers using massively parallel reporter assays. *R.Y. Birnbaum[1], R.P. Patwardhan[2], M.J. Kim[1], G. Finlay[2], J. Zhao[1], R. Bell[3], R.P. Smith[1], A.A. Ku[1], J. Shendure[2], N. Ahituv[1].* 1) Department of Bioengineering and Therapeutic Sciences, Institute for Human Genetics, University of California San Francisco, San Francisco, California, USA; 2) Department of Genome Sciences, University of Washington, Seattle, Washington, USA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA 94143, USA.

Protein coding exons that also function as enhancers (eExons) have been shown to regulate transcription of the genes they reside in or nearby genes. Mutations in these eExons could lead to multiple phenotypes due to alterations in protein function and/or transcriptional regulation. However, the functional consequences of these mutations are not well known. Here, using ChIP-seq with enhancer marks (p300, H3K27ac, H3K4me1) on human hepatocytes and mouse liver, we show that ~6% of all ChIP-seq peaks overlap coding exons (excluding 1st exon and promoter regions) and demonstrate that 8 of 15 tested sequences function as enhancers in mouse liver and HepG2 cells. Using massively parallel reporter assays, we further dissect in vivo the enhancer activity of three liver eExons (*SORL1*, *PPARG*, *TRAF3IP2*) in a single nucleotide resolution. We find that deleterious enhancer mutations are correlated with the location of transcription factor binding sites and synonymous and non-synonymous mutations have a similar effect on enhancer activity. We also show that the regulatory repertoire that controls the enhancer activity of these eExons is different across cell types leading to differences in deleterious mutation profiles. Combined, these results demonstrate that eExons mutations can disrupt both the protein structure and enhancer activity with differential effect across cell types and can cause multiple phenotypes.

HSA21 Single-minded 2 (Sim2) binding sites co-localize with super-enhancers and pioneer transcription factors in pluripotent mouse ES cells. *A. Letourneau[1], G. Cobellis[2], F. Santoni[1], E. Falconnet[1], A. Vannier[1], M. Guipponi[1], C. Borel[1], S.E. Antonarakis[1,3].* 1) Genetic Medicine & Development, University of Geneva Medical School, Geneva, Switzerland; 2) Department of Biophysics, Biochemistry and General Pathology, Seconda Università di Napoli, Italy; 3) iGE3 Institute of Genetics and Genomics of Geneva, Switzerland.

Down syndrome (DS) results from trisomy of chromosome 21 (HSA21). Some DS phenotypes may be directly or indirectly related to the increased expression of specific HSA21 genes, in particular transcription factors. The HSA21 Single-minded 2 (SIM2) transcription factor has key neurological functions and appears therefore as a good candidate for some DS features, in particular mental retardation. In order to identify DNA binding sites and downstream targets of Sim2, we deep sequenced Sim2-immunoprecipitated DNA from a mouse embryonic stem cell (mESC) line overexpressing a Flag-tagged mouse Sim2 under the control of a Tet-off system. Non-expressing mESCs were used as controls. Reads uniquely mapped with BWA were submitted to HOMER for the identification of Sim2 targets and the discovery of binding site motifs. We identified 1229 potential Sim2 DNA-binding sites, mainly located in intergenic regions (57%). A gene ontology analysis on the nearby genes confirmed the importance of Sim2 in developmental and neuronal processes and revealed a potential role of master transcription regulator. Sim2 gene targets were then validated by RNA-Seq transcriptome comparison of the Sim2 expressing and non-expressing mESCs. The identification of the Sim2 binding motifs revealed high sequence similarities with motifs previously described for pioneer transcription factors such as Oct4, Nanog or Klf4. Correspondingly, a significant fraction of Sim2 binding sites overlaps with loci experimentally known to be occupied in mES cells by one or several of these master transcription factors including Oct4, Nanog, Klf4 or Sox2. In addition, we found that Sim2 binding sites overlap significantly with marks of open chromatin and active enhancer elements such as H3K27ac, P300 or DNaseI hypersensitive sites. More importantly, 67% of the identified Sim2 peaks overlap with regions bound by the Mediator coactivator Med1, suggesting that some of the Sim2 binding sites could even predict a particular sub-category of enhancers known as super-enhancers. All together, we provide evidence that Sim2 binds specific enhancer elements thus explaining how Sim2 can regulate its gene network in DS neuronal features. We hypothesize that those enhancer loci are initially occupied by pioneer transcription factors like Oct4, Sox2 and Nanog known to actively open chromatin enabling the recruitment of Sim2.

Splicing QTL analysis from primary immune cells identifies regulatory effects putatively associated with autism and Alzheimer's disease. *J.M. Replogle[1,2,3,4], T. Raj[1,2,3,4], K.L. Rothamel[5], C. Benoist[2,3,5], B.E. Stranger[4,6,7], P.L. De Jager[1,2,3,4], Immunological Variation Consortium.* 1) Department of Neurology, Brigham & Women's Hospital, Boston, MA; 2) Program in Medical & Population Genetics, The Broad Institute, Cambridge, MA; 3) Harvard Medical School, Boston, MA; 4) Division of Genetics, Department of Medicine, Brigham & Women's Hospital, Boston, MA; 5) Department of Microbiology and Immunobiology, Harvard Medical School; 6) Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, IL; 7) Institute of Genomics and Systems Biology, University of Chicago.

Alternative splicing acts as an abundant source of transcriptional and phenotypic diversity in humans. Recently, advances in sequencing and array technologies have facilitated high-throughput quantification of mRNA expression at the exon level, and previous studies highlight significant tissue- and population-specificity of alternative splicing. Several splicing quantitative trait loci (sQTL) studies have identified putative functional links between variants associated with complex traits and alternative splicing. However, many of these studies have identified sQTLs in immortalized cell lines, and we have little knowledge about how these discoveries will translate to primary cell-types, which may be most relevant for unraveling disease phenotypes. Here we performed an sQTL analysis in two primary immune cell-types, CD4+ T lymphocytes and CD14+CD16- monocytes, obtained from 377 individuals of European ancestry as part of the ImmVar Consortium. To maximize statistical power, we limited the number of tests performed by focusing our analysis on genetic variants with a high probability of influencing splicing: SNPs located in gene splice sites. Using 851 potential splice variants, we found 783 genes containing at least one potential splice variant. To deconvolute variants' effects on overall gene expression with effects on exon abundance, we calculated a normalized intensity (NI), or splicing index, of expression for each exon, dividing each exon's expression by the overall gene expression level. Testing the association between exon NI and splicing SNP genotype, we identified 53 significant sQTLs (27 genes) in CD4+ lymphocytes. In CD14+ monocytes, we failed to detect any significant sQTLs. Although our array-based expression quantification is more susceptible to reporting spurious associations than RNA-seq data, we replicated previously-reported, experimentally-verified sQTLs in *OAS1* and *CAST*. Examining overlaps between our results and Genome-Wide Association Studies, we found that rs1143674, previously associated with autism susceptibility, correlates with alternative splicing of *ITGA4*, and rs3826656 and rs3865444, previously associated with Alzheimer's disease risk, correlate with alternative splicing of *CD33*. In the future, we plan to expand our sQTL analysis to include CD4+ and CD14+ cells from individuals of African American and East Asian ancestry in order to increase power and characterize the sQTL variation between populations.

Transcription in the human brain: DNA methylation in a single nucleosome may regulate an opioid gene as a region-specific `epigenetic switch'. *G. Bakalkin, T. Yakovleva, H. Watanabe, O. Kononenko, R. Henriksson, I. Bazov.* Uppsala University, Uppsala, Sweden.

Regulation of gene transcription in human brain has not been yet systematically addressed. We focus on the opioid genes including prodynorphin (PDYN) that control emotions, processing of nociceptive information, and reward. Dynorphin opioid peptides may induce a number of pathological processes associated with substance addiction and depression, and also when mutated cause profound neurodegeneration in SCA23 subjects. To address transcriptional / epigenetic mechanisms of PDYN regulation, we analysed 1.7 kB PDYN promoter DNA methylation in post-mortem specimens of the human prefrontal (PFC) and motor (MC) cortices (discovery sample: n = 14 subjects / group; replication sample: n = 8 subjects / group) using bisulfite treatment / pyrosequencing. Methylation of each CpG in the promoter short CpG island (CGI), but not that of CpGs located proximally or distally demonstrated strong and negative correlation with PDYN mRNA levels. Strong positive correlations between CpGs in the CGI, but not between these CpGs and those in the proximal and distal domains were also observed. The CPI encompassing approximately 150 bp apparently formed a single nucleosome. Search for transcription factor (TF) binding sites found a canonical E-box in the CGI, and Upstream Regulatory Factor-2 (USF2) was identified as a dominant E-box binding factor in the human brain by EMSA. USF2 was i) colocalized with PDYN protein in neurons using immunostaining; and ii) bound to the PDYN CGI using ChIP-qPCR. PDYN mRNA / peptides, CpG methylation in the CGI, and USF2 correlated with each other. These correlations were impaired and the CGI methylation was decreased in the model human pathology analysed, i.e. human alcoholism (DSM-4; discovery sample: n = 14 subjects / group; replication sample: n = 8 subjects / group), which was characterized by PDYN upregulation. No changes were evident in the MC, which showed no PDYN activation in alcoholics. We hypothesize that the PDYN CGI functions as the brain-area specific 'epigenetic switch' affected by alcohol. The CGI demethylation may promote USF2-mediated recruitment of histone modifiers to the promoter resulting in PDYN activation in alcoholics. These findings also propose a novel transcription function for short CGIs, which may form a single nucleosome and which DNA methylation may be selectively regulated. Support: Swedish FAS, VR, FORMAS. Tissues were received from the NSWTRC, University of Sydney supported by NIH/NIAAA R24AA012725.

Sex chromosomes and sexual dimorphism in human transcriptome. *D. Nguyen, C. Disteche.* Pathology, University of Washington, Seattle, WA.

X-linked recessive mutations that increase male-fitness but are potentially disadvantageous to females are more easily fixed than autosomal mutations because of X hemizygosity in males and random X inactivation in females. Mutations that enhance female-specific fitness are also preferentially selected because the X chromosome spends 2/3 of its time in females. In addition, up to 25% of human X-linked genes appear to escape X-inactivation and thus would have higher expression in females, although only a limited number of tissues, cell lines, and individuals have been assayed. We have measured the sexual dimorphic expression of X-linked, Y-linked, and autosomal genes in a wide range of human tissues based on more than 500 RNA-seq datasets and 8000 expression arrays in 65 tissues from disease-free individuals deposited in public databases. We used global normalization to compare arrays across tissues, and RPKM for RNA-seq datasets. A standard student-t test with step-down Benjamini-Hockberg correction at 5% FDR was applied throughout to assess genes with at least 1.2 fold expression difference between the sexes. We selected tissues with at least 15 individuals per tissue and similar number of female and male individuals. Genes located within the largest human pseudoautosomal region (PAR1) had significantly higher expression in male tissues, possibly due to spreading of silencing in the inactive X in females. In contrast, escape genes outside the PAR had significantly higher, but rarely doubled, expression in females compared to males, in a tissue-specific manner. This female bias was most pronounced for genes known to escape X inactivation but was also seen for other X-linked genes perhaps due to partial escape in specific tissues. Such female-specific bias was particularly pronounced in the gyrus and the cortical regions of the brain, in the skin, in CD4 positive blood cells, and in reproductive organs. These studies led us to identify the first comprehensive sex biased human transcriptome in brain, non-brain, immune cells, and sex organs, which consisted of a female biased gene set containing 279 X-linked and 7229 autosomal genes (21% of the genome) and a male biased gene set containing 95 X-linked and 3015 autosomal genes (9% of the genome).

FREM1 Regulates Genes Important for HIV-1 Replication and Cell Migration. *M. Luo[1,2], J. Sainsbury[1], P. Lacap[1], F. Plummer[1,2].* 1) HIV and Human Genetics, Public Health Agency of Canada, Winnipeg, Manitoba, Canada; 2) Department of Medical Microbiology, University of Manitoba, Winnipeg, Canada.

Introduction: FREM1 has been identified as a novel candidate gene in resistance to HIV-1 infection in the Pumwani sex worker cohort established in Nairobi, Kenya. Several molecular features of FREM1 suggest its potential role in HIV-1 vaginal transmission. It is an essential component for epidermal integrity and in the right path of HIV-1 infection. A splice variant of FREM1 is a co-receptor for IL-1R1 and toll-like receptor involved in enhancing NFKB activation. However, the precise role of FREM1 in HIV-1 infection and how its variants influence resistance and susceptibility to HIV-1 infection need to be investigated. In this study we studies the role of FREM1 in regulating genes important in HIV-1 replication and cell migration, the two important factor in vaginal HIV-1 transmission. **Method:** We knocked down FREM1 expression in 293F cells and over expressed FREM1 in the HeLa cells derived from cervical tissue and examined the effect on the expression of genes in signal transduction pathways important for HIV-1 transmission by real time PCR array (SABioscience). **Results:** The results showed that knocking down or over expression of FREM1 influences the expression of many important genes involved in NF-κB and inflammatory response, apoptosis, epithelial adhesion and cell migration. As immune response is of paramount importance to HIV-1 transmission and replication, regulation of immune system genes by FREM1 may be a major factor in mediating resistance to mucosal acquisition of HIV-1. **Conclusion:** These suggest that FREM1 may play an immunomodulatory role in cellular activation, which is important for HIV replication. FREM1 may also influence target cell recruitment and HIV infection at vaginal mucosa as suggested by its potential role in epithelial integrity and cell migration through its different functional domains.

***In vivo* UAS$_{Gal}$ gene regulation analysis using the a novel approach.** *H. Guillen Ahlers[1], A. Ludwig-Kubinski[1], K. Lazarova[1], A.M. Greene[1], J. Kennedy-Darling[2], M. Levenstein[2], C. Anderson[1], J. Barfknecht[1], R. Knoener[2], M. Scalf[2], Y. Yuan[2], R. Cole1[1], M. Shortreed[2], L. Cirillo[1], L. Smith[2], M. Olivier1[1].* 1) WI CEGS , Medical College of Wisconsin, Milwaukee, WI; 2) WI CEGS, University of Madison, Madison, WI.

The Wisconsin Center for Excellence in Genomics Science is developing a novel technology to identify the proteins that are associated with DNA at any desired region of the genome. Sequence-specific hybridization to formaldehyde-crosslinked chromatin is used to capture the target region along with its interacting proteins. The novel approach builds on the previous GENECAPP technology developed by the present group and does not require restriction enzyme digestion. The new approach utilizes an optimized capture oligonucleotide mixture that greatly increases the efficiency of the process while reducing costs. This technology was used to study the Gal upstream activator sequence (UAS$_{Gal}$) in *S. cerevisiae*. Cells were grown using either glucose or galactose as the carbon source, so that the difference in gene modulation at the UAS$_{Gal}$ region could be observed. Bound proteins were identified by tandem mass spectrometry using an Orbitrap Velos instrument. The development of this technology has shown steady improvements and highlights the great potential offered for an unbiased analysis of DNA-protein interactions. Funded by the Wisconsin CEGS through NIH/NHGRI grant 1P50HG004952.

Functional impact of polymorphic inversions on gene expression in humans. *M. Oliva[1], S. Villatoro[1], L. Pantano[1], C. Aguado[1], D. Vicente-Salvador[1], D. Izquierdo[1], M. Puig[1], T. Marques-Bonet[2,4], JI. Lucas Lledó[1], R. Castelo[3], M. Cáceres[1,4].* 1) Institut de Biotecnologia i de Biomedicina, Universitat Autònoma de Barcelona, 08193 Bellaterra (Barcelona), Spain; 2) Institut de Biologia Evolutiva, (CSIC-Universitat Pompeu Fabra), PRBB, Barcelona 08003, Spain; 3) Department of Experimental and Health Sciences, Universitat Pompeu Fabra, Barcelona, Catalonia, Spain; 4) Institució Catalana de Recerca i Estudis Avançats (ICREA), 08010 Barcelona, Spain.

Despite the significant advances made over the last few years, our understanding of the prevalence and functional impact of inversions in the human genome is scarce. Moreover, little is known about inversions that associate to gene expression changes in humans. The only exceptions are a few studied examples, such as the association of the 17q21.31 inversion with decreased MAPT expression or the 8p23.1 inversion with decreased PPP1R3B expression. Here, we analyzed the overlap of a set of polymorphic inversions in the human genome with genes and the correlation between inversion genotypes and gene expression profiles in a genome-wide fashion, looking for both *cis* and *trans* effects. First, we recorded the gene content of 48 human inversions (identified by our group) and generated 1000 permuted sets to build an empirical null distribution of gene counts for each inversion. We confirmed that inversions break fewer genes than expected by chance ($p<0.05$). Next, we looked for associations of 37 validated inversions with gene expression changes by analyzing microarray expression datasets of lymphoblastoid cell lines of 90 Yoruba, 90 European, 45 Chinese and 45 Japanese HapMap individuals. For each gene expression profile, we searched for inversion eQTLs using linear models in which we adjusted for confounding factors using surrogate variable analysis (SVA) and tried to quantify the effect of each inversion. Possible influencing variables (gender, population) were also taken into account in the model. We further analyzed the two well-characterized inversions (17q21.31, 8p23.1) to evaluate the reliability of our methodology in detecting known effects of inversions on the expression of particular genes. Our results show that 30% (11/37) of studied inversions associate to the expression of at least one gene in *cis* (FDR<10%) and a subset of them also seem to affect expression of genes in *trans*. Additional analyses of expression datasets derived from alternative technologies (RNA-Seq) were performed to assess the robustness of our findings. Insight gained in this study could contribute to a better understanding of the role of polymorphic inversions in the regulation of gene expression across the entire human genome. Support: European Research Council (ERC) Starting Grant (INVFEST) under the European Union Seventh Research Framework Programme (FP7).

Targeted sequencing of promoter-associated tandem repeats identifies common functional effects on gene expression levels in the human genome. *A.J. Sharp[1], A. Guilmatre[1], P. Garg[1], G. Highnam[2], D. Mittelman[2,3].* 1) Genetics & Genomics Sci, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Virginia Bioinformatics Institute, Virginia Tech, Blacksburg, VA, USA; 3) Department of Biological Sciences, Virginia Tech, Blacksburg, VA, USA.

Tandem repeats (TRs) are stretches of DNA comprised of two or more contiguous copies of a motif arranged in a head-to-tail pattern, and comprise ~2% of the human genome. They are characterized by high mutation rates and account for >25% of indel variants, therefore representing an important source of genetic variation. However, due to technical difficulties in studying them, TRs remain poorly studied and have often been considered as mere 'junk DNA'. We hypothesized that many TR variations might operate as expression quantitative trait loci (eQTLs). To investigate this hypothesis we have conducted a cis-association analysis of variation in promoter-associated TRs with neighboring gene expression levels. Utilizing a custom solution-based capture approach (PMID: 23696428) we studied 120 CEU and YRI HapMap individuals, obtaining a median coverage of 47x informative reads for >4,000 TRs located within 1kb of RefSeq gene transcription start sites. TR genotypes were called using the RepeatSeq algorithm (PMID: 23090981). We then performed an eQTL association analyses using published RNAseq data, identifying 432 TRs in the CEU and/or YRI population that show significant association ($p<0.05$) with the expression level of adjacent genes. This included many TR loci that have not previously been reported as polymorphic. TRs scored as significant eQTLs were enriched for overlaps with transcription factor binding sites and putative enhancers, providing a strong biological rationale for their effects. After phasing of SNP and TR genotypes using BEAGLE, we analyzed patterns of linkage disequilibrium between TRs and nearby SNPs, and observed that most TR variants are poorly tagged by SNP markers. Only 8% of TRs had $R^2 \geq 0.8$ with any SNP within 250kb, and the majority had $R^2<0.3$ with the best tagging SNP. Thus although many TR variants show clear evidence of functional effects, this indicates that the majority are not effectively assayed by SNP-based GWAS approaches, potentially explaining some of the 'missing heritability' of the genome. Our eQTL study represents the first systematic attempt to assign biological significance to TR variations in the human genome, and suggests that potentially there are many thousands of TR variations in the genome that exert functional effects via alterations of local gene expression or epigenetics. We conclude that specific studies that focus on genotyping TR variants are required to fully ascertain functional variation in the genome.

Targeted CD4+ Effector Memory T-Cell Gene Expression Profiling Identifies State-Specific cis-eQTLs Among Rheumatoid Arthritis and Celiac Disease Risk Variants. *X. Hu[1,2,3,4,5], H. Kim[1], C. Baecher-Allan[4,6], T. Raj[3,6], P. Brennan[1,4], P. De Jager[3,6], M. Brenner[1,4], S. Raychaudhuri[1,2,3,4,5,7,8].* 1) Division of Rheumatology, Immunology and Allergy, Department of Medicine, Brigham and Women's Hospital, Boston, MA, USA; 2) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA, USA; 3) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 4) Harvard Medical School, Boston, MA USA; 5) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA USA; 6) Department of Neurology, Brigham and Women's Hospital, Boston, MA, USA; 7) Partners Center for Personalized Genetic Medicine, Boston, MA, USA; 8) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

Motivation: We recently demonstrated that common single-nucleotide polymorphism (SNP) variants associated with rheumatoid arthritis (RA) and celiac disease (CeD) both implicate genes specifically expressed in CD4+ effector memory T (TEM) cells. We hypothesize that some variants may be expression quantitative trait loci (eQTL) that contribute to the development of disease by regulating gene transcription in a cell-specific manner. Methods: We performed genome-wide SNP analysis in 174 healthy, non-Hispanic, Caucasian volunteers. In conjunction, we isolated highly purified CD4+ TEM cells (CD45RA-, CD45ROhigh, CD62Llow/-) from the peripheral blood of the same individuals, and assayed the expression of 215 genes within RA and CeD loci along with 15 control genes for calibration using Nanostring nCounterTM, before and after T cell receptor (TCR) stimulation by anti-CD3/anti-CD28 antibodies. We assessed the presence of cis-eQTL within 1Mb of the transcription start site changes of each gene. Results: The genes with the largest fold changes in expression following stimulation were GZMB (average fold change: 182.2; range: 6.5-573.4) and IL2RA (average fold change: 105.9; range: 8.7-711.0). The genes with the greatest fold change were also those most specifically expressed in CD4+ TEM cells (Spearman rho = 0.26, $P = 5.4\times10^{-4}$). Six of the 35 RA variants in high-density genotyped regions, and four of the 50 CeD variants were in tight linkage disequilibrium with cis-eQTLs (permutation-based $P < 0.01$, $R2 > 0.7$). One disease-associated eQTL (rs1980422/CD28, shared between RA and CeD) influenced CD28 expression specifically in cells before stimulation; rs12936049 and rs4840565 were associated with differential expression of GSDMB and BLK, respectively, both before and after stimulation. Remaining disease-associated eQTLs were associated with differential expression only after stimulation. None of the eQTL SNPs were significantly associated with the proportion of CD4+ TEM cells or with cell proliferation. Conclusion: Most RA- and CeD-associated eQTLs are specific to either resting or stimulated CD4+ TEM cell state. Genetic variants may contribute to the development of autoimmune diseases by regulating gene transcription in specific cell populations such as CD4+ TEM cells.

Introduction: Analysis of whole genome expression quantitative trait loci (eQTL) provides a means for transcriptional regulatory relationships at a genome-wide scale and thus for identifying regulatory pathways affecting disease susceptibility and other relevant traits **Methods:** We performed eQTL analyses in 890 randomly selected fasting participants from the population-based KORA F4 study and replicated the results in independent non-fasting samples (EGUT, N=842). Linear regression models using additive effects with adjustments for principal components were applied. Genome-wide statistical significance was defined as 0.05/number of tests performed. **Results:** 4,210 eQTLs, (4,116 cis-eQTLs, defined as 500 kb window around the transcription start and end site of a gene, and 94 trans-eQTLs) reached genome-wide significance. Of those, 87% and 80% of the cis- and trans-eQTLs, respectively, were confirmed in the replication samples. (The replication in a second cohort is ongoing and looks similar.) Network analysis for the significant eQTLs using Ingenuity Pathway analysis software identified an enrichment of pathways involved in the development and the activity of the immune system and a central role of the HLA-system. Furthermore, for the set of significant cis-eQTL we observed (1) an overlap of 19% of genes detected in genome-wide analysis studies (GWAs) and recorded in the GWAs catalog so far (http://www.genome.gov/gwastudies, July, 18th, 2012), (2) major cross-tissue similarity (46–70%) with previously published cis-eQTLs found in monocytes, LCLs, lymphocytes, lung tissue, and liver tissue, and (3) five chromosomal regions with simultaneous impact on multiple gene expression levels. Amongst the set of significant trans-eQTLs, a triangular relationship between an eQTL-SNP residing in a gene desert on chromosome *6q24.1*, the gene expression probe of a known type 2 diabetes susceptibility gene (*IGFBP2*), and adiponectin was identified. **Conclusion:** The present study identified numerous eQTLs in whole blood in a large Western European sample and provided evidence that these results offer a valuable resource for investigators studying the genetic architecture of regulatory pathways in whole blood. The high replication rate also in non-fasting subjects demonstrates the robustness of the regulatory effects in whole blood. Furthermore whole blood seems to be an informative tissue for an abundance of transcriptional regulatory relationships also in other tissues.

Paired eQTL analysis of monocytes and differentiated macrophages. *S. Makino[1], V. Naranbhai[1], J. Knight[1], B. Fairfax[1,2].* 1) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 2) Oxford Cancer Centre, Churchill Hospital, Oxford, OX3 7LJ.

Monocytes and macrophages form crucial cellular subsets of the innate immune system. Monocytes are short-lived circulating cells that upon migration into inflamed or damaged tissue differentiate into resident macrophages, promoting either resolution or chronicity of inflammation. Multiple eQTL analyses have determined that a proportion of eQTL exhibit high cellular specificity. The degree to which the activity of genetic determinants of gene expression is retained during cellular differentiation is unclear however. Here we aimed to investigate whether eQTL observed in CD14+ monocytes are maintained after their differentiation into macrophages. Primary CD14+ monocytes were isolated from peripheral blood mononuclear cells of 64 healthy Europeans. They were ex vivo differentiated into macrophages over18 days with Tumour Necrosis Factor (TNF) and Granulocyte-Macrophage Colony Stimulating Factor (GMCSF). Differentiation into a macrophage phenotype was confirmed with quantitative PCR (qPCR) of the monocyte and macrophage markers, CD14, CD68 and CD163. Gene expression was subsequently analyzed with total RNA from monocytes and macrophages using Illumina HumanHT-12v4 BeadChips. Individuals were genotyped at 730,000 markers using Illumina OmniExpress v1 beadchips. eQTL analysis was performed using a linear model incorporating expression principal components as covariates. Here we report the results of this analysis. Major observations include the diminishment of the previously reported master regulatory region at 12q15 at the LYZ-YEATS4 locus upon macrophage differentiation, a result validated with parallel qPCR of LYZ. This analysis supports the plastic nature of eQTL activity which is dependent in part upon the cellular differentiation state. It also provides the first reported analysis of eQTL from differentiated macrophages.

Human Cytomegalovirus pUL23 Protein Potentially Associated with Viral Latency. *H. Li, B. Zeng, J. Li, H. Liu, Y. Ran, Y. Li, T. Zhou, Z. Deng.* College of Life Science and Technology, Jinan University, Guangzhou, Guangdong, China.

Most human individuals are latently infected with human CMV, a prototypic β-herpesvirus, frequently acquired during early childhood. The latent infection can be reactivated in the absence of adequate immune control, and the otherwise asymptomatic infection can be dangerous and play a pathological role in some life threatening diseases. This study is aiming on identifying potentially interesting virus-host interactions responsible for CMV latency. o enable efficient replication and to maintain lifelong latency in immunocompetent hosts, CMVs have evolved numerous molecules mediating immune evasive properties, targeting both innate and adaptive immune responses. One of the striking immune evasive strategies is to interfere with JAK/STAT signal transduction, block IFN-stimulated gene (ISG) expression following viral gene expression, also during an initial ISG activation phase. CMVs encode more than 100 genes that are nonessential for growth in vitro and hence are likely to modulate the virus-host interaction in vivo, including immune modulatory genes. UL23 gene, encoding pUL23 protein, is one member of the human cytomegalovirus (HCMV) US22 gene family. The intracellular target of the pUL23 protein was investigated by using a yeast two-hybrid screening system with pUL23 as bait. Following the two-hybrid screen, a list of interesting interactors was generated and the interactions validated using Western blots using commercial antibodies recognizing the interactors identified. From these results, we are focusing on specific partners associated with STAT1 and IFN receptor. Glutathione S-transferase pull-down experiment revealed some interactors associated with HCMV pUL23 protein with a higher affinity than STAT-1 did. Therefore, it is suggested that pUL23 protein has the ability to interact strongly with host proteins and consequently to bring about the disruption of the complex formed from STAT-1 and the IFN receptor, probably resulting in suppression of the IFN signal transduction pathway.

Resolving regulatory genetic variants in severe sepsis due to community acquired pneumonia by mapping context specific expression quantitative trait loci. *E.E. Davenport[1], J. Radhakrishnan[1], P. Humburg[1], T. Mills[1], P. Hutton[2], C. Garrard[2], C. Hinds[3], J.C. Knight[1], The GAinS Investigators.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Adult Intensive Care Unit, John Radcliffe Hospital, Oxford, United Kingdom; 3) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, London, United Kingdom.

Severe sepsis remains a major area of unmet clinical need with a mortality rate of over 30% despite optimal current antibiotic therapy and intensive care support. New insights into disease pathophysiology and opportunities for early effective intervention and patient stratification are urgently required. We present data for a large cohort of 300 patients of European ancestry with severe sepsis due to community acquired pneumonia. Detailed transcriptomic profiling has been carried out for a total leukocyte cell population rapidly purified at the bedside using the Ambion LeukoLOCK Total RNA Isolation System. We quantified gene expression from serial samples taken following admission to the intensive care unit (ICU) using Illumina HumanHT-12 v4 Expression BeadChip arrays for 47,000 probes. We hypothesised that specific genetic modulators of gene expression may be important in this disease context and we proceeded to compliment detailed transcriptomic profiling by mapping gene expression as a quantitative trait (eQTL). Genotyping was performed for 730,525 SNPs using the Illumina HumanOmniExpress BeadChip. Following quality control, eQTL analysis was carried out for 240 patients using 16,874 probes and 644,390 SNPs. We incorporated principal components analysis (PCA) to define 4010 unique probes associating with local, likely cis-acting, expression associated SNPs (eSNPs) that are within 1Mb of the probe (FDR<0.05). Extensive clinical phenotyping including survival up to six months after ICU admission allows analysis of gene expression and eQTL data in the context of outcome and resolution of endophenotypes. Additionally, we will show how with complex heterogeneous clinical datasets, such as presented here, defining variance using PCA and inclusion of known covariates significantly increases the yield of eQTL identified. We will demonstrate how analysis of context specific eQTL in a disease setting reveals novel eSNPs not currently identified by analysis of lymphoblastoid cell lines or primary cells from healthy volunteers. This novel dataset and approach is informative for genome-wide association studies in sepsis, infectious disease and other immune-related traits.

A comparative transcriptome analysis identifies FGF23-regulated genes in HEK293 cells stably expressing KLOTHO. *S. Diener[1], T. Schwarzmayr[1], A. Schmittfull[1], T. Wieland[1], B. Lorenz-Depiereux[1], T.M. Strom[1,2].* 1) Institute of Human Genetics, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Bavaria, Germany; 2) Klinikum Rechts der Isar der Technischen Universität München, Institute of Human Genetics, Munich, Bavaria, Germany.

Phosphate is the most abundant anion in the human body and is crucial for various biological functions like cellular activity and bone mineralization. Phosphate homeostasis is regulated in a complex process that involves the interplay of different organs, tissues and systems. A key regulator of phosphate homeostasis is the fibroblast growth factor 23 (FGF23). It is mainly secreted from osteocytes and osteoblasts, circulates in the blood and binds to a specific receptor complex composed of FGF receptor 1 (FGFR1) and KLOTHO in the kidney. As elevated FGF23 levels are the main cause of hypophosphatemia in monogenic disorders of phosphate homeostasis (XLH (MIM 307800), ADHR (MIM 193100), ARHR1 (MIM 241520) and ARHR2 (MIM 613312)), further studies on the regulation of phosphate metabolism are necessary to identify possible therapeutic targets. FGF23 activates FGFR1/KLOTHO to inhibit renal phosphate reabsorption and to suppress 1,25-dihydroxyvitamin D_3 synthesis. However, little is known about FGF23/FGFR1/KLOTHO signaling and downstream targets of FGF23 contributing to its phosphaturic action. For this purpose, we established an *in vitro* cell system of FGF23-inducible HEK293 cells that stably express KLOTHO (HEK293-KL). To find differentially expressed FGF23-induced transcripts, we performed whole transcriptome analysis. We used the technology of RNA-Seq, which is a massively parallel sequencing approach to allow genome-wide analysis of gene expression profiles at a far higher resolution than is available with microarray-based methods. Genome-wide transcriptional changes in HEK293-KL cells specifically caused by FGF23 were defined by comparing the transcriptome of FGF23-induced HEK293-KL cells with the transcriptome of not induced HEK293-KL cells. We tried to identify new FGF23-responsive genes that might belong to a network of factors involved in the regulation of phosphate homeostasis.

Circulating miRNAs associated with High Altitude Sickness at the Qinghai-Tibetan Plateau. *NE. Buroker[1], X-H. Ning[2], Z-N. Zhou[3], K. Li[4], W-J. Cen[4], X-F. Wu[3], W-Z. Zhu[5], CR. Scott1[1], SH. Chen[1].* 1) Pediatrics, 356320, University of Washington, Seattle, WA; 2) Division of Cardiology, Seattle Children's Hospital. Institute. Foundation, Seattle, WA; 3) Laboratory of Hypoxia Physiology, Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, Shanghai, China; 4) People's Hospital of the Tibet Autonomous Region, Lhasa, China; 5) Center for Cardiovascular Biology and Regenerative Medicine, University of Washington, Seattle, WA.

Circulating miRNAs isolated from dried blood spots (DBS) were found to be associated with high altitude sickness (HAS) patients in Tibet. HAS arises from two different diseases which are acute (AMS) and chronic (CMS) mountain sickness. Circulating miRNAs differences were found between AMS Han Chinese patients and normal Han controls and between CMS Tibetan Chinese patients and normal Tibetan controls. HAS arises from hypoxia which afflicts some high altitude inhabitants or visitors and not others. The difference results from each individual's genetic makeup where hypoxia related genes have been shown to be a major contributor to these sicknesses. Several fold changes increases (up regulation) were found in the hypoxia associated miRNAs let-7f-5p, miR-9-5p, miR-19a-3p, miR-23a-3p, miR-98-5p, miR-125a-5p, miR-181b-5p, mir-202-3p, miR-372, miR-381-3p, miR-519d, miR-520d-3p, and miR-656 for both HAS groups compared to their controls. Other miRNAs (miR-19a-3p, 302c-3p and 875-3p) were found to be up regulated in one HAS group and down regulated in the other HAS group indicating the genetic differences between the two sickness groups.

641W

Genetic and epigenetic regulation of human LincRNAs gene expression variation. *K. Popadin, M. Gutierrez-Arcelus, E.T. Dermitzakis, S.E. Antonarakis.* Department of Genetic Medicine and Development,, University of Geneva Medical School, Geneva, Switzerland.

Large intergenic non-coding RNAs (lincRNA) are still poorly functionally characterized in spite of the fact that they represent at least one fourth of the number of protein-coding genes in the human genome. To provide transcriptome-wide description of human lincRNAs, we have analyzed the natural variation of lincRNA expression levels by RNA-Seq (10–50 M reads) as well as the genetic (Illumina 2.5M Omni chip) and epigenetic (450K Illumina Infinium HD Methylation Assay) regulation of lincRNAs in the GenCord collection of three cell types (fibroblasts, lymphoblastoid cell lines and T-cells) from 195 unrelated European individuals. We have observed eight hallmarks of lincRNA functionality: (i) a negative correlation between the lincRNA gene size and their level of expression; (ii) high conservation score of ubiquitously expressed lincRNAs; (iii) genomic co-localization of expressed lincRNA genes with protein-coding genes involved in zinc-ion binding; (iv) a higher abundance of cis expression Quantitative Trait Loci (cis-eQTLs) in lincRNAs compared to protein-coding genes and the prevalent localization of these cis-eQTLs very close to Transcription Start Sites (TSS) of lincRNAs; (v) regulation of lincRNA expression by genetic variation independently of regulation of the neighboring protein-coding genes; (vi) an independent transcription when lincRNA and protein-coding genes found near each other; (vii) epigenetic regulatory patterns similar to protein-coding genes: presence of both positive and negative correlations between DNA methylation and gene expression, with negative correlations being closer to the TSS, and similar landscape of passive and active roles of DNA methylation in gene regulation; (viii) an enrichment of frequently expressed lincRNAs in enhancer chromatin marks. Based on these results we rank all human lincRNAs according to the described evidences of functionality in the investigated human cell types. Computational analyses provide strong signatures of independent functions of the lincRNAs in these cell types.

642T

Heritability of Gene Expression Levels in Genome-Wide Analyses. *T. Huan[1], C. Liu[1], R. Joehanes[1,2], X. Zhang[1], M. Larson[3], B. Chen[1], C. Yao[1], A. Johnson[1], P. Munson[2], P. Courchesne[1], C. O'Donnell[1], D. Levy[1].* 1) Division of Intramural Research, National Heart, Lung and Blood Institute; the NHLBI's Framingham Heart Study; 2) Mathematical and Statistical Computing Laboratory, Division of Computational Bioscience, Center for Information Technology, NIH; 3) Department of Mathematics and Statistics, Boston University, Boston, Massachusetts;.

Genome-wide expression quantitative trait locus (eQTL) mapping studies reveal common genetic variants regulating gene expression. In addition to mapping eQTLs, we systematically evaluated the heritability (h^2) of the whole blood transcriptome in Framingham Heart Study (FHS) families, and explored the proportion of the heritability of gene expression explained by *cis*- and *trans*- components, as a means of identifying the role of eQTLs in promoting phenotype differences and disease susceptibility. Peripheral whole blood samples were collected and large-scale transcriptomic microarray measurements were performed on 5,626 FHS participants. The pedigree structure consisted of 704 extended pedigrees (of size ≥2) from two-generations of FHS participants. Heritability estimates of ~18,000 transcripts were obtained by variance-component methodology. Of all transcripts, about 40% displayed heritability $h^2>0$ with $p<0.05$, and 10% displayed $h^2>0.2$ ($p <$ 1.8e−6). We then investigated the proportion of *cis*-/*trans*- eQTLs in each of the heritability categories at h^2 = 0.2-0.29, 0.3-0.39, 0.4-0.49, 0.5-0.59 and ≥0.6. We discovered that transcripts with higher heritability estimates tended to have larger proportion of *cis*-eQTLs. In contrast, there was no apparent trend for the proportions of *trans*-eQTLs in the different heritability categories. In addition, we discovered that single *cis*-eQTLs explain 27-68% of variance in gene expression levels with $h^2>0.2$. However, *trans*-eQTLs only account 1-6% of variance in transcripts with $h^2>0.2$. Interestingly, we observed that the top *cis*-eQTL tended to explain more variance in the respective transcript as the heritability of the transcript increased, but the top *trans*-eQTL tended to explain more variance in the respective transcript when the heritability of the transcript decreased. By cross-linking the eQTLs with GWAS results of multiple metabolic traits, we discovered that a few trait-associated GWAS single nucleotide polymorphisms (SNPs) explained a large proportion of genetic variance in multiple transcripts, although these SNPs only explained a small proportion of phenotypic variance for the metabolic traits. Using body mass index and blood pressure as case studies, we found that several differentially expressed genes were associated with the same GWAS SNPs. These gene signatures explained a larger proportion of variance in the respective traits than did the GWAS SNPs.

Cis and Trans Effects of Human Variations on Gene Expression. *J. Bryois[1,2,3], A. Buil[1,2,3], D.M. Evans[4,5], J.P. Kemp[4,5], S.B. Montgomery[1,7], D.F. Conrad[6], K.M. Ho[5], S. Ring[5], M. Hurles[6], P. Deloukas[6], G.D Smith[4,5], E.T Dermitzakis[1,2,3].* 1) Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 2) Institute of Genetics and Genomics in Geneva (iGE3), Geneva, Switzerland; 3) Swiss Institude of Bioinformatics (SIB), Geneva, Switzerland; 4) MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, Bristol, United Kingdom; 5) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 6) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 7) Departments of Pathology and Genetics, Stanford University, Stanford, California, United States of America.

Gene expression is a heritable cellular phenotype that defines the function of a cell and can lead to diseases in case of misregulation. In order to detect human variations affecting gene expression, we performed genome-wide association analysis of single nucleotide polymorphisms (SNPs) and copy number variants (CNVs) with gene expression measured in 869 lymphoblastoid cell lines in cis and in trans. Using a threshold defined by permutations, we discover that 3925 genes (false discovery rate (FDR)=4%) are affected by an expression quantitative trait locus (eQTL) in cis and 83 genes (FDR<20%) are affected in trans. We found that CNVs are more likely to be eQTLs than SNPs (odd ratio for cis-eQTLs=7.62 (pval<2.2e−16), odd ratio for trans-eQTL=44.1 (pval=1.7e−7)). In addition we found that GWAS SNPs are enriched for cis and trans eQTLs (pval<0.01) and that trans-eQTLs are enriched for cis-eQTLs (pval<0.01). As a variant affecting both a gene in cis and in trans suggests that the cis gene is functionally linked to the trans gene expression, we looked specifically for trans effects of cis-eQTLs. We estimated the proportion of probes affected by each cis-eQTL from the pvalue distribution of their trans effects and discover that many of them have pleiotropic effects. Using a threshold defined by permutations, we found that 51 cis-eQTLs are associated to 151 genes in trans (FDR<11%) with the cis-eQTLs of the transcriptions factors BATF3 and HMX2 affecting the most genes with 54 and 23 genes affected respectively. We then explored if the variation of the level of expression of the cis genes were causally affecting the level of expression of the trans genes using Bayesian networks and a causal inference test. We discover 19 causal relationships between variation in the level of expression of the cis gene and variation of the level of expression of the trans gene. However, most of the trans associations (73.8%) are independent of the cis gene expression, implying that the trans associations are due to other functional variants in linkage with the cis-eQTLs or through other functional elements regulated in cis. This analysis shows that a large sample size allows the discovery of secondary effects of human variations on gene expression that can be used to construct short directed gene regulatory networks.

644W

Common genetic variation within transcription factor binding sites is associated with bipolar disorder. *D.T.W. Chen[1], N. Akula[1], L. Hou[1], L. Jing[1], G. Hawariat[1], S. Detera-Wadleigh[1], X. Jiang[1], BiGS. Consortium[2], F.J. McMahon[1].* 1) Human Genetics Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, MD; 2) Department of Psychiatry, University of San Diego, La Jolla, CA 92093-0603.

Genome-wide association studies (GWAS) have uncovered a number of loci associated with bipolar disorder (BD), but functional alleles have not been identified. Some GWAS signals may reflect genetic variation in sequences regulating gene expression via binding of transcription factors (TFs). This study tested the hypothesis that signals obtained via GWAS reflect genetic variation in transcription factor binding sites (TFBS). Genetic association data were extracted from a meta-analysis of worldwide GWAS in BD comprising ~14,000 cases/controls. This set of 700,000+ single nucleotide polymorphisms (SNPs) was mapped onto published TFBS identified in human lymphoblastoid cells. GWAS signal enrichment near TFBS was tested with the Kolmogorov-Smirnov (K-S) rank-sum statistic. Biological function of the TFBS was explored by use of the bioinformatics tools INRICH, GREAT, and DAVID. Significant enrichment of GWAS signals (empirical p= 9.1×10-3) was noted among SNPs near TFBS. This enrichment was not attributable to linkage disequilibrium between SNPs, or differing allele frequency spectra among SNPs detected in the GWAS. Genes nearest these SNPs significantly clustered into relatively few functional pathways. This clustering was not due to gene size or variable assignment of SNPs to nearby genes. Eight genes emerged most often (CAMK2G, ERN1, DDR1, MAP3K5, MAP4K5, MARK2, RAF1, BMPR1A); four of which encode proteins in the serine/threonine-protein kinase pathway. These findings suggest that regulation of gene expression by transcription factors plays an important role in the genetic etiology of bipolar disorder.

645T

Effect of Transcription Factor Binding Variation Depends on Genomic Context. *D.A. Cusanovich[1], B. Pavlovic[1,2], J.K. Pritchard[1,2], Y. Gilad[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Howard Hughes Medical Institute, University of Chicago, Chicago, IL.

A major goal of human genetics is to understand the regulatory logic of transcription factors (TFs) binding to DNA, namely TF-DNA interactions that result in functional output. Research in this field to date has largely relied on DNA sequencing technologies (e.g. ChIP-seq, DNase-seq, etc.) to determine transcription factor binding locations and the chromatin modifications associated with such binding. However, factors are often bound throughout the genome and it is unclear to what extent transcription factor binding influences gene expression levels at a given locus. In order to better tease apart the genomic context of functional transcription factor binding, we knocked down 59 different TFs using RNA interference and measured the resulting global gene expression levels in a Yoruba HapMap lymphoblastoid cell line. The number of genes differentially expressed (DE) in each of the knockdown experiments ranged from 39 to nearly 4,000 (FDR = 0.05). We intersected the gene expression data with transcription factor binding data from previous studies to identify functionally relevant binding events. As expected, we found that only a subset of genes whose regulatory regions were bound by a TF were measurably perturbed by the knockdown of the TF. On average, 14.3% of bound genes were differentially expressed in the knockdown experiments. Using annotations of chromatin states across the genome, we determined that genes identified as differentially expressed in a particular factor knockdown were likely to have that factor bound in a nearby enhancer (e.g. adjusted P-value = 1.2×10^{-4} for the *IRF4* knockdown) and were unlikely to have that factor bound in an active promoter (e.g. adjusted P-value = 4.9×10^{-3} for the *RELA* knockdown). These results were consistent across multiple factors and suggest a model whereby factor binding to a genomic location otherwise marked as an active enhancer is likely to contribute to gene expression regulation and binding at a promoter may be robust to changes in factor concentration in the cell. In conclusion, these experiments give us insight into the role of DNA binding factors in determining gene expression levels and knowledge of both their direct and indirect targets.

646F

Localizing ancient causal regulatory variants from global genetic analyses of gene expression. *M.K. DeGorter[1,2], S.B. Montgomery[1,2].* 1) Department of Pathology, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA.

The availability of dense genetic and gene expression data from diverse human populations, when combined with rich epigenomic data, provides new opportunity to localize ancient causal regulatory variants. Specifically, by taking advantage of the divergent haplotype structure of diverse populations, we are able to more precisely map causal variants whose functional mechanism can then be determined. Using dense genetic data for 540 individuals representing seven populations, we identify shared *cis*-expression quantitative trait nucleotides (*cis*-eQTN) between populations. In particular, we combine 2.2 million phased SNPs (Illumina Omni2.5 BeadChip) genotyped by the 1000 Genomes Project and gene expression data obtained from lymphoblastoid cell lines using the Human-6 Expression BeadChip (v2) to discover *cis*-eQTN. These shared *cis*-eQTN are then intersected with data from the Encode project to elucidate their overall enrichment in functionality and their specific mechanistic roles. Furthermore, shared variants are intersected with GWA data to illuminate particular disease-predisposing variants that have escaped purifying selection. This activity provides enhanced resolution of causal regulatory variants and genes that have remained polymorphic since early out-of-Africa migration.

Regulatory Function of *CACNA1C* Schizophrenia-Associated Variants. *N. Eckart[1], R. Wang[2], M. Szymanski-Pierce[1], M. Zeledon[1,2], S. Goswami[2], D. Valle[1], D. Avramopoulos[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD.

Schizophrenia (SZ). is a complex psychiatric disorder affecting approximately 1% of the population with an estimated heritability between 70-90%. Genome wide association studies have identified many potential susceptibility variants for SZ, some of which have also been shown to be associated with Bipolar Disorder (BP). One such variant, rs1006737 in an intron of the CACNA1C gene, has been reported to be associated with both disorders. Two others in the same gene, rs7972947 and rs4765913, have been reported to be associated with SZ or BP. However, little is known about the identity of the causative variants and the mechanisms by which they contribute to pathogenesis. Because these variants are in non-coding regions, we hypothesized that they contribute to disease by disrupting normal regulation of gene expression. To test this hypothesis, we genotyped the three variants with Taqman assays and used RT-qPCR to measure expression of 3 alternative transcripts of CACNA1C in postmortem superior temporal gyrus (STG) brain samples from pathology-free controls. Then, we used generalized linear models to identify correlations between genotype and transcript levels. We found that the minor allele of rs1006737 is associated with decreased abundance of all CACNA1C transcripts in the STG. To identify the functional variant(s) underlying this effect, we made a series of dual luciferase constructs for all SNPs tagged by rs1006737 with an r2 > 0.80 and included approximately 1kb of genomic context in each case. Dual luciferase reporter assays in two cell types showed that 4 of the 12 genomic loci harboring tagged variants had statistically significant allele-specific effects on luciferase expression. Furthermore, electrophoretic mobility shift assays (EMSAs) showed that 4 of the 6 SNPs included in these 4 constructs also have allelic differences in binding protein complexes from nuclear extracts of the same cell lines. From this data, we conclude that rs1006737, the non-coding variant in CACNA1C that is associated with both SZ and BP, marks a regulatory haplotype that differentially affects the expression of multiple CACNA1C transcripts in the STG. The presence of multiple functional variants in the haplotype raises many interesting questions. Further planned studies include identification of the proteins that bind the regulatory elements in an allele specific manner and characterization of any complex chromatin interactions that mediate the observed effects.

Extensive Variation in Chromatin States Across Human Individuals and Populations. *F. Grubert[1], M. Kasowski[1], S. Kyriazopoulou-Panagiotopoulou[2], J. Zaugg[1], A. Kundaje[3], Y. Liu[4], A. Boyle[1], Q. Zhang[1], F. Zakharia[1], D. Spacek[1], J. Li[1], D. Xie[1], L. Steinmetz[1,5], M. Kellis[3], S. Batzoglou[2], M. Snyder[1].* 1) Dept Genetics, Stanford University, Stanford, CA; 2) Department of Computer Science, Stanford University, CA; 3) Department of Computer Science, Massachusetts Institute of Technology, Cambridge MA; 4) Department of Chemistry, Stanford University, Stanford, CA; 5) Genome Biology EMBL Heidelberg, Germany.

The vast majority of disease-associated variants identified by GWAS lie outside protein-coding regions, suggesting that variation in regulatory regions may play a major role in disease predisposition. Here, we study differences in chromatin states using six histone modifications, cohesin, Pol2 and CTCF in lymphoblastoid lines from 19 individuals of diverse ancestry. We find extensive signal variation in regulatory regions as well as switches of chromatin state across individuals, most frequently between active and repressed states. Enhancer activity is particularly diverse among individuals, and is strikingly divergent across populations. Consistently, chromatin marks show strong inheritance in family trios. Overall, our results provide fundamental insights into epigenetic differences of humans and how regulatory elements might evolve within a species.

649F

Identification of enhancer-promoter interactions in the mammalian genome. *Y.-C. Hwang[1], Q. Zheng[2,4], C.-F. Lin[3,5], O. Valladares[3,5], B.D. Gregory[1,2,4], L.-S. Wang[1,3,4,5].* 1) Genomics and Computational Biology Graduate Program, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Biology, University of Pennsylvania, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Penn Genome Frontiers Institute, University of Pennsylvania, Philadelphia, PA; 5) Institute for Biomedical Informatics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Genome-wide association studies have shown the majority of disease-associated DNA variations are within non-coding DNA regions and gene deserts. One of class of DNA regulatory element that is non-coding in nature is enhancer elements. Because an enhancer element can be distal and orientation-independent from the gene it regulates, probing all possible pairs of DNA-DNA contacts could be extremely laborious. In order to systematically uncover the enhancer-target gene interactions in mammalian cells, we reanalyzed published Hi-C data from human (e.g. LCL, K562, hESC, and IMR90) and mouse cells (mESC and cortex), with read depths spreading from 60M to 1612M. We applied a geometric distribution-based analysis pipeline to identify DNA interacting hotspots within the Hi-C datasets. By further classifying these Hi-C interaction hotspots, we then identified candidate enhancer elements as hotspots overlapping known enhancer-associated histone modifications from ENCODE and interacting with a promoter element. In addition, we implemented a streamlined analysis pipeline to ensure that this information can be quickly and efficiently extracted from all future Hi-C datasets, which uses a set of Hi-C paired-end FASTQ files as input. The pipeline automates the analyses from mapping the reads, identifying hotspots, detecting hotspot interactions, to identifying enhancer-target gene pairs by incorporating also commonly mapping softwares such as BWA, samtools, bedtools. All analysis commands are generated automatically by the pipeline, including job submission, controlled job dependencies and error checking. The pipeline efficiently functions on Oracle Grid Engine allowing jobs to be parallelized. Using our pipeline, we have identified 159,522 to 449,124 Hi-C hotspots and thousands of enhancer-target gene interactions throughout the human and mouse genomes. Additional genomics evidence supports these findings: these identified enhancers are 6- to 17-fold enriched in p300 binding sites and their target promoters are 1.2 to 1.5-fold more likely to be near RNA polymerase II binding sites. We also discovered that the enhancer-regulated genes tend to express in a tissue-specific manner. Using these comprehensive enhancer-target promoter datasets will allow us to identify disease-linked polymorphisms that lie within these regulatory elements, as well as study the evolutionary conservation of enhancer-target gene pairs between human and mouse.

Small introns of firefly luciferases: structural characterization and their insufficient substrates for splicing in CHO cells. *M. Ishii[1,3], R. Kojima[1], S. Fukuda[1], Y. Tanji[1], M. Sakaguchi[1], Y. Sugahara[1], M. Kamaya[2,3], F. Oyama[1,3].* 1) Biotechnology Laboratory, Department of Applied Chemistry, Faculty of Engineering, Kogakuin Univ, Hachioji, Tokyo 192-0015, Tokyo, Japan; 2) Enviroment Analytical Chemistry Laboratory, Department of Environmental and Energy Chemistry, Faculty of Engineering, Kogakuin Univ, Hachioji, Tokyo 192-0015, Tokyo, Japan; 3) The Firefly-Breeding Project at Hachioji Campus, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan.

Most eukaryotic genes contain segments of coding sequences (exons) interrupted by noncoding sequences (introns). Introns are removed through splicing, which is nearly universal in eukaryotes. However, the general function and evolutionally importance of introns remains unclear. We cloned and sequenced the genomic and cDNA clones encoding luciferase in the Japanese firefly, Luciola cruciata. The luciferase genes contained six introns, all of which were very short (less than 100 bases long). We also found that mouse acidic mammalian chitinase (AMCase) possessed the small intron (intron 9, 86 bases long). We carried out comparative analyses and subsequent the structural characterization of the small introns. Although the GT and AG dinucleotides at the 5' and 3' splice sites and an A nucleotide required for branch point formation were conserved in the introns of the firefly luciferase gene, they were characterized by a high A+T content (70–80% average) and lacking the pyrimidine tract located between the branch point and 3' splice site, which were observed in the small intron of the AMCase. The luciferase gene (with 6 introns) and cDNAs (without introns) were inserted into mammalian expression vectors and transiently expressed in CHO cells respectively. Western blot analysis and photoluminescence measurement indicated that the luciferase gene didn't express functional luciferase in the CHO cells, whereas cDNA did. RT-PCR analysis also showed that all of firefly introns didn't be spliced from pre-mRNA transcribed the luciferase gene. These results suggest that there are different mechanisms in splicing and splicing factors between insect and mammal.

651T

A comprehensive genomic landscape of NRSF binding in various cell types. *P. Jain, FP. Behn, GM. Cooper, RM. Myers.* HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Neuron Restrictive Silencing Factor (NRSF/REST) is a master regulator of neuronal genes and is dysregulated in various neurodegenerative diseases and cancers. To more comprehensively understand the roles of NRSF, we have used ChIP-seq, RNA-seq, DNA Methylation (Reduced Representation for Bisulphite Sequencing), DNAse I hypersensitivity, and histone modifications assays for genome wide mapping of regulatory profiles of NRSF and its cofactors within multiple cell lines. We also leveraged ENCODE data to systematically compare NRSF binding activity with binding of dozens of other transcription factors. We have identified key components of differential regulation of target genes by NRSF. We find that NRSF repression function is greatly influenced by other co-binding TFs and not restricted to its known cofactors like sin3a and CoREST. The data suggest that co-occupancy of other TFs with NRSF reduces NRSF repression activity, with transcriptional repression usually observed only in the absence of co-factor binding. Additionally, higher levels of DNA methylation at NRSF target genes coincide with lower expression. We also find that NRSF motif conservation is very high within binding sites near repressed genes. Our data suggest that while NRSF binds widely in human cells, only a small subset of target genes, that tend to also be methylated, have highly conserved motifs, and be depleted for binding of other TFs, are actually repressed by NRSF. This conclusion poses interesting questions as to the nature and consequences, or lack thereof, of most NRSF binding activity in human genomes.

652F

Distal co-regulated regions are crucial for human phenotypes. *K.J. Karczewski[1,2], A. Battle[3], D. Knowles[3], M. Snyder[1], S.B. Montgomery[1,4].* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Program in Biomedical Informatics, Stanford University School of Medicine, Stanford, CA; 3) Department of Computer Science, Stanford University, Stanford, CA; 4) Department of Pathology, Stanford University School of Medicine, Stanford, CA.

The human genome is a complex and efficiently-packed system, where regions on different chromosomes may be close to each other in conformational space and thus, may be co-regulated. However, accurate detection and functional characterization of these interactions has been difficult: large sample sizes are required to discover trans eQTLs, while long-range interaction data, such as Hi-C, do not provide a functional framework. Characterizing the layout and interplay between these regions will be crucial for understanding protein function, and thus, human phenotypes and disease. Previously, the most common model for long-range associations has involved SNPs affecting transcription factor function, which then modulate transcription in trans, as seen in model organism trans-eQTL studies. However, direct contact may be an additional unexplored component to this type of regulation. Using trans-eQTL and Hi-C data, we observe that reciprocally regulated inter-chromosomal regions are enriched for co-localization in 3-D conformational space. We investigate the properties of these reciprocally regulated regions, compared to known cis and trans eQTLs. Additionally, these regions are enriched for shared functions as well as shared disease associations. Finally, we investigate the role of these regions on allele-specific expression and highlight a sequencing-based validation strategy. Our data suggest that long-range regulation is crucial for understanding the complexity of human phenotypes.

653W

Regulatory motif centric validation, dissection, and construction of transcriptional enhancers. *P. Kheradpour[1,2], J. Ernst[1,2,3], A. Melnikov[2], P. Rogov[2], L. Wang[2], X. Zhang[2], J. Alston[2], T.S. Mikkelsen[2], M. Kellis[1,2].* 1) MIT Computer Science and Artificial Intelligence Lab, Cambridge, MA; 2) Broad Institute, Cambridge, MA; 3) UCLA Department of Biological Chemistry, Los Angeles, CA.

Large scale studies have associated thousands of variants with phenotypes. However, due to genomic linkage structure, only a fraction of these variants likely play a causative role. While variants that may affect protein coding sequences can be computationally predicted, identifying variants with regulatory effect is much more difficult. To assess the feasibility of introducing variants and measuring the regulatory , we predicted causal regulators and employed a large-scale experimental approach to validate their instances. Using motif enrichments and depletions in ENCODE candidate enhancer regions, we predicted five activators (HNF1, HNF4, FOXA, GATA, NFE2L2) and two repressors (GFI1, ZFP161) to be active in K562 and HepG2 cell lines. We synthesized and performed a massively parallel reporter assay (MPRA) on 2,104 wild-type sequences centered on motif instances for these factors and an additional 3,314 engineered enhancer variants containing targeted motif disruptions.

We find robust evidence that activator motif disruption, even with just 1-bp changes, abolishes enhancer function, while silent or motif-improving changes do not. We also find that evolutionary conservation, nucleosome exclusion, motifs for other factors, and strength of the motif match predict sequences whose manipulation would result in less enhancer activity. Moreover, we found that scrambling repressor motifs leads to aberrant reporter expression.

We then swapped the motif with variable surrounding context for the ten most expressed sequences for each of four of the tested activators. We found that the context plays a significant cell type specific role. We also examined the role of regulatory motifs in promoters by testing evolutionarily conserved instances for 70 factors. We found that these instances appears to be considerably less cell type specific, suggesting they may be easier to experimentally dissect because identifying a relevant cell type may be less vital.

654T

Discovery and analysis of over 50,000 common functional regulatory variants in the human genome. *M.T. Maurano, E. Haugen, E. Rynes, R. Humbert, J.A. Stamatoyannopoulos.* Department of Genome Sciences, University of Washington, Seattle, WA.

Common disease- and trait-associated variants preferentially localize in regulatory DNA marked by DNaseI hypersensitive sites. Here we perform genomic footprinting across 81 cell types, and show that high density, allelically resolved in vivo DNaseI cleavage mapping can systematically delineate functional regulatory variants on a large scale. We identified 348,521 heterozygous variants in regulatory regions, of which 50,936 mark significantly altered chromatin accessibility in vivo. Of these, 15.5% lie in promoters, and the remaining majority are in distal enhancer regions. Functional variants systematically perturb the recognition sequences of hundreds of individual transcription factors. We show that these variants can be used to functionally map the in vivo protein-DNA interface, providing a new and powerful code for accurately interpreting the functional significance of noncoding regulatory variation.

655F

The Impact of Post-Mortem Sample Collection on Gene Expression in the Genotype-Tissue Expression Project. *T.R. Young, D.S. DeLuca, G. Getz, K. Ardlie, The GTEx Consortium.* The Broad Institute of MIT and Harvard, GTEx Project, Cambridge, MA.

The Genotype-Tissue Expression project (GTEx) is creating a vast public resource for the study of gene expression in up to 30 human tissues using tissue samples collected from deceased donors. Although GTEx samples are collected within 24 hours of death, RNA degradation throughout the post-mortem interval (PMI) is a key concern of the project. While some studies report that post-mortem tissue can yield high quality RNA and retain biologically relevant gene expression profiles, others report alterations in the expression profiles of some genes measured in post-mortem vs. premortem tissue. Using publicly available gene datasets from the GTEx Pilot Study and the Gene Expression Omnibus (GEO), we have attempted to characterize the impact of PMI on the gene expression profiles of GTEx samples. In order to assess how well the GTEx samples represent the gene expression patterns of samples collected from living donors we performed a metagene projection as described by Tamayo and colleagues. Here, we first train a support vector machine (SVM) classifier on the GTEx expression data and then use the SVM to predict the tissue type of 532 GEO samples from 23 GEO datasets. We examined the changes in gene expression patterns that accrue during the post-mortem interval via differential gene expression analyses on two sets of GTEx samples: pre-mortem vs. postmortem blood and low-PMI vs. high-PMI muscle. Finally, we investigated the suitability of GTEx data for expression Quantitative Trait Loci (eQTL) analysis by attempting to replicate known tissue-specific eQTLs within the GTEx Pilot Study. The metagene projection was highly accurate in classifying GEO samples indicating that the biologically relevant expression patterns are retained. In contrast, differential expression analyses identified several thousand differentially expressed (DE) genes and subsequent GO enrichment revealed DE gene sets unique to each tissue type. After correcting for the first principal component of the gene expression data, which is highly correlated with PMI, we were able to replicate the majority of known eQTLs. These results indicate that although post-mortem collection does alter the gene expression profiles of GTEx samples, the samples remain highly representative of living tissue.

Human Transcriptome Landscape Characterized by Deep RNA Sequencing in 957 Individuals. *x. zhu[1], S. Mostafavi[2], A. Battle[2], K. Beckman[3], C. Haudenschild[4], C. McCormick[4], D. Koller[5], AE. Urban[1,5], DF. Levinson[1], SB. Montgomery[5,6].* 1) Psychiatry, Stanford University, Palo Alto, CA; 2) Computer Science Department, Stanford University, Palo Alto, CA; 3) Biomedical Genomics Center, University of Minnesota, Minneapolis, MN; 4) DNA sequencing services, DNA Sequencing Business, Illumina, Inc. Hayward, CA; 5) Deparment of Genetics, Stanford University, Palo Alto, CA; 6) Department of Pathology, Stanford University, Palo Alto, CA.

Various RNA species represent the direct interpretations of genetic information in a cell: they convey the message from DNA to proteins, as well as perform regulatory roles such as catalyzing biological reactions, controlling gene expression, or participating signal transduction. The recent ENCODE project reported a complete catalogue of transcribed regions based on 15 human cell lines, including polyadenylated (poly-A) and non-poly-A RNA, long and short fragments within various cellular compartments. While being highly dynamic in terms of expression levels, cellular localization and isoform compositions, around ~75% of the human genome can be transcribed, which is much higher than the previous estimate. Despite the recent progress in deciphering novel transcription activities, however, the functional levels of these new transcripts remains unclear, due to limited number of test subjects and extremely low expression levels. Our group expanded the study into a much larger cohort of 957 individuals with European-ancestry from two primary tissues: 922 fresh whole blood and 35 brain specimens. All subjects were genotyped and their polyadenylated RNA molecules were studied with high depth sequencing (~ 70 million reads). New algorithms were developed to account for the stochastic noises in the transcription machinery and the sequencing experimental procedures. We then carried out a systematic characterization for a number of novel transcription events: 1) candidate novel exons as intronic elements expressed and spliced to nearby exons 2) alternative splicing 3) alternative 5' untranslated region (5' UTR) and upstream open reading frames (uORF) 4) alternative 3' untranslated region (3' UTR) and polyadenylation sites 5) Large intergenic non-coding RNAs (lincRNA) and 6) viral RNA expression. In addition to compile these findings to a new catalogue, we also studied the expression quantitative trait loci (eQTLs) that are associated with the newly defined transcription events. Together with a number of other features such as evolutionary conservation scores, we were able to estimate the functional levels of the new transcripts. The recent population genetic studies have discovered a great number of genetic variations that may contribute to disease phenotypes. Our study focused on an extensive characterization on the intermediate message layer, and this will help us to further understand the connections between genotypes and phenotypes.

657T

Chromatin enhancer maps in early differentiating T helper cells reveal regulatory SNPs associated with autoimmune diseases. *D. Hawkins[1], A. Larjo[2], S. Tripathi[3], U. Wagner[4], Y. Luu[4], S. Raghav[3], L. Lee[4], S. Raghav[3], R. Lund[3], B. Ren[4], H. Lahdesmaki[2], R. Lahesmaa[3].* 1) Medicine and Genome Sciences, University of Washington, Seattle, WA; 2) Department of Information and Computer Science, Aalto University, Aalto, FI; 3) Turku Centre for Biotechnology, Turku, FI; 4) Ludwig Institute for Cancer Research, Department of Molecular and Cellular Biology, UCSD, San Diego, CA.

Naïve CD4+ T cells can differentiate into specific helper and regulatory T cell lineages in order to combat infection and disease. The correct response to cytokines and a controlled balance of these populations is critical for the immune system and the avoidance of autoimmune disorders. To investigate how early cell fate commitment is regulated, we generated the first human genome-wide maps of histone modifications that reveal enhancer elements after 72 hrs of in vitro polarization toward T helper-1 (Th1) and T helper-2 (Th2) cell lineages. Our analysis indicated that at this very early time point, cell-specific gene regulation and enhancers are at work directing lineage commitment, and likely opposed a role in cell maintenance as in fully differentiated cells. We determined a unique set of enhancer elements relative to recent ENCODE data in fully differentiated cells. Nucleosome-free regions were determined within enhancer chromatin structures. Examination of enhancers at nucleosome resolution identified transcription factor binding site (TFBS) motifs for expressed TFs with known and unknown T cell roles as putative drivers of lineage-specific gene expression.

An integrative analysis of immunopathogenic associated single nucleotide polymorphisms (SNPs) suggests a role for distal regulatory elements in disease etiology. We found SNPs overlapping enhancers associated with asthma, Crohn's disease, multiple sclerosis (MS), psoriasis, rheumatoid arthritis (RA), type 1 diabetes (T1D) and ulcerative colitis. Guided by the motif analysis, we used DNA Affinity Precipitation Assays (DAPA) to determine if autoimmune disease-associated SNPs overlapping TFBS motifs could disrupt TF binding. We successfully found that individual SNPs associated with rheumatoid arthritis, type 1 diabetes and ulcerative colitis are enough to disrupt TF binding at enhancer sequences.

Lastly, we are using computational approaches to predict target genes of enhancers that overlap autoimmune disease-associated SNPs. We are also mapping histone modifications to find novel or alternative promoters that may also overlap associated SNPs. Collectively, our approach sheds new light on the functionality of non-genic disease-associated SNPs and begins to provide novel insight on the etiology autoimmune diseases.

658F

Analysis of allele specific expression in mouse liver by RNA-Seq: marked differences compared to cis-eQTL identified using genetic linkage. *P.-F. Roux[1, 2, 3], S. Lagarrigue[1, 2, 3], L. Martin[4], F. Hormozdiari[5, 6], A. van Nas[6], O. Demeure[1, 2, 3], A. Ghazalpour[6], E. Eskin[5, 6], A.J. Lusis[4, 6, 7].* 1) INRA, UMR1348 Pegase, Rennes, France; 2) Agrocampus Ouest, UMR1348 Pegase, Rennes, France; 3) Université Européenne de Bretagne, France; 4) Department of Medicine/Division of Cardiology, University of California, Los Angeles, United States of America; 5) Department of Computer Sciences, University of California, Los Angeles, United States of America; 6) Department of Human Genetics, University of California, Los Angeles, United States of America; 7) Department of Microbiology, Immunology and Molecular Genetics, University of California, Los Angeles, United States of America.

We report an analysis of allele specific expression [ASE] and parent-of-origin expression in adult mouse liver using next generation sequencing (RNA-Seq) of reciprocal crosses of heterozygous F1 mice from the parental strains C57BL/6J and DBA/2J. The genes exhibiting ASE differed markedly from the putative cis-acting expression quantitative trait loci (cis-eQTL) identified in an intercross between the same strains. While about 60% of the ASE, mapped by RNA-Seq, were found in the eQTL gene set, only a small fraction of the eQTL, mapped by linkage analysis, were found in the ASE gene set. We discuss the various biological and technical factors that contribute to these differences, in particular strengths of the two approaches in making a distinction between local and cis eQTL.

We also identify genes exhibiting parental imprinting and complex expression patterns. Our study demonstrates the importance of biological replicates, which is not currently the norm, to limit the number of false positives with such RNA-Seq data.

659W

A large-scale transcriptome study in the Sardinian population. *M. Pala[1,2,6], M. Marongiu[2], Z. Zappala[1], A. Mulas[2], R. Cusano[2], F. Crobu[2], F. Reinier[3], R. Berutti[3,6], M.G. Piras[2], C. Jones[3], D. Schlessinger[5], G. Abecasis[4], A. Angius[2], S. Sanna[2], F. Cucca[2,6,7], S. Montgomery[1,7].* 1) Pathology and Genetics Dept, Stanford University, Stanford, CA; 2) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, 09042, Italy; 3) CRS4, Advanced Genomic Computing Technology, Pula, Italy; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 5) Laboratory of Genetics, National Institute on Aging, Baltimore, Maryland, USA; 6) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy; 7) co-senior authors.

The interpretation of genome-wide association studies (GWAS) is very challenging since most candidate loci fall in non-coding regions and are difficult to interpret. Given the important role of regulatory variation in phenotypic complexity, expression quantitative trait loci (eQTLs) have been proposed as an informative intermediate phenotype between genetic variation and human disease. To study the role of transcriptional mechanisms on regulating eQTL targets, we sequenced the polyA RNA fraction of peripheral blood mononuclear cells (PBMCs) isolated from 624 related individuals (259 families). These individuals had been subject to whole genome sequencing and characterized for more than 800 quantitative traits (including > 250 immune cell traits) by the SardiNIA project. To assess the impact of eQTLs on lincRNAs, we also sequenced the RNA of a subset of 80 individuals after ribosomal RNA depletion. Our preliminary results show that the expression levels of 10,389 genes are associated with a genetic variant (top SNP with p-value $\leq 10^{-8}$ uncorrected), 40 of which are present in the GWAS catalog. We also assessed splicing events and identified 27,904 donor splice sites that are associated with a genetic variant (top SNP with p-value $\leq 10^{-8}$ uncorrected), of which only 4 are present in the GWAS catalog. Using a subset of 68 individuals, we identified 9,427 heterozygous sites which show allele-specific expression (p-value $\leq$ 0.05) 39 of which show high allelic imbalance (a mean of 0.80 for the most expressed allele) and low variability between individuals. These sites are enriched for missense variants and located near genes implicated in disease. In addition, we developed a statistical method to identify genes that are specifically and significantly over or under expressed within single families compared to the majority of the population. We identified 39 genes that have family specific expression (p-value $\leq$ 0.01; FDR 0.462). Interestingly, these genes are also enriched for rare variants within 70kb upstream of their transcriptional start site, and we hypothesize that they may have a role in rare diseases. We are now extending these analyses to the entire cohort and will present these analyses. Our goal is to identify associations between genotype and gene expression in order to enhance our overall understanding of gene regulation and correlate these molecular events with clinical data in order to characterize their role in phenotypic complexity and disease.

660T

ChIP-Enrich analysis of ENCODE ChIP-seq data reveals biological and technical insights into the regulation of pathways. *M.A. Sartor[1,2], R.G. Cavalcante[1], C. Lee[1], N.A. Comment[1], S. Ramdas[1,4], N.M. Dehaan[3], R.P. Welch[2], S. Patil[1], L.J. Scott[2].* 1) Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI., USA; 2) Biostatistics, University of Michigan, Ann Arbor, MI., USA; 3) Environmental Health Sciences, University of Michigan, Ann Arbor, MI., USA; 4) Human Genetics, University of Michigan, Ann Arbor, MI., USA.

A given transcription-related factor (TRF) can bind and influence similar or disparate sets of genes in different cell types. Furthermore, a TRF may regulate the same pathway in multiple cell types by regulating different genes with similar functions. Regulation of similar pathways via different genes may not be detected through assessment of overlapping peaks or target genes. An alternative method to assess differences in TRF binding patterns across cell types is to use gene set enrichment testing to detect biologically relevant pathways or processes. Using ChIP-Enrich, which empirically adjusts for potential confounding by the locus length (the length of the gene body and its surrounding non-coding sequence), we examined ChIP-seq data from four Tier 1 or 2 cell lines from ENCODE (K562 (leukemia), GM12878 (lymphoblastoid), H1-hESC (embryonic stem cells), and HeLaS3 (epithelial carcinoma)), and eight TRFs (GABP, JunD, MAX, MXI1, cMyc, NRSF, POL2, and TBP). We compared the p-values for gene set enrichment across cell types for each TRF by assessing the strength of the correlation between -log10 p-values from each TF between each pair of cell types, and identifying common and cell type-specific pathway regulatory activity. We found similar patterns of gene set enrichment for most TRFs, with POL2 having the highest concordance (Pearson's r = 0.78 - 0.95) among the four cell types. In contrast, H1-hESC had the most tissue-specific enrichment, most strikingly for NRSF (Pearson's r = 0.058 - 0.20) with the 3 other cell types. And overall, NRSF had the lowest correlation across cells types (r= 0.058 - 0.77). The two carcinoma cell lines (K562 and HeLaS3) showed greatest correlation (r= 0.82 - 0.95) for 5 of the 8 TRFs (GABP, MAX, MXI1, POL2, and TBP) even though these two cell lines are derived from different types of cancer. We are investigating the sensitivity of these findings to differences in number of peaks and peak calling algorithms as we have seen in other ENCODE data that use of MACS tends to result in more powerful enrichment testing results than use of spp, and that including more peaks (using a less stringent cutoff) generally results in more powerful enrichment results. In summary, we find that cell type-specificity of regulation can vary widely by TF but that similar cells have more similar patterns of enrichment. The use of gene set enrichment testing can shed light on the tissue-specificity of regulatory networks of TRFs.

Establishing an eQTL map of the Japanese population. *M. Narahara, F. Matsuda, K. Higasa, Y. Tabara, T. Kawaguchi, R. Yamada.* Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Variation in gene expression is one of the major factors that lead to phenotypic variation and disease susceptibility. Many loci identified by genome-wide association studies (GWAS) are located in non-coding regions, which suggests the importance of transcript differences regulated by genetic variations on phenotypic variations. Expression quantitative trait loci (eQTL) mapping is an approach to locate genetic loci that regulate transcription. Genome-wide eQTL map can significantly improve our understanding of local and distal genetic transcriptional regulation, and improve interpretability of results of GWAS. Establishing ethnic-specific eQTL map is of great necessity because ethnic specificity has been demonstrated in several studies. In this study, we report genome-wide eQTL mapping in the Japanese population.

After a standard quality control, we obtained genotypes of 1,425,832 SNPs and 34,872 gene expression phenotypes from peripheral blood cells of 298 unrelated subjects recruited from the Japanese population. We carried out a genome-wide eQTL mapping for all the phenotypes. We identified 207,462 local eQTLs (located within 500kb of a gene) that are significantly associated by FDR < 5%. The genotypes of the local eQTLs explained more than 10% of variance for 2,099 probes. We observed that magnitudes of association were related to distance from eQTL to gene, and eQTLs located at upstream of gene tend to have stronger effect than those at downstream. Distribution of statistics obtained from distal eQTLs suggested only a small fraction of distal eQTLs have regulatory effects. We identified 9,946 distal eQTLs that are significantly associated by Bonferroni-corrected P < 5%, all of which explains more than 15% of phenotypic variance. 55% of the distal eQTLs were located on the same chromosome as their target genes, and thus, intra-chromosomal effects were enriched. Both local and distal regulations were identified for 50 probes.

This study provides a genome-wide eQTL map of the Japanese population. Our analysis indicates that, although local eQTLs are detected more abundantly than distal eQTLs, many distal eQTLs have strong effects. It is suggested that eQTL studies should focus on both local and distal regulation.

Genetic, evolutionary, and structural properties of protein fragility. *D. Vuzman, C. Cassa, D. Jordan, S. Sunyaev.* Brigham and Women's Hospital and Harvard Medical School, Bosto, MA.

Whole genome and exome sequencing data reveal that disease-associated genes harbor numerous completely benign missense mutations alongside pathogenic variants. Moreover, variants in some genes, such as LDLR, are almost exclusively pathogenic, while other genes, such as Dicer1, contain mostly benign variants. Factors determining robustness of individual genes to sequence variations are unclear. We suggest that the robustness of genes is based on intrinsic structural properties of their encoded proteins, which we name 'fragility'. We have constructed 'fragility score', which estimates the chance for a random amino-acid change to critically impact protein function, using DNA sequencing data on thousands of individuals from the general population from the Exome Sequencing Project (ESP) dataset and data on pathogenic alleles reported in the human gene mutation database (HGMD). High fragility score was assigned to proteins with significantly fewer missense mutations in the general population than in disease-associated populations, since most substitutions are deleterious. Using statistical and computational approaches, we estimated important evolutionary and functional predictors of pathogenicity, such as selective constraints and conservation of sequence across species. We analyzed hundreds of protein tertiary structures from the protein data bank to determine structural and thermodynamic determinants of protein fragility. Our results demonstrate that protein fragility derived from sequencing data is correlated to evolutionary conservation scores, to folding free energy change due to a missense mutation, and to the extent of intrinsically disordered regions within proteins. Characterization of fragility elucidates the biophysical constraints of protein structure and can inform various aspects of research on human genetic variation, ranging from basic population and evolutionary genetics, to genetic of complex traits, and clinical genetic diagnostics.

Whole Transcriptome Array to Identify Alternative Splicing Signals Controlled by SNPs in Human Brain. *H. Zhou, L. Chen, A. Kutlu, C. Molony, D. Stone.* Merck, Boston, MA.

The goal of this study was to use a novel, whole-transcriptome array to identify SNPs that affect alternative splicing in human brain. RNA was extracted from the prefrontal cortex of 371 samples (190 Alzheimer's disease, 74 Huntington's disease, and 107 controls) collected at the Harvard Brain Tissue Resource Center. A custom Affymetrix array with ~1 million probe sets specific to exons and junctions of 20,000 well-established human genes and un-annotated stretches of the genome was designed. This allows expression measurement at exon level in addition to gene level. Quality control on the new whole-transcriptome data was conducted using principal component analysis. Gene level expression was summarized by averaging expression of constitutive probe-sets (exon probe-sets that cover more than 50% of alternative transcripts). SNP genotyping was conducted on an Illumina 650K array. After quality control and imputation, a total of 11.5 million SNPs were used in the analysis. Linear regression was performed to test associations between individual SNPs and probe-set level expression or gene level expression. An FDR value of 10% based on permutation was used to determine the significance level for cis probe-set level associations and cis gene level associations separately. As a result, 2503 cis gene level expression signals were identified. To further identify splicing signals controlled by SNPs, probe-set level associations where probe-set expression was highly correlated with gene level expression ($r2>0.5$) were excluded. As a result, 7941 genes with cis splicing signals were identified. Based on the patterns of alternative splicing, splicing signals were classified into categories such as exon skipping, alternative donors or acceptors, complex changes of multiple event types. To confirm the identified splicing signals, Illumina targeted RNA-seq is being performed on several candidate signals selected from different categories. To our knowledge, this is the first whole transcriptome array study to identify alternative splicing signals controlled by SNPs using human brain samples. As brain demonstrates a higher rate of alternative splicing than any other tissue and a large number of neurological disorders have been linked in aberrant splicing, the findings of the current study will help us understand genetic mechanisms underlying complex neurological disorders.

Gene Expression Profiling of Young and Adult Mouse Cochlea by RNA-Seq in Strains with Normal and Age-Related Hearing Loss. *A.B.S. Giersch[1,3], J. Shen[1,3], N.G. Robertson[1], K. Wong[2], C.C. Morton[1,2,3].* 1) Pathology, Brigham and Women's Hospital, Boston, MA., USA; 2) Obstetrics and Gynecology, Brigham and Women's Hospital, Boston MA, USA; 3) Harvard Medical School, Boston, MA, USA.

Purpose: Age-related hearing loss is the most common sensory deficit in humans, reducing the quality of life in the aged population. Its social impact will become more pronounced as life expectancy continues to increase. Despite the discovery of many deafness genes, understanding of the pathophysiology of progressive hearing impairment due to the aging process remains elusive. We hypothesize that gene expression profiling of the cochlea from mouse models with various degrees of age-related hearing loss will reveal the molecular mechanism and inform potential target selection for prevention and treatment. Methods: We performed gene expression profiling of mouse cochlea by next-generation sequencing (RNA-Seq). A multi-factorial design was used. Cochleas from mouse strains with good hearing past one year of age (CBA/CaJ and B6.CAST-Cdh23Ahl+) or with documented age-related hearing loss (CochG88E/G88E and Coch-/- in a CBA background, and C57BL/6J) were dissected at discrete ages ranging from one week through late adulthood. Poly(A) selected mRNAs were extracted and the derived cDNA samples were fragmented, indexed, pooled, and sequenced by Illumina HiSeq. Biological replicates were used for all conditions. Expression levels of all transcripts were analyzed and differential gene expression analyses were performed. Results: We have obtained gene expression profiles of mammalian cochlea at various ages by RNA-Seq. With total reads of at least 30 million, more than 16,000 genes were detectable in each sample, and the expression levels were highly reproducible. We detect significant systematic differences in gene expression profiles between C57BL/6J and CBA/CaJ strain backgrounds, regardless of age. Comparing mouse models with or without age-related hearing loss of the same genetic background, we have found that few genes show statistically significant differential expression at young ages before the onset of hearing impairment, but the number of genes dramatically increases to hundreds at later stages. In addition, hundreds of genes show significant temporal changes on both genetic backgrounds. Summary: We have surveyed gene expression in mammalian cochlea by RNA-Seq and identified genes that show age-related differential expression. Systematic differences exist between different genetic backgrounds. Temporal gene expression profiles in the cochlea may suggest candidate targets for prevention and treatment of age-related hearing loss.

Transcriptional response to 1,25(OH)2 vitamin D in the human colon of African- and European- Americans. *S. Kupfer[1], K. Ceryes[1], M. Chase[1], J. Maranville[2], A. Di Rienzo[2].* 1) Medicine, University of Chicago, Chicago, IL; 2) Human Genetics, University of Chicago, Chicago, IL.

$1,25(OH)_2$ vitamin D (vitD) is a steroid hormone with anti-inflammatory and anti-proliferative effects that functions through direct transcriptional mechanisms. In colonic diseases, such as colorectal cancer, vitD is thought to play a protective role; however, it is not known to what extent inter-individual and inter-ethnic differences in transcriptional response could underlie differences in disease susceptibility especially in African-Americans (AA) who have the highest incidence of colorectal cancer in the US. To study differences in transcriptional response in the colon, we have optimized an *ex vivo* culture system using colonic biopsies obtained during colonoscopy, thereby eliminating biological, technical and environmental confounders. Four biopsies obtained from the rectosigmoid junction are cultured; 2 biopsies each are treated with 0.1M $1,25(OH)_2$ vitD or vehicle control (EtOH). Samples are incubated for 6 hours at 37°C and placed in RNAlater. After extraction, RNA from two treatment replicates are pooled and hybridized to Illumina HumanHT-12 expression chips. We have conducted an initial study in 24 individuals equally split between AA and European-Americans (EA). We found 508 of 11,317 differentially expressed genes in response to vitD treatment (FDR< 0.01). Among 307 up-regulated genes, we found several known vitD responsive genes including *CYP24A1* ($p<2.2\times 10^{-16}$), *TRPV6* ($p=6.93 \times 10^{-8}$), and *CD14* ($p<2.2 \times 10^{-16}$). In addition to *CD14*, we found a number of up-regulated immune-related genes including *IRF8* and *TLR4*. In a preliminary study of 24 additional individuals, we have replicated these findings. We also noted that for 33 genes there were significant differences in genome-wide log-fold change between AA and EA. Among these, suppressor of AP-1, regulated by IFN (*SARI* or *BATF2*) was significantly upregulated in response to vitD in EAs but not in AAs. In summary, we found significantly up- and down-regulated genes in response to $1,25(OH)_2$ vitD in human colon biopsies. Several known vitD-responsive genes were up-regulated. We noted several up-regulated immune-related genes including *CD14* and *TLR4*. We also found genes with significantly different log-fold change in response to vitD between AA and EA suggesting that inter-ethnic differences in the vitD pathway include transcriptional response to a given amount of vitD. Further studies of genes identified in this study may reveal important vitD responsive pathways that underlie disease disparities.

Participation of individual genes, signaling pathways and biological processes related to inflammation in gestational diabetes mellitus. *N.B. Cezar[1], A.F. Evangelista[1], D.J. Xavier[1], A.F. Assis[1], T.C. Arns[1], M.C. Foss-Freitas[2], M.C. Foss[2], E.T. Sakamoto-Hojo[3], E.A. Donadi[2], G.A. Passos[1].* 1) Department of Genetics - Faculty of Medicine of Ribeirão Preto - University of São Paulo; 2) Department of Clinical Medicine - Faculty of Medicine of Ribeirão Preto - University of São Paulo; 3) Faculty of Philosophy, Sciences and Letters of Ribeirão Preto, Department of Biology, University of São Paulo.

Gestational diabetes mellitus (GDM) is the most common metabolic disorder found during gestation and has been defined as an abnormal glucose metabolism first diagnosed during pregnancy. Women who have a history of GDM usually present postpartum diabetes, insulin resistance, metabolic syndrome, hypertension and dyslipidemia. Several studies have reported the induction of genes involved with inflammatory response in GDM, providing the basis to propose that inflammation may be associated with the disease. We have previously shown that meta-analysis of the transcription profile of patients with type 1 diabetes are closer to GDM than to type 2 diabetes, and that inflammation genes were primarily modulated. In this study, we compared the transcription profiling of peripheral blood mononuclear cells of 18 GDM patients and 10 healthy pregnant women. Total RNA samples were hybridized to Agilent ® 4 x 44 K oligo microarrays encompassing the whole human functional genome. Differentially expressed mRNAs were obtained by Rank Products analysis, which classifies transcripts according to their fold change values. The hierarchical clustering of mRNAs and samples were performed using the Cluster program, dendrograms and spatial representations of mRNAs were constructed using the TreeView software. A total of 731 differentially and significantly expressed mRNAs were observed when patients were compared to controls. Molecular functions and biological pathways were analyzed using the DAVID database identifying 130 biological processes and nine signaling pathways ($P<0.05$), most of these related to inflammation and immune system. Major induced and biologically relevant transcripts exhibiting greatest fold change values were associated with inflammatory response, including *CXCL2*, *NFKBIA*, *IL1*β and *TNF*, which were individually validated by real-time PCR. Besides these genes, GDM patients exhibited modulated genes previously associated with metabolic abnormalities (*IGFBP2* and *TCF3* up regulated and *OLR1* and *TCF7L2* down regulated) and induced genes related to the Major Histocompatibility Complex (*HLA-DRB6*, *DQB1*, *DQB2*, *DOA* and *DOA2*). The modulation of genes associated with inflammation signaling pathways and immune system response in GDM patients reinforce the hypothesis that inflammation may be associated with hyperglycemia and insulin sensitivity dysregulation, suggesting that mRNAs that regulate inflammatory responses represent major functional genes in GDM patients.

Gene Expression Studies by RNA-Seq in Airway Epithelial Cells (AECs) from Asthmatic and Non-Asthmatic Individuals. *R.A. Myers[1], J. Nicodemus-Johnson[1], D.K. Hogarth[2], J. Sudi[2], J.F. McConville[2], E.T. Naureckas[2], A.I. Sperling[2], J. Solway[2], J.A. Krishnan[2], S.R. White[2], D.L. Nicolae[1,2,3], C. Ober[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL.

Asthma is a chronic inflammatory disease characterized by reversible airflow obstruction. Airway epithelial cells (AECs) form the interface between the environment and the host and are functionally important in asthma pathogenesis. We hypothesized that transcript abundance in AECs differs between asthmatic and non-asthmatic individuals. In this study, we characterized the transcripts present and identify differentially expressed genes by RNA-Seq in 48 airway epithelial cell samples (27 asthmatics, 21 non-asthmatics) using the Illumina HiSeq 2000 platform. Sequences were mapped to the genome using BWA and the number of sequences mapped to protein coding genes was determined using BEDTools. We used edgeR to test for differential expression controlling for technical and biological factors that influence gene expression. We identified as expressed 14,484 genes with at least one count per million sequences (cpm) in at least nine samples. At a false discovery rate of 10%, 43 genes were differentially expressed, 25 with increased expression and 18 with decreased expression in asthmatics compared to non-asthmatics. The gene with the most significant differential expression is regulator of G-protein signaling 2 (*RGS2*, p-value = 5.39 ×10-9), which showed increased expression in asthmatics. *RSG2* inhibits G-protein signal transduction by increasing GTPase activity of G-protein alpha subunits. As expression of *RGS2* is induced by long acting beta2-adrenoceptor agonists and glucocorticoids, the gene expression pattern may reflect responses to medication in the individuals with asthma. Other differentially expressed genes included *ALOX15B*, involved in arachidonic acid metabolism; *TC1* (*C8orf4*), a regulator of inflammation response; chemokine receptors *CCR2* and *CX3CR1*; and *KCNJ5*, a subunit of a G-protein activated potassium channel. Ten pathways showed enrichment (p < 0.01) of differentially expressed genes (p-values < 0.05 and fold changes > 2), including the antigen presentation pathway (p-value = 0.0005), atherosclerosis signaling, (p-value = 0.0019), and cAMP-mediated signaling (p-value = 0.0027). Through RNA sequencing in AECs, we identified differentially expressed genes and pathways that may be potential targets for asthma treatment. This work is supported by NIH grant U19 AI095320.

668W

Age-related variations in the transcriptome and methylome of human monocytes. *L.M. Reynolds[1], J. Ding[1], K. Lohman[1], J.R. Taylor[1], A. de la Fuente[2], T.F. Liu[1], C. Johnson[3], R.G. Barr[4], T.C. Register[1], K.M. Donohue[4], M.V. Talor[5], D. Cihakova[5], C.C. Gu[6], J. Divers[1], J.Z. Kuo[7], D. Siscovick[3], G. Burke[1], W. Post[5], S. Shea[4], D.R. Jacobs Jr[8], I. Hoeschele[9], C.E. McCall[1], S.B. Kritchevsky[1], D.M. Herrington[1], R.P. Tracy[10], Y. Liu[1].* 1) Depts of Epidemiology and Prevention, Internal medicine, and Translational Research Inst, Wake Forest School of Medicine, Winston-Salem, NC; 2) FBN, Leibniz Institute for Farm Animal Biology, Genetics and Biometry, Mecklenburg-Vorpommern, Germany; 3) Cardiovascular Health Research Unit, Depts of Medicine and Epidemiology, University of Washington, Seattle, WA; 4) Depts of Medicine and Epidemiology, Columbia University Medical Center, New York, NY; 5) Johns Hopkins University, Maryland, MD; 6) Washington University School of Medicine, St. Louis, MO; 7) Medical Genetics Inst, Cedars-Sinai Medical Center, Los Angeles, CA; 8) Div of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, MN; 9) Virginia Bioinformatics Inst, Virginia Tech, Blacksburg, VA; 10) Dept of Pathology, University of Vermont College of Medicine, Colchester, VT.

Identifying age-associated variations in the human transcriptome and epigenome may provide novel insights into the molecular basis of aging. Published transcriptomic and epigenomic studies of aging have been limited by small samples sizes, mixed cell types, and the lack of both expression and methylation profiles from the same samples. We analyzed genome-wide mRNA expression and DNA methylation profiles in purified peripheral CD14+ monocytes from 1,264 subjects ranging in age from 55 to 94 years. A total of 2,498 genes were significantly associated with chronological age (false discovery rate (FDR) ≤0.001) after adjustment for technical and biological covariates. We further identified six networks of co-expressed genes that included prominent genes from three correlated pathways: autophagy, oxidative phosphorylation, and translation, with expression patterns suggesting these pathways decline with age. The most significant age-associated gene network (first eigenvector: R^2 = 9.7%, p=1.79×10^{-30}) contained three up-regulated genes including *MCL1* (Myeloid Cell Leukemia sequence 1), an inhibitor of autophagy. Methylomic analyses revealed 2,093 CpG sites whose methylation levels were significantly associated with both age and with mRNA expression of nearby genes (± 1Mb). Mediation analyses (structural equation modeling) support methylation of 279 of these CpG sites as mediators between age and expression of 202 genes, which were enriched for antigen processing and presentation genes. One of the most significant age-associated methylation sites (cg13007871) was located in a predicted enhancer region in the gene body of an MHC Class I gene, *HLA-E*, and was negatively associated age (FDR=7.54×10–24) and with mRNA expression of *HLA-E* (FDR=3.08×10–11), while *HLA-E* expression was positively associated with age (FDR=1.19×10^{-8}). In summary, the data from this large cross-sectional population-based study in humans provide evidence that age-related differences in methylation may mediate the relationship between age and expression of antigen processing and presentation genes, and support previous in vitro and in vivo findings that autophagy and mitochondrial function decline with age. The identification of important molecular features of aging in humans may lead to new insights about the aging process and possible targets for interventions of aging-associated disease and disability.

669T

Transcriptome profiling of human ulcerative colitis mucosa shows altered expression of pathways overlapping genome-wide association susceptibility loci. *C.J. Cardinale[1], Z. Wei[2], J. Li[1], J. Zhu[2], R.N. Baldassano[3], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 3) Division of Gastroenterology, Hepatology, and Nutrition, Children's Hospital of Philadelphia, Philadelphia, PA.

Tissue of the human colonic mucosa which has been altered by inflammation due to ulcerative colitis (UC) displays a drastically altered pattern of gene expression based on microarray transcript profiling. We have utilized three independently-generated, publically-available sets of gene expression data from endoscopic biopsies of the colon in healthy controls, ulcerative colitis inflamed tissue, tissue uninvolved in inflammation in UC patients, and Crohn's disease lesions in both adult and pediatric patient populations. We show that gene expression patterns in active UC lesions are easily distinguishable from healthy control tissue, while the grossly uninflamed tissue or Crohn's lesions may show patterns consistent with healthy mucosa, inflammatory gene expression, or an intermediate pattern. Gene set enrichment analysis (GSEA) illustrates that all three data sets share in common 87 gene sets upregulated in UC lesions and 8 that are downregulated (false discovery rate < 0.05). The upregulated pathways are dominated by gene sets involved in immune function and signaling as well as the control of mitosis. We compared these pathways with GSEA pathway-based meta-analysis obtained from GWAS loci from six European cohorts with 5584 UC cases and 11587 controls, giving 56 gene sets (FDR < 0.05). The upregulated pathways show substantial ovelap, with 33 of the 87 expression-derived gene sets being represented among the 56 GWAS gene sets. Future sequencing work is being conducted to determine allelic expression influences of the major gene expression networks involved.

670F

EQTLs and allele specific expression of HLA haplotypes and amino acids associated to autoimmune diseases. *A. Zhernakova[1], M. vd Sijde[1], J. Gutierrez-Achury[1], P.J. McLaren[2], D.V. Zhernakova[1], P.I.W. de Bakker[3,4], H.J. Westra[1], L. Franke[1], C. Wijmenga[1], J. Fu[1].* 1) Genetics, UMCG, Groningen, Netherlands; 2) 2.School of Life Sciences, École Polytechnique Fédérale de Lausanne, Switzerland; 3) 3.Department of Medical Genetics, and Department of Epidemiology, University Medical Center Utrecht, Utrecht, The Netherlands; 4) 4.Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA.

HLA is the strongest associated locus in autoimmune diseases. Recent studies in celiac disease (CeD) and rheumatoid arthritis (RA) indicated the major role of DR3-DQ2 and DR4-DQ8 in both diseases, and identified additional independently associated variants both in the DR-DQ locus and in the extended HLA locus. We hypothesized that the mechanism of downstream effect of associated variants and haplotypes is due to an impact on the expression level of HLA genes We investigated this hypothesis in a dataset of 60 unrelated CEU individuals, for whom RNAseq data, dense HLA genotyping and imputation of HLA alleles was available. We selected CeD and RA associated amino acids, HLA-haplotypes and SNPs, and assessed allele specific expression and eQTLs in the HLA locus. eQTL analysis allowed us to assess the dosage effect of HLA variants on gene expression, whereas the allele-specific analysis, performed in heterozygous individuals for each variant, indicated if one or another allele of a SNP or amino acid was preferentially expressed. In both analyses we observed that an amino acid at position 52 of the DQB1 gene (DQB1_AA52) was significantly associated with expression of DQB1 gene both in eQTL and in allele-specific analysis. DQB1_AA52 is associated to CeD independently from the most associated DQB1 variant (AA55). We therefore confirmed that imbalanced allelic expression is the downstream effect of some HLA variants associated with autoimmune diseases. This analysis is currently ongoing in the population cohort of 760 individuals, for whom RNAseq data is available.

671W

Host and pathogen transcriptome profiling during *Leishmania major* infection. *L.A.L. Dillon[1,2], R. Suresh[1], K. Okrah[3], M. Mangione[1], J. Choi[1], H. Corrada Bravo[2,4], D.M. Mosser[1], N.M. El-Sayed[1,2].* 1) Department of Cell Biology & Molecular Genetics, University of Maryland, College Park, MD; 2) Center for Bioinformatics and Computational Biology, University of Maryland, College Park, MD; 3) Department of Mathematics, University of Maryland, College Park, MD; 4) Department of Computer Science, University of Maryland, College Park, MD.

Leishmaniasis, caused by protozoan parasites of the *Leishmania* genus, affects roughly 1.5 million people worldwide and is endemic primarily to South America and the Middle East. The parasite's lifecycle is divided between its insect vector, the phlebotomine sand fly, and its mammalian host, where it resides inside of macrophages. In order to establish an infection, the parasite must evade host immune system responses to infect macrophages and to survive and replicate within cellular phagolysosomes. Little is known about changes that take place at the transcriptional level in either the host or the pathogen during an infection and how *Leishmania* is able to direct these changes through manipulation of host cellular machinery.

Using the mouse as a model system, we have performed RNA-seq on the Illumina HiSeq platform to simultaneously measure global changes in gene expression in both *L. major* and host macrophages at multiple time points during the *L. major* lifecycle, including as the parasite replicates inside of host cells. Transcripts were aligned to the mouse and *L. major* genomes using TopHat and differential expression analysis was performed using limma after ComBat batch correction and voom data transformation. Gene ontology category enrichment analysis was done using GOseq. Genes that are differentially regulated in *L. major* include histones, antioxidant genes, cell surface markers, membrane transporters, and signaling molecules while those that are differentially expressed in mouse include those involved in immune system responses (e.g., inflammation, wound healing, leukocyte activation), cell signaling, metabolism, and apoptosis.

The identification and quantification of up- and down-regulated genes has provided evidence regarding the mechanisms used by *L. major* to elude host defenses and survive in the intracellular environment and has enabled connections to be made between changes in gene expression and the parasite's biology and lifecycle. These findings are revealing new insights into the dynamics of an infection and will help identify markers and targets for the prevention, diagnosis, and treatment of Leishmaniasis and related kinetoplastid diseases.

Comparative analysis of gene expression profiles in the cerebellum and granule neurons of the *Cstb*$^{-/-}$ mouse, a model for the Unverricht-Lundborg disease (EPM1). *T. Joensuu[1,2,3,4], S. Tegelberg[1,2,3,4], E. Reinmaa[1,2,4], M. Segerstråle[4,5], P. Hakala[1,2,3,4], H. Pehkonen[6], E.R. Korpi[6], J. Tyynelä[7], T. Taira[4,5], I. Hovatta[5,8], O. Kopra[1,2,3,4], A-E. Lehesjoki[1,2,3,4].* 1) Folkhälsan Institute of Genetics, FI-00290 Helsinki, Finland; 2) Department of Medical Genetics, Haartman Institute, University of Helsinki, FI-00014 Helsinki, Finland; 3) Research Programs Unit, Molecular Neurology, University of Helsinki, FI-00014 Helsinki, Finland; 4) Neuroscience Center, University of Helsinki, FI-00014 Helsinki, Finland; 5) Department of Biosciences, Faculty of Biological and Environmental Sciences and Department of Veterinary Biosciences, Faculty of Veterinary Medicine, University of Helsinki, FI-00014 Helsinki, Finland; 6) Institute of Biomedicine, Pharmacology, University of Helsinki, FI-00014 Helsinki, Finland; 7) Institute of Biomedicine, Biochemistry and Developmental Biology, University of Helsinki, FI-00014 Helsinki, Finland; 8) Mental Health and Substance Abuse Services, National Institute for Health and Welfare, FI-00300 Helsinki, Finland.

Progressive myoclonus epilepsy of Unverricht-Lundborg type (EPM1) is an autosomal recessively inherited disorder characterized by stimulus-sensitive myoclonus, epilepsy and progressive neuronal degeneration with ataxia and dysarthria appearing later. EPM1 occurs worldwide, but it is enriched in Finland and in the Western Mediterranean region. It is caused by mutations in the gene encoding a cysteine protease inhibitor cystatin B (*CSTB*). Altogether fourteen *CSTB* mutations have been reported to underlie EPM1, of which an unstable repeat expansion of at least 30 copies in the promoter region is found in 90% of the disease alleles worldwide. Despite identification and characterization of the underlying *CSTB* gene and mutations, the disease mechanisms in EPM1 are poorly understood. A *Cstb*$^{-/-}$ mouse, the model for the disease, shows EPM1 like disease phenotype with myoclonic seizures that develop by one month of age and progressive ataxia by six months of age accompanied with early microglial activation, neuron loss and sensitivity to oxidative stress. In an approach towards understanding the molecular basis of disease mechanisms in EPM1, we have characterized the genomewide gene expression profiles from postnatal day 30 (P30) and P7 *Cstb*$^{-/-}$ mice, as well as from the cultured cerebellar granule cells using a pathway-based approach. The microarray profiling revealed multiple biological pathways related to activation of inflammatory processes, ion homeostasis, synaptic function and plasticity, cell cycle, cellular architecture of cytoskeleton and intracellular transport reflecting the ongoing neuropathology in the *Cstb*$^{-/-}$ mice. As the altered genes from P7 *Cstb*$^{-/-}$ cerebellum implied changes in neuronal functions, which could reflect the hyperexcitablity and motor symptoms seen in EPM1, the GABAergic signaling pathway was selected for further characterization using electrophysiological recordings for spontaneous post-synaptic currents in Purkinje cells, as well as ligand binding and immunohistological analyses. Electrophysiological recordings from *Cstb*$^{-/-}$ Purkinje cells revealed a shift of balance towards decreased inhibition, while the amount of inhibitory interneurons did not change. The ligand binding capacity of GABA receptors was decreased along with reduced number of pre-synaptic GABAergic terminals. These results suggest that changes in GABAergic signaling could lead to reduced inhibition and neuronal hyperexcitability in *Cstb*$^{-/-}$ cerebellum.

Peripheral blood microarrays identify dysregulated genes and pathways unique to psoriatic arthritis compared to psoriasis without arthritis. *R. Pollock[1], V. Chandran[1,2], C. Virtanen[3], F. Pellett[1], C. Rosen[4], K. Liang[5], D. Gladman[1,2].* 1) Psoriatic Arthritis Program, Toronto Western Research Institute, Toronto, Canada; 2) Division of Rheumatology, Department of Medicine, University of Toronto, Toronto, Canada; 3) Ontario Cancer Institute Genomics Centre, Toronto, Canada; 4) Division of Dermatology, Department of Medicine, University of Toronto, Toronto, Canada; 5) Department of Statistics and Actuarial Science, University of Waterloo, Waterloo, Canada.

Psoriatic arthritis (PsA) is an inflammatory arthritis that develops in about 30% of patients with psoriasis (PsC). We aimed to identify a gene expression signature of PsA compared to PsC and controls to identify biomarkers and improve our understanding of the pathology of arthritis in psoriasis patients. Gene expression was measured in peripheral whole blood from 20 PsA patients, 20 PsC patients without arthritis, and 20 controls using Agilent Whole Human Genome Oligo microarrays. Statistical analyses were performed using commercial (GeneSpring GX) and open-source (Bioconductor) packages to identify significant differentially expressed genes (DEGs) between PsA vs. controls, PsC vs. controls, and PsA vs. PsC. DAVID and Ingenuity Pathway Analysis were performed to identify enriched annotations and pathways relative to the Agilent probe set reference. Eleven candidate biomarker genes were validated by qPCR using Taqman assays. Expression levels across all three groups were compared using one-way ANOVA and 1547 DEGs were found. Student's t-test found 790 DEGs between PsA vs. controls, 98 between PsA vs. PsC, and 0 between PsC vs. controls. DEGs in PsA vs. controls included genes involved in peptide loading onto the MHC Class I (TMTC3 and PDIA3), epidermal development and maintenance (CSTA), histone acetyltransferase complexes (EP300, CREBBP, MYST4), toll-like receptor 2 signaling (AKAP13), and NK/T cell migration (S1PR5). Two-way hierarchal clustering of the DEGs with a fold change > 2 grouped 16 out of 20 PsA patients together, with the remaining 4 patients clustering with the controls. DEGs in PsA vs. PsC included genes involved in toll-like receptor 4 signaling (LY96), T cell adhesion and activation (CD58), bone remodeling (TNFSF10), NK/T cell activation (CLEC4D, CLEC2B), and inflammation (BCL2A1, S100A12). Clustering of top DEGs grouped 19 out of 20 PsA samples together and 17 out of 20 PsC samples together. Enriched annotations and pathways in PsA vs. controls and PsA vs. PsC were related to the regulation of gene expression and activation of the PPARα/RXRα pathway. DNA double-strand break repair by non-homologous end joining was enriched in PsA vs. PsC ($p=1.7\times10{-}3$). Microarray and qPCR results were highly correlated (overall $r=0.92$, $p<0.001$, 95% CI 0.71-0.98). These data demonstrate that there is a unique peripheral blood gene expression signature of PsA compared to PsC, and microarrays can identify potential biomarkers of PsA in PsC patients.

Deep Sequencing of microRNAs and novel tRF RNAs in human monocytes. *C. Li[1], H. Ge[1], C. Lindvay[1], M. Chhoa[2], E. Lamas[1], S. Escobar[3], H. Arnett[3], T. Juan[2], R. Sandrock[1].* 1) Genome Analysis Unit, Amgen Inc., San Francisco, California, 94080; 2) Protein Sciences, Amgen Inc., Thousand Oaks, California, 91320; 3) Inflammation Research, Amgen Inc., Seattle, Washington 98119, USA.

microRNAs play essential roles in modulating the level of gene expression post-transcriptionally in cells. Certain microRNAs have been shown to be up- or down-regulated during the process of immune responses. Using next-generation sequencing (NGS), we performed transcriptome analysis of small RNAs ranging from 18- to 30-nt in unstimulated human monocytes or those treated with an activating stimulus, lipopolysscharide (LPS). Upon aligning and counting fragments that mapped to the human genome, we found that 20 microRNAs accounted for approximately 75% of the entire microRNA population in monocytes. Within around 5-order range of differential expression, *miR-155* was the most abundant up-regulated gene in LPS-induced monocytes followed by *miR-146a*, *miR-193a*, *miR-9*, *miR-147b*, and *miR-31*. No significant down-regulation of microRNAs was observed in human LPS-treated monocytes. Activation of mature and precursor forms of the signature set of microRNAs was further confirmed in LPS-treated monocytes by a semi-quantitative analysis of tagged RT-PCR. In addition to known microRNAs, we identified 18 *tRNA* fragments (*tRFs*) sequences, an emerging type of novel small RNAs, of which little biological significance is known, that were originally identified in cancer cells that mapped to 50 different *tRNA* gene loci of which 13 were novel. *tRFs* are an emerging type of novel small RNAs, of which little biological significance is known, that were originally identified in cancer cells. Only *tRNA-TyrGTA* showed differential expression in human LPS-treated monocytes. Our study provides a comprehensive quantitative catalog of microRNA expression and demonstrates an analysis pipeline for identification of novel *tRF* RNAs that lays the groundwork for further investigation regard to the biological significance of *tRFs* in human monocytes.

Platelet RNA And eXpression-1 Study Demonstrates RNA Expression Differences that Correlate with Ancestry. *L. Simon[1], E. Chen[1], L. Edelstein[2], P. Bray[2], C. Shaw[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Thomas Jefferson University, The Cardeza Foundation for Hematologic Research and the Department of Medicine, Jefferson Medical College, Philadelphia, PA, USA.

Cardiovascular disease, cancer and many drug responses show striking differences between groups with different ethnicity or ancestral background. The Platelet RNA And eXpression-1 (PRAX1) study was designed to investigate the function of platelets by profiling mRNAs and microRNAs (miRNAs) and identifying inter-individual variation in samples from individuals of European American (EAs) and African American (AAs) ancestry. Platelets present a unique opportunity for study of racial differences for many reasons including the breadth of functional variation and the ease with which samples from normal individuals can be obtained for functional and molecular characterization. We profiled the RNA levels in platelets of 154 healthy adults using genome-wide RNA expression analysis, and discovered large-scale differences in platelet gene expression between EAs and AAs. These observations are consistent with prior findings of other studies, including the 1000 Genomes Project as well as expression profiling of lymphoblastoid cell lines from the HapMap project. These studies have revealed genetic differences and cell line gene expression differences between groups of distinct ancestry. The differences we identified in PRAX1 are observed in purified human platelets both at the mRNA and miRNA level. At the mRNA level, race (ancestry) is significantly associated with the first principal component of variation in the genome wide expression data. In addition, mRNAs with predicted binding sites for miRNAs up-regulated in AAs are enriched among down-regulated mRNAs in AAs. A cluster of miRNAs encoded at the DLK1-DIO3 locus on human chromosome 14q32 is strongly up-regulated in EAs compared to AAs. The results of PRAX1 provide a comprehensive view of the population differences in human platelets measured at the level of RNA expression and suggest that ancestry should be taken into account.

676F

Genetic variation underlying protein expression variation in brain samples and lymphoblastoid cell lines. *R.J. Hause[1,2,3], C.T. Archer[3,4], L. Cheng[5], J.A. Badner[6], C. Liu[5], R.B. Jones[1,2,3].* 1) Ben May Department for Cancer Research, University of Chicago, Chicago, IL; 2) Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL; 3) Institute for Genomics and Systems Biology, University of Chicago, Chicago, IL; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Department of Psychiatry, University of Illinois at Chicago, Chicago, IL; 6) Department of Psychiatry and Behavior Neuroscience, University of Chicago, Chicago, IL.

Genome-wide association analyses have discovered many DNA variants that influence complex psychiatric disorders. Because gene expression is a molecular phenotype that acts as an ‘intermediary’ between genetic and physiological variation, expression quantitative trait loci (eQTL) mapping has been used to try to better understand complex disease by identifying regulatory variation that affects mRNA expression levels. An implicit assumption made in these analyses is that eQTLs explain subsequent differences in protein levels, even though previous experiments have shown imperfect correlations between mRNA and protein expression levels. To improve our understanding of the genetic basis of protein expression variation and how this variation is related to genetic risks for complex disease, we have recently extended micro-western and reverse phase lysate array technologies to quantify 441 protein levels across 68 unrelated Yoruba lymphoblastoid cell lines (LCLs) and examined the correlations between mRNA levels, protein levels, and known physiological covariates. In this study, we sought to translate our protein analysis work to examine protein levels in the brain. We quantified the levels of 50 proteins related to cell signaling, transcription, and neurobiology across brain samples derived from a population of 129 unrelated individuals of Caucasian descent who were classified as normal controls ($n = 43$) or diagnosed as cases with depression ($n = 12$), schizophrenia ($n = 39$), or bipolar disorder ($n = 35$). We first identified several proteins that were differentially expressed between cases and controls, such as brain-derived neurotrophic factor (BDNF), and between particular psychiatric sub-classes and controls, such as thymus-specific serine protease (PRSS16) that was significantly overexpressed in depressed patients. We then performed association analyses on these protein levels to identify protein quantitative trait loci (pQTLs). We observed that up to a quarter of pQTLs previously identified in LCLs replicated in this brain cohort. Our approach represents a general method for the identification of novel protein variation associated with neuropsychiatric disorders and genetic variation that contributes to protein variation. In the future, we will investigate the overlap of pQTLs with SNPs previously implicated in neuropsychiatric disorders and scale up our investigation to analyze a substantially larger protein set.

677W

Identification of novel non-coding RNAs associated with smoking. *M.J. Peters[1,2], F.A.S. Smouter[1], J.G.J. van Rooij[1,2], D. Schmitz[1], M. Jhamai[1], P. Arp[1], F. Rivadeneira[1,2,3], A. Hofman[3], A.G. Uitterlinden[1,2,3], J.B.J. van Meurs[1,2].* 1) Department of Internal Medicine, Erasmus Medical Center Rotterdam, the Netherlands; 2) The Netherlands Genomics Initiative-sponsored Netherlands Consortium for Healthy Aging (NGI-NCHA), Rotterdam, the Netherlands; 3) Department of Epidemiology, Erasmus Medical Center Rotterdam, the Netherlands.

Background Smoking is the leading cause of premature death from diseases such as lung cancer and chronic respiratory disease; it harms nearly every organ and reduces the health of smokers in general. Since the toxin ingredients in cigarette smoke (like nicotine) are absorbed into the bloodstream, we hypothesized that smoking will alter the gene expression patterns of many coding and non-coding RNAs in the circulation. Our aim was to identify these RNAs changing with smoking. Oxidative stress is thought to be the general cause; smoking causes an imbalance between the systemic manifestation of reactive oxygen species and the system’s ability to repair the resulting damage. Methods We performed RNA sequencing in 92 women of the Rotterdam Study: 30 smokers and 62 non-smokers. Whole-blood was collected using PAXgene-tubes and the RNA was sequenced using the Illumina HiSeq 2000 (4 samples/lane). We aligned the reads to the Human Reference Genome (v19) using TopHat and we estimated the relative abundance using Cufflinks (Tuxedo Suite); transcripts with a coverage <3 were removed and they needed to be present in >2 samples. We used logistic regression to model the outcome variables and adjusted for age, RNA quality, technical batch, and cell counts. We mapped the transcripts to different RNA reference databases to distinguish known and novel coding and non-coding RNAs. Results We identified a total of 112 RNAs differentially regulated between smokers and non-smokers ($p<0.01$), of which 71 were present in any RNA reference database and 41 were novel. Examples of transcripts known to be associated with smoking behavior are ANKRD13B, GFRA2, UBQLNL, PIGO and OLFML1. We newly identified the TXNRD3 transcript: four smokers had transcribed this gene, while none of the non-smokers had detectable TXNRD3 RNA levels. The TXNRD3 protein catalyzes the reduction of thioredoxin, and is implicated in the defense against oxidative stress. 41 novel RNAs were differentially regulated between smokers and non-smokers: most interesting are the ones present in >=10 non-smokers and not present in smokers at all. These new intergenic transcripts are located upstream the LEF1 gene and upstream the CSTF1 gene. Conclusions These results show that transcription profiles alter during smoking. While replication is pursued, identification of both known and novel RNAs associated with smoking will add to our understanding of the molecular response in blood to cigarette smoke exposure.

Using Metabolomics and ex vivo Activity Approaches to Understand the Functional role of Epoxide Hydrolase 2 gene in Anorexia Nervosa.
P. Shih[1], C. Morisseau[2], J. Yang[2], T. Clarke[3], A. Van Zeeland[4], A. Bergen[5], P. Magistretti[6], N. Schork[4], W. Berrettini[3], B.D. Hammock[2], W. Kaye[1], Price Foundation Collaborative Group. 1) Dep of Psychiatry, Univ California, San Diego, La Jolla, CA; 2) Dep of Entomology, Univ California, Davis, Davis, CA; 3) Dep of Psychiatry, Univ of Pennsylvania, Phila., PA; 4) The Scripps Translational Science Institute, La Jolla, CA; 5) SRI International, Menlo Park, CA; 6) The University of Lausanne, Lausanne, Switzerland.

Individuals with Anorexia nervosa (AN) restrict eating and become emaciated. They tend to have an aversion to foods rich in fat. Understanding genetic basis of fat metabolism may unravel AN molecular psychopathology. We recently identified a novel AN susceptibility gene, Epoxide Hydrolase 2 (*EPHX2*), through a series of complementary genetic study designs (GWAS, exon-sequencing, single-locus association and replication studies) in 1205 AN and 1948 controls (p=0.0004 to 0.00000016). The molecular mechanism by which *EPHX2* influences AN risk remains elusive; here we utilize metabolomics and *ex vivo* enzyme activity assays to evaluate the biological function of *EPHX2*. *EPHX2* codes for soluble epoxide hydrolase (sEH) which hydrolyzes and converts derivatives of arachidonic acid (AA), Epoxyeicosatrienoic acids (EETs) to Dihydroxyeicosatrienoic acids (DHETs). We measured AA metabolite markers (8,9-, 11,12- and 14,15-EETs) and their corresponding DHETs using the LC/MS/MS method in 14 AN and 6 age-,sex- matched controls with Arg287Gln (rs751141) and 3'-UTR SNP (rs1042064) genotypes. EET-to-DHETs ratios were calculated as proxy markers of *in vivo* sEH activity. Direct sEH activity was also measured *ex vivo* using a radioactive surrogate substrate on buffy coat in an independent sample of 36 controls. No significant differences in AA metabolite markers were observed between AN and controls except for increased 8,9- and 14,15-EETs in AN (p=0.05). Variant allele carriers of Arg287Gln and 3'-UTR showed decreased levels of all 3 EETs (p=0.04 to 0.00002) and lower 11,12- and 14,15- EET-to-DHETs ratios (p=0.04 to 0.0016), suggesting elevated basal sEH activity in variant allele carriers. However, the *ex vivo* measurement of sEH activity did not show association with genotypes. Our earlier work using the bacculovirus expression system found the Arg287Gln variant allele to associate with decreased *in vitro* sEH activity; here, through joint assessment of sEH's biochemical target, AA epoxide derivatives, we found variant alleles associated with elevated sEH activity. This suggests that sEH expression/activity *in vivo* is complex, context-dependent, and likely to be influenced by interactions of multiple loci instead of single variant(s) with a large effect. This study suggests *EPHX2* influences AN risk through biological interaction with the AA pathway, and demonstrated the importance of a multi-disciplinary approach to examine molecular functions of risk genes.

The African Genome Variation Project Phase II: Down-sampling of African whole genome sequence data.
T. Carstensen[1], D. Gurdasani[1,2]. 1) Genetic Epidemiology, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 2) Cambridge University, Cambridge, Cambridgeshire, United Kingdom.

/Background Although several studies have focused on the utility of ultra-low coverage (ULC) designs and dense chip arrays in European populations, the utility of such platforms for large scale genomic studies in Africa, which has much greater genetic diversity, is unknown. Here, we present preliminary findings on the utility of ULC whole genome sequencing (WGS) designs and dense chip arrays for genomic research in Africa. /Methods We sequenced whole genomes and genotyped samples from 320 individuals from 3 geographically distinct African populations; i.e. Baganda in Uganda, Zulu in South Africa and Amhara, Oromo and Somali from Ethiopia. Sequencing and genotyping were carried out on the Illumina HiSeq 2000 and Illumina Omni 2.5M platform, respectively. We randomly down-sampled 4x WGS data to 2x, 1x and 0.5x. Variant calling was carried out using GATK followed by genotype refinement with BEAGLE using the multi-ethnic 1000 Genomes Project reference panel. We compared the accuracy and sensitivity of ULC-WGS at different depths and imputed chip array data to 4x WGS. The effective sample size was calculated for all designs as n*R2 where R2 is the correlation between imputed sequence/chip data and actual chip array genotypes, and n are the number of samples that can be sequenced/genotyped for a given cost. /Results The correlation between sequence data and genotype data was 0.8-0.9 for 0.5x and greater than 0.9 for all other ULC-WGS designs for common (MAF>5%) variants. For rare variants (MAF<5%) it was 0.6-0.7, 0.7-0.8, 0.8-0.9 and 0.9 in the 3 populations at 0.5x, 1x, 2x and 4x, respectively. Imputation markedly improved accuracy of WGS data with respect to chip data at all coverage depths, and appeared to be the primary determinant of accuracy. Sensitivity of imputed chip array data was comparable to 2x data with respect to capture of variants obtained with 4x. The effective sample size for both common and rare variants was greater for all ULC-WGS and chip array designs than for 4x. /Conclusions We show that high accuracy in genotype calling can be obtained with ULC-WGS and chip array designs for common variants in African populations when large multi-ethnic panels are used for imputation. Even for rare variants, greater effective sample sizes are achieved with ULC-WGS and chip designs compared to 4x WGS for a given cost. Developing additional Africa-specific reference panels for imputation is likely to augment accuracy of ULC-WGS designs even further.

SRD5A2 gene polymorphisms affect the risk of benign prostatic hyperplasia.
V.K. Choubey[1], S.N. Sankhwar[1], J. Carlus[2], A.N. Singh[1], D. Dalela[1], R. Singh[3]. 1) Department of Urology, King George's Medical University, Lucknow, Lucknow, India; 2) Centre for Genetics and Inherited Diseases (CGID), Taibah University, Al- Madinah, Kingdom of Saudi Arabia; 3) Division of Endocrinology, Central Drug Research Institute, Lucknow, India.

Abstract Background Benign prostatic hyperplasia (BPH), characterized by an enlarged prostate, affects the quality of life in the elderly people, and prostate cancer (PC) is the second leading cause of death in men. Since prostate is an androgen dependent tissue, androgen metabolism is likely to affect the risk of developing BPH and PC. Methods We have analyzed common polymorphisms in the SRD5A2 gene in 210 BPH patients, 192 PC cases and 171 controls. Published data on V89L and (TA)n repeat polymorphisms was pooled for performing meta-analysis to quantitate the BPH risk associated with these polymorphisms. In total, six studies on V89L polymorphism comprising a total of 878 patients and 586 controls and three studies on (TA)n polymorphism comprising a total of 768 patients and 460 controls, were included in meta-analysis. Results We did not observe any polymorphism at the A49T polymorphic site. All the subjects showed 'AA' at this site without any substitution. The presence of 'VV' increased BPH risk (p = 0.047); however, no significant difference in the genotype distributions comparison between PC vs Controls was observed. Comparison of genotypes at (TA)n locus found highly significant difference between cases and controls such that shorter repeats increased BPH risk (p = 0.003). However, no significant difference in comparison of PC vs Controls was observed. Meta-analysis also showed high frequency of 'V' at V89L and (TA)0 repeats in the BPH cases, though the differences were not statistically significant. Conclusion A49T locus of SRD5A2 gene is monomorphic in the study population. The presence of VV at V89L Locus and shorter (TA)n repeats increased BPH risk, though the meta-analysis suggest no overall correlation between SRD5A2 polymorphisms and the risk of BPH. None of these polymorphisms appears to affect the risk of PC. Keywords: SRD5A2, benign prostatic hyperplasia, prostate cancer, 5α-reductase type 2.

681T

High-resolution personal genome-wide maps of meiotic double-strand breaks in humans. *F. Pratto[1], K. Brick[1], P. Khil[1], F. Smagulova[2], G. Petukhova[2], R.D. Camerini-Otero[1].* 1) Genetics and Biochemistry Branch, National Institutes of Health, Bethesda, MD, USA; 2) Department of Biochemistry and Molecular Biology, Uniformed Services University of Health Sciences, Bethesda, MD, USA.

Meiotic recombination contributes to genetic diversity and ensures the correct segregation of chromosomes. It is initiated by the introduction of double strand breaks (DSBs) by the SPO11 protein and occurs in narrow regions of the genome called hotspots. Computational analysis of patterns of linkage disequilibrium (LD) allowed for the identification of ~30,000 population hotspots in humans. Here, we use an approach previously developed by us to generate high-resolution genome-wide personal maps of meiotic DSBs. The Zn-finger protein PRMD9 has been shown to define the location of the majority of meiotic DSB hotspots. We mapped DSBs in six individuals; two carrying the most common Prdm9 allele (A), two heterozygous for the A allele and a closely related variant, the B allele, one heterozygous for the A allele and the C allele (a variant commonly found in African populations) and one heterozygous for the C allele and a C-type variant, L4. The A and B alleles of Prdm9 defined similar recombination initiation hotspots while the C allele defines a distinct set of hotspots. Approximately 60% of population LD hotspots are explained by A-defined hotspots, while C-defined hotspots explain an additional 12%. This shows that relatively minor alleles significantly contribute to the LD map. We also found that the DSB distribution exhibits a strong telomeric bias which resembles that of male, but not female crossovers indicating that frequency of DSBs is a major determinant of crossover distribution and frequency in human males. Examination of the two AA individuals revealed inter-individual variation at about 5% of hotspots. Whole genome sequencing of these individuals determined that no more than 40% of AA polymorphic hotspots could be explained by a single nucleotide variant at a putative PRDM9 binding site. Interestingly, we also found that polymorphic hotspots were frequently found in clusters. We used H3K4me3 ChIP-Seq signal strength as a proxy for PRDM9 binding affinity. Unlike in mouse, we found that the hotspot strength is not well correlated with the strength of the H3K4me3 signal. In aggregate, these data indicate that PRDM9 binding is not the only factor modulating hotspot strength in humans. Finally, we explored the role of DSB hotspots in genomic rearrangements. We found that DSB hotspots were enriched at structural variants that arise via homology-mediated mechanisms and that meiotic DSBs occur at well known disease-associated chromosomal breakpoints.

682F

Comparative analysis of biological activity of 11 mammalian paralogs of the novel human interferon IFNλ-4 (IFNL4) associated with viral clearance. *W. Tang[1], M. Dennis[2], L. Prokunina-Olsson[1].* 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, NCI; 2) Department of Genome Sciences, University of Washington.

Interferons (IFNs) are proteins produced by host cells in response to infections. Recently, we discovered a new type III-interferon, interferon-λ4 (IFNL4). IFNL4 is encoded by a gene located upstream of the IFNL3 (former IL28B) on chromosome 19. We showed that the ancestral dG allele of a dinucleotide variant, ss469415590 (dG/TT), which creates a frameshift and leads to a generation of a full-length functional IFNL4 protein, is strongly associated with the inability to clear HCV infection spontaneously or after treatment (Prokunina-Olsson et.al, Nat Gen, 2013). Utilizing public databases and targeted re-sequencing, we now explored the existence of IFNL4 in other species. The IFNL4 genomic region was absent in mouse and rat, likely due to a deletion in a common murine ancestor, and not found in any non-mammals. All mammals with available genomic sequence were found to be monomorphic for the presence of the IFNL4-generating dG allele. We created expression constructs for 11 synthetic IFNL4 paralogs based on predicted open-reading frames deduced from corresponding genomic sequences. Expression constructs encoding the human, chimpanzee, orangutan, cynomolgus, rhesus, marmoset, megabat, dog, pig, cow, elephant and panda IFNL4 proteins were transfected into a hepatic HepG2 cell line stably expressing a luciferase reporter assay under the control of an interferon-stimulated response element (ISRE). The activity of IFNL4 paralogs was evaluated as their ability to induce ISRE-Luc activation and compared to the activity of human IFNL4. We found that the human IFNL4 was the most biologically active. Paralogs separated into three groups: orangutan, cynomolgus monkey and megabat achieved ~70% biological activity; chimpanzee, dog and pig were around 50%; and cow, elephant, marmoset, panda and rhesus were around 20%, compared to human IFNL4. Interestingly, in non-primates the IFNL4 activity was lowest in herbivorous species (panda, cow and elephant) compared to omnivorous species (dog, pig) and megabat (consumes insects and blood). In primates, the strong diversity in IFNL4 biological activity could be attributed just to a few single point amino-acid differences, suggesting functional importance of these variants. In conclusion, we identified and characterized biological activity of IFNL4 paralogs in 11 mammalian species. Further analysis will explore evolutionary forces that shaped the IFNL4 protein sequence and biological activity.

Analysis of the expression of celiac disease associated genes in T-cells. *C. Coleman, E. Quinn, R. Grealy, V. Trimble, R. McManus.* 1.Genomic Research, Institute of Molecular Medicine, Trinity Centre for Health Sciences, St. James' Hospital, Dublin 8, Ireland.

Coeliac disease (CD) is a common, complex and chronic immune-mediated disease affecting the small intestine. It is triggered in genetically sensitive individuals by the ingestion of gluten proteins, which initiate an immune reaction that leads ultimately to the destruction of the normal architecture of the gut wall, most obviously the loss of the villus architecture and the development of crypt hyperplasia. There is a strong inherited component to the disease, demonstrated by the fact that concordance rates in monozygotic twins are at least 75%. HLA-DQA1 and HLA-DQB1 alleles are necessary but not sufficient to cause disease and recent genome-wide association studies (GWAS) have succeeded in identifying almost 40 non-HLA risk loci. For the majority of these non-HLA loci very little is known with regards their potential role in immune function and/or the mechanism by which they might be contributing to disease biology. Given that the activation of T cells in the intestinal mucosa in response to gluten exposure is thought to play a key role in the pathogenesis of the disease, we measured the mRNA levels of disease associated candidate genes specifically in activated and resting CD4+ T cells in a group of coeliac individuals and unaffected controls. Results indicate that a number of genes that have been genetically associated with the disease also show significantly different expression at the mRNA level in CD4+ T cells and further investigation of these genes through the integration of Immunochip derived genetic data and pathway analysis will hopefully lead to a greater understanding of their role in disease biology.

684T

Alternative promoter activation leads to the expression of a novel variant of human lysyl oxidase (*LOX-v2*) that functions as an amine oxidase. *Y. Kim, S. Park, S. Kim.* Department of Biochemistry, Wonkwang University School of Medicine, Iksan, Jeonbuk, South Korea.

Lysyl oxidase (LOX) is a copper-dependent amine oxidase that is responsible for the lysine-mediated cross-links found in the extracellular matrix proteins, such collagen and elastin. Four additional *LOX*-like genes (*LOXL1*, *LOXL2*, *LOXL3*, and *LOXL4*) have been identified in human, each encoding the functional domains of LOX, such as a copper-binding domain, residues for lysyl-tyrosyl quinone (LTQ) and a cytokine receptor-like (CRL) domain. Several novel functions including tumor suppression, tumor progression, cellular senescence, and chemotaxis have been recently attributed to LOX. The presence of LOX paralogues, thus, suggests that the diverse multiple functions of LOX may be derived from differential regulation of the LOX paralogues. In searches of more human *LOX* paralogues, we identified several expressed sequence tag (EST)-clones that showed an alternative exon-intron splice pattern from LOX. Those ESTs corresponded to the *LOX* transcript variant 2 (*LOX-v2*) that was recently reported in the GenBank (accession no. NM_00117812). *LOX-v2* is lack of exon 1 of *LOX*, encoding a 188 amino acid-long polypeptide of 22 kDa. In peroxidase-coupled fluorometric assays, LOX-v2 showed a significant amine oxidase activity toward collagen and elastin. In RT-PCR analysis with human tissues, *LOX-v2* showed distinct tissue specificity from *LOX*. An alternative promoter element present in the intron 1 region of *LOX* was sufficient for the differential transcriptional activation of *LOX-v2*. These findings indicate that the human *LOX* gene encodes two variants, LOX and LOX-v2, both of which function as amine oxidases with distinct tissue specificities from one another.

Real-time PCR for Indel markers detection in cffDNA. *M.D. Santos[1], F.M.F. Nunes[2], A.L. Simões[1].* 1) Department of Genetics, University of Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil; 2) Department of Genetics and Evolution, Federal University of Sao Carlos, Sao Carlos, Sao Paulo, Brazil.

Fetal DNA present in pregnant women plasma is fragmented and in lower concentrations than maternal DNA. Therefore, prenatal detection of fetal genotype require methods based on genetic markers detectable by analysis of small segments of the genome, as well as being able to avoid competition between maternal and fetal DNA primer binding site. In this context, we developed a methodology based on real-time PCR for insertion/deletion polymorphism (Indel) detection in cell-free fetal DNA (cffDNA) present in pregnant women plasma.Three Indel loci (MID1386, MID818 and MID856) were chosen, for which three primers were designed. Primers flanking the insertion region were used in standard PCR to confirm mothers (n=150) and their newborns (n=150) genotype. The primer complementary to the insertion segment and a complementary flanking primer were used in real time PCR in presence of SYBR Green I followed by melting curve analysis to detect the insertion polymorphism in DNA samples extracted from maternal plasma. Melting curve analysis indicated the melting peak at 71.3°C, 81.5°C and 73.8°C, corresponding to the presence of insertion sequence of loci MID1386, MID818 and MID856, respectively, in plasma of pregnant women homozygous for deletion polymorphism, whose newborns were identified as heterozygotes by conventional PCR. The real-time PCR method presented in this study was able to detect fetal DNA present in maternal plasma by avoiding competition for primer binding site. Increasing number of these markers will allow its use in non-invasive prenatal identification and diagnosis when is no possible use STRs markers. Acknowledgement: we thank Zilá Luz Paulino Simões, PhD for Applied Biosystems 7500 Real-Time PCR System grant.

Haplotyping single nucleotide polymorphisms and distinguishing deletion carrier status. *D. Maar, S. Tzonev, N. Klitgord, S. Cooper, G. Karlin-Neumann, K. Hamby, J. Regan.* Bio-Rad Laboratories, Pleasanton, CA.

Haplotype information is routinely used to make critical medical decisions, such as HLA allele matching for successful tissue transplantation. With increasing frequency, other examples are emerging where cis-acting sites rather than single sites alone appear to be required to produce a certain phenotype. Examples include: a β-globin locus associated with less severe sickle cell disease, an IL10 promoter region associated with a lower incidence of graft-versus-host disease, and an ApoE locus that when configured in cis affects lipid metabolism. However, the lack of tools to haplotype certain alleles has slowed the discovery of additional associations. To speed discovery, the HapMap Consortium initiated the HapMap Project in 2002 to map roughly 3 million SNPs. Project contributors used pedigrees, allele-specific PCR (AS-PCR), long-range sequencing, and somatic cell hybrids to assist in mapping these SNPs. These methodologies have limitations, namely: late-onset diseases cannot be reasonably investigated because pedigree analysis typically depends on linkage disequilibrium of microsatellite and SNP markers across several generations; AS-PCR is hampered by the inefficiencies of long-range PCR and is prone to false positives; long-range sequencing is limited to targets within ~3000 bp of each other; and somatic cell hybridization is costly and time consuming. Here, we introduce droplet digital PCR (ddPCR) for digital linkage analysis, which is a low cost, rapid methodology to haplotype heterogeneous loci that are up to at least 30 kb apart. The technique is independent from PCR efficiency, does not rely on long-range PCR, and does not require pedigree analysis. We establish the effect sample preparation has on extending the limits of this approach. We also show that this approach can be used to map tagging SNPs within adjacent haplotype blocks, allowing for the spanning of unstable hot-spot regions known to frequently undergo homologous recombination. Lastly, we demonstrate this technique can effectively determine whether 2 copy genes are arranged in cis or trans, a useful technique to identify disease carriers. Such a technique will prove valuable in validating haplotypes derived from whole-genome association studies.

Deep Mutational Scanning to Assess How Mutations Impact Protein Aggregation. *D.M. Fowler.* Genome Sciences, University of Washington, Seattle, WA.

Protein aggregation plays a critical role in many common diseases including Alzheimer's and Parkinson's, each of which afflicts tens of millions of individuals. These diseases remain largely intractable, with grim, inexorable clinical courses. The protein aggregates found in these diseases are called amyloid and have a highly organized, fibrous structure known as the cross-β sheet. The exact role of amyloid formation in amyloid diseases is under active debate, but the importance of amyloid is highlighted by the existence of early onset, familial forms of these diseases in which mutations increase the aggregation propensity of the offending protein. To better understand protein aggregation, we are leveraging deep mutational scanning, a method that uses high-throughput DNA sequencing to enable the functional characterization of hundreds of thousands of mutants of a protein simultaneously. To generate these large-scale mutagenesis data for aggregation-prone proteins, we are using an assay that links growth of the budding yeast S. cerevisiae to the aggregation of a plasmid-encoded protein expressed as a dihydrofolate reductase (DHFR) fusion. Aggregation of the fusion protein inactivates DHFR and results in a reduced growth rate in the presence of methotrexate, a DHFR inhibitor. We have demonstrated differential growth of yeast carrying aggregation-enhancing versus aggregation-reducing mutations of both Aβ, which aggregates in Alzheimer's disease, and α-synuclein, which aggregates in Parkinson's disease. Screening of libraries of mutants of each of these proteins will yield aggregation propensity maps, detailing the impact of nearly all possible single mutations and many double mutations on aggregation. These maps will reveal the underlying physicochemical features responsible for amyloidogenesis in these proteins, yielding insight into the mechanism of aggregation and the structure of the aggregates in vivo. Finally, because these data describe the aggregation propensity of each possible single mutation in these aggregation-prone proteins, they could be used to interpret the significance of variants found in individuals' genomes.

Allele level sequencing and phasing of full-length HLA class I and II genes using SMRT® sequencing technology. *S. Ranade[1], J. Chin[1], B. Bowman[1], K. Eng[1], S. Suzuki[2], Y. Ozaki[2], T. Shiina[2].* 1) Pacific Biosciences, Menlo Park, CA; 2) Department of Molecular Life Sciences, Tokai University School of Medicine, Isehara, Kanagawa, Japan.

MHC gene family is comprised of three classes of genes, which are instrumental in determining donor-recipient compatibility for organ transplant as well as susceptibility to autoimmune diseases via cross-reacting immunization. Specifically Class I HLA-A, -B, -C, and Class II HLA-DR, -DQ and -DP genes are considered medically important for genetic investigation to determine histocompatibility. Highly polymorphic in nature, thousands of alleles of these HLA genes have been implicated in disease resistance and susceptibility, and the importance of full-length HLA gene sequencing for genotyping, detection of null alleles and phasing is being widely acknowledged. Although DNA-sequencing-based HLA genotyping is now routinely done, only 7% of the HLA genes have been characterized by allele-level sequencing, while 93% are still defined by partial sequences only. The gold-standard Sanger sequencing technology, though widely used, is unable to generate phased reads from heterozygous alleles. Second-generation, high-throughput clonal sequencing methods, although better at heterozygous allele detection, are inadequate at generating full-length haploid gene sequences from enhancer promoter to 3'UTR along with phasing information. The best way to overcome these challenges is to sequence these genes with a technology that is clonal in nature and has the longest possible read lengths. We have employed Single Molecule Real-Time (SMRT®) sequencing technology from Pacific Biosciences for sequencing full-length HLA class I and II genes. PCR systems were developed to amplify entire HLA genes ranging between 4.6 kb and 9.7 kb. For HLA genes that were too long, like HLA-DRB1 and -DPB1 (13–21 kb), the PCR regions were divided into two parts (enhancer-promoter to exon 2, and exon 2 to 3'-UTR for HLA-DRB1; and enhancer-promoter to intron 2, and intron 1 to 3'-UTR for HLA-DPB1). The long-range PCR amplicons were converted into SMRTbell™ libraries, and long reads ranging from ~3,500 to 20,000 bases were generated on the PacBio® RS. Full-length consensus reads were obtained with correct phasing information and accurate genotypes for all the alleles of each of the HLA genes based on the zygosity and presence of pseudo genes. The resolving power of SMRT Sequencing for simultaneously genotyping, determination of phasing information, and detection of novel alleles makes it a uniquely suitable DNA-based method for unambiguous allele-level characterization of HLA genes.

The Role Of MDR1 C3435T and C1236T Single Nucleotide Polymorphisms in Male Infertility. *S. Aydos[1], A. Karadag[1], T. Ozkan[1], B. Altinok[1], M. Bunsuz[1], S. Heidargholizadeh[1], K. Aydos[2], A. Sunguroglu[1].* 1) Ankara University, Faculty of Medicine, Department of Medical Biology Ankara, Turkey; 2) Ankara University, Faculty of Medicine, Reproductive Health Research Center Ankara, Turkey.

Infertility is a common problem, affecting one in six couples.In 30% of infertile couples, the male factor is a major cause due to defective sperm quality.However, the factors responsible for defective sperm quality remain largely unknown.The multi-drug resistance1 (MDR1) gene encoding a Pglycoprotein, which has a role in active transport of various substrates, including xenobiotics, and thus has a protective function in various tissues and organs. In the present case-control study, we investigated the effect of MDR1 gene C3435T and C1236T SNPs and on male infertility in Turkish population.The study was performed on 192 patients with infertil and 102 healthy control.The genotyping of C3435T and C1236T SNPs was done by PCR-RFLP.In statistical analysis were tested with chisquare test and SHEsis program. 101 patients were compared with sperm parameters. Frequencies of the C and T alleles of the 1236 locus were found to be 61.2(n=235) and 38.8(n=149)% in the infertil patient, similar to the 59.8 and 40.2% found in the healthy control, respectively.The C allele was detected more frequently in the patient.The frequencies of MDR1 1236 CC,CT and TT genotypes were 34.4%,53.6%,12% in the patient; those in the control were 34.3%,51%,14.7%, consecutively. However, the observed genotype frequencies did not show significant difference in either group(P>0.05).Frequencies of the C and T alleles of the 3435 locus were found to be 56.2, 43.8 % in the infertil patient, similar to the 51%, 49% found in the healthy control, respectively.The frequencies of MDR1 3435 CC,CT and TT genotypes were 27.6%,57.3%,15.1% in the patient; those in the control were 26.5%, 49%,24.5%, consecutively.However,the observed allel and genotype frequencies did not show significant difference in either group (P>0.05).Each of the four possible haplotypes was noted in both infertil patient and control. When the frequency distributions of estimated haplotypes were compared between the patient and control, the frequency of the T-T haplotype was found to be significantly higher in the control than in infertil patients (P=0.006).There was no correlation between sperm parameters and genotypes.Our findings show that two SNPs do not play a role in the genetic susceptibility to male infertility, controversial to Polish population.But T-T haplotypes may be a protective factor for the fertility,because this haplotype was found to be statistically lower in infertile patients than in control.

Interactions between Epigenetic and Genetic Signatures in the Asthmatic Airway. *J. Nicodemus-Johnson[1,5], R.A. Myers[1,5], D.K. Hogarth[2], J. Sudi[2], J.F. McConville[2], E.T. Naureckas[2], A.I. Sperling[2], J. Solway[2], J.A. Krishnan[2,4], S.R. White[2], D.L. Nicolae[1,2,3], Y. Gilad[1], C. Ober[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL; 4) Current Address: Department of Medicine, University of Illinois Hospital & Health Sciences System, Chicago IL; 5) co-first author.

A large number of genes are differentially expressed in airway epithelial cells of asthmatic and non-asthmatic individuals, yet neither the epigenetic mechanisms underlying these difference nor epigenetic interactions with asthma-risk alleles have previously been investigated. To address this gap in knowledge, we obtained genome-wide methylation profiles (450K array), gene expression by RNA sequencing and genetic variation (SNPs) in freshly isolated airway epithelial cells from 26 asthmatic and 20 non-asthmatic subjects. We identified differentially methylated regions (DMRs) and characterized their locations with respect to nearby genes, and assessed the influence of SNPs on nearby CpG methylation levels and gene expression. We identified 276 DMRs at a false discovery rate (FDR) of 5%. DMRs near genes are enriched for asthma relevant pathways in the airways such as focal adhesion, cytokine-cytokine receptor interactions, and calcium signaling (FDR < 5%). We identified methylation quantitative trait loci (meQTLs) for nearly half of all DMRs, some of which were associated with asthma in published genome-wide association studies. For example, we identified a significant interaction effect between the asthma-associated TSLP promoter SNP (rs1837253) and asthma status on methylation patterns: the asthma risk allele (T) is associated with decreased methylation in asthmatics and increased methylation in non-asthmatics (interaction p=0.010). In contrast, an asthma associated SNP at the HLA-DQ locus was a meQTL in both asthmatics ($p=5.6\times10^{-9}$) and non-asthmatics ($p=1.4\times10^{-10}$). However, the same SNP was associated with HLA-DQB1 transcript abundance in asthmatic subjects only (interaction p=0.027). These examples provide evidence for two distinct functional mechanisms by which previously reported genetic associations with asthma can be explained by variation in methylation patterns. Collectively, these data highlight the importance of epigenetic variation in promoting asthma phenotypes in the lung, both independently and in conjunction with local genetic variation. This work was supported by NIH grant AI095230.

Investigation of Cytotoxic T-lymphocyte-associated Protein 4 Gene Polymorphisms in Systemic Lupus Erythematosus. *H. Yang[1,2], T. Chen[3], C. Lee[1,2,4], S. Chang[1], W. Chen[1], W. Lin[1], C. Lin[1], Y. Lee[1,5,6,7,8].* 1) Dept. of Medical Research, Mackay Memorial Hospital, New Taipei City, Taiwan; 2) Department of Nursing, Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 3) Dept. of Rheumatology, Mackay Memorial Hospital, Taipei, Taiwan; 4) Department of Internal Medicine, Mackay Memorial Hospital, Taipei, Taiwan; 5) Dept. of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 6) Institute of Biomedical Science, Mackay Medical College, New Taipei City, Taiwan; 7) Dept. of Medicine, Mackay Medical College, New Taipei City, Taiwan; 8) Dept. of Pediatrics, Taipei Medical University, Taipei, Taiwan.

Systemic Lupus Erythematosus (SLE) is a chronic inflammatory, multisystemic, and autoimmune-related disease. The prevalence of SLE in Taiwan is around 37.0/100.000 persons and associated with gender, especially in childbearing age. SLE characterized by T and B cell hyperactivation, autoantibody production, and immune complex deposition. Cytotoxic T-lymphocyte-associated protein 4 (CTLA4) is expressed on CD4+ and CD8+ activated both T and B cells. Protein expression of CTLA4 was increased in T cells from patients with SLE. Numerous studies have been found in association between CTLA4 polymorphisms and SLE in different ethnic groups. However, large-scale study of CTLA4 polymorphisms in SLE is still elusive in Taiwan. For this case-control cross-sectional study among Taiwanese, 283 patients with SLE and 920 controls were enrolled. Genotyping of -318 C/T, +49 A/G, and CT60 A/G single nucleotide polymorphisms (SNPs) was performed by PCR-RFLP and TaqMan assays. The genotype, allele, and haplotype frequencies were calculated by direct counting or with Haploview 4.2 software. Genotype, allele, and haplotype frequencies of the CTLA4 SNPs studied were equally distributed in SLE patients and controls. No significant associations between SLE and these 3 SNPs were observed. Our data suggest that CTLA4 -318 C/T, +49 A/G, and CT60 A/G SNPs do not confer increased susceptibility to SLE.

Large scale identification of alternative polyadenylation through next generation sequencing. *C.M. Lopes-Ramos[1,2], A.A. Camargo[1], P.A.F. Galante[1], R.B. Parmigiani[1].* 1) Molecular Oncology Center, IEP, Hospital Sírio-Libanes, São Paulo, Brazil; 2) Fundação Antonio Prudente, AC Camargo Cancer Center, São Paulo, Brazil.

Most eukaryotic mRNAs acquire an uncoded polyA tail at their 3' ends during maturation in a process called polyadenylation (polyA). This process involves the cleavage of mRNA at a specific site and the subsequent addition of adenosine residues. Cleavage position is defined by recognition of specific sequences, called polyA signals. More than half of mammalian genes have multiple polyA signals, which can lead to the formation of transcript variants with different 3' untranslated regions (UTRs) or even different coding regions. Alternative polyA may influence the location, stability and transport of transcripts, in tissue or disease-specific manner. This is a result of many cis-acting elements involved in post-transcriptional regulation located within the 3'UTRs, such as miRNA binding sites. Here we studied alternative polyA events in two colon cancer cell lines (HCT116 and SW480) through next generation sequencing. We developed an original cDNA library protocol to enrich for the transcripts' 3' ends, enabling the preferential sequencing of the 3'UTRs and identification of polyA sites. Using a SOLiD sequencer (Life Technologies), more than 50 million sequences were generated for each cell line. Alternative polyA generating transcripts shorter than the reference gene (RefSeq with the longest 3'UTR) was verified for more than 6000 genes, corresponding to 30% of genes expressed in these cells. Besides the above-mentioned effects, evidences of alternative polyA functional impact may be demonstrated by the loss of miRNA target sites. In fact, 2400 polyA variants have lost at least one conserved miRNA target site, which represent about 30% of all identified variants. Preferential usage of shorter polyA variants allows escaping from the inhibitory regulation of miRNAs on the expression of such target genes. We have also evaluated miRNA expression profile of these two cell lines and identified more than 50 miRNAs being differently expressed. miRNA expression profile and polyA variants expression might be tightly associated. Therefore, identification of inverse correlation of miRNA and polyA variants expression is underway. This innovative approach increased our capacity of identification and expression analysis of polyA variants for several genes. By focusing on variants that lose binding sites for miRNAs, it may rise possibilities to better understand how this phenomenon regulates different cellular processes in physiological and pathological situations.

Identification of DNA editing in retrotransposons of diverse genomes.
B.A. Knisbacher, E.Y. Levanon. The Mina & Everard Goodman Faculty of Life Sciences, Bar-Ilan University, Ramat Gan , Israel.

Retrotransposons comprise a large fraction of mammalian genomes. Their dynamics contribute to genomic plasticity and enhance evolution. Yet, retrotransposons must be kept in check to retain genomic stability and avoid detrimental mutagenesis. The APOBECs, a family of cytidine deaminases, take that responsibility and restrict mobilization of retrotransposons in the genome. Through their ability to bind and edit DNA they can cause deleterious hypermutation in nascent retrotransposon DNA, right after reverse transcription, which will typically cause its degradation. However, in some cases, the retrotransposons can complete mobilization despite being hypermutated. Such an event results in the insertion of a unique retrotransposon sequence, thus increasing genomic diversity and the probability of developing a novel functional unit at this genomic locus. In this study, we computationally screened retrotransposon sequences in >80 genomes (the UCSC reference genomes), for edited integrants. By generating pairwise alignments of retrotransposons we revealed that DNA editing is abundant in many lineages and especially in mammals. In total, these genomes contain tens of thousands of edited sequences harboring hundreds of thousands of edited sites. Our analyses of the edited elements and editing rates, including comparative genomics, gives valuable insights into the evolutionary impact of DNA editing and the role of retrotransposon restrictors in distinct species.

Association between estrogen receptor and intraocular pressure in mice.
F. Mabuchi[1], R. Yamagishi[2], K. Kashiwagi[1], M. Aihara[3]. 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Ophthalmology, Univ Tokyo, Bunkyo-ku, Tokyo, Japan; 3) Shirato eye clinic, Shinjuku-ku, Tokyo, Japan.

Purpose: To evaluate intraocular pressure (IOP) in transgenic mice with a knockout of estrogen receptor alpha (*ESR1*) or estrogen receptor beta (*ESR2*) gene. **Methods:** Heterozygous B6.129P2-*Esr1*^{tm1Ksk}/J (*ESR1* gene knockout) or B6.129P2-*Esr2*^{tm1Unc}/J (*ESR2* gene knockout) mice, and corresponding wild-type mice were anesthetized. A fluid-filled glass microneedle connected to a pressure transducer was then inserted through the cornea into the anterior chamber to measure IOP. All measurements were made between 9:00 PM and 11:00 PM. The IOP of fifteen *ESR1* $^{+/-}$ and wild-type *ESR1* $^{+/+}$ mice, and IOP of nine *ESR2* $^{+/-}$ and wild-type *ESR2* $^{+/+}$ mice were measured at 6 to 8 weeks after birth. **Results:** The IOPs of the *ESR1* $^{+/-}$ and wild-type *ESR1* $^{+/+}$ mice were 20.5 ± 1.0 mmHg (mean ± standard deviation) and 20.3 ± 1.2 mmHg respectively, and there was no statistically significant difference (P = 0.81, Mann-Whitney U test) between them. In contrast, the IOPs of the *ESR2* $^{+/-}$ and wild-type *ESR2* $^{+/+}$ mice were 18.3 ± 1.2 and 19.9 ± 1.6 mmHg respectively, and there was a statistically significant difference (P = 0.04, Mann-Whitney U test) between them. **Conclusion:** These results suggest that the *ESR2* is associated with IOP regulation.

CCL3L1 copy number, HIV load, and immune reconstitution in sub-Saharan Africans. *E.J. Hollox[1], L. Odenthal-Hesse[1], J. Bowdrey[1], A. Habtewold[2,3], E. Ngaimisi[2,4], G. Yimer[2,3], W. Amogne[5,6], S. Mugusi[7], O. Minzi[4], E. Makonnen[3], M. Janabi[8], F. Mugusi[8], G. Aderaye[5], R. Hardwick[1], B. Fu[9], M. Viskaduraki[10], F. Yang[9], E. Aklillu[2].* 1) Department of Genetics, University of Leicester, Leicester, United Kingdom; 2) Department of Clinical Pharmacology, Karolinska Institutet, Stockholm, Sweden; 3) Department of Pharmacology, Addis Ababa University, Addis Ababa, Ethiopia; 4) Unit of Pharmacology, School of Pharmacy, Muhimbili University of Health and Allied Sciences, Dar es Salaam, Tanzania; 5) Internal Medicine, Addis Ababa University, Addis Ababa, Ethiopia; 6) Institution of Medicine, Unit of Infectious Diseases, Karolinska Institutet, Karolinska University Hospital, Huddinge, Sweden; 7) Department of Internal Medicine, Muhimbili National Hospital, Dar es Salaam, Tanzania; 8) Department of Internal Medicine, Muhimbili University of Health and Allied Sciences, Dar es Salaam, Tanzania; 9) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 10) College of Medicine, Biological Sciences and Psychology, University of Leicester, Leicester, United Kingdom.

The role of genome copy number variation of the CCL3L1 gene, encoding MIP1α, in contributing to the host variation in susceptibility and response to HIV infection is controversial. Here we analyse a sub-Saharan African cohort from Tanzania and Ethiopia, two countries with a high prevalence of HIV-1 and a high co-morbidity of HIV with tuberculosis. We use a form of quantitative PCR called the paralogue ratio test, we determine CCL3L1 gene copy number in 1134 individuals and validate our copy number typing using array comparative genomic hybridisation and fiber-FISH. We find no significant association of CCL3L1 gene copy number with HIV load in antiretroviral-naïve patients prior to initiation of combination highly active anti-retroviral therapy. However, we find a significant association of low CCL3L1 gene copy number with improved immune reconstitution following initiation of highly active anti-retroviral therapy (p=0.012), replicating a previous study. Our work supports a role for CCL3L1 copy number in immune constitution following antiretroviral therapy in HIV, and suggests that the MIP1α-CCR5 axis might be targeted to aid immune reconstitution.

696W

Role of translocator protein (TSPO) in antipsychotic-induced weight gain. *J.G. Pouget[1,2], V.F. Gonçalves[1], A.K. Tiwari[1], J.A. Lieberman[3], H.Y. Meltzer[4], D.J. Müller[1,5], J.L. Kennedy[1,5].* 1) Pharmacogenetics Research Clinic, Neuroscience Department, Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Institute of Medical Sciences, University of Toronto, Toronto, ON, Canada; 3) Department of Psychiatry, College of Physicians and Surgeons, Columbia University and the New York State Psychiatric Institute, New York City, NY, USA; 4) Northwestern University Feinberg School of Medicine, Chicago, IL, USA; 5) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

Background: Weight gain is a common side effect of second-generation antipsychotics (SGAs), contributing to patient non-compliance and cardiovascular disease. With heritability estimates ~60%, genetic markers may improve prediction of patients at greatest risk of AIWG. Translocator protein (TSPO), part of the mitochondrial permeability transition pore (mtPTP), regulates cytosolic reactive oxygen species (ROS) levels and shows enhanced functioning after SGA treatment. The present study explores the association between genetic variation in TSPO and AIWG. **Methods:** Genomic DNA was obtained from blood samples of schizophrenia patients with weight change observed after up to 14 weeks of antipsychotic treatment (n=235). Eight putative functional SNPs in the TSPO region (rs138926, rs80411, rs6971, rs6973, rs113515, rs138911, rs5759197, rs739092) were genotyped using TaqMan assays (Applied Biosystems), capturing 77% of common variation across TSPO. Pairwise interactions of TSPO markers significantly associated with % weight change from baseline and markers in other mtPTP genes (SLC25A4: rs10024068, rs7660552; VDAC1: rs13169435, rs4279383, rs2288834, rs2066944, rs10491289; HK1: rs16926246, rs7072268) were assessed using model-based multifactor dimensionality reduction. **Results:** No significant association with % weight change was observed for any TSPO SNPs in the total sample. In a sub-analysis of European patients on clozapine or olanzapine (n=82), drugs with the greatest propensity for weight gain, nominal association was observed between % weight change and the rs6971 Thr allele after multiple testing correction (p=0.02). rs6971 Thr/Thr homozygotes showed 4.65% greater weight change from baseline (95% CI: 0.03 - 9.26%, p=0.05) compared to Ala/Ala homozygotes. A significant interaction was observed between TSPO rs6971 and ANT1 rs10024068 ($P_{10\ 000}$=8.0×10^{-3}). **Discussion:** The rs6971 Thr allele may predispose European patients treated with clozapine or olanzapine to AIWG. Previous functional studies indicate rs6971 predicts a large portion of variance in TSPO binding, with the Thr allele conferring lower binding affinity. TSPO rs6971 may interact with rs10024068, a marker 1.1kb upstream of SLC25A4, to influence AIWG. These findings provide preliminary support for the role of the mtPTP in AIWG. Replication, in addition to functional studies clarifying the underlying mechanisms, is required to elucidate the role of these variants in AIWG.

697W

Association between polymorphisms in genes coding for cellular drug transporters and the effectiveness of antiretroviral therapy against HIV-1 among Brazilians. *C.C. Cardoso, J.Z.C. Dias, M.B. Arruda, R.M. Brindeiro, O. Ferreira, A. Tanuri, R.S. Aguiar.* Genetics Department, Biology Institute, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil.

Background: The highly active antiretroviral therapy (HAART) improved the life expectation and prognostic of the HIV+ patients. However, about 10-20% of patients develop HAART failure, mostly due to the emergence of virus mutations associated with drug resistance. Moreover, human genetics polymorphism can also be associated with antiretroviral failure, mainly in genes related to drug absorption, activation and metabolism. Here we investigate the association between 40 single nucleotide polymorphisms (SNPs) in the genes SLC22A1, SLC22A2, SLC22A3 (organic cation ransporters 1-3) and ABCB1 (P-Glycoprotein) and HAART effectiveness. Methods: We have conducted a case-control study including 237 HIV+ individuals (117 cases of HAART failure and 120 controls), from Curitiba and Porto Alegre cities (Brazil). The case definition was based on the reduced HIV-1 viral load to undetectable levels in the first-line therapy. All patients were treated for at least 6 months. Human SNPs were genotyped using SnapShot, TaqMan and Sanger sequencing. All samples were also genotyped for additional 32 ancestry informative SNPs. Pairwise linkage disequilibrium patterns were estimated by the r2 coefficient. The frequencies of each SNP and haplotypes in cases and controls were compared by logistic regression models adjusted for the covariates age, genetic ancestry and therapy scheme. Results: Logistic regression models showed an association between the SNPs rs2229109 and rs6961419 in ABCB1 gene and therapeutic failure. The presence of allele A for the SNP rs2229109 was associated with an increasing risk of HAART failure with OR values of 7.33 (95% CI: 1.85-29; p = 0.001). Moreover, patients sharing alleles rs2229109A/rs6961419G were more susceptible to develop HAART failure (OR=8.04; 95% CI: 2.02-32; p = 0.003). Our results are in concordance with functional data that associated the substitution S400N codified by this SNP (rs2229109) with higher extrusion levels of drugs mediated by P-Glycoprotein. Conclusion: Our data describe a clear association between ABCB1 gene and HAART failure, suggesting that polymorphisms in this gene may affect intracellular drug concentrations and influence treatment effectiveness. Studies of host genetics are crucial to predict more effective treatment for HIV+ patients.

Differential effects at candidate SNP loci on reduction in plasma LDL cholesterol, apolipoprotein B, LDL particle number, and mean LDL particle size with statin therapy.
A.Y. Chu[1], B.J. Barratt[2], B. Ding[3], F. Nyberg[3,4], S. Mora[1,5], P.M Ridker[1,5], D.I. Chasman[1,6]. 1) Division of Preventive Medicine, Brigham & Women's Hospital, Boston, MA USA; 2) Personalized Healthcare and Biomarkers, AstraZeneca Research and Development, Alderley Park, United Kingdom; 3) Global Epidemiology, AstraZeneca Research and Development, Molndal, Sweden; 4) Unit of Occupational and Environmental Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; 5) Division of Cardiology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA USA; 6) Division of Genetics, Brigham and Women's Hosp, Boston, MA USA.

Statins differentially reduce LDL cholesterol (LDL-C), apolipoprotein B (apoB), total number of LDL particles (LDL-P) and mean LDL particle size (LZ). Variations in the reduction of these measures and possibly their relationship to cardiovascular risk reduction may be under genetic control. We performed a candidate SNP analysis for association with change in LDL-C, apoB, LDL-P and LZ after 12 months of statin therapy, focusing on 156 SNPs previously associated with either statin-induced reduction in LDL-C (6 SNPs) or untreated serum lipid levels from metabochip analysis by the Global Lipids Consortium (150 SNPs). The study population included 3,534 statin-allocated participants of European ancestry in JUPITER (NCT00239681), a randomized, placebo-controlled trial of rosuvastatin (20 mg/d) for primary prevention of cardiovascular disease. Residuals for all LDL change measures were calculated adjusted for age, sex, region and population stratification and further transformed by inverse-quantile normalization. Genetic associations were assessed by linear regression applying the standard additive assumption for estimating effects on quantile normalized lipoprotein measures (β_q). Of the 156 candidate SNPs, 42 were nominally associated with at least one of the four LDL-change measures ($p<0.05$) and could be clustered into 4 groups depending on whether the association was primarily with change in LDL-C, apoB, LDL-P or LZ. A Bonferroni corrected threshold of $p<8.3e-5$ (=0.05/156x4 tests) identified novel associations for variants at *APOA1-A5* for change in LZ (rs964184; β_q=0.17, p= 4.1e−5), and at *CILP2* for change in apoB (rs10401969; β_q=0.17, p=7.2e−5). The *APOA1-A5* SNP was associated only with change in LZ (associations with LDL-C, apoB and LDL-P p>0.05; all β_q different from LZ β_q, p<0.05 for all three comparisons). The SNP at *CILP2* was primarily associated with change in apoB, but also was nominally associated with change in LDL-P (β_q=0.13, p=8.0e-3; pairwise comparison p>0.05). Additionally, variants in *ABCG2* and *LPA*, previously identified for change in LDL-C in JUPITER (Circ Genetics 2012;5:257) were associated with change in apoB and LDL-P. None of these SNPs were associated with change in the four LDL-associated measures in the placebo arm (n=3512). Differential genetic effects of statin-induced change in LDL-C, apoB, LDL-P and LZ based on candidate SNP analysis suggest distinct pathways underlying the change of these LDL-related measures with statins.

699W

A hypothesis driven association analysis of nuclear-encoded mitochondrial genes with antipsychotic-induced weight gain in schizophrenia subjects.
V.F. Gonçalves[1, 2], C. Zai[1, 2], A. Tiwari[1], A. Derkach[3], H. Meltzer[4], J. Lieberman[5], A.D. Paterson[6], L. Sun[3, 7], D. Mueller[1, 2], J.L. Kennedy[1, 2]. 1) Department of Psychiatry, University of Toronto, Toronto, Canada; 2) Neuroscience Section, Centre for Addiction and Mental Health, Toronto, Canada; 3) Department of Statistical Sciences, University of Toronto, Toronto, Canada; 4) Department of Psychiatry and Behavioral Sciences, Northwestern University, Chicago, USA; 5) Department of Psychiatry, College of Physicians and Surgeons, Columbia University and the New York State Psychiatric Institute, New York City, USA; 6) Program in Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Canada; 7) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada.

Antipsychotic-induced weight gain (AIWG) is an important phenotype that often leads to obesity and metabolic syndrome. We are proposing that mitochondrial system might play a role in its development since mitochondria is main source of energy for neurons and control energy homeostasis in the hypothalamus. In our study, we investigated the hypothesis that nuclear-encoded mitochondrial genes, particularly those with altered gene expression or involved in the oxidative stress, mitochondrial biogenesis, inflammation and apoptosis, would be associated with AIWG. In total, we selected 28 genes and analyzed 60 SNPs, most of them classified as functional or regulatory elements, in schizophrenia subjects (N=164), treated with atypical medications up to 14 weeks. Single-SNP genetic association was tested using linear regression with percentage of weight gain from baseline as the dependent variable and treatment duration and baseline body weight as covariates. Assuming MAF of 0.15, we had more than 80% power to detect a mean difference of 2.4% between carriers and non-carriers of the risk genotype in the additive model. Several multi-SNP analyses were also carried out, including haplotype analysis, stepwise linear regression, and gene-gene interactions. The statistical strength of our biological hypothesis was measured by comparing the sum of the observed association evidence across all 60 SNPs with the value expected under the null based on a phenotype permutation method (10,000 permutation replicates). We observed a significant association between rs6435326 in the NDUFS1 gene and percentage of weight gain (N= 150, Pcorrected=0.02). The haplotype carrying the risk alleles for rs6435326 and two other SNPs in NDUFS1 was also significantly associated with weight-gain (%) (P=0.005). In addition, we observed a significant interaction between the TT risk genotype of rs6435326 in NDUFS1 and AG genotype of rs3762883 in COX18 (Pcorrected=0.001). Finally, permutation-based test showed that the set of 60 SNPs from the 28 nuclear-encoded mitochondrial genes selected based on our hypothesis, collectively, was associated with weight gain (P=0.02). To the best of our knowledge, this is the first study to explore genetic variation in the mitochondrial genes in the context of AIWG. This study provides evidence implicating mitochondrial genes to be involved in the regulation of the energy homeostasis and body weight in schizophrenia subjects under atypical antipsychotic treatment.

PAX4 genetic variant is associated with therapeutic effect of repaglinide in the Chinese type 2 diabetes patients.
C. Hu, M. Chen, R. Zhang, Y. Bao, K. Xiang, W. Jia. Shanghai Diabetes Inst, Shanghai Jiao Tong University, Shanghai, Shanghai, China.

A recent genome-wide association study (GWAS) identified a novel diabetes-associated locus near PAX4 (rs10229583) in Chinese population and other populations. However, whether this single-nucleotide polymorphism (SNP) influence the therapeutic effects of oral antihyperglycemic drugs has not been reported. The aim of this study was to investigate the association of PAX4 variants rs10229583 with therapeutic effects of repaglinide or rosiglitazone in patients with type 2 diabetes. A total of 209 newly diagnosed type 2 diabetes patients were recruited and treated with repaglinide or rosiglitazone randomly for 48 weeks (104 and 105 patients, respectively). In the repaglinide cohort, individuals who were GG homozygotes of rs102229683 showed lower fasting plasma glucose , 2h glucose and HbA1c levels than the A allele carriers. Moreover, carriers of GG genotype exhibited significantly higher cumulative attainment rates of target fasting plasma levels (Plog-rank = 0.0009) than the A allele carriers, and this difference was still significant (P = 0.0037) even after adjusting for age, gender, and body mass index (BMI) at baseline. Besides, significant linear relationships were detected between the number of rs10229583 A alleles and increments in fasting insulin levels (P= 0.0426, adjusted for age, gender, dosage, and BMI at baseline). However, no effect of rs10229583 on the efficacy of rosiglitazone was found in our study. In conclusion, the PAX4 variant rs10229583 was associated with therapeutic effect of repaglinide in Chinese patients with type 2 diabetes.

Multi-ethnic cytochrome P450-2D6 (CYP2D6) allele frequency profiling and full gene single-molecule real-time (SMRT®) sequencing. *S. Martis[1], Y. Yang[1], A. Gaedigk[2], R. Sebra[3], R. Vijzelaar[1], R. Kornreich[1], R.J. Desnick[1], S.A. Scott[1].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Division of Clinical Pharmacology & Therapeutic Innovation, University of Missouri-Kansas City, Kansas City, MO; 3) MRC Holland, Willem Schoutenstraat 6, Amsterdam, The Netherlands.

The polymorphic cytochrome P450-2D6 (CYP2D6) isoenzyme is involved in the oxidative metabolism of approximately 25% of commonly used medications, underscoring its importance in human drug metabolism. Common variant CYP2D6 alleles have been implicated in interindividual drug response variability and adverse reactions; however, the CYP2D6 gene is difficult to interrogate due to high sequence homology with its neighboring CYP2D7P1 pseudogene. To determine the multi-ethnic frequencies of an extensive panel of CYP2D6 variant alleles, *2 - *12, *14, *15, *17, *29, *35, *41, and the gene duplication were genotyped among 464 healthy adult African-American, Asian, Caucasian, Hispanic, Ashkenazi, and Sephardic Jewish individuals using the xTAG CYP2D6 Kit (Luminex Molecular Diagnostics). The frequencies of functional, reduced function, and non-functional alleles in the tested populations ranged from 0.46-0.76, 0.11-0.43, and 0.11-0.21, respectively. In addition, multiplex ligation-dependent probe amplification (MLPA) with probes for CYP2D6 exons 1, 4, 6 and 9 was performed on all samples, which validated the deletion (*5) and duplication genotyping. However, discrepant copy number results between genotyping and MLPA were observed predominantly in the Asian population, which likely was indicative of the CYP2D6*36-*10 tandem allele as it correlated with genotype detection of *10 and the increased MLPA-detected copy number in these samples was restricted to the exon 1, 4, and 6 probes. Additionally, in an effort to devise a unique full gene sequencing strategy that could identify novel CYP2D6 alleles, establish the phase of genotyped variants, and specifically characterize the duplicated CYP2D6 copy when present, long-read third-generation single-molecule real-time (SMRT®) sequencing (Pacific Biosciences) of 5.0 kb CYP2D6 full gene amplicons was performed on 12 publically available DNA samples with previously reported discrepant CYP2D6 genotypes. Importantly, in contrast to Sanger and short-read second-generation sequencing, SMRT® sequencing can determine the phase of CYP2D6 diplotypes in these samples, including the specific identity of the duplicated copies when present. Taken together, these data identify the broad allelic spectrum of the CYP2D6 gene in a racially diverse and multiethnic population and support the use of long-range SMRT® sequencing for full gene and phased CYP2D6 characterization, including novel allele discovery.

Association of Cyclooxygenase-2 genetic variant with cardiovascular disease. *S.A. Ross[1], J.W. Eikelboom[1], S.S. Anand[1], N. Eriksson[2], H. Gerstein[1,3,4], S.R. Mehta[1], S.J. Connolly[1], L. Rose[5], P.M. Ridker[5,6], L. Wallentin[2], D. Chasman[5,6], S. Yusuf[1], G. Pare[1].* 1) Population Health Research Institute, Hamilton Health Sciences and Departments of Medicine, Epidemiology, Pathology McMaster University, Hamilton, ON, Canada; 2) Uppsala Clinical Research Center and Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Department of Medicine, McMaster University, Hamilton, ON, Canada; 4) Department of Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, ON, Canada; 5) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 6) Harvard Medical School, Boston, Massachusetts, USA.

Background: Cyclooxygenase (COX) enzymes convert arachidonic acid to prostaglandin H2 leading to the production of biologically active prostanoids, prostacyclin and thromboxane, which are believed to play key roles in atherothrombosis. The non-selective COX inhibitor aspirin is associated with a decreased risk of cardiovascular disease (CVD) whereas selective COX-2 inhibitors have been associated with an increased risk. A genetic variant (rs20417) of the PTGS2 gene, encoding for COX-2, has been associated with decreased COX-2 activity and a decreased CVD risk. However, this genetic association and the role of COX-2 in CVD remains controversial. Methods: The association between rs20417 and major adverse cardiovascular outcomes (non-fatal myocardial infarction, stroke or cardiovascular death) was prospectively explored in 49,233 subjects (ACTIVE-A, CURE, epiDREAM/DREAM, ONTARGET, RE-LY, and WGHS) and the effect of potentially modifiable risk factors on the genetic association was further explored in 4,465 non-fatal myocardial infarction cases and 4,898 controls from the INTERHEART study. We also examined the effects of rs20417 on urinary thromboxane and prostacyclin metabolite concentrations in 119 healthy individuals. Results: Carriage of the rs20417 minor allele was associated with a decreased risk of major CVD outcomes (OR=0.78, 95% CI: 0.70 - 0.87; $P=1.2\times10^{-5}$). The genetic effect was significantly stronger in aspirin users (OR: 0.74, 95% CI: 0.64-0.84; $P=1.20\times10^{-5}$, N=22,441) than non-users (OR: 0.87, 95% CI: 0.72-1.06; P=0.16, N=26,719) with an interaction p-value of 0.0041. Carriers had significantly lower urinary levels of thromboxane (97.0 vs. 125.5 ng/mmol creatinine; P=0.02) and prostacyclin (3336.0 vs. 4702.0 ng/mmol creatinine; P=0.01) metabolites as compared to noncarriers. Conclusion: The rs20417 polymorphism is associated with a reduced risk of major cardiovascular events and lower levels of thromboxane and prostacyclin. Our results suggest that a genetic decrease in COX-2 activity may be beneficial with respect to CVD risk and may vary in effect size depending on ASA use.

703W

Influence of CYP4F2 on dose, anticoagulation control and risk of hemorrhage among African American and European American warfarin users. *A. Shendre[1], T.M. Beasley[2], D.A. Nickerson[3], N.A. Limdi[4, 1].* 1) Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 2) Biostatistics, Section on Statistical Genetics, University of Alabama at Birmingham, Birmingham, AL; 3) Genome Sciences, School of Medicine, University of Washington, Seattle, WA; 4) Neurology, University of Alabama at Birmingham, Birmingham, AL.

The management of warfarin therapy is complicated by a wide variation in dose and response across patients. A significant portion of variability in dose is explained by single nucleotide polymorphisms (SNPs) in CYP2C9 and VKORC1 across racial groups. CYP4F2 (rs2108622; p.V433M) explains variability in dose among European Americans but its influence on warfarin dose, anticoagulation control, and risk of hemorrhage has yet to be fully examined, especially in African Americans. Herein we assess the influence of CYP4F2 on stable warfarin dose, anticoagulation control (percent time in target range; PTTR) and risk of major hemorrhage in 649 European and 430 African Americans patients in a prospective warfarin pharmacogenetics study. We evaluated the influence of the CYP2F2 genotypes on the 3 outcomes of interest using an additive model with adjustment for clinical factors, co-medications, and established genetic predictors (i.e., VKORC1; CYP2C9). For warfarin dose and anticoagulation control (PTTR) as outcomes, multivariable linear regression modeling was performed. The association of CYP4F2 with risk of hemorrhage was examined using Cox proportional hazards regression.The frequency of the minor (A) allele was higher in European (52%) compared to African (16%) Americans. Compared to the GG genotype, the CYP4F2 A allele was associated with a 7.0% higher (p=0.03) warfarin dose [5.5% higher (p=0.08) for AG and 13.4% higher (p= 0.03) for AA genotype] in European Americans. CYP4F2 did not significantly influence warfarin dose in African Americans [0.1% higher (p=0.98) for AG and 13.6% higher (p=0.6) for AA genotype]. PTTR was not influenced by CYP4F2 for either European American (p=0.59) or African American patients (p=0.78).The incidence of hemorrhage was lowest among patients with the AA genotype (1.05/100pyrs) compared to the AG (8.1/100pyrs) and GG (6.8/100pyrs) genotype. Patients with AA genotype had a lower risk of hemorrhage [HR: 0.17 (0.02-1.37), p=0.09] compared to patients with GG or AG genotype. Incorporation of CYP4F2 genotype can provide additional improvement in warfarin dosing among European Americans. Additionally, CYP4F2 AA genotype appears to provide a protective effect against the risk of hemorrhage but further research is needed to confirm these associations and to establish the utility of CYP4F2 in the care of a racially diverse patient population.

A mechanism for docetaxel induced neutropenia: The role of Cwc27. *T. Wiltshire[1], C.S. Benton[1], F. Muhale[2], O. Suzuki[1], A. Frick[1], O.J. Trask[2], R. Thomas[2], S. Cai[3], H.L. McLeod[1].* 1) School of Pharmacy, University of North Carolina, Chapel Hill, NC; 2) The Hamner Institutes for Health Sciences, Research Triangle Park, NC; 3) Washington University School of Medicine.

Chemotherapy-induced neutropenia (CIN) often results in dose reduction or treatment delay, negatively impacting response rates and overall survival for cancer patients. Previous studies have suggested that genetic factors play a role in CIN, and genetic information could be used to better identify patients who are likely to develop CIN prior to drug and dose selection. To identify genes that mediate docetaxal-induced neutropenia, we conducted a genome-wide association analysis in twenty-one genetically diverse mouse inbred strains. After a 14-day treatment with docetaxel, we found a significant inter-strain difference in the development of neutropenia and this phenotypic difference was not correlated to docetaxel serum levels or AUC. Using genomewide-association analysis, we found a locus on Chr 13 that was significantly linked to docetaxel-induced neutropenia (−logP >3.0). Within this locus is the spliceosome associated protein homolog, Cwc27 gene. We observed a 2-fold reduction in IC50 values following Cwc27 shRNA knockdown cells compared to control (shRNA-Cwc27 = 19.5 nM, eGFP = 38.7 nM, and shRNA scramble = 41.2). Furthermore, shRNA knockdown of Cwc27 resulted in greater signal intensity for α tubulin, caspase 3, and phosphohistone H3, which suggests that the increased cell loss observed following Cwc27 knockdown was likely due to dysregulated microtubule assembly and organization that prevented cells from undergoing mitosis. These results along with the data from the FACs analysis of bone marrow samples indicated that strains with severe neutropenia had a greater than two-fold reduction in the numbers of progenitor cells compared to strains with moderate neutropenia. These data imply that the impact of docetaxel was not specifically in loss of neutrophils, but in the ability to replenish them after drug treatment. Altogether, our findings suggest that Cwc27 mediates risk to CIN through its role in cellular differentiation and consequently, hematopoietic stem cell mobilization and neutrophil production.

705W

ABCB1 rs3842 polymorphism affects tacrolimus pharmacokinetics during the first week after liver transplantation in Chinese. *J. Shi[1], C. Zhang[1], D. Chen[2], J. Fan[2], K. Zhang[1], Z. Peng[2], W. Huang[1,3].* 1) Department of Genetics, Chinese National Human Genome Center at Shanghai, Shanghai,China; 2) Department of General Surgery, Shanghai First People's Hospital, Shanghai Jiao Tong University, Shanghai, China; 3) Rui Jin Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China.

Immunosuppressive drug, tacrolimus, is widely used in solid organ transplantation to prevent allograft rejection. However, it has a narrow therapeutic index with high inter-individual variations in its pharmacokinetics, which makes it difficult to establish an empirical dosage regimen in organ transplant recipients. Tacrolimus is a substrate for the multidrug efflux transporter P-glycoprotein, encoded by ABCB1 gene. A considerable number of reports have studied the correlation between the ABCB1 gene polymorphisms and the metabolism of tacrolimus. However, the obtained results are conflicting. The reason for these conflicting results might be the fact that the studies were mostly focused on 1236C>T (rs1128503), 2677G>T/A (rs2032582) and 3435C>T (rs1045642). However, these polymorphisms are not the only polymorphisms capable of influencing the P-glycoprotein function. Thus, we selected ten variations with minor allele frequency great than 3% in Han Chinese and examined genotypes for both recipient and donor in 115 liver transplantation patients, to clarify the influence of these genetic variants on tacrolimus dose requirements after liver transplantation. The recipient ABCB1 variant rs3842 significantly influenced the mean tacrolimus trough blood concentrations ($P=2.6\times10^{-4}$), and the mean dose-adjusted trough concentrations ($P=8.8\times10^{-3}$) during the first week post transplantation. A significantly higher trough blood concentration was observed for recipients with the homozygous variant rs3842 GG genotype compared to those with the homozygous AA genotype. This association remained significant after adjusting for age, sex, clinical outcome parameters and information of combined drugs. None of the donar ABCB1 polymorphism showed correlation with tacrolimus pharmacokinetics. The extensively studied 3435C>T, 2677G>T/A and 1236C>T in both donor and recipient showed no correlation with tacrolimus pharmacokinetic. This study indicates, for the first time, that recipient ABCB1 polymorphism rs3842 is associated with tacrolimus dose requirements limited to the early post-transplant period. The result highlights the importance of screening the comprehensive polymorphisms in ABCB1 gene region and examining the impact of polymorphisms in different post transplant time, which might provided new clues of the association of ABCB1 and tacrolimus pharmacokinetic.

706W

Effect of APOE genotype on response to donepezil and placebo in subjects with mild-to-moderate Alzheimer's dementia. *D.P. King, J.F. Waring, Q. Tang, W.Z. Robieson, U. Das, J. Dubow, S. Dutta, G.J. Marek, L.M. Gault.* AbbVie Inc., North Chicago, IL.

Background: Previous studies examining the influence of the apolipoprotein E (APOE)-ε4 allele on the clinical response to acetylcholinesterase treatment in Alzheimer's dementia patients have yielded inconsistent results. Data on the donepezil response from 3 studies in subjects with mild-to-moderate Alzheimer's dementia were pooled to examine this relationship. Methods: Data from 3 multinational, randomized clinical studies with a 12-week treatment duration, similar study design and a statistically significant response to donepezil were pooled. Patients with mild-to-moderate Alzheimer's dementia (Mini-Mental Status Examination [MMSE] score of 10-24, inclusive) provided DNA during study screening. APOE-ε4 carrier status was determined using pyrosequencing. The change from baseline to final observation on the 13-item ADAS-Cog total score in the intent-to-treat population was analyzed using ANCOVA with terms of age, treatment, study site, APOE-ε4 allele status, using baseline ADAS-Cog score as a covariate. Results: Placebo (N=170) and donepezil (N=165) patients had a mean (SD) age of 72 (8.5) years and a mean (SD) baseline MMSE of 19 (3.9). Although the interaction between APOE-ε4 carrier status and treatment was not significant (P=0.61), donepezil significantly improved ADAS-Cog scores versus placebo in both the APOE-ε4 carriers (donepezil [N=81], placebo [N=94], LS mean difference from placebo = −2.34, P=0.01) and noncarriers (donepezil [N=84], placebo [N=76], LS mean difference from placebo = −1.71, P= 0.05). The baseline to final change in ADAS-Cog scores did not differ significantly (P=0.89) among donepezil patients in terms of APOE-ε4 allele copy number: 0 APOE-ε4 alleles (LS mean [SE] change from baseline = −4.09 [0.67], N=84); 1 allele (−2.97 [0.73], N=72); 2 alleles (−2.74 [1.98], N=9). Of note, the magnitude of the donepezil treatment response was similar in APOE-ε4 carriers and noncarriers; however, the carrier group exhibited a smaller placebo response than the noncarrier group (LS mean difference baseline to final = −0.60 versus −2.38, P=0.05). Conclusions: There was no significant effect of APOE-ε4 genotype on the donepezil response in these mild-to-moderate Alzheimer's dementia patients. APOE-ε4 carriers in the placebo group exhibited a smaller change from baseline on the ADAS-Cog than noncarriers. Thus, APOE-ε4 genotype status may be useful for randomization in future clinical trials. Support: AbbVie.

The Role of Multidrug Resistance-1 (MDR1) Variants in Response to Atorvastatin among Jordanians. *K.H. Alzoubi[1], O.F. Khabour[2], S.A. Alazzam[1].* 1) Clinical Pharmacy, Jordan University of Science and Technology, Irbid, Jordan; 2) Medical Laboratory Sciences, Jordan University of Science and Technology, Irbid, Jordan.

The MDR1 gene encodes for P-glycoprotein (P-gp), which is an efflux transporter at the cell membrane. The P-gp has wide substrate specificity for multiple medications including the lipid lowering drug, atorvastatin. In this study, we investigated the possible association between three common MDR1 gene polymorphisms (G2677T, C3435T, and C1236T), and the lipid lowering effect of atorvastatin among Jordanians. Lipid and liproproteins were measured in blood samples collected from patients (n = 201) at baseline and during atorvastatin treatment. MDR1 polymorphisms were genotyped using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP). Both the TT genotype of G2677T and the TT genotype of the C3435T polymorphisms were associated with lower levels of low-density lipoproteins (LDL) after atorvasatin treatment. However, the effects of atorvastatin on the levels of total cholesterol (Tchol), triglycerides (TG), and high-density lipoprotein (HDL), were not correlated with any of the genotypes in both polymorphisms. Finally, the C1236T polymorphism was not associated with the lipid lowering effect of atorvastatin. In conclusion, the MDR1 gene polymorphisms G2677T, and C3435T, but not C1236T were associated with the lipid lowering effect of atorvastatin among Jordanians.

Association of *ABCB1*, *SLC15A1*, *CES1* and *NEU2* gene polymorphisms with side effects by oseltamivir in a Mexican population. *M. Bermudez de Leon Sr[1,2], R.N. Gonzalez-Ríos[1,2,4], R.A. Leyva-Parra[1], E. González-González[1,4], A. Alvarado-Díaz[1,4], O.E. Vázquez-Monsiváis[2], V.L. Mata-Tijerina[2], B.L. Escobedo-Guajardo[2], M.J. Currás-Tuala[2], M.E. Aguado-Barrera[2], B. Silva-Ramírez[3], J.M. Alcocer-González[4], A.M. Salinas-Martínez[5].* 1) Dept of Mol Biol, Centro de Investigación Biomédica del Noreste. Instituto Mexicano del Seguro Social, 64720 Monterrey, Nuevo León, Mexico; 2) Laboratory of Molecular Diagnostics, Centro de Investigación Biomédica del Noreste. Instituto Mexicano del Seguro Social, 64720 Monterrey, Nuevo León, Mexico; 3) Dept of Immunogenetics, Centro de Investigación Biomédica del Noreste. Instituto Mexicano del Seguro Social, 64720 Monterrey, Nuevo León, Mexico; 4) School of Biological Sciences, Universidad Autónoma de Nuevo León, San Nicolás de los Garza, Nuevo León, Mexico; 5) Epidemiology Research and Health Services Unit, Instituto Mexicano del Seguro Social, 64000 Monterrey, Nuevo León, Mexico.

Oseltamivir is a neuraminidase inhibitor extensively used during the latest pandemic influenza to prevent the release of progeny virions and thereby limit the spread of infection. Oseltamivir phosphate is a prodrug that is absorbed by Peptide transporter PEPT1 and effluxed by P-glycoprotein. Once inside of the cell, oseltavimir phosphate is converted by human carboxilesterase 1 to oseltamivir carboxilate, which is the active form to inhibit influenza virus neuraminidase. However, oseltamivir also has an inhibitory effect on human sialidases, that are important in varios cellular functions including lysosomal catabolism. There are reports about deaths and neuropsychiatric events in Japanese population with the use of oseltamivir, suggesting that this drug could inhibit also to human sialidases in a similar way that viral sialidase. Then, the aim of this study was to determine the single nucleotide polymorphisms (SNPs) for PEPT1(*SLC15A1* gene), P-glycoprotein (*ABCB1* gene), carboxilesterase 1 (*CES1* gene) and sialidase (*NEU2* gene) in >700 Mexican patients with oseltamivir therapy, and these data were correlated with side effects reported between 2010-2012. The SNPs evaluated were Gly185Val (rs1128501), Ser893Thr/Ala (rs2032582) and Ile1145Ile (rs1045642) for *ABCB1* gene; Ser117Asn (rs2297322) for *SLC15A1* gene; Gly143Glu and Arg199His (rs71647871 and rs2307243, respectively) for *CES1* gene; and Arg41Gln (rs2233385) for *NEU2* gene. Clinical data of each patient were obtained from institutional electronic files. This work was approved by the Ethics Committee of Mexican Social Security Institute. We found that eight percent of patients showed side effect as depression, anxiety, seizures, hallucinations among others. Genetic and allelic frequencies are presented and associated with the side effects of oseltamivir in a Mexican population. The authors thank Consejo Nacional de Ciencia y Tecnologia for financial support (Grant number SALUD-2011-1-162243).

PGRN Network-wide Project: Transcriptome Analysis of Pharmacogenes in Human Tissues. *E.R. Gamazon[1], C.E. French[2], S.W. Yee[3], A. Chhibber[3], X. Qin[4], E. Theusch[5], A. Webb[6], A. Konkashbaev[1], S. Weiss[7], S.E. Brenner[2], S.E. Scherer[4], N.J. Cox[1], K.M. Giacomini[3], A. on behalf of PGRN RNASeq Group[3].* 1) University of Chicago, Chicago, IL; 2) University of California, Berkeley, CA; 3) University of California, San Francisco, CA; 4) Baylor College of Medicine, Houston, TX; 5) Children's Hospital Oakland Research Institute, Oakland, CA; 6) Ohio State University, Columbus, OH; 7) Harvard School of Public Health, Boston, MA.

Gene expression variation impacts many common disorders and pharmacological traits; however, the nature and extent of this variation remains poorly understood. The NIH Pharmacogenomics Research Network (PGRN) Network-wide RNA-seq project aims to create a community resource containing quantitative information on known and novel isoforms of genes involved in therapeutic and adverse drug response (pharmacogenes, see http://www.pharmgkb.org/search/annotatedGene/). Using 160 samples from 6 major tissues of pharmacologic importance (liver, kidney, adipose, heart, lymphoblastoid cell lines [LCLs], and brain), some with extensive pharmacogenomic phenotyping, we performed transcriptome sequencing. The data were analyzed for expression quantification, junction analysis, and transcript reconstruction. We utilized the JuncBASE pipeline developed by members of our consortium to identify and classify splicing events. In samples from heart, kidney, liver and adipose tissues, similar numbers of transcripts and genes were detected; however, notable differences in expression levels of important pharmacogenes across the various tissues were observed. For example, as expected, many CYP enzymes (e.g., CYP2A7 and CYP2D6) were highly expressed in the liver and showed low levels of expression in other tissues. Other important drug metabolizing enzymes such as DPYD and PPARD showed more balanced gene expression patterns across the tissues. We uncovered substantial variation in both annotated and novel splicing events. For example, LDLR--a major target of the statins—showed markedly different splice variant patterns across the various tissues. In addition, given the importance of LCLs as a pre-clinical model for human genetic studies, we systematically investigated differential expression and splicing between LCLs and the other tissues. These studies provide mechanistic insights into pharmacogenomic findings and facilitate an understanding of the factors that lead to inter-individual differences in drug response.

Systematical functional characterization of CYP2D6 alleles in the Chinese Han population. *S. Qin, Q. Xu, Z. Wu, L. He.* Bio-X Institutes, Shanghai Jiaotong University, Shanghai, Shanghai, China.

Cytochrome P450 2D6 (CYP2D6) plays a crucial role in the metabolism of approximately 30% of drugs presently on the market and CYP2D6 gene polymorphisms exhibit high individual variability in catalytic activity. Based on the database of CYP2D6 gene polymorphisms in the Chinese Han population established by our group, we functionally characterized CYP2D6 alleles in this population, including four novel alleles CYP2D6*75 (g.4046G>A, p.441R>H), MU1 (g.100C>T + 2467G>A. p.34P>S + 231P>L), MU2 (g.100C>T + 2851C>T. p.34 P>S + 296R>C), MU3 (g.2467G>A + 2851C>T. p.231P>L + 296R>C) and CYP2D6*2, CYP2D6*10, CYP2D6*14. And we have successfully established the phenotype profile of CYP2D6 in the population. CYP2D6 proteins of wild-type (CYP2D6.1) and the seven variants were heterologously expressed in yeast cells and the kinetic parameters (Km, Kcat, Vmax,CLint and Kcat/Km) for debrisoquine 4-hydroxylation were determined. The data suggests the enzyme activity of CYP2D6.75 has been decreased than that exhibited by CYP2D6.1 , indicating R441 plays an important role in catalytic reaction. The kinetic parameters of CYP2D6.2 were much the same with CYP2D6.1. As a most prevalence variant in Chinese population, CYP2D6.10 showed decreased enzyme activity. We found that four alleles MU1, MU2, CYP2D6.10 and CYP2D6.14 which all harbor 100C>T site exhibited similar activity, suggesting P34 is crucial for CYP2D6 enzyme activity and catalytic efficiency. This is the first study to conduct systematic phenotype profile analysis of CYP2D6 alleles in the Chinese Han population. These findings might be useful for optimizing pharmacotherapy and the design of personalized medicine.

A pharmacogenomic study of inhaled short-acting beta-agonist response in African American individuals identifies SPATA13-AS1. *B. Padhukasahasram[1], J.J. Yang[2], A.M. Levin[2], M. Yang[1], E.G. Burchard[3,4], R. Kumar[5], P. Kwok[6,7], D.E. Lanfear[1,8], L.K. Williams[1,8].* 1) Center for Health Policy and Health Services Research, Henry Ford Health System, Detroit, MI; 2) Department of Public Health Sciences, Henry Ford Health System, Detroit, MI; 3) Departments of Medicine, University of California, San Francisco, CA; 4) Department of Bioengineering & Therapeutic Sciences, University of California, San Francisco, CA; 5) Department of Pediatrics, The Ann and Robert H. Lurie Children's Hospital of Chicago, Northwestern University Feinberg School of Medicine, Chicago, IL; 6) Department of Dermatology, University of California, San Francisco, CA; 7) Cardiovascular Research Institute, University of California, San Francisco, CA; 8) Department of Medicine, Henry Ford Health System, Detroit, MI.

Inhaled short-acting beta2-agonists (SABAs) are commonly used in patients with asthma to rapidly reverse airway obstruction and improve acute symptoms. However, treatment response to SABA medication is highly variable and is likely to be genetically influenced. We performed a genome wide association study of SABA medication response in 328 healthy, non-asthmatic African Americans and replicated these findings in 1073 individuals with asthma and 149 without asthma. Healthy, non-asthmatic individuals were used for discovery as SABA response might be less obscured by unrelated factors associated with lung disease. A linear mixed model approach was first used for SNP associations, and results were then combined to generate gene-based associations. We also assessed whether genes associated with SABA response were related to the amount of SABA use among those with asthma. Gene-based association tests identified SPATA13-AS1, an antisense RNA encoding segment within the SPATA13 gene as being significantly associated with SABA response. In replication, this gene was also associated with SABA response among 1073 African American individuals with asthma ($p = 0.011$). The same association was also replicated in an additional 149 healthy African American individuals ($p = 0.027$). Lastly, SPATA13-AS1 was also associated with annual SABA medication use among individuals with asthma ($p = 0.047$). SPATA13 is a recently discovered protein that is likely to be involved in airway smooth muscle contraction-relaxation through its interactions with Rho family GTPases such as RhoA, Rac1 and Cdc42. Elucidating the precise mechanism of action of this protein may reveal new SABA response pathways as well as targets for future asthma therapeutics.

Genome-wide analysis of Methotrexate pharmacogenomics in rheumatoid arthritis reveals novel risk variants and leads for *TYMS* regulation. *B.K. Thelma[1], S. Senapati[1], S. Singh[1], M. Das[1,2], A. Kumar[3], R. Gupta[4], U. Kumar[5], S. Jain[6], R.C. Juyal[2].* 1) Dept Genetics, Univ Delhi, South Campus, New Delhi, Delhi, India; 2) National Institute of Immunology, New Delhi, India; 3) Department of Rheumatology, Fortis Flt. Lt. Rajan Dhall Hospital, New Delhi, India; 4) Division of Rheumatology & Clinical Immunology, Medanta Bone & Joint Institute, Medanta - The Medicity, Gurgaon, India; 5) Department of Rheumatology, All India Institute of Medical Sciences, New Delhi, India; 6) Department of Physics, University of Delhi, Delhi, India.

Objective: Methotrexate (MTX) is the drug of first choice for rheumatoid arthritis (RA) treatment but is effective only in around 60% of the patients. Further, early initiation of MTX in a brief critical window period of around 6 months is crucial for the effective treatment. Therefore, identification of predictive markers is critical for the choice of early and appropriate treatment regimen. To date, genetic determinants underlying MTX response have remained elusive despite extensive candidate gene association studies. In the present study, we used genome-wide genotype data to identify potential risk variants associated with MTX (non)response in a north Indian RA cohort. **Methods:** Genome-wide genotyping data from Illumina 660w quad array for a total of 457 RA patients (297 good [DAS 28-3 < 3.2] and 160 poor [DAS 28-3 >5.1] responders) on MTX monotherapy were tested for association using additive model. Other tools including support vector machine (SVM) and genome-wide pathway analysis were used to identify additional risk variants and pathways. All risk loci were imputed to fine-map the association signals and identify causal variant(s) of therapeutic/diagnostic relevance. **Results:** Nine novel suggestive loci from GWAS ($p \leq 5 \times 10^{-5}$) and two from SVM analysis were associated with MTX (non)response. Association of published candidate genes namely *DHFR* (p=0.014), *FPGS* (p=0.035) and *TYMS* (p=0.005) and purine and nucleotide metabolism pathways were reaffirmed. Imputation followed by bioinformatic analysis indicated possible interaction between two reversely oriented overlapping genes namely *ENOSF1* and *TYMS* at post-transcriptional level. **Conclusion:** In this first ever genome-wide analysis on MTX treatment response in RA patients, 11 new risk loci were identified. Further, *TYMS* expression at post-transcriptional level seems probably regulated through an antisense-RNA involving the 6bp *ins/del* marker in the overlapping segment at 3' UTR of *TYMS-ENOSF1*, a finding with impending pharmacogenetic applications.

713W

Using Neuroimaging Endophenotypes to Identify Molecular Markers for Treatment Response to Major Depressive Disorder. *T. Carrillo-Roa[1], C.A. Lareau[2], C.L. McGrath[3], B.W. Dunlop[3], M.E Kelley[4], E.B. Binder[3], H.S Mayberg[5].* 1) Max Planck Institute for Psychiatry , Munich, Germany; 2) Department of Mathematics, University of Tulsa; 3) Department of Psychiatry and Behavioral Sciences, School of Medicine, Emory University; 4) Department of Biostatistics and Bioinformatics, School of Public Health, Emory University; 5) Department of Psychiatry and Behavioral Sciences and Department of Neurology, School of Medicine, Emory University.

Major depressive disorder (MDD) is a prevalent disease with high rates of treatment resistant and non-remission. However biological measures to guide optimal treatment have been lacking. Recently, our group described that resting state brain activity patters (BAPs) of specific brain regions (i.e. right insula, right inferior temporal cortex, left amygdala, left premotor cortex, right motor cortex and precuneus) can predict differential response to either escitalopram (sCIT) or psychotherapy. The aim of this study was to identify molecular markers that associate with these BAPs, in the hope to identify predictive measures that are more easily obtained in clinical practice than neuroimaging measures. Patients were recruited at Emory University and randomized at baseline to either 12 weeks sCIT, or 16 sessions of cognitive behavioral therapy (CBT). Pre-treatment BAPs of the six brain regions of interest (ROIs) were used as neuroimaging endophenotypes for this study. In peripheral blood DNA drawn at baseline genome-wide SNP genotypes (Illumina OmniExpress) and DNA methylation patterns (Illumina HM 450K) were measured. Genome-wide univariate and multivariate association analyses including all possible ROIs combinations were conducted in 76 MDD patients. Tests for association between methylation status at ~485,000 CpG sites and BAPs were performed for each of the ROIs. We observed genome-wide significant association of rs34383296, ($p = 9.4 \times 10^{-9}$) in a multivariate analysis that included the right insula, left amygdala and left premotor cortex. Univariate analyses did not reveal genome-wide significant associations. The associated variant lies in a gene dense region on chromosome 9 within the NDOR1 gene locus and it is an eQTL for ARRDC1, a gene ~400kb downstream and is related to arrestin-mediated internalization of cell surface receptors. No genome-wide significant association of DNA-methylation status was observed with any of the ROIs. Our data suggest that using quantitative neuroimaging endophenotypes and genomic approaches may be able to identify markers to guide individualized depression therapy choices in clinical routine. Further analysis will test surrounding CpG sites for the associated SNP as mQTLs as well as imputation of additional variants in the locus and tests for association with treatment response in independent samples.

714W

Genome-wide association study loci are enriched for clinically relevant drugs targets for common human diseases. *R. Li[1], V. Forgetta[2], O. Yu[3], Z. Dastani[4], M. Lathrop[5], J.B. Richards[1,6]*. 1) Departments of Medicine, Human Genetics, Epidemiology and Biostatistics, Centre Clinical Epidemiology, Jewish General Hospital, Montreal, Quebec, Canada; 2) Departments of Epidemiology and Biostatistics, McGill University, Montreal, Quebec, Canada; 3) Department of Medicine, McGill University, Montreal, Quebec, Canada; 4) Departments of Epidemiology, Biostatistics and Occupational Health. Jewish General Hospital, Lady Davis Institute, McGill University Montreal, Quebec, Canada; 5) McGill University and Génome Québec Innovation Centre, Montreal, Quebec, Canada; 6) Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

While many genetic loci have been recently mapped to common human disease it is not yet apparent if this information will aid in drug development. We reasoned that if GWAS loci identified such targets then these loci would be enriched for the targets of drugs that are already on the market. To test this hypothesis, we determined enrichment of GWAS loci for clinically relevant drugs for multiple common human diseases. We selected easily definable, representative, common diseases, with relatively high heritabilities for which large-scale GWAS meta-analyses had been published. These included, type 2 diabetes, hypercholesterolemia (LDL), osteoporosis, Crohn's disease, hypertension, psoriasis and asthma. We also included an additional disease, COPD, whose current therapies are largely aimed at symptom control. Pipeline was used to identify marketed drugs and their targets and this list was refined to include only drugs accepted by relevant American clinical guidelines. The NHGRI GWAS Catalog was used to collect all genome-wide significant SNPs for each disease and genes within 100kb or 500kb were identified. The nearest network neighbours for each drug target were identified using STRING. Finally, since several immune-mediated diseases have promising interleukin-based therapies in development we assessed whether drugs in phase III of development were enriched at GWAS loci. On average, there were 9 drug targets per disease that achieved guideline-level acceptance. Assessing all genes within 500kb of GWAS SNPs and the nearest network neighbours of drug targets, 80% of guideline-accepted LDL drug targets were identified. The proportion of such targets identified for osteoporosis was 80%, 71% for type 2 diabetes, 43% for Crohn's, 22% for psoriasis, 15% for hypertension, 9% for asthma and 0% for COPD. Consideration of Phase III drugs improved these proportions to 56% for Crohn's, 45% for psoriasis and 29% for asthma. Genes within 100kb of GWAS SNPs were strongly enriched for guideline-accepted drug targets for some diseases (eg. 40-fold [95% CI: 14-118] for LDL and 35-fold [95%CI: 12-104] for osteoporosis). GWAS loci for some common diseases identify a large proportion of drug targets that are targeted by clinically relevant medicines. This implies that other clinically relevant drug targets exist among the novel loci identified from GWAS.

Conditional analysis using HLA-A*31:01 as a covariant to detect additional genetic risk factors for carbamazepine-induced cutaneous adverse drug reactions in Japanese population. *T. Ozeki[1], T. Mushiroda[1], A. Takahashi[2], M. Kubo[3], Y. Shirakata[4], Z. Ikezawa[5], M. Iijima[6], T. Shiohara[7], K. Hashimoto[4], Y. Nakamura[1]*. 1) Laboratory for Pharmacogenomics, RIKEN Center for Integrative Medical Sciences, Yokohama, Kanagawa, Japan; 2) Laboratory for Stastical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Kanagawa, Japan; 3) Laboratory for Genotyping Development, RIKEN Center for Integrative Medical Sciences, Yokohama, Kanagawa, Japan; 4) Department of Dermatology, Ehime University Graduate School of Medicine, Ehime, Japan; 5) Department of Dermatology, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 6) Department of Dermatology, Showa University School of Medicine, Tokyo, Japan; 7) Department of Dermatology, Kyorin University School of Medicine, Tokyo, Japan.

An anticonvulsant, carbamazepine (CBZ), is known to show incidences of cutaneous adverse drug reactions (cADRs) including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug-induced hypersensitivity syndrome (DIHS). Previously, to identify a gene(s) susceptible to CBZ-induced cADRs, we conducted a genome-wide association study (GWAS) and following HLA typing in 61 cases and 376 patients who showed no cADRs by administration of CBZ (CBZ-tolerant controls), and found that HLA-A*31:01 was present in 60.7% (37/61) of the patients with CBZ-induced cADRs, but in only 12.5% (47/376) of the CBZ-tolerant controls (odds ratio (OR) = 10.8, 95% confidence interval (CI) = 5.9–19.6, $P = 3.64 \times 10^{-15}$). To confirm associations of HLA-A alleles other than HLA-A*31:01 with CBZ-induced cADRs, we pick-upped a paired HLA-A allele of HLA-A*31:01 using case-control subjects carrying at least one HLA-A*31:01 allele, which consisted of 56 CBZ-induced cADR cases and 54 CBZ-tolerant controls. There was no HLA-A allele that reached significant association after Bonferroni correction with $P < 4.17 \times 10^{-3}$ (0.05/12 HLA-A alleles). To detect additional genetic marker for CBZ-induced cADRs, we performed genome-wide imputation using the GWAS data and genotype data from 1000 Genomes Project as reference panels by MaCH-Admix software. For a conditional logistic regression analysis of the imputed genotype data, we selected rs1633021 as the covariant with the firmest association observed in the analyzed GWAS peak of association. After the conditional analysis, there were 22 loci that reached GWAS-level significant association ($P < 5 \times 10^{-8}$). The replication analysis using independent population are ongoing.

716W

Whole genome association study identifies novel antidepressant response loci for the treatment of obsessive-compulsive disorder with selective serotonin re-uptake inhibitors. *H.D. QIN[1], Y. Wang[2], M.A. Grados[2], M.A. Riddle[2], B.D. Greenberg[4], J.A. Knowles[5], A.J. Fyer[6], J.T. McCracken[7], D.L. Murphy[8], S.A. Rasmussen[4], B. Cullen[2], J. Piacentini[7], D. Geller[3], D. Pauls[3], E. Stewart[10], O.J. Bienvenu[2], Y. Chen[9], F.S. Goes[2], B. Maher[2], J.F. Samuels[2], G. Nestadt[2], Y.Y. Shugart[1].* 1) Unit of Statistical Genomics, Intramural Research Program, Division of Intramural Research Program, National Institute of Mental Health, NIH, Bethesda, MD 20892, USA; 2) Department of Psychiatry and Behavioral Sciences, School of Medicine, Johns Hopkins University, Baltimore, Maryland; 3) Departments of Psychiatry and Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts 02114, USA; 4) Department of Psychiatry and Human Behavior, Brown Medical School, Butler Hospital; 5) Department of Psychiatry, Keck Medical School, University of Southern California; 6) College of Physicians and Surgeons at Columbia University; 7) Department of Psychiatry and Biobehavioral Sciences, School of Medicine, University of California, Los Angeles; 8) Laboratory of Clinical Science, NIMH, NIH, Bethesda; 9) Department of Medicine, University of Maryland School of Medicine; 10) Department of Psychiatry, University of British Columbia, A3-118, West 28th Avenue, Vancouver, BC, Canada V5Z 4H4.

Selective serotonin reuptake inhibitors (SSRIs) are first line medications for the treatment of obsessive-compulsive disorder (OCD). Although SSRIs are currently the most frequently used drug therapy for OCD, approximately 30% of OCD patients show limited or no response to these medications, and >7% cannot tolerate side effects. Genetic predictors for OCD treatment responsiveness are in demand. We hypothesized that genetic variations in genes expressed in human brain influence SSRI response. To test this hypothesis, we conducted an association study on SSRI drug effect in 1,773 OCD cases from a family-based GWAS study. We used a powerful Quasi-Likelihood Score Test, namely, MQLStest, to conduct association test correcting for the relatedness coefficients (based on identity-by-descent). A sex-, age- and cognitive behavioral therapy (CBT)- adjusted logistic model was used to evaluate effect size. The significant variants ($P < 10^{-4}$) with large effect-size (odds ratio ≥1.75) for drug response are reported. We identified 15 significant loci (PMQLS_Robust $<10^{-4}$) with large effect-size (adjusted odds ratio ≥1.75) for OCD patients' response to SSRIs. The top two significant SNPs are rs17162912 and rs9957281, with $P = 3.44\times10^{-7}$, OR = 2.91 (95%CI 1.94-4.36) and $P = 1.43\times10^{-5}$, OR = 2.08 (1.36-3.2), respectively. rs17162912 is intergenic variation near DISP1 gene on 1q41-q42, a microdeletion region related to mental retardation. rs9957281 is located within a newly identified obsessive-compulsive disorder susceptibility gene DLGAP1, a member of the neuronal postsynaptic density complex. The 13 other significant variants are located in six genes, namely LINC00256B, CDYL2, PAFAH1B1 (LIS-1), TACC1, CSMD1, and GAS2. Interestingly, all these genes are expressed in human brain, In particular, DLGAP1 and CSMD1 have the most biological relevance to SSRI response based upon the current literature, suggesting these top ranked variants or genes may play an important role in SSRI drug-response in OCD patients. The importance of identification of drug response loci is for the development of 'personalized medical treatment' of OCD patients treated with SSRIs. The potential results would provide also new targets for developing novel drugs for the treatment of non-responders. Further well-designed case-control studies with large sample size and using next-generation sequencing are needed to explore the role of causal exonic variations or rare CNVs of the most significant genes.

717W

Integrative genome modeling reveals common genetic architecture of neuropathy resulting from distinct environmental exposures. *H.E. Wheeler[1], C. Wing[1], M. Komatsu[1], S. Delaney[1], E.R. Gamazon[1], C. Rodriguez-Antona[2], N.J. Cox[1], M.E. Dolan[1].* 1) Dept Medicine, University of Chicago, Chicago, IL; 2) Human Cancer Genetics Programme, Spanish National Cancer Research Center, Madrid, Spain.

Chemotherapy-induced peripheral neuropathy is the major dose-limiting toxicity for several mechanistically distinct anticancer drugs. Diabetic neuropathy affects a large proportion of diabetes patients due to prolonged exposure to high levels of glucose. Our goal is to elucidate the molecular genetic mechanisms underlying such neuropathies by integrating results from patient and lymphoblastoid cell line (LCL) genome-wide association studies (GWAS) with functional results from iCell Neurons derived from human induced pluripotent stem cells (iPSCs). When comparing modestly sized pharmacogenomic GWAS from patients and LCLs treated with the same drug, SNPs rarely overlap at stringent thresholds such as $P < 10^{-6}$, but significant overlaps of SNPs at more relaxed thresholds determined by enrichment analysis through random sampling are possible. Under this cumulative hypothesis, large numbers of common variants with small effects account for substantial heritability. For example, we observed an enrichment of paclitaxel-induced LCL (n = 247) cytotoxicity SNPs in the peripheral sensory neuropathy-associated SNPs from ovarian and lung cancer patients (n = 143) treated with paclitaxel and carboplatin (empirical $P = 0.034$). Interestingly, we also observed an enrichment of paclitaxel cytotoxicity SNPs in diabetic neuropathy-associated SNPs from patients (n = 1651) in the GoKinD cohort (empirical $P < 0.001$). These enrichments demonstrate that susceptibilities to increased cytotoxicity in LCLs and increased chemotherapy- and diabetes-induced neuropathy in patients likely have some genetic mechanisms in common. We are using iPSC-derived iCell Neurons to develop models for functional screens of candidate targets of interest from these enrichment analyses. Upon treatment of iCell Neurons with increasing concentrations of paclitaxel (0.001-100 μM) for 72 h, we identified a reproducible 3–5 μm (12–14%) decrease in cell median neurite process length and a 13–19 μm (10–13%) decrease in cell total neurite outgrowth per order of magnitude increase in drug. Paclitaxel binds to beta-tubulin to exert its cytotoxic effect. As a proof of concept, we have shown that decreased expression of the beta-tubulin isotype *TUBB2A* by siRNA transfection causes decreased median neurite process length (interaction $P < 10^{-3}$) and decreased total neurite outgrowth (interaction $P < 10^{-9}$) of iCell Neurons 48 h post-paclitaxel treatment. This work was supported by NIH grants U01GM61393 and F32CA165823.

Genetic variants associated with elevated triglyceride levels in patients with genotype 2/3 chronic hepatitis C treated with cyclophilin inhibitor alisporivir. *Y. Li[1], M. Healey[1], M. Waldvogel[2], N. Hartmann[2], G. Nabel[1], L. Li[1], F. Staedtler[2], W. Zhang[3], C.A. Brass[4], N.V. Naoumov[5], K.J. Johnson[1], B. Li[1].* 1) Novartis Institutes for Biomedical Research, Cambridge, MA, USA; 2) Novartis Institutes for Biomedical Research, Basel, Switzerland; 3) Novartis Pharmaceuticals Corporation, Shanghai, China; 4) Novartis Pharmaceuticals Corporation, East Hanover, NJ, USA; 5) Novartis Pharmaceuticals Corporation, Basel, Switzerland.

Background: Host-targeting antiviral alisporivir (ALV) inhibits cyclophilin A that is essential for HCV replication. In the phase IIb VITAL-1 study involving treatment-naïve genotype 2/3 patients with chronic hepatitis C, ~81% patients achieved SVR24 with IFN-free or IFN-containing ALV treatment with or without ribavirin. In a proportion (8.8%) of patients treated with ALV IFN-free regimens, maximum fasting triglyceride (TG) level of >400mg/dL was detected over the course of 24 weeks of treatment. The goal of this investigation was to evaluate the contribution of genetic variants to elevated TG levels observed in some patients in this study. Methods: DNA samples were obtained from 196 patients who consented to pharmacogenetic assessment and received ALV-containing treatment. Samples were genotyped using the Illumina Omni5Exome array and TaqMan allelic discrimination assays for APOE genotyping. Linear regression was performed to evaluate association between genotype and log-transformed maximum on-treatment TG level. The analysis was adjusted for race, log-transformed baseline TG, ALV exposure and presence of pegIFN treatment. Results: Targeted analysis of APOE genotype found that the APOE ε2 carriers had higher levels of TG than non-carriers, in patients treated with ALV (p = 0.035). However such a trend was not identified for ε4 carriers versus non-carriers (p = 0.12). Genome-wide association analysis (GWAS) with maximum fasting TG level while on ALV treatment identified one SNP in CNTNAP4 gene (in all races combined analysis; p= 2.63×10^{-9}) and one SNP in THSD7B gene (in Caucasians only; p=1.12×10^{-8}) to be statistically associated with elevated level of TG, after adjusting for multiple testing, although functional relevance of these genes (CNTNAP4 and THSD7B) to level of triglyceride is unclear. Conclusions: Overall, these findings suggest a potential role of genetic variation contributing to the elevated TG level observed in some patients treated with ALV. Targeted analysis revealed a trend of association between elevated TG level and the presence of the APOE ε2 allele in patients treated with ALV. Other genetic variations have also been identified from GWAS analysis to be associated with level of TG while treated with ALV-containing therapy without clear functional interpretation. Testing of these candidate variants in independent studies is needed for validation.

719W

Variants of the cysteinyl leukotriene 1 and 2 genes are additively associated with atopy in a founder population. *M. Thompson[1], J. Stankova[2], V. Capra[3].* 1) Lab Medicine, Banting Inst, Univ Toronto, Toronto, ON, Canada; 2) University of Sherbrook, Sherbrook, QC, Canada; 3) University of Milan, Milan, Italy.

The cysteinyl leukotriene receptor 1 (cysLT1) and 2 (cysLT2) genes have been investigated because they are functionally and pharmacologically implicated in the atopy phenotype affecting many asthma patients. In a founder population, we reported that the G300S variant of the cysLT1 receptor gene and the M201V variant of the CysLT2 receptor gene are implicated in atopic asthma. Here we discuss the statistical association of both variants with the atopy phenotype - a phenomenon suggesting that the interaction of cysLT1 and cyLT2 gene variants gives rise to atopy in the population we studied. The functional interaction of cysLT1 and cysLT2 proteins within the cell may represent a mechanism for the etiology of atopy in some individuals with atopic asthma.

720W

Identification of expression quantitative trait locus associated with drug biotransformation. *H.-C. Yang[1,2], C.-W. Chen[1].* 1) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 2) School of Public Health, National Defense Medical Center, Taipei, Taiwan.

Scientific evidence has shown that drug response may vary with genetic background of populations. Pharmacogenomics association studies without accounting for population stratification and/or population admixture will cause false positive findings. Ancestry informative markers which exhibit different genetic distributions and reflect genetic ancestry in populations can be applied to adjust for population stratification and/or population admixture in genetics and pharmacogenomics association studies. This study aims to identify the ancestry informative markers which regulate gene expression and cause a down-stream consequence, differential drug responses in populations. We analyzed single nucleotide polymorphism and gene expression data of 210 independent samples in the HapMap II Project and identified a large number of cis- and trans-acting eQTL for each population by a partial least square method. Then we used our developed BIASLESS (Biomarkers Identification and Samples Subdivision) software (http://www.stat.sinica.edu.tw/hsinchou/genetics/prediction/BIASLESS.htm) [Yang et al., BMC Genomics, 2012, v13, 346] to identify ancestry informative eQTL that they are able to classify samples from different populations with a high testing accuracy in a cross-validation procedure. The identified eQTL were correlated with single nucleotide polymorphisms on drug biotransformation genes. We found that the differential allelic distributions of cytochrome P425 enzymes, which are the essential enzymes involving in drug metabolism, in populations were found. The results provide an insight into the complex relationship of genetic ancestry, gene regulation and pharmacoresponse.

Genome-wide association study of combined paclitaxel and carboplatin treatment-induced severe neutropenia/leucopenia for patients in Biobank Japan. *S. Low[1], S. Chung[2,3], A. Takahashi[1], T. Mushiroda[4], M. Kubo[5], Y. Nakamura[2,3].* 1) Laboratory for Statistical Analysis, Center for Integrative Medical Sciences, RIKEN, Tokyo, Japan; 2) Department of Medicine, The University of Chicago, Chicago, IL; 3) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 4) Laboratory for Pharmacogenomics, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 5) Laboratory for Genotyping Development, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan.

Chemotherapeutic agents are notoriously known to have narrow therapeutic range that often resulted in life-threatening toxicity. Hence, it is clinically important to identify the patients who are at high risk for severe toxicity through pharmacogenomics approach. In this study, a genome-wide association study was performed with cancer patients who administered combined paclitaxel and carboplatin treatment to identify genetic variants that are associated with the risk of severe neutropenia/leucopenia in the Japanese population. A total of 477 patients' DNA were recruited from the Biobank Japan with 166 patients who did not develop any adverse drug reactions, 161 develop mild (grade1/2) and 150 develop severe (grade3/4) neutropenia/leucopenia after administering the combined treatment. All of these samples were genotyped using Illumina OmniExpress BeadChip™. After sample and SNP quality control, Two genetic loci, rs12310399 (P=2.46×10^{-7}, OR=1.85, 95% CI =1.33-2.58) at *FGD6* gene and rs10785877 (P=7.38×10^{-7}, OR=2.58, 95% CI =1.77-3.77) near *RXRA* gene, were identified to be suggestively associated with paclitaxel and carboplatin treatment induced severe neutropenia/leucopenia when genome-association study was performed with patients who do not develop any adverse drug reaction versus those who develop severe neutropenia/leucopenia. Weighted genetic risk score analysis using six SNPs with P<1.0×10^{-5} identified that individuals who carry the highest range of genetic risk score possess 188 times (95% CI =36.1-979) higher risk to develop severe neutropenia/leucopenia compare to patients who belong to the lowest range of genetic risk score. Interestingly, individuals who developed grade 1/2 (mild neutropenia/leucopenia) were found to show intermediate risk scores between patients with severe neutropenia/leucopenia and those without any adverse reactions. Although we failed to identify genetic variants that surpassed the genome-wide significance level (P≤5.0×10^{-8}) through GWASs probably due to insufficient statistical power and complex clinical features, we were able to shortlist some of the suggestive associated loci. The current study is at the relatively preliminary state, but could highlight the complexity and problematic issues in retrospective pharmacogenomics studies. However, we hope that verification of these genetic variants through local and international collaborations could improve the clinical outcome of cancer patients.

722W

Expression of Mx1, OAS1, PKR and TP53 - interferon stimulated genes during treatment of hepatitis C patients. *B. Swiatek[1], I. Bereszynska[2], D. Januszkiewicz-Lewandowska[1,2,3], J. Wysocki[2], I. Mozer-Lisewska[2], A. Kowala-Piaskowska[2], J. Rembowska[1], J. Nowak[1].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 2) University of Medical Sciences, Poznań, Poland; 3) Department of Medical Diagnostics, Poznań, Poland.

Interferon stimulated genes (ISGs) such as Mx1, OAS1, PKR play a key role in antiviral responses against HCV infection. Moreover, it is suggested that ISGs pre-activation is associated with anti-HCV treatment failure. Also, it was observed that interferon stimulates transcription of TP53 gene. The aim of this prospective study was to examine the association between Mx1, OAS1, PKR (EIF2AK2) and TP53 expression and response to pegylated interferon and ribavirin treatment in 35 chronic hepatitis C (CHC) patients. Viral load was determined using one-step quantitative RT-PCR. Analyses were performed before as well as at 4 and 12 week of treatment.Rapid Virological Response (RVR) and complete Early Virological Response (cEVR) was achieved by 13 (37.1%) and 10 (28.6%) patients, respectively. 12 (34.3%) did not response to pegIFN and ribavirin combination treatment during 12 weeks (Primary Non-Response, PNR; less than 2 log10 decrease in viral titer after 12 weeks of therapy). The mean baseline viral load was comparable in RVR, cEVR and PNR group (6.7, 7.3 and 3.5×104 IU/ml, respectively). Expression of classical ISGs (Mx1, OAS1, PKR), but not TP53 increased during CHC treatment. The expression was low in RVRs and higher in cEVRs and PNRs before therapy and increased noticeable in cEVRs and PNRs and poorly in RVRs at week 4. The espression of studied ISGs was stable or poorly decreased in RVRs, was stable or poorly increased in cEVRs and noticeable decreased in PNRs group between week 4 and 12 of therapy. These results indicate that exogenous IFN can stimulate transcription of Mx1, OAS1, PKR in PBL in chronic hepatitis C patients. Moreover, increase in ISGs expression at week 4 of CHC therapy might depend on baseline level and next changes of HCV presence. In addition, level of ISGs tested might predict the outcome of combination CHC treatment. It looks like, pre-activation of the endogenous interferon system is associated with RVR and thereby with high likelihood of achieving SVR. It is also possible that treatment failure during first 12 weeks of anti-HCV therapy (PNR) may be related to noticeable decrease in ISGs expression between week 4 and 12. Lastly, it can be suggested that there is no association between TP53 expression during interferon treatment of CHC patients. This research was supported by National Science Centre grant no 2011/01/B/N26/04258.

Analysis of the CYP3A4, CYP3A5, CYP2C9, CYP2C19 and CYP2D6 polymorphism in Nayarit population: Involvement in drug metabolism. *LE. Wong-Ley, AB. Martinez Rizo, JB. Velázquez Fernández, V. Mondragón Jaimes, AY. Bueno Durán, A. Zambrano Parra, FJ. Medrano Valenzuela.* Dept Gen, SSN-UAN, Tepic, Mexico.

Know that there is individual variability in the response to specific drugs given by genetic polymorphisms involved in metabolism. Drugs used in the treatment of multiple diseases have a different therapeutic range, with the possibility of death from toxicity, possibility of adverse effects that may limit the dose administered. The dose intensity is an important determinant of response to treatment. Many of the drugs used in the clinic are substrates of the CYP3A4, CYP3A5, CYP2D6, CYP2C9 and CYP2C19 polymorphism. They have been reported in different expression of these proteins in combination with polymorphisms in genes encoding them, so it is likely that these polymorphisms are involved in the response to these drugs. In Mexico there are few studies of the allelic frequencies of these genes and their correlation with the treatment of various diseases. The objective the present study is to know the association between the CYP3A4 *1B, CYP3A5 *3, CYP3A5 *6, CYP2D6 *4, CYP2C9 *2, CYP2C9 *3 and CYP2C19 *2 polymorphisms and the response to therapy of various drugs in Nayarit, a West Mexican population. They were included in the study 200 healthy patients. All patients signed an informed consent and a questionnaire was answered. DNA was obtained from lymphocytes and followed the identification by PCR and enzymatic digestion of CYP3A4 *1B, CYP3A5 *3, CYP3A5 *6, CYP2D6 *4, CYP2C9 *2, CYP2C9 *3 and CYP2C19 *2 variants. All genes studied are in Hardy-Weinberg equilibrium. The allelic frequencies of CYP3A4 * 1B, CYP3A5 * 3, CYP3A5 * 6, CYP2D6 * 4, CYP2C9 * 2, CYP2C9 * 3 and CYP2C19 * 2 genes in our state have relatively high frequencies compared to other populations, such as Caucasians, Asian or African, indicates a strong relationship between therapeutic response shown in our population and the polymorphisms studied. It is important to establish individualized treatments for better therapeutic management of diseases. We believe that this will be possible through better understanding of the physiology of both, the disease and the patient, thus allowing for personalized treatments.

724W

Can IL28B polymorphism identify patients who achieve early virological response during treatment of hepatitis C? *J. Nowak[1], B. Swiatek[1], J. Wysocki[2], I. Bereszynska[2], A. Kowala-Piaskowska[2], I. Mozer-Lisewska[2], J. Rembowska[1], D. Januszkiewicz-Lewandowska[1,2,3].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 2) University of Medical Sciences, Poznań, Poland; 3) Department of Medical Diagnostics, Poznan, Poland.

Large number of factors affecting response to hepatitis C therapy makes it difficult to optimize. Identification of molecular markers playing role in predicting anti-HCV treatment outcome before its beginning would facilitate therapeutic decision-making and therapy optimizing. Recently IL28B rs12979860 (C/T) polymorphism has been identified as a strong predictor of Sustained Virological Response (SVR) in chronic hepatitis C (CHC) patients treated with pegylated interferon and ribavirin (pegIFN+RBV). Moreover, monitoring viral kinetics, particularly during the first few weeks of therapy, can help identify patients with high chances of treatment success. The aim of this prospective study was to examine the association between SNP rs12979860(C/T) in the IL28B gene and on-treatment virological response (week 4. and 12.) in CHC patients. The study consisted of 35 patients who were treated with pegylated interferon α2a/2b and ribavirin. To determine treatment effects, serum HCV-RNA was measured on the first day of therapy and then at 4 and 12 week of treatment by one-step quantitative RT-PCR. DNA, isolated from peripheral blood lymphocytes, was used for IL28B rs12979860 (C/T) genotyping by High Resolution Melting method.13 patients (37.1%) became HCV RNA negative at week 4 (RVR-Rapid Virological Response) and 10 (28.6%) at week 12 (cEVR-complete Early Virological Response). 12 patients (34.3%) did not achieve virological response until 12 weeks (PNR-Primary Non-Response, less than 2 log10 decrease in viral titer after 12 weeks of treatment). The mean baseline viral load was comparable - 6.69×104 IU/ml vs 7.32×104 IU/ml vs 3.51×104 IU/ml in RVR, cEVR and PNR group, respectively. The rs12979860 CC, CT and TT genotypes found in 8 (22.9%), 23 (65.7%), 4 (11.4%) patients, respectively. Among patients with CC genotype, 75% achieved RVR and 25% achieved cEVR. Among CT genotype RVR, cEVR and PNR were observed in 30.5%, 30.5% and 39% of patients, respectively. 25% of patients with the genotype TT achieved cEVR and 75% achieved PNR. Favorable CC was not observed in PNR and unfavorable TT genotype was not observed in RVR group.The initial results confirm that IL28B rs12979860 C/T polymorphism may identify those CHC patients, treated with pegIFN and ribavirin, who achieve virological response during early phase of treatment and thereby who are more likely to achieve SVR. This research was supported by National Science Centre grant no 2011/01/B/N26/04258.

Effect of genetically tailored statin therapy on health behaviors and outcomes: A pilot study in the primary care setting. *J.H. Li[1], S.V. Joy[2], S.B. Haga[1], L.A. Orlando[1], W.E. Kraus[1], G.S. Ginsburg[1], D. Voora[1].* 1) Duke University Medical Center, Durham, NC; 2) University of Colorado Denver Anschutz Medical Campus, Aurora, CO.

Background: Despite the cardiovascular benefits of statins, long-term adherence is often limited by real or perceived side effects. The **5* variant in the hepatic transporter *SLCO1B1* is a risk factor for myopathy, a common side effect. The risk conferred by **5* is statin-specific: greatest with simvastatin and atorvastatin (S/A) and least with pravastatin and rosuvastatin (P/R). We hypothesized that providing *SLCO1B1*5* genotype guided statin therapy (GGST) would be associated with improved patient adherence, provider behavior, and laboratory outcomes in primary care patients who were initially nonadherent to statins in a pilot study. **Methods:** Patients (n=58) and their providers received **5* genotype results and GGST recommendations pushed to them via the electronic medical record (EMR). Noncarriers were not at increased risk of side effects and were reassured to restart any statin, while carriers had a higher risk of side effects from S/A and were recommended therapy with P/R. The primary outcome was the change in patients' perceived need for statins and concerns about risks from baseline to 4 months, measured by a validated survey. Concurrent controls (n=59) receiving standard of care were gathered from the same clinic for comparison of secondary outcomes: 1) proportion with new statin prescriptions written by their providers, 2) change in low-density lipoprotein cholesterol (LDLc), 3) patient-reported statin usage over 1 year. **Results:** The largest changes were in the 'need for statin to prevent sickness' (pre: 2.9±0.9 vs. post: 3.3±0.9, p<0.001) and the 'concern for statin to disrupt life' (pre: 3.2±1.4 vs. post: 2.8±1.2, p=0.006). Overall, GGST patients expressed a trend toward higher necessity (p=0.2) and lower concern (p=0.2) for statins at 4 months compared to baseline. Compared to controls, GGST patients had a higher proportion of new statin prescriptions (55% vs. 20%, p<0.001), greater change in LDLc (-17.0±48.3 vs. 6.3±37.8, p=0.03), and higher patient-reported statin use (45% vs. 15%, p<0.001) during follow-up. **Conclusions:** Delivery of *SLCO1B1*5* genotype results coupled with genotype guided recommendations to tailor statin therapy is feasible via the EMR in the primary care setting. This novel intervention improved patients' perceptions of statins and was associated with physician and patient behaviors that promoted higher statin adherence and lower LDLc. The impact of **5* genotyping should be further explored in a larger randomized control trial.

Incidental pharmacogenetic variants identified by massively parallel sequencing in the ClinSeq® study. *D. Ng[1], J.J. Johnston[1], K.L. Lewis[1], S.G. Gonsalves[1], W. Newman[2], P.D. Stenson[3], D.N. Cooper[3], M. Vemulapalli[4], J.C. Mullikin[4,5], L.G. Biesecker[1,4], NIH Intramural Sequencing Center.* 1) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Manchester Centre for Genomic Medicine, St. Mary's Hospital, Manchester, UK; 3) Institute of Medical Genetics, School of Medicine, Cardiff University, Heath Park, Cardiff, UK; 4) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 5) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Massively parallel sequencing can identify incidental, medically relevant genetic variants in asymptomatic individuals. This represents a major paradigm shift in medicine, from the treatment of manifest disease to predictive medicine aimed at monitoring asymptomatic individuals with disease susceptibility. One of the aims of ClinSeq® is to study the analysis and return of incidental, clinically relevant genetic variants (secondary findings). As part of our ongoing endeavor to study secondary variants, we selected 20 genes associated with drug metabolism or transport for analysis. Whole exome sequences (WES) from 951 ClinSeq® participants were annotated for variants in 20 drug metabolism genes selected from the Affymetrix DMET plus array using the Human Gene Mutation Database (HGMD®) cDNA/protein reference. Of the 327 variants targeted by the Affymetrix DMET plus chip, 70.6% (231/327) had sequence coverage in ≥80% (761–951) and 20.5% (67/327) were covered in <80% (1–759) of participants. WES identified 360 variant positions in the 20 genes. Ninety-two of the pharmacogenetic variants interrogated by the Affymetrix chip were identified by WES in one or more ClinSeq® participants. Two hundred sixty-eight variant positions were novel. Twenty-four of these variants were predicted to cause a loss of function (frameshift, nonsense, splice). The remainder of the 244 coding changes were missense variants without a reported phenotype. The 92 variants identified by WES, and targeted by the Affymetrix chip were categorized in HGMD® as follows: functional polymorphism (n=66), disease-associated polymorphism (n=8), disease-associated polymorphism with additional supporting functional evidence (n=11) and disease-causing mutation (n=7). Variants with potential medical relevance include VKORC1 p.Asp36Tyr reported to predispose to warfarin resistance (n=5 individuals), SLCO1B1 p.Val174Ala associated with higher basal cholesterol (n=20 individuals) and CYP2C8 p.Ile264Met associated with an increased risk of coronary artery disease among smokers (n=67 individuals). Three hundred and sixty variants were identified in 20 genes associated with drug metabolism. WES identified insertion/deletion variants, but not promoter or deep intronic SNPs. Ninety-two variants have published data suggestive of a role in drug metabolism. Further research is needed to determine which of these variants have clinical utility thereby meriting the return of genetic results to participants.

High Throughput Scaling and Performance Assessment of Gene Panel Capture with Molecular Inversion Probes. *L.S. Felker, A. Gordon, M.B. Beightol, T. Shaffer, D.R. Crosslin, J.D. Smith, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

Molecular Inversion Probes (MIPs) are a customizable, scalable and affordable method to perform massively parallel target capture and sequencing with a minimal amount of genomic DNA input. With the intention of streamlining and scaling a MIP capture platform to process thousands of samples with any given panel of gene candidates, we characterized the capture efficiency of a 10-gene panel of pharmacologically significant genes that contain a spectrum of challenging capture targets; highly paralogous, repetitive and GC-rich (i.e., CYP2D6) to unique sequence (i.e., COMT). All MIPs in our 10 gene panel were pooled at equimolar ratios and captured at an initial genomic DNA target to MIP ratio of 1:200. Due to the complexity of the gene panel, we observed non-uniform MIP capture across our targets requiring rebalance of the MIP pool to increase the likelihood of capture for inefficient MIPs. To eliminate the need for time-consuming successive pool rebalancing for individual samples, we assessed capture repeatability in two ways: intra-sample (using 12 replicates of a single sample) and inter-sample (across four HapMap trios that represent diverse ancestry and CYP2D6 genotype). Pairwise comparisons between capture reactions from both repeatability assessments show high correlation. Utilizing the normalized MIP capture events, we developed a method to rebalance the 10 gene panel MIP pool to compensate for poorly performing probes. We observed that MIP performance correlates with the nature of the gene complexity and the sample ancestry and diversity. Additionally, we included a 96 'fingerprint' target MIP pool to serve as a capture efficiency control, for sample identity confirmation and to provide quality control monitoring for sample contamination. In summary, we have optimized the MIP capture platform by eliminating successive pool rebalancing, simplifying reagents, and incorporating robotics for making and rebalancing probe pools to increase throughput.

728W

Pharmacogenetic Genotyping of Clinical Specimens using Next-Generation Sequencing. *S.M. Jacobs-Helber, T. Reynolds.* American International Biotechnology Services, LLC, Richmond, VA.

An outcome of the era of personalized medicine has been more frequent genotyping of Cytochrome P450 and other risk factor genes of patient samples to assist physicians in drug dosing as well as the determination of risk based on genetic factors. Such analysis requires high throughput methods capable of multiplex analysis that can generate results for patients in a timely manner. AIBiotech has developed a multiplex pharmacogenomics panel using Next Generation Sequencing technology that assists physicians in the treatment of their patients. The Personalized Medicine Panel (PMP) consists of 10 genes including the Cytochrome p450 genes CYP2C19, CYP2C9(with VKORC1), CYP2D6, CYP3A4, and CYP3A5, as well as the cardiac risk factors Factor II (prothrombin) Factor V Leiden, APOE (for cardiovascular risk) and MTHFR. The AIBiotech PMP delivers genotype data on all 10 markers, giving clinicians actionable data to assist in the therapeutic treatment of their patients and reduce the risk of adverse events. After only a year of testing AIBioTech has processed more than 20,000 patient samples on this platform. Using data generated from these samples, AIBiotech will present genotyping frequencies on all markers for >10,000 deidentified clinical specimens tested. Comparisons will be made between published frequencies from smaller studies in four different ethnic populations (African-American, Caucasian, Hispanic, and Asian). The data generated from this study will generate new insight in to the ethnic frequency of mutations that affect drug dosing and management.

729W

Development of a scoring tool to prioritize clinical pharmacogenomic testing. *S. Manzi, Clinical Pharmacogenomics Oversight Committee.* Research Connection, Boston Children's Hospital, Boston, MA.

A scoring tool was developed to assist in the process of prioritizing drug/gene pairs for clinical implementation of pharmacogenomic testing. The provision of clinical interpretation of genotype data in the electronic medical record (EMR) along with decision support at the point of ordering and dispensing is complex and requires resources to build and implement. Once the capability to provide pharmacogenomic testing with EMR decision support becomes publicized, an increasing number of requests for testing for a specific service or patient population are filed. Competing demands for IT support, balancing the needs of a single patient population for whom the information will be critical against the needs of many for whom the information will be important, providing a comprehensive test, and ensuring cost containment are some of the many factors that we incorporated into the tool. Additionally, factors such as commercial availability of the test, published knowledge base tools and guidelines and the projected utilization were also included. The tool was designed from review of the available literature and revised based upon input from our Clinical Pharmacogenomics Service Oversight committee members. We will demonstrate a use case for the tool via an example of prioritizing between TPMT genotyping for mercaptopurine use in Acute Lymphoblastic Leukemia (ALL) and cyp2D6 genotyping for opioid drugs in acute pain management. The overall score for TPMT (thiopurine S-methyltransferase) genotyping was 27 points compared with a score of 20 points for cyp2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) genotyping. The major dissenting areas included delayed toxicity (present for thiopurines, not present for opioids), overlapping toxicities with concomitant agents (present for thiopurines, not present for opioids), frequency of use (limited for thiopurines, extensive for opioids) and the commercial availability of a comprehensive test at the time of evaluation (present for TPMT, not present for cyp2D6). To our knowledge, no other decision tool designed to assist with prioritization of movement of drug/gene pair data from research to the clinical realm has been published. We will demonstrate the tool and scores relevant to our program.

Assessment of the predictive effect of genetic variation in key genes associated with drug therapy of cardiovascular diseases in the Azores Islands (Portugal). *L. Mota-Vieira[1,2,3], M.S. Melo[1,4], L. Balanco[1,4], R. Cabral[1], C.C. Branco[1,2,3], T. Pereirinha[1].* 1) Molecular Genetics and Pathology Unit, Hospital of Divino Espírito Santo of Ponta Delgada, EPE, Azores, Portugal; 2) Instituto Gulbenkian de Ciência, Lisbon, Portugal; 3) BioFig, Lisbon, Portugal; 4) The University of the Azores, Ponta Delgada, Portugal.

New understandings of individual genetic variants are increasingly reshaping, in various aspects, the drug treatment of cardiovascular diseases (CVD). Three highly prescribed drugs - clopidogrel (platelet aggregation inhibitor), warfarin (anticoagulant) and simvastatin (cholesterol-lowering drug) - are examples with strong genetic evidence. Here, we investigate the predictive effect of relevant pharmacogenes - *CYP2C19* (clopidogrel bleeding risk), *CYP2C9* and *VKORC1* (warfarin bleeding risk), and *SLCO1B1* (simvastatin-induced myopathy risk, from myalgia to rhabdomyolysis) - associated with drug response in Azoreans. This population could benefit from these pharmacogenetic data, since CVD are the first cause of mortality and morbidity in Azores Islands. According to SNP information available on PharmGKB, Pubmed, dbSNP and SNPedia databases, DNA of 170 blood donors was genotyped by TaqMan® genotyping assays (Applied Biosystems). Our results demonstrate that in Azoreans the influence of the *CYP2C19* loss-of-function alleles (**2* and **3*) on clopidogrel response is only due to the **2* allele. Therefore, clinicians should prescribe a non-*CYPC19* dependent thienopyridine, such as prasugrel or ticagrelor, in homozygous (1.9%) and prefer, if possible, the use of these alternative medications in heterozygous (21.8%). These individuals correspond to the poor and intermediate clopidogrel responders, respectively. Regarding warfarin, the joint analysis of *CYP2C9* (**2* and **3*) and *VKORC1*3* revealed that 82.4% of Azoreans will need intermediate or low drug doses, guided by a clinical algorithm, if treatment is started. In what concerns the *SLCO1B1* c.521T>C SNP, known to cause high plasma levels of simvastatin, three genotypes were observed: TT (individuals with two functional alleles, 70.6%), TC (one functional allele plus one reduced-function allele, 27.6%) and CC (two reduced-function alleles, 1.8%). Thus, clinicians should be alert to simvastatin-induced myopathy in patients with intermediate and high risk (TC and CC, respectively) and, whenever needed, proceed to dose adjustment or prescribe another drug in order to achieve desired lipid levels. In conclusion, this population study constitutes an initial step in how clinicians can use the patient's genetic makeup to provide a better and safer CVD therapy. (lmotavieira@hdes.pt; funded by the Government of the Azores).

731W

Sequence-based characterization of ADME variation in two Northeast Asian and 19 1000 Genomes Project Populations. *D.H. Hovelson[1], Z. Xue[2], M. Zawistowski[1], M.G. Ehm[2], S. Stocker[2], A. Gross[2], I.J. Jang[3], I. Ieiri[4], J.E. Lee[5], L.R. Cardon[2], S.L. Chissoe[2], G. Abecasis[1], M.R. Nelson[2].* 1) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Quantitative Sciences, GlaxoSmithKline, Research Triangle Park, NC; Sydney, AUS; Stevenage, UK; 3) Seoul National University, Seoul, Korea; 4) Kyushu University, Fukuoka, Japan; 5) DNA Link, Inc., Seoul, Korea.

Identifying factors which influence the pharmacokinetics of a drug (the body's exposure to the drug) and selecting optimal doses is a crucial part of drug development. Variation in genes that regulate drug absorption, distribution, metabolism and excretion (ADME) can contribute to variability in drug pharmacokinetics; in addition, the frequency of variants in ADME genes may differ between ethnic groups. Despite this, there have been few systematic studies to identify and characterize the extent of variation in ADME genes in different ethnic groups. To address this, we called single nucleotide variants (SNVs), short insertion-deletions (indels) and gene copy number variants (CNVs) in exome sequence data from healthy Northeast Asian (NEA) subjects (Korean N=126; Japanese N=125) and subjects from 19 different ethnic groups in the 1000 Genomes Project (1000G; N=1181). Average depth across the core (N=38) and extended (N=266) ADME genes (as defined by PharmaADME.org) is ~60X and ~130X for the NEA and 1000G subjects, respectively. Approximately 75% of ADME coding bases were well-captured (sequenced to an average depth >20X) in the combined sample (NEA+1000G). NEA subjects carried on average approximately 180 nonsynonymous (NS; 15% predicted to be deleterious) and 3 loss-of-function SNVs across all ADME coding regions. On average, each NEA subject carried ~9 NS ADME coding SNVs currently uncharacterized in public databases of functional ADME variation, of which 90% are predicted to be deleterious. NEA subjects carried on average ~1 frameshift indel in ADME coding regions and exhibit evidence of potentially novel disruptive gene deletions or duplications in UGT and CYP gene families. Restricting focus to well-captured ADME regions across the combined sample, NEA subjects carried slightly fewer NS variants (~135 SNVs per person) than 1000G subjects (Asian (ASN): ~136; European (EUR); ~141; African (AFR): ~174). Quantities of uncharacterized NS ADME variation predicted to be deleterious were similar in the NEA, ASN and EUR subjects (2.0, 2.2 and 2.0 per person, respectively) and higher for the AFR subjects (4.5 per person). Follow-up experiments to validate uncharacterized ADME variation (including SNVs, indels, and CNVs) are being performed. Ultimately, these results will help enhance understanding of ADME gene variation across ethnic groups which has not been captured in existing genotyping panels and which warrants further functional characterization.

The *CYP2C1917 Variant is not Independently Associated with Clopidogrel Response.** *J. Lewis[1, 2], S. Stephens[1,2], R. Horenstein[1,2], J. O'Connell[1,2], K. Ryan[1], C. Peer[3], W. Figg[3], S. Spencer[4], M. Pacanowski[5], B. Mitchell[1,2], A. Shuldiner[1,2,6].* 1) Endocrinology, Diabetes & Nutrition, University of Maryland, Baltimore, Baltimore, MD; 2) Program in Personalized and Genomic Medicine, University of Maryland, Baltimore, Baltimore, MD; 3) Clinical Pharmacology Program, National Cancer Institute, Bethesda, MD; 4) Applied and Developmental Research, SAIC-Frederick Inc., National Cancer Institute, Frederick, MD; 5) U.S. Food and Drug Administration, Center for Drug Evaluation and Research, Office of Clinical Pharmacology, Silver Spring, MD; 6) Geriatric Research and Education Clinical Center, Veterans Administration Medical Center, Baltimore, MD.

Background: Cytochrome P450 2C19 (CYP2C19) is the principle enzyme responsible for converting clopidogrel into its active metabolite and genetic variants have been identified, most notably *CYP2C19**2 and *CYP2C19**17, that are believed to alter its activity/expression. We evaluated whether the consequences of the *CYP2C19**2 and *CYP2C19**17 variants on clopidogrel response were independent of each other or genetically linked through linkage disequilibrium (LD). **Methods:** We genotyped the *CYP2C19**2 and *CYP2C19**17 variants in 621 members of the Pharmacogenomics of Anti-Platelet Intervention (PAPI) Study and evaluated the effects of these polymorphisms singly then jointly, taking into account LD, on clopidogrel prodrug level, clopidogrel active metabolite level, and ADP-stimulated platelet aggregation pre- and post-clopidogrel exposure. **Results:** The *CYP2C19**2 and *CYP2C19**17 variants were in LD (lD'l=1.0; r2=0.07). In association analyses that did and did not account for the effects of *CYP2C19**17, *CYP2C19**2 was strongly associated with levels of clopidogrel active metabolite (beta=-5.24, P=3.0×10^{-9} and beta=-5.36, P=3.3×10^{-14}, respectively) and post-treatment ADP-stimulated platelet aggregation (beta=7.55, P=2.9×10^{-16} and beta=7.51, P=7.0×10^{-15}, respectively). In contrast, *CYP2C19**17 was associated with clopidogrel active metabolite levels and ADP-stimulated platelet aggregation before (beta=1.57, P=0.04 and beta=-1.98, P=0.01, respectively) but not after (beta=0.40, P=0.59 and beta=-0.13, P=0.69, respectively) adjustment for the *CYP2C19**2 variant. Stratified analyses of *CYP2C19**2/*CYP2C19**17 genotype combinations revealed that *CYP2C19**2, and not *CYP2C19**17, was the primary determinant in altering clopidogrel response. **Conclusions:** Our results suggest that *CYP2C19**17 has a small (if any) effect on clopidogrel-related traits and that the observed effect of this variant is due to LD with the *CYP2C19**2 loss-of-function variant.

A pharmacogenomic approach to targeted medicine. *A. Albayrak, J.D. Hogan, A.P. Peter, B.R. Braun, F.D.G. Schacherer.* Pharmacogenetics, BIOBASE International, Beverly, MA.

The advent of next-generation sequencing technology enables comprehensive screening of an individual's genomic variations. However, due to the millions of variants discovered in each patient, the interpretation of this data poses a challenge, particularly in a clinical context. To address this challenge, we have developed a manually curated database of pharmacogenomic variants from the scientific literature. The aim of the database is to provide a comprehensive resource for all variants that have been reported as significant in a pharmacogenomic context in human studies. The database is designed to provide rich information as evidence for these associations, including information on the exact genomic location and sequence changes, resulting phenotype, drugs administered, patient population, study design, disease context, statistical significance, and a link to the reference from which the information was taken. The database is available through an online search interface, or for download for integration into existing tools and data processing pipelines. To make the database useful for exome or whole genome screening, we have developed algorithms that allow matching of the entries in the database against a sampled subject's variants, taking into account that in many cases, haplotypes need to be matched, exact nucleotide changes must be considered, and complex star alleles must be resolved properly. The online user interface enables the database to be easily searched by drug, disease, gene, haplotype or variation, and also provides information on SNPs that are in linkage disequilibrium with reported pharmacogenomic variants. Detailed reports on each of these data types are presented for in-depth review.

Exome sequencing of asthmatics with extreme corticosteroid response. *Q.L. Duan[1], M.H. Cho[1], R. Kelly[1], W. Qiu[1], E.R. Mardis[4], E.R. Bleecker[5], D.A. Meyers[5], G.A. Hawkins[5], S.P. Peters[5], J.J. Lima[6], K.G. Tantisira[1,2], S.T. Weiss[1,3].* 1) Channing Div Network Med, Brigham & Women's Hosp, Boston, MA; 2) Pulmonary Division, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 3) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA; 4) The Genome Institute at Washington University School of Medicine, St. Louis, MO; 5) Center for Genomics and Personalized Medicine, Wake Forest School of Medicine, Winston-Salem, NC; 6) Center for Pharmacogenomics and Translational Research, Nemours Children's Clinic, Jacksonville, FL.

Corticosteroids (CS) are potent, anti-inflammatory drugs used for the treatment of numerous diseases including asthma, which affects over 300 million individuals worldwide and 20 million Americans. However, great inter-individual variability in response to this class of drugs has been described, whereby up to 25% of patients are non-responsive. Previous pharmacogenetic studies of CS response focused primarily on the contribution of common polymorphisms, whereas increasing evidence suggests that rare variants are important genetic determinants of complex traits and confer larger effect sizes. We hypothesize that novel rare variants, identified through next-generation sequencing of whole exomes, contribute to the heterogeneity of CS response in asthma patients. To test this, we selected 196 individuals including equal numbers of poor and good responders to inhaled CS, measured as ≤0% and ≥13% change in FEV_1 (forced expiratory volume in one second) following 4 to 8 weeks of therapy. Exome sequencing was performed using the NimbleGen SeqCap EZ v2.0 array on the Illumina Hi-Seq 2000. Sequences were aligned using BWA, and variants called using Samtools and VarScan. We identified 403,373 single nucleotide variants (SNVs), of which 347,802 passed quality control in 188 individuals (91 poor and 97 good responders). Of these, 75,206 coded for non-synonymous, splice, or stop variants, the majority of which were rare (60,725 or 81% with MAF < 0.05). Our primary analysis in SKAT-O was a per-gene burden test of these rare variants, weighted by MAF, and adjusted for gender, age, and height. Our top genes (P-values between 2.8 to 9.2×10^{-4}) were *FBXO6*, *CD163*, *ZDBF2*, *ARHGEF16*, *PCK1*, *FOXK1*, *CASC5*. Although none of these were exome-wide significant after correction for the number of genes tested, several of the top loci are differentially expressed in response to dexamethasone (a corticosteroid) in the lymphoblastoid cell lines of asthmatics. Furthermore, *CD163* and *PCK1*, are excellent biological candidates that are known to be regulated by glucocorticoids. In conclusion, exome sequencing of extreme CS response in asthmatics may identify novel loci that contain rare variants that could predict a CS response phenotype. A secondary analysis using Illumina Exome Chip data in nearly 400 asthma trios is under way.

Genome-wide association studies for drug-induced liver injury (DILI) have found strong associations with large effect sizes to classical human leukocyte antigen (HLA) alleles. However, the frequencies of the risk alleles in the treated population are three orders of magnitude higher than the prevalence of DILI (approximately 8/100,000), suggesting a role for other genes in DILI. It has been proposed that part of the missing heritability in complex diseases can arise from non-additive genetics, such as epistasis. Therefore, we hypothesize that there might be a two-hit model involved in conferring risk for DILI. To test this hypothesis, we genotyped samples with two DILI phenotypes (flucloxacillin DILI: n=69; co-amoxiclav DILI: n=124) and ancestry-matched controls (n=3159) on the Illumina HumanExome array. When we imputed the classical HLA alleles and performed single-variant association tests, we obtained similar results to what had previously been reported [flucloxacillin: HLA-B*57:01 (p= 3e-35, OR=50); co-amoxiclav: HLA-DQB1*06:02/HLA-DRB1*15:01 (p=3e-18, OR=3.4)]. However, single-variant tests for rare variants did not yield any significant associations, suggesting we are underpowered to detect rare risk variants with moderate effect sizes. To test the two-hit model of disease, we calculated binomial probabilities of observing an excess of cases with rare alleles at two unlinked genes and then calculated empirical p-values using permutation testing to control for population stratification. We also implemented a conditional scanning approach by incorporating what is known about the biology of DILI from the literature. For example, Monshi et al. showed flucloxacillin covalently binds to lysine residues in albumin and three of these residues occur in amino acid sequences that are predicted to bind to HLA-B*57:01 (Hepatology, 2013). Therefore, we looked for sets of variants that mimicked this scenario in other genes expressed in the liver and found three variants that look promising for flucloxacillin DILI in *CYP4V2*, *FMO3*, and *CD68*. In this work, we demonstrate novel approaches for testing a two-hit model in a complex disease and present results that demonstrate the utility of testing such a model in pharmacogenetic studies.

Pharmacogenomics of glucuronidation in American Indians: The Strong Heart Family Study. *PE. Melton[1], N. Franceschini[2], K. Haack[3], C. Bizon[4], ET. Lee[5], JG. Umans[6], LG. Best[7], SA. Cole[3], LA. Almasy[3].* 1) Centre for Genetic Origins of Health and Disease, University of Western Australia, Crawley, Western Australia, Australia; 2) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) Renaissance Computing Institute, University of North Carolina, Chapel Hill, NC; 5) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 6) Medstar Health Research Institute, Hyattsville, MD; 7) Missouri Breaks Research Industries, Inc, Timber Lake, SD.

Glucuronidation is a phase II (conjugation) process facilitating both biliary and renal clearance of both drugs and endogenous substances. Bilirubin serves as an endogenous glucuronidation biomarker, as its levels are affected by the UDP glucuronisyl transferase (UGT) and organic anion transporter (OAT) products encoded by the genes *UGT1A1* and *SLCO1B1*, respectively. Polymorphisms in these genes are also known to impact clearance of several cardiovascular (CVD), and antineoplastic drugs. Previous research on genes influencing bilirubin in American Indians from the Strong Heart Family Study (SFHS) detected a QTL (LOD=6.61) on chromosome 2q near the *UGT1A1* gene, but linkage conditional on an associated repeat promoter polymorphism, rs5839491, did not completely explain the linkage signal. Genetic testing of this particular variant is used routinely to guide dosing of irinotecan, an antineoplastic agent. To elucidate additional functional variants influencing glucuronidation and bilirubin metabolism, we conducted whole exome sequencing (Illumina TruSeq Exome Enrichment Kit) in SHFS participants from Arizona (n=47) and Oklahoma (n=47). Genetic diversity was maximized by selecting founders from distant relatives (Arizona) or by principal component analysis (OK). Average sequence coverage was 36x and 263,378 variants passed quality control. Using a priori evidence we identified 398 variants in 31 genes from the UGT family and 7 genes involved in bilirubin metabolism. Of these variants, 83 were non-synonymous and 8 were novel. These included the *UGT1A1* exon variant, rs4148323, which was detected in 4% of sequenced SFHS participants and was significantly associated with total bilirubin (p=0.0004). This SNP is known to influence bilirubin metabolism and is associated with increased irinotecan toxicity in East Asian populations but is absent in Europeans. We also detected the exonic *SLCO1B1* SNP rs4149056 in 4% of these SHFS participants, which is known to impact statin metabolism, effect, and toxicity. This variant was not significantly associated with total bilirubin (p=0.66) in these SHFS participants. These results demonstrate the efficacy of whole exome sequencing to identify novel pharmacogenetic markers in American Indians and may have implications for recommended testing to decrease adverse drug events in this population.

Primary action of clozapine exposure on activation of SREBP-controlled lipogenic gene expression may explain benefit and detriment.

J.S.A. de With[1,2], T. Wang[2], E. Strengman[2], S. de Jong[2], W.G. Staal[3], R.A. Ophoff[2]. 1) Donders Institute for Brain, Cognition and Behavior, Department of Cognitive Neuroscience, Radboud University Medical Center Nijmegen, Utrecht, Netherlands; 2) UCLA Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, California, USA; 3) Karakter, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands.

Clozapine is an atypical antipsychotic drug with superior efficacy in the treatment of treatment resistant schizophrenia. However, its use is complicated by metabolic adverse effects, weight gain and clozapine-induced agranulocytosis (CIA), a potential lethal adverse effect occurring in approximately 1% of patients. This study aimed to investigate the mechanism behind the (adverse) effects of clozapine by studying gene expression profiles and the genetic background of response variation in clozapine exposed lymphoblast cell lines. We performed two experiments to study the molecular basis of clozapine exposure at the cellular level. First, we established gene expression profiles of four lymphoblast cell lines that were exposed to a range of concentrations of clozapine (2µM to 100µM) for 24h. Secondly, we exposed 90 lymphoblast cell lines (HapMap CEU trios) to a range of concentrations of clozapine (2µM to 140µM) for 48h to create survival curves. The survival of cells for each cell line is used as quantitative trait measure for genetic mapping. Available gene expression data of these cell lines will be used to gain insight in molecular mechanisms behind differences in cell survival in response to clozapine exposure. We observed significant gene expression changes after exposure to clozapine in lymphoblast cell lines. Using a network approach we found a gene co-expression module significantly associated with clozapine exposure. Gene enrichment analyses showed very strong activation of Sterol Regulatory Element Binding Protein (*SREBP*) together with *SREBP* target genes involved in sterol biosynthesis. Cell survival curves of the 90 cell lines showed individual differences suggestive of genetic factors playing a role in clozapine response, which may be important for identification of agranulocytosis susceptibility loci; genetic analysis is ongoing. The observed gene expression upregulation of genes from the *SREBP* pathway is a recurrent theme in different cell types including neuronal, liver and and blood-derived lymphoblast cells. The consistent finding of activation of the *SREBP* system in different cell types is suggestive of a systematic and primary lipogenic molecular underlying mechanism. Accordingly, this atypical APD could have beneficial effects on myelination in the brain and simultaneously cause metabolic side effects. The results of the cytotoxicity assay could elucidate possible mechanisms behind CIA, enabling prediction of CIA susceptibility.

A Phenome-Wide Association Study of ADME Core Variants in an EMR-linked Biobank.

M.T. Oetjens[1], J.C. Denny[2], N.B. Gillani[3], M. Herrera[1], L. Olson[1], H.H. Dilks[1], D.M. Richardson[1], E. Bowton[4], D.M. Roden[3,5,6,7], D.C. Crawford[1]. 1) Center for Human Genetics Research and Departments of Molecular Physiology and Biophysics; 2) Biomedical Informatics; 3) Department of Pharmacology; 4) Office of Research; 5) Department of Medicine; 6) Oates Institute for Experimental Therapeutics; 7) Office of Personalized Medicine, Vanderbilt University, Nashville, TN.

Many of the genes that participate in drug metabolism harbor deleterious variants at high frequencies compared with the gene networks of other disease pathways. For instance, a functional copy of the CYP2D6, a PharmGKB designated Very Important Pharmacogene, is absent in 7% of individuals from European-descent populations. Other common alleles impacting drug metabolism are found in a continuum between abolished function and gene amplification. The high frequency of functional variants in CYP2D6 and other pharmacogenes is a partial explanation to the stronger effect sizes detected in pharmacogenetic studies designed to identify associations between genes and drug response when compared to those of complex disease. Yet the effect of many of the deleterious variants in pharmacogenes have not been explored in the context of pleiotropy because they are often found in regions of the genome, that for technological reasons, are difficult to genotype accurately and are often missing from fixed-content genotyping platforms. As part of the Vanderbilt Electronic Systems for Pharmacogenomics Assessment (VESPA) 'Grand Opportunities' stimulus grant from the NIH, ~10,000 DNA samples linked to de-identified electronic medical records (EMR) have been genotyped on the ADME Core Panel, a genotyping platform that with specialized assays that accurately target 184 of functional variants across 34 VIPs. The demographics of our cohort are as follows: 83% of the individuals are of European descent, 12% are of African descent, 49% are female, and the median BMI is 27.4kg/m^2. We are applying a reverse genetics methodology, termed phenome-wide association study (PheWAS), to explore of pleiotropic relationships and undiscovered mechanisms of action of these clinically important genes. Our analysis includes a broad range of phenotypes that can be derived from ICD9 code-derived phenotypes, ranging from chronic diseases to environmental effects and/or injury.

Swedegene: Genome-Wide Association Studies of Adverse Drug Reactions.

M. Wadelius[1], N. Eriksson[2], Q. Ying-Yue[3], E. Eliasson[4], H. Melhus[1], P. Hallberg[1]. 1) Department of Medical Sciences, Clinical Pharmacology, Uppsala University, Uppsala, Sweden; 2) Uppsala Clinical Research Center and Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Medical Products Agency, Uppsala, Sweden; 4) Department of Laboratory Medicine, Karolinska Institutet, Stockholm, Sweden.

Background: Adverse drug reactions (ADRs) are common reasons for hospitalisation of adults. Most ADRs are dose-dependent and pharmacologically predictable (type A). Others are non-predictable and have no known pharmacological cause (type B). They are on the other hand often serious and sometimes lead to withdrawal of the drug from the market. The knowledge about possible genetic causes of type B reactions is small. **Objective:** Swedegene wishes to discover genetic and clinical factors that predispose patients to ADRs with the aim to prevent them in the future. **Method:** We are assembling a biobank at Uppsala University (www.swedegene.se) by contacting patients with ADRs reported to the register at the Swedish Medical Products Agency. Consenting patients are interviewed concerning their medical and drug history, and a blood sample is drawn. Supplementary information is collected from their medical records. We have initially chosen to collect drug-induced liver reactions, severe skin reactions, agranulocytosis, long QT syndrome/torsade de pointes, CNS toxicity, neuropsychiatric reactions, statin myopathy, fluoroquinolone-induced tendon rupture and phototoxicity, angioedema and cough related to ACE-inhibitors or angiotensin receptor blockers, osteonecrosis due to bisphosphonates, weight gain due to neuroleptics and antidepressants, and hyponatremia due to antidepressants and antiepileptic drugs. When a sufficient number is collected, genetic analyses are performed, mainly in the form of genome-wide association studies (GWAS). We have access to 5000 unrelated population controls with GWAS data through collaboration with the Swedish Twin registry. **Results:** Swedegene started in 2010 and currently has >1100 cases with DNA and complete phenotypes. We have promising GWAS results on Swedish cases with drug-induced agranulocytosis and on cases with angioedema and cough related to ACE-inhibitors or angiotensin receptor blockers. However, we need more samples for conclusive results. **Conclusion:** Serious ADRs are often too rare to study in a single country, even using a nationwide register. We therefore collaborate with researchers abroad and invite new collaborators interested in collecting cases with the aim to detect genetic and clinical risk factors for ADRs.

Pharmacogenetics at NCBI.

A.J. Malheiro, W. Rubinstein, B. Kattman, J. Lee, D. Maglott, V. Hem, M. Ovetsky, G. Song, K. Katz, C. Wallin, R. Villamarin, J. Ostell. National Center for Biotechnology Information (NCBI), NLM, NIH, Bethesda, MD.

Medical professionals are beginning to practice precision medicine by ordering pharmacogenetic tests to guide drug selection and dosing. The National Center for Biotechnology Information (NCBI) at the National Institutes of Health (NIH) offers free access to comprehensive pharmacogenetics information via user-friendly websites tailored to clinicians and researchers. We will focus on the Genetic Testing Registry (GTR) and ClinVar. The GTR is a centralized, international registry of genetic test information covering clinical and research tests for Mendelian disorders and drug responses. The GTR is a primary resource for locating detailed, practical information about pharmacogenetic tests and the indications for which tests are performed (www.ncbi.nlm.nih.gov/gtr). As of June 2013, laboratories have voluntarily provided information for 14 pharmacological responses (e.g., abacavir, clopidogrel, warfarin). Registered tests describe target patient population, indications, gene/variant targets, and ordering details. NCBI staff work with authoritative groups including the Pharmacogenomics Knowledge Base (PharmGKB), and the Clinical Pharmacogenetics Implementation Consortium (CPIC). Customized links are provided to practical information in PharmGKB such as dosing guidelines and clinical annotations of gene variants. When available, succinct, curated synopses of drug responses by CPIC are presented. Practice guidelines from CPIC, the Pharmacogenetics Working Group of the Royal Dutch Association for the Advancement of Pharmacy (KNMP), and other authorities facilitate the translation of genetic test results into clinical actions for specific drugs. GTR also links to the FDA labels from NLM's DailyMed. The lack of structured, open-access, peer-reviewed, comprehensive gene-drug information is a deterrent to clinical implementation. To fill this gap, NCBI collaborates with CPIC and other experts to create Medical Genetics Summaries, available from NCBI's Bookshelf (http://www.ncbi.nlm.nih.gov/books/NBK61999/). These summaries display in GTR condition and test pages and are supplemented with links to PubMed and OMIM. GTR also provides information about the genes involved in the drug response and variants that affect drug metabolism. Clinicians and researchers can access ClinVar (www.ncbi.nlm.nih.gov/clinvar) for a comprehensive dataset of clinically relevant variants observed in humans, their phenotypic relationships, current interpretations, and supporting evidence.

741W

AlleleTyper Software: a flexible application for mapping SNP genotype and CNV data patterns to pharmacogenetic allele nomenclature. *T. Hartshorne, N. Mehmet, E. Shelton, H. Leong.* Genetic Analysis, Life Technologies, South San Francisco, CA.

Pharmacogenetic (PGx) studies require genetic testing of individuals for multiple variants in drug metabolism enzyme and transporter genes. For phenotype interpretation purposes, genotyping results must be translated to 'star allele' nomenclature. Star alleles are haplotype patterns that have been defined at the gene level and, in many cases, associated with protein activity. Genetic variants within a haplotype can include SNPs, InDels, and copy number variations. Knowing the combination of variants within a given haplotype, and the diploid content in an individual, is of key importance for studying drug metabolism, drug response and adverse drug reactions. To facilitate the translation of results for individuals genotyped in studies using TaqMan™ Drug Metabolism Genotyping Assays and TaqMan™ Copy Number Assays, we developed a web-based flexible software tool called AlleleTyper™. This software uses genetic pattern information in user-defined translation tables to map sample genotyping data to star allele nomenclature. Typically, haplotype information in public resources such as the Cytochrome P450 Allele Nomenclature or PharmGKB databases is used to create a translator for gene alleles of interest. A translator can include one or more genes. A monoallelic translation table is first prepared that contains the star allele/haplotype pattern information for each TaqMan assay in a study. This is imported into AlleleTyper, which automatically converts it to a biallelic translator containing diploid genetic pattern information. The biallelic translator is reviewed and edited, if needed. Subsequently, a study is created in AlleleTyper, the biallelic translator is imported, and then genotype results that have been exported from TaqMan Genotyper Software and/or CopyCaller Software are also imported. AlleleTyper matches the genetic information in these files to the patterns in the biallelic translator and reports the star allele genotypes determined for each individual. The software includes error reporting for missing data, unmatched patterns, etc. A review of the software workflow and features will be presented, along with data analysis examples. AlleleTyper Software greatly facilitates PGx study data analysis, particularly for high throughput studies. This software is also flexible enough to be used for other genotyping applications requiring translation of data from multiple TaqMan assays, including triallelic SNP data analysis and blood genotyping.

Genetic ancestry modifies effects of naltrexone on smoking cessation in African Americans: an analysis of a randomized controlled trial. *A.P. Bress[1], C. Wing[2], A. King[3], R. Kittles[4].* 1) Pharmacy Practice, University of Illinois at Chicago, IL; 2) Health Policy and Administration, University of Illinois at Chicago; 3) Department of Psychiatry & Behavioral Neuroscience, University of Chicago; 4) Department of Medicine, University of Illinois at Chicago.

Nearly 1/5 Americans smoke cigarettes and 443,000 Americans die of smoking every year. Several pharmacotherapies substantially increase smoking cessation rates. However, treatment effects vary across ethnic groups, especially African Americans (AA). To determine if genetic background explains these differences between AA and European Americans, we studied the effects of naltrexone therapy on smoking cessation rates among AA patients with different levels of west African (WA) genetic ancestry. We used data from a previously published randomized, double blind trial of naltrexone vs. placebo for smoking cessation in 315 smokers from Chicago. Ninety five participants were AA and provided a DNA sample. We genotyped 105 autosomal DNA ancestry informative markers using the SEQUENOM iPLEX MassArray platform. Individual ancestry was estimated for all subjects using STRUCTURE. We used logistic regression models to estimate the effects of naltrexone on 4-week quit rates for AAs with high and low WA ancestry. The models adjusted for baseline clinical and demographic characteristics and confidence intervals and p-values were estimated using the bootstrap. In the total pooled sample of AAs, 4-week quit rates were not statistically different between naltrexone (41%) and placebo (33%) groups (p=0.44). However the pooled analysis masks treatment effect heterogeneity by WA ancestry. The median WA ancestry among the 95 AAs in our sample was 80%, so we defined subjects above the median as high WA ancestry and those below median as low WA ancestry. Among those AAs with low WA ancestry, quit rates were higher in the naltrexone group than the placebo group (59% vs. 29%) so that the treatment effect for those AAs with low WA ancestry was 30 percentage points (95%CI -0.02 to 0.58, p=0.04). In contrast, for those AAs with high WA ancestry, quit rates were actually lower in the naltrexone group (26 vs. 39%) so that the treatment effect was -13 percentage points (95%CI -0.41 to 0.13 p= 0.33). The difference in naltrexone treatment effects on quit rates across high and low WA ancestry groups was statistically significant (p=0.04). Naltrexone efficacy on quit rates varies across AA subjects with different levels of WA ancestry. Our data suggest naltrexone is effective for AAs with low WA ancestry and is not effective in AAs with high WA ancestry. These results suggest that genetic factors may partially explain racial differences in treatment effects.

743W

Assessment of viability of human lymphocytes exposed to ionizing radiation and curcumin. *B. Gonzalez[1], C. Monterrubio[1], H. Pimentel[1], R. Silva[1], L. Rodríguez[1], C. Barba[1], N. Pérez[1], B. Inda[1], J. Vidal[1], E. Flores[1], H. Reyes[1], L. Bobadilla[1,2], A. Corona[1,2].* 1) Laboratorio de Citogenética, Genotoxicidad y Biomonitoreo, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Unidad de Citogenética, Serv. Hematol. Oncol. Pediát., Div. Pediatría, Hosp. Civil Dr. Juan I. Menchaca; Guadalajara, Jalisco, Mexico.

Introduction: Curcumin is a polyphenol with antioxidant, anti-inflammatory and antineoplastic properties. In vitro it inhibits tumoral cell proliferation but in contrapart there are reports of cytotoxicity and genotoxicity effects on healthy human lymphocytes. Ionizing radiation induces cell damage and genotoxicity. Cytotoxicity can be assessed on individual cells by trypan blue testing or flow cytometry or assessment on cells poppulation under XTT assay. Statement of Purpose: To evaluate the effect of curcumin on human lymphocytes viability under the effect of ionizing radiation with three viability assessment methods. Methods Used: Peripheral blood lymphocytes from 5 healthy individuals where obtained and cultured for 72hrs, under the next conditions: 1) control group, 2) 25μM of curcumin for 48hrs, 3) 2Gy radiation after 72hrs culture, and 4) curcumin for48hrs with radiation after 72hrs. XTT, trypane blue, CD45+ and 7AAD flow cytometry where done for cell viability assessment. Results: Viability percentages were as follows: XTT testing showed viability of 18.5 for the cells under condition 2, 106.66 for condition 3, 11.23 for condition 4 and 100 for control. Flow cytometry showed viability of 41.84 for condition 2, 60.74 for condition 3, 36.16 for condition 4, and 66.34 on control group. Under trypane blue: condition 2 had viability of 53.07, condition 3 of 63.05, condition 4 of 39.37, while control had a viability of 67.91. Flow cytometry results were significant when comparing group 2 and control (p=0.003), and group 3 and control (p<0.001), the same found under XTT testing (group 2 vs control with p=0.009; group 3 vs control with p<0.001). Trypane blue results analysis only found significant difference between group 3 and control (p=0.022). Conclusions: Our findings show that curcumin under 25μM, for viability is reduced when compared with the control group with 3 methods as shown before. The viability of the group exposed to 2Gy radiation showed no significant difference to control, regarding this, it has been reported that lymphocytes repair acute radiation damage. Flow cytometry and trypane blue did not showed statistically significant differences between them, however, XTT results where different, which is related that the later study evaluates groups of cells, while the first two assess individual cells. Sebastiá and cols. on 2012 reported a cytotoxic effect of curcumin on cultures, which is supported by our results.

Fine-mapping classical HLA variation associated with ankylosing spondylitis susceptibility.
A. Cortes[1], S.L. Pulit[2], P.I.W. de Bakker[2], M.A. Brown[1], International Genetics of Ankylosing Spondylitis Consortium. 1) The University of Queensland Diamantina Institute, Brisbane, QLD, Australia; 2) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands.

Ankylosing spondylitis (AS) is a common, highly heritable, arthritis. 27 susceptibility loci have been identified in and outside the MHC. The HLA-B27 allele is the major genetic risk factor to AS and its role in disease aetiology remains elusive. Potential mechanisms include disorders of the antigenic presentation function of HLA class I proteins, or on abnormal intracellular effects unique to the B27 protein variant. Prior studies have suggested that other HLA-B alleles and MHC genes are involved in AS-susceptibility. In this study we aim to better define the MHC associations and to identify functional and potentially causal variants to shed light on the mechanisms by which the B27 molecule confers risk to disease. We genotyped 7,264 MHC SNPs in 9,069 affected subjects and 13,578 controls of European descent using the Immunochip. Genotyping was followed by imputation of HLA class I and II alleles and amino acid positions of HLA proteins. Association to disease susceptibility was assessed by logistic regression correcting for population structure. Association was observed with SNPs in the HLA-B locus (P<10-320). Analysis of HLA-B alleles revealed other non-B27 alleles affecting susceptibility of moderate effect size (B40:01, OR=1.13; *40:02, OR=1.59; *51:01, OR=1.36; *07:02, OR= 0.77; *57:01, OR=0.73). After controlling for the associated haplotypes in HLA-B we observed independent association signals with SNPs in the HLA-A locus and in HLA-DRB1. Analysis of polymorphic amino acid positions demonstrated that the most significant polymorphisms in the HLA-B and HLA-DPB1 loci were amino acid residues located in the binding pocket of these molecules. We have previously shown that AS is associated with ERAP1 polymorphisms only in HLA-B27 carriers. Additionally, we show that amongst B27 negative cases, ERAP1 variants are AS-associated in B40-positive but not -negative subjects, indicating that ERAP1 variants also interact with B40. This study has identified susceptibility alleles in HLA class I and II loci. The identification of multiple HLA-B alleles affecting susceptibility and the interaction between the alleles HLA-B27 and *40 with ERAP1 (rs30187) further supports antigen presentation as the molecular mechanism by which HLA-B27 confers risk to disease. The presence of associated polymorphism in both HLA class I and II loci suggests that antigen presentation to both CD4+ and CD8+ T lymphocytes are important in AS pathogenesis and/or tissue specificity.

Mapping an Otitis Media Gene within an Indigenous Population: Evidence for Locus Heterogeneity.
E.M. Cutiongco-de la Paz[1,3], G.T. Abes[2,4], M.R.T. Reyes-Quintos[2,4], C.M. Chiong[2,4], M.L. Tantoco[2], M.C. Garcia[4], E.G. Llanes[2,4], T.L. Gloria-Cruz[2,4], A.L. Chan[2,4], J.W. Belmont[5], S.M. Leal[5], R.L.P. Santos-Cortez[5]. 1) Philippine National Ear Institute, University of the Philippines (UP) Manila - National Institutes of Health (NIH), Manila, Philippines; 2) Philippine National Ear Institute, UP Manila - NIH, Manila, Philippines; 3) Department of Pediatrics, UP College of Medicine - Philippine General Hospital (PGH), Manila, Philippines; 4) Department of Otorhinolaryngology, UP College of Medicine - PGH, Manila, Philippines; 5) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA.

Otitis media (OM) is a major cause of hearing loss across all age groups and continues to incur a huge cost to health systems due to changes in pathogen patterns and antibiotic resistance. Identification of genes that have a role in development of OM is expected to illuminate biologic pathways that may be targeted for treatment. Although strong evidence for genetic susceptibility to OM exists, the identification of causal mutations remains elusive. From an indigenous population that has a high prevalence of OM, 49 individuals that can be connected by a single large pedigree were examined for occurrence of different types of OM. DNA samples from 37 individuals with evidence of current or previous OM and 5 individuals with no history of OM were successfully genotyped using the exome chip. Linkage analysis and haplotype reconstruction were performed. A statistically significant maximum multipoint LOD score of 3.6 was achieved within the 10q21 region, while a maximum multipoint LOD score of 2.8 was achieved at chromosome 5p13. However linkage heterogeneity was detected within the pedigree. Reanalysis of the genotypes with the pedigree broken into smaller families resulted in a maximum multipoint LOD score of 2.1 at chromosomes 10p15-q21 and 9p24-q21. Examination of the haplotypes within each genomic region showed that a haplotype within the 10p region is carried by 30% of individuals with OM, with haplotype segregation within three families. On the other hand, a 9p haplotype is carried by 40% of OM individuals that are from five other families. Additionally a maximum multipoint LOD score between 1.5 and 2.0 was obtained at five other chromosomal regions. DNA samples from selected individuals have been submitted for whole-exome sequencing. The identification of potentially causal genetic variants is best guided by linkage mapping data in order to reduce the search space within the exome and to identify haplotypic regions with incomplete segregation with phenotype which is possibly due to phenocopies or genetic heterogeneity.

Candidate-gene association study of pain crisis rate in sickle cell anemia patients.
G. Galarneau[1,2], G. Lettre[1,2]. 1) Montreal Heart Institute, Montréal, Québec, Canada; 2) Université de Montréal, Montréal, Québec, Canada.

Sickle cell disease (SCD) is a monogenic disease caused by a mutation in the β-globin gene. Pain crisis, causing acute pain in the limbs due to ischemia, is one of the major and most frequent complications of SCD and is responsible for a major fraction of SCD patients hospitalizations. This complication is also the best predictor of overall SCD morbidity. Small studies have hinted that inter-individual variation in the rate of pain crisis in SCD patients is heritable. We aimed to verify if there were any genetic variants associated with SCD-related pain crisis within genes already known to be implicated in pain, based on the Pain Genes Database (LaCroix-Fralish, M.L., Pain, 2007). For our study, we had access to three different genotyping datasets, all originating from the Cooperative Study of Sickle Cell Disease: (i) 1,434 individuals were genotyped on the IBC array, a gene-centric array targeting ~2,100 genes related to heart, lung and blood diseases, (ii) 1,409 individuals were genotyped on the exome chip and (iii) 1,279 were genotyped on the Illumina 610-Quad array. 873 patients were genotyped on the three platforms. To maximize the number of samples included in each analysis, we analyzed the three datasets independently. We concentrated our analysis on sickle cell anemia patients with a minimum follow-up time of a year. Because the clinical definition of pain crisis is variable, we only analyzed patients who never experienced pain crisis (controls) and patients with pain crisis rates above the 90th percentile (cases). We used simulations to quantify how phenotype misclassification within the middle of the pain rate distribution can affect statistical power. SNPs with a minor allele frequency above 5% located less than 50kb from a gene implicated in pain were included in the common variants analysis. We performed a logistic regression using as covariates: fetal hemoglobin levels, hematocrit, sex, age and principal components. The significance threshold of 7×10^{-6} was determined by calculating the overall number of independent signals tested in the three datasets. We also conducted a rare variants analysis with SKAT-O. This analysis included functional variants with a minor allele frequency lower than 5%. No gene showed significant association (1×10^{-4}). Given our limited power, we can only conclude that there are no variants of strong phenotypic effect in genes previously implicated in pain that associate with pain crisis rate in SCD patients.

747W

Genetic Linkage Analysis and Candidate Gene Approach in Inbreed Puerto Rican Families with Congenital Scoliosis. *J.E. Baez[1], J.C. Orengo[1], E. Suarez[2], C. Burgos[3], V. Franceschini[3], A.S. Cornier[1,3,4].* 1) School of Public Health, Ponce School of Medicine and Health Sciences, Ponce 00717-0211, PR; 2) Department of Microbiology, Ponce School of Medicine and Health Sciences, Ponce, PR; 3) Department of Molecualr Medicine, La Concepcion Hospital, San German, PR; 4) Clinical Research Center, San Jorge Children's Hospital, San Juan ,PR.

Scoliosis can be either idiopathic or secondary to congenital vertebral abnormalities. Idiopathic typically occurs in children and adolescents who are otherwise healthy. Congenital is due to anomalous development of the vertebrae (failure of formation and/or segmentation). Incidence is estimated in 1/1,000 to 1/2,000 but the true incidence remains unknown. Etiology is unknown. Age and Range Mean 6 years (range few days of life to 25 years).Genes of the Notch signaling pathways have been identified as responsible, they are involved in various biologic processes, including somatogenesis, and neurogenesis. We have found compound heterozygozity status in two families with 7 affected individuals with single mutations on the MESP2, Hes 7 and DLL1 genes. Homozygozity linkage analysis in three other inbreed families have proved evidence of linkage (LOD scores 1.75 to 2.5) in chromosomes 2 and 14 respectively. Evidence of genetic linkage to these chromosomes is new and may help identifying new candidate genes resposible for vetrebral malformations and congenital scoliosis.Understanding and defining the natural history of specific mutation(s) and the developmental (molecular) mechanisms in vertebral patterning, will aid in the identification of protective factors for normal spinal development and toward the prevention of disfiguring congenital scoliosis.

748T

GENE POLYMORPHISMS AS RISK FACTOR FOR EARLY PRIMARY OSTEOARTHRITIS OF THE KNEE IN ASIAN INDIANS. *S. poornima, k. subramanyam, q. Hasan.* Genetics & Molecular Medicine, Kamineni Hospitals, Hyderabad, India.

Primary Osteoarthritis (OA) also know “Degenerative arthritis” it is a slowly progressive and irreversible pathology, which is considered as a part of the ageing process. It affects all the joints of the body, predominantly affecting large joints. Symptoms of OR are pain, swelling stiffness and limitations of joint movements. It is estimated that ~10 % of the world’s aged population ≥60 years have symptomatic OA. At present therapy for OA is only palliative and includes the use of pain relieving medicines, physical, exercise and joint replacement surgery. The increasing incidence of OA in individuals below the age of 50 years and the fact that several members of a single family are affected suggests a genetic predisposition. Current evidence indicates an important role of gene polymorphisms in the aetiology of complex diseases like diabetes, cardiovascular disease and arthritis. Three candidate gene polymorphisms (i) A28602G (rs73297147) of COL2A1 on chromosome12q (ii) G8206T (rs72772941) of CRTL1gene on chromosome 5q and (iii) A1412C (rs74063383) of CRTM gene on chromosome 1p have been selected for evaluation in the present study. Each of these are considered to have a functional role in the pathogenesis of Osteoarthritis. All three polymorphisms were assessed in 100 primary osteoarthritis patients and 100 age and sex matched controls from the Asian Indian population. Genomic DNA was isolated from peripheral blood using salting out method. Genotyping was done by polymerase chain reaction followed by restriction digestion and gel electrophoresis. Results indicate that the COL2A1 G allele was associated with OA (2.7373 95% CI 1.5136-4.9504 p=0.0009) and the T allele of CRTL1 was also associated with OA (2.4371 95% CI 1.2748-4.646 P=0.0068). While CRTM A1412C polymorphism showed a deviation from Hardy-Weinberg principle with a total absence of CC genotype in both cases and controls. After Yates correction the odds ratio did not showed any association with OA (2.0415 95% 0.6048-6.891 p=0.2502). Muiti -dimensional regression (MDR) analysis for the three gene polymorphisms showed a negative interaction, suggesting that the COL2A1 A 28602 G and CRTL1 G 8206 T polymorphisms can be used as independent markers to assess the risk of primary OA in Asian Indian population.

749F

Prevalence of specific cell adhesion molecule gene polymorphisms in recurrent aphthous stomatitis. *A. Alkhateeb[1,2], J. Karasneh[3], H. Abbadi[1], A. Hassan[4], M. Thornhill[5].* 1) Dept Biotechnology and Genetics, Jordan Univ Science & Tech, Irbid, Jordan; 2) Deparmtment of Molecular Genetics, Shafallah Medical Genetics Center, Doha, Qatar; 3) Department of Oral Medicine and Oral Surgery, Jordan Univ Science & Tech, Irbid, Jordan; 4) Department of Oral Medicine and Oral Diagnosis, College of Dentistry, Al Mustansiriya University, Baghdad, Iraq; 5) Unit of Oral and Maxillofacial Medicine and Surgery, The University of Sheffield, School of Clinical Dentistry, Sheffield, UK.

Introduction: Recurrent aphthous stomatitis (RAS) is a common oral ulcerative condition. At ulcer sites vascular adhesion molecule-1 (VCAM-1), E-selectin and intercellular adhesion molecule-1 (ICAM-1) are strongly expressed on blood vessels, and ICAM-1 is expressed on keratinocytes. Expression of these molecules would promote leukocyte accumulation and invasion of the epithelium. Thus, polymorphisms in these candidate genes might contribute to RAS susceptibility. Aim: To determine if inheritance of specific selectin, ICAM and VCAM gene polymorphisms are associated with RAS susceptibility. Methods: 100 RAS cases and 153 controls were recruited from a Jordanian population. Blood was collected for hematological investigations and genotyping. Six SNPs were genotyped; E-selectin rs5361 and rs1805193, L-selectin, rs2205849, ICAM-1 rs5498, ICAM- 5 rs885743 and VCAM-1 rs1800821. Results: significant association between inheritance of the A allele of the E-selectin rs5361 gene polymorphism and increased susceptibility to RAS (P= 0.006, Pcorr= 0.027). None of the other SNPs showed a significant association. Conclusions: This is the first report to link inheritance of the A allele of the E-selectin rs5361 polymorphism with increased risk of RAS. Further studies in different patient cohorts are needed to confirm the association and functional analyses might clarify the biological significance of the association.

Role of the DIVERSIN gene in neural tube defects in humans. *R. Allache[1,2], P. De Marco[3], E. Merello[3], V. Capra[3], Z. Kibar[2].* 1) Pathology and Cell Biology, University of Montreal, Montreal, Quebec, Canada; 2) Obstetrics and Gynecology, CHU Sainte Justine Research Center and University of Montréal, Montreal, Quebec, Canada; 3) Neurosurgery Department, G. Gaslini Institute, Genova, Italy.

DIVERSIN (DIV) is a core member of the planar cell polarity (PCP) pathway that controls the process of convergent extension (CE) during gastrulation and neural tube closure in vertebrates. It acts as a molecular switch where it activates the non-canonical Wnt/PCP pathway while simultaneously inhibiting the canonical Wnt/β-catenin pathway. The Wnt/PCP pathway has been strongly implicated in the pathogenesis of neural tube defects (NTDs) in animal models and human cohorts. In this study, we analyzed the role of DIV in these malformations by re-sequencing analysis of its open reading frame and exon-intron junctions in a cohort of 450 unrelated NTD patients. We identified 4 rare heterozygous and 1 homozygous missense mutations in DIV that were absent in all controls analyzed. Polyphen and SIFT analyses predicted those mutations to be functionally deleterious. Functional validation of these mutations on both Wnt/PCP and Wnt/β-catenin pathways using gene reporter assays is currently underway. Our study demonstrates that DIV could act as predisposing genetic factors to NTDs in a subset of patients and further expands our knowledge on the role of PCP genes in the pathogenesis of these malformations.

751T

Epistatic interactions between SNPs in PHF11 and IFNG genes increase risk to allergic phenotypes. *AK. Andiappan[1,2], KJ. PUAN[1], WS. Yeo[2], BT. Lee[1], R. Melchiotti[1], M. Poidinger[1], DY. Wang[3], O. Rotzschke*[1], FT. Chew*[2].* 1) Singapore Immunology Network, Singapore, Singapore; 2) Department of Biological Sciences, National University of Singapore; 3) Department of Otolaryngology, National University of Singapore.

Allergic diseases, such as asthma and allergic rhinitis (AR) are complex diseases resulting from interactions between genetic and environmental factors. According to Allergic Rhinitis and its Impact on Asthma (ARIA), asthma and AR affect nearly 300 million and 500 million of the world population respectively. Genetic variants in PHF11 and IFNG have been associated with asthma and other allergic phenotypes in multiple populations.Here we report a case control study to evaluate the association of PHF11 and IFNG SNPs to allergic rhinitis and asthma either through indivual SNPs or through SNP-SNP epistasis using a population of 2880 ethnic Chinese in Singapore with 2163 having atopy, 795 with AR and 718 having asthma. A total of 8 tagSNPs from PHF11 and 3 from IFNG gene were selected based on linkage disequilibrium. We used PLINK software to evaluate single SNP and SNP-SNP interaction in association to phenotypes. Our association results show that none of the SNPs were significantly associated (P<0.05) individually to any of the allergic phenotypes. In contrast however we identified SNP pairs interacting to increase risk significantly to atopy, asthma and AR (table attached). We also used Synergy Factor (SF) to evaluate the strength of interaction, which allows assessment of binary interactions in case-control studies considering both size and significance. The results validated that the SNP pair rs9526569 (PHF11) and rs2069728 (IFNG) increased risk with SF= 1.78 (P=0.01) for atopy, SF= 1.92 (P=0.017) for AR and SF= 2.22 (P= 0.0035) for asthma. We then tested the hypothesis in a pilot study of 174 more individuals with genotypes for rs9526569 (PHF11) and rs2069728 (IFNG) and also IFNG expression in T cells. Preliminary results suggest that the allele combination of T allele from rs9526569 and G allele of rs2069728 resulted in lesser IFNG expression which could possibly associate to increased risk seen in the genetic association.This is supported by a possible biological interpretation where the transcriptional activator PHF11 regulates Th1 cytokine gene expressions such as IFNG which could in turn control risk for allergy.

Table 1: SNP-SNP epistasis using PLINK software

Chromosome 1	Gene 1	SNP1	Chromosome 1	SNP2	Gene 2	OR_INT	STAT	P
							(Chi-sq)	
Atopy								
12	IFNG	rs2069728	13	rs3794381	PHF11	1.592	5.915	0.015

752F

Associations of FOXO3A and human lifespan in the Long Life Family Study. *H.T. Bae[1], A.B. Newman[3], J.S. Sanders[4], T.T. Perls[2], P. Sebastiani[1].* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) New England Centenarian Study, Section of Geriatrics, Department of Medicine, Boston University School of Medicine, Boston, MA; 3) Center for Aging and Population Health, Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 4) Center for Aging and Population Health, University of Pittsburgh, Pittsburgh, PA.

The gene forkhead box O3 (*FOXO3A*) is a homologue of *daf-16*, which is part of the insulin-IGF1 signaling (IIS) pathway that modulates lifespan in model organisms. Willcox et al. first reported three SNPs in *FOXO3A* to be associated with longevity in long-lived Japanese-American men, and these were replicated in several centenarian studies with different genetic backgrounds. The purpose of this work was to better understand the role of *FOXO3A* in longevity by 1) replicating the known associations, 2) trying to identify new variants of this gene associated with longevity, and 3) attempting to build a network model of the relationships among *FOXO3A* alleles, longevity and some of its sub-phenotypes in the Long Life Family Study (LLFS). The association analysis (N=4656) was performed using Cox proportional hazard models for age at death, censored at the last age at contact for living subjects, adjusting for sex and the top 10 principal components. Correlation within-family was modeled using random effects with variance covariance matrix proportional to the kinship matrix. Gene-wide significance threshold was determined by applying Bonferroni correction to the number of independent loci (M_{eff}=20) in *FOXO3A*, estimated by the simpleM method (Gao et al. 2010). In the LLFS, 6 out of 11 known variants replicated (p<0.05), one of which almost reached gene-wide significance (rs12206094, p= 0.0027, HR=0.83), but no novel variants were identified in 113 tested SNPs. Next we tried to dissect the significant associations between independent *FOXO3A* alleles and lifespan by building a network model (N=3136) that included age at enrollment, sex, birth year cohort, and the Health Aging Index (HAI)~a composite score consisting of age-related phenotypes including systolic blood pressure, pulmonary vital capacity, serum creatinine, fasting glucose, and Modified Mini Mental Status Exam score. The network was built by fitting regression models of follow-up time, HAI, age at enrollment, and by identifying statistically significant predictors through a forward search. These models were linked through the common variables to build the joint network model and the network showed that the association of one *FOXO3A* allele with longevity was completely mediated by the HAI, while a different *FOXO3A* allele was still associated with lifespan after adjusting for the HAI. The analysis suggests that different *FOXO3A* alleles may affect exceptional longevity through different age-related mechanisms.

753W

Association of Endothelial nitric oxide synthase (eNOS) gene polymorphisms (-786T>C, 894G>T and 4a/b) with T2D and its complications (CAD and ESRD). *A.J.S. BHANWER, P. RAINA, R. KAUR, K. MATHAROO.* HUMAN GENETICS, GURU NANAK DEV UNIVERSITY, Amritsar, PUNJAB, India.

Type 2 diabetes (T2D) has become a medical catastrophe of worldwide dimension. The chronic hyperglycemia associated with T2D causes long-term damage and dysfunction of different organs especially kidney, eyes, nerves, heart and blood vessels ensuing to a variety of microvascular and macrovascular complications. T2D patients have two to four times increased risk of developing coronary artery disease (CAD) and end stage renal disease (ESRD) as compared to their non diabetic counterparts. Endothelial dysfunction is prevalent in T2D and is believed to be an important susceptibility factor for development of CAD and ESRD among T2D patients. It is primarily due to deregulation of endothelial nitric oxide synthase (eNOS) enzymatic activity and inactivation of nitric oxide (NO) through oxidative stress. In the present study, polymorphisms in the endothelial nitric oxide synthase (eNOS) gene have been evaluated for association with T2D, CAD and ESRD in the population of Punjab. A total of 936 patients (567 with T2D, 169 T2D with CAD and 200 T2D with ESRD) and 592 healthy controls were genotyped for one insertion deletion (4a/b ins/del) and two RFLP based polymorphisms (-786 T>C and 894 G>T). Statistically significant difference for genotype (p=0.001) and allele frequencies (p=0.002) for -786 T>C promoter polymorphism between pooled cases and controls was observed. Genotype and allele frequencies for T2D cases with CAD (p= 0.003, p= 0.006) and allele frequencies for T2D cases with ESRD (p=0.009) were significantly different in comparison to controls. The C allele provided 1.35, 1.52 and 1.45 fold risk to development of T2D [OR=1.35(1.12-1.64 at 95%CI)], CAD [OR=1.52(1.12-2.04 at 95%CI)] and ESRD [OR=1.45(1.09-1.92 at 95%CI)], respectively. T-allele of 894 G>T exonic polymorphism contributed 1.35 fold increased risk to ESRD (p=0.043, OR=1.35(1.01-1.79 at 95%CI). The deletion allele (a) of intronic ins/del polymorphism 4a/b, was also observed to increase the risk of ESRD by 1.4 fold [(p=0.024, OR= 1.39(1.04-1.85 at 95%CI)]. In conclusion, eNOS -786 T>C polymorphism seems to be associated with risk of T2D and its progression to CAD and ESRD complications. eNOS 894 G>T and 4a/b polymorphisms appears to play a significant role in predisposition to development of ESRD but not CAD in T2D patients in the population of Punjab.

754T

Contribution of FTO (rs9939609), PON1 (rs705379) and SLC6A4 (5-HTTLPR) genes with the genetic risk for obesity in children from Yucatan, Mexico. *L. Gonzalez-Herrera, M.J. Lopez-Gonzalez, Z. Carballo-Cardeña, G. Perez-Mendoza, N. Mendez-Dominguez, D. Pinto-Escalante*. Dept Genetica, Univ Autonoma de Yucatan, Merida, Yucatan, Yucatan, Mexico.

Genetic variation plays a major role in determining the susceptibility to the obesogenic environment. Significant associations of the SNP rs9939609-FTO with body mass index (BMI) and with the risk for obesity have been suggested in homozygotes AA. The central role of FTO might be through an effect on cerebrocortical insulin sensitivity; as homozygous have a reduced insulin response in the brain. Moreover, significant associations have been found between 5-HTTLPR polymorphism of the serotonin transporter SLC6A4 and being overweight, hypothesizing that it regulates behavioral and metabolic responses associated with the development of obesity through feeding and satiety. Because obesity is associated with oxidative damage and that PON1 has been found in the interstitial space between unilocular fat cells of the adipose tissue; some PON1 polymorphisms have been associated with obesity. In this study, we evaluated the association of these three polymorphisms with the risk for obesity in children from Yucatan, Mexico; where child obesity is the first cause of morbidity. We included 76 obese children, and 155 non-obese healthy children under a case-control association study. Genotype and allele frequencies between cases and controls were compared using SNPstats software. Genotype and allele frequencies were distributed according to Hardy-Weinberg expectations (p>0.05) in cases and controls, except for rs9939609-FTO in controls (p=0.007). Risk alleles frequencies in the studied population were: 16.45% for the SNP rs9939609-FTO, and 38.70%; for both the SNP rs705379-PON1 and SLC6A4 (5-HTTLPR). Significant differences were found for the heterozygous AT genotype of the SNP rs9939609-FTO (p= 0.11) between cases and controls, suggesting that the heterozygous AT genotype of FTO is a genetic risk factor an associated with child obesity in the population of Yucatan. The SNP rs705379-PON1 did not show any significant difference for genotype or allele frequencies (p>0.05), suggesting a lack of association with the genetic risk for obesity, whereas the short allele S of 5-HTTLPR polymorphism in the SLC6A4 gene, showed significant differences between cases and controls (p= 0.0003); suggesting association with child obesity in the studied population. We demonstrated the contribution of the heterozygous AT genotype of the SNP rs9939609-FTO and of the short allele S of the 5-HTTLPR polymorphism; to the genetic risk for child obesity in the population of Yucatan, Mexico.

Polymorphisms in IL12, NOD1, and TLR pathway genes associated with tuberculosis disease and resistance to *M. tuberculosis* infection. *N.B. Hall[1], R.P. Igo[1], L.L. Malone[3], F. Qiu[1], A. Schnell[1], S. Zalwango[3], T.R. Hawn[4], H. Mayanja-Kizza[5], W.H. Boom[2,3], C.M. Stein[1,3], Tuberculosis Research Unit (TBRU).* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Medicine, Case Western Reserve University, Cleveland, OH; 3) CWRU-Makerere University Research Collaboration, Cleveland, OH; 4) Department of Medicine, University of Washington School of Medicine, Seattle, WA; 5) Makerere University School of Medicine and Mulago Hospital, Kampala, Uganda.

Tuberculosis (TB), caused by *Mycobacterium tuberculosis* (Mtb), remains a major public health threat globally, with a high burden in Sub-Saharan Africa. According to the World Health Organization in 2011, Uganda's TB incidence rate was 193 per 100,000 people, compared to 3.9 per 100,000 in the United States. Human host genetics have been demonstrated to be involved in the pathogenesis of TB, focusing on innate and adaptive immunity genes. Though millions of people are exposed to TB worldwide, not everyone who is exposed becomes infected with Mtb as diagnosed by a positive tuberculin skin test (TST), and of those infected, it is estimated that only about 1 out of 10 individuals develops active tuberculosis disease. The two main phenotypes of interest in TB pathogenesis, therefore, are active TB disease and remaining persistently TST negative (PTST-) despite continued exposure to the bacteria. In this analysis, we used data collected through a large ongoing household contact study in Kampala, Uganda, to identify genetic association with these phenotypes. We focused on 29 genes involved in the TNF, TLR/NLR, and IFNG/IL12 pathways, genotyping 546 haplotype-tagging single nucleotide polymorphisms within these genes. The 890 subjects from 299 households included in this analysis were enrolled between 1995-1999 and 2002-2008. Analysis was conducted using generalized estimation equations, clustering the data by family. For each outcome, TB and PTST-, both the dominant and the additive model were run, with sex and HIV as covariates. We found SNPs in IL12RB2 and NOD2 to be associated with both PTST- and TB. 3 SNPs in IL10, 3 in SLC6A3, and 2 each in NOD1 and NOD2 were found to be associated with PTST-, with IL12A, IL12B, and TLR pathway genes, associated with TB. Among the most significant SNPs associated with TB were IL12RB2 rs2307147 (3.5e-7), and TLR2 rs1816702 (9.4e-7). For PTST- the most significant were TOLLIP rs5743942 (0.012), SLC6A3 rs409588 (0.014), and IL12RB1 rs17852635 (0.019). Though these were not significant after correcting for multiple testing, some of these regions identified are understudied, which provides an impetus to focus future research in these regions.

756W

Mannose-binding lectin (MBL2) gene variations and malaria risk in Indian populations. *A.N. Jha[1], P. Sundaravadivel[1], L. Singh[1], T.P. Velavan[2], K. Thangaraj[1]*. 1) Evolutionary and Medical Genetics, Centre for Cellular and Molecular Biology, Hyderabad, AP, India; 2) Institute of Tropical Medicine, University of Tübingen, Tübingen, Germany.

The pathogenesis of malaria and its severity depends on complex interplay of host genetic make-up, the parasite virulence and transmission dynamics and the host immune responses. MBL2 is a pattern recognition receptor of the innate immunity, which, recognize and react to specific repertoire of carbohydrates on the surface of invading organisms and plays an important role in the course of infectious diseases. In this study, we aim to investigate the association of *MBL2* variants with *P. falciparum* malaria infection in Indian populations. We re-sequenced the complete MIF gene along with 1 kb each of 5' and 3' region in 434 individuals from malaria endemic regions of the Orissa and Chhattisgarh states of India. The subjects comprised of 176 cases of severe malaria, 101 of mild malaria, and 157 ethnically matched asymptomatic controls. Since the entire Indian subcontinent represents malaria endemic region, we extended our study to 830 individuals from 32 socially, linguistically and geographically diverse Indian populations. The *MBL2 -221C* (*X*) allelic variant is associated with increased risk (mild malaria OR:1.9, P^{Corr}=0.0036; severe malaria OR:1.6, P^{Corr}=0.02). The functional variant *MBL2*B* increases the risk (mild malaria OR:2.1, P^{Corr}=0.036; mild vs. severe malaria OR:2.5, P^{Corr}=0.039) and *MBL2*C* increases the risk towards severity (mild vs. severe malaria OR:5.4, P^{Corr}=0.045). The exon1 (*MBL2*D/*B/*C*) increases the risk towards severe malaria (OR:3.4, P^{Corr}= 0.000045). The lower MBL secretor haplotypes were observed more in severe malaria compared to asymptomatic (OR:2.0, P^{Corr}=0.00002). The *MBL2*LYPA* haplotypes confers protection whereas *MBL2*LXPA* increases the malaria risk. Further, the frequency of low MBL2 haplotype varies significantly among Indian populations (0 - 62.5%) and *MBL2* variant *MBL2*B* is the prevalent form of structural variant in most of the Indian populations contrary to MBL2*C in the African populations. Study suggests that the functional *MBL2* variants are significantly associated with malaria pathogenesis in Indian populations. Further, the high and low serum MBL haplotypes are not restricted to a particular geographic region. In same geographic region, populations show varied prevalence of *MBL2* haplotypes. Increased understanding on the genetic basis of disease susceptibility will help to identify the high-risk individuals, their treatment and effective disease management strategies.

757T

Cytotoxic T-lymphocyte-associated protein 4 (CTLA4) gene and Graves disease: Case-control study. *Y. Lee[1,2,3], C. Huang[1,4], W. Ting[1,4], F. Lo[5], C. Lin[6], Y. Wu[7], M. Chien[8], C. Wang[8], W. Chen[1], W. Lin[1], S. Chang[1], C. Lin[1].* 1) Dept Pediatrics & Med Res, Mackay Memorial Hosp, New Taipei City, Taiwan; 2) Department of Biomedical Sciences, Mackay Medical College; 3) Department of School of Medicine, Taipei Medical University; 4) Department of , Mackay Medicine, Nursing and Management College; 5) Department of Pediatrics, Chang Gung Memorial Hospital; 6) Department of Pediatrics, Mackay Memorial Hospital HsinChu Branch; 7) Department of Pediatrics, Changhua Christian Hospital; 8) Department of Endocrinology and Metabolism, Mackay Memorial Hospital, Taipei, Taiwan.

Graves disease (GD) is one of the most common autoimmune diseases characterized by the presence of TSH receptor antibodies. T cell-mediated autoimmunity against thyroid antigens and B cells producing TSH receptor antibodies can be demonstrated. The *CTLA4* gene encodes cytotoxic T-lymphocyte-associated protein 4 which is involved in the control of the proliferation and apoptosis of T lymphocytes. We investigated whether the *CTLA4* gene was associated with GD in Han Chinese. **Materials** The patients were 504 unrelated subjects (217 children, 287 adults). GD was diagnosed on the basis of clinical and laboratory evidence (positive autoantibodies to TSH receptor). The controls were 920 subjects. **Methods** dbSNP rs5742909 (-318C/T), rs231775 (+49A/G), and rs3087243 (CT60A/G) of the *CTLA4* gene were genotyped by PCR-RFLP or TaqMan Allelic Discrimination Assay. **Statistical analysis** We assessed the Hardy-Weinberg equilibrium for the SNPs, estimated the frequencies of haplotypes with an accelerated expectation-maximization algorithm, and tested pairwise linkage disequilibrium (LD) between the SNPs in both patients and controls using Haploview 4.2. Statistical difference in genotype, allele, carrier, and haplotype distributions between patients and controls were assessed by the chi-square test. Odds ratios (OR) and 95% confidence intervals were also calculated. The Bonferroni correction was used for multiple comparisons. A *Pc* value of less than 0.05 was considered statistically significant. **Results** The genotype distributions of the 3 SNPs in patients and controls were in Hardy-Weinberg equilibrium ($P > 0.42$). They were in linkage disequilibrium with each other in controls (D' >0.87). The distributions of genotype, allele, and carrier of rs5742909 were not statistically different between patients and controls. Genotypes A/A and A/G, allele and carrier A of rs231775 significantly reduced the risk of GD. However, genotype G/G, allele and carrier G conferred a significantly increased risk of GD. Genotypes A/A and A/G, allele and carrier A of rs3087243 rendered significant protection against GD, however, genotype G/G, allele and carrier G conferred a significantly increased risk of GD. Haplotype CGG was significantly more frequent in patients than in controls and conferred a rick of GD, however, haplotype CAA was less frequent in patients than in controls and rendered protection against GD. **Conclusion** The *CTLA4* gene was associated with GD in children and adults.

758F

Variation near the *CETP* gene strongly associated with HDL levels shows a sex-specific association with type 2 diabetes in Pima Indians. *A.K. Nair, A. Malhotra, R.L. Hanson, S. Kobes, W.C. Knowler, C. Bogardus, L.J. Baier.* Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Phoenix, AZ 85004.

Recent studies have provided evidence that high density lipoproteins (HDL) regulate plasma glucose level by affecting insulin action, non-insulin mediated glucose uptake and insulin secretion and consequently affect the risk for type 2 diabetes (T2D). A recent longitudinal study reported that subjects who developed T2D had on average 0.14mmol/l lower HDL at baseline and this effect was stronger in women. In Pima Indians, high HDL cholesterol levels had a protective effect against T2D only in women. The objective of the present study was to analyze variants associated with lipid levels in a prior GWAS of 1100 Pima Indians to determine whether any of these variants increase risk for T2D. The strongest finding to date is with a SNP (rs6499863) in the cholesterol ester transfer protein gene (*CETP*). *CETP* is a known genetic and functional locus for HDL levels with higher CETP levels inversely related to HDL levels. Genotyping of this SNP in 3519 full heritage Pima Indian samples informative for T2D and lipid levels confirmed a strong association of the T allele with lower HDL levels ($p = 5.6\times10^{-11}$) and identified an association with higher risk for T2D ($p = 4.6\times10^{-4}$; 1.26[1.11-1.43) with the evidence for T2D association coming only from female subjects (N=1949; $p=2.7\times10^{-5}$; 1.44[1.21-1.71).We replicated the female-specific association with T2D by genotyping a non-overlapping sample of 3901 (2111 female) mixed heritage American Indians (in females, $p=0.036$; 1.25[1.01-1.55]). The strongest evidence for a T2D association came from combining females from both samples (N=4060; $p = 5\times10^{-6}$; 1.36[1.19-1.55]). Further analysis of this variant in individuals with measures of pre-diabetic traits (N=402) identified an association with insulin action in female subjects (N=172, $p=0.008$), where the risk allele for insulin resistance predicted risk for T2D. Although the association with HDL levels independently replicated in the additional samples, where the allele predicting lower HDL levels increased risk for T2D, there was no evidence for sex interaction in the association of genotypes with HDL. These observations are consistent with prior findings that lower HDL concentration was a stronger predictor of future T2D in women as compared to men. rs6499863 maps to the 5' near gene of *CETP* in close proximity to a distant promoter. Our future studies will involve dense mapping in and around this region and studying functional variants in *CETP* for their role in T2D.

759W

Identification of genes that contribute to diabetic nephropathy in type 2 diabetes through family-based association testing of genetic variants detected by targeted exome sequencing. *M.G. Pezzolesi[1,2], J. Jeong[1], A.M. Smiles[1], J. Skupien[1,2], J.C. Mychaleckyj[3], S.S. Rich[3], J.H. Warram[1], A.S. Krolewski[1,2].* 1) Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA.

Genome-wide linkage analysis in extended pedigrees from the Joslin Study of Genetics of Nephropathy in Type 2 Diabetes Family Collection previously identified four genomic regions with evidence for linkage with urinary albumin excretion levels (chromosomes 5q, 7q, 21p, and 22q) and two genomic regions linked to variation in renal function (chromosomes 2q and 7p). To identify the susceptibility genes that contribute to these diabetic nephropathy (DN) sub-phenotypes, we performed targeted exome sequencing of all protein-coding genes across these loci in this collection. One-hundred twenty-six DN cases from 42 families with an excess of renal disease (~3 cases per family) were selected for resequencing of the coding region of 361 genes across the six linkage regions using a custom target enrichment library followed by next-generation sequencing. The resulting data achieved greater than 70X on-target read depth and exceeded 20-fold sequence coverage across 70% of the target regions. Multi-sample variant calling using GATK identified a total of 2,442 non-reference variants, including 966 potentially damaging variants. Among these, 14 rare functional variants were significantly over-represented in T2D DN cases relative to the NHLBI's Exome Sequencing Project reference panel. To improve our ability to detect associations at these loci, we are currently expanding our sequencing efforts to all members of the selected families. While these efforts are ongoing, we recently inferred genotypes for the identified potentially damaging variants in the remaining individuals from each family using MERLIN and performed gene-based family association analyses using FBAT. These analyses identified a significant association at the *DEPDC5* gene on chromosome 22 among diabetic family members with proteinuria or end-stage renal disease ($P = 0.016$). The strength of this association improved further when all relatives were analyzed together ($P=3.82\times10^{-3}$). These preliminary data suggest that variants in this gene may contribute to the linkage peak identified at this locus. We anticipate that complete sequencing of the genes across the six linkage regions identified in the Joslin Study of Genetics of Nephropathy in Type 2 Diabetes Family Collection in all members of these families will allow us to establish the genes that contribute to variation in urinary albumin excretion and renal function at these loci.

Imputation of Turkish Population Genotypes Using Immunochip Data and 1000 Genomes Reference Reveals Behçet's Disease Association of SNPs in the *EGR2* Locus.
E.F. Remmers[1], M. Takeuchi[1], D. Ustek[2], N. Mizuki[3], I. Tugal-Tutkun[4], E. Seyahi[5], Y. zyazgan[5], A. Gül[4], D.L. Kastner[1]. 1) Inflammatory Disease Sect, NHGRI/Med Genetics Branch, Bethesda, MD; 2) Dept. of Genetics, Institute of Experimental Medicine, Istanbul University, Istanbul; 3) Dept. Ophthalmology and Visual Science, Yokohama City University, Yokohama; 4) Istanbul Faculty of Medicine, Istanbul University, Istanbul; 5) Cerrahpaşa Faculty of Medicine, Dept., Istanbul University, Istanbul.

Behçet's disease is a genetically complex multisystem inflammatory disease with common occurrence of orogenital ulcers, uveitis, and skin lesions. It can also involve inflammation of the gastrointestinal, pulmonary, musculoskeletal, cardiovascular and neurological systems. The disease is common among modern-day populations who live along the ancient silk trade routes and is a leading cause of blindness in these countries. We recently completed a genome-wide association study of Behçet's disease in the Turkish population with a discovery collection of 1209 cases and 1278 controls genotyped for 311,459 SNPs for which 799,465 autosomal SNPs were imputed using a reference panel of 96 Turkish samples genotyped for this purpose. With independent replication data and meta-analysis the study identified disease-associated SNPs that exceeded genome-wide significance at genomic regions encompassing the major histocompatibility complex, *IL10*, *IL23R*, *CCR1*, *STAT4*, and the natural killer complex gene cluster on chromosome 12p13.2. In addition, variants in *ERAP1* acted recessively and predominantly exerted their effects in individuals with the disease-associated *HLA-B*51* type. We surmised that even with imputation, the 311K genotyped discovery collection SNPs do not fully inform the variation present in the population and predicted that additional loci could be identified by denser genotyping and by imputation using 1000 Genomes haplotypes as a reference. We genotyped 2014 cases and 1826 controls from Turkey using the Illumina Immunochip, which provides dense coverage for 186 immunologically relevant genes, and evaluated the loci for disease association. We found a chromosome 10 region encompassing *ZNF36*5, *ADO*, and *EGR2* contained many SNPs with near genome-wide significance. We therefore used IMPUTE2 to impute additional SNP genotypes with the 1000 Genomes reference haplotypes. The imputation revealed 2 disease-associated SNPs with $P < 5 \times 10^{-8}$. These SNPs clustered 5' of the *EGR2* gene (early growth response 2), which encodes a transcription factor, E3 SUMO-protein ligase. Defects in this gene are responsible for several Charcot-Marie-Tooth disease types and variants 5' of the gene are associated with increased risk of Ewing sarcoma. Recent work has shown roles of EGR2 and EGR3 in controlling inflammation and in promoting T and B cell antigen receptor signaling, suggesting a contribution of *EGR2* variants to the hyperinflammatory state of Behçet's disease.

Interrogating the *PBX-WNT-TP63* pathway in human nonsyndromic cleft lip/ palate.
R. Silva[1,2,3], A. Letra[1,2,3], L. Maili[3], J.B. Mulliken[4], S. Slifer[5], S.H. Blanton[5], J.T. Hecht[2,3]. 1) Department of Endodontics, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 2) Center for Craniofacial Research, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 3) Department of Pediatrics, Pediatric Research Center, University of Texas Health Science Center Medical School at Houston, Houston, TX; 4) Children's Hospital of Boston, Boston, MA; 5) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Nonsyndromic cleft lip/palate (NSCL/P) is the most common human craniofacial birth anomaly and results from defects during morphogenesis of craniofacial structures. Mutations in genes involved in the morphogenesis and patterning of the craniofacial structures, such as the Wnt and Bmp gene families, *Irf6*, and *p63*, lead to CL/P in mice and humans. Recently, a new regulatory module comprised of *Pbx-Wnt-p63-Irf6* was suggested to control facial morphogenesis in mice. Loss of *Pbx* genes in mice resulted in a fully penetrant CL/P phenotype and perturbed Wnt signaling and *p63* function. Here, we investigated if variations in *PBX1, PBX2, WNT3, WNT9B* and *TP63* genes and their interactions were associated with NSCL/P in humans. Twenty-two SNPs flanking and within selected genes were genotyped in our NSCL/P datasets consisting of simplex and multiplex families, including 513 white, nonHispanic (WNH) American (primarily western European) families and 316 Hispanic families from Texas. Family-based association analyses and association in the presence of linkage were performed for individual SNPs in the families, stratified by ethnicity and family history of NSCL/P. Gene-gene interaction calculations were performed for several genes previously associated with NSCL/P. Evidence of association was found for *WNT3* rs7216231 with NSCL/P in the overall Hispanic dataset (p=0.0007). Associations were also observed for *PBX1* rs1044263 (p=0.002) and *PBX2* rs176095 (p=0.0005) in Hispanic multiplex families. Haplotype analyses showed the association of several marker haplotypes with NSCL/P in both datasets. Evidence of gene-gene interaction was found between *TP63* rs1515490 and *WNT3A* rs752107 (P=0.00005). In summary, we provide the first evidence for a role of *PBX1* and *PBX2* and continuing support for the role of *WNT* and *TP63* genes in the etiology of human NSCL/P. Additional studies across multiple populations will determine the possible involvement of these genes in human NSCL/P.

762W

Genetic heterogeneity of midline facial defects with ocular hypertelorism.
M. Simioni[1], E.L. Freitas[1,2], I. Lopes-Cendes[1], V.L. Gil-da-Silva-Lopes[1]. 1) Department of Medical Genetics, FCM/UNICAMP, Campinas, Brazil; 2) Department of Genetics and Evolutionary Biology, Bioscience Institute, University of São Paulo (USP), São Paulo, Brazil.

Midline Facial Defects with Ocular Hypertelorim (MFDH) is a rare and heterogeneous association of features, with a wide spectrum of abnormalities. Most common ones are ocular hypertelorism, broadening of the nasal root and orofacial clefting, which suggest the involvement of genes related to regulation of embryological development of the frontonasal process. Structural and functional anomalies of the central nervous system (CNS) are also frequently in MFDH. Regarding the etiology of this condition, mutations in ALX1, ALX3 and ALX4 genes were described in some families with frontonasal dysplasia, the most recognizable form of MDFH. SHH, FGF8 and PAX3 genes participate of pattern and growth controlling during developmental facial primordia and central nervous system processes. Mutations in these genes have been associated with other craniofacial disorders. Also, few cases of MFDH with chromosomal abnormalities have been reported. We performed array-CGH and investigated mutations in SHH, FGF8 and PAX3 genes by direct sequencing and in 14 patients with MFDH. Recognized monogenic disorders and well-known syndromic conditions were excluded. Array-CGH detected chromosomal abnormalities in almost 15% of sample: a deletion of 6.2 Mb at 2q36.1-q36.3; a deletion at 9p24.1-9p24.3 (6.36 Mb) and a duplication at 20p13 (14.83 Mb). In first case, PAX3 gene was located between the deleted region. Despite of several single nucleotide polymorphisms (SNPs), no pathogenic mutations were found, which could be related to the size of sample. However, these results reinforce the heterogeneity of MFDH and justified the indication of array-CGH in routine care and genetic investigation of these patients.

763T

Analysis of Candidate Gene Sequences in Suicide Severity. *C.C. Zai, V. Goncalves, A.K. Tiwari, V. de Luca, J.B. Vincent, J.L. Kennedy.* Dept Neurogenetics, CAMH, Toronto, ON, Canada.

Background: A number of novel candidate genes have been identified in recent genome-wide association studies of suicide attempt in bipolar disorder (Willour et al, 2011; Perlis et al, 2010). However, the historical candidate genes, including NTRK2, HTR1A, and HTR1B, did not appear to be among the top findings in these studies. Perhaps a combination of rare and common variants may contribute to the predisposition to suicidal behaviour. Method: We analyzed variant data from high-throughput DNA sequencing of 202 genes (Nelson et al, Science 2012) in our bipolar disorder cases of self-reported and genetically ascertained European ancestry. We analyzed the phenotype of suicide attempt as well as suicide severity score (from the Schedule for Clinical Assessment in Neuropsychiatry SCAN: 0=non-suicidal; 1=suicide plan/ideation; 2=suicide attempt without serious harm; 3=suicide attempt with serious harm; 4=suicide attempt designed to end life; N=227). We conducted preliminary analysis using PLINK, with history of alcohol use disorder as well as sex and age were included as covariates. A total of 3199 DNA variants across the 202 gene regions were analyzed. Results: Among the findings, we found a number of DNA variants in NTRK2 (rs41312188, rs2289656; p<0.05) and HTR1A (rs34118353; p<0.05) to be nominally associated with suicide severity scores. These regions are also nominally significant for the analysis of lifetime history of suicide attempt. Conclusions: We conducted a high-throughput targeted sequence analysis of suicide severity in bipolar disorder and found a number of gene regions to be possibly associated with suicidality. We will be using various methods to analyze rare variants, including gene-based tests, and incorporating functional annotation. The top findings will be validated by Sanger sequencing or SNP genotyping. We will attempt to replicate the validated results in other bipolar disorder samples. We will further explore the interaction of these gene variants with history of alcohol abuse/ dependence.

764F

Targeted sequencing of 100 psoriasis candidate loci in 4,845 samples of European descent. *M. Zawistowski[1], P. Stuart[2], L. Tsoi[1], Y. Li[1], E. Ellinghaus[3], V. Chandran[4], T. Tejasvi[2], C. Helms[5], K. Callies Duffin[6], M. Weichenthal[3], J.J. Voorhees[2], A.M. Bowcock[5], P. Rahman[7], A. Franke[3], G.G. Krueger[6], D.D. Gladman[4], R.P. Nair[2], H.M. Kang[1], G.R. Abecasis[1], J.T. Elder[2].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Dept of Dermatology, University of Michigan, Ann Arbor, MI; 3) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 4) Toronto Western Hospital, Toronto, ON; 5) Department of Genetics, Washington University at St. Louis, St. Louis, MO; 6) School of Medicine, Dermatology, University of Utah, Salt Lake City, UT; 7) 7Memorial University, St. John's, NF, Canada.

Psoriasis is a chronic, immune-mediated inflammatory disease of the skin with prevalence ranging from 0.2 to 2% in different populations. To date, genome-wide association studies have identified 36 psoriasis susceptibility loci in Europeans, with several showing strong evidence for multiple associated variants, indicating both genetic and allelic heterogeneity. In most cases, the precise causal variants at each locus are yet to be determined. With the goal of identifying these causal variants, we selected 100 candidate regions from among the confirmed psoriasis loci as well as additional less strongly-associated regions, totaling 5.7 Mb of sequence and containing 769 genes, for deep, targeted resequencing. In each region, we sequenced all exons of transcription units within 250 Kb of the strongest previous association signal; except in the MHC, where we targeted five specific candidate genes comprising 137 Kb of sequence. In addition, we used a whole-region sequencing strategy that included non-coding intergenic and intronic sequence for ten regions with the most significant association signals, and a full transcription unit plus flanking sequence approach for four established loci of lesser significance. The dataset consists of 4,845 samples of predominantly European ancestry from six different centers and included ~30% psoriatic arthritis cases, ~30% cutaneous psoriasis cases and ~40% controls. We predict that our sample should capture >99% of variants in the target regions with allele frequency at least 0.1%. The sequencing averaged 80x coverage across the target regions and discovered over >140,000 total variants, including ~9,000 protein-altering coding variants not previously observed by either the 1000 Genomes or the NHLBI Exome Sequencing projects. We will assess the role of rare variation in psoriasis using single variant and multi-marker gene-level burden tests. Based on a set of preliminary variant calls, we designed a custom exome array to validate the genotype calls within the sequencing dataset, particularly for singletons, as well as for replication of interesting findings in independent samples.

765W

Admixture mapping of uterine leiomyomata in the African American population. *K. Zhang, H. Wiener, B. Aissani.* Univ Alabama at Birmingham, Birmingham, AL.

Background. The genetic basis of susceptibility to uterine leiomyomata (UL or fibroids), a condition with an estimated cumulative incidence of more than 80% among African American women of age 50, remains largely unexplored. The higher prevalence of UL among African American women compared to European American women prompted us to adopt admixture mapping to evaluate candidate chromosomal regions for UL. Study design. We genotyped a total of 1,583 MALD (mapping by admixture linkage disequilibrium) SNPs in a sample of 393 premenopausal UL cases ascertained by ultrasonography in the NIEHS uterine fibroid study. We selected 1,167 MALD SNPs overlapping candidate chromosomal regions recently identified by other groups through linkage scan (2q37, 3p21, 5p13, 10p11, 11p15, 12q14 and 17q25) and admixture mapping (2q37, 4p16.1, 10q26). We also genotyped an additional set of 252 MALD SNPs on chromosome 1 to re-assess suspected UL loci on this chromosome as well as 164 randomly selected MALD SNPs on chromosomes 15, 16, 18, 19 and 21. Analysis. The ADMIXMAP program was used in case-only models to compare ancestry at test SNPs with genome-wide ancestry and statistical significance was assessed using standard normal Z statistics, with a threshold of Z >4.0 considered statistically significant. Results. In models with no stratification for body mass index (BMI), a phenotype associated with UL albeit in a complex relationship, SNP loci at several chromosomes (1, 2, 3, 4, 5, 11, 12 and 15) reached statistical significance (Z >4.0; p=5.5E-05-3.9E-15), with those on chromosomes 1p11, 2q37 and 12q24 being the most significant (Z >5.0). After stratification by BMI, only chromosomes 1q42, 2q37 and 15q24 remained significant at p=0.05 across all the BMI categories (BMI<25; 25-30 and >30), with the association peaking at rs756784 on 1q42 (Z=4.0-4.7; p=7.6E-05-1.4E-08), at rs256552, rs256550 and rs12479375 on 2q37 (Z=4.8; p=2.2E-02-1.7E-06), and at rs1562250 and rs8030499 on 15q24 (Z=2.4-3.2; p=1.8E-02-3.6E-03). Our data show that only rs756784 on 1q42 remains significant across the BMI categories after correction for multiple testing. Conclusion. While this study replicated previous findings, only the new candidate 1q42 remained statistically significant after correction for multiple testing. Co-localization of UL-associated phenotypes such as the age at menopause and obesity-related traits on 1q42 further supports a candidate status for this region.

766T

Characterizing genetic risk factors of obesity in a coronary artery disease cohort. *S.G. Gregory[1], L.K. Kwee[1], E. Grass[1], C. Haynes[1], N. Stitziel[2], S. Kathiresan[2], E.R. Hauser[1], W.E. Kraus[1], S.H. Shah[1].* 1) The Duke Institute of Molecular Physiology, Duke University Medical Center, Durham, NC; 2) Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Purpose: Obesity is a chronic metabolic disorder that is contributing to morbidity and mortality at epidemic proportions in western and, increasingly, developing nations. Although lifestyle contributes to the development of obesity, there is an established genetic role in the disease state, which has only been partly elucidated by the common variant common disease hypothesis. While obesity leads to the development of several chronic metabolic disorders, here we report the identification of obesity genetic risk factors in a coronary artery disease (CAD) cohort using a single nucleotide variant (SNV) 'exome' microarray that contains both common and rare coding variants. Methods: DNA was obtained from subjects selected from the CATHGEN biorepository of patients referred for cardiac catheterization at Duke University. Samples were genotyped on the Illumina Infinium HumanExome BeadChip, which includes >240K coding SNVs from >20,000 coding and genomic sequences with a combination of rare and common non-synonymous variants. After quality control measures and filtering of monomorphic probes, 65,853 polymorphic autosomal SNVs were available for analysis in European Americans (EA, n=1192), and 97,118 SNVs in African Americans (AA, n=1528). We used race-stratified linear regression models to test each genetic variant for association with BMI, adjusting for age, sex and ethnicity (via principal components obtained from Eigenstrat analysis). We combined the EA and AA results using meta-analysis. Results: Three and six SNVs were significantly associated with BMI in the AA and EA samples, respectively, after Bonferroni correction for multiple tests. No SNVs were significantly associated with BMI in the meta-analysis. Several other SNVs in genes that may play a role in the development of CAD and obesity were suggestively associated with BMI (p<10-5) (AA: ACACB, IFT88 and GRB7; EA: DYNC1H1, MTRR, MUC5B and PRSS2; meta-analysis: ITGB2). Conclusion: We have identified coding and putatively causal variants within several genes that are associated with BMI (and implicated in the development and CAD). These variants may provide the functional link between previous association studies that have identified the gene but not the coding variant in the candidate gene. We are currently carrying out interaction analysis and validation of our initial results.

767F

Discovery and fine-mapping of BMI loci using Metatochip: a trans-ethnic meta-analysis from the Population Architecture using Genomics and Epidemiology (PAGE) Study. *J. Gong[1], F. Schumacher[2], L. Hindorff[4], U. Lim[3], J. Haessler[1], C. Carlson[1], S. Rosse[1], P. Bůžková[6], R. Cooper[10], G. Ehret[11], C. Gu[12], M. Irvin[9], M. Graff[14], L. Fernandez-Rhodes[14], E. Boerwinkle[7], T. Matise[5], L. Marchand[3], C. Kooperberg[1], D. Crawford[8], C. Haiman[2], K. North[13,14], U. Peters[1], the Population Architecture using Genomics and Epidemiology (PAGE) Study.* 1) Public Health Science, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Preventive Medicine, Keck School of Medicine / Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA; 3) Epidemiology Program, University of Hawaii Cancer Center, Honolulu, HI; 4) Division of Genomic Medicine, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 5) Department of Genetics, Rutgers University, Piscataway, NJ; 6) Department of Biostatistics, University of Washington, Seattle, WA; 7) The Human Genetics Center and Institute of Molecular Medicine, The University of Texas Health Science Center at Houston, Houston, TX; 8) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 9) Department of Biostatistics, University of Alabama, Birmingham, AL; 10) Preventive Medicine and Epidemiology, Loyola University, Chicago, IL; 11) Division of Cardiology, Geneva University Hospital, Geneva, OH, Switzerland; 12) Department of Biostatistics, Washington University, St. Louis, MO; 13) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC; 14) Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Genome-wide association studies (GWAS) primarily performed in European-ancestry (EA) populations have identified numerous loci associated with body mass index (BMI). However, it is still unclear whether EA associations can be generalized to other ancestry groups. In addition, for the most part the putative functional variant(s) in these BMI loci remain under investigation. Different local Linkage Disequilibrium (LD) structure between ethnic groups can help narrow in or fine-map these BMI-related loci. Therefore, we used the Metabochip to densely genotype and evaluate 21 BMI GWAS loci identified in EA studies in 29,151 African Americans (AA), 15,000 Asians, and 6,211 Hispanics from the Population Architecture using Genomics and Epidemiology (PAGE) consortium. Our preliminary analysis showed that among the 21 loci, FTO was associated with BMI in all of the three ethnic groups; MC4R in AA and Hispanics; SEC16B, TMEM18, ETV5, GNPDA2, TFAP2B, and BDNF in AA (at 5.8×10-5 significant level; 0.05/average number of SNPs across 21 loci). Moreover, Metabochip-wide trans-ethnic meta-analyses (fixed-effects models) revealed two novel BMI loci, COBLL1-GRB14 (rs10184004, p=2.2×10-7) and TCF7L2 (rs7903146, p=5.4×10-8) loci, that were significant when adjusting for the total number of SNPs tested across the chip (2.5×10-7). The analysis in AA showed that fine-mapping in AA is a powerful approach to narrow in on the underlying causal variants in BMI GWAS loci identified. We will expand upon this work by including additional Asian, Hispanic and Native American samples into this study (totaling ~20,000 Asian, 20,000 Hispanics and 500 Native Americans) providing improved power to study known loci and identify novel loci in a trans-ethnic meta-analysis.

768W

Fine-mapping type 2 diabetes susceptibility loci with the Metabochip. *A.P. Morris[1], T.M. Teslovich[2], T. Ferreira[1], A. Mahajan[1], Y. Lee[2], N.W. Rayner[1], H. Chheda[3], L. Eisele[4], M. Genome-wide association studies (GWAS) have been successful in identifying loci for type 2 diabetes (T2D). These loci are usually characterised by common lead SNPs with association signals that map to large genomic intervals. Consequently, there has been limited progress in localising causal variants for T2D and establishing the functional impact of these loci in the pathogenesis of the disease. To address these shortcomings, we combined Metabochip data from 25,154 type 2 diabetes (T2D) cases and 50,269 controls of European ancestry, supplemented by imputation up to the 1000 Genomes Project reference panel (March 2012 release), to facilitate fine-mapping of 39 established loci for the disease that are covered on the array. We aimed to: (i) delineate association signals in established loci arising from multiple independent causal variants; (ii) assess the evidence for association with low-frequency (LF) variants, minor allele frequency (MAF) <5%, in established loci; and (iii) define 'credible sets' of SNPs that account for 99% of the probability of including the causal variant at each association signal.

We undertook approximate conditional analyses implemented in GCTA, using 3,298 cases and 3,708 controls from GoDARTS as reference, to identify loci with multiple SNPs at nominal significance ($p<10^{-5}$), reflecting increased prior odds of association in Metabochip fine-mapping regions. These data suggest that association signals mapping to *TCF7L2* and *KCNQ1* can each be explained by three causal variants, whilst those at *DGKB*, *CDKN2A/B*, *KCNJ11*, *HMGA2*, *HNF1A* and *GIPR* can be delineated by two. The conditional analysis suggests that LF associated variants mapping to *TCF7L2* (rs140820620, MAF=1.9%, $p=6.5\times10^{-13}$; rs180726800, MAF=2.0%, $p=1.9\times10^{-6}$), *KCNJ11* (rs61763083, MAF=0.3%, $p=7.5\times10^{-7}$), *HMGA2* (rs116521220, MAF=0.6%, $p=6.3\times10^{-6}$), and *HNF1A* (rs1800574, MAF=2.6%, $p=1.5\times10^{-6}$), are independent ($r^2<0.05$) of the common lead SNPs at these loci. The 99% credible sets map to <10kb at *MTNR1B* (rs10830963 only), *CDKN2A/B* (both signals map to the same <2kb interval), *TCF7L2* (primary signal includes 3 SNPs, 4.3kb), *HNF1B* (7 SNPs, 5.8kb), and *GCK* (3 SNPs, 9.8kb).

We are currently following up these association signals in an additional 12,413 T2D cases and 32,091 controls to confirm fine-mapping intervals for functional investigation.

769T

GTF2IRD1 is an epigenetic regulator involved in facial skin patterning that may underpin facial abnormalities of William-Beuren Syndrome patients. *C.P. Canales[1], S. Corley[2], P. Kaur[3], I. Smyth[4], M. Wilkins[2], E.C. Hardeman[1], S.J. Palmer[1].* 1) Cellular and Genetic Medicine Unit, University of New South Wales, Kensington, Sydney, New South Wales, Australia; 2) School of Biotechnology and Biomolecular Sciences, The New South Wales Systems Biology Initiative, University of New South Wales, Sydney, Australia; 3) Epithelial Stem Cell Biology Laboratory, Peter MacCallum Cancer Centre, Melbourne, Australia; 4) Dept of Biochemistry and Molecular Biology, Monash University, Melbourne, Australia.

Williams-Beuren Syndrome (WBS) is a genetic disorder associated with multisystemic abnormalities, including craniofacial dysmorphology. It is caused by a deletion of 1.55 Mb including 28 genes on chromosome 7q11.23. Analysis of genotype-phenotype correlations in atypical smaller deletions has implicated two evolutionary-related transcription factors GTF2I and GTF2IRD1 as prime candidates for the cause of the facial dysmorphology. We have investigated the involvement of GTF2IRD1, a transcriptional repressor discovered in our laboratory, in the control of epidermal proliferation and differentiation and its role in the causation of the typical WBS craniofacial features. Protein interaction studies indicate that GTF2IRD1 gene silencing occurs via chromatin-modifying epigenetic mechanisms. We have generated a targeted Gtf2ird1 knockout (KO) mouse that shows striking similarities to aspects of the human disease including enlarged lips caused by an extreme thickening of the epidermal layer, associated with an expansion of the basal proliferative zone. The expression of Gtf2ird1 in facial skin shows a dynamic pattern during development that matches with the affected areas of the KO mice, revealing how the expression of this protein correlates with patterning of the future lips. To assess the basis of the facial abnormalities, we have evaluated expression of the cell proliferation marker Ki67 and markers of epidermal differentiation, K10 and K14, and tested skin barrier function by toluidine blue whole mount embryo staining. Our results show increased Ki67, K10 and K14 expression in lips of null animals confirming a hyperproliferative phenotype that begins very early in life. CT-scan analysis of skulls showed no major differences in hard tissue morphology suggesting that the role of Gtf2ird1 is restricted to soft tissue. In order to elucidate gene expression alterations due to the lack of this transcriptional repressor in the skin, we have performed comparative RNA-seq analysis from lip skin samples, which has revealed important clues concerning the molecular mechanisms involved. We conclude that GTF2IRD1 plays an important role in how facial skin is patterned during development. It is a crucial component of the transcriptional machinery for proper cell proliferation and differentiation in specific regions of the skin, including playing an important role in regulation of components that define proper distribution of the epidermal keratin network.

Probabilistic method with correction for imputation error improves fine-mapping resolution. *B. Pasaniuc[1], G. Kichaev[2], N. Zaitlen[3], G. Bhatia[4], E. Kostem[5], F. Hormozdiari[5], E. Eskin[5], A.L. Price[4].* 1) Pathology and Laboratory Medicine, Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Dept of Biostatistics, UCLA; 3) School of Medicine, UCSF; 4) Dept of Epidemiology and Biostatistics, Harvard School of Public Health; 5) Dept of Computer Science, UCLA.

Standard statistical approaches for fine-mapping causal variants use marginal association statistics to prioritize SNPs for functional assays. Here, we propose a probabilistic approach that uses information across all SNPs in a locus to approximate the posterior probability that a given SNP is causal. This approach provides appropriate weights to SNPs both within and between loci. We use simulations based on 1000 Genomes data to show that our approach drastically reduces the total number of SNPs that need to be tested in functional assays before identifying the causal SNPs. For example, an average of 69 SNPs per locus need to be tested to identify 90% of causal SNPs, as compared to 110 SNPs per locus for locus-specific ranking based on marginal association statistics or 304 SNPs per locus for genome-wide ranking based on marginal association statistics. Although our simulations use a flat prior for a SNP being causal, our framework naturally allows for priors that incorporate external information such as functional annotations. Differential imputation error across SNPs leads to biases in the prioritization of SNPs, because imputation error deflates the estimated effect size and reduces the priority of a SNP (e.g. an average of 131 SNPs to be tested per locus to identify 90% of causal variants if the causal is imputed vs. 69 if causal is typed). We use the fact that observed effect sizes at nearby SNPs follow a multivariate normal distribution (determined by effect sizes at causal SNPs and population LD) to incorporate imputation error in approximating the posterior probability of being causal. We use 1000 Genomes simulations to show that our approach leads to superior performance vs. the standard approach of ignoring imputation error (e.g. an average of 96 vs. 131 SNPs per locus need to be tested to identify 90% of causal variants). Differential imputation error across ethnicities can be incorporated into the model, further improving fine-mapping resolution in multi-ethnic fine mapping studies. Finally, we extend our approach to model admixture association signals in recently admixed populations and show that this provides a further boost in fine-mapping resolution.

771W

The association of common SNPs with cholesterol and lipid levels in Latvian population. *J. Klovins, I. Radovica, D. Fridmanis.* Latvian Genome Ctr, Latvian Biomedical Ctr, Riga, Latvia.

Low high density lipoprotein (HDL) cholesterol level, high low density lipoprotein (LDL) cholesterol level and high triglyceride (TG) level are well known risk factors for coronary artery disease (CAD) and mortality in type 2 diabetes (T2D) patients. Recent genome-wide association studies (GWASs) and other human genetic studies have localized many common SNPs in different loci that influence blood lipid levels including previously known loci that are potentially involved in lipid metabolism. There are at least 40 loci associated with one or more blood lipid levels and far more SNPs, but not all of them are successfully replicated. In this study we report an association of 139 SNPs selected from more than 30 genes with quantitative measures of blood lipids in 1345 individuals selected from Genome Database of Latvian Population. 26 SNPs were nominally ($p<0.05$) associated with TH, 58 SNPs were associated with HDL-C, 22 SNPs with LDL-C and 40 SNPs were associated with TG. We have performed an imputation of SNPs for the densest genotyped loci. Allele dosage test was also performed and indicated a strong correlation between the number of risk alleles and quantitative measures of all available lipids. SNPs from CEPT gene were most strongly associated with HDL-C levels (rs3764261; p= 2.2 × 10-10). In summary we have shown that genetic variation strongly affects blood lipid levels in Latvian population.

Genetic Variation and Lumbar Spine Bone Mineral Density in National Health and Nutrition Examination Survey 1999-2002. *J. McLean[1], A. Yesupriya[2], T. Fakhouri[2], Y.-H Hsu[3, 4], D. Kiel[3, 4], A. Looker[2].* 1) Division of Health and Nutrition Examination Surveys, NOVA Research/National Center for Health Statistics, Hyattsville, MD; 2) National Center for Health Statistics,Centers for Disease Control and Prevention, Hyattsville, MD; 3) Institute for Aging Research, Hebrew SeniorLife, Boston, MA; 4) Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA.

Bone mineral density (BMD) is a heritable and multifactorial trait used to diagnose fracture risk and osteoporosis. Genome wide association studies (GWAS) of BMD have identified significant genetic variants in European and Asian populations. Since BMD varies across populations, we aimed to replicate GWAS results in a multiethnic population. The relationship between 23 polymorphisms within 14 candidate genes and lumbar spine BMD (g/cm^2) (LSBMD) was examined by race/ethnicity (non-Hispanic white, non-Hispanic black, and Mexican American) in a nationally representative sample of 7226 participants' age 20+ years from the National Health and Nutrition Examination Survey 1999-2002. We used linear regression that assumed an additive genetic model and controlled for age. False discovery rate (FDR) adjusted p-values were used to correct for multiple comparisons and analyses accounted for the NHANES survey design. Ten polymorphisms within ESR1 (rs1038304 and rs4870044), TNFRSF11B (rs11995824, rs4355801, rs6469804, and rs6469804), MEPE (rs1471403), LRP5 (rs3736228), and CCDC170 (rs6929137) were significantly related to LSBMD in non-Hispanic whites. The two polymorphisms within ZBTB40 (rs6426749 and rs7524102) that have been associated with BMD in East Asian and Northern European populations were significantly associated with LSBMD in non-Hispanic blacks but not in non-Hispanic whites. There were no statistically significant relationships between polymorphisms and LSBMD in Mexican Americans. Significant results from GWAS in European and Asian populations are not consistent with race/ethnic specific results for non-Hispanic whites, non-Hispanic blacks and Mexican Americans in the United States. This indicates a need for further research focusing on these groups.

773F

Polymorphisms of DNA leading to increased susceptibility for Type 2 Diabetes in South Asians: A systematic review and meta-analysis. *Z.N. Sohani[1,2,3], W.Q. Deng[1,3], S.S. Anand[1,2,3].* 1) Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, Ontario, Canada; 2) Population Genomics Program, McMaster University, Hamilton, Ontario, Canada; 3) Population Health Research Institute, Hamilton General Hospital, Hamilton, Ontario, Canada.

Background: Type 2 diabetes (T2D) is a metabolic disorder resulting from interplay between pancreatic β cell function and insulin resistance. People of South Asian ancestry are up to four times more likely to develop T2D than white Europeans and are forecasted to carry 25% of the world's burden by the year 2030. Single Nucleotide Polymorphisms (SNPs), which explain the most genetic variation in humans, may contribute to the increased susceptibility for T2D in South Asians. However, risk from genetic variants has not been fully quantified for this ethnic group. The purpose of this study was to i) ascertain risk estimates from T2D associated polymorphisms in South Asians, and ii) compare effect sizes, risk alleles, and risk allele frequencies (RAFs) from this meta-analysis with genome wide estimates in white Europeans. Methods: A MEDLINE, EMBASE, and CINHAL search identified 3499 studies. An additional 17 studies were identified by hand-search and consultation with experts. We included 88 case control studies, which met our inclusion criteria. Data were extracted independently by two reviewers. SNPs were meta-analyzed using a random effects model and weighted by inverse variance. Odds ratios were determined for the risk allele. Results: After considering the linkage disequilibrium structure, 264 SNPs were considered from all included reports comprised of 65317 cases and 88511 controls. From these, 71 SNPs were conducive to a meta-analysis. Significant association with T2D was found in 22 SNPs from 17 nuclear genes (ADCY5, CDKAL1, CDKN2A/2B, ENPP1, FTO, GLIS3, HHEX, IDE, IGF2BP2, ITLN1, KCNJ11, PGC1α, PPARγ, SLAMF1, SLC30A8, TCF7L2, and UCP2) and 2 SNPs from mitochondrial DNA (mtDNA). The majority of SNPs from nuclear genes increased odds of T2D by between 15-35% per risk allele. Risk alleles from mtDNA SNPs increased odds of T2D by 90%. Interestingly, effect sizes in South Asians were similar to those reported in white Europeans. However, we observed variation in RAFs and alleles. Specifically, risk allele for HHEX was the minor allele in South Asians and common allele in Europeans. Conclusions: This is the first meta-analysis to investigate polymorphisms associated with T2D in South Asians. We demonstrate that similar effect sizes for T2D SNPs are apparent between South Asians and Europeans, but there is variation in RAFs. Differences in risk allele for HHEX may be indicative of selection or a result of genetic drift. Further investigation is warranted.

774W

Assessment of Cytochrome P450 Genetic Variability on Methadone Dose and Tolerance. *H. Tsai[1,2], S. Wang[3], S. Liu[3], I. Ho[3,4,5], Y. Chang[3], C. Chen[3], K. Lin[3], A. Chen[6], Y. Liu[3,7,8].* 1) Dept Pediatrics, Northwestern Univ Sch Med, Chicago, IL; 2) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Miaoli County, Taiwan; 3) Center for Neuropsychiatric Research, National Health Research Institutes, Zhunan, Miaoli County, Taiwan; 4) Center for Drug Abuse and Addiction, China Medical University Hospital, Taiwan; 5) Graduate Institute of Clinical Medical Science, China Medical University, Taiwan; 6) Department of Psychiatry, College of Physicians and Surgeons, Columbia University, New York, New York, USA; 7) Graduate Institute of Drug Safety, China Medical University, Taiwan; 8) Department of Psychiatry, National Taiwan University Hospital and National Taiwan University College of Medicine, Taipei, Taiwan.

Objectives: Methadone is well known as a maintenance drug to prevent heroin-addicted patients from experiencing withdrawal symptoms. Importantly, previous studies have suggested that methadone dose is one of the key factors in relation to success in individuals with methadone maintenance treatment (MMT). In this study, we constructed gene matrix using previously identified gene polymorphisms from CYP2C19, CYP2B6 and CYP3A4, individually, and simultaneously determined whether there was genetic influence on methadone dose and methadone tolerance. Methods: A total of 366 heroin addicts undergoing MMT were recruited in this study. Data were collected using interviewer-administered assessments. The SNPs genotyped and used to construct gene matrix included two from CYP2C19; four from CYP2B6; and five from CYP3A4, separately. After adjusting covariates, regression analyses were performed to examine associations of CYP2C19, CYP2B6 and CYP3A4, separately, with methadone dose and methadone tolerance. Results: Our results indicated that methadone dose and methadone tolerance were dominantly affected by gene dose of CYP2C19, but not CYP2B6 and CYP3A4. In addition, the results also suggested that dominant genetic influence of the CYP2C19 gene dose on methadone dose was only found among the study patients with negative unrine morphine, not with positive urine morphine. Conclusions: The findings in this study have suggested that accounting for the CYP2C19 gene dose may serve as a potential indicator when assessing methadone dose and methadone tolerance, respectively. Ultimately, taking into account genetic information of CYP2C19 and other CYP isoenzymes together in methadone treatment will facilitate understanding interindividual variability of the clinical pharmacokinetics of methadone.

775T

Mapping expression quantitative traits in mesenchymal stem cell cultures derived from nonsyndromic cleft lip and palate patients' *orbicularis oris* muscle. *C. Masotti[1], A.C. Nica[2], S. Ferreira[1], L. Bomilcar[1], D. Meyer[1], D.Y. Sunaga[1], D.F. Bueno[1], N. Alonso[3], D. Franco[4], E. Dermitzakis[2], M.R. Passos-Bueno[1].* 1) Department of Genetics, University of São Paulo, Univ de Sao Paulo, Sao Paulo, Brazil; 2) Department of Human Genetics and Development, University of Geneva, Switzerland; 3) Department of Plastic Surgery, Faculty of Medicine, University of São Paulo, Brazil; 4) Department of Plastic Surgery, Hospital Clementino Braga Filho, Faculty of Medicine, Federal University of Rio de Janeiro, Brazil.

Mesenchymal stem cells derived from dental pulp of nonsyndromic cleft lip and palate (NS CL/P) patients exhibit a distinct expression signature at loci related to extracellular matrix modeling and epithelial-mesenchymal transition processes. *Orbicularis oris* muscle is compromised in NS CL/P patients and is an accessible source of mesenchymal stem cells. In this work we established mesenchymal stem cell cultures derived from *orbicularis oris* muscle (OOMMSC) of 43 NS CL/P patients and four controls in order to identify genetic variants associated with gene expression variation and disorder susceptibility. By correlating genome-wide expression and genotype microarrays, we mapped 119 expression quantitative trait loci (eQTLs) related to 18 genes ($p<0.0001$; FDR=14%). We did not observe significant enrichment of any GO term among genes for which we identified eQTLs. Thirty out of the 119 eQTLs are shared with other tissues or cell types, such as lymphoblastic cell lines, liver, brain cortex, T-cells, and fibroblasts. Twelve previously reported NS CL/P candidate genes have at least one OOMMSC eQTL located within their putative regulatory regions, but none of these genes is directly regulated by these eQTLs. Four eQTLs for *SENP5* and *CEP19* genes ($p<0.05$, FDR=57%) are in linkage disequilibrium with NS CL/P genome-wide associated SNPs in 3q29 region ($r^2>0.52$; $D'>0.9$). The haplotype containing the at-risk variant (rs10489880) is associated with higher expression of SENP5 and lower expression of *CEP9*. *SENP5* is a SUMO-specific protease that plays a critical role in the regulation of sumoylated protein levels in the cell, and sumoylation was demonstrated as an essential mechanism for palate development. Further case-control association study of OOMMSC eQTLs will elucidate the potential role of these variants in NS CL/P susceptibility. Funding: FAPESP/CNPq.

Kawasaki disease (KD; MIM611775) is a systemic vasculitis syndrome with unknown etiology which predominantly affects infants and children. Recent findings of susceptibility genes for KD have suggested up-regulation of Ca^{2+}/NFAT pathway as one of the main pathophysiological processes in KD. In this study, we focused on *ORAI1*, a gene for a channel involved in store operated Ca^{2+} entry located on 12q24 where positive linkage signal was seen in our previous sib pair study of KD, and conducted a genetic association study. By re-sequencing 23kb of *ORAI1* region for 24 subjects including 12 KD cases and 12 controls, we identified 68 variants and then performed linkage disequilibrium analysis with 94 Japanese healthy individuals. After selecting 9 tagging SNPs which represent 37 variants with minor allele frequencies larger than 5%, we performed an association study using 730 KD cases and 1315 controls. Among the 9 SNPs examined, a non-synonymous SNP (rs3741596; p. S218G) showed a nominal association with KD (OR = 1.19, 95%CI 1.02~1.40, P = 0.028). The same trend of association was observed in an independent case control panel (1586 KD cases and 1097 controls) and a significant P value was observed in a meta-analysis (OR = 1.20, 95%CI 1.08~1.33, P = 0.00098). Furthermore, we also found a rare 6 base-pair insertion polymorphism which cause elongation of proline repeat within N-terminal cytoplasmic domain of the ORAI1 protein was overrepresented in KD cases (rs78448924; OR = 3.91, 95%CI 1.30~11.80, P = 0.010). These data indicate altered ORAI1 function confers susceptibility of KD and further highlight importance of the Ca^{2+}/NFAT pathway in the disease pathogenesis.

Elucidation of auto-antibody profiles and genetic risk alleles associated with antinuclear antibody (ANA) positive fraction of healthy population. *P. RAJ[1], L. WANG[1], Quan-Z. LI[1], D. KARP[1], I. DOZMOROV[1], N. OLSEN[2], KM. SIVILS[3], JA. JAMES[3], JA. KELLY[3], B. LAUWERYS[4], PK. GREGERSEN[5], EK. WAKELAND[1].* 1) IMMUNOLOGY, UT SOUTH WESTERN MEDICAL CENTER, UNIVERSITY OF TEXAS, DALLAS, TX; 2) Division of Rheumatology, Penn State Hershey Medical Center, 500 University Drive, Hershey PA 17033; 3) Oklahoma Medical Research Foundation, 825 North East 13th Street, Oklahoma City, Oklahoma 73104, USA; 4) Service de Rhumatologie, SSS/IREC/RUMA, Cliniques Universitaires Saint-Luc & Université catholique de Louvain Avenue Hippocrate 10, bte B2.5390, 1200 BRUXELLES, Belgium; 5) Feinstein Institute for Medical Research in Manhasset, New York, USA.

Antinuclear antibodies (ANA) are the serologic hallmarks of autoimmunity and are frequently seen in patients with systemic autoimmune diseases such as SLE. Many studies have shown that a good number of healthy individuals also display ANA, raising questions concerning the clinical significance of being ANA positive and the relevance of ANA to diagnosis of autoimmune disease. We screened 2223 healthy Caucasians and 143 SLEs for ANA by ELISA and found that ANA is a continuous trait with > one normal distribution in the general population, leading to the delineation of subsets of individuals who manifest low, moderate, and high ANA levels without any apparent disease. Our data show that about 26% of the normal population are ANA positive, with 17% (382 of 2223) having moderate (20-40 ELISA units) and 9% (197 of 2223) having high (>40 ELISA units) ANA levels. Further, to elucidate the disease associated auto-antibody profiles and to distinguish ANA positive normal subjects from SLE patients, we performed protein array screening to detect antibodies against over 90 different auto-antigens implicated in various autoimmune diseases. We found that ANA positive fraction of healthy population makes significant amount of IgG and IgM antibodies against many antigens with more significant and frequent antibodies to extracellular matrix proteins such as collagens and antiphospholipids such as cardiolipin. We noticed stronger and diverse autoantibody signatures in females than males. Next, we genotyped all the ANA negative and ANA positive individuals with Immunochip and performed a quantitative association test on 1583 PCA corrected Caucasians with ANA as dependent variable, and we found strongest association of HLA alleles with ANA. LD analysis of data suggested multiple independent association signals in HLA class I, II and III region. As expected, HLA-DR and DQ alleles were also found associated with ANA as peak SNP rs9268832 in HLA-DRA gene and rs2395252 in HLA-DQA2 gene reached suggestive genome wide p value of 7.63606E-07 and 7.50887E-05, respectively. The minor allele of rs3135388 SNP, a tag of DRB1*1501 allele was found significantly (p=5.23E-03) associated with high ANA level. Further, we studied the expression of HLA-DRB1 in human macrophages by RNAseq and found that ANA associated alleles of rs3135388 and rs9268832 SNPs are also associated with significant (>2 fold) increase in HLA-DRB1 expression. More results and conclusion from study will be discussed.

Meta-analysis followed by replication identifies novel genetic variants in X chromosome associated with systemic lupus erythematosus in Asians and analysis of genetic differences between male and female cases. *J. Yang, Y. Zhang, W. Yang, Y.L. Lau.* Paediatrics and Adolescent Medicine, University of Hong Kong, Pokfulam, Hong Kong.

Systemic lupus erythematosus (SLE) is an autoimmune disease with a strong genetic component and dramatic gender difference in disease prevalence. Involvement of genetic variants on the X-chromosome in SLE susceptibility, especially in non-European populations, has not been adequately explored. In this study, we aimed at identifying genetic variants on the X chromosome associated with disease susceptibility in Asian populations. Meta-analysis was performed on two genome-wide association studies (GWAS) on SLE on Chinese Han populations, focusing on X chromosome SNPs and female samples at first. The prominent signals were further replicated in three independent cohorts, with a total of 5021 female cases and 5700 matched controls. Furthermore, 355 male cases and 4388 corresponding male controls were also used for replication to explore possible gender differences. Variants in or near PRPS2, NAA10 and TMEM187 were shown to be associated with SLE in Asian populations, surpassing genome-wide significance. In addition, two previously reported loci in European populations, IRAK1 (rs1059702), and MECP2 (rs2734647) were also replicated in our study. We also identified a variant upstream of L1CAM with suggestive association, which showed clear interaction with SNPs in NAA10. Independent contributions of these variants were tested using various methods and clearly independent effect of IRAK1 and MECP2 was demonstrated. This study delineates multiple independent signals towards SLE susceptibility from the X-chromosome in Asian populations, expanding our understanding of the role of X-chromosome variants in SLE susceptibility. A comparison was conducted genome-wide on effect sizes of susceptibility variants between male and female cases, and their implication on the sex differences on SLE prevalence was discussed.

779F

Variable set enrichment analysis of exome sequencing data reveals interesting candidate genes for left ventricular hypertrophy. *W. Yang[1], U. Broeckel[3], A.J. Stoddard[3], D. Zhi[4], M.R. Irvin[5], H.K. Tiwari[4], S.C. Hunt[6], D.C. Rao[1], D.K. Arnett[5], C.C. Gu[1,2].* 1) Division of Biostatistics, Washington Univ in St Louis, St Louis, MO; 2) Department of Genetics, Washington Univ in St Louis, St Louis, MO; 3) Department of Medicine, Medical College of Wisconsin, Milwaukee, WI; 4) Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 5) Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 6) Department of Internal Medicine, University of Utah, Salk Lake City, Utah.

Backgrounds: Analysis of variants from next-generation sequencing (NGS) studies of complex diseases poses a great challenge because of the large number of rare variants, effects of which may vary in size and direction. Many existing methods 'collapse' clusters of rare variants to detect aggregate effects, and their power can be seriously compromised when the clusters contain only a few informative variants or when the effects are inconsistent. On the other hand, set enrichment analysis, which has been widely used for microarray gene expression and pathway-based genome-wide association studies, remains powerful even when a large number of irrelevant variants exist in the set. Methods: A recently developed method called Variable Set Enrichment Analysis (VSEA) was applied to the exome sequencing data of 21 African American subjects from the HyperGEN (Hypertension Genetic Epidemiology Network) study, to prioritize genes associated with a left ventricular mass trait (LVMHT27). It evaluates the enrichment of association signals indiscriminate of rare or common variants within genes, based on SNP level statistics. We tested 3 SNP level statistics including the t-score, log likelihood ratio, and the regression coefficient in a linear model. Their performance was compared with that of a step-up collapsing method. Results for chromosomes 17 and 18 are completed and reported below. Results: Among the 1192 genes that have data on chromosomes 17 and 18, VSEA test returns 52~68 genes with false discovery rates (FDR) q-value<0.05, depending on the type of SNP level statistics in test. Despite the small sample size, VSEA detected many known candidate genes for heart disease and related traits, including ACE (min q-value=0.0021), ITGA3(0.0046), IGF2BP1(0.0051), ALOX15(0.021), and LPO(0.041). Genes from several highly related families, like calcium channel, potassium channel, integrins, the solute-carrier family, and the Wnt family, were also identified, though the relationship of these genes with heart diseases is less clear. In contrast, the test using step-up collapsing only discovered two solute-carrier family genes (p=0.042~0.046). Conclusion: The analyses demonstrate power of the variable set enrichment analysis empirically in presence of large number of rare and common variants. While more research is needed to evaluate the influence of SNP-level test statistics, the VSEA approach seems to provide a simple and effective way to prioritize genes in NGS studies.

780W

Novel IRF6 Mutations in Families with Van Der Woude Syndrome and Popliteal Pterygium Syndrome from Sub-Saharan Africa. *A. Butali[1], P.A Mossey[2], W.L Adeyemo[3], M.A Eshete[4], L.A Gaines[1], R.O Braimoh[5], S.B Aregbesola[5], R. Rigdon[1], C.I Emeka[3], O. James[3], M.O Ogunlewe[3], A.L Ladeinde[3], A. Fikre[4], M. Ibrahim[4], E.G Paul[4], A.A Adeyemo[6], J.C Murray[1].* 1) Pediatrics, Univ Iowa, Iowa, IA; 2) University of Dundee, UK; 3) University of Lagos, Nigeria; 4) Addis Ababa University, Ethiopia; 5) Obafemi Awolowo University, Nigeria; 6) National Institute for Health, MD.

Orofacial clefts (OFC) are complex genetic traits that are often classified as syndromic or non-syndromic clefts. To date, over 500 syndromic clefts have been identified and included in the Online Mendelian in Man (OMIM) database and for many of these; the underlying genetic factors have been identified. Van der Woude syndrome (VWS) is an autosomal dominant disorder affecting 1/40,000 people worldwide and is one of the most common syndromic clefts, accounting for 2% of all OFC. Popliteal pterygium syndrome (PPS) is a rare dominant disorder affecting 1/300,000 people worldwide and in most cases is an allelic, but more severe form of VWS. Variants in the IRF6 gene have been reported world-wide to cause VWS and PPS. We conducted Sanger sequencing of the high risk exons for IRF6 (exons 3, 4, 7 and 9) in four families with VWS and one family with PPS from Nigeria and Ethiopia. For the VWS families, we found a novel nonsense mutation in exon 4 (p.Lys66X), a novel splice site mutation in exon 4 (p.Pro126Pro) and a previously reported splice mutation in exon 7 that changes the acceptor splice site. A previously known missense mutation was found in exon 4 (p.Arg84His) in the PPS family. All the mutations segregate in the families. Our data confirms the presence of IRF6-related VWS and PPS in sub-Saharan Africa and highlights the importance of screening for novel variants in known genes when studying diverse global populations. This is important for counseling and prenatal diagnosis for high risk families, especially in Africa where there are limited genetic counselors. Funding: This study was support by the NIH/ NIDCR Grants K99/R00 5K99-DE022378-02, R37-DE08559 and Face Base grant U01 DE-20057.

A replication study for four keloid loci at 1q41, 3q22.3-23 and 15q21.3 in the Japanese population. *A. Watanabe[1, 2], R. OGAWA[3], M. SASAKI[2], A. FUJITA[2], B.T. Naing[1], S. AKAISHI[3], H. HYAKUSOKU[3], T. SHIMADA[1, 2].* 1) Dept Biochem & Molec Biol, Nippon Med Sch, Tokyo, Japan; 2) Div Pesonalized Genetic Med, Nippon Med Sch Hosp, Tokyo, Japan; 3) Dept Plastic and Reconstructive Surgery, Nippon Med Sch Hosp, Tokyo, Japan.

Keloid is a dermal fibroproliferative growth that results from dysfunction of the wound healing processes. A previous genome-wide association study (GWAS) reported four novel keloid-susceptibility loci at 1q41, 3q22.3-23 and 15q21.3 (Nakashima M, et al. Nature Genet. 2010;42,768-772). Here, we investigated the association of these loci with keloid by using an independent Japanese sample set. We performed case-control association analysis using 204 patients with keloid subjects in Nippon Medical School Hospital. The four SNPs at 1q41, 3q22.3-23 and 15q21.3 were genotyped using Small Amplicon Genotyping method. In this study, the two from four loci identified by previous GWAS, rs873549 on chromosome 1 (odds ratio (OR) =4.8, 95% CI: 1.941-14.192) in recessive manner and rs8032158 located in NEDD4 on chromosome 15 (OR= 3.019, 95% CI: 1.712-5.308) in dominant manner were significantly associated in keloid compared with control. Especially, in rs8032158, the risk for severe type of in the scar severity scale (OR= 2.563, 95% CI: 1.264-5.238) increased in comparison with mild type. Individuals with two risk alleles of the two loci showed higher risk of developing keloid than those with one risk allele alone. Our findings elucidated the significance of genetic variation at these 2 loci in keloid in the Japanese population.

782F

Identification of potentially causative variants underlying triglyceride levels. *S.M. Raj[1], A. Coventry[1], C. Ballantyne[2], C.F. Sing[3], R. Gibbs[2], E. Boerwinkle[2, 4], A.G. Clark[1].* 1) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY 14853; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI 48105; 4) Human Genetics Center, Health Sciences Center, University of Texas, Houston, TX 77030.

There is enormous incentive to identify the causative variants that underlie associations identified in GWA studies. Here we present an approach to optimize the allocation of sequencing resources for GWAS follow-up studies. The method specifies both informative individuals and the specific genomic regions to resequence, and it specifies an analytical approach to identify phenotypic effects. This approach was applied to a known GWAS signal for serum triglyceride levels in European-Americans from the Atherosclerosis Risk in Communities (ARIC) study. We also explored methods for querying GWAS genotype data to identify rare variants responsible for differences in triglyceride levels. We first carried out single-marker association tests to identify markers that show the strongest association with triglyceride levels. The shared haplotype structure in the region of these associations specified a 110 kb region on chromosome 7 that we sequenced (to 30-fold depth) in 502 individuals from the tails of the distribution of triglyceride levels. Analysis of these data revealed strong associations with TRIG levels at candidate sites that also showed strong prior biological relevance. We identified a 2 kb region in *BCL7B* which is the target of many transcription-factor binding sites as a candidate for influencing triglyceride biology. The method used here lends stronger support for candidate regions to motivate biochemical or molecular-based validation of their role in disease etiology. Identification of potentially causative variants may therefore be useful in developing therapeutic applications.

783W

The contribution of regulatory variation to facial masculinity in humans. *A.A. Zaidi[1], P. Claes[2], W. Yao[1], K. Daniels[2], M.D. Shriver[3].* 1) Genetics, Pennsylvania State University, University Park, PA., United States; 2) University of Leuven, Leuven, Belgium; 3) Anthropology, Pennsylvania State University, University Park, PA., United States.

The genetic basis of sexual dimorphism in the human face is an understudied phenomenon. Here we present an objective measure of facial masculinity and that it has a bimodal distribution with a great deal of overlap between the two sexes (t=43.32, N = 999, p-value < 2.2 × 10-16). This dimorphism is likely to be under the influence of sex-specific hormones such as testosterone and estrogen. According to our hypothesis, sexual dimorphism in the face is a signature of sexual selection in humans and might be different across populations due to differences in mate preference. In order to test this, we compiled a list of putative androgen response elements (AREs), identified in a previous study using chromatin immunoprecipitation (ChIP) for the androgen receptor (AR) protein. This list was filtered for AR binding sites that also overlap with other potentially functional non coding regions such as DNAseI hypersensitivity clusters, using ENCODE data. A subset of these with high Fst were then selected to represent regions that have recently diverged across human populations. We then tested for association between genetic variants in these regions with overall facial masculinity and with specific regions of the face that are observed to be different between males and females in a sample of 416 individuals with varying levels of African and European ancestry. With this approach, we have found a number of putative androgen response elements that are significantly associated with facial masculinity.

Genetic associations with high-grade dyaplasia and colorectal cancer in patients with colonic inflammatory bowel disease: preliminary results from ImmunoChip using a targeted analytic approach. *J. Knight[1,2], M. Waterman[3,4], J.M. Stempak[3], K. Krishnaprasad[5], I. Cleynen[6], L.P. Schumm[7], S. Vermeire[8], D.P. McGovern[9], S.R. Brant[10], G. Radford-Smith[5], M.S. Silverberg[2,3], International IBD Genetic Consortium.* 1) Neuroscience Research, Centre of Addiction and Mental Health, Toronto, Ontario, Canada; 2) University of Toronto, Toronto, ON, Canada;; 3) Division of Gastroenterology, Mount Sinai Hospital, Toronto, Toronto, ON, Canada; 4) Department of Gastroenterology, Rambam Health Care Campus, B. Rappaport Faculty of Medicine, The Technion - Israel Institute of Technology, Haifa, Israel; 5) Inflammatory Bowel Diseases Research Group, Queensland Medical Research Institute, Brisbane, QLD, Australia; 6) Translational Research in GastroIntestinal Disorders, K.U.Leuven, Leuven, Belgium; 7) University of Chicago, Chicago, IL; 8) Department of Gastroenterology, University hospitals, Leuven, Belgium; 9) Inflammatory Bowel and Immunobiology Research Institute, Cedars Sinai Hospital, Los Angeles, CA; 10) The Meyerhoff Inflammatory Bowel Disease Center, Johns Hopkins Hospital, Baltimore, MD.

Colonic IBD is a significant risk factor for colorectal cancer (CRC) and high-grade dysplasia (HGD). Extensive involvement of the colon, the co-existence of primary sclerosing cholangitis (PSC), disease activity, family history of CRC and disease duration have been shown to increase the risk for CRC. However, no specific genetic association has been repeatedly shown to be associated with CRC in patients with colonic IBD. We aimed to identify genetic associations with CRC/HGD in patients with colonic IBD using data from the ImmunoChip in a large multi-national cohort of patient with colonic IBD.

Members of the International IBD Genetic Consortium (IIBDGC) were asked to identify patients with colonic IBD who developed CRC or HGD, verified by pathology. Demographic and clinical data were also collected. For each HGD/CRC case 1-2 controls were matched (by IBD subtype, disease duration, endoscopic extent (Montreal Classification), ethnicity, co-existence of PSC and gender). Phenotypic variables were compared between CRC/HGD cases and controls using $\psi 2$ for categorical variables and student's t-test for continuous variables. Preliminary analysis of genotypes generated using the iChip data was undertaken using logistic regression with appropriate covariates. Specifically investigating recently-reported IBD associations, PSC associations and SNPs in CRC-associated genes.

Overall, 585 colonic IBD cases (390 UC, 171 CD, 19 IBDU) were reported, 274 had either HGD or CRC and 311 were matched controls. There were 58% males, 95% Caucasian, and 12% current smokers. The mean age at diagnosis was 33. Disease duration to CRC/HGD diagnosis was significantly longer than length of F/U in controls (230 months vs. 180 months, p=0.005). There was no significant difference in proportions of patients with extensive disease between the groups. However, PSC was more common in cases vs. controls (11.3% vs. 2.9%, p=0.0004). Genetic data from iChip were available on 120 cases, 227 controls (59.3% of the total cohort; 50% males). Only Caucasians were selected for analysis. There were no significant genetic associations.

In this initial analysis, no genetic associations could be found related to risk of CRC/HGD in IBD. The IIBDGC will continue to gather cases to increase the sample size.

785F

Association of genetic variations in anti-inflammatory cytokine pathway genes in the outcome of tuberculosis. *S. Aggarwal[1, 2], S. Ali[2], R. Chopra[2], A. Srivastava[2], R.N.K. Bamezai[2].* 1) Department of Biochemistry, All India Institute of Medical Sciences, Raipur, 492099 Chattisgarh, India; 2) National Centre of Applied Human Genetics, School of life Sciences, Jawaharlal Nehru University, New Delhi, 110067, India.

Tuberculosis (TB) constitutes the major cause of death due to infectious diseases. Cytokines play a major role in defense against Mycobacterium tuberculosis infection. Polymorphisms in the genes encoding various cytokines have been associated with tuberculosis susceptibility or resistance. This study aimed to investigate potential associations of forty SNPs in anti-inflammatory cytokines (IL10, TGFB1, IL6, IL4 and IL13) and receptors (IL10RA, IL10RB, TGFBR1, TGFBR2, IL6R, IL4R, IL5RA, IL5RB and IL13RA1) with tuberculosis. Our study included 327 clinically categorized tuberculosis patients representing North Indian population and 1294 unrelated healthy individuals. Analysis of rs3024498 located in the 3'UTR region of IL10, was observed to be significantly associated with the risk towards tuberculosis (AA/AG+GG, OR=1.52, 95%CI=1.11-2.10, P=0.01). Other polymorphisms, rs7281762 of IL10RB, (GG/GA+AA, OR=0.7, 95%CI=0.55-0.89, P=0.004) provided protection and rs2228048 of TGFBR2 (TT/CT+CC, OR=2.7, 95%CI=1.2-6.02, P=0.02) risk towards the disease, respectively. Our results demonstrate that the polymorphisms in cytokine genes may be valuable markers to predict the protection or risk towards tuberculosis. In conclusion, this study provides an interesting cue to cumulative polygenic host component which regulates tuberculosis pathogenesis.

Assessing genetic association and gene-gene interaction between PTPN22 and CSK for SLE susceptibility in Asians. *X.R. Kim-Howard[1], C. Sun[1], A. Adler[1], S.C. Bae[2], S.K. Swapan[1].* 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Department of Rheumatology, Hanyang University Hospital for Rheumatic Diseases, Seoul, Korea.

Regulation of effector T cell responses are essential for maintaining immune homeostasis and tolerance. Protein tyrosine phosphatase non-receptor type 22 (PTPN22) negatively regulates T cell activation associated with multiple autoimmune diseases, including systemic lupus erythematosus (SLE). It encodes intracellular lymphoid-specific phosphatase (Lyp), which has a prominent role in lymphocyte activation and differentiation. While functional coding variant (R620W, rs2476601) is robustly replicated in European derived populations the risk variant is absent Asian populations. Regulatory variant (rs34933034) of CSK, encodes protein c-Src tyrosine kinase (Csk), is associated with SLE in European-Americans. Lyp physically interacts with Csk during activation of downstream Src kinases, which may increase susceptibility to SLE. Our goals are to (a) assess these variants in an Asian population (Korean) using imputation-based association, (b) explore gene-gene interactions, and (c) identify association with SLE clinical manifestations (i.e, lupus nephritis) and autoantibodies (i.e, anti-Ro, anti-La, anti-dsDNA). We genotyped SNPs from PTPN22 and CSK in 1710 SLE cases and 3164 controls from Korea. Next, a comprehensive imputation-based analysis was used to add out-of-study GWAS controls and increase SNP density using 286 Asians available from 1000Genomes Project. Case-only analysis used specific SLE clinical manifestations as the phenotype. Since we observed significant association for PTPN22 and CSK SNPs we tested for potential genetic interaction between SNPs. This data analysis is in progress. We analyzed 138 SNPs from PTPN22 and 57 SNPs from CSK. As expected, known PTPN22 SNP rs2476601 was monomorphic in our Korean cohort. The most significant PTPN22 SNPs were in complete LD (r2=1), intronic rs12746551 and rs33965092 (P=9.2×10-6, OR=2.09). In CSK published SNP (rs34933034) was not significant (P=0.30) in Koreans. The most significant SNP was intronic rs4886627 (P=4.0×10-4, OR=1.15). We observed suggestive interaction (P=0.07) between intronic SNPs rs33965092 (PTPN22) and rs11635664 (CSK). Clinical phenotype analysis is ongoing. Previously reported functional variants rs2476601 (PTPN22) and rs34933034 (CSK) were monomorphic and non significant, respectively. However, other potentially SNPs from both genes could be associated with SLE. Additionally, we observed suggestive SNP-SNP interaction.

787T

Correlation between SNPs within the MHC region and immune responsiveness to childhood vaccinations. *Y.A. Talzhanov[1], B. Yucesoy[2], V.J. Johnson[3], N.W. Wilson[4], R.E. Biagini[6], W. Wang[2], B. Frye[2], D.N. Weissman[5], D.R. Germolec[7], M.I. Luster[2], M.M. Barmada[1].* 1) Center for Computational Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Toxicology and Molecular Biology Branch, CDC/NIOSH, Morgantown, WV; 3) BRT-Burleson Research Technologies, Morrisville, NC; 4) Department of Pediatrics, School of Medicine, University of Nevada, Reno, NV; 5) Division of Respiratory Diseases Studies, CDC/NIOSH, Morgantown, WV; 6) Biomonitoring and Health Assessment Branch, CDC/NIOSH, Cincinnati, OH; 7) Toxicology Branch, DNTP/NIEHS, Research Triangle Park, NC.

The present study investigated association between genetic variability in major histocompatibility complex (MHC) and immune response to childhood vaccinations. 141 healthy infants who have been immunized, according to standard vaccination scheme, with hepatitis B (HBV), 7-valent pneumococcal conjugate (PCV7), and diphtheria, tetanus, acellular pertussis (DTaP) vaccines were participated in the study. Using multiplex immunoassays we have assessed vaccine specific antibody responses and total serum immunoglobulin levels (IgM, IgA, IgG and IgG subclasses). We collected genotype information using Illumina Goldengate MHC panels. Our analysis showed association between single nucleotide polymorphisms (SNP) within MHC region and vaccine specific antibody responses, serum levels of immunoglobulins (IgG, IgA, IgM) and IgG isotypes (IgG1-IgG3). Functional annotation of SNPs using RegulomeDB showed that both significant and correlated SNPs regulate the expression of a group of genes involved in antigen processing and presentation, including HLA-G, HLA-A, HLA-DRB5, HLA-DQA1, HLA-DQB1 and TAP-2. The results suggest that immune response to common childhood immunization is affected by genetic variations within MHC region, which in turn may influence vaccine efficacy. These novel regions within MHC may serve as candidates for future genetic and mechanistic studies.

788F

The CTLA4 gene and severe bacterial infections. *H. Chi[1,2,3], NC. Chiu[1,2], FY. Huang[1], SC. Chang[4], WF. Chen[4], WS. Lin[4], CL. Lin[4], YJ. Lee[1,4,5,6].* 1) Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan, 92, Sec. 2, Zhongshan N. Rd., Zhongshan District Taipei; 2) Department of Nursing, Mackay Medicine, Nursing and Management College; 3) Department of Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine; 4) Department of Medical Research, Mackay Memorial Hospital Tamsui District; 5) Department of Biomedical Sciences, Mackay Medical College; 6) Department of School of Medicine, Taipei Medical University.

The CTLA4 gene encodes a T-cell receptor, namely, cytotoxic T-lymphocyte antigen 4 (CTLA4), which is involved in controlling the proliferation and apoptosis of T lymphocytes. Among them, rs3087243 G>A and rs231775 A>G are the most associated markers with autoimmune diseases. In this study, we investigated whether the CTLA4 gene was associated with severe bacterial infections in Han Chinese children. Subjects and Methods Patients The patients were 142 unrelated children (54 boys, 88 girls) with severe bacterial infections (SBI) (bacterial septicemia, meningitis, pneumonia, or cellulitis). Their age at diagnosis was 4.9 ± 3.6 years (range 0.0 - 17.7 years). Among them, 55 were infected by pneumococcus. The control subjects were 920 subjects. They included hospital personnel and individuals who underwent routine health examinations or minor surgery. All patients and control subjects were ethnic Han Chinese in Taiwan. Our institutional review board approved this study, and all subjects or their guardians gave informed consent. CTLA4 genotyping We genotyped -318 C/T, +49 A/G, and CT60 polymorphisms of the CTLA 4 gene by PCR-restriction fragment length polymorphism (PCR-RFLP) using MseI, BstEII, and NcoI enzymes, respectively as we have reported. The -318 C/T polymorphism was amplified with modified primers 5'-GTT AGG GAT GCC CAG AAG AT-3' and 5'-CTC AAC TGA ACA AAA CAA GC-3'resulting in a 172 bp product. The +49 A/G polymorphism was amplified with primers 5'-AAG GCT CAG CTG AAC CTG GT-3' and 5'-CTG CTG AAA CAA ATG AAA CCC-3' resulting in a 153 bp product. The CT60 polymorphism was amplified with primers 5'-CAC CAC TAT TTG GGA TAT ACC-3' and 5'-AGG TCT ATA TTT CAG GAA GGC-3' resulting in a 216 bp product. Statistical analysis Genotype, allele and carrier frequencies of the -318 C/T, +49 A/G, and CT60 polymorphisms of the CTLA4 genes were determined by direct counting. Agreement with Hardy-Weinberg equilibrium (HWE) was tested for genotype frequencies of the controls using Haploview 4.2 Results The -318, +49, and CT60 polymorphisms of the CTLA4 gene were in Hardy-Weinberg equilibrium in controls and in patients. Statistical analysis revealed that no significant difference in the frequencies of genotypes, alleles, carriers, or haplotypes of the 3 SNPs of the CTLA4 gene between patients and controls. The results were similar when patients with pneumococcal infections were analysed separately. Discussion More patients must be collected.

789W

Association of Toll-like receptor 4 with otitis media in the Finnish population. *E. Einarsdottir[1], L. Hafrén[2], E. Kentala[2], E. Leinonen[3], J. Kere[1,3], P.S. Mattila[2].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Dept of Otorhinolaryngology, Helsinki University Central Hospital, University of Helsinki, Finland; 3) Folkhälsan Institute of Genetics, Helsinki, Finland.

Background & aims: Otitis media (OM) is one of the most common infectious diseases in childhood, leading to doctor's visits and antibiotic prescriptions. Despite being an infectious disease, the risk of developing recurrent (RAOM) and chronic (COME) otitis media with effusion has a strong genetic component. Toll-like receptor 4 (TLR4), a receptor for LPS and an important component of the innate immune system, has been suggested previously as a plausible candidate for variation in OM susceptibility. Genetic variation within this locus has, however, not been studied comprehensibly previously. The aim of the current study was to get a clear picture of TLR4 involvement in otitis media in Finnish patients.

Study design: We studied 21 SNPs within and upstream of the TLR4 coding region. Markers were chosen to tag the common variation in the LD block within which TLR4 lies. Two rare coding variants (Asp299Gly and Thr399Ile) were also considered. 592 cases and 746 controls from Finland were analyzed. All participants gave their informed consent to participate in the study. Cases were recruited when coming for surgery due to RAOM or COME; controls were healthy blood donors. In addition to all OM, we also looked at patient subgroups with COME, RAOM, early onset of OM, and patients requiring multiple rounds of draining tubes. Plink was used to look at association of each marker & haplotypes to OM, Haploview was used to visualize LD patterns.

Results: We identified association of variants at the TLR4 locus to OM in all patient groups (all OM and all sub-phenotypes). The strongest association (p-uncorr = 0,004-0,000038) was found to two markers upstream of the TLR4 gene, with ORs approx. 1,3 in RAOM, COME and all OM. The two patient groups with the more severe phenotypes (early onset & multiple draining tubes) yielded association to the same markers, with ORs of 2,4 and 1,6, respectively. The previously studied rare coding variants in TLR4 were excluded as major risk variants for OM in Finland.

Conclusions: Our results suggest genetic variation within the TLR4 locus as an important modifier of otitis media susceptibility in the Finnish population.

Multiple eQTLs of *TNFSF8* are associated with pathological immune responses in leprosy. *V.M. Fava[1,2], A. Cobat[1,2], V.T. Nguyen[3], N.N. Ba[3], M. Orlova[1], J. Manry[1,2], A.C.P. Latini[4], M.M.A. Stefani[5], M. Mira[6], V.H. Thai[3], L. Abel[7,8,9], A. Alcais[7,8,9], E. Schurr[1,2].* 1) The McGill International TB Centre, The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 2) Departments of Human Genetics and Medicine, McGill University, Montreal, Quebec, Canada; 3) Hospital for Dermato-Venereology, Ho Chi Minh City, Vietnam; 4) Lauro de Souza Lima Institute, Bauru, São Paulo, Brazil; 5) Tropical Pathology and Public Health Institute, Federal University of Goiás, Goiânia, Brazil; 6) Core for Advanced Molecular Investigation, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil; 7) Laboratoire de Génétique des Maladies Infectieuses, Institut National de la Santé et de la Recherche Médicale, U980, 75015 Paris, France; 8) Université Paris René Descartes, Faculté Médicine Necker, 75015 Paris, France; 9) Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, The Rockefeller University, New York, NY 11065, USA.

A genome-wide association study (GWAS) in Chinese leprosy patients identified six genes associated with leprosy. While five of these genes have been validated, one gene, *TNFSF15*, has resisted all attempts of replication by independent groups. While evaluating the clinical characteristics of the leprosy GWAS sample, we noted that more than 85% of the patients presented with disabilities. Leprosy type 1 reversal reactions (T1R) are the major cause of nerve damage in leprosy patients due to excessive immune responses directed against Schwann cells. We hypothesized that the lack of validation of *TNFSF15* was in truth due to an association with the endophenotype T1R. To test our hypothesis, we studied SNPs in the *TNFSF15* genomic region as risk factors for T1R in three independent populations: a family based sample from Vietnam and two case-control samples from Brazil, comprising a total of 1768 subjects. For the family-based design, we used a set of leprosy families without T1R as controls. In Brazil, the cases were T1R patients while the controls were leprosy patients without T1R. In total, we genotyped 56 SNPs across all three samples. In the Vietnamese sample, eight SNPs were strongly associated with T1R ($p<0.001$). Unexpectedly, the majority of SNPs were in four bins that extended to the neighboring *TNFSF8* gene and not to the physically closer *TNFSF15* gene. Indeed, of the 19 cis-eQTL for *TNFSF8* described in public data bases, 17 had $p < 0.05$ in support of association with T1R. Multivariate analyses revealed independent association of two bins that carried numerous eQTLs for *TNFSF8*. The bins associated with T1R in the Vietnamese sample were fragmented in the Brazilian samples. Yet, two bins were validated. In Goiania, four SNPs of an eQTL bin displayed $p<0.05$ while in Rondonópolis eleven distinct SNPs presented $p<0.05$ in favour of association with T1R. Taken together, our results identify a set of genetic risk factors for T1R in Vietnam and Brazil. These risk SNPs are eQTLs for *TNFSF8* that despite of being in the same SNP bin may independently act on *TNFSF8* expression levels. Our results illustrate the importance of taking in account endophenotypes in genetic association studies.

791F

Immuno-genetic role of mannan-binding lectin in Indian visceral leishmaniasis. *A. Mishra[1], A. Nath Jha[1], H. V. Tong[2], L. Singh[1], T. P. Velavan[2], K. Thangaraj[1].* 1) Centre for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India; 2) ITM, University of Tubingen, Wilhelmstr, Germany.

Introduction Visceral leishmaniasis (VL) is endemic in middle east region of India and accounts for more than 90% of Indian VL and always fatal if untreated. It is multifactorial disease where host immunity and genetic factor play their role in outcome of VL. The mannose-binding lectin (MBL) play important role in innate immunity. In human mutation in MBL2 gene (chromosome 10), affects level of MBL in serum. Higher MBL level is associated with disease progression while lower level protect against development of VL. The aim of this study is to define the role of MBL2 immuno-genetic factor in Indian VL. Method The study was designed as matched case-control study (by caste, age group, sex and geographical location) and conducted in endemic region of Indian VL. Total 322 unrelated subjects (197 case and 125 Controls) were selected for study, Mean age of cases were (29.62+/- 16.95) while controls have (32.98+/- 15.04); the male:female ratio in cases were (113:84) while in controls were (69:56). Asertainment of cases was based on presence of typical clinical features of VL while control subjects had never suffered from or been treated for VL or other infectious disease. We have analyzed MBL serum level (ELISA) and several regulatory polymorphisms at promoter and exon 1 (genotyping) in MBL2 gene via case-control approaches. Result Serum level of MBL were higher ($p = 0.027$) in individuals with VL than in controls. We have not found any association in genotype and allele frequency distribution along with haplotype carriage between case-control groups of VL, although haplotype LYQC is significantly associated (OR 0.4 (CI 0.15-1), p = 0.48) but present in 7.14% subjects. Conclusion This is first case-control genetic study which indicates level of MBL in serum and distinct polymorphism role of MBL2 gene in Indian VL (no association). This study is totally different from Brazil study (another major foci of VL), overall it reflect the clinical complication and unique genetic architecture of Indian population.

792W

Association of single nucleotide polymorphisms (SNPs) in the gene coding for the lens epithelium-derived growth factor (LEDGF/p75) with the outcome of HIV infection in Brazilian HIV+ patients. *C.PB. Passaes[1,2,3], C.C. Cardoso[4], D.G. Caetano[3], S.L.M. Teixeira[3], M.L. Guimarães[3], D.P. Campos[5], V.G. Veloso[5], M.O. Moraes[6], M.G. Morgado[3].* 1) Service d'Immuno-Virologie Commissariat à l'énergie atomique et aux énergies alternatives, CEA, Fontenay aux Roses, France; 2) Unité de Régulation des Infections Rétrovirales, Institute Pasteur, Paris, France; 3) Laboratório de AIDS e Imunologia Molecular, Instituto Oswaldo Cruz - Fiocruz - Rio de Janeiro, Brasil; 4) Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brasil; 5) Instituto de Pesquisa Clinica Evandro Chagas, Fiocruz, Rio de Janeiro, Brazil; 6) Laboratório de Hanseníase, Instituto Oswaldo Cruz - Fiocruz - Rio de Janeiro, Brasil.

The lens epithelium-derived growth factor p75 (LEDGF/p75), coded by the *PSIP1* gene, is an important host co-factor which interacts with HIV integrase (IN) to target integration of viral cDNA into active genes. The aim of this study was to investigate the association of SNPs in PSIP1 with disease outcome in Brazilian HIV infected patients. We performed a case-control study in a cohort of 171 HIV+ patients followed up at Instituto de Pesquisa Clínica Evandro Chagas and classified as rapid progressors (RP, n=69), typical progressors (TP, n=79) and long-term non progressors (LTNP, n=23) according to the time of HIV infection, CD4+ T cells counts, date of the last negative serology and presence of an AIDS-defining events. A group of 96 healthy volunteers was used as population controls. The *PSIP1* exons 8-14 (coding for the integrase binding domain) were sequenced and the SNP rs61744944 was characterized. To increase gene coverage, 9 tag SNPs were selected from HapMap database and genotyped using TaqMan assays. The control population was analyzed separately to determine the frequency of each SNP, as well as deviations from Hardy-Weinberg Equilibrium (HWE). Pairwise linkage disequilibrium (LD) patterns were also estimated for this population using the r^2 coefficient. The association between PSIP1 SNPs/haplotypes and disease progression was assessed by logistic regression models. After HWE analyses, a total of 8 SNPs were characterized. No additional SNPs were identified in PSIP1 exons 8-14. There were no clear LD patterns among the SNPs analyzed ($r^2<0.8$). The logistic regression models suggested that patients carrying the allele T at rs61744944 were more likely to develop the LTNP outcome (OR = 4.98; $_{95\%}$CI = 1.03 - 24.19; p = 0.05) using TP as control group. The same trend was observed when LTNPs were compared to the RP group (OR = 3.26). These results were reinforced when all SNPs were combined, since the haplotype rs61744944.T/rs17337140.G/rs2737829.C/rs10119931.C/rs10283923.G/rs10962048.G/rs7470146.G/rs2277191.G was associated to the LTNP status (OR = 6.05; p = 0.08 f and OR = 3.44; p = 0.12 for comparisons against TP and RP, respectively). In spite of the limited number of LTNPs, these data suggest that PSIP1 gene could be associated to the outcome of HIV infection. Further analyses of this gene may guide the identification of causative variants to help predicting disease progression.

Identification of genetic susceptibility loci for dengue shock syndrome at the PLCE1 gene using a targeted re-sequencing approach. *E. Png[1], T.N. Chau[2], N.M. Nguyet[2], D.T. Kien[2], N.T. Quyen[2], D.T. Trung[2], J. Pang[1,3], B. Wills[2,4], N. Van Vinh Chau[5], C.C. Khor[1,3,6], C.P. Simmons[2,4], M.L. Hibberd[1,3].* 1) Infectious Diseases, Genome Institute of Singapore, Singapore, Singapore; 2) Oxford University Clinical Research Unit, Hospital for Tropical Diseases, Ho Chi Minh City, Viet Nam; 3) School of Public Health, National University of Singapore, Singapore; 4) Centre for Tropical Medicine, University of Oxford, Oxford, United Kingdom; 5) Hospital for Tropical Diseases, Ho Chi Minh City, Viet Nam; 6) Department of Paediatrics and Department of Ophthalmology, School of Medicine, National University of Singapore, Singapore.

In our recent genome wide association study (GWAS) of dengue shock syndrome (DSS), we identified common SNPs within the PLCE1 gene to be significantly associated. These SNPs reside within a 50Kb region with high linkage disequilibrium and hence, could be merely tagging causal variant(s). To fine map and identify functionally important variants, we performed targeted re-sequencing of this region of interest (ROI) in 240 DSS cases and 240 controls from Vietnam . We used the Fluidigm Access Array to perform long range PCR to generate 1Kb amplicons to cover the ROI. An aliquot of the pooled amplicons was used to generate library using the NexteraXT kit from Illumina. The libraries were barcoded and sequenced at 96 plex per lane using 100bp paired end reads on Illumina HiSeq 2000 platform. The sequenced data was aligned to the human reference (Hg 19) using BWA software, and genetic variants were identified using GATK Unified Genotyper. On average each library yielded 191Mb of sequences that allowed each targeted base of the ROI to be covered ≤4000x. After performing quality control filters, we identified 414 variants in 429 samples, of which 70% were novel. We performed association analysis on this dataset and found 23 variants exceeding a nominal $P \leq 0.05$. The smallest P value was observed at rs147206950 (P 0.005, OR= 0.36, 95% C.I. 0.17- 0.76), which had a significantly larger effect size than the previously reported GWAS SNP, and is predicted to be a regulatory variant. The eight sequencing SNPs that overlapped with the previous Illumina Human 660W BeadChip data had >99% concordance, emphasizing the confidence of the sequencing SNP calls. We further used this dataset as reference to impute the genotype of all the variants found through sequencing into the entire GWAS dataset of 2,008 cases and 2,018 controls. We found we could accurately recapitulate the previous GWAS associations and also identified an additional 22 variants with predicted P values $\leq 1 \times 10\text{-}7$. We next plan to perform de-novo genotyping of these variants in an additional 1,800 DSS cases and 2,900 controls from Vietnam, looking to validate these new associations and identify the causative variant(s).

794F

Nha Trang Birth Cohort Study: a population-based study for the identification of phenotype expression of genetic risk factors for childhood infectious diseases in Vietnam. *M. Yasunami[1], R. Miyahara[1], L.-M. Yoshida[1], H. Nakamura[1], K. Takahashi[1], D.T. Vu[2], X.M. Trinh[3], T.C. Bui[3], D.A. Dang[2], H.T. Le[4], K. Ariyoshi[1].* 1) Clinical Medicine, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 2) National Instituteof Hygiene and Epidemiology (NIHE), Hanoi, Vietnam; 3) Pasteur Institute Nha Trang, Nha Trang, Vietnam; 4) Khanh Hoa Health Service Department, Nha Trang, Vietnam.

The differential susceptibility to certain infectious disease is attributable to genetically-determined responsiveness to microbial pathogens in part. The genetic polymorphisms associated with functional variations in Toll-like receptors (TLRs) are candidates for such risk factors of infection/infectious diseases. We conducted a population-based study of innate immune phenotype analysis for the better understanding of genetic predisposition to infectious diseases. 1,999 newborn babies, who were born in Khanh Hoa Provincial Hospital, a principal medical facility in Nha Trang City, central Vietnam from May 2009 to May 2010, were enrolled to a longitudinal study. Genomic DNA samples were prepared from umbilical cord blood collected at the entry. The events of severe diseases were passively but comprehensively identified by admissions to the pediatric ward of the same hospital in which they were born. The cohort children were invited to medical check at community health stations at 24 month of age and venous blood samples were collected upon their guardians' informed consent. A simple procedure of small-scale whole blood culture was established; fresh whole blood was mixed with cell culture medium at 1:9 ratio and incubated at 37 degree in the presence of LPS, Pam3CSK4 or other chemical stimulants of immune-competent cells. Twenty hours later, the cells were collected for RNA preparation. The levels of induced mRNA expression of cytokine genes such as IL8 and those of internal standards such as RPLP0 were quantified by real time RT-PCR assay using Fluidigm Biomark platform. Among 1,999 cohort children, 1,494 were responded to the invitation to 24-month medical check and 1,348 blood samples were successfully collected. The first 368 blood samples were examined for gene expression phenotype by the small-scale whole blood culture. The incidence of severe acute lower respiratory tract infection (ALRI) was 77.3/person/year (231 events in 1,494 persons in two years). A major haplotype of eight SNPs in the TLR10-TLR1-TLR6 region (4p14) was associated to ALRI as well as basal and inducible expression of several immune-related genes including chemokines CCL3 and IL8, and TLR1 itself. We observed a significant non-additive interaction between genetic polymorphism (a dose-effect of SNP haplotype) and gene expression phenotype (classification of multiple chemokine mRNA levels by cluster analysis) to the establishment of the risk for ALRI (hazard ratio of approx. 3).

795W

Systematic characterization of allelic architecture at the non-coding type 2 diabetes locus 9p21 using haplotype analysis in complete sequence data, imputation, and functional testing. *V. Agarwala[1,2,3], J. Wright[2], J. Flannick[2,4], A. Morris[5], M. Rasmussen[6], A. Mahajan[5], H. Kang[7], C. Fuchsberger[7], M. Kellis[6], M. Boehnke[7], M. McCarthy[5], D. Altshuler[2,4,8], The Go-T2D Consortium.* 1) Program in Medical & Population Genetics, Broad Institute, Cambridge, MA; 2) Harvard-MIT Division of Health Sciences and Technology, MIT, Cambridge, MA, USA; 3) Program in Biophysics, Graduate School of Arts and Sciences, Harvard University, Cambridge, MA, USA; 4) Department of Molecular Biology, Massachusetts General Hospital, Boston, MA, USA; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 6) Computer Science and Electrical Engineering Department, MIT, Cambridge, MA USA; 7) Department of Biostatistics, University of Michigan, Ann Arbor, MI, USA; 8) Department of Genetics, Harvard Medical School, Boston, MA, USA.

The causal variant(s) underlying signals discovered in genome-wide association studies for complex traits are, in most cases, unknown. The allelic architecture at these loci - the number, frequencies, and effect sizes of causal mutations - is not yet understood, in part because GWAS directly tested only common SNPs. The non-coding chr9p21 GWAS locus (near CDKN2A/B) harbors one of the strongest known signals for type 2 diabetes (T2D). Interestingly, multiple independent signals at this locus create a three-tiered (risk, neutral, and protective) haplotypic association. The availability of whole-genome sequencing data enabled us to test, for the first time, three current hypotheses about allelic architecture at 9p21: (1) that common variant(s) causally modulate risk of T2D, (2) that rare variants create 'synthetic' common variant associations, and (3) that rare variants (individually or in aggregate) have effects on T2D, independent of the common signals. To systematically test these hypotheses, we identified all variants, common and rare, across a 5Mb region around the 9p21 locus in ~2800 whole-genome sequenced Europeans. We confirmed the known haplotypic association, and enumerated all variants present on the risk/protective haplotypes by integrating estimated phase data with information from ancestral recombination graphs. We tested variants, individually and in combination, for (a) association to T2D, and (b) ability to explain the common signals. We performed analysis in the sequenced sample, and also after imputation into ~35K samples densely genotyped on Metabochip. Observed genetic data place an upper bound on the contribution of rare variants at 9p21. Moreover, we reject the synthetic association hypothesis: we find no set of rare variants (excluding singletons) that can explain the haplotypic association, suggesting that causal variants underlying this GWAS signal are indeed common. After imputation, the credible set of variants with >99% probability of explaining the signal included only 1 common variant on the risk and 4 common variants on the protective haplotypes. Lastly, we conducted functional screens for regulatory activity across the 9kb region in multiple cell types. These experiments identified a sub-fragment which has beta cell-specific activity, and which includes the sites of the top candidate causal variants. The approach described here represents a general method for elucidating the causal architecture at disease-associated loci.

796T

A reliable algorithm for identifying modifier genes and the mutants who carry them in family-based studies of complex disorders. *P. Belleau[1], S. Dubois[1], S. Desjardins[1], R. Arsenault[1], E. Shink[1], J.L. Anctil[2], G. Côté[2], M.A. Walter[3], M.A. Amyot[4], V. Raymond[1].* 1) Neurosensory Systems Laboratory, CHUL Research Center (CHU de Québec), Quebec City, QC, Canada; 2) Ophthalmology, Universite Laval, Quebec City, QC, Canada; 3) Medical Genetics, University of Alberta, Edmonton, AB, Canada; 4) Ophthalmology, Universite de Montreal, Montreal, QC, Canada.

Our goal is to characterize gene-gene interactions implicated in open-angle glaucoma, a genetically complex disorder of the eye. Using a pedigree-based genome-wide linkage strategy and 154 heterozygotes for the autosomal dominant glaucoma myocilin K423E mutation, we recently mapped at 20p13, a modifier locus for variability of ages-at-onset (AAO). To characterize this modifier, we designed a pedigree-based algorithm that optimizes the identification of reliable double-mutants for genome-targeted sequencing. Our three-stage algorithm exploits a dataset obtained after genotyping 184 pedigree members with microsatellite and SNP markers covering the locus. The 1st stage is the identification of alleles associated with the modifier. The 2nd stage is the identification of double-mutants which simultaneously carry $MYOC^{K423E}$ and 1 marker allele associated with extreme values for AAO within the distribution of all AAO. The 3rd stage is haplotypes building starting with the alleles defined in 2. More formally, we first define Φ as the kinship coefficient ($\Phi(X,Y) \geq 0.0625$ meaning that X and Y are people closer or equal to first degree cousins). Second, let D be a double-mutant carrying $MYOC^{K423E}$ and the allele A under study. The neighborhood of D is then defined as X, the set of MYOC carriers **not** carrying A where $\Phi(D,X) \geq 0.0625$. We compute for each $MYOC^{K423E}$+A double-mutant the difference between this double-mutant AAO and the median of the AAO of his/her neighborhood. For all double-mutants, we then evaluate the median of the preceding difference and call this median I. We next compare I with the value Ip (p: permutation) calculated from permutations of AAO within the respective neighborhood of each double-mutant of the pedigree. The alleles for which the proportion of Ip > I is max. or min. are considered associated with the modifier. From the pool of $MYOC^{K423E}$ heterozygotes which carry the **associated alleles (As)**, we only keep for sequencing the double-mutants who are at the extremes of the distribution of the AAO. Conversely, we keep as controls, $MYOC^{K423E}$ carriers who **do not harbor** the As alleles at the opposite extremes. Finally, we test for **associated haplotypes** starting at the As alleles. In conclusion, we designed a reliable pedigree-based algorithm that selects those unequivocal double-mutants that participate in gene-gene interactions. This algorithm can be applied to other quantitative traits and to other types of allelic markers for complex traits.

797F

Fine-mapping of Type 2 Diabetes susceptibility loci via trans-ethnic meta-analysis. *M. Horikoshi[1, 2], J.R. Huyghe[3], F. Takeuchi[4], A. Mahajan[1], J. Asimit[5], E. Zeggini[5], N. Kato[4], YY. Teo[6], A.P. Morris[1], M.I. McCarthy[1, 2], T2D-GENES.* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK; 3) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Michigan, US; 4) Research Institute, National Center for Global Health and Medicine, Tokyo, Japan; 5) Wellcome Trust Sanger Institute, Cambridge, UK; 6) Department of Statistics & Applied Probability and Department of Epidemiology & Public Health, National University of Singapore, Singapore, Singapore.

Nearly 70 type 2 diabetes (T2D) susceptibility loci have been identified to date, but the underlying causal variant(s) are not well characterized. One approach to fine-map these loci is to combine genome-wide association (GWA) data from diverse populations to increase sample size and leverage differences in linkage disequilibrium (LD) between ethnicities. We previously reported trans-ethnic fine-mapping analyses undertaken in five T2D loci: *CDKAL1*, *CDKN2A/B*, *FTO*, *IGF2BP2* and *KCNQ1*, which demonstrate strong signals of association and differential patterns of LD across ancestry groups. In the current analysis, we increased the sample size to 64,727 (21,997 T2D cases and 42,730 controls), representing five ancestry groups (European, East Asian, South Asian, Hispanic and African American), and combined GWA data imputed up to the 1000 Genomes March 2012 reference panel of 1092 individuals from diverse ancestry groups. Using trans-ethnic meta-analysis, we defined 'credible sets' of SNPs at each locus that have 99% probability of containing the causal variant, and evaluated the evidence for multiple independent association signals via conditional analyses. None of the lead SNPs at any of the loci showed substantial evidence for heterogeneity in allelic effects between ethnicities, suggesting that the underlying causal variants are shared across ancestry groups and are amenable to trans-ethnic fine-mapping. By comparing credible sets of SNPs identified through ancestry specific and trans-ethnic meta-analyses, we saw improved resolution in fine-mapping at all five loci by combining data from diverse populations. The resolution was most improved at *CDKAL1*, where the 99% credible set included 5 SNPs mapping to 12.3kb, compared with 15 SNPs in 34.4kb in East Asians and 8 SNPs in 40.5kb in Europeans, South Asians and Hispanics. We observed evidence for multiple independent association signals at genome-wide significance at *KCNQ1* and *CDKN2A/B* after conditional analysis. At *KCNQ1*, we observed three association signals defined by rs2237896 ($P_{cond}=9.5\times10^{-12}$), rs234864 ($P_{cond}=8.4\times10^{-9}$), and rs231353 ($P_{cond}=1.7\times10^{-11}$). At *CDKN2A/B*, there are two distinct signals defined by rs10965248 ($P_{cond}=7.2\times10^{-40}$), and rs10757282 ($P_{cond}=2.0\times10^{-12}$), which capture the previously reported haplotype effect at this locus. Our study demonstrates the benefits of trans-ethnic analysis for dissecting association signals at GWA loci and prioritizing regions for functional follow-up.

798W

Fine mapping of inflammatory bowel disease risk loci using immunochip. *H. Huang[1,2], L. Jostins[3], KK. Farh[1,2], B. Bulik-Sullivan[1,2], The International IBD Genetics Consortium.* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge CB10 1HH, UK.

Inflammatory bowel disease (IBD) is an autoimmune disorder that affects 2.5 million people of European ancestry. There are two etiologically related forms of IBD, Crohn's disease and ulcerative colitis. The latest study in IBD genetics reported 163 risk loci. Comprehensively assessing variants in these loci gives insights into the genetic mechanisms of IBD. Here we propose a Bayesian based fine mapping approach that can define the number of independent association signals in each locus, the disease form of each signal and a minimal set of variants that we are 95% confident to contain the causal variants.

We constructed a posterior probability function to characterize the relation between genomic variants and the observed diseases. The most probable causal variants were identified by maximizing this function. Due to the LD, multiple variants may be tied for the causal signal. We therefore reported a credible set of variants such that the sum of their posterior probabilities ≥ 95%;. We apply this approach to 66,849 QC'ed European samples from the International IBD Genetics Consortium's immunochip project (18,603 CD, 14,307 UC and 33,938 controls). Out of 186 high-density regions in the immunochip, 76,862 variants in 110 regions have overlaps with the reported risk loci. These variants were imputed to the 1000 genome reference. 237,736 variants passed the imputation quality threshold and were used in the fine mapping.

We found that known causal variants were usually mapped as the only or the top variant in the credible set. For example, 3 NOD2 causal variants, fs1007insC, R702W and G908R were the only credible variants for the first 3 independent associations respectively. Out of the 110 fine-mapped regions, 50 have multiple independent associations and 78 have genome-wide significant (GWS) primary associations. Here we report fine-mapping results for these 78 associations. We reduced 11 associations to a single variant and 33 associations to ≤5 variants. Credible sets for 34 associations were localized to a region < 10Kb (28 of them have ≤ 5 variants). 13 associations have coding variants in the credible sets and 2 of them are the only variant. 9 out of the 11 single-variant credible sets are non-coding, suggesting high confident non-coding causal variants. We observed that in general, sizes of the credible set decrease with sample size, or the significance of the association signal.

Exome array analysis of rare and low-frequency variation in multiple sclerosis. *M. Mitrovic[1], C. Cotsapas[1,2,3], International Multiple Sclerosis Genetics Consortium.* 1) Department of Neurology, Yale University School of Medicine, New Haven, CT; 2) Department of Genetics, Yale University School of Medicine, New Haven, CT; 3) Medical and Population Genetics, the Broad Institute of Harvard and MIT, Boston, MA.

Multiple sclerosis (MS) is a common complex disorder in which genetically susceptible individuals encounter environmental triggers and initiate an inflammatory reaction against self-antigens in the central nervous system. As a consortium, we have performed several genome-wide association studies (GWAS) and identified almost 100 loci harboring common variants contributing to MS risk. However, these only explain a fraction of the total heritability of disease risk. Low-frequency and rare variants may explain a further portion of this heritability and define new loci modulating pathobiology. To assess the contribution of this fraction of genetic variation to MS susceptibility, we are currently genotyping 42,000 cases and 36,000 unaffected controls drawn from our diverse collection using the Illumina HumanExome beadchip. We will test the following hypotheses: i) rare and/or low-frequency coding variants collectively contribute significantly to the disease risk; ii) genes perturbed by those variants form clusters with group enrichment for association; iii) cumulative rare/low-frequency scores are conditional on common variants; and iv) whether genes with evidence of conservation are more burdened in cases than controls. In the context of this experiment we aim to establish the role of rare variation in the architecture of common disease. MS is a prototypical common, complex disease with a polygenic architecture that has been tractable to GWAS. It thus serves as a model for other such diseases and the conclusions we draw here are likely applicable across the spectrum of phenotypes currently under genetic investigation.

Variations in *Shank3* in Colombian individuals with Autism Spectrum Disorders. *L. Munera, P. Katherine, M. Oscar, M. Lattig, Liga Colombiana de Autismo (LICA).* Universidad de los Andes, Bogotá, Colombia.

Autism spectrum disorders (ASDs) are a group of common and very highly hereditable neurodevelopmental impairments, characterized by the presence of three main behaviours: alteration of social interactions, abnormal language development and the presence of stereotype behaviours. These disorders are highly heterogeneous and in some cases its cause can be explain by highly penetrant de novo mutations; or by the impact of various mutations in a particular individual, each with a moderate effect, that act in synergy producing the autistic behaviours. It has been shown that a variety of genes are associated with ASDs and interact with the neuroligins and neurexins in the glutamatergic synapsis, being SHANK3 one of these genes. The relationship between SHANK3 and ASDs has been demonstrated with diverse genetic and functional studies that suggest a role of this gene in the pathogenesis of autism and in the formation of the dendritic spines. To recognize the importance of variations on this gene on our population, we made a screening of variations in a group of ten Colombian individuals with a diagnostic of ASDs and we determined the possibly pathogenic effect of each of these changes. We found 9 variations, of which just one was found in the exonic region. As far as the intronic variations two changes occurred (rs113644328, MAF=0.005 and rs148315568, MAF=0.004) and stood out because of their low frequency, regardless, the bioinformatic analysis of these two changes did not show any significant importance. A missense mutation in exon 19 (rs61729471; p.Ala721Thr) with low frequency (MAF= 0.012) was found in heterozygosity in one individual. Based in the structure and conservation of this position, the bioinformatic analysis suggest that this change produces a possible reduction in the stability of the protein; and the evaluation of different scenarios indicate that the effect might possibly be due to changes in the protein phosphorylation. Given the heritability of this change from an apparently healthy mother and the presence of the variation in a control population of other study, it can be presumed that even though this change is not responsible of ASDs in this individual, it might have a small effect which in synergy with other changes produces the autistic phenotype.

801W

The Role of Mitochondrial Variants in the Risk of Age-related Macular Degeneration (AMD) in the National Health and Nutrition Examination Surveys (NHANES). *N. Restrepo, R. Goodloe, S. Mitchell, D. Murdock, J. Haines, D. Crawford.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Substantial progress has been made in identifying susceptibility variants for age-related macular degeneration (AMD), one of the most common causes of adult onset blindness. Major autosomal risk factors include Complement Factor H (CFH) Y402H (rs1061170) and Age-related Maculopathy Susceptibility-2 (ARMS2) rs10490924. Non-autosomal variants such as those in the mitochondria also contribute risk towards AMD. To further characterize the association between AMD risk and mitochondrial variants, we as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study accessed the National Health and Nutrition Examination Surveys (NHANES) III and 2007-2008 for targeted genotyping of 60 mitochondrial SNPs. Fundus photography was available for participants >40 years. AMD cases were defined among older adults >60 years that presented with early/late AMD. Controls were defined among older adults >60 years without evidence of AMD. A total of 332, 37, 47 cases and 1500, 430, 270 controls from non-Hispanic whites, non-Hispanics blacks, and Mexican Americans, respectively, were available for study. We performed tests of association between AMD and mitochondrial variants using logistic regression assuming a dominant genetic model unadjusted and adjusted for age, sex, body mass index, and smoking status (current vs. none). Tests were performed for individual SNPs and by haplogroups J, T, and U. In non-Hispanic whites at a liberal significance threshold $p<0.05$, two variants were associated with AMD: rs28357682 (MT-CYTB) (OR= 2.17, 95% CI= 1.05-4.52; padjusted=0.04) and mt16362 (OR= 1.81, 95% CI=1.10-3.00; padjusted=0.02). In our Mexican Americans, mt16111 was associated with AMD (OR=2.90, 95% CI=1.17-7.18; padjusted=0.02) and mt16362 (OR=2.48, 95% CI=1.01-6.15; padjusted=0.05). After adjustment for covariates, no mitochondrial variant or haplogroup was associated in non-Hispanic blacks, and no association generalized across all three race/ethnicities. The lack of associations in non-Hispanic blacks reflects the relatively low sample sizes and subsequent lower power to detect associations for this disease in African-descent populations, highlighting the need for further genetic association studies in diverse populations.

802T

Fine mapping of the Glucose-6-Phosphate Dehydrogenase (G6PD) gene in a multicentre study of severe malaria provides evidence for balancing selection. *G.M. Clarke, K.A. Rockett on behalf of The MalariaGEN Consortium.* Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

G6PD deficiency is the most common human enzyme defect affecting more than 400 million people worldwide. Approximately 140 different molecular variants have been identified in the G6PD gene making it one of the most polymorphic loci in the human genome. The specific variants causing G6PD deficiency are localized to specific geographic regions. The most common deficiency haplotype in sub-Saharan Africa is composed of a derived allele at two non-synonymous SNPs at coding positions 202 and 376. Individuals carrying this haplotype exhibit around 12% of normal enzyme; individuals carrying a derived allele only at 376 exhibit around 85% of normal enzyme activity. G6PD deficiency is associated with protection from malaria infection by the plasmodium falciparum parasite, although reports are conflicting as to whether the effect is in males, females, both or neither. Derived alleles at 202 and 376 are not present in Vietnam and Papua New Guinea and are at a lower frequency in Gambia. At these sites and others there are additional variants that play a role in G6PD enzymopathy. To further investigate the association between G6PD deficiency and severe malaria, we genotyped 17,900 controls and 12,131 severe malaria cases from ten African and two Asian sites at 143 SNP variants spanning the G6PD locus. Variants typed included 202 and 376 as well as another 13 with mutations classed as causing G6PD deficiency by the World Health Organization (WHO). The strongest association with severe malaria was at 202 where we found significant evidence of an increased risk of severe malarial anaemia (SMA) in males with a similar trend in females and a significant reduction in the risk of cerebral malaria (CM) in males with a similar trend in females. To investigate the net effect of the WHO classified G6PD variants, many of which are extremely rare and/or exert only modest or weak effects of G6PD deficiency, we developed a surrogate score of G6PD deficiency for each individual. Increases in the G6PD deficiency score were also associated with an increased risk of SMA and a decreased risk of CM suggesting that the effects on severe malaria seen at 202 are indicative of the effect of G6PD deficiency per se. We present detailed results of our analyses and an investigation of the evidence that the contrasting effects of G6PD deficiency on CM And SMA may plausibly lead to balancing selection through a complex interaction of environmental heterogeneity and genetic factors.

803F

Bayesian conditional analysis of 180,000 individuals for migraine reveals local genetic substructure and nine additional genes.

V. Anttila[1,2,3], H. Huang[1,2], N. Eriksson[4], B.M. Neale[1,2], M.J. Daly[1,2], A. Palotie[2,3,5]. 1) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 4) 23andMe, Mountain View, CA, USA; 5) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, UK.

Migraine is a common, episodic neurovascular disorder with significant heritability. Recently, our Consortium conducted a GWAS meta-analysis of 23,000 migraineurs and 95,000 controls, uncovering genome-wide significant association at 12 loci (Anttila et al, Nature Genetics, in press). In addition, we identified 134 additional loci with genome-wide suggestive p-values (less than 1 × 10-5). We set out to apply a new Bayesian analysis framework to the dataset, allowing for a rapid testing of SNPs conditional on local genotypes from summary-level data. Additionally, we wanted to identify new genetic loci for migraine, using existing data and new samples from 23andme, for a total of 34,000 migraineurs and 147,000 controls. SNP data from the 146 implicated loci were analyzed in a meta-analysis of the previous cohorts and the new samples. In the conditional analysis, six new significant genes (TMEM51, MBOAT4, SUV39H2, PRKG1, HPSE2, TMEM91) were identified. All genes are from loci with p-values <1 × 10-6 in the single-marker analyses. In addition, multiple signals were identified at four previously reported loci (PRDM16, MEF2D, TRPM8, LRP1), where accounting for the multiple signals increases the association p-values by several orders of magnitude (e.g. LRP1 p-value decreases from 3.94 × 10-19 to 1.41 × 10-26). In the expanded meta-analysis including the additional samples, four new loci showed significant association to migraine (FGF6, ASTN2 [distinct locus from previously reported], PRKG1 [significant also in the conditional analysis], MRVI1). At the MRVI1 locus, significant association is observed to a missense variant for the first time in migraine. In addition, MRVI1 interacts directly with PRKG1 in regulating many cellular functions; PRKG1 is a master regulator of many pathways involving in nociception and learning as well as modulating intracellular calcium in neuronal cells, an emerging mechanism in neuropsychiatric diseases. We report the analysis of common variants influencing the genetic susceptibility to migraine, including nine new loci, as well as multiple local independent associations underlying previously reported loci. The newly identified loci include the first common missense variant in common forms of migraine. The implication of the genes at these loci, especially the PRKG1/MRVI1 pair and their biological pathways and mechanisms, make these findings a potentially interesting addition to our knowledge of the genetics of migraine.

804W

Evidence for shared genetic loci between body mass index and menarche timing among 5,357 Hispanic/Latina women in the Population Architecture using Genomics and Epidemiology Study.

L. Fernández-Rhodes[1], C. Carty[2], C. Kooperberg[2], U. Peters[2], T. Matise[3], J.L. Ambite[4], E. Demerath[5], J. Dreyfus[5], M. Gross[5], N. Pankratz[5], E. Ramos[6], L. Hindorff[6], M. Daviglus[7], R. Kaplan[8], S. Castañeda[9], G. Heiss[1], U. Lim[10], C. Haiman[11], L. Le Marchand[10], K.E. North[1], N. Franceschini[1]. 1) University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Rutgers University, Piscataway, NJ; 4) Information Sciences Institute, Marina del Rey, CA; 5) University of Minnesota, Minneapolis, MN; 6) National Human Genome Research Institute, Bethesda, MA; 7) Northwestern University, Chicago, IL; 8) Albert Einstein College of Medicine, Bronx, NY; 9) San Diego State University, San Diego, CA; 10) University of Hawaii, Honolulu, HI; 11) University of Southern California, Los Angeles, CA.

Prior studies have identified several genetic loci for both body mass index (BMI), a measure of obesity, and age of menarche, a marker of puberty timing in population studies. The epidemiologic literature supports an inverse association among these traits, wherein childhood obesity associates with early menarche, which in turn associates with increased BMI and obesity in adulthood. We recently reported the association of several BMI-related single nucleotide polymorphisms (SNPs) with menarche timing among women of European ancestry. We found that 58 of 64 BMI SNPs were associated with menarche in the expected inverse direction and several of the associations had not been previously reported with menarche timing. However, the association of BMI loci with age at menarche has not been investigated among Hispanic/Latina (H/L) women, a diverse ethnic group with disparities in both obesity and early pubertal development. We examined the associations of SNPs in 25 validated BMI loci with fine mapping on the MetaboChip array with self-reported age at menarche among 5,357 H/L women, primarily of Mexican descent, in two studies (Multiethnic Cohort Study and Women's Health Initiative, reported at an average of 69 and 60 years respectively). Due to differences in linkage disequilibrium (LD) between European and H/L populations, we interrogated all SNPs within 500kb of the published European SNP at each BMI locus. Each study performed a linear regression analysis for the association of SNPs with menarche timing (additive genetic model, adjusted for birth year and ancestry); these results were combined in a fixed-effect meta-analysis. SNPs in 9 of 25 BMI loci were significantly associated with menarche when accounting for multiple testing (*NEGR1, TNNI3K, CDKAL1, TFAP2B, MAP2K5, SH2B1, FTO, MC4R, QPCTL*; p<0.002). Three of these loci also showed inverse effects for BMI as compared to menarche (*NEGR1, MC4R, QPCTL*; prior information on BMI effects was missing for the remaining loci). At six loci the significant SNPs were in low LD (r^2<0.2 HapMap CEU) with the published SNP(s) suggesting allelic heterogeneity in these regions. Two BMI SNPs at *KCTD15* also had inverse effects on BMI and menarche (p<0.02). Our study provides evidence supporting the association of BMI loci with age at menarche in H/L women, a diverse admixed population, and shows the contribution of allelic heterogeneity at these loci.

805T

A polymorphism of *Interleukine-13 (IL13)* is associated with susceptibility to food allergy in the Japanese population. *T. Hirota[1], M. Tamari[1], M. Kubo[2], S. Sato[3], M. Ebisawa[3], T. Imai[4], M. Sakashita[5], S. Fujieda[5].* 1) Laboratory for Respiratory and Allergic Diseases, IMS, RIKEN YokohaLaboratory for Respiratory and Allergic Diseases, IMS, RIKEN, Yokohama, Japanma, Yokohama, Kanagawa, Japan; 2) Laboratory for Genotyping Development, IMS, RIKEN, Yokohama, Japan; 3) Clinical Research Center for Allergy and Rheumatology, Sagamihara National Hospital, National Hospital Organization, Sagamihara, Japan; 4) Department of Pediatrics, Showa University School of Medicine, Tokyo, Japan; 5) Department of Otorhinolaryngology-Head & Neck Surgery, Faculty of Medicine, University of Fukui, Fukui, Japan.

Background: The prevalence of food allergy (FA) has increased over the past two decades in Japan. FA is an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food. Recent GWASs have shown that *IL13* locus on chromosome 5q31 is associated with bronchial asthma and atopic dermatitis. But influences of genetic variations in the *IL13* gene on susceptibility to FA in the Japanese population are unclear. Objective: To investigate the association between polymorphisms of *IL13* gene and FA and FA related phenotypes in the Japanese population. **Methods:** We resequenced the *IL13* region by PCR-directed sequencing. Four tag SNPs were selected using the Tagger algorithm and genotyped by Taqman and Invader methods. We performed an association study of FA using a total of 603 subjects with FA and 938 controls in the Japanese population. Among the FA cases, a total of 182 subjects have bronchial asthma. **Results:** We identified a total of 17 polymorphisms including a non-synonymous substitution (Arg144Gln). We found that rs1295686 was associated with FA under an allelic model ($P = 0.000047$; OR, 1.37; 95% CI, 1.18-1.60). In further analyses of patient subgroups, we observed a strong association between rs1295686 and FA with bronchial asthma ($P = 0.0000081$; OR, 1.68; 95% CI, 1.34-2.12). **Conclusion:** rs1295686 of *IL13* gene is significantly associated with FA in the Japanese population. Although further genetic and functional analyses are needed, our findings could help elucidate common genetic factors for bronchial asthma, atopic dermatitis, and FA.

806F

No association between the neuropeptide Y gene polymorphisms and smoking habit in Japanese. *M. Isomura, C. Matsuda, T. Nabika.* Functional Pathology, Shimane University, Shimane, Shimane, Japan.

Purpose: Smoking induces various adverse effects such as chronic obstructive pulmonary diseases, lung cancer, as well as heart diseases. Quit smoking has been a large issue in public health to reduce smoking related diseases. Because nicotine in a cigarette produces activities in brain reward system, smoking habit has a strong potential for addiction. Recently, it has been shown that a NPY (neuropeptide Y) participates in brain reward system and genetic polymorphisms in NPY gene associates with smoking habits. To explore relationship between NPY and smoking habits, we have conducted genetic association study. Methods 3,020 individuals attending health check examinations carried out at rural area in Shimane prefecture in Japan. Smoking history and status were self-reported. Mental status of participants was assessed from response to questionnaire. Three SNPs in NPY gene were genotyped by TaqMan method. Concentrations of NPY in serum were measured by using Neuropeptide Y EIA Kit (Phoenix pharmaceuticals). Results: Genotypes of three SNPs in NPY gene were successfully determined. Association between genotypes and smoking habits were examined by comparing allele frequencies of these SNPs according to smoking status (never, or ever smoker). However, no statistical differences were observed in allele or genotype frequencies between these groups ($p=0.095$). Although several reports showed that NPY concentrations in serum vary among genotypes of a SNP, rs16147, no difference was observed between CC genotype (1.52ng/ml) and TT genotype (1.57ng/ml) in our study. Discussion: In Japanese, polymorphisms in NPY gene showed no association with smoking habit, even though several confounding factors were adjusted. Discrepancy of published result and our result may be due to difference in ethnic group. Our results indicated that polymorphisms in NPY gene had little contribution to smoking habits in Japanese.

807W

Use of eQTLs to Unravel the Etiology of Nonsyndromic Oral Clefting. *C. Malcher[1], C. Masotti[1], L.A. Brito[1], C.F.S. Bassi[1], A.G. Morales[1], S.G. Ferreira[1], D.F. Bueno[1], G.S. Kobayashi[1], N. Alonso[2], M.R. Passos-Bueno[1].* 1) Human Genome Research Center, Institute of Biosciences, University of São Paulo, São Paulo, Brazil; 2) Division of Plastic Surgery, Department of Surgery, School of Medicine, University of São Paulo, São Paulo, Brazil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a complex disorder determined by the interaction between genetic and environmental susceptibility factors. Among the genetic factors, several susceptibility loci have been found, but the underlying molecular mechanisms remains elusive. Considering that variation of gene expression is an important mechanism in complex diseases, we investigated if expression quantitative trait loci (eQTLs) mapped by our group in mesenchymal stem cells derived from orbicular oris muscle (OOMMSC), a tissue affected in the NSCL/P phenotype), are associated with the disease itself. We conducted a structured association test in a sample of 454 NSCL/P patients and 379 controls. Informed consent was obtained from each participant included in this study, as approved by the Research Ethics Committee of the Institute of Biosciences, University of São Paulo, Brazil. We tested 5 putative OOMMSC eQTLs: rs5011163, rs1505443, rs4793213, rs4793229 and rs1242500. These eQTLs regulate or are located within genes related to RNA processing, *FGF* pathway, DNA repair and cell growth and differentiation, and these processes are known to be relevant for NSCL/P susceptibility or palate development. All individuals were genotyped for these five variants with the Taqman method. To correct for population structure, the individuals were also genotyped for a panel of 40 ancestry-informative markers (AIMs). Chi-square analysis showed no evidence of deviation from HWE for all of the variants in our control sample. The mean ancestry contribution of European, African and Amerindian in the case group was 0.6/0.22/0.18, while it was 0.7/0.19/0.11 in the control group. We did not find association for any of the OOMMSC eQTLs tested: rs5011163 ($p=0.057$), rs1505443 ($p=0.664$), rs4793213 ($p=0.6$), rs4793229 ($p=0.9$), rs1242500 ($p=0.4$). Despite the lack of association, our results exclude some potential molecular mechanisms through which these variants could be involved in the etiology of NSCL/P. A genomic approach will be necessary in order to evaluate the role of the eQTLs in NSCL/P susceptibility. Support: FAPESP/CNPq.

808T

ECM Remodelling genes in intracranial aneurysm: a south Indian perspective. *S. Sathyan[1], L. Koshy[1], H. Easwer[2], S. Premkumar[3], J.P Alapatt[3], M. Banerjee[1].* 1) Human Molecular Genetics, Rajiv Gandhi centre for biotechnology, Thiruvananthapuram, KERALA, India; 2) Department of Neurosurgery, Sree Chitra Tirunal Institute for Medical Science and Technology,-Thiruvananthapuram, KERALA, India; 3) Department of Neurosurgery, Calicut Medical College, Calicut,KERALA, India.

Subarachnoid Hemorrhage accounts for 15% of strokes, and occurs at a fairly young age. Intracranial aneurysm (IA) accounts for 85% of Subarachnoid Hemorrhage. In general population 2-3% individuals harbor intracranial aneurysm and the aggregate worldwide incidence of SAH is 10.5 cases per 100,000 person-years. Extracellular matrix remodeling plays an important role in maintaining the structure of intracranial arteries. Elastin (ELN) and collagen(COL3A1 and COL1A2) fibers form the structural framework for ECM providing elasticity and strength to the artery,while proteoglycan versican (VCAN) is known for its adhesive property. Lysyl oxidase's (LOX and LOXL2) is an important class of copper containing enzyme involved in covalently cross linking of these fibrous proteins by formation of aldehydes between lysine residues, which insolubilize these extracellular proteins, thus giving strength to intracranial arteries. Matrix metalloproteinase's (MMP2 and MMP9) is involved in maintaining structural protein concentration by their degrading ability. Therefore, to understand the functional significance of SNP variants of these genes involved in ECM remodeling in intracranial aneurysm patients, we screened SNPs from these genes based on functionality and tagging status. The study populations consist of 200 radiologically confirmed aneurismal cases and 235 ethnically and age matched controls from Dravidian Malayalam speaking population of Kerala. We do observe a significant allelic and genotypic association with the variants of COL1A2 MMP2 and VCAN in South Indian population. However, many of the extracellular matrix remodeling genes were not found to be associated in our population. These observations are in sharp contrast to reports in Caucasians and European ancestry. These conflicting results may be due to sampling strategies resulting in genetic heterogeneity, phenotypic heterogeneity, epigenetic variability, pertaining to complex disorder like intracranial aneurysm.

809F

Common Variants Associated with Normal Tension Glaucoma Are Also Associated with Glaucoma in Exfoliation Syndrome. *D. Wang[1], B. Fan[1], H. Levkovitch-Verbin[2], I. Pasquale[1], J. Haines[3], J. Wiggs[1].* 1) Ophthalmology, Massachusetts Eye & Ear Infirmary, Boston, MA; 2) Goldschleger Eye Institute, Sheba Medical Center, Tel-Hashomer, Israel; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Genome-wide association studies have identified several genomic regions associated with primary open angle glaucoma (POAG), including TMCO1 at 1q24, CAV1/CAV2 at 7q31, CDKN2BAS at 9p21, SIX1/SIX6 at 14q22 and GAS7 at 17p13. Recently we showed that SNPs in the CDKN2BAS region and a novel regulatory region on 8q22 are associated with the normal-tension POAG subgroup with increased susceptibility to optic nerve degeneration suggesting that the CDKN2BAS and 8q22 SNPs primarily influence the development of optic nerve disease in glaucoma. To further investigate this hypothesis we evaluated the association of SNPs located in these genomic regions with exfoliation syndrome-related glaucoma (EG) where elevated intraocular pressure is due to the accumulation of fibrillar aggregates in the ocular fluid drainage pathways. Glaucomatous optic nerve degeneration develops in approximately 50% of exfoliation syndrome (ES) patients. The lead SNP from each genomic region associated with POAG was analyzed in a discovery dataset of 222 unrelated patients with ES (108 with EG) and 344 control subjects recruited from the United States and in a replication dataset of 92 unrelated patients with ES (67 with EG) and 102 control subjects recruited from Israel. The lead SNPs rs284489 at 8q22 and rs1412829 at CDKN2BAS were significantly associated with EG in the US dataset (P = 0.02 and 0.01 respectively) and in the meta-analysis of both datasets (P = 0.008 and 0.02 respectively). No evidence of association was found between the lead SNPs from the other POAG associated regions and EG in either population. There was no evidence of association between these lead SNPs and ES without glaucoma. These results suggest that genetic variants in the 8q22 and 9p21 regions may contribute to optic nerve disease in exfoliation glaucoma, and thus may be risk factors for optic nerve disease related to glaucoma generally.

810W

Alternatively Spliced Isoform Expression of PTPN2 in Rheumatoid Arthritis. *M. Houtman, K. Shchetynsky, L. Padyukov.* Rheumatology Unit, Department of Medicine Solna, Karolinska Institutet and Karolinska University Hospital, Stockholm, Sweden.

Background: Rheumatoid arthritis (RA) is a prototype autoimmune disease with unknown etiology. Despite extensive genetic association studies, the mechanism of disease in relation to putative function of found loci remains unclear. Expression analysis is one of the tools to link findings from genetic epidemiology studies with biological mechanisms of the disease. Variations within the gene encoding the intracellular protein tyrosine phosphatase non-receptor type 2 (PTPN2), which has been implicated in T cell receptor signaling, have recently been associated with a number of chronic inflammatory diseases, including RA. The *PTPN2* gene codes for at least two alternatively spliced isoforms - TC45 and TC48, which differ in their C-termini and localize differentially to the nucleus and cytoplasm. In this study, we investigate mRNA expression of *PTPN2* isoforms in peripheral blood cells of RA patients and healthy controls. Methods: We studied the relative mRNA expression of all *PTPN2* splice forms combined and the specific *PTPN2* splice forms by TaqMan real-time PCR in relation to house-keeping gene *ZNF592* in whole blood samples from 75 RA patients and 77 healthy controls of Caucasian ancestry. The Mann-Whitney U-test was used to evaluate differences and $P < 0.05$ was considered to be significant. Results: There was no significant difference in total *PTPN2* expression in whole blood samples from RA patients and healthy controls. However, the *PTPN2* splice forms were differentially expressed in these samples. We saw an increase in expression for *TC45* (median relative quantity (RQ) = 1.119 (interquartile range (IQR) 0.664); $P = 0.0259$) and *TC48* (median RQ = 1.047 (IQR 0.529); non-significant) in RA patients. This difference was more pronounced when comparing the ratio of splice forms ($P = <0.0001$). Conclusions: Our study shows that *PTPN2* expression of the canonical and the alternatively spliced isoform in whole blood samples of RA patients is different compared to healthy controls, although expression of total *PTPN2* did not show this clearly. It is an example of expression analysis where detection of overall gene expression without considering transcription/translation diversity may generate false negative results. Our results suggest that the structural differences between the two isoforms might affect events in the pathogenesis of RA.

811T

Comparative analysis of eQTL structures in chronic obstructive pulmonary disease (COPD) and Genotype-Tissue Expression (GTEx). *T. Huang, Q. Long, B. Zhang, S. Yoo, J. Zhu, Z. Tu, the GTEx Consortium.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Expression quantitative trait loci (eQTLs) can help people to understand the mechanisms of disease associated SNPs as majority of them are in non-transcribed regions and presumably function through gene expression regulation. GTEx, like many existing eQTL data collections (e.g., seeQTL and Genevar), is based on tissues from relatively healthy individuals. It is unclear that to what extent eQTLs identified in these normal tissues could replicate in disease populations from which GWA studies were performed. Answers to this question are important and will provide guidance on the appropriate usage of GTEx eQTLs for GWAS SNPs interpretation and may shape the future direction for projects like GTEx. To help answer this question, we calculated eQTLs in all the nine tissues from GTEx with sufficient samples, and eQTLs from COPD lung tissues profiled from Lung Genomics Research Consortium (LGRC) project. Raw data from both data sets was processed in strict parallel to ensure fair comparison. The eQTLs from LGRC COPD lung, LGRC control lung, GTEx adipose, artery, heart, lung, muscle, nerve, skin, thyroid and whole blood tissues were compared from multiple angels. Several interesting results are found: first, eQTLs from GTEx lung share a great similarity with eQTLs from LGRC control lung compared to LGRC COPD lung. Second, among the nine GTEx tissues, lung is the one showing highest similarity with LGRC COPD/control lung with respect to eQTL structures. Third, 35.6% of eQTLs linked to COPD GWAS SNPs (or SNPs in high LD, $r^2 > 0.8$) in LGRC COPD tissues are shared in GTEx. This indicates that genetic regulatory structures are partially conserved across disease and normal individuals. Interestingly, the GTEx tissue with most similar eQTL pattern for GWAS COPD associated SNPs with LGRC eQTLs is not lung but muscle. This may reflect certain pathological changes related to respiratory muscular systems in COPD lung tissues. In conclusion, we performed a comprehensive comparison of eQTL structures in disease and normal tissues and report our findings on the conservativeness of eQTL structures across disease/normal tissues, tissue specificities of these eQTLs, and their relevance to GWAS SNPs. These findings shed some new insights to the complex disease systems and may help to better utilize GTEx for disease studies.

Phenotypic analysis of Peptidylarginine deiminase type 4 knock-out mice. *A. Suzuki[1], Y. Kochi[1], H. Shoda[2], K. Fujio[2], R. Yamada[1, 3], K. Yamamoto[1, 2].* 1) IMS, RIKEN, Yokohama, Japan; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Center for Genomic Medicine, Kyoto University, Kyoto, Japan.

Rheumatoid arthritis (RA) is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development. Previouly, peptidylariginine deiminase type 4 (PADI4) was identified as a susceptibility gene for RA in a Japanese population by case-control association study (Ref 1). PADI4 is a member of the PADI gene family and converts arginine residue (peptidylarginine) to citrulline residue (peptidylcitrulline). PADI4 is highly expressed in bone marrow, macrophages, neutrophils and monocytes. Peptidylcitrulline is an interesting molecule in RA, because it is an antigen of ACPA and only PADs (translated protein from PADI genes) can provide peptidylcitrullines, via modification of protein substrates. To evaluate the importance of PADI4 gene in the progression of RA, we generated Padi4 -/- DBA1J mice. We used Padi4-/- mice to show that PAD4 is significantly affected to progress of collagen induced arthritis (CIA), well known as an RA model animal. In Padi4-/- CIA mice sera, the concentrations of serum anti-CII IgM, IgG, and levels of inflammatory cytokines decreased significantly rather than in WT CIA mice. Futhermore, the transcription levels of inflammatory cytokines in CD11b positive splenocytes from Padi4 -/- CIA mice are also significantly lower than those from WT CIA mice. As the results, we suggested that Padi4 enhanced collagen-initiated inflammatory responses. 1) Suzuki, A. et al Nat. Genet.34, 395-402 (2003).

Defective PGRN gene expression in two patients with frontotemporal dementia (FTLD) with potential decreased mRNA stability due to exon 6 PGRN deletion G.101349_101355delCTGCTGT associated with familial FTLD. *E. Vitale[1,2], A. Iuliano[2], A. Polverino[2], G. Milan[3], S. Pappata'[4], P. Sorrentino[3], A. Postiglione[5], V. Alesi[8], A. Novelli[7], G. Sorrentino[2,6].* 1) Cybernetics, CNR-National Research Council, Pozzuoli (NA), Napoli, Italy; 2) School of Movement Sciences (DiSIST), University of Naples 'Parthenope', Napoli, Italy; 3) Geriatric Center "Frullone" ASL Napoli 1, Naples, Italy; 4) CNR-National Research Council, Bioimaging and Biostructures, Naples, Italy; 5) Department of Clinical and Experimental Medicine, University of Naples Federico II, Naples, Italy; 6) Neurological Institute for Diagnosis and Treatment Hermitage Capodimonte, Naples, Italy; 7) Mendel Laboratory, IRCCS Casa Sollievo della Sofferenza Hospital, Roma, Italy; 8) Medical Genetics Unit, San Pietro Hospital Fatebenefratelli, Rome, Italy.

Frontotemporal dementia (FTLD) is a neurodegenerative disease with hallmark deficits in social and emotional functions, characterized by genetic and clinic heterogeneity and progressive declines in behavior or language associated with frontal and temporal lobar degeneration. The phenotypic heterogeneity consistently reveals three different clinical manifestations such as a behavioral variant of FTD (bvFTD), primary progressive aphasia (PPA) and FTD overlapping with motor neuron disease (FTD-MND or FTD-ALS). It can also present with parkinsonian syndromes, progressive supranuclear palsy (PSP) and corticobasal syndrome (CBS). The progranulin gene (PGRN) was recently reported to cause tau-negative frontotemporal dementia linked to chromosome 17. Here we report a four-generation Southern Italian family segregating FTLD in four affected family members, two of them still alive. We collected these two cases (one male and one female) along with the unaffected brother. The two phenotypes are clinically heterogeneous for the behavioral variant (bvFTLD) in the males and for a Primary Progressive Aphasia (PPA) in the female. These individuals were analyzed by sequencing PGRN and other genes in search for a mutation. We found a g.101349_101355delCTGCTGT deletion in PGRN exon 6 CDS in the two affected individuals. The g.101349_101355delCTGCTGT deletion has been already described in two sporadic cases as causing a premature stop codon with a frameshift introduction and could be causing mRNA non-sense mediated decay resulting in PGRN protein haploinsufficiency. We ascertained this mutation in about 50 healthy controls matched by age, sex and geographic regions using allele-specific PCR mutation-primers (ARMS) and we found no deletions carried by these individuals. Moreover, a CGH assay performed on the DNA of the two patients showed no additional genomic alterations. Quantitative RT-PCR of the PGRN gene using exon 7-8 forward and reverse primers was performed on mRNA obtained from WBC from the two patients and from controls. We found a defective PGRN gene expression in the two patients leading to a possible decreased mRNA stability. These results suggest that PGRN may be a possible modifier gene that could lead the FTLD phenotype. Further investigations will focus on understanding how PGRN mutations lead to neurodegeneration and, specifically, on development of FTLD in this family.

814T

Biomarkers and Perinatal Risk Factors in Autism Spectrum Disorder. *H. Xu[1,2], H. Wang[1], Q. Dai[1], A-Q. Zhou[1], M-R. Wu[1], X-Y. Wang[1].* 1) Children's Development and Health, Hubei Provincial Maternal and Children's Health Hospital, Wuhan, Hubei, China; 2) Chinese Alliance of Translational Medicine for Maternal and Children's Health, China.

Autism spectrum disorder (ASD) has been given more and more attention with the increasing incidence rate worldwide. Despite the complicated behavior observation scales that have been created for the diagnosis of ASD, few studies have focused on the use of biomakers for early diagnosis of ASD, which may bring the identification and prevention of ASD to an earlier age. Here we have investigated the possible use of plasma secreted amyloid precursor protein alpha (sAPP) and brain-derived neurotrophic factor (BDNF) as the peripheral biomarkers in the diagnosis of ASD from more than 150 children with ASD. A sensitive ELISA method was used to detect plasma APP and BDNF levels. There were significantly increased levels of total sAPP in 67.5% ,sAPP- α in 57.4%, sAPP- β in 62.8% , BDNF in 51.22% of the clinically diagnosed autistic children. The association was statistically significant among the total sAPP (F=59.4965 P =0.0083), sAPP- α (F= 7.5036, P <0.0001), sAPP- β (F=11.7575, P =0.0083) or BDNF (F=10.0685, P = 0.0180) between case groups and control. Correlation analysis of sAPP and BDNF with age results show: the total sAPP, sAPP- α, sAPP- β significantly positively associated with age (β were: -1.90849, -0.80611, -0.75111 respectively; P<0.05 respectively). We have also used a self-designed questionnaire to screen risk factors for ASD and found 11 perinatal factors. We have therefore concluded that prenatal high-risk factors may have certain relationship with ASD; expressions of sAPP, sAPP- α, sAPP- β and BDNF in plasma are of different severity in children with different levels of ASD. It is a potential way for early diagnosis of autism by peripheral biomarkers both in plasma and cord blood, which will promote to build a brand new ASD diagnostic system.

815F

Analysis of DNA-protein interactions using nuclear extracts around the -224 A/G single nucleotide polymorphism in the neuropeptide receptor Y2 (*NPY2R*) gene in predisposition to hypertension. *E. Albino, A. Nuñez, J. Dutil.* Biochemistry, Ponce School of Medicine, Ponce, PR.

Previous work in animal models and human populations identified Neuropeptide Y receptor 2 (*NPY2R*) as a candidate gene for HTN. In two independent Japanese populations, the GG genotype single nucleotide polymorphism (SNP) located 224 bp upstream of the transcription start site was associated with an increased risk of HTN. In addition, the luciferase activity induced by the NPY2R promoter with the G allele in position -224 was reduced by 34% compared to the promoter containing an A in that position. The aim of this study was to assess the DNA-nuclear protein interactions surrounding the *NPY2R*-224 A/G SNP. Two versions of double stranded oligonucleotide probes (50bp) corresponding to the sequence flanking *NPY2R*-224 A/G were synthesized and incubated with different amounts nuclear protein extracts for an electrophoretic shift assay (EMSA). The ENCODE project proposes CTCF as a functional element that binds to the -224 SNP in the *NPY2R* gene. We used CTCF antibody for a gel super shift assay. The DNA/nuclear protein reactions were loaded on a 4% non-denaturing polyacrylamide gel. Interestingly, the EMSA showed an allele-specific binding with the oligonucleotide containing an A nucleotide in -224 position. However, the oligonucleotide containing the G nucleotide in -224 position shows no DNA/nuclear protein interaction. Also, we were able to detect a super shift using the CTCF antibody. The data provides strong evidence for a functional role of *NPY2R* in genetic predisposition to HTN.

Experimental Assessment of the Function of Disease-Associated Genetic Variants. *P. An, A. McLenithan, S. Johnson, S. Limou, CA. Winkler.* Basic Science Program, SAIC-Frederick, Inc., Basic Research Laboratory, Frederick National Laboratory for Cancer Research, Frederick, MD.

In the genomics era, one major challenge is the identification of causal functional SNPs and genes. Indeed, thousands of SNPs have been associated with various diseases through candidate gene and genome-wide association studies, but, only a few have experimental functional evidence to support their disease causality. This hinders the process of translating genetic association signals to targeted therapy. Our group has identified multiple genetic variants associated with several complex diseases, including HIV/AIDS, hepatitis B and C, and kidney diseases. Here, we employ multifaceted experimental approaches aided by bioinformatics tools to evaluate the functional effects of some of these individual genetic variants. Disease-associated SNPs functionality was assessed by real-time PCR to quantify gene expression in the Epstein-Barr virus-transformed lymphoblastoid cell lines (LCLs) from patients, by disease target cell-based gene reporter assay to test the regulatory potential of SNPs, and by electrophoretic mobility shift assays (EMSA) to estimate the impact of SNPs on DNA transcription factor binding. Several SNPs in *APOBEC3F*, *ZNRD1*, *CD4* and *SERPINA1* of AIDS candidate genes were found to affect transcription factor binding, with patterns often differing in cell types. A *ZNRD* SNP in the 5'-upstream region showed differential transcription factor binding pattern and altered promoter activity. Integration of these experimental data with in silico bioinformatics data provided a new insight into SNPs function relevant to the disease susceptibility. The biological function beyond genetic association may help understand the operating mechanisms of genetic variants in causing various diseases. (Funded by the National Cancer Institute Contract HHSN261200800001E).

Generation of CLEC16A inducible knockout mouse as a novel model to study the pivotal role of NK cells in the pathogenesis of Type 1 Diabetes.
M. Bakay[1], M. Rankin[1], S. Yoeun[1], J. Kushner[2], H. Hakonarson[1]. 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Texas Children's Diabetes and Endocrinology Center, Texas Children's Hospital, Houston, TX.

CLEC16A was recently found to be associated with several autoimmune disorders including Type 1 Diabetes (T1D). The C-type lectin domain family 16, member A (CLEC16A) gene encodes protein with C-type lectin domain structure, which makes it potentially related to the immune response. Although CLEC16A has no known function so far, the discovery of the C-type lectin gene as a diabetes gene, could eventually translate preventive therapy for the disease. We hypothesize that CLEC16A plays an important role in the immune system and that knockout (KO) mouse for CLEC16A will give valuable clues in this respect, particularly in exploring effects of CLEC16A knockdown that cannot be studied ex vivo. We generated CLEC16A mutant mouse by introducing mutation in exon 3 that leads to a frameshift and a premature STOP codon. Homozygotes for the mutation had a phenotype: small body size, weak tail, they may live to adulthood but die prematurely and do not breed. Heterozygotes have a normal phenotype and lifespan and are fertile. Homozygotes were approximately 50% the weight of their unaffected littermates at one month of age. They may live until adulthood, but die by 9 months of age, none of females has reproduced. Intercrossing heterozygotes produced smaller litters and less than the expected number of homozygotes. To overcome this problem and determine the role of CLEC16A in adult mice, we have generated inducible CLEC16A KO mice (Clec16a loxP/loxP Ins-CreERT). By our design, Ozgene (Australia) has generated a conditional KO mouse for CLEC16A, by floxing exon 3. This introduces a frameshift inactivating all downstream exons. We have crossed Ozgene mice with UBC-CreERT mice (inducible cre recombinase driven by the human ubiquitin C promoter). Tamoxifen treatment will inducibly activate Cre transgene which will lead to removal exon 3, flunked by loxP sites, in Clec16a gene. This event is predicted to result in a frameshift mutation, leading to the introduction of novel amino acids and early termination codon. Deletion will be confirmed in islets and other tissues by quantitative RT-PCR and Western Blot.

Since a whole body CLEC16A KO is a new mouse model, we are in a process of characterizing this model and studying if CLEC16A affects glucose metabolism, insulin secretion and tolerance. We also will determine the role of CLEC16A and its functions in the progression of T1D by studying an inducible whole body knockout model with focus on NK cells.

Genetic Polymorphism and Pathophysiology in Patients with Vitiligo.
S. Chettiar[1], K. Mistry[1], P. Agarwal[1], A. Patel[4], D. Jhala[3], D. Umarigar[2], R. Uppala[5]. 1) Department of Biotechnology, SRKI,, surat, India; 2) Department of Dermatalogy, Civil Hospital, Surat; 3) Department of Zoology, Gujarat Unviersity, Ahmedabad; 4) Genexplore Diagnostic Research Laboratory, Navrangpura, Ahmedabad; 5) Department of surgery-Transplant, University of Nebraska Medical center, Omaha, NE, USA.

Vitiligo is an acquired, idiopathic, hypomelanotic, depigmentary disorder characterized by the appearance of white patches resulting from the loss of functional melanocytes and melanin from the skin and mucous. It affects 1-4% of the world population, where as 0.5-2.5% in India with a high prevalence of 8.8% in Gujarat and Rajasthan states. Oxidative stress plays a vital role in etiology of depigmentation in skin by cellular loss, while catalase (CAT) is proven enzymatic defense system, catalyzing break down of hydrogen peroxide. Altered activity of the enzyme and increased stress markers have been reported in vitiligo patients. To investigate CAT gene polymorphism association to vitiligo suseptiblity, we investigated two CAT gene SNP including promoter region rs7943316 (T/C) and exon 9 rs769217 (A/T) with recognition site of BstXI and Hinf I respectively, in 54 vitiligo patients and 45 healthy volunteers. Catalase activity from the serum of affected and normal individual showed a significant difference, thus supporting that oxidative stress might be involved in the pathophygiology of the disorder. The genotype distribution and allele frequency of promoter region were not significantly different between vitiligo patients and healthy controls. But, the exon 9 showed significant correlation between affected and healthy individuals. Although the haplotype of two polymorphisms also showed association with vitiligo. This study suggests possible association between the CAT gene and the vitiligo susceptibility.

819W

Allele-specific regulation of DISC1 expression by miR-135b-5p.
I. Hovatta[1,2], M. Rossi[1,2], H. Kilpinen[1,3], M. Muona[1,2], I. Surakka[1,2], C. Ingle[3], W. Hennah[1,2], S. Ripatti[1,2,3]. 1) University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, UK.

The *Disrupted-in-schizophrenia-1* (*DISC1*) gene is a risk factor for neuropsychiatric phenotypes. MicroRNAs (miRNAs) are important regulators of protein coding genes. The miRNA-mRNA target recognition mechanism is vulnerable to disruption by DNA polymorphisms. We therefore investigated whether polymorphisms in the DISC1 3'UTR affect binding of miRNAs and lead to allele-specific regulation of *DISC1*. We identified four predicted polymorphic miRNA binding sites in the 3'UTR region of *DISC1*. We tested the effect of nine miRNAs on endogenous *DISC1* expression in vitro by over-expressing these miRNAs in 293FT cells and measuring the *DISC1* expression level by qPCR. To determine whether these miRNAs regulate DISC1 levels by targeting the predicted sites, we used a luciferase reporter gene assay. We cloned either the full length *DISC1* 3'UTR or the miRNA binding sites into a luciferase expression vector and co-transfected them into 293FT cells with either the miR-135b-5p or the miR-559 precursor. We also investigated the putative allele-specificity of miR-135b-5p binding. The 293FT cell line is homozygous for the A allele of rs11122396, predicted to create a novel binding site for miR-135b-5p. Therefore, we created constructs with the G allele at rs11122396. Two of the nine miRNAs, miR-135b-5p and miR-559, significantly reduced endogenous *DISC1* mRNA expression: miR-559 by 23.7 % (p=0.009) and miR-135b-5p by 16.2 % (p=0.039). In the luciferase assays expression from the *DISC1* full length 3' UTR construct was reduced 32.1% (p=0.003) by miR-135b-5p, and by 10.3 %, (p=0.03) from the construct expressing the 60 nt miRNA binding site and flanking sequences. In contrast, miR-599 over-expression did not affect the expression of *DISC1*. When investigating the putative allele-specificity of miR-135b-5p binding we observed that miR-135b-5p had no effect on the luciferase activity of either the full length 3' UTR with G allele at rs11122396 (p= 0.49), or on the construct with the ~60 nt miRNA binding site insert (p= 0.18), indicating that miR-135b-5p binding is specific to the derived (A) allele at rs11122396. Thus, the G allele may be functionally related to the DISC1-associated phenotypes by abolishing regulation by miR-135b-5p, leading to elevated DISC1 levels.

CELSR1 mutations are associated with human spina bifida.
Y. Lei[1], H. Zhu[1], W. Yang[3], M. Ross[4], G. Shaw[3], R. Finnell[1,2]. 1) Dell Pediatric Research Institute, The University of Texas at Austin. 1400 Barbara Jordan Blvd, Austin, TX, 78723; 2) Department of Chemistry and Biochemistry, College of Natural Sciences, The University of Texas at Austin, Austin, Texas; 3) Department of Pediatrics, Division of Neonatology, Stanford University School of Medicine, Stanford, CA; 4) Center for Neurogenetics, Brain and Mind Research Institute, Weill Cornell Medical College, New York, NY.

Spina bifida is one of the most common neural tube defects (NTDs), yet its complex etiology remains poorly understood. Recently, mutations in planar cell polarity (PCP) genes have been associated with NTDs, including spina bifida, in both animal models and human cohorts. We studied CELSR1, one of the PCP core genes in a California cohort to determine if CELSR1 mutations increase the risk of spina bifida. We sequenced the coding region of CELSR1 in 192 spina bifida infants. Novel and rare variants were genotyped in a control group of 190 ethnically-matched infants without malformations. Six missense mutations, absent in controls, were predicted to be deleterious by both SIFT and PolyPhen computational algorithms. Two TG dinucleotide repeat variations were detected in two spina bifida infants separately, but were not observed in controls. In functional analyses, the two TG dinucleotide repeat variants altered the subcellular localization of GFP-tagged CELSR1 protein in transfected cells. Both variants impaired interactions with VANGL2, and reduced the ability to recruit VANGL2 to the cell membrane. In total, 4.1% of spina bifida cases possessed deleterious or predicted-to-be-deleterious CELSR1 mutations. Our findings indicated that CELSR1 mutation is a risk factor for spina bifida.

821F

Functional impact of polymorphisms in the *MMP3* and *TIMP2* gene promoters in human nonsyndromic cleft lip/palate. *A. Letra[1,2,3], M. Zhao[1], R.M. Silva[1,2,3], A.R. Vieira[4], J.T. Hecht[2,3].* 1) Department of Endodontics, University of Texas Health Science Center School of Dentistry at Houston, Houston, TXHouston, Houston, TX; 2) Department of Pediatrics, Pediatric Research Center, University of Texas Health Science Center Medical School at Houston, Houston, TX; 3) Center for Craniofacial Research, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 4) Departments of Oral Biology and Pediatric Dentistry, University of Pittsburgh School of Dental Medicine, Pittsburgh, PA.

Matrix metalloproteinases (MMPs) and their inhibitors (TIMPs) are responsible for tissue remodeling during craniofacial development. Evidence from biological and human studies strongly support a role for MMP and TIMP genes as candidate genes for cleft lip/palate. We have previously shown the association of promoter polymorphisms in *MMP3* and *TIMP2* genes with cleft lip/palate. In this study, we assessed whether the previously associated promoter variants in *MMP3* (-709 A/G) and in *TIMP2* (-180 C/T) genes have functional implications and modulate gene transcription by changing the affinity of their gene promoters for transcription factors. Electrophoretic mobility shift assays, mass spectrometry analysis and luciferase reporter gene assays were performed for each gene variant. For the *MMP3* -709 A/G variant, EMSA showed DNA-protein binding complexes specific for the A allele, in which 34/204 proteins identified by mass spectrometry analyses were specific for this allele. Luciferase assays showed that allele A has lower promoter activity than the G allele in the presence of a known functional polymorphism in the *MMP3* promoter (-1171 5A6A). For the *TIMP2* -180 C/T variant, EMSA showed that both C and T alleles present potential binding sites for NF-Kappa B transcription factor, while super shift assays confirmed binding to NF-Kappa B with a higher binding affinity for allele C. Luciferase assays showed a 2.5 fold increase in promoter activity in the presence of allele T when compared to allele C. Taken together, these results show that variations in *MMP3* and *TIMP2* gene promoters may perturb gene transcription and/or function with effects on craniofacial development. Our study provides new evidence implicating *MMP3* and *TIMP2* variants in the occurrence of cleft lip/palate.

822W

Indian Hedgehog (IHH) and LRBA: New genes for Hirschsprung disease. *R.M.W Hofstra[1], Y. Sribudiani[1], R. Chauhan[1], M. Alves[1], C. Kockx[2], T. van Essen[2], R. Brouwer[2], M. van den Hout[2], W. van Ijcken[2], I.T. Shepherd[3], A.S. Brooks[1].* 1) Clinical Genetics, ErasmusMC, Rottedam, Netherlands; 2) Center for Biomics, Erasmus Medical Center, Rotterdam, Netherlands; 3) Department of Biology, Emory University, Atlanta, USA.

Hirschsprung is characterized by the absence of enteric ganglia in a variable length of intestinal tract. A large, multi-generational Dutch family with five affected family members with HSCR, revealed linkage to 4q31.3-q32.3. As the family shows an autosomal dominant mode of inheritance with incomplete penetrance, we assume that the mutation in the linkage region is necessary but not sufficient to cause disease development. To identify the mutation in the linkage region, but also mutations elsewhere in the genome, we exome sequenced two patients. One variant rs140666848 (T > C) in exon 20 of the LRBA gene was found in the linkage region. In addition, missense mutations in RET (P398L) and IHH (Q50K) were identified in each patient, respectively. Functional analysis of the RET en IHH variants showed that both mutations give rise to a non functional protein. The LRBA variant is located downstream of MAB21L2, a gene which plays a role in the proliferation of enteric neural crest cells (ENCCs) during ENS development in Zebrafish. We hypothesize that this variant might regulate MAB21L2 expression in ENS. Luciferase assays showed that the region containing the variant does show enhancer activity. Currently we are testing whether the variant, when compared to wild type sequence, show significant differences on gene expression level, using luciferase assays. Our data shows that combinations of mutations, as expected, cause autosomal dominant disease with reduces penetrance. Furthermore, we show for the first time that IHH mutations can contribute to Hirschsprung disease.

823T

Genes located in type 1 diabetes risk loci are expressed in human islet and interact in functional networks. *C.A. Brorsson, J. Stoerling, F. Pociot.* Glostrup Research Institute, Glostrup University Hospital, Glostrup, Denmark.

Background: Genome-wide association studies of type 1 diabetes (T1D) have identified 50 susceptibility loci. Although most pin-pointed candidate genes have putative functions within the immune system studies in human pancreatic islets have shown expression for 60% of these genes. Assignment of candidate genes is often based on known biological function or location in relation to the most associated SNP in a locus which could introduce bias into functional studies as all genes in a locus potentially are equally good candidates. We investigated the expression and functional interactions of all genes located within T1D loci in human islets. Methods: A list of all 857 genes located within T1D GWAS loci were downloaded from t1dbase.org. Gene expression based on RNA-seq in human islets was determined from a published study by Eizirik et al. Only genes that had an expression level above 1 in all five islet preparations in the control and/or cytokine-stimulated condition were considered expressed. Protein-protein interaction networks of expressed genes were constructed in DAPPLE. Results: Of 857 genes in T1D loci 336 were expressed in the islets representing 44 loci and 33 previously pin-pointed candidate genes. The expressed genes included 8 pseudogenes, three lincRNAs, two miRNAs and two snoRNAs. In 16 of the loci only a single gene was expressed, including nine candidate genes (*STAT4*, *CENPW*, *TNFAIP3*, *SKAP2*, *GLIS3*, *ZMIZ1*, *LMO7*, *RASGRP1* and *PTPN2*). In addition, at 7p12.1 *COBL* was the only protein-coding gene of the two genes expressed. Using the 336 islet-expressed genes as input, DAPPLE detected 123 direct interactions. A network consisting of only direct connections contained 62 genes of which nine were candidate genes (*NCOA1*, *STAT4*, *ZMIZ1*, *ERBB3*, *SH2B3*, *LMO7*, *SMARCE1*, *PTPN2* and *TYK2*). Based on the connectivity of each of the proteins 48 genes were highlighted as significant functional candidates including several HLA genes and five candidate genes (*SH2B3*, *GPR183*, *TNFAIP3*, *NCOA1* and *ERBB3*). Conclusions: These findings provide evidence that many of the genes located in T1D risk loci are expressed at the mRNA level in human islets and interact in networks. This suggests that variation that gives rise to alterations in expression levels of these genes is likely to affect network function in a way that could promote deleterious events leading to T1D. Further studies are needed to elucidate the function of the islet expressed genes in the T1D pathogenesis.

824F

Elucidating the genetics of type 2 diabetes by integrative analysis of the genome, transcriptome and epigenome of skeletal muscle and adipose tissue samples from Finnish individuals spanning the range of glucose tolerance. *J.R. Huyghe[1], S.C. Parker[2], M.R. Erdos[2], H. Koistinen[3], P.S. Chines[2], H.M. Stringham[1], L.J. Scott[1], L. Taylor[2], T. Blackwell[1], H. Jiang[1], C. Ma[1], A.U. Jackson[1], R. Welch[1], N. Narisu[2], A.J. Swift[2], L.L. Bonnycastle[2], M.L. Stitzel[2], L. Kinnunen[3], R.M. Watanabe[4,5], T. Lakka[6], M. Laakso[6], J. Tuomilehto[3], F.S. Collins[1], M. Boehnke[1].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 3) National Institute for Health and Wellfare, Helsinki, Finland; 4) Department of Preventive Medicine, University of Southern California (USC) Keck School of Medicine, Los Angeles, CA, USA; 5) Department of Physiology and Biophysics, Keck School of Medicine of USC, Los Angeles, CA, USA; 6) University of Eastern Finland, Kuopio, Finland.

Genome-wide association studies (GWAS) have identified >70 loci associated with type 2 diabetes (T2D) risk, and have significantly advanced our understanding of the pathophysiology of T2D. Yet, for most identified loci, the causal genes and functional variants remain elusive because the associated region resides in noncoding DNA. Despite the incomplete annotation of the noncoding genome, there is overwhelming evidence that GWAS loci for complex traits cluster near transcriptional regulatory elements in disease-relevant tissues. Therefore, a crucial next step in functional investigations of GWAS-identified variants is the examination of their relationship to gene expression in disease-relevant tissues, collected from subjects representing different stages of progression to T2D. To that end, as part of the Finland-United States Investigation of NIDDM Genetics (FUSION) study, we collected biopsies from two major insulin target tissues: skeletal muscle and adipose tissue. Skeletal muscle accounts for ~80% of insulin-responsive glucose uptake. Adipose tissue, while not a major site of glucose disposal, plays a key role in insulin resistance and T2D by mechanisms that remain unclear. We obtained biopsy samples from *vastus lateralis* skeletal muscle and abdominal subcutaneous adipose tissue from 324 clinically well-characterized Finnish individuals spanning the range of glucose tolerance: 125 normal glucose-tolerant, 72 impaired glucose-tolerant, 41 impaired fasting glucose, and 86 newly diagnosed T2D cases without antihyperglycemic medication. As of May 2013, sequencing of high quality (RIN 7.3-9.1) mRNA extracts to a median depth of 46.8 million aligned read pairs has been completed for 132 samples. RNA-seq quality control metrics and analyses of spiked-in RNA controls indicate excellent data quality. Genome-wide genotype and DNA methylation data are being generated using the Illumina Omni 2.5M-Quad SNP chip and Illumina HumanMethylation450 chip. A primary study aim entails examining the relation between expression quantitative trait loci (eQTL) and GWAS-associated SNPs for T2D and related traits. Integration with epigenetic marks will help to nominate putative causal variants and genes for functional follow-up. Further, this rich data resource will enable the study of the diverse molecular processes involved in insulin resistance which is a biomedical priority as most interventions proven to delay T2D onset act to reduce insulin resistance.

825W

Altered expression of *ARAP1*, at a type 2 diabetes GWAS locus, influences insulin secretion from pancreatic beta cells. *J.R. Kulzer, M.P. Fogarty, K.L. Mohlke.* Department of Genetics, UNC Chapel Hill, Chapel Hill, NC.

The biological mechanisms underlying association of the *ARAP1* locus with type 2 diabetes and proinsulin levels are unknown. The risk allele of index SNP rs11603334 increases transcriptional activity at an *ARAP1* promoter and is associated with increased levels of *ARAP1* mRNA expression in human islets. However, the functional effects of altered *ARAP1* expression on insulin processing and secretion are unknown. ARAP1 is a GTPase activating protein (GAP) that catalyzes hydrolysis of GTP bound to Arf and Rho GTPases, rendering the GTPases inactive. Arf and Rho GTPases regulate Golgi transport, membrane trafficking, and actin cytoskeleton dynamics, processes that are important to insulin processing and secretion in the beta cell. We hypothesized that ARAP1 acts through one or more Arf or Rho GTPases to exert a regulatory role on insulin processing and/or secretion. In cell culture or *in vitro*, ARAP1 has been shown to hydrolyze GTP-bound Arf1, Arf5, Arf6, RhoA, and Cdc42. The specific Arf and Rho GTPases regulated by ARAP1 in beta cells are unknown. To investigate the effects of altered ARAP1 expression on insulin processing and secretion, we knocked-down and overexpressed ARAP1 in 832/13 and MIN6 beta cell lines and measured levels of secreted insulin. Preliminary results show a 57% decrease in glucose-stimulated insulin secretion (P = .026) upon 55% siRNA knockdown of *ARAP1*. Transient overexpression of wild-type ARAP1 resulted in a 70% increase in KCl-stimulated insulin secretion (P = .028). To determine which Arf and Rho GTPases are regulated by ARAP1 in beta cells, we used GTP pull-down assays to measure the levels of GTP-bound Arf1 remaining after ARAP1 overexpression. Exogenous wild-type ARAP1 decreased Arf1-GTP levels by 47%. Exogenous ARAP1 variants with either a catalytically inactive Arf GAP domain or an inactive Rho GAP domain decreased Arf1-GTP levels by ~30%. Overexpression of an ARAP1 variant with both catalytically inactive GAP domains did not decrease Arf1-GTP levels, suggesting that both domains play a role in catalyzing Arf1-GTP hydrolysis. Arf1-GTP regulates transport between the endoplasmic reticulum and the Golgi apparatus, a critical step to the efficient packaging of secretory hormones. Ongoing work assesses the effects of ARAP1 overexpression on Arf5, Arf6, Cdc42, and RhoA. Our results suggest that altered expression of ARAP1 may affect Arf1 activity and interfere with proper regulation of insulin trafficking and secretion.

826T

The widely presumed type 2 diabetes causal variant, rs7903146, within *TCF7L2* binds a specific protein complex not seen with its closest non-causal proxy. *Q. Xia[1], S. Deliard[1], C.X. Yuan[2], M.E. Johnson[1], S.F.A. Grant[1,3,4].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Proteomics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Institute of Diabetes, Obesity and Metabolism, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

There have been many efforts to resolve the underlying causative mechanism for a given GWAS signal. However, in the vast majority of situations, there still remains only a list of candidate variants that could represent the causal event. The situation is somewhat more advanced for the strongest associated type 2 diabetes (T2D) locus reported to date, *TCF7L2*, where follow-up analyses in multiple ethnicities have strongly implicated rs7903146 as the causal variant within intron 3. As such, we carried out oligo pull-down combined with mass spectrophotometry (MS) to elucidate the transcriptional machinery across the SNP. Nuclear lysates from HCT116 cells, where TCF7L2 is abundantly expressed, were incubated with biotin-labeled, double-stranded 60bp oligonucleotides spanning rs7903146. The DNA-protein complexes were precipitated with streptavidin-agarose beads, and the bound proteins were isolated by denaturing SDS-PAGE. One major band was observed with the rs7903146-specific oligo that was absent with the scrambled oligo. Furthermore, an oligo coinciding with a SNP in strong linkage disequilibrium with rs7903146 in Caucasians but not in other ethnicities and widely rejected as the causal variant, namely the proxy rs12255372, also did not yield this extra band. Following digestion with trypsin, the samples were analyzed by MS. We observed that poly (ADP-ribose) polymerase 1 (PARP-1) is by far the most abundant binding factor. Among the next most abundant binding proteins, a number were shown to dimerize with the TCF7L2 protein, which resonates with our previous TCF7L2 ChIP-seq work that characterized 4 sites within the *TCF7L2* gene itself. To test for evidence of a feedback mechanism for TCF7L2 operating at this location, we cloned the genetic elements in both orientations upstream of a luciferase reporter gene. The combination of TCF7L2 and β-catenin over-expression produced a striking increase of up to 5 fold in transcription levels in 293T cells; in addition, we observed differences between alleles for rs7903146. We also found evidence for an allelic difference in the MS results for proteins with less abundant binding, namely X-ray repair cross-complementing 5 (XRCC5) and RPA/p70. Our results point to a protein complex binding across rs7903146 within *TCF7L2* and reveals a possible mechanism by which this locus confers T2D risk. Furthermore, we implicate PARP-1 as playing a role in T2D pathogenesis, a target which has classically been pursued for cancer.

827F

A role for IRF6 in cell cycle regulation and DNA damage response in mesenchymal stem cells. *G.S. Kobayashi[1], L. Alvizi[1], B.V.P. Almada[1], L.C. Andrade-Lima[2], C.F. Menck[2], M.R. Passos-Bueno[1].* 1) Human Genome Research Center, Institute for Biosciences, University of São Paulo, Brazil; 2) Institute of Biomedical Sciences, University of São Paulo, Brazil.

Purpose: The transcription factor IRF6, which regulates orofacial and epidermal development, is associated with both syndromic and non-syndromic cases of cleft lip/palate (CL/P). The most prevalent syndromic form of CL/P is van der Woude syndrome (VWS), which is thought to be caused by haploinsufficiency of IRF6. Despite the established role of IRF6 in regulating differentiation and cell cycle progression in some tissues of epithelial origin, little is known about its functions in non-epithelial cells. We have recently reported that mesenchymal stem cells from non-syndromic CL/P patients exhibit impairment of DNA repair mechanisms, which are known to be tightly related to cell cycle regulation (Kobayashi & Alvizi ***et a***l., 2013). Therefore, our objective was to verify if IRF6 participates in these cellular processes in mesenchymal stem cells, in order to further clarify its biological role in non-epithelial cells and in the aetiology of CL/P itself. **Methods:** We quantified DNA double-strand break (DSB) formation using flow cytometry for anti-γH2AX at 6 and 24 hours after exposure to H_2O_2 (100μM), using 2 VWS and 2 control *orbicularis oris* muscle-derived stem cell (OOMDSC) cultures. The proliferative profile of the cell cultures was assessed using an XTT-based assay. Real-time quantitative PCR (RT-qPCR) was carried out in 3 independent experiments to measure IRF6 mRNA expression in untreated and G_0/G_1-synchronised OOMDSCs (serum-starved for 48 hours and contact-inhibited under confluence). Synchronisation was confirmed by flow cytometry analysis using propidium iodide and RT-qPCR for proliferation marker *MKI67*. **Results/Conclusion:** VWS OOMDSCs were more sensitive to the H_2O_2 treatment, exhibiting a clear accumulation of DSBs at 6 and 24 hours of exposure as compared to controls. We did not observe consistent differences between the proliferative potential of VWS and control OOMDSCs; however, in both cases, *IRF6* was markedly up-regulated in contact-inhibited but not serum-starved quiescent cells, suggesting that this gene also plays a role in cell cycle regulation in mesenchymal stem cells. Given these results, we hypothesise that, in this cell type, IRF6 may participate in a cell cycle-integrated response to oxidatively-generated DNA damage. Further investigation will be necessary in order to confirm these results and clarify their relationship with the aetiology of CL/P. Financial support: CEPID/FAPESP, CNPq, MCT.

828W

Novel regulatory variants in family studies with adult chronic atopic dermatitis. *W.B. Jones[1], T.C Pansuriya[1], K.J Gulewicz[1], I. Oh[1], B. Borgo[1], A. Shemer[2], J.G Krueger[3], E. Guttman-Yassky[3], C. de Guzman Strong[1].* 1) Dermatology, Washington University in St.Louis, St.Louis, MO; 2) Tel-Aviv University, Israel; 3) Icahn School of Medicine at Mt. Sinia New York, USA.

Atopic Dermatitis (AD) is a complex, chronic inflammatory skin disease with a high degree of heritability. Although up to 50% of moderate to severe cases of AD is attributed to mutations in the skin barrier gene filaggrin (FLG), other genomic regions (1q, 5q, 11q, 19p, and 20q) are implicated as well. We pursued genetic studies in a tight phenotypic adult cohort for AD to better resolve the genetic architecture of AD. An adult cohort representing chronic AD demonstrated baseline skin barrier impairment owing to down-regulation of Epidermal Differentiation Complex (EDC) genes in the unaffected skin areas. Only 2 out of 31 (6%) patients in our adult cohort were heterozygous for the two most common FLG mutations, R501X and 2282del4. Although fewer FLG copy number repeats were present in AD patients vs. controls (Wilcoxon rank sum test, p=0.03), we hypothesized additional variants in regulatory elements in linkage disequilibrium (LD) with FLG (rs877776, chr 1q21) or GWAS-tagged SNP (rs7927894, chr 11q13.5) to explain the persistence of AD in this adult cohort. SNP discovery using targeted next-generation sequencing of ENCODE-annotated enhancers surrounding rs877776 and rs7927894 in our pooled AD cohort identified a total of 18 variants. Two of the variants were novel (absent in 1000 Genomes and dbSNP NCBI database) in 2 independent patients. These novel variants correlated to previously described conserved noncoding elements (184 and 180) that demonstrated enhancer and repressor activities, respectively, and are bioinformatically predicted to disrupt NFE2L2 and Sox9 transcription factor binding. The function for each of the variants was assessed using cell-based reporter assays . No appreciable difference was observed for the novel variant in CNE 180. However, the rare variant in CNE 184 exhibited a significant and surprising increase in enhancer activity. Moreover, chromosomal conformation capture (3C) assays provide compelling evidence for genomic interactions between these regulatory elements and the dysregulated EDC genes. Our results present a framework for discovering variants in regulatory elements in LD with GWAS-tagging SNPs for a complex disease. More importantly, we identify a functional novel regulatory variant nearby clinically-relevant genes that could contribute to the persistence of FLG-deficient AD into adulthood.

Meta-analysis on eQTL mapping identify insertion and deletion (INDEL) specific eQTLs in LCL, PBMC and skin tissues. *J. HUANG[1], J. CHEN[2], J. Esparza[3], J. Ding[4], J. Elder[5], Y. Lee[3], M. Moffatt[6], W. Cookson[6], L. Liang[1,2].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) Max-Delbrück-Center for Molecular Medicine, Berlin, German; 4) Laboratory of Genetics, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA; 5) Department of Dermatology, University of Michigan Medical School, Ann Arbor, MI 48109-0932, USA; 6) National Heart and Lung Institute, Imperial College London, London, UK.

Large scale genome-wide association studies (GWAS) for gene expression quantitative trait loci (eQTL) mapping have been primarily focused on single nucleotide polymorphisms and have helped interpret findings from GWAS for a variety of complex diseases and traits. The functional effect of structure variants, especially short insertions and deletions (INDEL) have not been systematically investigated due to limitation in the availability of high throughput techniques. In this study, we imputed 1,380,133 INDELs based on the latest 1000Genomes project panel into 3 eQTL datasets from multiple tissues including lymphoblastoid cell lines (LCLs), peripheral blood mononuclear cell (PBMC) and skin. An eQTL Meta analysis combining 741 samples from these datasets identified INDEL specific eQTLs for 325 genes (FDR<5%), which cannot be mapped to any SNP at genome-wide significant level even after imputation. Among these significant INDEL eQTL pairs, 3,232 (1.9%) show significant tissue specific effect, compared to 9,775 (1.5%) for significant SNP eQTLs pairs. We also show that INDEL specific eQTLs were enriched in Gene Ontology categories apoptosis, cell adhesion and cell cycle. Finally, imputation of 1000Genomes SNP, INDEL and cross-tissue meta-analysis together identify cis eQTLs for 6,228 genes. All eQTL results are available on our newly developed web browser. This study provides new insights into the underlying genetic architecture of gene expression, and furthermore, we illustrate how this newly developed database for SNP and INDEL specific eQTLs based on multiple tissues could help explain the association to available disease phenotypes, including asthma, atopic dermatitis and psoriasis.

Integrative Genomics Approach to Unravel the Molecular Mechanisms Underlying Genome-Wide Association Results For Lung Function Measures. *M. Obeidat[1], K. Hao[2], Y. Bossé[3,4], D. Nickle[5], D. Postma[6], M. Laviolette[4], A. Sandford[1], D. Daley[1], C. Brandsma[7], M. Berge[6], R. Vessey[8], G. Opitec[8], W. Timens[7], D. Sin[1], P. Paré[1].* 1) UBC James Hogg Research Centre, Vancouver, BC, Canada; 2) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, USA; 3) Department of Molecular Medicine, Laval University, Québec, Canada; 4) Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Québec, Canada; 5) Merck Research Laboratories, Boston, MA, USA; 6) Department of Pulmonology, University of Groningen, University Medical Center, Groningen, GRIAC research institute, Groningen, The Netherlands; 7) Department of Pathology and Medical Biology, University of Groningen, Groningen, University Medical Center Groningen, GRIAC research institute, Groningen, The Netherlands; 8) Merck & Co. Inc., Rahway, NJ, USA.

Background: SpiroMeta and CHARGE consortia published a large scale meta-analysis of lung function measures (n~49,000), which identified 26 novel loci (Artigas et al. Nat. Gen. 2011). However, the exact mechanisms underlying these associations are not fully understood. Hypothesis: A subset of SNPs which influence lung function act as eQTL in the lung to change the level of expression of their gene product. Aim: To identify SNPs that are associated with both lung function measures and mRNA levels (eQTL) in lungs. Methods: The lung eQTL were derived from genome-wide genotyping and gene expression analysis of 1,111 lung tissue samples. The study identified ~470,000 SNPs related to the level of gene expression in cis and ~17,000 SNPs in trans, at 0.1 FDR (Ke Hao et al. PLoS Gen. 2012) The SpiroMeta and CHARGE consortia have made available the top 2000 SNPs associated with forced expiratory volume in one second (FEV1), and its ratio to Forced Vital Capacity (FEV1/FVC). We undertook an integration of these 4000 SNPs with the lung specific eQTL at a 0.1 FDR. Results: From the CHARGE study associations with FEV1, 1293 SNPs were associated with cis eQTL and 976 trans eQTL, and for the FEV1/FVC associated variants, 809 were associated with cis eQTL and 236 with trans eQTL. For SpiroMeta associations' results for FEV1, 594 SNPs were associated with cis eQTL and 54 with trans eQTL, and among the FEV1/FVC associated variants, 578 SNPs were associated with cis eQTL and 91 SNPs with trans eQTL. 48 eQTL overlapped between SpiroMeta and CHARGE for FEV1 and an equal number (48 eQTLs) for FEV1/FVC, and 7 eQTL were common to both consortia associations' with FEV1 and FEV1/FVC. The mRNA levels of a number of genes regulated by the integrated SNPs also correlate with lung function measures in the lung eQTL study. Gene Ontology and pathway enrichment analyses showed lung function genes to be involved in inflammatory, tissue remodeling and developmental pathways. Future work will focus on prioritizing a number of genes for validation at protein level. Conclusion: A large number of lung function associated SNPs act as lung specific eQTL for either FEV1 or FEV1/FVC in the two consortia studied, Additionally 7 eQTL were overlapping in the two cohorts and affected both FEV1 and FEV1/FVC. The data suggest that a number of the identified variants influence lung function by modulating gene expression levels in lung.

Identifying the molecular mechanisms at the vascular *PLXND1* locus associated with human waist-hip ratio. *T.S. Roman[1], J.E.N. Minchin[2], J.F. Rawls[2], K.L. Mohlke[1].* 1) Genetics, The University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Molecular Genetics and Microbiology, Duke University, Durham, NC.

Genome-wide association studies for waist-hip ratio (WHR), a measure of body fat distribution, have identified numerous loci including several located near genes related to angiogenesis. Stimulation of angiogenesis alters adipose metabolism, and inhibition of angiogenesis abrogates adipose tissue expansion. One locus associated with WHR by the GIANT consortium is *PLXND1* ($P = 4\times10^{-6}$, Heid 2010). *PLXND1* encodes Plexin D1, a transmembrane co-receptor expressed in endothelial cells that plays a role in physiological and pathological angiogenesis. *Plxnd1*$^{-/-}$ null mice have vascular defects and die shortly after birth, and *plxnd1*$^{-/-}$ null zebrafish are viable but also have vascular patterning defects. Human adipose tissue biopsies showed a positive correlation between *PLXND1* mRNA levels and a hypertrophic adipose morphology in visceral but not subcutaneous adipose, suggesting adipose-specific effects of Plexin D1 signaling. The DNA elements regulating *PLXND1* expression and the identity of the underlying functional GWAS variants are unknown. We hypothesize that WHR-associated DNA variants are located within *cis*-regulatory DNA elements that control tissue-specific expression of *PLXND1* and regulate fat deposition and morphology. All 37 WHR-associated DNA variants at the *PLXND1* locus are non-coding (r^2>.8, 1000 Genomes Phase 1 CEU), and all overlap with open chromatin or histone modifications that mark gene regulatory regions in human umbilical vein endothelial cells (HUVEC). We defined and tested *cis*-regulatory elements for effects on *PLXND1* expression using zebrafish transgenesis reporter assays and transcriptional reporter assays in mammalian cells. Candidate *cis*-regulatory elements recombined into a GFP expression vector were injected into one-cell stage *Tg(flk1:mCherry)* zebrafish embryos to test for regulatory activity. This zebrafish reporter assay enables identification of temporal-specific or cell-type specific regulatory elements. The same candidate *cis*-regulatory elements were tested in transcriptional reporter assays transfected into HUVEC. Preliminary data suggests that at least 3 regulatory elements show greater than 1.5-fold enhancer activity relative to an empty vector control in HUVEC. Identification of the *cis*-regulatory elements at *PLXND1* will provide greater insight into the molecular mechanisms and cell types important for regulating *PLXND1* expression, and lead to a greater understanding of how *PLXND1* influences WHR and fat deposition in humans.

832T

Genome-wide enrichments for regulatory regions across thousands of unlinked disease-associated variants. *A.K. Sarkar[1,2], L. Ward[1,2], M. Kellis[1,2].* 1) Massachusetts Institute of Technology, Cambridge, MA., USA; 2) The Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Genome-wide association studies have identified thousands of non-coding genetic variants associated with disease, but many additional variants lie below the stringent p-value threshold given current cohort sizes. Here, we investigate both top-scoring and weakly-associated variants using functional genomics annotations of regulatory regions in 100 human tissues and cell lines from ENCODE and the Epigenomics Roadmap project. We find top-scoring non-coding variants are highly enriched for regulatory annotations of relevant cell lines, suggesting regulatory variation may be contributing to the molecular basis of the disease phenotype, and guiding the search for relevant cell types for QTL studies in a number of cases. We also find some surprising enrichments, suggesting new and unexpected tissue and cell types may be playing roles in previously unsuspected diseases, which can help guide directed experiments to reveal potentially novel pathways, tissues, and cell types. We also tested the enrichment of non-coding variants below the genome-wide significance threshold. Surprisingly, we found that an unprecedented number of variants are enriched for predicted enhancer regions in matching cell lines, spanning thousands of independent loci, even after excluding regions containing top-scoring variants. Our results suggest that the architecture of some human diseases is dramatically more complex than previously recognized. In particular, we find that variants associate with Type 1 Diabetes and Rheumatoid Arthritis are strongly enriched for enhancer regions active in immune cell lines and showing evidence of H3K4me1, a histone modification mark associated with active and poised enhancer regions, and H3K27ac, associated with active regulatory regions. These also show evidence of DNase Hypersensitivity in T-cells and B-cells, and are precisely enriched within high-resolution footprints and dips in the chromatin signal associated with nucleosome displacement characteristic of transcription factor binding. These results are robust to diverse permutation corrections, enrichment and association statistics, LD pruning strategies, and null distributions. We find more than 1000 distinct regions after LD pruning and excluding the MHC, and include both common and unique variants between the two traits. Overall, our results suggest a dramatically large number of additive interactions of variants with individually small effect sizes may underlie numerous human traits.

833F

Enabling phenomics with high-throughput whole-organism 3D pan-cellular imaging at cell resolution. *K. Cheng[1], P. La Riviere[2].* 1) Jake Gittlen CA Res Inst ,H059, Penn State College of Medicine, Hershey, PA; 2) Dept of Radiology, University of Chicago, Chicago, IL.

Genes and environment can impact any cell type at any developmental stage. Ideally, the comprehensive study of those influences in a multicellular organism therefore requires the ability to visualize, identify, and characterize every cell type in the whole organism across all life stages at cell resolution. The most common medical implementation of cell imaging, histology, is achieved using tissue sections of about 5 micron thickness, differential color staining of cell components, and opticical resolutions in the range of 1 micron. The destructive and tedious nature of histology precludes the study hundreds of thousands of samples, as would be required to study the functions or effects of tens of thousands of genes or chemicals. A collaborative team is working towards the ideal of high-throughput tomographic imaging and characterization of all cell types in whole small model organisms and millimeter scale tissue samples in a way that is immune to tissue opacity and pigmentation, based on the use of X-rays. Pan-cellular stains, fields of view, and phase contrast through use of monochromatic X-rays are possible at the Advanced Photon Source at Argonne National Labs and have made possible 3D imaging of whole zebrafish at larval and juvenile stages at cell resolution. We are able to recognize and characterize virtually all cell types and achieve elemental imaging of samples containing multiple stains. We propose that high-throughput adaptations of pan-cellular, whole-organism microCT can be used as a powerful foundation for a computational phenomics that will allow us to probe the function of all genes (genetic phenomics) and the effects of environmental manipulations including chemical exposures (environmental phenomics). Current barriers to automated, high-throughput, quantitative morphometric analysis and visualization can be eliminated by adoption of existing and imminent technologies. We envision the creation of one or more beamlines at the Advanced Photon Source at Argonne National Labs dedicated to high-throughput imaging of millimeter scale specimens, including whole invertebrate organisms such as flies and small vertebrate model organisms such as zebrafish. 3D images can be created, analyzed and visualized, and made available to the public in real time. Such data may profoundly enhance our understanding of the impacts of genes and environment on biological systems.

834W

Genetic variants and regulation in human complex diseases and traits. *C. Yao[1], R. Joehanes[1], A.D. Johnson[1,2], B. Chen[1], Tx. Huan[1], J.E. Freedman[3], P.J. Munson[4], D. Levy[1,2,5].* 1) National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, Massachusetts; 2) Division of Intramural Research, National Heart, Lung, and Blood Institute, Bethesda, Maryland; 3) Department of Medicine, University of Massachusetts Medical School, Worcester, MA; 4) Mathematical and Statistical Computing Laboratory, National Institutes of Health, Bethesda, Maryland; 5) Center for Population Studies, National Heart, Lung, and Blood Institute, Bethesda, Maryland.

Numerous single nucleotide polymorphisms (SNPs) have been found to be associated with complex traits and diseases through genome-wide association studies (GWAS). However, for most of these disease associated SNPs, it is still unclear how genetic variation mediates the phenotype. Here, we present a systematic analysis of SNPs associated with common complex disease and traits. Using 4967 SNPs associated (at $P<5\times10^{-8}$) with 427 complex traits from dbGaP and the NHGRI GWAS Catalog, we constructed a disease network by virtue of common SNP associations. We found several 'hub' loci (HLA region, GCKR, CFH, ZNF259) associated with more than 20 traits. The network identified three large clusters: immune-associated phenotypes, metabolic-associated phenotypes, and cancer, suggesting that genetic variants and their corresponding phenotypes might be related to each other at a higher functional level. We then explored the gene expression associations of trait-associated SNPs (expression quantitative trait loci, eQTLs) in 5257 individuals from the Framingham Heart Study. At FDR <0.05, we identified 886 cis-eQTLs(local regulation) and 59 trans-eQTLs(distant regulation) for 243 complex traits. We found that genes regulated by SNPs related to immune disease and cancer are highly enriched in chr6p21 (HLA region), allograft rejection and genes regulated by metabolic related SNPs are highly associated with metabolic pathways. Furthermore, we found that the expression of transcripts regulated by trait-associated SNPs is also significantly associated with corresponding phenotypes. For example, body mass index (BMI) associated SNP rs10838738 is significantly associated with expression of PTPRJ ($P=5.8\times10^{-27}$), and expression of PTPRJ in turn is also significantly associated with BMI ($P=4.5\times10^{-14}$), suggesting that variants associated with disease phenotypes may exert their function by altering mRNA expression. In exploring eQTLs across multiple tissues (lymphoblastoid, liver and brain) from GTEX and MRCA database, we found 40% of eQTLs on average appeared in more than one tissue, suggesting many trait-associated eQTLs found in blood may have impacts in other tissues. Our findings may provide new insight into complex genetic regulatory mechanisms.

835T

READ1, a Regulatory Element within *DCDC2*, Epistatically Affects Reading and Language with both Deleterious and Protective Alleles. *N.R. Powers[1, 2], J.D. Eicher[1], Y. Kong[4, 5], L.L. Miller[6], S.M. Ring[6], J.R. Gruen[1, 2, 3].* 1) Dept of Genetics, Yale University, New Haven, CT; 2) Dept of Pediatrics, Yale University, New Haven, CT; 3) Dept of Investigative Medicine, Yale University, New Haven, CT; 4) Dept of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT; 5) W.M. Keck Foundation Biotechnology Resource Laboratory, Yale University, New Haven, CT; 6) School of Social and Community Medicine, University of Bristol, Bristol, UK.

Learning disabilities are neurobehavioral disorders involving unexpected difficulty with a particular mode of learning. Two of the most common are reading disability (RD, also known as dyslexia) and language impairment (LI), which involve difficulty processing written and verbal language, respectively. Both RD and LI are substantially heritable, but like many complex genetic disorders and traits, most of this heritability is missing despite decades of study. Our lab previously identified READ1 (Regulatory Element Associated with Dyslexia 1), a highly polymorphic, purine-rich, compound short tandem repeat localized to intron 2 of the RD-associated gene *DCDC2.* In the Avon Longitudinal Study of Parents and Children (ALSPAC), a large prospective birth cohort based in the UK, we showed a six-marker risk haplotype in strong linkage disequilibrium with allele 5 of READ1 to be strongly associated with severe RD. We also showed another risk haplotype in the same haplotype block~and in strong linkage disequilibrium with allele 6 of READ1~to be strongly associated with LI. We subsequently showed READ1 to bind the potent transcriptional silencer ETV6, and to participate in a synergistic genetic interaction with a known risk haplotype in the 5' region of *KIAA0319*, another known RD-associated gene, to adversely affect performance on reading, language, and IQ measures. We have followed up on these findings by genotyping READ1 in the entire ALSPAC cohort, and examining the effect of individual alleles or groups of alleles on these phenotypic measures. As expected from previous results, READ1 alleles 5 and 6 associated strongly with severe RD and LI, respectively. Interestingly, however, some other READ1 alleles appear to have a protective effect, with odds ratios as low as 0.5 for severe RD. Whether an allele is protective or deleterious seems to depend on its structure: longer alleles relative to the most common allele tend to be deleterious, while shorter alleles tend to be protective. Strikingly, the protective alleles also show epistasis to the *KIAA0319* risk haplotype~while deleterious alleles synergize with it, protective alleles abrogate its effect on phenotype entirely. We postulate that this behavior is due to a direct regulatory interaction through ETV6 between READ1 and the *KIAA0319* promoter, and have undertaken chromatin and expression studies to test this hypothesis.

836F

A computational framework for identifying genes perturbed by MS associated variants through regulatory element disruption. *P. Shooshtari[1, 2], C. Cotsapas[1, 2].* 1) Neurology, Yale University, New Haven, CT; 2) Broad Institute of Harvard and MIT, Cambridge, MA.

Multiple sclerosis (MS) is a progressive neurological disease affecting ~1/700 women in North America, over 60% of whom will die as a direct result. Genome-wide association studies (GWAS) have uncovered tens of genomic loci harboring genetic variants predisposing to the disease. As with other complex traits, majority of these risk variants appear non-coding and we have recently shown that they are enriched in DNase I Hypersensitive Sites (DHS) active in immune cell populations. Although highlighting their regulatory effects, enrichment of these variants on DHS alone is not enough to infer their sites of action. The challenge is thus to understand how these risk variants alter gene regulation, which genes are perturbed and how they fit together into biological processes underlying the disease. For an MS causal SNP to affect the regulation of a gene, it must perturb the DHS regulating that gene's expression. Thus, we reasoned that DHS correlated to relevant genes would be enriched for GWAS p-values compared to those correlated to bystander genes in the same region. We thus devised a two-step test to identify such candidate genes: first, correlate DHS signal to the expression of nearby genes across tissues to determine which they regulate; then calculate a summary GWAS association statistic for each DHS. If these values are correlated, then DHS regulating the gene have evidence of perturbation by risk variants, and thus the gene is likely involved in disease biology. We used DHSs data and exon array data from the ENCODE project for 78 cell types. As a specific example, we studied STAT3, a gene thought to be involved in MS, and identified significantly correlated DHSs that possibly could effect regulation of this gene. Considering a window spanning 50 kbp of each side of STAT3, we found that 24% of significant MS GWAS SNPs on this region are located on correlated DHSs. Given that significantly correlated DHSs ($p < 2.5e-4$) comprise less than 4% of all DHSs surrounding STAT3, this observation implies that MS SNPs are enriched on correlated DHSs, and highlights impact of these SNPs on regulation of STAT3. Our approach thus unites functional genomics analysis and GWAS to identify genes underlying complex traits. It is a general analytical framework that can be applied to other genomic markers (e.g. methylation) and complex traits. We are currently applying this genome-wide to MS GWAS signals to robustly identify implicated genes and will discuss these findings.

TNF-β Nco1 polymorphism and sepsis susceptibility following major elective surgery. *R.Nath. Srivastava[1], K. Baghel[1,2], S. Raj[1,2], A. Chandra[2], S.K. Goel[3].* 1) Orthopaedic Surgery, King George's Medical University, Lucknow, Uttar Pradesh, India; 2) Surgical Gastroenterology, King George's Medical University, Lucknow, Uttar pradesh, India; 3) Petroleum Toxicology Division, Indian Institute of Toxicology Research, Lucknow, Uttar Pradesh, India.

Background: Postoperative sepsis remains a significant cause of morbidity and mortality. In injured patients, it has been shown that a polymorphism of the tumor necrosis factor-β (TNF-β) gene is related to the development of sepsis. We investigated relation of TNF-β gene polymorphism and serum level of cytokine TNF-α with the development of sepsis after elective major surgery. Methods: The study group consists of 211 patients undergoing major elective surgery. TNF-β NcoI polymorphism was studied in genomic DNA by analyzing restriction fragments of Nco1-digested DNA fragment using Polymerase Chain Reaction. All patients were followed for 1 month following surgery for any evidence of sepsis. Serum TNF-α levels were measured pre and postoperatively by Enzyme Linked Immunosorbent Assay. Genotypes and TNF-α production were related to the occurrence of sepsis if any. Results: 21.80% (n=46) of the patients developed postoperative sepsis. The overall mortality was 4.2% (n=9). The overall allele frequency of TNF-β genotype was 0.32 for TNFB1 and 0.68 for TNFB2. In TNF-β genotype, 11.84% (n=25) patients were homozygous recessive TNFB1, 41.23% (n=87) were heterozygous TNFB1/ TNFB2 and 46.91% (n=99) were homozygous dominant TNFB2. Incidence of postoperative sepsis was significantly (p=0.01) higher in patients homozygous for the allele TNFB2. When compared with patients carrying at least one TNFB1 allele (TNFB1 homozygous and heterozygous genotype), the TNFB2 homozygous genotype was associated with an Odds ratio of 2.60 (p=0.005; 95% CI 1.32 to 5.15) for the development of sepsis. Compared with the heterozygous genotype, the Odds ratio for the homozygous TNFB2 genotype was 3.00 (p=0.003; 95% CI 1.39 to 6.44). In patients with postoperative sepsis, TNF-α serum cytokine levels were significantly higher (p=0.02) in TNFB2 homozygous individual as compared to other genotypes. Conclusion: The development of sepsis was associated with higher capability to produce TNF-α after surgery. TNF-β Nco1 gene polymorphism is found to be associated with development of postoperative sepsis with increased TNF- α serum level. In patients without postoperative sepsis, the TNF-β polymorphism was not related to different levels of TNF-α production. This indicates an association between TNF-β polymorphism and postoperative sepsis, suggesting the B2/B2 genotype as a high risk factor for the development of sepsis after elective surgery.

838T

Genetic variation in the serotonin receptor gene affects immune responses in rheumatoid arthritis. *E. Hesselberg, O. Snir, P. Amoudruz, L. Klareskog, I. Zarea-Ganji, A.I. Catrina, L. Padyukov, V. Malmström, M. Seddighzadeh.* Department of Medicine, Karolinska Institutet, Stockholm, Sweden.

The functional effects of genetic variants associated with the risk of developing rheumatoid arthritis (RA) remain elusive. To assess the impact of the RA-associated serotonin receptor 2A (HTR2A) haplotype on immune cells, we genotyped patients with established RA (n=379) for the risk haplotype via two single-nucleotide polymorphisms (SNPs) in the HTR2A locus: rs6314 and rs1328674. Low-resolution HLA-typing was also performed, and anti-citrullinated protein antibody (ACPA) levels were measured. Patients with and without the RA-associated TC haplotype were selected and T-cell and monocyte function was monitored following in vitro stimulations with staphylococcal enterotoxin B (SEB) and lipopolysaccharide (LPS) using multiparameter flow cytometry. Within the cohort, 44 patients were heterozygous for the TC haplotype (11.6%) while none were homozygous. Upon stimulation, T-cells from TC-carrier patients produced more proinflammatory cytokines (tumor necrosis factor alpha (TNF-α), interleukin-17 (IL-17), interferon gamma (IFN-γ), IL-2, and IL-10) and monocytes produced higher levels of TNF-α compared with patients carrying the non-TC haplotype (P<0.05 and 0.01, respectively). CD4+ and CD8+ T-cells reacted similarly to each other, however, this effect was more significant in CD4+ cells. Such cytokine production could be inhibited in the presence of the selective 5-HT2 receptor agonist (2,5-Dimethoxy-4-iodoamphetamine, DOI); interestingly, this effect was more pronounced in TC carriers. DOI presence also enhanced production of IL-6 and IL-10 with LPS for some patients. HLA type and ACPA-status was not found to significantly correlate to cytokine production variability in this study. Our data demonstrate that association of RA with a distinct serotonin receptor haplotype has functional impact by affecting the immunological phenotype of T-cells and monocytes.

Regulation by the Asthma Susceptibility Gene DENND1B of Rab35 and TNFα signaling. *M.E. March, P.M.A. Sleiman, C. Hou, J. Bradfield, C.E. Kim, J.T. Glessner, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Asthma is a chronic inflammatory condition of the lungs, characterized by excessive responsiveness of the lungs to stimuli, in the forms of infections, allergens, and environmental irritants. Currently, 22.9 million Americans suffer from asthma, and the prevalence has increased dramatically since 1980. Asthma is the leading chronic illness in U.S. children, with 6.8 million affected in 2006. Twin studies have shown that there is a genetic element to asthma susceptibility (with heritability of the condition estimated at between 0.36 and 0.77), but only a fraction of the heritability is explained with previously identified loci. In a genome wide association screen (GWAS), we identified DENND1B as a novel asthma susceptibility locus. At least two splicing isoforms of DENND1B exist, and we have attempted to examine the relative activities of these isoforms. Overexpression of the short or long isoform of DENND1B had opposite effects on the response of cells to TNFα stimulation, with the long isoform enhancing the response and the short isoform diminishing it. The long isoform shows localization to the plasma membrane, while the short isoform shows primarily cytoplasmic staining. The conserved DENN domain functions as a guanonucleotide exchange factor for the small GTPase Rab35. We have demonstrated that TNFα stimulation activates Rab35 through promotion of the GTP-bound form of the protein. We are currently determining the role of Rab35 in TNFα signaling and the influence of both DENND1B isoforms on that signaling.

840W

Mild deficiency of Methylenetetrahydrofolate reductase (MTHFR) increases resistance to malaria in mice. *D.N. Meadows[1], M. Pyzik[1,2], Q. Wu[3], S. Torre[1,2], P. Gros[1,2,4], S. Vidal[1,2,5], R. Rozen[1,3].* 1) Department of Human Genetics, McGill University, McGill University Health Centre, Montreal, Quebec, Canada; 2) Complex Traits Group, McGill University, McGill University Health Centre, Montreal, Quebec, Canada; 3) Department of Pediatrics, McGill University, McGill University Health Centre, Montreal, Quebec, Canada; 4) Department of Biochemistry, McGill University, Montreal, Quebec, Canada; 5) Department of Microbiology and Immunology, McGill University, Montreal, Quebec, Canada.

A common polymorphism (677C→T (A222V)) in methylenetetrahydrofolate reductase (*MTHFR*) results in a mild enzymatic deficiency and hyperhomocysteinemia. MTHFR generates 5-methyltetrahydrofolate, the primary circulatory form of folate, which is utilized in homocysteine remethylation to methionine. Homozygosity for this SNP is a risk factor for neural tube defects and may also increase risk for vascular disease, pregnancy complications and cancer. Despite these selective pressures against the T allele, homozygosity is frequent (~5-15% in many populations, with highest levels in the Mediterranean region and Hispanic populations). To determine whether mild MTHFR deficiency may have been maintained through a selective advantage against malaria, as suggested for other human mutations in the Mediterranean region, we examined Mthfr-deficient mice and MTHFR-overexpressing mice for resistance to cerebral malaria infection with *Plasmodium berghei* ANKA (*Pb*A). Male mice received 10^5 parasites and survival was monitored over 2 weeks. Compared with wild-type littermates, $Mthfr^{+/-}$ mice survived infection longer (p=0.02; log-rank test), and $MTHFR^{Tg}$ mice died more quickly (p<0.05; log-rank test). Percent parasitemia revealed a trend (p=0.067) toward lower values in $Mthfr^{+/-}$ (5.5±0.5) compared with $Mthfr^{+/+}$ (7.0±0.4) mice, with no differences in this parameter in $MTHFR^{Tg}$ mice. Splenocytes analyzed by flow cytometry with several markers for T and NK cell populations, showed increased numbers of total lymphocytes, as well as more $CD4^+$ and $CD8^+$ T cells and more $CCR4^+$ NK cells in $Mthfr^{+/-}$ animals, compared with $Mthfr^{+/+}$ mice (p<0.05 for all cell types). $MTHFR^{Tg}$ mice showed decreased numbers of NK cells (p<0.05) as well as decreased numbers of $CCR4^+$ NK cells (p<0.01). Serum interferon-γ (IFNγ) levels, measured by ELISA, were lower in $Mthfr^{+/-}$ mice (88.7±27.3 pg/mL) compared with $Mthfr^{+/+}$ mice (217.1±49.6pg/mL) (p<.05). IFNγ levels in tissues, measured by immunoblotting, were higher (by ~40%) in spleen (p<0.01) and brain (p<0.001) of $Mthfr^{+/-}$ compared with $Mthfr^{+/+}$ mice. Our results suggest that differences in the balance between pro- and anti-inflammatory immune modulators in $Mthfr^{+/-}$ mice may protect them from *Pb*A infection. This is the first time that mild MTHFR deficiency has been shown to confer an advantage, in the outcome of malarial infection, suggesting a possible mechanism that may have maintained the 677 polymorphism in human populations.

***In vivo* modeling of genetic mechanisms associated with sickle cell disease nephropathy.** *B.R. Anderson[1], E.E. Davis[2], M.J. Telen[3], A.E. Ashley-Koch[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Pediatrics, Duke University Medical Center, Durham, NC; 3) Department of Medicine, Duke University, Durham, NC.

End-organ damage in patients with sickle cell disease (SCD) has become an emergent clinical priority over recent decades due to the increased lifespan of affected individuals. Renal failure, which occurs in 4-12% of SCD patients and is strongly associated with early mortality, has become a particular concern. The detection of sickle cell disease nephropathy (SCDN) relies on relatively late markers of the disease process, namely proteinuria and reduced glomerular filtration rate (GFR). Therefore, at-risk SCD patients cannot be identified prior to end-organ damage. A genomic region on human chromosome 22 containing two genes, *MYH9* and *APOL1*, has been associated with non-SCD nephropathy, although the primary gene responsible has remained elusive due to strong linkage disequilibrium in this region. Our group demonstrated that both *MYH9* and *APOL1* are strong, independent genetic predictors of risk for proteinuria in SCD (Ashley-Koch *et al*., 2011). Here, we use zebrafish as a model to study the contribution of each gene (*myh9* and *apol1*) to kidney function and filtration. To test independent effects of the knockdown of *myh9* or *apol1*, we injected morpholino antisense oligonucleotides in wild-type zebrafish embryos; this resulted in generalized edema and reduced glomerular filtration (as measured by quantitative dextran clearance) for both gene suppression models. These morphant phenotypes were rescued significantly by co-injection of each respective wild type human *MYH9* and *APOL1* mRNA. Importantly, co-injection of human mRNA corresponding to other *APOL* gene family members did not significantly rescue the observed phenotype, suggesting that *apol1* is indeed the functional ortholog to the human gene. Next, we investigated the possibility of a genetic interaction between *MYH9* and *APOL1* by co-suppression of each of the zebrafish orthologous genes. We observed no additive or synergistic effects. Instead, the double morphants were indistinguishable from the *myh9* morpholino alone, and neither single morpholino could be rescued by the human mRNA of the other gene. These data suggest that *MYH9* and *APOL1* may function independently, but converge on the same biological process to give rise to SCDN. By offering new insights into the contribution of genes that regulate renal function, these results further our understanding of the pathogenesis of SCDN and provide genetic markers for the identification of at-risk SCD patients prior to the onset of kidney dysfunction.

Evolution and functional genomics of host-pathogen interaction in Crohn's Disease. *B.M.P. Bowen, W. Zhang, K. Hui, J.H. Cho, TAGC.* Department of Genetics, Yale University, New Haven, CT.

Crohn's disease (CD), a type of inflammatory bowel disease, affects over a million people worldwide.The prevalence of CD among individuals of Ashkenazi Jewish (AJ) ancestry is 4-7 times higher than that of non-Jewish Europeans. Genome-wide association studies have shown a remarkable overlap between the most strongly associated CD genes and mycobacterial susceptibility genes (but opposite risk alleles), which is of particular interest given the history of mycobacterial resistance documented in the AJ population. In order to determine if the role of CD genes in response to mycobacteria contributes to the AJ CD prevalence discrepancy, we combined computational and functional genomics data from AJ and European non-Jewish (EA) cases and controls. We completed whole genome sequencing of 128 AJ genomes as part of The Ashkenazi Genome Consortium, which revealed a number of CD/mycobacterial susceptibility genes containing variants with derived allele frequencies that were lower or absent in non-Jewish Europeans. This observation led us to hypothesize that these common derived alleles that currently confer susceptibility to CD conferred a past fitness advantage in terms of controlling mycobacterial infection. We then performed functional genomic studies of host response to acute and latent mycobacterial infection in monocyte-derived macrophages (MDMs) from AJ CD cases and controls, as well as EA CD cases and controls. In response to the pathogen Mycobacterium bovis BCG, a mycobacterial strain with antigenicity similar to that of tuberculosis, we report marked inter-individual variability in the efficacy of mycobacterial killing and population differences in serum cytokine levels of TNF, IFN, IL10, and IL1b throughout the course of infection. Lastly, we previously reported a NOD2 co-expression network connecting many CD susceptibility genes identified in the Immunochip, and here we identify that same co-expression network in MDM responses to BCG infection in AJ cases and controls, suggesting that CD susceptibility genes do play a role in mycobacterial clearance.

843W

Identification of a regulatory variant that binds a transcriptional activator complex including FOXA1 and FOXA2 at the *CDC123/CAMKD* type 2 diabetes GWAS locus. *M.P. Fogarty[1], S. Vadlamudi[1], M.E. Cannon[1], K.J. Gaulton[2], K.L. Mohlke[1].* 1) Dept Genetics, Univ North Carolina, Chapel Hill, NC, USA; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

For many of the type 2 diabetes (T2D) loci identified through genome-wide association studies, signals are localized to non-protein-coding intronic and intergenic regions and likely contain variants that regulate gene transcription. The *CDC123/CAMK1D* T2D association signal on chromosome 10 spans an intergenic region between *CDC123* and *CAMK1D* and also overlaps the *CDC123* 3'UTR. To gain insight into the molecular mechanisms underlying this association signal, we examined all SNPs in LD $r^2 \geq .7$ (CEU, 1000G phase 1) with the GWAS index SNP rs12779790 overlapping a predicted regulatory region. Maps of islet and liver open chromatin, histone modifications and transcription factor ChIP-seq were used to identify potential regulatory elements. Based on these criteria, two regions containing T2D-associated variants were tested for enhancer activity using luciferase reporter assays. A 151 bp region surrounding rs11257655 located 15 kb from the 3' end of *CDC123* and 84 kb from the 5' end of *CAMK1D* displayed allele-specific transcriptional activity in rat 832/13 and mouse MIN6 insulinoma cells as well as in human HepG2 hepatocellular carcinoma cells. The rs11257655 risk allele T showed greater transcriptional activity then the non-risk allele C in all cells tested (832/13 $P = 6 \times 10^{-3}$, MIN6 $P = 2 \times 10^{-5}$, HepG2 $P = 8 \times 10^{-6}$). Site-directed mutagenesis of a second SNP included in the 151 bp region due to proximity verified rs11257655 as the driver of allelic differences in enhancer activity. Increased transcriptional activity with the rs11257655 T2D risk allele T is consistent with the direction of an eQTL for *CAMK1D* in blood (Voight, Nat Genet 42; 579). Data from the ENCODE consortium demonstrate binding of FOXA1 and FOXA2 transcription factors in HepG2 cells to a region that overlaps rs11257655. We next used DNA affinity capture and electromobility shift and supershift assays to assess whether a 20 bp region containing alleles of rs11257655 differentially binds these factors. The rs11257655 T allele showed allele specific binding of FOXA1/FOXA2 in beta cell lines and hepatocellular carcinoma cells. Taken together these results demonstrate the utility of maps of regulatory activity to guide identification of regulatory variants. The results suggest that rs11257655 is part of a *cis* regulatory complex affecting transcriptional activity through binding of a protein complex that includes FOXA1 and FOXA2 providing a potential molecular mechanism at this GWAS locus.

844T

Gene-gene interaction and RNA splicing profiles of MAP2K4 gene in rheumatoid arthritis. *K. Shchetynsky, M. Roninnger, D. Protsyuk, L. Klareskog, L. Padyukov.* Rheumatology Unit, Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden.

Background and objectives: MAP2K4 encodes a mitogen activated protein kinase kinase 4 (MKK4), important for optimal activation of JNK1-3 and p38 ~ the two members of the MAP kinase family. In this study we explore the interaction between MAP2K4 locus and two major known genetic risk factors for autoantibody positive rheumatoid arthritis (RA) ~ HLA-DRB1 shared epitope (SE) alleles and PTPN22 rs2476601. We also address the balance in the expression of alternative MAP2K4 splice forms and its association with known SE and PTPN22 genotypes and the autoantibody profile of the disease. **Methods:** The genotypes from 1985 patients with RA and 2252 matched healthy controls from the Swedish EIRA study population and from 863 RA cases and 1181 controls from the NARAC were used in the study. The interaction analysis was performed on 22 SNPs from the MAP2K4 locus, HLA-DRB1 shared epitope alleles and rs2476601 from PTPN22 by calculation the attributable proportion due to interaction (AP). We studied transcript diversity of MAP2K4 and investigated relative expression of MAP2K4 forms in peripheral mononuclear cells for 44 RA patients and 44 controls of Caucasian ancestry. These results were analyzed against available genotypic and phenotypic data. **Results:** We found MAP2K4 rs10468473 in statistical interaction with SE, and PTPN22 rs2476601 in autoantibody positive RA (AP 0,197 [95% CI 0,098 - 0,296] and AP 0,28 [95% CI 0,074-0,48] respectively; EIRA+NARAC) in two independent cohorts and a combined meta-cohort. In our assessment of allelic expression, RA patients heterozygous for rs10468473 demonstrated significantly elevated MAP2K4 expression in comparison to individuals homozygous for G allele. We also observed a novel 'skipped exon' type RNA splice variant of MAP2K4 in our study material, and a potential protein isoform of corresponding molecular weight. MAP2K4 splice forms were differentially expressed in peripheral blood material from 88 RA cases and controls. Within the group of RA patients, a correlation was observed between MAP2K4 variants expression and number of carried SE alleles, as well as with other phenotypic data. **Conclusion:** Our data suggest interaction between MAP2K4, PTPN22 and HLA-DRB1 in development of autoantibody positive rheumatoid arthritis. We also found an allele-specific effect of rs10468473 on MAP2K4 expression, and splicing events in transcripts from the MAP2K4 locus that could be relevant in disease pathogenesis.

845F

A polymorphism in human estrogen-related receptor beta (ESRRβ) associated with physiologic measures of noise-induced hearing loss. *I. Bhatt[1], S. Phillips[1], S. Richter[2], R. Morehouse[3], D. Tucker[1], K. Lundgren[1], V. Henrich[4].* 1) Communication Sciences and Disorders, University of North Carolina at Greensboro, Greensboro, NC. 27402, USA; 2) Department of Mathematics and Statistics, The University of North Carolina at Greensboro, Greensboro, NC 27402, USA; 3) Department of Communication Sciences & Disorders, Appalachian State University, Boone, NC, 28608, USA; 4) Center for Biotechnology, Genomics & Health Research, The University of North Carolina at Greensboro, Greensboro, NC 27402, USA.

Noise-induced hearing loss (NIHL) is a common form of hearing loss and a growing health concern despite national standards for hearing protection and public health awareness campaigns. An NIHL gene association study with college-aged musicians has associated a non-synonymous single nucleotide polymorphism (rs61742642; C→T, P386S) in the ligand-binding domain of human estrogen-related receptor beta (ESRRβ, OR = 2.8, CI = 1.4-5.9, p = 0.003) with increased susceptibility to bilateral 4 to 6 kHz hearing loss. ESRRβ is expressed in major cochlear structures except hair cells. Methods: The purpose of the study was to examine the effects of the ESRRβ polymorphism on both pre-noise exposure (baseline) cochlear physiology and on temporary changes in hearing sensitivity following a brief noise exposure. We examined baseline cochlear physiology by pure-tone audiometry, distortion product otoacoustic emissions (DPOAE growth function and high resolution DPgram), transient-evoked otoacoustic emissions (TEOAE) and TEOAE suppression in 40 and 20 participants carrying the ESRRβ rs61742642 CC vs. CT genotype respectively. Temporary changes in hearing sensitivity were induced by 10 minutes exposure to 90 dB SL narrowband noise (center frequency = 2 kHz) and the changes were evaluated by audiometry (at 2, 3 and 4 kHz). Results: Baseline DPOAE amplitudes were lower across the 2 to 4 kHz frequency range (DPgram overall mean difference (MD) = 2.66 dB, p = 0.03; DP growth function overall MD = 1298.7μPa^2, p = 0.026) in the participants with a CT genotype compared to a CC genotype. Baseline TEOAE contralateral suppression was reduced (MD = 0.35 dB, CI = -0.69 to -0.006, p = 0.046) in participants with the CT genotype. Regression analysis showed that individuals carrying the CT genotype acquired greater deterioration (p <0.001) in hearing sensitivity (MD = 3.47 dB, CI = 1.94 - 4.99) following 10 minutes of noise exposure compared to the participants with CC genotype. Conclusions: The results indicate that individuals with the ESRRβ polymorphism show reduced outer hair cell activity possibly due to poor chemical regulation. They also showed impaired activity of medial olivocochlear nerve fibers and acquired greater deterioration in hearing sensitivity following the noise exposure. These data suggest that the ESRRβ polymorphism increases susceptibility to NIHL, and also indicate the efficacy of otoacoustic emissions testing for identifying sound processing endophenotypes.

846W

Genetic risk variants for autoimmune diseases regulate gene expression in thymus. *I.S.M. Gabrielsen[1], S. Svanstrøm Amundsen[1], H. Helgeland[1], S. Tennebø Flåm[1], N. Hatinoor[1], K. Holm[2], M.K. Viken[1], B.A. Lie[1].* 1) Medical Genetics, Oslo University Hospital, Oslo, Oslo, Norway; 2) Norwegian PSC Research Center, Division of Cancer Medicine, Surgery and Transplantation, Oslo University Hospital, Oslo, Norway.

Genome-wide association studies (GWAS) have boosted our knowledge of genetic risk variants in autoimmune diseases (AIDs). Despite the fact that AIDs are extremely heterogeneous, GWAS indicate that certain loci and genes seem to predispose to multiple immune-related diseases. Most of the genetic risk variants for AIDs are located within or near genes with immunological functions, but because the majority is found to be non-coding, it's considerable to believe that these risk variants have a regulatory role. Expression quantitative trait locus (eQTL) screening is a widely used method to investigate gene regulation, and by correlating genetic association data with gene expression data, genetic risk factors acting through regulatory variants could be determined. Based on this, and the fact that thymus is an immunological important organ, we have performed an eQTL screen to investigate whether single nucleotide polymorphisms (SNPs) associated with AIDs influence gene expression in thymic tissue (i.e. whether disease associated SNPs serve cis-acting regulatory functions). The genotypes from 42 Norwegian thymic tissue samples genotyped using the Immunochip were analyzed for 420 AID-associated SNPs selected from the National Institute of Health's catalog of GWA studies (NHGRI). Gene expression was measured using Illumina Human WG-6 v3 and genotypes were correlated with gene expression of surrounding genes (± 1Mb of the SNP). By logistic regression analysis, we robustly identified 7 genes (FCRL3, LOC339804, ERAP1, RNASET2, LOC728734, SIRPG and LOC388814) that correlated with disease-associated SNPs at a study-wide level of significance ($P < 2.12\times10^{-5}$). Fine mapping of these regions led to the discovery of even stronger correlating SNPs within four regions: rs10181042 (LOC339804, $P < 3.5\times10^{-10}$), rs30377 (ERAP1, $P < 3.3\times10^{-11}$), rs429083 (RNASET2, $P < 2.2\times10^{-09}$) and rs991774 (LOC388814, $P < 7.2\times10^{-07}$). The regulatory function of the risk polymorphisms and proxy SNPs in strong linkage disequilibrium (r^2>0.8) were evaluated using the RegulomDB. Newly defined SNPs associated with AIDs from recent Immunochip projects were also included. Combining these resources we have highlighted functional variants for 7 genetic regions that potentially can represent causal autoimmune risk variants. We conclude that our study shows that several autoimmune risk variants act as eQTLs in thymus.

847T

The apical sodium-dependent bile acid transporter ASBT (*SLC10A2*) affects the progression of primary biliary cirrhosis in Japanese patients via its transcriptional activity. *K. Taira[1], T. Inamine[1], A. Kawauchi[1], S. Kondo[1], M. Nakamura[2,3], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch, Nagasaki, Japan; 2) Dept Hepatology, Nagasaki Univ Grad Sch, Omura, Japan; 3) Clin Res Center, Natl Hosp Organi Nagasaki Med Center, Omura, Japan.

PURPOSE Primary biliary cirrhosis (PBC) is a chronic liver disease characterized by destruction of the intrahepatic small bile ducts, leading to cholestasis, fibrosis, cirrhosis, and eventually liver failure. In order to identify the genetic determinants of PBC progression, we focused on apical sodium-dependent bile acid transporter (ASBT, encoded by *SLC10A2*), which plays a key role in reabsorption of luminal bile acids in epithelial cells of the intestines under the enterohepatic circulation, examined an association between *SLC10A2* polymorphisms and the susceptibility to PBC progression, and investigated the function of these polymorphisms. METHODS A total of 309 Japanese PBC patients were classified into the following two groups (early stage and late stage) based on liver biopsy results and/or clinical manifestations. The 12 tag single nucleotide polymorphisms (SNPs) in *SLC10A2* were genotyped by PCR-restriction fragment length polymorphism or -direct DNA sequencing. Furthermore, the 2.5-kb upstream promoter sequences of *SLC10A2* were subject to PCR-direct DNA sequencing in order to identify new SNPs within this region. The frequencies of alleles and genotypes of 15 SNPs including 3 newly identified SNPs were compared between PBC patients in early and late stages by chi-square test. To investigate the function of the SNP associated with PBC progression, the 50-bp promoter sequence containing the allele of the associated SNP, which was incorporated into luciferase reporter plasmid, was transfected into Caco-2 cells, and the luciferase activities were compared between two alleles of the associated SNP. RESULTS Five SNPs of *SLC10A2*, including 3 newly identified SNPs in the promoter region, showed the significant association with PBC progression. Among them, one of the newly identified SNPs indicated more stronger association with PBC progression and affected the transcriptional expression of *SLC10A2* in Caco-2 cells. CONCLUSION Our results suggest that PBC patients with the low-risk allele of *SLC10A2* may represent lower expression of ASBT and then diminution of reabsorption of luminal bile acids in comparison to those without the allele, resulting in a decrease in enterohepatic circulation of bile acids and eventually leading to slower PBC progression. Thus, *SLC10A2* appears to be a genetic determinant of PBC progression in Japanese patients.

Comprehensive functional assays for variants of unknown significance. *J.O. Kitzman[1], L. Starita[1,2], R. Lo[1,2], R. Qiu[1], S. Fields[1,2], J. Shendure[1].* 1) Dept Genome Sciences, Univ Washington, Seattle, WA; 2) Howard Hughes Medical Institute.

With the relative ease of variation discovery by massively parallel sequencing, functional interpretation becomes an increasingly critical bottleneck in human genetics. As a case in point, clinical diagnostics frequently reveal missense variants of uncertain significance (VUS), even in genes with clear disease relevance such as the tumor suppressor BRCA1, the primary risk factor for inherited breast cancer. To address this bottleneck, we demonstrate a massively parallel mutagenesis approach called PALS (Programmed ALlelic Series). This approach uses libraries of microarray-derived mutagenesis primers to direct synthesis of every possible missense mutant of a gene of interest. As a proof of principle, we designed a library comprising all possible single-codon substitutions in the human tumor suppressor gene TP53 and a similar library for the well-characterized yeast transcription factor GAL4. Deep sequencing and tag-directed assembly (Hiatt et al., Nat Methods 2010) revealed that each library covered the majority of the designed mutational space. To demonstrate how PALS libraries could be used to comprehensively profile loss-of-function mutations, we subjected the GAL4 library to a function-dependent, in vivo screen in budding yeast. In this type of selection experiment, mutant haplotypes' fitness values are determined by deep sequencing to estimate their abundances before and after selection. This assay revealed a subset of missense variants which, together with the clear loss-of-function variants (premature stops and frameshift mutations), exhibited no activity and were depleted by selection. This approach - massively parallel synthesis and sequencing coupled to functional selection - provides a general framework for deep surveys of the functional impacts of mutations to clinically relevant genes.

Expression of Two Genes from the Candidate Locus of Chromosome X in Rheumatoid Arthritis and Systemic Sclerosis. *L.M. Diaz-Gallo[1,2], K. Shchetynsky[1], A. Nordin[1], A.I. Catrina[1], J. Martín[1,2], L. Padyukov[1].* 1) Karolinska Institutet, Stockholm, Stockholm, Sweden; 2) 2.Instituto de Parasitología y Biomedicina López-Neyra, IPBLN-CSIC, Granada, Spain.

There is increasing evidence of association between variants at Xq28 genomic region and autoimmune diseases (AIDs). The genes interleukin-1 receptor-associated kinase 1 (IRAK1) and methyl-CpG-binding protein 2 (MECP2) are located there. We evaluated if there was differential mRNA expression of the IRAK1 and MECP2 between rheumatoid arthritis (RA) patients, systemic sclerosis (SSc) patients and healthy controls. Additionally, we assessed the correlation of IRAK1 and MECP2 expression levels with the rs1059702 and rs17435 polymorphisms located in this locus and previous associated to AIDs. The gene expression of IRAK1 and MECP2 was measured using quantitative PCR by TaqMan assays. We studied 50 RA patients, 35 SSc patients and 52 healthy controls from a European descendent population, all females. Predesigned TaqMan 5' SNP genotyping assays were used to genotype the mentioned SNPs in the available genomic DNA from the studied subjects. The IRAK1 and MECP2 expression was significantly different between the RA patients, SSc patients and controls (p=0.0003, p= 0.0006 respectively, Kruskal-Wallis test). When we compared each group of patients against controls we observed that the IRAK1 expression was significantly decreased in the RA patients compared with controls (p= 0.0022;RA relative quantity (RQ) mean=42.37; controls RQmean=60.28, Mann-Whitney test). But there was no significant difference between the levels of IRAK1 expression between SSc patients and controls (p=0.39; SSc RQmean=46.8; controls RQmean=42.12). We found no significant difference in the MECP2 expression levels between RA patients and controls (p=0.05; RA RQmean=45.72; controls RQmean=57.06). Meanwhile, the SSc patients exhibited a significant increased expression level of MECP2 compared with controls (p=0.017; SSc RQmean=51.86; controls RQmean= 38.71). Finally, we observed that there was a moderated positive correlation between the IRAK1 and MECP2 expression in the studied individuals (correlation coefficient=0.613, p<0.0001). Although the difference was not statistically significant, the homozygous for the minor allele of the rs1059102 tend to express higher levels of both IRAK1 and MECP2 genes. Our study showed an altered expression of IRAK1 and MECP2 genes in both RA and SSc compared to the controls. This study increases the evidence that suggest an important pathogenic role of this X chromosome locus in AIDs.

850T

An enhancer element harboring variants associated with systemic lupus erythematosus engages the *TNFAIP3* promoter to influence A20 expression.
S. Wang[1], F. Wen[1], G.B. Wiley[1], M.T. Kinter[2], P.M. Gaffney[1]. 1) Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma city, OK, 73104; 2) Free Radical Biology and Aging Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, 73104.

Functional characterization of causal variants present on risk haplotypes identified through genome-wide association studies (GWAS) is a primary objective of human genetics. In this report, we evaluate the function of a pair of tandem polymorphic dinucleotides, (rs148314165, rs200820567, collectively referred to as TT>A) recently nominated as causal variants responsible for genetic association of systemic lupus erythematosus (SLE) with tumor necrosis factor alpha inducible protein 3 (*TNFAIP3*). *TNFAIP3* encodes the ubiquitin-editing enzyme, A20, a key negative regulator of NF-κB signaling. A20 expression is reduced in subjects carrying the TT>A risk alleles, however, the underlying functional mechanism by which this occurs is unclear. We used a combination of electrophoretic mobility shift assays (EMSA), mass spectrometry (MS), reporter assays, chromatin immunoprecipitation-PCR (ChIP-PCR) and chromosome conformation capture (3C) EBV transformed lymphoblastoid cell lines (LCL) from individuals carrying risk and non-risk *TNFAIP3* haplotypes to characterize the effect of TT>A on A20 expression. Our results demonstrate that the TT>A variants reside in an enhancer element that binds NF-κB and SATB1 enabling physical interaction of the enhancer with the *TNFAIP3* promoter through long-range DNA looping. Impaired binding of NF-κB to the TT>A risk alleles or knockdown of SATB1 expression by shRNA, inhibits the looping interaction resulting in reduced A20 expression. Together, these data reveal a novel mechanism of *TNFAIP3* transcriptional regulation and establish the functional basis by which the TT>A risk variants attenuate A20 expression through inefficient delivery of NF-κB to the *TNFAIP3* promoter. These results provide critical functional evidence supporting a direct causal role for TT>A in the genetic predisposition to SLE.

Gene-gene interactions of EG-VEGF, PKR1 and PKR2 genes and the risk of recurrent miscarriages.
M. Su[1], P. Kuo[1], S. Lin[2]. 1) National Cheng-Kung University Hospital, Tainan City, Taiwan; 2) Insitute of clinical medicine, National Cheng-Kung Univeristy, Tainan City, Taiwan.

Background: Endocrine gland-derived vascular endothelial growth factor (EG-VEGF) and its receptor genes (PKR1 and PKR2) play an important role in human early pregnancy. Our previous study showed that PKR1 and PKR2 polymorphisms are associated with recurrent miscarriages (RM). This study was conducted to find EG-VEGF, PKR1 and PKR2 variants in the coding regions of idiopathic RPL patients and further evaluate gene-gene interactions in 3 genes. Methods: Two hundred and ninety one blood samples from 142 RPL women and 149 controls were nucleotide sequenced in the coding regions of EG-VEG, PKR1 and PKR2. Gene-gene interaction was evaluated in 3 gene variants using multifactor dimensionality reduction (MDR) method. Result(s): One each nonsynonymous variant of 3 genes were identified, and PKR1(I379V) and PKR2(V331M) were significantly associated with idiopathic RM (p=0.006 and p=0.002, respectively). Genetic interactions were founded not only between PKR1(I379V) and PKR2(V331M), but also among EG-VEGF (V67I), PKR1(I379V) and PKR2(V331M) (p=0.01 and p=0.01, respectively). Women carried low-risk genotypes reduced 77% risk of experiencing miscarriages compared with those carried high-risk genotypes. Conclusion(s): The present study corroborates the clinical relevance of the EG-VEGF system in human early pregnancy, and provides evidence for the gene-gene interactions of EG-VEGF and PKR variants.

Occupational asbestos exposure has been found to increase lung cancer risk based on epidemiologic studies. In order to clarify the respective roles of genetic factors and asbestos exposure on lung cancer risk, we conducted the asbestos exposure-gene interaction analyses among Caucasian populations who are current or ex-smokers. The stage 1 discovery stage included 833 Caucasian cases and 739 Caucasian controls using Illumina Human 610-Quad BeadChips. Several independent populations were included in the second replication stage. Cumulative lifetime asbestos exposure score (AES), which was previously developed and validated in our study population, was calculated from self-reported duration and intensity of occupational and nonoccupational exposures. The top ranked SNPs from discovery stage were replicated within International Lung and Cancer Consortium (ILCCO). A two-stage replication approach was conducted. First in silico replication was conducted in those groups that have GWAS and asbestos exposure data, including 1548 cases and 1544 controls. Followed by de novo genotyping to replicate the results from in silico replication, 1539 cases and 1761 controls were genotyped. In order to have the data comparable between studies, genotyping results were imputed by MACH using 1000 Genome dataset. Asbestos exposure measurements were recategorized as 'high' or 'low and none' asbestos exposure effects based on each group's previous findings. Logistic regression adjusted for potential confounders was used to assess the SNP-asbestos exposure interaction effect on lung cancer risk. The top associated findings been found are located at 22q13.31, 8p22, 16p11.2, which have been reported in association with carcinogenesis and inflammatory response. Further functional analysis will be conducted among the regions.

853T

***RBMS1* genotype strongly influences adiposity and liver function in rural but not urban dwellers.** *M.E.S. Bailey[1], C.A. Celis-Morales[2], M. Staunton[1], N. Ulloa[3], C. Calvo[3], F. Perez-Bravo[4], J.M.R. Gill[5].* 1) School of Life Sciences, College of Medical, Veterinary and Life Sciences, University of Glasgow, Glasgow, United Kingdom; 2) Human Nutrition Research Centre, Institute for Ageing and Health, Newcastle University, Newcastle, UK; 3) Department of Clinical Biochemistry and Immunology, Faculty of Pharmacy. University of Concepcion, Chile; 4) Laboratory of Nutritional Genomics, Department of Nutrition, Faculty of Medicine, University of Chile, Santiago, Chile; 5) Institute of Cardiovascular and Medical Sciences, CMVLS, University of Glasgow, Glasgow, UK.

RBMS1 encodes a set of single-stranded DNA-binding proteins that may have roles in regulation of DNA replication, gene expression, cell cycle and cell fate. GWAS meta-analysis and other studies have implicated *RBMS1* as a risk gene in obesity and type 2 diabetes. We show that *RBMS1* strongly influences levels of subcutaneous body fat and cardiometabolic risk-related phenotypes across populations but only in those living a more traditional lifestyle. We analysed an *RBMS1* SNP, rs7593730 (C/T alleles), for association with a range of quantitative trait measures in a cross-sectional population sample from Chile (n=300), including male and female adults of both native American (Mapuche) and European ethnicity living in urban and rural environments. Participants were assessed for a wide range of physical, metabolic, social and environmental variables, including body fat (aggregate of 4 skinfold measures). The T allele (f=0.14 in Europeans, 0.05 in Mapuche) was found to be strongly associated with lower levels of subcutaneous fat, insulin resistance (HOMA-IR) and ALT, and with higher levels of HDL cholesterol (all p<0.00015), with similar effect sizes in Europeans and Mapuche. The association with body fat was still observed (genotype p= 0.009) after adjustment for age, sex, ethnicity, sociodemographic factors, activity (sedentary time, MVPA) and overall food intake. This SNP was also weakly associated with several other variables, including cardiorespiratory fitness. The genotypic association with HOMA-IR was partially independent (genotype p=0.009) of body fat. Genotype was found, in fully adjusted models, to interact strongly with both living environment (rural vs urban; interaction p=0.0004) and fitness (interaction p=0.006) in its effect on adiposity. In stratified analyses, genotype was found to influence body fat strongly in rural dwellers but not urban dwellers, and more strongly in fitter individuals. In fully adjusted models, rs7593730 explained >17% of the variance in adiposity in the rural group (p<0.00001), each copy of the T allele lowering fat levels by >0.4 SDs. These findings support the idea that there may be subgroups defined by genotype in whom activity-boosting interventions to reduce adiposity may be more effective. Furthermore, they suggest that a portion of the cardiometabolic disease risk associated with a Westernised lifestyle may result from the suppression of specific genetic influences on primary risk factors in the urban environment.

Gene-Lifestyle Interaction and Type 2 Diabetes. *R.A Scott on behalf of The InterAct Consortium.* MRC Epidemiology Unit, Cambridge, United Kingdom.

Rapid progress has been made in the understanding of the genetic basis of type 2 diabetes (T2D). It is uncertain whether testing for genetic susceptibility to T2D may be useful to guide decisions about lifestyle interventions. The InterAct study includes 12,403 incident T2D cases and a representative subcohort of 16,154 individuals from a total cohort of 340,234 participants from 8 European countries followed for 3.99 million person-years. We studied the combined effects of an additive genetic T2D risk score comprising 49 variants associated with T2D and modifiable and non-modifiable risk factors using Prentice-weighted Cox-regression and random effects meta-analysis methods. The effect of the genetic score differed significantly by age at study entry (p_{int}=1.20×10^{-4}), due to a larger genetic effect in cases who developed diabetes early (<55 years), compared to later. Relative genetic risk (per standard deviation (4.4 risk alleles)) was also larger in participants who were leaner, both in terms of BMI and waist circumference (WC) (HR normal weight 1.62 (1.50, 1.74), overweight 1.46 (1.37, 1.56), obese 1.27 (1.17, 1.39), p_{int}=1.50×10^{-3}; HR low WC 1.60 (1.49, 1.72), medium WC 1.53 (1.39, 1.68), large WC 1.29 (1.18, 1.40), p_{int}=7.49×10^{-9}). Only one variant (ADCY5 rs11717195 for SNP by BMI interaction) was below the Bonferroni-corrected threshold for individual significance (p_{int}=7.2×10^{-6}), again showing a larger genetic effect size in smaller individuals. Absolute risk demonstrated the strong overall preponderance of obesity for T2D risk; the cumulative T2D incidence over 10 years (per hundred) rose from 0.25, 0.44, and 0.53 to 0.89 across quartiles of the genetic score in normal weight individuals, compared to 4.22, 5.78, 5.83 and 7.99 in obese individuals. We detected no significant interactions between the genetic score and sex, diabetes family history, physical activity, or dietary habits assessed by a Mediterranean diet pattern score. The high absolute risk associated with obesity at any level of genetic risk highlights the importance of universal approaches to lifestyle intervention.

855W

Gene carbohydrate and gene fiber interactions and type 2 diabetes in diverse populations from the National Health and Examination Surveys as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study. *R. Villegas, R.J. Goodloe, B. McClellan Jr, J. Boston, D.C. Crawford.* Med, Vanderbilt Univ, Nashville, TN.

Both environmental and genetic factors impact Type 2 diabetes (T2D). Environmental modifiers of known genotype-T2D associations may account for some of the "missing heritability" of these traits. To identify such modifiers, we genotyped 15 T2D-associated variants identified through genome-wide association studies (GWAS) in 6414 non-Hispanic white, 3073 non-Hispanic black and 3633 Mexican American samples collected for the National Health and Nutrition Examination Surveys (NHANES). In this paper we evaluated interactions between these variants with carbohydrate intake and with fiber intake. We performed logistic regression analysis testing for SNP associations with T2D levels in self-identified European American, African American and Mexican American. Only 1 association generalized across all three populations, rs7903146 (TCF7L2). High intake of carbohydrates was associated with higher risk of T2D while fiber was inversely related to T2D risk in analysis conducted in all participants and in analysis stratified by race. However the trend for the association between fiber and T2D in blacks was no significant and the association between carbohydrate intake and T2D in Mexicans was of marginal significance. We identified one SNP × carbohydrates interactions at a significance threshold of p < 0.05, in blacks (with IGFBP2, rs4402960) and one in Mexican Americans (with PPARG rs1801282). We found one gene-fiber interactions with ADAMT59 rs4607103 in African Americans and another gene-fiber interaction among Mexican Americans with PPARG rs1801282, both at P<0.05 level. We also evaluated the combined effect of genetic variants by calculating a genetic risk score (GRS) and interactions of the GRS with carbohydrate intake and fiber across the racial/ethnic groups. The odds ratio for T2D with each GRS point (per risk allele) was 1.10 (95% CI: 1.06-1.14) for European Americans, 1.07 (95% CI: 1.02-1.13) from non- Hispanic blacks and 1.12 (95% CI: 1.06-1.18) for Mexican Americans. The interaction factor between the GRS and both carbohydrate intake and fiber intake was significant in the non-Hispanic Blacks group but no association was found between the GRS with these 2 nutrients in non-Hispanic Whites or in Mexican Americans. Our results suggest that carbohydrate and fiber may modify genotype-phenotype associations and that this association differs by race.

856T

Variants in the Glucagon Gene are Associated with Baseline Weight and Glycemic Response to Metformin and Intensive Lifestyle Interventions in the Diabetes Prevention Program. *A.H. Winters[1], K.A. Jablonski[2], S.E. Kahn[3], W.C. Knowler[4], E.S. Horton[5], K.J. Mather[6], R.F. Arakaki[7], J.C. Florez[8, 9, 10], T.I. Pollin[11], DPP Research Group.* 1) Human Genetics, University of Maryland, Baltimore, Baltimore, MD; 2) The George Washington University Department of Epidemiology and Biostatistics The Biostatistics Center Rockville, MD; 3) Division of Metabolism, Endocrinology and Nutrition Department of Medicine VA Puget Sound Health Care System and University of Washington Seattle, WA; 4) Diabetes Epidemiology and Clinical Research Section National Institute of Diabetes and Digestive and Kidney Diseases Phoenix, AZ; 5) Joslin Diabetes Center, Harvard Medical School, Boston, MA; 6) Division of Endocrinology and Metabolism, Indiana University School of Medicine, Indianapolis, Indiana; 7) Department of Medicine Clinical Research, University of Hawaii, Honolulu, Hawaii; 8) Center for Human Genetic Research and Diabetes Research Center (Diabetes Unit) Massachusetts General Hospital; 9) Program in Medical and Population Genetics Broad Institute; 10) Department of Medicine Harvard Medical School; 11) Endocrinology, Diabetes and Nutrition, University of Maryland, Baltimore, Baltimore, MD.

The glucagon gene (*GCG*) codes for glucagon, glucagon-like peptides 1 and 2 (GLP1 and GLP2), glicentin, and oxyntomodulin, which have a number of different physiological effects including glucose homeostasis, weight gain and satiety. We hypothesized that variation in *GCG* affects glycemic traits and weight and modifies glycemic response to weight- and glucose-lowering interventions. The Diabetes Prevention Program (DPP) was a clinical trial testing metformin or a lifestyle intervention (systematic caloric and fat intake reduction and increase in physical activity) versus placebo on reducing type 2 diabetes development in those at high risk. We evaluated whether SNPs in *GCG* modify effects of these interventions in the DPP. Thirteen SNPs tagging common variations in *GCG* were evaluated for association with weight, fasting and two hour glucose, glycated hemoglobin and oral disposition index at baseline and 1 year. Among 2815 DPP participants, the T allele of rs2892827 (DPP minor allele frequency=0.14-0.19) was associated with greater weight at baseline (β=1.46[0.19, 2.73] kg/T allele; p=0.02). There were no significant SNP x treatment interactions on baseline-adjusted one year weight (interaction p=0.25 for lifestyle and p = 0.24 for metformin). There was a significant interaction on fasting glucose with both treatments (p=0.02 for SNP*lifestyle and p=0.04 for SNP*metformin), explained by a borderline association with increased baseline-adjusted fasting glucose at one year in the placebo group (β=1.53[-0.03, 3.08]; p=0.055), but not in the lifestyle (β=-0.93[-2.14 ,0.28]; p=0.13) or metformin (β=-0.59[-1.75, 0.57]; p=0.32) groups. Three other SNPs in *GCG* had significant interactions with lifestyle on weight change as measured by baseline-adjusted one year weight (rs11897425 p=0.03; rs13010545 p=0.006; rs10200420 p=0.02), showing evidence that lifestyle reduces the effect of the SNP on weight. No other significant interactions with metformin were seen. rs2892827 is 5' of *GCG* near its known transcription factor binding sites, and the major A allele is conserved in mammals. Thus the T allele may directly influence glycemic response to anti-diabetic interventions, or alternatively be in linkage disequilibrium with other variants with these effects. Further exploration of these genetic factors will increase our understanding of the contributions of glucagon gene products to glucose homeostasis and as modifiers of the effects of metabolic interventions.

857F

Genetic and Environmental Influences on the Age of Onset of Age-Related Macular Degeneration (AMD) in the Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging (GERA) Cohort. *L. Shen[1], R. Melles[1], S. Sciortino[1], D. Ranatunga[1], L. Walter[1], L. Sakoda[1], R. Whitmer[1], T. Hoffmann[2], M. Kvale[2], Y. Banda[2], N. Risch[2], C. Schaefer[1], E. Jorgenson[1].* 1) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 2) Institute for Human Genetics University of California, San Francisco.

Age-Related Macular Degeneration (AMD) is a highly heritable, common disease with a prevalence of 30% in non-Hispanic white adults aged 75 years or older. In addition to genetic factors, environmental risk factors, including smoking behavior, are known to affect the risk of developing AMD. Here we evaluate the effect of previously identified AMD risk variants and environmental risk factors on the age at onset of AMD in the Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging (GERA) cohort (n=110,266). Cohort members completed a health survey questionnaire that included information on smoking behavior and alcohol consumption. A genetic risk score (GRS) was calculated based on 10 independent risk variants that had been identified in prior studies. During the 6 year follow-up period after the GERA enrollment, 3,278 non-Hispanic white AMD incident cases were identified from the electronic medical record (EMR). These cases had an average of 13.9 years of continuous observation via EMR prior to the first AMD diagnosis, limiting the possibility that subjects might have been diagnosed with AMD at a younger age. The mean onset age was 76.16 years (SD=8.52). Subjects were divided into quintiles based on the distribution of the GRS in 78,697 non-Hispanic white GERA cohort members. Cases in the highest GRS quintile had a mean age of onset 2.44 years younger (p=0.01) than those in the lowest quintile. Current smokers had a 2.34 year earlier onset (p=0.007) than non-smokers. Subjects who exceeded the NIAAA daily safe drinking limit at least once per month at the time of the survey had a 2.14 year (p=7.2*10^-6) earlier age of onset. Stratified analyses revealed an interaction between alcohol consumption and GRS (p=0.0134). Exceeding the NIAAA daily limit was associated with a 3 year earlier age of onset in subjects in the top half of the GRS distribution, whereas age of onset was only 0.8 years earlier in the bottom half. Our findings suggest that both genetic and environmental factors influence the age of onset of AMD, and suggest that it may be possible through lifestyle changes to delay the onset of AMD in subjects at high genetic risk.

858W

Perfect pitch in Costa Rica: contribution of genetic and environmental factors. *G. Chavarria-Soley.* Escuela de Biología, Universidad de Costa Rica, San José, Costa Rica.

Absolute pitch (AP), also known as perfect pitch, is the unusual ability to recognize a pitch without an external reference. The most popular current view is that both environmental (such as an early age at the beginning of musical training) and genetic (as evidenced by familial aggregation and twin studies) factors are involved in the acquisition of the trait. With the goal of attempting to dissect the influence of genes versus environment on the manifestation of AP, 89 musicians were subjected to an interview and musical tone identification test. Subjects were recruited using a mixed strategy, which included university music students as well as volunteers who responded to a newspaper article. Therefore, prevalence cannot be estimated. The test consisted of the identification of 40 piano and 40 'pure' tones, with four seconds between tones. Subjects who correctly identified 75 or more tones were considered AP possessors. A total of 16 AP possessors were identified, eight of whom correctly named all 80 tones. None of the AP possessors reported family members with perfect pitch. In most of the cases, however, the parents and siblings of the subjects had no musical training. A new test for AP, which does not rely on the naming of specific tones, could help elucidate whether familial aggregation is present. Interestingly, the average age at the beginning of musical training did not differ between AP (7.8 ± 3.9 years) and non AP (8.8 ± 4.1 years) subjects (t test= 0.81, d.f.= 87, p=0.42), challenging the assumption that early musical training is a requirement for the development of AP. A total of 56% (9 out of 16) of AP possessors began their musical training after age 7; 6 of these after age 10. A possible interpretation is that in the presence of a strong genetic predisposition, musical training can start at more advanced ages. Additionally, there is an interesting group of 16 non-AP possessors who correctly identified more tones than predicted by chance and for whom most incorrectly identified tones were off by only a semitone. They represent a middle category between true AP and true non-AP possessors. In agreement with the likely complex nature of perfect pitch, this category possibly includes individuals in whom genetic predisposition was high and environmental exposure was not enough to develop the trait, or the other way around.

859T

Interplay of Genetic Risk (CHRNA5) and Environmental Risk (partner smoking) on Smoking Cessation Success. *L. Chen[1], T.B. Baker[2], M. Munafò[3], L.J. Bierut[1].* 1) Psychiatry, Washington University School of Medicine, St. Louis, MO, USA; 2) 2Tobacco Research and Intervention, University of Wisconsin, School of Medicine, Madison, WI 53711, USA; 3) 3Department of Biological Psychology, School of Experimental Psychology, University of Bristol, 12a Priory Road, BRISTOL BS8 1TU, United Kingdom.

Objective: Identifying predictors affecting individual variation in quitting success is important for both clinical response prediction and public health. Smoking cessation success can be predicted by both genetic factors such as variants in the nicotinic receptor gene (*CHRNA5*) and environmental factors such as partner smoking. This study tests whether a specific genetic risk for cessation success is moderated by an environmental feature. Method: In a community-based, longitudinal study (N=1,856) of pregnant women who were smokers before pregnancy, and a randomized comparative effectiveness smoking cessation trial (N=1,065), we examine if the effect of partner smoking on smoking cessation varies with a genetic variant in *CHRNA5*. Smoking cessation was defined as the trajectory of amount smoked over time in the observational study of pregnant women, and as the trajectory of alveolar carbon monoxide (CO) levels in the cessation trial. Results: While the pregnant women decreased their smoking quantity over time, both the genetic risk (rs16969968(A)) and partner smoking predict heavier smoking during pregnancy. However, rs16969968 interacted with partner smoking: the genetic risk is significantly increased for expectant mothers who have a partner who smokes (b=0.071, 95% CI=0.013-0.13, p=0.017). Similarly, among the smoking cessation trial participants receiving the placebo, a similar interaction was found between rs16969968 and partner smoking on cessation: The genetic risk is significantly increased for smokers with a partner who smokes (b=0.20, 95%CI=0.049-0.36, p=0.010). This interaction between genetic and environmental factors occurs only in the placebo group and not in the active pharmacotherapy group (significant interaction, b=-0.25, 95% CI=-0.42 to -.091, p=0.0023). Conclusions: The risk of partner smoking and the *CHRNA5* genetic marker interact in both studies of smoking cessation. The risk associated with *CHRNA5* is moderated by the environment, suggesting that the genetic vulnerability may be mitigated by altering environmental factors such as partner smoking. The increased risk of cessation failure with combined genetic and environmental risks can be ameliorated by cessation pharmacotherapy. Incorporating both genetic and environmental factors is critical in designing successful smoking cessation treatments.

Genetic Predisposition for Hypertriglyceridemia is Modified by Extremes of Adiposity. *C. Cole[1], M. Nikpay[1], R. Dent[2], R. McPherson[1].* 1) Atherogenomics Laboratory, Univ Ottawa Heart Institute, Ottawa, ON, Canada; 2) Weight Management Clinic, The Ottawa Hospital, Ottawa, Canada.

We determined the predictive value of a genetic risk score (GRS) for plasma lipids in 2 cohorts of obese and lean subjects genotyped on Affy 6.0. OBLE: 959 OB & 869 LE, BMI 43.1/20.3. CC: 830 OB & 1,044 LE; BMI 35.8/21.5 kg/m2. GRS predicted TG variance better for OB vs LE in both cohorts, whereas the opposite was observed for HDL-C.

Triglycerides					
OBLE cohort	beta GRS mmol/L	adjusted R2	C C cohort	beta GRS mmol/L	adjusted R2
lean	0.094 (5.8e-10)	0.042	lean	0.102 (4.2e-06)	0.024
obese	0.154 (<2e-16)	0.090	obese	0.153 (1.5e-07)	0.044
HDL-C

Education Influences the Association between Genetic Variants and Refractive Error: A Meta-analysis of Five Singapore Studies. *Q. Fan[1], R. Wojciechowski[2], M.K. Ikram[1,3], C-Y. Cheng[1,3], P. Chen[1], X. Zhou[1], C-W. Pan[1], C-C. Khor[1,4], E.S. Tai[5], T. Aung[1,3], T-T. Wong[1,3], Y-Y. Teo[1,6], S-M. Saw[1,3].* 1) SSH School of Public Health, National University of Singapore, Singapore, Singapore; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA; 3) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore, Singapore; 4) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore, Singapore; 5) Department of Medicine, National University of Singapore, Singapore, Singapore; 6) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Refractive error is a complex ocular trait governed by both genetic and environmental factors and possibly their interplay. Thus far, data on the interaction between genetic variants and environmental risk factors for refractive errors are largely lacking. By using findings from recent genome-wide association studies, we investigated whether the main environmental factor, education, modifies the effect of 40 single nucleotide polymorphisms (SNP) on refractive error among 8,461 adults from five studies including ethnic Chinese, Malay and Indian residents of Singapore. Three genetic loci exhibited a strong association with myopic refractive error in individuals with tertiary or university education ($P = 1.68 \times 10^{-4}$ to 3.6×10^{-6}), whereas the association at these loci was non-significant or of borderline significance in those with secondary education or lower (P for interaction: 3.82×10^{-3} to 4.78×10^{-4}). The evidence for interaction was strengthened when combining the genetic effects of these three loci (P for interaction = 4.40×10^{-8}), and significant interactions with education were also observed for axial length and myopia. Our study shows that low level of education may attenuate the effect of risk alleles on myopia. These findings further underline the role of gene-environment interactions in the pathophysiology of myopia.

862T

A genome-wide interaction study suggests contrasting interaction effects with smoking in ACPA-positive versus ACPA-negative rheumatoid arthritis. *X. Jiang[1], H. källberg[1], L. Ärlestig[2], S. Rantapää-Dahlqvist[2], L. Klareskog[3], L. Padyukov[3], L. Alfredsson[1], The Swedish Epidemiological Investigation of Rheumatoid Arthritis (EIRA) Study Group.* 1) Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Public Health and Clinical Medicine, Rheumatology, Umeå University; 3) Rheumatology Unit, Department of Medicine, Karolinska Institute, Stockholm, Sweden.

Background: Rheumatoid arthritis (RA) is believed to have a multifactorial etiology, involving both genetic and environmental components, and can be divided into two major subsets based on the presence/absence of anti-citrullinated protein/peptide antibodies (ACPA). Smoking is the most established environmental risk factor. Despite progress from genome-wide association studies (GWAS), identified genetic variants only explain a small proportion of RA occurrence, and gene-environment interaction could add etiologic understanding of the disease. The aim of current study is to investigate large scale gene-environment interaction between smoking and SNPs for each RA subset. Methods: We analyzed data from the Swedish EIRA case-control study using logistic regression models. Smoking history (never/ever smoking) was collected through questionnaires. Genetic markers was obtained from a custom made Illumina Immunochip scan. Interaction between smoking and 133648 genetic markers that passed quality control were examined for the two RA subsets (1590 ACPA positive cases, 891 ACPA negative cases; compared with 1856 controls). Attributable proportion (AP) due to interaction was evaluated for each smoking-SNP pair and corrected for multiple comparisons. We performed replication in a case-control study of RA from northern Sweden. To further validate the results we also performed interaction analysis using GWAS data for the EIRA study. Results: In ACPA positive RA, 102 SNPs were significantly interacting with smoking after Bonferroni correction, all located in the HLA region (one in HLA class I region, the rest in HLA class II region); 51 were replicated in the independent case-control study from northern Sweden. No additional loci besides from chromosome 6 turned up in the GWAS validation. After adjusting for HLA-DRB1 shared epitope (SE), 15 SNPs remained significant for ACPA positive RA, with 8 of them replicated. For ACPA negative RA, no SNP passed threshold for significance. 10 genes were identified for ACPA positive RA, with dominance on antigen presentation pathways: HLA-DOB, HLA-DQA1, HLA-DQA2, HLA-DRA, HLA-DRB1, HLA-DRB5, TAP2. Conclusion: Our study presents the most explicit picture to date regarding the patterns of gene-smoking interaction in ACPA positive/negative RA, suggesting contrasting etiology of the two subsets. Except for HLA-DR, the study additionally linked RA risk to the class I HLA, implicating the function of cytotoxic T cells in RA pathogenesis.

863F

A study on genetic variation associated with visceral adipose tissue and interaction of life style on the expression of genetic variation. *H. Kwon*[1,2], *K. Sohn*[1], *B. Cho*[1], *H. Choi*[1]. 1) Seoul National University Hospital, Seoul, South Korea; 2) Healthcare Research Institute, Seoul, South Korea.

Introduction : Obesity, especially abdominal obesity is known as a risk factor for various diseases, and also to increase mortality. Among components of abdominal obesity, visceral adipose tissue (VAT) is a risk for various metabolic diseases and mortality. Genetic variations affecting abdominal obesity have been identified, and interactions between genetic variations and lifestyle factors also have been studied. But there has been no study on genetic variations altering VAT in Koreans, nor study on interaction between genetic variations and life style factors affecting VAT in Koreans. In this study, I have tried to find the association of VAT and SNPs which were previously known to be associated with obesity, and also to test the interaction of life style such as smoking, alcohol drinking and physical activity on the association of VAT and SNPs. Methods : I have selected 17 SNPs previously known to be associated with obesity, and analyzed selected SNPs through realtime PCR from the blood of Korean men aged 20 to 65 who took comprehensive health checkup programs including abdominal fat analysis with CT scan. I have tested the association between selected SNPs and obesity traits including VAT with linear regression analysis, and also checked interaction of life style factors on the association. I also tried stratified analysis with the criteria of body mass index 25kg/m2. Results : Rs9939609 was associated with VAT in dominant model, with AT/AA allele type tends to 6.8cm2 higher in VAT, 0.6kg/m2 higher in body mass index, 1.4cm thicker in waist circumference, 0.7% more in body fat, and 11.2cm2 higher in abdominal subcutaneous fat. On interaction analysis, rs1514175, rs2112347, rs10767664 were affected by alcohol drinking, and rs1718537 and rs3817334 were affected by physical activity on their association with VAT, but on stratified analysis by life style factors there was no significant difference in VAT according to allele type. On stratified analysis by body mass index, rs713586 and rs3810291 were associated with VAT only in subjects with body mass index higher than 24kg/m2 Conclusions : Rs9939609, rs713586 and rs3810291 were associated with VAT in Korean male, and this finding could be implemented in practice and study in the field of obesity.

Lineages based genome-wide association analysis in tuberculosis. *S. Mahasirimongkol*[1], *N. Smittipat*[2], *T. Juthayothin*[2], *T. Mushiroda*[3], *S. Wattanapokayakit*[1], *N. Wichukchinda*[1], *S. Nedsuwan*[4], *K. Dokladda*[2], *K. Ruksseree*[2], *P. Billamas*[2], *P. Palittapongarnpim*[5], *B. Chaiyasirinroj*[6], *A. Chaiprasert*[7], *H. Yanai*[8,9], *K. Tokunaga*[9]. 1) Medical genetics section, National Institute of Health, Nonthaburi, Thailand; 2) National Center for Genetic Engineering and Biotechnology, National Science and Technology Development Agency, Pathumtani; 3) Laboratory for Pharmacogenetics, Center for Integrative Medical Sciences, RIKEN, Japan; 4) Chiangrai prachanukroh hospital, Chiangrai, Thailand; 5) Department of Microbiology, Faculty of Science, Mahidol University; 6) TB/HIV research foundation, Chiangrai, Thailand; 7) Department of Microbiology, Faculty of Medicine Siriraj Hospital, Bangkok, Thailand; 8) Division of Medical Diagnostics, Department of Clinical Laboratory, Fukujuji Hospital, Japan; 9) Department of Human Genetics, Graduate School of International Health, Tokyo, Japan.

Objectives: Genome wide association of tuberculosis in Asians identified a locus near *MAFB* associated with young tuberculosis (Mahasirimongkol, Yanai et al. 2012). Beijing or Modern lineages of *M.tuberculosis* is prevalent in young tuberculosis in Thailand, and genetic heterogeneity based on pathogen diversity in M. tuberculosis is a potential confounding factor contributing to inconsistent association evidences in genetic epidemiology of tuberculosis across populations. Global spatial distribution of *M.tuberculosis* lineages support plausible co-evolution with human populations(Gagneux 2012). Two major lineages of ***Beijing***(belong to Modern) and East African Indians (***EAI*** belong to Ancient) circulating in the Thai tuberculosis populations, allowing study of lineages based association in tuberculosis; we did genome wide association analysis based on two major *M.tuberculosis* lineages to determine the lineage specific association in tuberculosis.

Methods: *M. tuberculosis* were genotyped using the large sequence polymorphisms (LSP)-based PCR and direct repeats (DR)-based spoligotyping methods. The genome-wide genotyping was carried out with the Illumina 610 array following manufacturer protocol, data analysis was carried out with GenABEL. List of 242 TB candidate genes were retrieved from the HugeNet database. The association analysis specific to modern strains and ancient strains were carried out and reported.

Results: In this analysis, 201 Modern TB and 204 Ancient TB were available for the genome-wide association analysis. The comparisons were made against each group of TB, in each comparison; the additional 835 controls genetically matched samples were used as control group. For this analysis, QQ plots, Manhattan plots and regional association plots were analyzed and presented.

Conclusion: Candidate genes analysis supported genetic heterogeneity based on lineages of TB. The most interesting association from this analysis is the heterogeneity within MHC class II in TB. Among the top 50 SNPs, a locus associated with Ancient TB near Leukocyte receptor cluster (LRC) was identified, replication analysis of these findings are required for concrete confirmatory evidences.

865T

FTO genetic variants, dietary intake, and body mass index: results from 177,330 individuals. *Q. Qi[1], T. Kilpeläinen[2,3], M. Downer[1], T. Tanaka[4], C. Smith[5], T. Sørense[3], F. Hu[1], R. Loos[6], J. Nettleton[7], L. Qi[1], FTO Gene and Dietary Intake Consortium.* 1) Department of Nutrition, Harvard School of Public, Boston, MA; 2) MRC Epidemiology Unit, Institute of Metabolic Science, University of Cambridge, Cambridge, United Kingdom; 3) The Novo Nordisk Foundation Center for Basic Metabolic Research, Section of Metabolic Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 4) Translational Gerontology Branch, National Institute on Aging, Baltimore, Maryland, United States of America; 5) Nutrition and Genomics Laboratory, Jean Mayer USDA HNRCA at Tufts University, Boston, Massachusetts, United States of America; 6) The Genetics of Obesity and Related Metabolic Traits Program, The Charles Bronfman Institute for Personalized Medicine, The Mindich Child Health and Development Institute, Department of Preventive Medicine, Mount Sinai School of Medicine, New York City, N; 7) Division of Epidemiology, Human Genetics, and Environmental Sciences, The University of Texas Health Science Center, Houston, Texas, United States of America.

FTO is the strongest known genetic susceptibility locus for obesity. Experimental studies in animals suggest the potential roles of FTO in regulating food intake and energy expenditure. The interactive relation among FTO variants, dietary intake of energy-dense macronutrients, and body mass index (BMI) are complex and results from previous often small-scale studies in humans are highly inconsistent. We performed large-scale analyses based on cross-sectional data from 177,330 adults from 40 studies according to a standardized analytical plan to examine: 1) the association between the FTO-rs9939609 variant (or a proxy SNP) and total energy and macronutrient intake; and 2) the interaction between FTO variant and dietary intake on BMI. Macronutrient intake was expressed as the percentage of total energy intake. Dietary variables were dichotomized into two categorical variables based on the median intake in each study for the interaction analysis. The BMI-increasing allele of the FTO variant showed a significant association with higher dietary protein intake (effect per allele =0.08 [95% CI 0.06, 0.10]%, P=2.4×10-16), lower total energy intake (-6.4 [-10.1, -2.6]kcal/day, P=0.001), and lower dietary carbohydrate intake (-0.07 [-0.11, -0.02]%, P= 0.004). The associations of the FTO variant with total energy intake (P = 0.002) and protein intake (P=7.5×10-9) remained significant after adjustment for BMI. We did not find significant interactions between the FTO variant and dietary intake of total energy (P=0.25), protein (P=0.87), carbohydrate (P=0.80), or fat (P=0.13) on BMI. The magnitude of the association between the FTO variant and BMI was similar between participants in the low intake and the high intake groups of these dietary factors. In conclusion, the BMI-increasing allele of FTO seems to be associated with increased dietary protein intake. There is no obvious evidence supporting interactions between the FTO genetic variant and intakes of total energy or macronutrients in relation to BMI.

866F

Genome-wide environmental interaction (GWEI) analysis using multi-dimensional data reduction principles to identify asthma pharmacogenetic loci in relation to corticosteroid therapy. *F. Van Lishout[1,2], K. Bessonov[1,2], QL. Duan[3], K. Tantishira[3,4], K. Van Steen[1,2].* 1) Systems and Modeling Unit, Montefiore Institute, University of Liège, 4000 Liège, Belgium; 2) Bioinformatics and Modeling, GIGA-R, University of Liège, 4000 Liège, Belgium; 3) Channing Division of Network Medicine, Brigham & Women's Hospital and Harvard Medical School; 4) Pulmonary Division, Brigham & Women's Hospital and Harvard Medical School.

Genome-wide gene-environment (GxE) and gene-gene (GxG) interaction studies share a lot of challenges via the common genetic component they involve. GWEI studies may therefore benefit from the abundance of methodologies that are available in the context of genome-wide epistasis detection methods. One of these is Model-Based Multifactor Dimensionality Reduction (MB-MDR), which does not make any assumption about the genetic inheritance model. MB-MDR involves reducing a high-dimensional GxE space to GxE factor levels that either exhibit high or low or no evidence for their association to disease outcome. In contrast to logistic regression and random forests, MB-MDR can be used to detect GxE interactions in the absence of any main effects or when sample sizes are too small to be able to model all main and GxE interaction effects. In this ongoing study we demonstrate the opportunities and challenges of MB-MDR for genome-wide GxE interaction analysis and analyzed the difference in prebronchodilator FEV1 following 8 weeks of inhaled corticosteroid therapy, for 565 Caucasians from the Childhood Asthma Management Program (CAMP). In particular, we first followed standard marker quality control procedures. Missing genotypes were imputed with MaCH using 1000 Genomes Project Reference Panels (8,221,073 SNPs). Second, residuals were computed based on a polygenic regression model to correct for different types of relatedness and population stratification and to account for possible confounders such as age and height at baseline and gender. Third, LD pruning with maximum correlation threshold (r2) between markers of 0.5 was applied yielding 687,859 SNPs. Third, we curtailed MB-MDR to perform a GxE interaction analysis, with E a dichotomous variable coding for corticosteroid therapy (1: inhaled corticosteroids 0: other). Amongst our top results, we found 3 SNPs mapped to potentially interesting genes: a) rs12442193 mapped to SLCO3A1, a member of the solute carrier organic anion transporter family identified as participant of neurodifferentiation. b) rs2515471 mapped to ANGPT2 and MCPH1, related to the vascular remodeling and DNA damage repair. c) rs10898318 mapped to DLG2, a member of the membrane-associated guanylate kinase family involved in signal propagation in synapses and cell signaling. Follow-up of these results include replication in independent datasets and formal testing and validation of identified interactions as corticosteroid-related pharamacogenetic loci.

867W

Empirical comparison of Multi-association for Type 2 diabetes in Koean population-based cohort. *J. Lee[1], J. Lee[1], S. Park[1], B. Kim[1], B. Han[1], S. Won[2].* 1) Structural & Genomics, Centers Disease Control and prevention , #187 Osong sangmyung2ro, South Korea; 2) Department of Applied Statistics, Chung-Ang University, #5ga Anam-dong, South Korea.

Type 2 diabetes mellitus(T2D) is one of world-wide disease, its prevalence is above 10 percent in Korea. T2D is very highly correlated risk factors for epidemic and clinical, but is not sufficiently significant in Genome -wide association analyses. In genome wide association study, many Single nucleotide polymorphisms(SNPs) were significant for various risk factors, but these SNPs account for small fraction. We have constructed community and twin-family based on cohort, which is an ongoing prospective studies and surveyed samples were drawn from the Korean Genome and Epidemiology Study (KoGES) and Korea Genome Analysis Project (KoGAP) in Korea. From community-based cohort(KARE; Korea Association REsource), we selected 8,842 subjects who were in their various age(n=10,038) in this cohort and surveyed their self-report questionnaires about 1,400 items and genotyped using Affy 5.0. The aim of this study was to estimate their multi-association(multi trait-multi genetic information). These were estimated and optimized Quantitative genetic analysis adjust age and sex. Then we compared empirically association and multi-association results.

868T

Influence of physical activity on body mass index in relation to well-replicated obesity loci in African-American adults: The ARIC Study.
K.L. Young[1, 2], A.E. Justice[2], E.W. Demerath[4], W-H.L. Kao[5], E. Boerwinkle[6], K.E. North[2,3], K.L. Monda[7]. 1) Carolina Population Center, University of North Carolina, Chapel Hill, NC; 2) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC; 4) Division of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, MN; 5) Department of Epidemiology, Johns Hopkins University, Baltimore, MD; 6) Division of Epidemiology, Schoool of Public Health, University of Texas Health Science Center, Houston, TX; 7) Center for Observational Research, Amgen, Inc, Thousand Oaks, CA.

Obesity is a known risk factor for many chronic diseases, and physical activity (PA) is often used to lower those risks by reducing weight. However, the impact of PA on obesity exhibits considerable variation, which is likely influenced by genetics. African Americans (AA) are at particularly high risk of obesity, but remain understudied. We investigate the modifying influence of PA on 24 BMI loci which generalize or for which a better SNP in the same locus has been reported in AA using the Atherosclerosis Risk in Communities (ARIC) Study, a population-based sample of adults aged 45-64 years at baseline. Our analyses were restricted to genotyped individuals of self-reported African descent (N=2,373). BMI (kg/m2) was computed from measured height and weight. PA was measured using a modified Baecke questionnaire, resulting in an ordinal score (range: 1.0-10.0). We assumed an additive genetic model, regressing BMI on SNP, PA level, SNP by PA, sex, age, current smoking, education, center, alcohol consumption, and principal components (PCs) to account for ancestry. Additionally, we performed main effects analyses controlling for sex, age, current smoking, center, and PCs. The majority of our sample was female (63%), with a mean age of 53.3 (SD 5.7) years, and at least a high school education. Mean BMI was 29.7 (SD 6.0) kg/m2, and PA was 6.98 units (SD 1.19, range: 2.0-9.0). SNPs were distributed on 15 of the 22 autosomes and ranged in minor allele frequency from 5.8% (PTBP2) to 42.4% (MIR148A/NFE2L3). In the main effects analysis, seventeen of the 24 loci were directionally-consistent with earlier findings. While none of the effect modification p-values were significant after Bonferroni correction ($p<0.002$), MAP2K5 reached suggestive significance ($p<0.05$). Each additional copy of the risk allele in MAP2K5 resulted in an increase of 0.04 kg/m2 for low PA individuals, but a decrease of 0.12 kg/m2 for high PA individuals (p-interaction=0.045). Mean BMIs for those with low PA increase with additional copies of the G (risk) allele (mean BMI for AA=30.8, AG=31.5, GG=31.1 kg/m2). Ten of 24 SNPs were directionally consistent with the expected effect modification with the effect of the BMI increasing allele decreasing in the context of high PA. Overall, as has been reported in European descent populations, our results suggest higher levels of physical activity may modify the influence of selected obesity susceptibility variants on BMI in African Americans.

Transcriptional response to acute respiratory virus infection - a prospective cohort study.
Y. Zhai[1,4], J. Belmont[1,4,6], R. Atmar[2,3], J. Quarles[5], N. Arden[5], K. Bucasas[1], J. Wells[3], D. Niño[3], X. Wang[4], G. Zapata[4], C. Shaw[1], L. Franco[1,2], R. Couch[3]. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Medicine, Baylor College of Medicine, Houston, TX; 3) Department of Molecular Virology and Microbiology, Baylor College of Medicine, Houston, TX; 4) Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX; 5) Department of Microbial and Molecular Pathogenesis, Texas A&M University System Health Science Center, College Station, TX; 6) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Objectives: Acute viral respiratory infections (ARIs) are responsible for a large number of outpatient visits and hospitalizations in the U.S., and the threat of pandemic influenza will likely add to these numbers. A new influenza A/H1N1 (pH1N1) virus, which emerged in April 2009, spread worldwide and continued to circulate in the following year. In this study we aim to identify functional gene networks and pathways that are correlated with immune response to influenza infection by time-course analysis of the host transcriptional profiles. Methods: 1618 healthy adults, enrolled in fall 2009 and 2010, were followed for acute viral respiratory disease. Subjects reporting moderate to severe acute respiratory illness had virus quantitation for 3 weeks. Peripheral blood samples for RNA extraction were obtained on the first day of illness (day 0) and then on 2, 4, 6, and 21 days after first symptoms. In addition to an RNA sample obtained at enrollment, a final RNA sample was obtained at the end of the study. RNA samples were analyzed using expression microarrays and the patterns of gene expression were analyzed to identify differentially expressed transcripts. Result: Among the 133 subjects who suffered viral respiratory and completed 5 illness day study visits, 73 had influenza infection, 64 influenza A and 9 influenza B. Of these, 24 had at least one other known viral respiratory pathogen e.g. human rhinovirus (HRV) or respiratory syncytial virus (RSV). Gene expression profiles showed highly similar patterns among the major subgroups. There was a dramatic up-regulation of interferon pathway and innate immunity on the first day of infection. This usually persisted for 2 days. A convalescent phase was observed on days 4 and 6 after infection. By day 21 the gene expression pattern had returned to levels indistinguishable from baseline. Using lineage and activation state specific transcripts to produce cell decomposition scores, patterns of acute depression of the B and T lymphocytes were observed accompanied by the evidence of dramatic activation of dendritic cells, NK cells, and, to a lesser extent, activated T cells. Conclusions: Transcriptional profiling gives a genome wide view of a coordinated systemic response to acute viral respiratory infection. There are two clear phases of gene expression, corresponding to intense activation of innate immunity pathways followed by a convalescent phase marked by cell proliferation and repair.

Insights into the molecular arms race between the Malaria parasite and its human host from genomic analysis of over 15,000 African individuals.
C.C.A. Spencer[1], L.S. Quang[1], G. Band[1], K. Rockett[1], D. Kwiatkowski[1,2], MalariaGEN. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

The continuing burden of death and illness that malaria inflicts in endemic regions underlines its likely important role in human evolution. To gain insights into the key molecular determinants of human susceptibility to severe malaria we studied over 15,000 individuals from eight countries across sub-Saharan Africa, using genome-wide SNP genotyping, as part of the MalariaGEN consortium (www.malariagen.net). We use these data, in combination with novel statistical methodology, to jointly describe patterns of association and natural selection across the genome. By systematically coupling signals of association with models of recent evolution across genes of different function we can test specific hypotheses. We assess the evidence for two broad classes of protective effects: the first, protective alleles that are maintained under balancing selection through deleterious effect (for example sickle cell disease) which have consistent effects across populations; the second, protective alleles that are under frequency-dependent selection, and are expected to have different effects on susceptibility across populations, due to an interaction with parasite diversity. These new observations reinforce the role of red blood cell surface proteins as important in severe malaria susceptibility, putatively by inhibiting parasite invasion mechanisms. In addition, our genome-wide data can be used to assess the relationship between recently reported shared human and chimpanzee polymorphisms and infectious disease caused by the malaria parasite. As well as helping to quantify the impact of malaria susceptibility alleles on human diversity in Africa, we are also able to use signals of natural selection to aid identification of new susceptibility loci.

871T

The *MTHFD1* 1958 G>A (R653Q) variant is associated with elevated C-reactive protein and body mass index in a Canadian premature birth cohort. *K.E. Christensen*[1,2], *M. Dahhou*[2], *M.S. Kramer*[2,3], *R. Rozen*[1,2]. 1) Dept. of Human Genetics, McGill University, McGill University Health Centre, Montreal, Quebec, Canada; 2) Dept. of Pediatrics, McGill University, McGill University Health Centre, Montreal, Quebec, Canada; 3) Dept. of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Quebec, Canada.

MTHFD1 1958 G>A (rs2236225) is a non-synonymous variant in the synthetase domain of the trifunctional MTHFD1 enzyme. It reduces stability and impairs *de novo* purine synthesis. *In vitro* data suggest that the variant's effects may be modulated by folate. This SNP has been associated with increased risk for birth defects (heart and neural tube) and pregnancy loss, particularly in the Irish population, which is not folate fortified. We have recently generated a mouse with partial synthetase deficiency (*Mthfd1S*$^{+/-}$) as a model for this variant. The majority of the mice were healthy and normal; however, the rate of developmental defects was higher in offspring of *Mthfd1S*$^{+/-}$ dams. In addition, nonpregnant female *Mthfd1S*$^{+/-}$ mice were heavier than their wild-type littermates, and white blood cell counts (specifically neutrophils) were reduced, particularly during pregnancy. To examine immune function and weight in women with the 1958 G>A SNP, we genotyped 206 women with spontaneous preterm births and 443 controls from a large multicentre cohort of Quebec women. There was no association with prematurity, with or without stratification by median plasma folate (29.6 nM). In grouped cases and controls, plasma C-reactive protein (CRP, an immune marker associated with low-grade inflammation) was increased due to the A allele (p=0.053, ANOVA; p for trend = 0.041) in women with folate < median. Using logistic regression of high versus low CRP including genotype, maternal age, smoking, BMI and education in the model, CRP was increased in GG compared to AA women with folate < median (p=0.055). There was also a strong association between pre-pregnancy BMI >= 30 and CRP in this analysis, both above and below median folate (p<0.001). A nonsignificant dose-response relationship was observed between mean BMI and genotype, especially in the low-folate group, when analyzed by ANOVA. However, there was a significant association between the 1958G>A variant and BMI, when examined for low (<18.5), normal (18.5-25), overweight (25-30) and obese (>=30) groups by chi-square analysis of combined cases and controls (p=0.0113). These results suggest that the *MTHFD1* 1958G>A variant may influence immune function and obesity, particularly if folate intake is low. Additional cohorts should be evaluated, particularly since the median folate level in this cohort was quite high.

Analysis of APOE-e4 and Facial Profile Convexity in Obstructive Sleep Apnea. *J.K. Hartsfield*[1,2,3], *J.J. Roedig*[1], *B.A. Phillips*[2], *L.A. Morford*[1,3], *J.E. Van Sickels*[1], *G. Falcão-Alencar*[3], *D.W. Fardo*[4], *G.T. Kluemper*[1]. 1) College Dentistry, Univ Kentucky, Lexington, KY; 2) College of Medicine, Univ Kentucky, Lexington, KY; 3) Center for Oral Health Research, Univ Kentucky, Lexington, KY; 4) College of Public Health, Univ Kentucky, Lexington, KY.

Objective: The inheritance of obstructive sleep apnea (OSA) is complex. Previously, APOE-e4 and increased facial convexity (mandibular retrognathism, i.e., a Class II (CII) sagittal skeletal jaw relationship) have independently been associated with OSA. We hypothesized that in OSA there is an association between APOE-e4 and non-CII compared to CII subjects. Associations between APOE-e4 with BMI, and Apnea-Hypopnea-Index (AHI); and jaw relationship with BMI and AHI were also studied. Materials and Methods: Seventy-six Caucasian OSA subjects with an AHI > 15 were classified into different sagittal skeletal jaw relationships by oral exam and profile photos. In addition to CII, Non-CII includes Class I with straight profile, and Class III with mandibular prognathism. DNA via saliva was extracted. Two SNPs (rs429358 and rs7412) were genotyped to determine APOE allele(s). Chi-square analysis assessed Hardy-Weinberg-Equilibrium (significance at p<0.05). Fisher's exact test was used to look for association between APOE-e4 status and the skeletal classification of OSA subjects. ANOVA compared BMI and AHI among the skeletal types. Results: Twenty-five CII subjects (mean BMI 30.7, AHI 33.6) and fifty-one non-CII subjects (mean BMI 37.4, AHI 44.2)were examined. Seventy subjects were obese, and six subjects had a normal BMI. All six individuals with a normal BMI were CII. APOE-e4 was not associated with different sagittal facial profiles. CII subjects had significantly lower BMI than CI 37.2 or CIII 37.8 subjects (p<.001). There was no difference among the facial profile groups for AHI (CII 33.6, CIII 39.5, CI 46.0). There was a significant difference between CII and CI for AHI. Conclusion: Patients who have OSA and CII have a lower BMI, and 1/5 are not even obese, suggesting that CII is a contributing factor to OSA with or w/out increased BMI. No association between non CII and APOE-e4 was found in this preliminary study.

Smoking and asthma: effect modification by phospholipase C, beta 1 and peroxiredoxin 6 polymorphisms. *I. Ahmed*[1,2], *M. Rava*[2,3], *M-H. Dizier*[4,5,6], *V. Siroux*[7,8], *M. Kogevinas*[9], *N. Probst-Hensch*[10,11], *F. Demenais*[4,5,6], *P. Tubert-Bitter*[1,2], *R. Nadif*[2,3]. 1) Biostatistics Team, Inserm U1018, Villejuif, France; 2) Univ Paris-Sud; 3) Respiratory and Environmental Epidemiology Team, Inserm U1018, Centre for Research in Epidemiology and Population Health, Villejuif, France; 4) INSERM UMRS-946, Paris, France; 5) Institut Universitaire d'Hématologie, Univ Paris Diderot, France; 6) Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain, Paris, France; 7) Environmental epidemiology applied to reproduction and respiratory health Team, Inserm U823, Grenoble, France; 8) Univ Joseph Fourier, Grenoble, France; 9) Centre for Research in Environmental Epidemiology (CREAL), Barcelona, France; 10) Department of Epidemiology and Public Health, Swiss Tropical and Public Health Institute Swiss TPH, Switzerland; 11) University of Basel, Switzerland.

The number of biological proofs of a role of oxidative/nitrosative stress in asthma is increasing. Tobacco smoke, which plays a role in asthma, is an environmental factors related to oxidative/nitrosative stress. Our goal was to identify polymorphisms (SNPs) in genes involved in the response to oxidative/nitrosative stress interacting with smoking on asthma. This study takes place in the framework of the French Epidemiological study of the Genetic and Environmental factors of Asthma (EGEA), which combines a case control study and a family study. 182 genes (5498 SNPs) were selected according to a pathway-based strategy integrating biological knowledge related to tobacco smoke metabolism. Tobacco smoke was expressed as current, ex- and non-smokers. SNP discovery was performed by combining marginal genetic associations and gene by smoking interactions as proposed by Dai (Dai, AJE, 2012). Both the marginal associations and gene interactions were estimated using GEE logistic regression models, adjusted for age, sex and principal components for population ancestry in 1570 adults (43 years old, 36.3% with active asthma, 24.8% smokers). 6 SNPs (5 in PARK2 (Parkinson protein 2) and 1 in PRKCA (protein kinase C, alpha)) had Dai P values lower than 1×10-3. All of them showed marginal associations with active asthma (p<5×10-4) but no evidence for interaction with tobacco smoke. Considering SNPs showing suggestive evidence for interaction with tobacco smoke revealed 14 signals (p<1×10-3) in PLCB1 (phospholipase C, beta 1), PRDX6 (peroxiredoxin 6) and NFE2L2 (nuclear factor (erythroid-derived 2)-like 2), a transcription activator of antioxidant genes. Although replication of our results is needed, it is interesting to note that oxidized phospholipids are associated to impair function of macrophages in mice exposed to chronic cigarette smoke (CS), and that chronic 6 months of CS exposure resulted in increased lung inflammatory response in prdx6 -/- mice.

874T

Pathogenic Role of MicroRNA in Pediatric Asthma. *X-Y. Dong*[1, 2], *N. Zhong*[1,2,3]. 1) Children's Hospital of Shanghai, Jiaotong University, Shanghai, China; 2) Chinese Alliance of Translational Medicine for Maternal and Children's Health, China; 3) New York State Institute for Basic Research in DD, Staten Island, NY.

Pediatric asthma is one of the most common children's respiratory diseases. The morbidity of asthma is stably increasing worldwide. Presently the etiology and pathogenesis of asthma are yet unclear but complicated. Hypothesis of that asthma is resulted from interactions of genetics, immune regulation, and environmental factor(s) has been proposed. This has led us to explore the epigenetic mechanism underlying pediatric asthma. For which, we have undertaken a stud of epigenomic regulation of genome wide microRNAs (miRNA) for the pediatric asthma. miRNA is one of the non-coding small RNAs, with a length of 21-25 nucleotides. Mature miRNA may bind to 3' UTR (or other regions) of target mRNA and result in degradation or translational repression of mRNA during development, cell proliferation, variation, and apoptosis. Recent studies determined that miRNA plays an important role in the pathogenesis of adults' asthma. We therefore proposed that miRNA might also involve in the pathogenesis of pediatric asthma. In out pilot study, 12 cases of children's asthma that had been confirmed with dust mite allergy, compared to 12 cases of age- and gender-matched normal children, were applied to Exiqon's genome wide microarray assays. Our preliminary results showed three miRNAs, two (miRNA 5588-5p, miRNA 4255) up-regulated and one (miRNA 27b-3p) down-regulated, are associated with inflammatory signaling pathway with impact on regulating mRNA expression of IL-6, -10, -13, TNF and INF. Functional analysis is being undertaken to understand how the miRNA regulates the mRNA expression within the inflammatory signaling pathway. Our study has opened a new avenue to uncover the molecular pathogenic mechanism underlying pediatric asthma.

875F

Occupational exposures to potential irritants and asthma: effect modification by glutathione S-transferase Z1 and ATP-binding cassette transporters polymorphisms. *M. RAVA[1, 2], I. AHMED[2,3], O. DUMAS[1,2], M. KOGEVINAS[4], N. PROBST-HENSCH[5,6], P. TUBERT-BITTER[2,3], N. LE MOUAL[1,2], F. DEMENAIS[7,8,9], R. NADIF[1,2].* 1) INSERM U1018, Centre for research in Epidemiology and Population Health (CESP), Respiratory and Environmental Epidemiology Team, Villejuif, France; 2) Univ Paris-Sud 11, UMRS 1018; 3) INSERM U1018, Centre for research in Epidemiology and Population Health (CESP), Biostatistics Team, F-94807, Villejuif, France; 4) Centre for Research in Environmental Epidemiology (CREAL), Barcelona, Spain; 5) Department of Epidemiology and Public Health, Swiss Tropical and Public Health Institute Swiss TPH, Switzerland; 6) University of Basel, Switzerland; 7) INSERM, UMRS-946, F-75010, Paris, France; 8) Univ Paris Diderot, Sorbonne Paris Cité, Institut Universitaire d'Hématologie, F-75007, Paris, France; 9) Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), Paris, F-75010, France.

Occupational asthma (OA) is a good model to study the pathophysiology of asthma. Around 15% of adult asthma would be caused by occupational exposures, and more than 400 distinct agents have been identified as causing OA. The mechanisms of asthma induced by potential irritants, such as cleaning and chemical products, are unclear but could be related to oxidative/nitrosative stress. Our goal was to identify polymorphisms (SNPs) in genes involved in the response to oxidative/nitrosative stress interacting with occupational exposures known to have an effect on asthma, in the familial case-control French Epidemiological study of the Genetic and Environmental factors of Asthma (EGEA, https://egeanet.vjf.inserm.fr/). A large set of genes (162 genes, 4979 SNPs) was selected according to a pathway-based strategy, that integrates biological knowledge related to occupational exposures. Occupational exposure to potential irritants was evaluated using the asthma job exposure matrix (Asthma JEM, http://cesp.vjf.inserm.fr/asthmajem/) and job-specific questionnaires for cleaners and healthcare workers. First, the marginal association between each SNP and current asthma, and the SNP by occupational exposures interactions were estimated separately using GEE logistic regression models, adjusted for age, sex and principal components for population ancestry in 1254 adults (45 years old, 38% with current asthma, 32% exposed). Then, the marginal genetic associations and the gene by environment interactions were simultaneously tested as proposed by Dai (Dai, AJE, 2012). 17 SNPs had Dai P values lower than 1×10-3. Among these SNPs, one in ABCC1 (ATP-binding cassette, sub-family C (CFTR/MRP), member 1) and one in GSTZ1 (glutathione S-transferase Z1) showed suggestive evidence for interaction with occupational exposures (p= 2×10-4 and 7×10-4 respectively). In addition, SNPs in PARK2 and NDUFS4 showed association signals with current asthma (p<1×10-3). Although replication of our results is needed, it is interesting to note that GSTZ1 is a member of the GSTs super-family which encodes multifunctional enzymes important in the detoxification of electrophilic molecules by conjugation with glutathione, and that ABCC1 mediates ATP-dependent transport of glutathione and glutathione conjugates, and other xenobiotics.

876W

Comparative Analysis of T2D Risk Allele Load in African Americans and European Americans. *J.M. Keaton[1,2,3], J.N. Cooke Bailey[2,3,4], N.D. Palmer[2,3,7], B.I. Freedman[5], C.D. Langefeld[6], M.C.Y. Ng[2,3], D.W. Bowden[2,3,7,8].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Molecular Medicine and Translational Science, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 7) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 8) Internal Medicine-Endocrinology, Wake Forest School of Medicine, Winston-Salem, NC.

The burden of type 2 diabetes (T2D) is greater in populations of African descent compared to other ethnicities. In the United States prevalence of T2D is 12.6% among African American adults compared to 7.1% for European Americans. Although lifestyle and environmental factors contribute to T2D risk, genetic contributors to T2D disparities have not been well documented. Genome-wide association studies (GWAS) have identified ≥60 common genetic variants that contribute to T2D risk in populations of European, Asian, African, and Hispanic descent. Previous studies have not comprehensively examined population ancestry-specific differences in cumulative risk allele load. Genetic risk load was analyzed in 1,990 African Americans (n=963 T2D cases, n=1027 controls) and 1,654 European Americans (n=726 T2D cases, n=928 controls) ascertained and recruited using a common protocol in the southeast US. 49 T2D index single nucleotide polymorphisms (SNPs) from 45 loci from GWAS in European, East Asian, South Asian, and African derived populations were analyzed. In African American subjects, risk allele frequencies ranged from 0.052 to 0.976. Risk alleles from 28 SNPs demonstrated directional consistency with previous studies, and 4 SNPs from *ADAMTS9*, *TCF7L2*, *INS-IGF2*, and *ZFAND6* showed evidence of association (P<0.05). African American individuals carried 38-69 risk alleles, and had an average risk allele load of 55. In European American subjects, risk allele frequencies ranged from 0.001 to 0.996. Risk alleles from 37 SNPs demonstrated directional consistency, and 10 from *BCL11A*, *PSMD6*, *ADAMTS9*, *ZFAND3*, *ANK1*, *CDKN2A/B*, *TCF7L2*, *PRC1*, *FTO*, and *BCAR1* showed evidence of association (P<0.05). European American individuals carried 38-65 risk alleles, and had an average risk allele load of 51.African Americans have a highly significant mean increase of 4.3 risk alleles ($P=1.6\times10^{-177}$; two sided t-test, two samples with unequal variances) compared to European Americans. This cumulative increase in T2D risk allele load may contribute to the observed disparity in disease prevalence between population ancestries.

877T

Melanocortin 1-receptor haplotypes associated to pigmentation phenotypes in the brazilian population. *L.A. Marano[1], A.L. Simoes[1], E.A. Donadi[2], C.T. Mendes-Junior[3].* 1) Departamento de Genetica, FMRP, Universidade de Sao Paulo, Ribeirao Preto, SP, Brazil; 2) Departamento de Clinica Medica, FMRP, Universidade de Sao Paulo, Ribeirao Preto, SP, Brazil; 3) Departamento de Quimica, FFCLRP, Universidade de Sao Paulo, Ribeirao Preto, SP, Brazil.

The MC1R (melanocortin 1-receptor) gene is one of the best characterized so far among the known genes influencing eye, skin and hair pigmentation variation. This gene activity happens due the coding of a transmembrane protein in melanocytes, responsible for regulating the production of melanin. MC1R importance relies on the determination of the ratio of eumelanin (brown/black) and pheomelanin (yellow/red) pigments present in melanocytes, accordingly to its higher or lower signaling activity. This study aims to use MC1R data obtained from 29 known SNPs in order to reconstruct haplotypes and evaluate their diversity influence on features like freckles and pigmentation variation of eyes, skin and hair in humans. We analyzed 29 known SNPs in the coding region of MC1R gene in 296 individuals from the region of Ribeirao Preto, Brazil. DNA extraction was performed using the salting-out technique. The MC1R gene coding region (951pb) was amplified in a single PCR reaction, which was sequenced on a ABI PRISM-310 genetic analyzer by capillary electrophoresis, using the same primers used for amplification. From the 29 SNPs evaluated, only 22 showed variation in the samples studied, half of them showing to be associated with pigmentation characteristics. Haplotype reconstruction generated 31 haplotypes. Four of them were associated with dark skin and other two had significantly high frequencies in fair skin. One haplotype was associated with green eyes, while two other had association with dark brown eyes. Darker hair color was associated with six different haplotypes, whereas red hair was associated with two and blonde hair with one haplotype. Finally, the absence or presence of freckles was significantly related to three haplotypes. This study shows substantial associations between MC1R haplotypes and external visible traits, confirming that this gene also plays a relevant role in the pigmentation variation in the Brazilian population.

878F

The IRF5-TNPO3 association has two components in systemic lupus erythematosus (SLE), which are shared with other autoimmune disorders. *L.C. Kottyan[1,2], E.Z. Zoller[1], K.M. Kaufam[1,2], J.B. Harley[1,2].* 1) Center for Autoimmune Genomics and Etiology, Division of Rheumatology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA; 2) Cincinnati Veterans Affairs Med. Ctr., Cincinnati, Ohio, USA.

Recent improvements in genetic methods allow for more complete identification of candidate causal variants. Exploiting genotyping, DNA sequencing, imputation, and trans-ancestral mapping, we modeled the IRF5-TNPO3 genetic association on chromosome 7, now implicated in two immunotherapies and seven autoimmune diseases. We capture 7,650 IRF5-TNPO3 genetic variants across five ethnicities in 8,395 systemic lupus erythematosus (SLE) cases and 7,367 controls. We resolve separate lupus-risk associations in the IRF5 promoter (all ancestries) and an extended European haplotype- strongly associated with lupus in subjects of European decent but non-polymorphic in subjects from Asia or Sub-Saharan Africa. Adjusting for two variants tagging each genetic effect removes the association of other variants in the region. Using both frequentist and Bayesian approaches, we identify the mostly likely causative variants to three IRF5 promoter variants (confined to 5.7 kb) and 22 variants of the 85.5 kb European haplotype that spans IRF5 and TNPO3. The possible statistical models from this sample virtually eliminate the previously purported IRF5 functional variants as causal. Strikingly, this model also appears to operate in Sjögren's syndrome and systemic sclerosis (both components) and primary biliary cirrhosis (haplotype only), demonstrating the nuances of similarity and difference in autoimmune disease risk mechanisms at IRF5-TNPO3. Finally, we performed case-only subphenotypic analyses to identify variants in the IRF5-TNPO3 region useful in predicting the disease progression of patients with lupus and found strong association with age-of-onset (variants in the haplotype) and the antigen specificity of autoantibodies anti-Ro and anti-dsDNA (variants in the IRF5 promoter). In conclusion, genetic variants in the IRF5-TNPO3 region critically regulate the development of multiple autoimmune diseases and the clinical presentation of lupus. Given the importance of this locus to multiple immune disorders, future studies will be aimed at understanding the mechanisms driving the genetic associations. (72 other collaborators- providers of samples, genetic, analytical, and financial resources will be provided at presentation.).

879W

Epiregulin (*EREG*) and human V-ATPase (*TCIRG1*) are not associated with pulmonary tuberculosis in West African populations from Guinea-Bissau and The Gambia. *S.M. Williams[1,2], M.J. White[1,2], A. Tacconelli[3], C. Wejse[4], P.C. Hill[5], G. Novelli[3], G. Sirugo[3].* 1) Department of Genetics, Institute for Quantitative Biomedical Sciences, Dartmouth College, Hanover, NH; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Centro di Genetica, Ospedale San Pietro FBF, Rome, Italy; 4) Bandim Health Project, Danish Epidemiology Science Centre and Statens Serum Institute, Bissau; 5) Centre for International Health, University of Otago School of Medicine, New Zealand.

Tuberculosis (TB) is caused by *Mycobacterium tuberculosis* (M. tuberculosis) and infects approximately one third of the world's population, with the majority of infection occurring in Africa and South-east Asia. Active TB, of which pulmonary TB (PTB) accounts for approximately 80%, has one of the highest mortality rates for an infectious disease. There is a large discrepancy between latent TB infection and incidence of active TB, with only a small percentage of those infected developing active disease, suggesting genetic factors influence host response to *M. tuberculosis* infection. Recent studies have identified two novel TB susceptibility candidate genes, *EREG* (Epiregulin) and *TCIRG1* (human ATPase, a3 isoform), in Vietnamese and Italian populations, respectively. The main aim of this study was to validate the associations between *EREG* and *TCIRG1* with PTB in 'at risk' populations from West African endemic areas. Using a discovery cohort from Guinea Bissau (n = 289 cases, 322 controls) and a replication cohort from the Gambia (n = 240 cases, 248 controls), we assessed association with 14 SNPs in *EREG* and *TCIRG1*; using single and multi-locus analysis to determine whether previously described associations generalized to African populations. Logistic regression analysis revealed one SNP in *TCIRG1*, rs10896289, as significantly associated with PTB (p=0.042) and another SNP in *EREG*, rs1563826, that was marginally associated with PTB (p= 0.056) in our discovery cohort; these associations were not observed in the Gambian replication cohort. Haplotype analyses were also performed to investigate associations with PTB; no significant results were found in either cohort. We also performed multi-factor dimensionality (MDR) analysis to elucidate possible interaction effects, between SNPs and demographic factors. Interestingly, although MDR identified the same variables in both our discovery and replication cohorts, further investigation revealed that the risk models differed. In conclusion, despite being adequately powered to detect the effect sizes previously reported, our single and multi-locus analyses were unable to validate *EREG* and *TCIRG1* as PTB susceptibility candidate genes in West African populations. Our findings suggest that associations of PTB with genetic variation in these genes may be influenced by inter-population differences in genetic or environmental context and/or the mycobacterial lineages that cause active disease.

880T

Exploring genetic load of known multiple sclerosis risk alleles in Hispanic whites. *J. McCauley[1], A. Hadjixenofontos[1], C.P. Manrique[1], A.H. Beecham[1], I. Konidari[1], P.L. Whitehead[1], P-A. Gourraud[2], M.A. Pericak-Vance[1], L. Tornes[3], M. Ortega[3], K.W. Rammohan[3], S.R. Delgado[3].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurology, School of Medicine, University of California at San Francisco, San Francisco, CA, USA; 3) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA.

Multiple Sclerosis (MS) is a demyelinating disease with autoimmune etiology and variable expression across populations. Studies on the genetic susceptibility to MS have primarily focused on Northern European (NE) populations, largely due to the increased prevalence in these countries. However, Hispanic patients are underrepresented in well-powered studies of disease presentation, and even more so in investigations into the underlying genetic architecture. Our previous studies have revealed potentially important clinical differences between Hispanic white and non-Hispanic white patients that warrant further investigation. As a first step we have calculated an MS risk score to capture the genetic load attributed to variants identified in NE populations, therefore we hypothesize that an admixed population will be characterized by a partly-overlapping set of genetic variants. The most recent study by the International MS Genetics Consortium has significantly increased the list of known MS risk variants while also fine-mapping previously discovered signals. We use 113 of these variants to construct a weighted MS genetic risk score. Our goal is to assess the extent to which the NE derived MS risk score is able to distinguish Hispanic white cases (n = 186) from non-Hispanic white cases (n = 161). Preliminary results suggest that the genetic load due to the variants included in the MS risk score is similar in Hispanic white cases (mean = 12.94, SD = 0.75) and non-Hispanic white cases (mean = 12.91, SD = 0.79) (t-test p-value = 0.67). A more comprehensive examination of the variation present in the known regions using information on local ancestry is underway. Our study highlights the need for further studies of MS risk factors among Hispanics with the goal of understanding the causes of the differences we see in MS presentation in this population.

881F

Genetic Basis of Height and Skin Pigmentation in Southern Africa. *B.M. Henn[1,2], J.M. Granka[3], A.R. Martin[2], C.R. Gignoux[4], M. Lin[1], J.M. Kidd[5], E.G. Hoal[6], M.W. Feldman[2], C.D. Bustmante[1].* 1) Dept of Ecology and Evolution, Stony Brook University, Stony Brook, NY; 2) Dept. of Genetics, Stanford University, Stanford CA; 3) Dept. of Biology, Stanford University, Stanford, CA; 4) University California, San Francisco, CA; 5) Dept. of Human Genetics, University of Michigan, Ann Arbor, MI; 6) Molecular Biology and Human Genetics, Stellenbosch University, Tygerberg, South Africa.

No two traits are as immediately recognizable for their variability among and within human populations as height and skin pigmentation. Many evolutionary hypotheses have been proposed to explain their variability, but relatively little is known about the genetic basis of these traits across human populations. In particular, the genetic basis of these phenotypes in the KhoeSan populations of southern Africa remain completely unknown. For the first time, we analyze the heritability of height and skin pigmentation in over 200 ≠Khomani Bushmen and Nama individuals from South Africa, and perform genome-wide association analyses for these traits with both high-coverage exome and SNP array data. We contrast estimates of heritability for height and skin pigmentation and find that most variation in innate skin pigmentation is potentially explained by common single nucleotide polymorphisms (SNPs); height is only moderately heritable and tanning is largely environmental. While varying amounts of European, west African and KhoeSan ancestry strongly correlate with skin pigmentation, ancestry does not appear to contribute significantly to variation in height in our samples. Finally, after controlling for kinship relationships in our data, we identify several large effect loci associated with height located near genes previously identified to be associated with body mass index/height (e.g. SLC1A3, VWA8, DGKH) Our results emphasize that analyses of phenotypically and genetically diverse endogamous populations have the potential to reveal novel insights into the genetic basis and evolutionary history of complex traits.

882W

Explicit modeling of genetic ancestry improves polygenic prediction accuracy. *C. Chen[1], J. Han[1,3,4], D. Hunter[1,4,5], P. Kraft[1,2,4,5], A. Price[1,2,5].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) Department of Dermatology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 4) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 5) Broad Institute of Harvard and MIT, Cambridge, MA.

Polygenic prediction using genome-wide SNPs can provide higher prediction accuracy than prediction using only known associated SNPs. It is widely known that the prediction accuracy of polygenic model in structured populations may be partly due to genetic ancestry. However, we hypothesized that explicitly modeling ancestry could improve polygenic prediction accuracy, by providing unbiased estimates for the polygenic component while incorporating associations between ancestry and phenotype as a separate component in the prediction model. This prevents ancestry effects from entering into each SNP effect and being over-weighted. We analyzed three large GWAS of hair color, tanning ability and basal cell carcinoma (BCC) in European Americans (sample sizes: 7,400 to 9,800) to demonstrate our approach, restricting to a set of 70,000 independent SNPs. We compared polygenic prediction without correction for ancestry to polygenic prediction with ancestry as a separate component in the model, using the top 5 principal components to model ancestry. In 10-fold cross-validation, the R^2 for hair color increased by 66% (from 0.0456 to 0.0755; p-value $< 10^{-12}$) when explicitly modeling ancestry in the polygenic prediction model. Similarly, the R^2 for tanning ability increased by 123% (from 0.0154 to 0.0344; p-value $< 10^{-12}$) and the liability-scale R^2 for BCC increased by 68% (from 0.0138 to 0.0232; p-value $< 10^{-12}$) when explicitly modeling ancestry in the polygenic model. For each of the three traits, an improvement in prediction accuracy remains when including known associated SNPs in the polygenic model. In summary, our results show that explicitly modeling ancestry can be important in polygenic prediction.

883T

Powerful detection of osteoarthritis susceptibility loci by comprehensive examination of clinically important endophenotypes. *K. Panoutsopoulou[1], S. Thiagarajah[2], A.G. Day-Williams[1,3], L. Southam[1], K. Hatzikotoulas[1], A. Matchan[1], M. Doherty[4], J.M. Wilkinson[2], E. Zeggini[1], arcOGEN Consortium.* 1) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Academic Unit of Bone Metabolism, Department of Human Metabolism, University of Sheffield, Sheffield, United Kingdom; 3) Biogen Idec, Cambridge, MA, USA; 4) Academic Rheumatology, Nottingham City Hospital, Nottingham, UK.

Osteoarthritis (OA) is a highly heterogeneous disease characterised by variable clinical features with possibly different genetic aetiologies. Thus far, the few genetic variants that have been robustly associated with OA (n=13 in Europeans) explain only a small proportion of its heritability. Studies performed to date have used very broad phenotypic definitions of OA which do not take into account the differences in pattern of joint involvement between individuals that may represent different physiological processes, and may thus have different genetic aetiologies. In a disease like OA the use of expanded and tighter phenotype definitions closer to the biology of the disease is likely to significantly enhance power to identify associations. We have been part of the largest genome-wide association study for OA (arcOGEN GWAS) and have previously established 9 OA associated loci using broad definitions of OA. Here we have comprehensively analysed an expanded set of narrower, clinically relevant OA endophenotypes derived from radiographs of 2,000 knee and 2,000 hip OA cases from arcOGEN. Variables studied relate to joint morphology, specific anatomic pattern of joint involvement, severity and bone response. Following 1000 Genomes Project-based imputation and stringent quality control, >7 million variants were tested for association with each phenotype. Our results indicate that the study of endophenotypes in OA has the potential to dramatically enhance power to detect OA-relevant associations. For example analysis by knee compartment involvement vs population-based controls yielded 25 independent loci for knee OA at $p<1\times10^{-6}$ vs 1 locus detected for knee OA vs controls in the equivalent binary trait GWAS. In hip OA endophenotype analyses several promising signals were identified some of which are found near genes that are very plausible biological candidates for OA: in the analysis of atrophic vs hypertrophic hip OA response a strong signal (OR[95% CI]=2.03[1.57-2.63], $p=2.5\times10^{-8}$) was detected in *GPR98*. *gpr98* knockout mice have a low bone mass phenotype, and a *GPR98* polymorphism has recently been associated with osteoporotic fracture in Japanese women. Pattern of hip migration shows strong association with variants in *LRCH1* ($p=2.9\times10^{-7}$) previously suggestively associated with OA and *BMP1* ($p=2.9\times10^{-7}$) which induces bone and cartilage development. This work has the potential to yield an unprecedented amount of information on OA susceptibility genes.

YAMANAKA[9], S. OGAWA[5], I. KOMURO[4], R. NAGAI[10], R. YAMADA[1], Y. TABARA[2], M. ISOBE[7], T. MIMORI[2], F. MATSUDA[1], Kyoto University Takayasu Arteritis Consortium.* 1) Center for Genomic Medicine, Kyoto University Graduate school of Medicine, Kyoto, Japan; 2) Department of Rheumatology and Clinical Immunology, Kyoto University Graduate school of Medicine, Kyoto, Japan; 3) Department of Molecular Pathogenesis, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 4) Department of Cardiovascular Medicine, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 5) Cancer Genomics Project, Graduate School of Medicine, The University of Tokyo; 6) Department of Bio-informational Pharmacology, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 7) Department of Cardiovascular Medicine, Tokyo Medical and Dental University, Tokyo, Japan; 8) Division of Clinical Nephrology and Rheumatology, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan; 9) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 10) Jichi Medical University, Tochigi, Japan.

Takayasu arteritis (TAK) is an autoimmune systemic vasculitis of which etiology is unknown. While previous studies have revealed that HLA-B*52:01 has an effect on TAK susceptibility, no other genetic determinants have been established so far. Here, we performed genome-scanning of 167 patients with TAK and 663 healthy controls using Illumina Human-Exome array, followed by a replication study consisting of 212 patients with TAK and 1,322 controls. As a result, we found that the *IL12B* region on chromosome 5 (overallp=1.7×10^{-13}, OR:1.75, 95%CI:1.42-2.16) and the *MLX* region on chromosome 17 (overallp=5.2×10^{-7}, OR:1.50, 95%CI:1.28-1.76) as well as the *HLA-B* region (overallp=2.8×10^{-21}, OR:2.44, 95%CI:2.03-2.93) exhibited significant associations. A significant synergistic effect of the SNP in the *IL12B* region and HLA-B*52:01 was found with a relative excess risk of 3.45, attributable proportion of 0.58, and synergy index of 3.24 (p≤0.00028) in addition to a suggestive synergistic effect between the SNP in the *MLX* region and HLA-B*52:01 (p≤0.027). We also found that the SNP in the *IL12B* region showed a significant association with clinical manifestations of TAK, including increased risk and severity of aortic regurgitation, a representative severe complication of TAK. Detection of these susceptibility loci in the current study will provide a new insight to the basic mechanisms of TAK pathogenesis. Our findings indicate that *IL12B* plays a fundamental role on the pathophysiology of TAK in combination with HLA-B*52:01 and that common autoimmune mechanisms underlie the pathology of TAK and other autoimmune disorders such as psoriasis and inflammatory bowel diseases in which *IL12B* is involved as a genetic predisposing factor.

Identification of CNVs association in saliva flow using PennCNV. *M. Lee[1], K. T.Cuenco[1], X. Zheng[1], E. Feingold[1], D.E. Weeks[1], R.J. Weyant[1], R.J. Crout[2], D.W. McNeil[2], M.L. Marazita[1].* 1) University of Pittsburgh, Pittsburgh, PA; 2) West Virginia University, Morgantown, WV.

Background/Objectives: Appalachian populations experience elevated amounts of poor health outcomes like oral disease. Families recruited through the Center for Oral Health Research in Appalachia (COHRA) participated in the NIH Gene, Environment Association Studies Consortium (GENEVA) genome-wide association study (GWAS) of dental caries. Caries is a complex trait also impacted by low saliva flow which helps establish the local environment that interacts with the teeth. The estimated heritability of saliva flow is 49% in COHRA subjects. Past GENEVA GWAS of saliva flow have not considered the potential impact of copy number variations (CNVs) as part of the genetic variability explaining saliva flow differences. The purpose of this study is to identify CNVs that are associated with saliva flow in the COHRA study population and to conduct a comprehensive investigation of these genetic variants. Methods: 1506 Caucasian subjects of age 5 to 75 years were available with saliva flow measures from the COHRA GENEVA population. Saliva flow was categorized as low (≤0.6 ml/min, n_1=925) or high (>0.6 ml/min, n_2=581). The Center for Inherited Disease Research generated genotypes and markers for CNVs with the Illumina 610-Quad platform. We generated CNV calls with the GC model wave adjustment procedure using the PennCNV software. Poor-quality samples identified with log R ratio standard deviation greater than 0.3 are excluded. CNVs with copy number <2 were defined as deletions, and those with copy number >2 were deemed duplications. Genome-wide CNV association analyses with saliva flow are being conducted. We also compare CNV association results with previous hits from single SNP GWAS to check long-range linkage disequilibrium between genome regions. Results: We are currently assessing CNV calls and their association with saliva flow. Identified associations of CNVs with saliva flow will enrich understanding of genetic variability in caries-related traits. Support: DE020127 (K T.Cuenco), and DE018903 and DE014899 (ML Marazita).

Zwick[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA; 3) Center for Statistical Genetics and Department of Biostatistics, University of Michigan School of Public Health, MI; 4) Sibley Heart Center Cardiology, Children's Hospital of Atlanta, GA; 5) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 6) Battelle Center Mathematical Medicine, Nationwide Children's Hospital, Columbus, OH; 7) Heart Center, Nationwide Children's Hospital, Columbus, OH; 8) Down Syndrome Center, Kennedy Krieger Institute, Baltimore, MD; 9) Knight Cardiovascular Institute, Oregon Health & Science University, Portland, OR; 10) Department of Physiology, McKusick Nathans Institute for Genetic Medicine, School Of Medicine, John Hopkins University, MD.

Atrioventricular septal defects (AVSD), a severe congenital heart defect (CHD), occur in the general population in ~1 in 10,000 births. Nearly 20% of infants with Down Syndrome (DS) have an AVSD, representing a ca. 2000-fold increased risk compared to the euploid population. We hypothesize that in the presence of an extra chromosome 21, otherwise benign copy number variants (CNVs) act in an additive manner to explain the increased penetrance of DS-associated AVSD. We have used the Affymetrix SNP 6.0 genotyping platform to comprehensively characterize CNVs in 538 DS samples, consisting of 243 cases (DS + complete AVSD) and 295 controls (DS - CHD). We implemented strict quality control filters to minimize false positive calls, including 3 algorithms to make the CNV calls (BEAST, GADA and GLAD). We also required each putative CNV call to contain > 10 SNPs within the interval. After excluding CNVs overlapping centromeres, we identified 1,711 total deletions (781 in cases and 930 in controls) and 1,302 duplications (607 in cases and 695 in controls). Association analyses in PLINK uncovered a ~275 kb deletion overlapping the MIR1324 gene on chr 3, which after permutation correction for multiple testing is genome-wide significant ($p<0.049$). Additionally, we have identified large rare duplications overlapping genes previously associated with CHD, including MAP3K3, POSTN, MYH11, CTSB and PLCB1, although standard burden tests in PLINK did not identify statistically significant differences between cases and controls in the number or size of the CNVs. This analysis suggests that the genetic factors contributing to the increased prevalence of DS- associated AVSD are complex and heterogeneous. Our efforts are currently focused on the analyses of rare variants in the data set that might contribute to AVSD susceptibility in this sensitized population.

887F

Analysis of Copy Number Variation on Chromosome 21 in Down Syndrome Associated Congenital Heart Defects. *B.L. Rambo-Martin[1], D. Ramachandran[1], J. Mulle[2], A.E. Locke[3], P. Bose[1], L.J. Bean[1], S. Le[1], T. Rosser[1], K. Dooley[4], D.J. Cutler[1], S.Y. Cheong[5], C.L. Cua[6], C.L. Maslen[7], R.H. Reeves[8], S.L. Sherman[1], M.E. Zwick[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA; 3) Center for Statistical Genetics and Department of Biostatistics, University of Michigan School of Public Health, MI; 4) Sibley Heart Center Cardiology, Children's Hospital of Atlanta, GA; 5) Battelle Center Mathematical Medicine, Nationwide Children's Hospital, Columbus, OH; 6) Heart Center, Nationwide Children's Hospital, Columbus, OH; 7) Knight Cardiovascular Institute, Oregon Health & Science University, Portland, OR; 8) Department of Physiology, McKusick Nathans Institute for Genetic Medicine, School Of Medicine, John Hopkins University, MD.

Atrioventricular septal defects (AVSD) are a life threatening congenital heart defect (CHD) inflicting substantial social and healthcare costs. Traditional genetic mapping strategies have revealed a limited but highly heterogeneous, set of aberrant genes responsible for AVSD, and suggest that many AVSD risk loci remain undiscovered. Children born with Down Syndrome (DS) are at a 2000-fold increased risk for AVSD over the general population, resulting in AVSD prevalence in DS of 1 in 5. These data suggest that individuals with trisomy 21 compose a sensitized cohort with respect to AVSD, and may help reveal novel AVSD susceptibility genes. In particular, we hypothesize that copy number variants (CNVs) on chromosome 21 influence the risk of AVSD in individuals with DS, and therefore explain the elevated risk for AVSD found in the DS population. We have performed high-density array comparative genomic hybridization of chromosome 21 in 221 cases (individuals with DS and complete AVSD) and 247 controls (individuals with DS without any CHD). We used the ADM2 algorithm that identifies a CNV as a region with a mean Log2 score significantly departing from the expectation of Log2 = 0. In cases and controls, 668 deletions and 303 duplications were detected. Duplications ranged in size from 1.9 to 782 kb and averaged 108 kb. Deletions ranged in size from 1.8 kb to 391 kb and average 31 kb. Initial analyses suggested no statistically significant differences in the overall rate or size of CNVs between our cases and controls. After filtering out common variants found in the Database of Genomic Variants, cases were found to have a significantly higher fraction of genes duplicated when adjusting for total duplication coverage in each sample (empirical p-value = 0.05). Continuing efforts include: evaluating additional CNV calling algorithms, testing for CNV enrichment over AVSD candidate genes on chromosome 21 and performing pathway analyses. Candidate CNV regions identified from association testing will be validated with Taqman PCR and breakpoint sequencing. Preliminary analyses suggest that the effect of a single or a few common CNVs on chromosome 21 alone do not explain the 2000-fold increased risk for AVSD in the DS population. Our data bolster arguments that there is a high level of heterogeneity found in the etiology of AVSD.

Bronchopulmonary dysplasia (BPD), defined as a requirement for oxygen supplementation at 36 weeks of postmenstrual age (PMA), is the most common chronic respiratory disease in premature infants and its treatment places major demands on health services. Despite considerable advances in the care of very-low-birth-weight (VLBW) infants, BPD still occurs among 20-40% of survivors. Besides the recognized detrimental effects of environmental factors, VLBW twin concordance studies suggested a role of genetic factors. Candidate-gene studies failed to identify robust associations in this setting. The objective of our work was to perform a first genome-wide association study (GWAS) in BPD. We prospectively evaluated 418 premature neonates (PMA lower than 28 weeks), of whom 22% developed BPD. Two discovery series were created using a DNA pooling strategy in neonates from white and African ancestries. Association between single nucleotide polymorphisms (SNPs) and BPD were investigated by two different analysis methods. SNPs associated with the disease were confirmed in an independent replication population. Selected genes were then explored by fine mapping and associations were replicated in an external Finnish population of 213 neonates. Validated genes expression patterns were studied in rat lung during physiologic development and after hyperoxia exposure. The *SPOCK2* locus was the only region identified by the two analysis methods in both discovery series. The most significant polymorphism (rs1245560; p=1.66 × 10-7) was confirmed by individual genotyping and in the replication population (p=0.002). Fine mapping confirmed the association of rs1245560 with BPD in both white and African populations with adjusted odds ratios (ORs) of 2.96 (95% confidence interval [CI], 1.37-6.40) and 4.87 (95% CI, 1.88-12.63), respectively. In white neonates, rs1049269 was also associated with the disease (OR=3.21; 95% CI, 1.51-6.82). These associations were replicated in the Finnish population. In newborn rat lungs, *SPOCK2* mRNA levels markedly increased during alveolarization. After rat exposure to hyperoxia, *SPOCK2* expression significantly increased relative to air-exposed controls. Immunofluorescent studies showed that the SPOCK2 protein was expressed throughout the pulmonary extra-cellular matrix. Thus, a GWAS identified *SPOCK2* as a new candidate susceptibility locus for BPD. Its pattern of expression during lung development points to a potential role in alveolarization.

889T

Dipeptidyl peptidase 10 (*DPP10*) is associated with severe retinopathy in type 1 diabetes. *S.M. Hosseini[1], K. Howard[2], L. Sun[3], A.P. Boright[4], D.A. Tregouet[5], N. Sandholm[6], M.S. Paterson[1,3], the DCCT/EDIC Research Group.* 1) Gen & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Dept of Ophthalmology & Visual Sciences, Univ Wisconsin, Madison, WI, USA; 3) Dalla Lana School of Public Health, Univ Toronto, Toronto, Canada; 4) Dept of Medicine, Univ Toronto and LMC Diabetes & Endocrinology, Toronto, Canada; 5) INSERM UMR_S 937, ICAN Institute for Cardiometabolism and Nutrition, Pierre & Marie Curie Univ, Paris, France; 6) Folkhälsan Inst of Genetics, Univ of Helsinki, Helsinki, Finland; 7) Steno Diabetes Center, Gentofte, Denmark; 8) INSERM U695 & Dept of Endocrinology, Bichat-Claude Bernard Univ Hosp, Paris, France; 9) Dept of Mathematics & Statistics, McMaster Univ, Hamilton, Canada; 10) Dept of Endocrinology & Diabetology, Univ of Poitiers, Poitiers, France; 11) Samuel Lunenfeld Research Institute, Toronto, Canada.

Background: Diabetic retinopathy (DR) is a major health problem affecting most patients with diabetes, yet only a subset progress to severe DR (SDR). Duration of diabetes and glycemia are the main risk factors for DR. Several lines of evidence suggest a genetic contribution to the risk of SDR; however, no genetic variant has shown convincing association with DR in genome-wide association studies (GWAS). **Purpose:** To identify common polymorphisms associated with SDR. **Methods:** White persons with type 1 diabetes (T1D) participating in the Epidemiology of Diabetes Interventions and Complications (EDIC, n=1304) and Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR, n=603) were genotyped by Illumina Human1M and Omni1-Quad assays, respectively. Following quality control procedures, genotypes of ~2.5M autosomal SNPs from phase 2 and 3 of HapMap were imputed in both studies. SDR status [level 53/<53 or worse on ETDRS scale or panretinal laser photocoagulation treatment] was identified by grading 7-field retinal photographs obtained at the most recent follow-up visit. Multivariable models accounted for glycemia (measured by A1C), diabetes duration and other relevant covariates in the association analysis of SDR with additive genotype. Four GWAS were performed separately in WESDR and the 3 subgroups of EDIC (primary cohort, secondary cohort by treatment group - conventional or intensive) prior to combining the results in a meta-analysis. The association of top SNPs was evaluated in three independent white T1D cohorts: Genesis-GeneDiab (n=502), Steno (n=936), FinnDiane (n=2194). **Results:** Several SNPs in *DPP10* showed genome-wide significant association with SDR in the meta-analysis (3 SNPs in strong LD with P<5E-8, 14 with FDR<0.05). In meta-analysis, each copy of the risk allele of any of the top 3 SNPs at this locus doubled the odds of SDR (OR=2.22, 95%CI:1.66-2.98). Although, the top SNPs did not show significant association with SDR in the three replication studies (P>0.05), the direction of effect remained consistent in all but one of the examined populations. *DPP10* is strongly expressed in the brain and pancreas and alters the expression and biophysical activity of voltage gated potassium channels. It has been associated with asthma by linkage/association mapping. Unlike DDP4, target for anti-diabetic gliptins, DPP10 does not show protease activity. **Conclusion:** *DPP10* is the first locus to show strong evidence for association with SDR in a meta-GWAS.

890F

Common Regulatory Variants Mapped in Human Adipose and Skeletal Muscle But Not Lymphoblastoid Cell Lines Tissue Explain Much of the Heritability of Type 2 Diabetes. *J.M. Torres, E.R. Gamazon, N.J. Cox.* Medicne/Genetic Medicine, The University of Chicago, Chicago, IL, IL.

Previous studies have shown that top signals from genome-wide association studies (GWAS) on type 2 diabetes (T2D) are enriched for expression quantitative trait loci (eQTLs) identified in skeletal muscle and adipose tissue. We therefore hypothesized that such eQTLs might account for a disproportionate share of the phenotypic variance in liability to type 2 diabetes (T2D) estimated from all SNPs interrogated through GWAS. To test this hypothesis, we applied genome-wide complex trait analysis (GCTA) to the WTCCC-T2D GWAS dataset representing subjects from the United Kingdom (1924 cases, 2938 controls). We estimated the proportion of phenotypic variance attributable to additive effects of all variants interrogated in these GWAS (i.e. chip-based heritability), as well as from a much smaller set of variants identified as eQTLs for human skeletal muscle and adipose tissue. The estimate of chip-based heritability explained by the total set of GWAS variants is 60% (SE = 6%). The estimates of heritability explained by SNP subsets enriched for eQTLs mapped in human adipose and skeletal muscle tissue are 21% (SE = 7%) and 22% (SE = 6%), respectively. The combined set of adipose and skeletal muscle eQTL-enriched SNP subsets explained 33% (SE = 7% p-value = 4×10-6) of the phenotypic variation whereas the complement set of genome-wide SNPs explained less heritability (30%, SE = 7%), despite representing 3X more variants. The heritability estimate corresponding to the combined eQTL-enriched set was also greater and more statistically significant than the estimate of 6% (SE = 5%, p-value = 0.1) corresponding to a SNP set enriched for eQTLs mapped in human lymphoblastoid cell lines (LCLs) despite there being a greater number of SNPs (8% more) represented in the LCL eQTL-enriched set. Taken together, these results support our hypothesis that common eQTLs mapped in insulin-responsive tissues account for a substantial portion of the variance in liability to T2D.

891W

Higher BMI genetic risk score is associated with presence of radiographic knee osteoarthritis but not progression in the Osteoarthritis Initiative Study. *M.S. Yau[1], R.D. Jackson[2], M.C. Hochberg[1], S. Krishnan[3], D.J. Duggan[3], B.D. Mitchell[1], L.M. Yerges-Armstrong[1].* 1) University of Maryland, Baltimore, MD; 2) Ohio State University, Columbus, OH; 3) Translational Genomic Research Institute, Phoenix, AZ.

Purpose: Increased BMI is highly associated with knee osteoarthritis, but the association could be a cause or effect of the condition. To distinguish between these alternatives, we assessed the association of BMI genetic risk score (GRS) with radiographic knee osteoarthritis (rKOA) and structural progression, reasoning that higher BMI GRS would be associated with greater rKOA presence if BMI were indeed a causal risk factor. **Methods:** We created a weighted GRS in the Osteoarthritis Initiative (OAI) based on published effect sizes for 32 robustly associated BMI risk alleles ($P<5\times10^{-8}$) and tested its association with rKOA presence and progression using logistic regression, adjusting for sex and age. The OAI is a longitudinal cohort of racially diverse high-risk individuals ages 45-79 years at baseline. The current analysis is restricted to Caucasian participants with at least two consensus radiographs over four years. Genome-wide genotyping was conducted on the Illumina 2.5M platform and imputed to the 1000 genomes (CEU/June2011) using Minimac. We defined rKOA cases as individuals who have a KL grade ≥ 2 (n=1,912) in one or more knees and rKOA controls as individuals who have a KL grade ≤ 1 in both knees (n=1,225). Progressive cases have an increase in KL grade from baseline KL grade=1, 2, or 3 in one or more knees or total joint replacement (n=608). Controls for progression have no change in KL grade from baseline KL grade=1, 2, or 3 in both knees (n=1,239). **Results:** BMI GRS was significantly associated with presence of rKOA (adjusted OR=1.22, 95% CI=1.07-1.40), but not with rKOA progression (adjusted OR=1.08, 95% CI=0.90-1.29). Adjusting for baseline BMI substantially attenuated the association between GRS alleles on rKOA (adjusted OR=1.13, 95% CI=0.98-1.30), further supporting a causal association between overweight/obesity and rKOA. Also, *FTO* rs1558902 alone was associated with rKOA (adjusted OR=1.37, 95% CI=1.05-1.79), adding to previous reports that *FTO* is associated with osteoarthritis. BMI GRS calculated without *FTO* rs1558902 also remained significant (adjusted OR=1.17, 95% CI=1.00-1.37). **Conclusions:** Higher BMI GRS is associated with rKOA, but not rKOA progression, even without the most robustly associated *FTO* allele. This supports the hypothesis that the effect of BMI precedes disease onset and plays a role in the onset of rKOA, but not in the trajectory of the disease. These results may have practical implications for management of rKOA.

Investigating Age-related Macular Degeneration in the Amish. *J.D. Hoffman[1], L.N. D'Aoust[1], J.N. Cooke Bailey[1], L. Jiang[1], R. Laux[1], A. Agarwal[2], W.K. Scott[3], M.A. Pericak-Vance[3], J.L. Haines[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Ophthalmology and Visual Sciences, Vanderbilt University, Nashville, TN, United States; 3) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL.

Age-related macular degeneration (AMD) is the leading cause of blindness among the adult population in the developed world. To further the understanding of this disease, we have studied the genetically isolated Amish population of Ohio and Indiana. The Amish are more genetically homogeneous than the general U.S. population and live a stricter lifestyle, thus reducing the variability of environmental effects on AMD in this population. For this analysis we set out to perform a genome-wide association scan for AMD and to characterize how known AMD associated loci contribute to disease risk in the Amish. Additionally, we examined how that risk compares to a general population based sample. We used genotyping data generated with the Affymetrix Human SNP Array 6.0 and Sequenom MassARRAY platforms. In total we analyzed 1,022 Amish individuals (96 with self-reported AMD). Case-control association analysis with adjustment for relatedness based on the complete 13-generation pedigree was carried out using MQLS (Thornton & McPeek 2007). Heterogeneity LOD (HLOD) scores were computed for affecteds-only parametric and nonparametric 2-point linkage using Merlin (Abecasis et al, 2002), with a disease allele frequency of 10%. Mean cumulative genetic risk scores were calculated using a previously described logistic regression model. In our cumulative genetic risk score analysis we observe a mean risk score of 1.12 (95% CI [1.10, 1.13]) in our Amish controls and 1.18 (95% CI [1.13, 1.22]) in our Amish cases. This mean difference in risk scores is statistically significant (p-value of 0.0042). We also observe a significant decrease in cumulative mean risk scores in the Amish when compared to the general sample population for both control (p-value of 0.012) and case datasets (p-value < 0.00001. Our most significant uncorrected MQLS p-value observed in the genome-wide scan is $8.36*10^{-8}$ for the intronic SNP rs16988305 on chromosome 20 in the gene encoding UBOX5. Additional signals are observed at rs17049426 (p-value of $1.67*10^{-7}$) on chromosome 3, and rs1451915 (p-value of $7.76*10^{-7}$) on chromosome 1. These results demonstrate that although the Amish have a similar burden of disease as compared to general populations, the lower cumulative genetic risk indicates that other AMD loci remain to be identified in the Amish.

Crohn's disease is (CD) an inflammatory bowel disease (IBD) induced by multiple genetic and environmental factors. The prevalence of IBDs is much lower in Asian countries, including Japan, than in Western countries, but it is rapidly increasing. Genome-wide association studies (GWAS) have identified many genetic factors for CD in the European population, but information in other ethnic groups is scarce. Recently, we reported two novel susceptibility loci for CD in a Japanese population. To search for additional candidate loci, we performed genome-wide genotype imputation in the GWAS cohort (372 cases and 3,366 controls) using 286 East-Asian subjects from the 1000 Genomes Project March 2012 release (phase 1, version 3) as a reference. From analysis of the imputed GWAS data, we found 44 additional candidate lead SNPs representing putative novel susceptibility loci for CD ($P < 1 \times 10^{-4}$). After applying quality control, we performed genotyping of 34 SNPs with sufficient accuracy. The replication study conducted real genotype data in 1,158 cases and imputed genotype data in 15,061 controls. We calculated combined association statistics using meta-analysis between the imputed GWAS data and mixed replication data (cases using real genotypes with imputed control data). As a result, rs11894081 on 2p25 showed a strong signal for CD in the Japanese population ($P = 3.58 \times 10^{-9}$). The nearest gene to rs11894081 was *SOX11* (SRY (sex determining region Y)-box 11). Although aberrant expression of *SOX11* activates histone marks in some B-cell neoplasms, the relationship between *SOX11* and CD is unknown. Moreover, this association was obtained from analysis of real genotype data for cases and imputed genotype data for controls. To clarify the association, we performed high-density mapping using real genotypes and identified the most responsible SNP for CD susceptibility.

Genome-wide association study identifying genetic risk loci for full-thickness rotator cuff tears. *J.M. Farnham[1], R.Z. Tashjian[2,3], C.C. Teerlink[1], L.A. Cannon-Albright[1,2].* 1) Div. of Genetic Epidemiology, School of Medicine, University of Utah, Salt Lake City, UT; 2) George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, Utah; 3) Dept. ofOrthopedics, School ofMedicine, University of Utah, Salt Lake City, UT.

Introduction. Limited data exits on the genetic predisposition for the development of rotator cuff tearing. Previous evidence suggests a familial predisposition for the development of rotator cuff tearing utilizing a large population database(1) The purpose of the present study was to further investigate the genetic predisposition by identifying potential genetic variants associated with the development of rotator cuff tears. Materials and Methods. A total of 175 patients were identified as having full-thickness posterosuperior rotator cuff tears as defined by MRI. DNA was obtained through a blood sample from these individuals. Samples were genotyped on the Illumina Omni5.0 SNP platform. We used 3293 Caucasian controls from the Illumina icontrols database genotyped on the Illumina 550K platform. The intersection of the two platforms contains 287,563 markers across the autosomal and X chromosomes. We performed typical quality control procedures using Plink software resulting in 272,641 markers for analysis. We used GEMMA software to conduct tests of association at each marker. GEMMA software empirically estimates a kinship covariance matrix for all pairs of individuals, which is used in the analysis to mitigate potential effects of population stratification and cryptic relatedness. Results. Two SNPs were identified that exceeded the threshold for significance (p < 1.8e-7) after adjusting for multiple testing. One SNP (rs12491628; p = 6.9e-12; OR = 2.77) resides on the 3p24.1, approximately 100Kb upstream of the LRRC3B gene. The other significant SNP (rs161811; p =1.2e-8; OR = 3.17) resides on 1p36.2 in the TNFRSF9 gene. Discussion We have identified two potential genetic variants associated with the development of rotator cuff tearing. To our knowledge, these findings represent the first attempt to identify genetic factors influencing the development of rotator cuff tears via a genome-wide association study. Further research is being conducted to further characterize these regions with the goal of identifying specific genes associated with tearing. References. 1. Evaluation of the common genetic architecture of problematic peer relationships. *B. St Pourcain[1,2], C.M.A. Haworth[3], O.S.P. Davis[3], N.J. Timpson[1], G. McMahon[1], J. Kemp[1], D. Evans[1], S.M. Ring[4], W. McArdle[4], J. Golding[4,5], R. Plomin[3], G. Davey Smith[1].* 1) MRC CAiTE, University of Bristol, Bristol, United Kingdom; 2) School of Oral and Dental Sciences, University of Bristol, UK; 3) MRC Social, Genetic & Developmental Psychiatry Centre, Institute of Psychiatry, UK; 4) School of Social and Community Medicine, University of Bristol, UK; 5) Centre for Child and Adolescent Health, University of Bristol, UK.

Peer interaction plays an important role in the development of social competence, and problematic childhood peer relationships often precede later maladjustment. Some links between early peer rejection and later maladaptive functioning however might be mediated through an underlying pathology. For example, impairments in social interaction skills are characteristic and heritable symptoms of the autistic dimension. Our study performed a twin study and a genome-wide analysis, to investigate genetic influences contributing to impaired peer relationships during childhood and adolescence. Heritability was estimated using ≤7366 UK twin pairs (TEDS) with parent-report on peer problems at 4, 7, 9 and 11 years. Using a multivariate (ACE) model, we found that a considerable proportion of the phenotypic variance is attributable to genetic factors ($0.60< h^2<0.71$), and that some genes affecting peer problems during development remain the same ($0.32< r_g<0.69$). Across development, we observed primarily non-shared environmental influences ($0.27< e^2<0.32$), with minimal evidence for shared environmental effects ($0.02< c^2<0.09$). A subsequent genome-wide screen was conducted in ≤6000 children from a large UK birth-cohort (ALSPAC) with parent-report on peer problem at 4, 7, 8, 10, 12, 13 and 17 years. The association between the skewed phenotypes and allele-dosage was assessed using a Poisson family model, and carried out for each time-point individually, thus allowing for genetic heterogeneity. The strongest signals ($2\times10^{-7}P\leq10^{-5}$) were eventually modelled longitudinally and further investigated in 793 autism pedigrees (AGRE). Two population-based signals contributed to risk for autism and were consistent in their direction of effect. However, combined evidence (based on P-values) only reached suggestive levels of significance. This included an age-independent SNP effect within the vicinity of *GLIS3* at 9p24.2 ($P_{ALSPAC}=4.9\times10^{-6}$, $P_{AGRE}=0.0030$, Fisher-Combined-$P=2.8\times10^{-7}$) and an age-dependent SNP effect (Age-SNP-$P_{ALSPAC}= 4.9\times10^{-5}$) near *GHR* at 5p12, which was strongest in later adolescence ($P_{ALSPAC,\ 17\ years}=2.5\times10^{-5}$, $P_{AGRE}=0.00058$, Fisher-combined-$P= 2.7\times10^{-7}$). Signals are currently being followed-up in ≤2835 independent individuals in TEDS (age 4-11 years). Together, our findings support the contribution of common genetic effects to variation in problematic peer relationships, though many more samples might be required to reliably identify individual SNP signals.

Reclassification in genetic risk prediction over time. *R. Barfield[1], J. Krier[2], R. Green[3], P. Kraft[1,4].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, Massachusetts; 2) Harvard Medical School Genetics Training Program, Boston, Massachusetts; 3) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts; 4) Program in Molecular and Genetic Epidemiology, Harvard School of Public Health, Boston, Massachusetts.

Genome wide association studies have identified hundreds of common alleles with modest effects on risk of complex disease. The clinical utility of genetic risk profiles based on these variants depends crucially on the number and effect size of identified loci, and how stable the predicted risks are as additional loci are discovered. Individuals flagged as high risk at one time may be reclassified as low risk or vice versa as more loci are identified. Motivated by the development of a risk report for common complex disease as part of the MedSeq project on the integration of whole genome sequencing into clinical medicine, we quantify this reclassification using breast cancer (BrCa) and heart disease (CHD) as examples. Published results for potential causal SNPs were taken from the NHGRI catalogue. We simulated genotypes for a EUR population (n=100000) for these SNPs from the 1000 genomes projects. We calculated the predicted odds of disease for an individual as the product of the genotype specific odds ratios across all the risk markers known in 2007, 2009, 2011 and 2013. The odds were then normalized by the mean odds for all members of the simulated cohort for that year. The range of the predicted risks increased from 2007 to 2013: the 95th risk percentiles rose from 1.34 and 1.33 times the population average to 2.11 and 2.22 for CHD and BrCa, respectively. This caused 6% of the population to be reclassified from lower than 2x average CHD risk in 2007 to higher in 2013. The reclassification proportion for BrCa was 7%. The proportion of subjects at very high risk (greater 5x population average) increased from 2007 to 2013 (0 to 4×10^{-4} and 7×10^{-4} for CHD and BrCa respectively). We used the distribution of GWAS-identified risk markers to estimate the number of as-yet-unknown common risk alleles and their effect distribution, and used this to project the number of risk markers identified in future studies. The future reclassification from above 2x risk to below (or vice versa) projected from doubling available GWAS samples was notably smaller. This suggests that risk estimates in the 0.5-2.0 times average range--a widely used clinical benchmark for common diseases--are stable for diseases that have been as extensively studied as CHD and BrCa. Finally, our projections place upper bounds on the contribution of rare variants to total heritability, giving insight into clinical utility of rare variants.

Genome-wide association study on Morbid Obesity in Taiwan Han Chienese. *H.C. Chang[1], W.J. Lee[2], H.C Yang[3], W.H. Pan[1].* 1) Institution of Biomedical Science, Academia Sinica, Taipei, Taiwan; 2) Ming-Sheng General Hospital, Taoyuan, Taiwan; 3) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan.

Development of obesity and successful weight loss are influenced by multiple genes, the combinations of which are most likely ethnic-specific. While there is yet to be any systematic research regarding the obesity genome of the Chinese Han ethnic group, the obesity rate in Taiwan has been increasing steadily over recent years. The need for such information in obesity prevention and management not only has medical urgency, but should also have commercial value. In this study, we intend to recruit 570 obese persons who were body mass index (BMI: weight in kilogram divided height in meter square) equal or over 35 (as morbid obesity, MO) from Bariatric Surgery center in Ming-Sheng General Hospital , and compare with the 570 control subject with BMI less than 24 from TGWAS (Taiwan genome wide association study). The variables considered in patient matching include: (1) gender, (2) age (±5 years old). Inclusion criteria include: (1) between 20-55 years of age and (2) parents claimed to be of Han ethnicity. Via Axiom Genome-Wide CHB Array Plate which has been specific designed for CHB populations from Affymetrix Company, we will conduct the genotyping. And then, we hope to perform a whole genome screening (via genome-wide association studies, GWAS) to investigate related DNA single-nucleotide polymorphism (SNP) focusing on individual BMI phenotype. Final, we aim to construct a sensitive and specific genome composed of obesity-related genes entirely specific to Taiwan's Han ethnic group. The results can be used in the future to screen for high-risk populations.

Genome-wide association study identifies novel loci associated with abdominal obesity in Africans. *A. Doumatey[1], A. Adeyemo[1], G. Chen[1], F. Tekola-Ayele[1], AR. Bentley[1], J. Zhou[1], H. Huang[1], D. Shriner[1], D. Ngare[8], O. Fansanmade[2], T. Johnson[2], J. Oli[3], G. Okafar[3], BA. Eghan[4], K. Agyenim-Boatang[4], J. Adeleye[5], W. Balogun[5], C. Adebamowo[5,7], A. Amoah[6], J. Acheampong[4], CN. Rotimi[1].* 1) NHGRI/CRGGH, National Institutes of Health, Bethesda, MD; 2) Department of Medicine, University of Lagos, Lagos, Nigeria; 3) Department of Medicine, University of Nigeria Teaching Hospital, Enugu, Nigeria; 4) Department of Medicine, University of Science and Technology, Kumasi, Ghana; 5) Department of Medicine, University College Hospital, Ibadan, Nigeria; 6) Department of Medicine and Therapeutics, University of Ghana Medical School, Accra, Ghana; 7) Department of Epidemiology and Public Health, School of Medicine, University of Maryland, Baltimore, MD; 8) Department of Mental Health and Behavioral Sciences, Moi University of Medicine, Eldoret, Kenya.

Obesity, especially abdominal obesity (AOb), is a risk factor for cardiovascular diseases and type 2 diabetes (T2D). AOb is heritable and several loci have been shown to influence its distribution at the population level. However, most prior studies of genes influencing AOb were performed in populations of non-African ancestry, a limitation given known differences in AOb by ethnicity. In this study, we conducted the first genome-wide association study of AOb in Africans. The study participants comprised 1808 Africans enrolled in the Africa America Diabetes Mellitus (AADM) study. Waist circumference (WC) and Waist-to-hip ratio (WHR) were used as measures of abdominal adiposity. Genotyping was carried out using the Affymetrix Axiom PANAFR SNP array (~2.1 million SNPs) imputed using the latest 1000 Genomes cosmopolitan reference for a total of 15 million SNPs included in the analysis. Association tests were adjusted for age, gender, T2D, BMI, and the first 3 principal components (PCs) of the genotypes. A cluster of SNPs on chromosome 2 (2p25.3, near FAM110C) and rs116158389 on chromosome 19 (19p13.2, near RDH8) were associated with WC at genome-wide significance level ($p<5\times10\text{-}8$). The top-ranked SNP on chromosome 2 (rs114441856, FAM110C, p=5.1×10-10) is in moderate- to complete LD($0.64<r2<1$) with the other associated SNPs in the region, indicating the likelihood of a single signal at the locus. FAM110C is expressed in adipocytes and has been implicated in metabolic processes including microtubule remodeling and Akt1 activation. The associated chromosome 2 variants are polymorphic in sub-Saharan Africans but are monomorphic in other continental populations. Several loci were nominally (7.6×10-8<p-value< 1.6×10-6) associated with WHR, including variants on chromosomes 19 (near RDH8, ZNF814, and MIR5589), 1 (RALGPS2), 2 (near REG3G), and 11 (in MMP13). This first GWAS of AOb in Africans identified novel loci that may provide new insights into the genetic architecture of obesity. While additional studies are needed to confirm and extend the findings, these results underscore the importance of studying multiple global populations in genetic studies of complex traits.

Genome-wide association analysis shows the highly polygenic character of age-related hearing impairment. *E. Fransen[1, 2], S. Bonneux[1], J.J. Corneveaux[3], I. Schrauwen[1, 3], F. Di Berardino[4], C.H. White[5], J.D. Ohmen[5], P. Van de Heyning[6], U. Ambrosetti[4], M.J. Huentelman[3], G. Van Camp[1], R.A. Friedman[5].* 1) Center Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) StatUa center for statistics, University of Antwerp, B-2000 Antwerp; 3) Neurogenomics Division, The Translational Genomics Research Institute, Phoenix, Arizona 85004 USA; 4) Audiology Unit, Dept. of Clinical Sciences & Community Health, University of Milan; Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; 5) Cell Biology and Genetics Division, House Research Institute, Los Angeles, CA 90057; 6) Department of Otolaryngology, University Hospital of Antwerp, B-2650 Edegem, Belgium.

We have performed a genome-wide association study (GWAS) to identify the genes responsible for age-related hearing impairment (ARHI), the most common form of hearing impairment in the elderly. Analysis of common variants, with and without adjustment for stratification and environmental covariates, rare variants and interactions, as well as gene-set enrichment analysis showed no variants with genome-wide significance. No evidence for replication of any previously reported genes was found. The phenotype depends on the aggregated effect of a large number of SNPs, of which the individual effects are undetectable in a modestly powered GWAS. We estimate that 22% of the variance in our dataset can be explained by the collective effect of all genotyped SNPs. A score analysis showed a modest enrichment in causative SNPs among the SNPs with a p-value below 0.01. This is the first time that ARHI GWAS data are analyzed in such a manner, and the results prove that ARHI is highly polygenic in nature, with probably no major genes involved.

900W

Metabolic pathways in relation to obesity: Untargeted metabolomic profiling in a large population-based study. *J. Kumar[1], A. Ganna[2], T. Fall[1], J. Prenni[3], C. Broeckling[3], J. Prince[2], L. Lind[4], E. Ingelsson[1].* 1) Department of Medical Sciences, Molecular Epidemiology, Uppsala University and Science for Life Laboratory, Uppsala, Sweden; 2) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 3) Proteomics and Metabolomics Facility, Colorado State University, Fort Collins, U.S.A; 4) Department of Medical Sciences, Uppsala University, Uppsala, Sweden.

Introduction: Obesity is the main cause of various disorders such as type 2 diabetes and cardiovascular diseases and has become a serious public health problem of increasing prevalence. In the present study, we investigated the associations of body mass index (BMI) with circulating metabolites in a non-targeted metabolomics experiment and then performed a genome-wide association study (GWAS) of associated metabolites. Materials and Methods: Ultra-performance liquid chromatography coupled with tandem mass spectrometry was employed to perform a non-targeted metabolite profiling in two population-based cohort studies (TwinGene; N=1520 and PIVUS; N=970). Linear regression analyses were performed to test the association of BMI with different metabolites adjusting for potential confounding factors (age, sex, seasonal variation, storage, handling time and time since last meal). Significant findings were selected by controlling a false discovery rate (FDR) of 1%. GWAS was performed on the significant metabolite features to identify their associated loci. Results: A total of 8,185 and 11,056 molecular features were observed after quality control in PIVUS and TwinGene, respectively. In total, 2,281 molecular features were found to be significantly associated with BMI in PIVUS (FDR<1%) and 1,216 of these features could be replicated in TwinGene (p<0.05). These 1,216 molecular features represent 113 different metabolites (based on similar retention time and high correlation) of which seven could be annotated with high confidence (1-oleoyl-2-hydroxy-sn-glycero-3-phosphocholine, Glycerophosphocholine, negatively associated with BMI; Alpha-Linolenic acid, Caffeine, Deoxycholic acid glycine conjugate, L-Carnitine and L-Tyrosine, positively associated with BMI) utilizing a private compound library. GWAS of these seven metabolites from PIVUS and TWINGENE showed that SNPs from carnitine gene (rs1171617, $p=2.41*10^{-30}$) were found to be significantly associated with levels of circulating carnitine. Conclusion: In conclusion, the application of non-targeted metabolite profiling to evaluate two large population-based cohorts revealed 113 metabolites to be significantly associated with BMI. Seven of these metabolites were annotated with high confidence. Genetic variants from the carnitine gene were found to be significantly associated with circulating levels of L-Carnitine. Further efforts to improve annotation of the remaining are underway through additional experiments.

Genomewide Association Studies of Lipids in Samoans. *R.L. Minster[1], N.L. Hawley[2,3], G. Sun[4], H. Cheng[4], S. Viali[5], R. Deka[4], D.E. Weeks[1,6], S.T. McGarvey[7].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Weight Control and Diabetes Research Center, the Miriam Hospital, Providence, RI, USA; 3) The Alpert Medical School, Brown University, Providence, RI, USA; 4) Department of Environmental Health, School of Medicine, University of Cincinnati, Cincinnati, OH; 5) Medical Specialist Clinic and National Health Services, Government of Samoa, Apia, Samoa; 6) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 7) Department of Epidemiology, International Health Institute, School of Public Health, Brown University, Providence, RI.

Genomewide association studies (GWAS) of quantitative traits in population isolates affords a unique opportunity to identify quantitative trait loci. Studies in populations like Samoans can detect genes that are novel and population-specific as well as those that affect traits across populations. Obesity has greater prevalence among Samoans compared to many other ancestry groups, and identifying variation that affects lipids levels against this background could reveal novel mechanisms for intervention. Here we report the results of GWAS of levels of total cholesterol, high-density lipoprotein, low-density lipoprotein and triglycerides in 3,122 adults from Samoa. Age, age^2, sex, BMI, smoking and alcohol use were considered as covariates for each of the four phenotypes. A total of 871,188 autosomal single-nucleotide polymorphisms (SNPs) were genotyped and extensive quality control of the genotypes was performed. Five loci were identified with genomewide significance ($p < 5 \times 10^{-8}$), all of which have been reported previously (*APOE*, *ZNF259*, *CETP*, *GCKR* and *LIPG*). Six loci, three of them novel, were identified with suggestive associations between $p = 10^{-6}$ and $p = 5 \times 10^{-8}$. An additional twenty-eight loci had suggestive associations with p values between 10^{-5} and 10^{-6} with one or more of the four lipid traits. Additional studies in related Polynesian populations are necessary to verify these new findings. This work was supported by U.S. National Institutes of Health grant R01-HL093093 (P.I. Stephen McGarvey).

Identification of genetic factors underlying asthma age-of-onset sub-phenotypes. *C. Sarnowski[1,2,3], M-H. Dizier[1,3], I. Ahmed[2,4], P. Margaritte-Jeannin[1,3], M. Lathrop[5,6], F. Demenais[1,3], E. Bouzigon[1,3], the EGEA cooperative group.* 1) UMR946, INSERM, PARIS, France; 2) Univ. Paris Sud, Paris, France; 3) Univ. Paris Diderot, Paris, France; 4) CESP, INSERM, UMRS 1018, Villejuif, France; 5) McGill Univ., Montréal, Canada; 6) CNG/CEA, Evry, France.

Asthma is a heterogeneous disease with variable clinical expression over the life span. The disease age of onset is one of the simplest features that can be used to differentiate asthma phenotypes. To characterize the genetic factors influencing asthma in age-of-onset specific manner, we conducted a GWAS using a multinomial regression model applied to 750 asthmatics categorized according to their age-of-onset and 1,085 non-asthmatics from the French EGEA study with HapMap2 imputed data. Asthmatics were split into four specific age-of-onset sub-phenotypes: A) age-of-onset ≤ 4yrs (early-onset), B) 5-12yrs (before puberty), C) 13-20yrs (between puberty and adulthood) and D) > 20yrs (adult-onset). First, we applied an association test allowing heterogeneity of SNP effect between sub-phenotypes (Morris et al. Genet Epidemiol 2010) and detected 60 SNPs with P-value $\leq 10^{-5}$. Then, we tested whether these SNPs had a heterogeneous effect among the four sub-phenotypes. We identified 53 SNPs located in 16 regions with an interclass heterogeneity P-value $\leq 10^{-3}$. Among these regions, six had intra-class association P-values $\leq 10^{-5}$. We confirmed the specific association between 17q12-q21 genetic variants and early-onset asthma ($P=10^{-6}$) (Bouzigon et al. N Engl J Med 2008). We also detected five new regions among which four loci with SNP effect restricted to one asthma age-of-onset sub-phenotype: 9q34 with phenotype A ($P=5\times10^{-6}$), 3q25 with phenotype B ($P=2\times10^{-7}$), 1p13-p12 and 3q27-q28 with phenotype C ($P\leq3\times10^{-7}$), and one locus (3p22) associated with both phenotypes C and D ($P=2\times10^{-7}$ and $P=8\times10^{-3}$ respectively). This analysis will be extended to GABRIEL Asthma consortium datasets. Thus, taking into account the age of onset in a multinomial regression framework can be a powerful approach to identify new loci underlying complex diseases. Genetic Association of Serum Magnesium Levels in African Americans: the Atherosclerosis Risk in Communities (ARIC) Study. *A. Tin[1], A.R. Folsom[2], N. Maruthur[3], C.A. Friedrich[4], J. Coresh[1], E. Boerwinkle[5], W.H. Kao[1].* 1) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) University of Minnesota School of Public Health, Minneapolis, MN; 3) Johns Hopkins University School of Medicine, Baltimore, MD; 4) University of Mississippi Medical Center, Jackson, MS; 5) University of Texas School of Public Health, Houston, TX.

Background. Magnesium (Mg) is important in enzymatic reactions and the regulation of mitochondrial function and vascular tone. Low serum Mg is associated with a greater burden of cardiovascular disease, hypertension, and diabetes. African Americans (AAs) have both lower serum Mg and dietary Mg intake versus European Americans (EAs). Genome-wide association studies (GWAS) in EA identified six loci associated with serum Mg, but no GWAS of serum Mg have been conducted in AA. Methods. We conducted the first GWAS of serum Mg in 2758 AA ARIC participants using linear regression controlled for age, sex, and population substructure. We interrogated the flanking region (+/-500kb or the two closest recombination hot spots) of the six published serum Mg index SNPs from EA studies in our AA sample (significance level p <0.05 / number of independent SNPs in each locus). We then determined the impact of a genotype score (the sum of the alleles of the index SNPs associated with decreased Mg in each population) on the association between serum Mg and self-reported race in 2758 AA and 8626 EA ARIC participants.We tested the correlation of serum Mg with African ancestry. Results. No locus reached genome-wide significance in AA. The most significant association was on chromosome 14 ($p=1.4\times10^{-7}$). Of the six known genome-wide significant loci in EA, five were nominally significant in AA (MUC1 at chr1:155184975, $p=1.9\times10^{-7}$; MDS1 at chr3:168830777, $p=5.5\times10^{-4}$; SHROOM3 at chr4:77638013, $p=1.2\times10^{-3}$; TRPM6 at chr9:77481834, $p=2.2\times10^{-6}$; DCDC51 at chr11:30979139, $p=6.1\times10^{-4}$). In AA, the index allele associated with lower Mg had larger effect sizes (5/5) but lower frequencies (4/5) compared with those in EA. The five index SNPs explained 2.7% of the variance in serum Mg in AA. After accounting for age and sex, self-reported AA status was associated with 0.04 mmol/L lower serum Mg ($p=1.7\times10^{-122}$), which became 0.06 mmol/L ($p=2.0\times10^{-190}$) after accounting for the genotype score. The correlation between serum Mg and African ancestry was -0.05 (p=0.02). Conclusions. In a large sample of EA and AA middle-aged adults, most of the top loci for serum Mg in EA were also associated with serum Mg in AA, but these loci did not explain the disparity in serum Mg levels between the two populations. Additional fine mapping of these loci to identify the causal variants will be important for understanding the genetic basis of hypomagnesemia and its possible relationships to other conditions.

Height, adiposity and fat distribution differ between men and women and change over time (e.g. following menopause). Previously, genome-wide association meta-analyses (GWAMAs) of anthropometric traits revealed sexually dimorphic loci for waist-hip ratio (WHR), a measure of fat distribution, but little is known of whether genetic effects on anthropometric traits change with age, and whether such changes differ between men and women. To detect age and sex dependent genetic effects, we conducted GWAMAs stratified by age (cut-off at 50 years, i.e. average age of onset of menopause) and by sex. We used 91 imputed GWA studies and 23 MetaboChip studies comprising >310,000 individuals of European ancestry from the GIANT consortium. Each study tested up to 2.8M SNPs for association with height, BMI and WHR in four strata (men≤50y, women≤50y, men>50y, women>50y). For each trait, we conducted inverse-variance weighted meta-analyses (one for each stratum), subsequently tested the pooled stratum-specific estimates for difference between the age-groups, between the sexes and for heterogeneity between the four strata and controlled each test at 5% FDR. To boost statistical power, we focused only on the SNPs that showed some overall association in the four strata combined (P<1E-5). For BMI, our analysis yielded 13 loci with significant age-difference (near *COBLL1, DDC, NEGR1, TNNI3K, SEC16B, TMEM18, ADCY3, AC016194.1, TCF7L2, STK33, FTO, MC4R* and *APOC1*), of which 10 showed a stronger effect in the younger subgroup. For WHR, our analysis yielded 25 loci with significant sex-difference (16 novel sexually dimorphic loci near *MSC, GANAB, RPS6KA5, GORAB, MEIS1, PLXND1, FAM13A, MAP3K1, NSD1, LY86, NFE2L3, NKX3-1, DNAH10, KCNJ2, EDEM2* and *EYA2*; and all nine previously established sexually dimorphic variants for WHR). Of the 25 loci, 23 showed a stronger effect in women. Although we did not find any loci with significant sex-difference for BMI or age-difference for WHR, our scan on the heterogeneity between the four strata identified two additional loci for BMI (near *CXXC5* and *TSHZ2*) and one additional locus for WHR (near *BMP2*), which might reflect potential age or sex dependency. Our analysis did not yield any age or sex dependent genetic effects for height. Our results underscore the importance of sex- and age-stratified analyses to illustrate a sexually dimorphic and age-dependent genetic underpinning for anthropometric traits.

905F

Targeted resequencing of genome wide associated candidate regions for pediatric venous thrombosis. *A. Witten[1], A. Arning[1], A. Barysenka[1], Ch. Grote[1], M. Hiersche[1], F. Ruehle[1], U. Nowak-Goettl[2], M. Stoll[1].* 1) Genetic Epidemiology of vascular disorders, Leibniz-Institute for Arteriosclerosis Research at the University of Münster, Münster, NRW, Germany; 2) Institute of Clinical Chemistry, University Hospital Schleswig-Holstein, Germany.

Venous thrombosis is a common multifactorial disease, which is influenced by environmental and genetic factors. Here we present a genome wide association study (GWAS) in 212 trios with pediatric venous thrombosis comprising affected children and their parents. For two SNPs exceeding the threshold for genome wide association (p>10-5) determined by 1.000.000 bootstrap permutations replication was conducted in 201 trios with thromboembolic stroke (TS). Among these, rs1304029 and a SNP curtly missing the threshold for permutated p-value (rs2748331) reside in a region on chromosome 6q13 comprising the gene for beta-1,3-glucoronyltransferase 2 (B3GAT2), and are associated with pediatric VTE (rs1304029; p=1.42×10-6, rs2748331; p=6.11×10-6). rs2748331 was replicated (p=0.00719) in our GWAS on pediatric TS (combined p=7.88×10-7). Twenty-seven additional SNPs were associated at confident permutated P-values (p<1×10-4). To investigate possible causative gene variants in the resulting linkage disequilibrium based candidate regions, we performed a next generation resequencing approach in 24 affected children and 24 unaffected siblings. The selected target regions of about 11 Mb in total comprise 30 gene regions from 16 chromosomes. Custom target enrichment was performed using the NimbleGen SeqCap EZ Choice technology. The resulting DNA libraries were paired-end sequenced (100 cycles) on an Illumina HiScanSQ instrument yielding in 142.5 Gb sequence data in total and 91.8% bases with a QScore > 30. Sequence reads were mapped by using the BWA algorithm and analyzed by GATK yielding in 83% median target specificity and median target region coverage of 196x. Variant annotation was done by using SNPEff and Annovar software tools. A sibling TDT test was applied on the 41,478 identified variants, 4,062 of which were novel to compare the two sample groups. 23 significant (p<0.05) coding non-synonymous or UTR SNPs in 10 genes were identified and selected for subsequent validation using capillary sequencing and genotyping within the full cohort of 257 nuclear families. Future studies elucidating the functional relevance of these genetic variants are warranted to further elucidate the role of these in the pathogenesis of DVT.

Blood levels of adiponectin, an adipocyte-secreted protein correlated with metabolic and cardiovascular risk, are highly heritable. Genome-wide association (GWA) studies have identified 14 loci harboring variants associated with adiponectin level. To identify novel adiponectin-associated loci, particularly those of importance in East Asians, we conducted a meta-analysis of GWA studies for adiponectin in 7,827 individuals, followed by *in silico* and *de novo* replication in 4,298 and 5,724 additional individuals of the Asian Genetic Epidemiology Network (AGEN). Of the adiponectin-associated loci previously reported, we confirmed the association at six loci including *CHD13*, *ADIPOQ*, *PEPD*, *CMIP*, *ZNF664* and *GPR109A*. We identified a novel signal on chromosome 10, ~300 kb from *WDR11* and ~300 kb from *FGFR2* ($P = 1.9\times10^{-14}$). We also provided suggestive evidence of another locus near *OR8S1-LALBA* on chromosome 12 ($P = 9.4\times10^{-8}$). *FGFR2* is a strong candidate gene implicated in adipocyte hyperplasia and hypertrophy; the novel signal at *WDR11-FGFR2* explained 0.6% of the total variation in adiponectin. Despite a consistent direction of allelic effect, the index SNP at *WDR11-FGFR2* did not show strong evidence of association ($P = 0.093$) in > 29,000 Europeans in the publicly released ADIPOGen data. The difference in the trait-increasing allele frequency (AGEN: 0.57; ADIPOGen: 0.24) and the significant level of association across populations suggested that a variant at *WDR11-FGFR2* might have a larger genetic effect on adiponectin level in East Asians than Europeans, or the pairwise LD between the index SNP and the un-typed causal variant vary across different populations. The adiponectin-increasing allele of the index SNP exhibited evidence of association with a decreased BMI-adjusted waist-hip-ratio in 17,560 East Asians ($P = 9.8\times10^{-3}$). At *WDR11-FGFR2*, twenty-two candidate variants that span 65 kb are in moderate to high LD ($r^2 > 0.6$) with the index SNP, and at least four candidate variants are located at or near enhancer marks in adipose nuclei and predicted to possibly alter the transcriptional activity of nearby genes. However, the reporter assays in differentiated adipocytes showed no allelic difference in transcriptional activity. Our findings improve knowledge of the genetic basis of adiponectin variation, demonstrate the shared allelic architecture of adiponectin and central obesity, and motivate further studies of underlying biological mechanisms.

907T

Genome-wide association analysis of skeletal muscle fiber types.
T. Karaderi[1], N. Oskolkov[2], C. Ladenvall[2], S. Keildson[1], A. Mahajan[1], L. Lind[3], E. Ingelsson[4,1], L. Groop[2], P. Franks[5], A.P. Morris[1], O. Hansson[2], C.M. Lindgren[1]. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, Malmö, Sweden; 3) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 4) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 5) Department of Clinical Sciences, Genetic and Molecular Epidemiology, Lund University, Malmö, Sweden.

The human body contains over 400 skeletal muscles, together constituting 40-50% of the total body weight. Skeletal muscle is a key organ in many basic bodily functions, such as movement, respiration and thermogenesis. Individual muscles consist of a combination of 3 types of fibers: type 1 fibers (red, slow and oxidative), type 2A (red, fast and oxidative) and type 2X (white, fast and glycolytic). It has been previously shown that muscle fiber composition is associated with obesity, weight loss and type 2 diabetes. Therefore, it is important to explore the genetic make-up of muscle fiber composition to better understand the factors affecting the risk of such conditions. We conducted a genome-wide association study (GWAS) of these three skeletal muscle fiber types in a total of 656 individuals from three independent cohorts from Sweden. Genotype data in each cohort were imputed up to 35 million variants from the 1000 Genomes 'all ancestries' reference panel (March 2012). Within each cohort, phenotypes were inverse rank normalized and tested for association with each high-quality imputed variant (info>0.4) under an additive model after adjustment for age and body-mass index. After a conservative double genomic control correction, the data was merged using fixed-effects meta-analysis, and filtered for total minor allele count ≥5. Four independent loci showed association at genome-wide significance ($p<5\times10^{-8}$) with either type 2A or 2X fibers, but none with type 1 fiber. Fiber type 2A is associated with rs74979762 (minor allele frequency (MAF)=0.005, $p=8.04\times10^{-9}$), which is located downstream of *SIPA1L2*, within a potential transcription factor binding site. There were also three loci associated with fiber type 2X. The first is intronic (rs145631867, MAF=0.02, $p=2.23\times10^{-8}$) and maps to *NYAP2* and the second locus is intragenic (rs7776803, near *STEAP1*, MAF=0.27, $p=2.29\times10^{-8}$). Finally, one associated SNP (rs149081100, MAF=0.02, $p=2.96\times10^{-8}$) maps in *ADRA1B*, within a DNase I hypersensitivity region and a possible strong enhancer-binding site for glucocortocoid receptors functioning in anti-inflammatory immune responses and regulation of glucose metabolism. In conclusion, we have performed the first GWAS of detailed physiological measures of human skeletal muscle fibre. The genetic associations we observe suggest that the make-up of fiber types in skeletal muscle are under at least partly genetic control.

908F

Genome-wide association study of skin pigmentation and tanning in African Americans. *K. Batai[1, 2], E. Shah[2, 3], R.A. Kittles[2, 3, 4].* 1) Institute for Health Research and Policy, University of Illinois at Chicago, Chicago, IL; 2) Institute of Human Genetics, College of Medicine, University of Illinois at Chicago, Chicago, IL; 3) Section of Hematology/Oncology, Department of Medicine, University of Illinois at Chicago, Chicago, IL; 4) Division of Epidemiology and Biostatistics, School of Public Health, University of Illinois at Chicago, Chicago, IL.

Background: Skin pigmentation is a complex trait that is strongly controlled by genes and sunlight exposure. The identification of pigmentation genes is important for understanding of skin cancer susceptibility and vitamin D status. Genome-wide association studies (GWAS) in European, Asian, and African-European admixed Cape Verdean populations have identified multiple loci associated with pigmentation traits. Many of these GWAS loci are similar across populations while several are population specific. To date, there has not been any GWAS performed in African Americans (AAs) that attempt to identify loci associated with pigmentation traits. Here, we report results of the first GWAS of skin pigmentation and tanning ability in AAs.

Methods: Skin pigmentation (M-Index) of 215 AA men from Washington, DC was measured on subjects' forehead and upper inner arm using reflectometer and samples were genotyped using Illumina Infinium 1M-Duo bead array. After quality control, 994,618 SNPs were available for analyses. We tested association for the inner-arm (constitutive) M-Index using linear regression model adjusting for age and first 4 principal components (PCs)s and for tanning ability (inner arm M-Index subtracted from forehead M-Index) adjusting for age and first 3 PCs.

Results: A cluster of *SLC24A5* SNPs were significantly associated with M-Index and three of them reached genome wide significant P-value ($P<5.02 \times 10^{-8}$). The strongest association was found for rs2675345 ($P=2.90 \times 10^{-8}$). SNP, rs3828107, in *NR5A2* (1q32) was the most strongly associated with tanning ability ($P=2.16 \times 10^{-7}$). When UV exposure was included in the regression model, association between this SNP and tanning ability was attenuated, but rs9392299 in *FLJ43763* located in 6p25, about 200kb upstream of *IRF4*, a gene that was associated with tanning ability and sun sensitivity in European descent populations showed marginal significance ($P=6.52 \times 10^{-6}$).

Conclusion: We found that *SLC24A5* SNP showed stronger association with M-Index than previously reported GWAS SNPs in South Asian and admixed Cape Verdean populations. We successfully confirmed previous GWAS findings of 6p25 SNPs and tanning ability in our AA population. Our study also provides evidence for a novel loci on chromosome 1 associated with tanning ability.

909W

The First Genome-wide Association Study of Serum Lipids among Africans. *A.R. Bentley[1], D. Shriner[1], G.J. Chen[1], F. Tekola-Ayele[1], A.P. Doumatey[1], H. Huang[1], J. Zhou[1], O. Fasanmade[2], T. Johnson[2], J. Oli[3], G. Okafor[3], B.A. Eghan, Jr[4], K. Argyenim-Boateng[4], J. Adeleye[5], W. Balogun[5], C. Adebamowo[6], A. Amoah[7], J. Acheampong[4], D. Ngare[8], A. Adeyemo[1], C.N. Rotimi[1].* 1) Center for Research in Genomics and Global Health, Natl Human Genome Research Institute, Bethesda, MD; 2) Department of Medicine, University of Lagos, Lagos, Nigeria; 3) Department of Medicine, University of Nigeria Teaching Hospital, Enugu, Nigeria; 4) Department of Medicine, University of Science and Technology, Kumasi, Ghana; 5) Department of Medicine, University College Hospital, Ibadan, Nigeria; 6) Department of Epidemiology and Public Health, School of Medicine, University of Maryland, Baltimore, MD; 7) Department of Medicine and Therapeutics, University of Ghana Medical School, Accra, Ghana; 8) Department of Mental Health and Behavioral Sciences, Moi University School of Medicine.

The burden of chronic disease in Africa is increasing rapidly, with sharper increases predicted, yet the genetic determinants underlying relevant traits among Africans are largely unstudied. We have conducted the first genome-wide association study of serum lipids in Africa. The study participants comprised 1808 primarily West Africans enrolled in the Africa America Diabetes Mellitus (AADM) Study, characterized for total cholesterol (TC), HDL-cholesterol (HDLC), LDL-cholesterol (LDLC), and triglycerides (TG) and genotyped on the Affymetrix Axiom PANAFR array (~2.1 million SNPs). Imputation using the 1000 Genomes cosmopolitan reference yielded ~15 million SNPs. Association models were adjusted for gender, age, BMI, type 2 diabetes, and the first 3 principal components of ancestry. The most statistically significant results were for variants in the *APOE* region with LDLC (-0.5 mg/dl, lowest $p=5.5 \times 10^{-17}$ [rs7412]). A larger effect size was observed for a nearby rare variant that has not been reported among non-African populations, rs192607279 (-4.5 mg/dl LDLC, $p=1.5 \times 10^{-10}$). Variants in this region were also associated with lower TC (lowest $p=4.4 \times 10^{-10}$ [rs61679753]). Common *LDLR* variants were associated with ~0.3 mg/dl lower LDLC. rs111590558 near *HTR2A* was associated with LDLC (0.6 mg/dl, $p=4.0 \times 10^{-9}$); this SNP is monomorphic among those of European ancestry. Although not reaching genome-wide significance, a lead association for HDLC was in a well-known HDLC locus, *CETP*. No TG association reached statistical significance. Replication of previous findings was attempted using both an exact method and an LD-based method. Of the 248 SNPs investigated, 61 replicated. This is the first replication for a high proportion (56%) of these results in any African ancestry population. This first African GWAS of serum lipids confirmed the relevance of some known lipids loci (*APOE*, *LDLR*, and *CETP*) in this population, as well as revealing some novel associations, particularly among variants not present among non-African ancestry populations. Replication attempts of known loci were successful for 25% of SNPs investigated. The large proportion of variants for which this is the first replication in an African ancestry population is consistent with the hypothesis that a reduced influence of environmental risk factors in Africans residing on the continent may simplify detection of genetic associations compared to Africans in the Diaspora with more Western lifestyles.

910T

Identification of asthma-related trans-acting epistatic eQTL using Model-Based Multifactor Dimensionality Reduction (MB-MDR). *K. Bessonov[1], D. Croteau-Chonka[2], W. Qi[2], VJ. Carey[2], BA. Raby[2], K. Van Steen[1].* 1) Department of Electrical Engineering and Computer Science (Institut Montefiore), University of Liege, Liege, Belgium; 2) Channing Division of Network Medicine,Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States.

Genetic epistasis likely underlies most complex traits, including gene expression, yet is very difficult to detect using standard approaches. When considering the interactive effects on expression Quantitative Trait Loci (eQTL), interactions between genes, scattered throughout the genome, are referred to as trans-epistasis. In this work we aimed at identifying transcripts whose expression is regulated by SNP-SNP interactions using Model-Based Multifactor Dimensionality Reduction (MB-MDR). This model-free approach for epistasis detection involves reducing a high-dimensional GxG space to GxG factor levels that either exhibit high, low evidence or no evidence at all for their association to gene intensities of interest. We applied this method to a dataset consisting of 19,451 CD4+ lymphocyte expression phenotypes and genotypes from ~516,000 SNPs from 174 Caucasian non-smoking subjects from CAMP asthma cohort. Univariate analysis highlighted 1,844 genome-wide significant cis-acting eQTL. With MB-MDR, each of these was tested for potential synergetic interaction with the remaining ~516,000 trans-SNPs, excluding cis-SNPs located in genetic range between 2 Mb upstream and downstream of the eQTL gene. Our preliminary results reveal evidence for the existence of epistatic interactions in the regulation of gene expression. Out of the total of 1,086,601 cis-SNP/trans-SNP pairs with marginal p-value ≤ 0.001 based on 999 permutations, the top 10 trans-genes were all related to signaling and cell-cell adhesion pathways (PTPRD, CDH13, CNTN5, LRP1B). For example, the top 2 cis-trans SNP pairs ranked on the basis of their associated MB-MDR statistic (shown in brackets) - rs622614/rs6039399 (49.526) and rs5756379/rs11069218 (46.219)-regulating lipid hydrolysis/protein degradation and host immune system activation, respectively, both implicated in PI(3) kinase-mediated signaling. Some of the previously literature reported loci with genome-wide significance for Asthma included rs7544426/rs3771166 (17.12), rs2241632/rs1342326 (11.004), rs17051336/rs744910 (15.214),and rs11244079/rs2284033 (13.041). When variants were ranked by the number of interacting partners, those with the highest number of trans-SNP effect modifiers belonged to pathways involving signaling, detoxification and DNA repair. Follow-up of these results include replication of the epistatic interactions in independent eQTL datasets, and formal testing of identified pairs as asthma-susceptibility loci.

911F

Genome-wide association study (GWAS) of major depressive disorder in N=9300 Han Chinese women using low-pass sequencing data. *T. Bigdeli[1], R.E. Peterson[1], Y. Li[2], W. Kretzschmar[2], F. Yang[3], H.H. Maes[1], A.H. Fanous[1], B.T. Webb[1], B.P. Riley[1], J. Wang[4], S. Shi[5], Y. Chen[6], J. Marchini[2], R. Mott[2], S.A. Bacanu[1], K.S. Kendler[1], J. Flint[2], CONVERGE consortium.* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University School of Medicine, PO Box 980126, Richmond VA, 23298, USA; 2) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford OX3 7BN, Oxfordshire, United Kingdom; 3) Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine, No. 600 South Wanping Road, Shanghai, P.R. China; 4) Beijing Genomics Institute, Floor 9 Complex Building, Beishan Industrial Zone, Yantian District, Shenzhen 518083, P.R. China; 5) Huashan Hospital of Fudan University, No.12 Middle Wulumuqi Road, Shanghai, P.R. China; 6) CTSU, Richard Doll Building, Old Road Campus, University of Oxford, Headington, Oxford OX3 7LF, United Kingdom.

Background: Major depressive disorder (MDD) is a common, complex psychiatric disorder and a leading cause of disability worldwide. Although modestly heritable (~30-40%), a complex genetic architecture has hindered efforts to identify robustly associated genetic risk variants. We sought to evaluate the evidence for common genetic variation in the etiology of MDD) in a large, ethnically homogenous Chinese sample.

Methods: Using single nucleotide polymorphism (SNP) data imputed from low-pass (1.2X) sequencing data, we tested for association between common SNPs and MDD in 4168 cases and 4614 controls from the CONVERGE (China, Oxford and VCU Experimental Research on Genetic Epidemiology) project. We estimated the proportion of variation in disease susceptibility captured by common SNPs using the Genome-wide Complex Trait Analysis (GCTA) utility and considered the predictive value of scores constructed from GWAS results.

Results: In our preliminary analysis of ~7.5*M* SNPs, no single variant attained genome-wide significance (5×10^{-8}). Based on an estimated prevalence of 12%, common SNPs accounted for an estimated 15.7% of the variance in MDD risk (95%CI=[10.3,21.1], $P=2.0\times10^{-10}$). A polygenic score based on results from the Psychiatric Genomics Consortium (PGC) GWAS of MDD accounted for less than a tenth of a percent of the variance in disease risk (P=0.03). However, when then CONVERGE sample was randomly divided into training and testing sets, and SNP effects estimated by the best linear unbiased prediction (BLUP) method in the training set, the resultant aggregate score was modestly associated with MDD in the testing set ($P= 6.4\times10^{-8}$), accounting for 0.79%; of the variability in disease risk.

Discussion: We have conducted a large GWAS of MDD in an ethnically homogenous sample using SNP data imputed from low-pass sequencing data. In our preliminary analysis, no single variant demonstrated genome-wide significant association with MDD. Aggregate risk scores based on GWAS in European and Chinese populations were found to be of differential predictive value. These observations support a complex etiology for MDD, and possible population differences in predisposing genetic factors.

912W

Genome-wide Association Study of serum minerals in pediatric African-American and Caucasian cohorts. *X. Chang, P. Sleiman, H. Hakonarson.* Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Calcium, magnesium, potassium and sodium cations as well as the chloride and phosphorus anions are major dietary minerals which can not be manufactured by the human body. They play important roles in various biological functions and are essential to sustain life and maintain optimal health, and thus are commonly measured in blood serum to monitor a range of health conditions. The mineral intake of children and adolescents are especially important due to their rapid growth. In this study, we performed a genome-wide association study to explore the contribution of potential common genetic variations to serum concentrations of the six major dietary minerals in Children as well as the ratio of concentrations between minerals. A total of 10,308 children, 5602 Caucasians and 4706 African-Americans were included in the analysis. All samples were genotyped on the Illumina HH550 or 610 arrays. Maximum serum concentration values of the six minerals, and the mineral ratios, were tested for association by linear regression as implemented in plink. In the African-American pediatric cohort, we report association of the serum calcium concentration with a missense variant in the calcium-sensing receptor (CASR) gene on 3q13 (rs1801725 5.6×10E-3. The SNP was previously reported to correlate with the level of serum calcium in both Caucasian and Indian-Asian populations, but no previous studies show a calcium concentration association in the African-American population or pediatric populations. The association between SNP rs1801725 and calcium concentration was also confirmed in our Caucasian pediatric cohort with a p-value of 1.03×10E-4; combined P-val 2.64×10E-6. Our results extended the understanding of CASR mediated calcium regulation in African-American and Caucasian pediatric populations. In the Caucasian pediatric population, our results also confirmed another previously reported serum magnesium concentration associated SNP rs4072037 with a p-value of 1.74×10E-5 located in gene MUC1 on 1q21. We also investigated the ratio of Calcium/Magnesium, Sodium/Potassium and Chloride/Phosphorus concentrations in blood serum. We report significant association of Calcium/Magnesium ratio with variants located that map to a locus on 10q26 that contains the Fibroblast growth factor receptor 2 gene (FGFR2). Results of the GWAS for the six minerals and the mineral ratios will be presented at the meeting.

913T

GWAS meta-analysis identified a novel locus associated with corneal curvature in Asian populations. *P. Chen[1], C.Y. Cheng[1,2,3,8], C.C. Khor[1,3,4,6], T. Aung[2], S.M. Saw[1,2], T.Y. Wong[2,3], E.S. Tai[1,5,7], Y.Y. Teo[1,6,9,10,11].* 1) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore National Eye Center, Singapore; 3) Department of Ophthalmology, National University of Singapore, Singapore; 4) Department of Paediatrics National University Health Systems, National University of Singapore, Singapore; 5) Department of Medicine, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 6) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore, Singapore; 7) Duke-National University of Singapore Graduate Medical School, Singapore; 8) Centre for Quantitative Medicine, Office of Clinical Sciences, Duke-NUS Graduate Medical School, Singapore; 9) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 10) Life Sciences Institute, National University of Singapore, Singapore; 11) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Corneal curvature (CC) is an ophthalmic biometric that has connection to various eye diseases. CC is highly heritable but there are only two loci discovered currently, *FRAP1* and *PDGFRA*. Both of the two genes have been reported in Asian populations for the first time in an Asian genome-wide association (GWAS) meta-analysis. Although *PDGFRA* has been well established to be associated with CC, *FRAP1* has not been replicated in other populations. Meanwhile in Asian populations, the proportion of variance which is explained by these two genes ranges from 1.8% to 11.1%. We conducted a genome-wide association study meta-analysis of CC to provide further evidence for the association of *FRAP1* with CC in additional samples, and discover more genes that are still hiding behind the scene. In total, we recruited 5326 Chinese, 2138 Malay and 2124 Indian individuals in Singapore from 7 GWAS. This study adopted a two-stage meta-analysis scheme. The discovery stage studies (SP2, SiMES, SINDI and SCORM) have been recruited by the previous meta-analysis. Two novel studies, SCES and STARS comprising 2473 Chinese individuals were employed in the replication stage. The radius of CC was defined as the average reading of right and left eye. Within each study, the radius was normalized by an inverse-normal transformation. Imputation of the SNP array genotypes was done using 1000 Genomes project phase 1 (March 2012, GRCh37) cosmopolitan haplotypes as reference panel. Effect of the allele dosage was evaluated in a linear regression model which adjusted for age and gender. Principle components were also adjusted for Malay and Indians to take care of the population stratification. The meta-analysis was done using a fixed effect inverse-variance weighting scheme. We successfully replicated the signals at *FRAP1* and *PDGFRA* gene region. Notably, the association of *FRAP1* was again replicated in our replication studies. Besides the two known genes, we found that *CMPK1* gene was associated with CC for the first time (array SNP meta-analysis P value = 2.81E-9), whereas the imputed genotypes brought us even more power with more significant signal (imputed top SNP meta-analysis P value = 3.27E-11). Our meta-analysis replicated the two known genes and identified a novel locus to be associated with CC. We provided further evidence that *FRAP1* is associated with CC in Asian populations. However, whether it is an Asian-specific CC susceptibility gene remains to be assessed in other populations.

914F

Uncovering loci associated with urinary incontinence in African and Hispanic American women. *C. Chen[1], A. Rajkovic[2], A. Park[3], G. Heiss[4], S. Hendrix[5], N. Franceschini[4].* 1) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) department of obstetrics, gynecology and reproductive science, University of Pittsburgh,Pittsburgh, PA; 3) Department of Obstetrics & Gynecology, Medstar Washington Hospital Center, Georgetown University School of medicine, Washington, DC; 4) Department of Epidemiology, Gillings School of Global Public Health, University of North Carolina, Chapel Hill, NC; 5) Department of Surgical Services, Michigan State University College of Osteopathic Medicine, East lansing, MI.

Urinary incontinence is an under-recognized health problem that negatively impacts women's quality of life. To date, genes contributing to urinary incontinence susceptibility have not been identified. We present the first genome-wide association study aimed to identify single nucleotide polymorphisms associated with overall urinary incontinence and two subtypes of urinary incontinence (stress/urge) in 11,526 US minority women from Women's health Initiative SHARe cohort. These women included 8,088 African American and 3,438 Hispanic American women. We report that the prevalence of overall urinary incontinence in these women aged 50-79 years was 55%, with 32% of women experiencing urge urinary incontinence, 29% of women having stress urinary incontinence and 8% of women had both. More African women reported having urge urinary incontinence while more Hispanic women reported having stress urinary incontinence. We show that rs2086297, located in the intron of PRCP, was significantly associated with stress UI (p-value<4.4×10-8) in trans-ethnic analysis. Each copy of the rs2086297 T allele showed around 20% reduction in the odds of stress urinary incontinence. Future studies on the UI of minority women may identify additional loci associated with urinary incontinence and will be helpful in broadening our understanding of urinary incontinence associated genetic pathways.

915W

Genome-wide association study of thyrotoxic periodic paralysis. *K.C. Chen[1], P.L. Chen[1,2,3,4], T.C. Chang[3,5].* 1) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 4) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan; 5) Department of Internal Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan.

Thyrotoxic periodic paralysis (TPP) is a unique disease characterized by episodic attacks of muscle weakness and hypokalemia in certain thyrotoxic individuals. TPP shows male predominance and huge inter-population prevalence difference; up to 10% of thyrotoxic males in Asia develop TPP, while only less than 0.1% thyrotoxic Caucasian males do. In 2010, Ryan *et al.* (Cell 140(1): 88-98) reported that mutations of the *KCNJ18* gene could be found in 33% of their patients (mainly of European descent), but not in controls. However, in 2012, Cheung *et al.* (Nat Genet 44(9): 1026-1029) published a genome-wide association study (GWAS) in ethnic southern Chinese and identify a single susceptibility locus at 17q24.3 near *KCNJ2*, with estimated odds ratio of 3.3. It is still an unsolved issue whether these two loci are genuine TPP-related loci, and whether there are more susceptibility loci to be identified. To address these issues, we conducted a GWAS using 41 TPP patients as cases and 725 thyrotoxic, non-TPP individuals as controls, all of them are ethnic Chinese in Taiwan. The genotyping platform was Axiom Genome-Wide CHB Array Plate, which contains 642,832 common (MAF>5%) SNPs in Han Chinese genome. We replicated the 17q24.3 association signals reported by Cheung *et al.*, with several SNPs showed p values smaller than 5×10^{-7} in the trend test and allelic test. There were also association signals at 2q31.2, 2q36.3, 9q22.1 and 18q21. Fine mapping of the novel loci is currently underway. On the other hand, we did not find association signals at or near *KCNJ18*. We are now performing Sanger sequencing of *KCNJ18* to search for possible multiple rare variants. Our results demonstrate that 17q24.3 is the genuine TPP susceptibility locus, at least in ethnic Chinese Han population. We also report several novel susceptibility loci awaiting replication.

916T

Common variations at chromosome 21q22 influence the risk of age-related nuclear cataract in Asians: the Singapore Epidemiology of Eye Diseases (SEED) Study. *C.Y. Cheng[1,2,3], J. Liao[1,3], P. Chen[2], X. Li[3,4], X. Wang[2], A.G. Tan[5], J.J. Wang[5,6], P. Mitchell[5], J.B. Jonas[7], S.M. Saw[2,3], C.C. Khor[1,8], E.S. Tai[2,9], T. Aung[1,3,10], Y.Y. Teo[2,4,11,12], T.Y. Wong[1,3,10].* 1) Department of Ophthalmology, National University of Singapore, Singapore; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 3) Singapore Eye Research Institute, Singapore; 4) Department of Statistics and Applied Probability, National University of Singapore, Singapore; 5) Centre for Vision Research, Department of Ophthalmology, University of Sydney, New South Wales, Australia; 6) Center for Eye Research Australia, University of Melbourne, Melbourne, Australia; 7) Department of Ophthalmology, Medical Faculty Mannheim, Ruprecht-Karls-University Heidelberg, Mannheim, Germany; 8) Human Genetics, Genome Institute of Singapore, Singapore; 9) Department of Medicine, National University of Singapore, Singapore; 10) Singapore National Eye Centre, Singapore; 11) Centre for Molecular Epidemiology, National University of Singapore, Singapore; 12) Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore.

Age-related cataract is the leading cause of visual impairment and blindness in the world. Although several mutations were identified as causative for congenital and juvenile cataracts, little is known about the genetic variants that influence the susceptibility of age-related cataract. We conducted a meta-analysis of genome-wide association studies (GWAS) on 2,369 Malays and 2,200 Indians aged 40 to 80 years enrolled in the Singaporean Epidemiology of Eye Diseases (SEED) Study. Participants underwent a comprehensive eye examination including slit-lamp lens photography and provided a blood sample for genotyping. Lens photographs were graded using the Wisconsin Cataract Grading System, with the grades ranging from 0.1 (the lowest grade) to 5.0 (the highest). Genotyping was performed with Illumina HumanHap610-Quad chips. We performed SNP imputation using the genotype data, together with the reference panels in the 1000 Genomes project (March 2012, GRCh37). The association between SNPs and the severity (i.e., grade) of nuclear cataract was assessed using linear regression analysis with adjustment for age, sex and genetic principal components. In the meta-analysis of GWAS in the Malay and Indian samples (n = 4,569), the strongest evidence was observed at chromosome 21q22 (β [the increase in nuclear cataract grade per risk allele] = 0.11, $P = 5.2 \times 10^{-9}$), reaching genome-wide significance. The results were similar after further adjustment for smoking status. Replication tests in two independent Chinese cohorts (n = 2,571) were performed. Using random effect models, the pooled estimates of the four cohorts confirmed the association at the 21q22 locus ($\beta = 0.08$, $P = 2.0 \times 10^{-9}$). To our knowledge, this is among the first GWAS to investigate age-related nuclear cataract. The results yield insights at the gene level for the pathogenesis of age-related cataract.

917F

Copy Number Variations are associated with Bone Mineral Density: A large-scale genome-wide analysis in the Framingham Study. *W. Chou[1], K. Nandakumar[1], D. Karasik[1], C. Liu[2], L. Cupples[2], D. Kiel[1], Y. Hsu[1].* 1) Institute for Aging Research, Hebrew SeniorLife, Harvard Medical School, Boston, MA; 2) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Bone mineral density (BMD) is a complex phenotype with high heritability. Our previous genome-wide SNP association study identified more than 56 BMD loci in Caucasian populations, explaining < 6% of BMD variation. Copy number variation (CNV), a type of genomic structural variation, accounts for > 20% variation of the human genomic structure between individuals. CNVs may explain the missing heritability of BMD. Thus, we conducted a genome-wide CNV association analysis with BMD in Framingham Study participants. This study included 7,451 adult Caucasians (4126 men and 3325 women) with mean age of 55 years. BMD at lumbar spine (LS) and femur neck (FN) was measured by dual energy X-ray absorptiometry. CNVs were estimated using Affymetrix 500K genotyping array and PennCNV package. A CNV was defined as a DNA segment longer than 1 kbp and composed of at least three consecutive genotyping probes. Under an additive genetic model, we employed a linear mixed effects model to account for family relatedness, and also adjusted for age, sex, estrogen usage, menopause status, cohorts within the Framingham Study and principal components for population stratification. To correct for multiple-testing, a genome-wide significant cutoff ($p < 4 \times 10^{-6}$) was defined by a false-discovery rate as less than one false-positive result among the genome-wide significant findings. Up to 6,398 individuals had valid CNV calls and information on covariates. Two CNVs (at chrom 2q14.2 and 6q25.3) and four (at chrom 5q23.1, 15q22.31, 17p13.1 and 17q21.2) were significantly associated with LS BMD and FN BMD, respectively. The length of the CNVs ranged from 133 kbp to 1,025 kbp. The most significantly associated CNV with $p = 1.9 \times 10^{-20}$ was located at chromosome 15q22.31 (*SMAD6*). The Smad6 protein inhibits signaling of bone morphogenetic proteins. Among 6,398 individuals included in the association analysis of the CNV, 5 had this CNV. Individuals with deleted CNVs had lower FN BMD. In addition, we identified three genome-wide suggestive CNVs associated with BMD at $p < 2.7 \times 10^{-6}$. In summary, we identified six genome-wide significant CNVs and three genome-wide suggestive CNVs associated with FN BMD or LS BMD in the Framingham Study. To replicate the CNV-BMD associations, we are performing analyses in independent samples. The newly identified CNVs in this study may provide additional biological information regarding the genetic determinants of BMD and may explain some of the missing heritability.

918W

Genetic associates of childhood wheezing phenotypes. *J.A. Curtin[1], D.C.M Belgrave[1,2], A. Custovic[1], A. Simpson[1].* 1) Centre for Respiratory Medicine and Allergy,Institute of Inflammation and Repair, University of Manchester, Manchester, Manchester, United Kingdom; 2) Centre for Health Informatics, Institute of Population Health, University of Manchester, UK.

Background: Much of the heritability of complex traits (e.g. asthma) remains unexplained by genome wide association studies (GWAS). One reason for this may be poor phenotype definition; most studies investigating genetic associates use phenotypes that encompass a number of different endotypes (e.g. doctor-diagnosed asthma). We recently identified four distinct childhood wheezing phenotypes (Transient early wheeze-TEW, Late-onset wheeze-LOW, Persistent controlled wheeze-PCW and Persistent troublesome wheeze-PTW) by joint modelling of parentally-reported and physician-confirmed wheeze. Methods: DNA was genotyped using Illumina 610 quad chips. Following standard QC we imputed additional genotypes (IMPUTE version 2.2.2) with the '1000 Genomes Phase I integrated variant set' reference genotypes; we excluded SNPs with INFO <0.4 and MAF <0.01. Genome-wide association study (GWAS) was performed for these four wheezing phenotypes (TEW, n=122; PTW, n=29; PCW; n=106; LOW, n=146), using Non Wheezers (n=469) as controls, and also using the traditional asthma definition of 'doctor diagnosed asthma' (192 cases, 610 controls). For each phenotype we used Ingenuity pathway analysis (IPA) to identify biological pathways common to genes found within 50KB of associated Single Nucleotide Polymorphisms (SNPs). Results: We identified distinct genome-wide significant ($p<5\times 10^{-8}$) associates for each of the phenotypes: TEW (86 SNPs), PTW (193 SNPs), PCW (126 SNPs), LOW (47 SNPs) and doctor diagnosed asthma (19 SNPs). The associated SNPs were unique for each phenotype except for 'chr12:98730665:D' which was significant in TEW and PCW. Using IPA we generated a network of 21 interconnected proteins important in mediating immune responses in relation to TEW, and found that many of the associated SNPs of PTW and PCW reside in genes related to respiratory disease. Conclusions: Childhood wheezing phenotypes may represent different diseases with unique genetic associates.

919T

Exploring the causes of heterogeneity in meta-analysis of genome-wide association studies. *H. Deng[1,2], Y. Pei[1,2], L. Zhang[1,2].* 1) Biostatistics and Bioinformatics, Tulane Univ, New Orleans, LA; 2) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China.

Meta-analysis of Genome wide association (GWA) data has been widely used to detect genetic variants responsible for complex diseases. Between-study heterogeneity is an important issue when conducting meta-analysis. Exploring the extent and possible sources for heterogeneity between studies is important to the result interpretation. To exemplify these issues, we used data from seven GWA studies on obesity. We first investigated the extent and distribution of the heterogeneity across the whole genome. Among the 4,325,550 SNPs tested, the I2 inconsistency metric was different from 0 (no detectable heterogeneity) for 43.8% of the total SNPs; inconsistency was moderate to very large (I2>25%) for 18.4% of the total SNP. Significant heterogeneity (pQ<0.1) existed for 11.0% of the total SNPs. Heterogeneity was enriched in SNPs with small p-values. Among SNPs with p-value less than 1.0×10-5, 190 (41.4%) SNPs showed moderate or larger heterogeneity. Meta-regression analyses were performed for the 190 SNPs to explore potential causes of heterogeneity. Five moderators, which included average age, ethnicity, gender composition, study base and imputation accuracy, were constructed to test their effects on heterogeneity. Among the tested factors, ethnicity, average age and imputation accuracy had significant effects on the heterogeneity. After adjusting for all the five moderators, almost all of the significant heterogeneity (96.2%) was removed. Our results have significant implications for the study design and results interpretation of GWA meta-analyses.

920F

Cross-disease analysis using Immunochip reveals four new loci for celiac disease and rheumatoid arthritis. *J. Gutierrez-Achury[1], G. Trynka[2,3], S. Raychaudhuri[2,3,4], J. Greenberg[5], D. Diogo[2,3], R. McManus[6], R.M Plenge[2,3], C. Wijmenga[1], A. Zhernakova[1], Celiac Disease Immunochip Consortium, RACI consortium.* 1) Department of Genetics, University Medical Centre Groningen - University of Groningen, Groningen, Netherlands; 2) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 3) Medical and Population Genetics Program, Broad Institute, Cambridge, MA, USA; 4) Institute of Inflammation and Repair, University of Manchester, Manchester, UK; 5) New York University School of Medicine, New York, NY; 6) Department of Clinical Medicine and Institute of Molecular Medicine, Trinity College Dublin, Dublin, Ireland.

Background: Autoimmune diseases are complex and heterogeneous but are known to share a subset of loci and pathways. Celiac disease (CeD) and rheumatoid arthritis (RA) are two examples in which GWAS and the Immunochip have identified strong associations to each trait and substantial overlap between loci. The Immunochip array was specifically designed to refine GWAS results. We aimed to jointly analyze the largest CeD and RA datasets available to date and genotyped using the Immunochip to identify new unique or shared loci and to fine-map the known regions. Methods: We meta-analyzed 6 European CeD cohorts (12,400 cases, 14,257 controls) and 7 European and North American RA cohorts (13,877 cases, 18,120 controls). We determined common SNPs between the datasets, aligned them in the same strand, removed duplicates and related individuals, and performed a principal component analysis (PCA) per cohort. We performed logistic regression by adjusting for first five PCAs per cohort. We then conducted meta-analysis using a fixed-effect model with inverse variance weighting. Results: From the joint meta-analysis of all 13 cohorts, 28 loci reached the threshold p-value of association, 1×10^{-8}, and 17 more reached a suggestive p-value of 1×10^{-5}. Of those that reached genome-wide significance, we report the new locus *NCF2* ($OR_{meta} = 1.25$, $p\text{-}val_{meta} = 1.24\times10^{-14}$) represented by a probably damaging missense mutation with a polyphen-2 score of 0.98. Three other loci (*AFF3*, *PTPN22* and *CXCR5*) had been previously reported in one disease but were now identified in the second phenotype and in the combined analysis. Using co-expression analysis based on approximately 80,000 microarrays, it was possible to determine that the new gene *NCF2* is involved in the defense response to Gram-positive bacteria, which points to its importance in the innate immune response and microbiota regulation. These aspects should be further analyzed by functional studies.

921W

A Large Scale Genome Wide Association Study of Asthma in the 23andMe Cohort. *D. Hinds, C. Tian, A.K. Kiefer, J.L. Mountain, N. Eriksson, J.Y. Tung.* 23andMe, Inc., Mountain View, CA.

Asthma and allergic disease are common, chronic conditions with substantial public health burdens. We carried out a genome-wide association study of self-reported asthma in the 23andMe participant cohort, including more than 17,000 cases and 87,000 controls with European ancestry, imputed against 1000 Genomes reference haplotypes. In addition to replicating established asthma GWAS findings, we see genome-wide-significant associations with several loci that have been associated with other forms of atopic disease, including rs17673553 in *CLEC16A*, rs12542017 near *ZBTB10*, and rs3001426 near *STAT6*. Using conditional logistic regression, we see evidence for multiple independent associations at the *IL1RL1* locus on chromosome 2, the *TSLP* locus on chromosome 5, and the *IL33* locus on chromosome 9.

We find novel associations with rs2070902 in *FCER1G*, encoding the gamma subunit of the high affinity IgE receptor; with rs4707609 in *BACH2*, or basic leucine zipper transcription factor 2; and with rs62192043 near *D2HGDH*, or mitochondrial D-2-hydroxyglutarate dehydrogenase, and *GAL3ST2*, or galactose-3-O-sulfotransferase. Variation in *BACH2* has previously been associated with a variety of autoimmune diseases. *GAL3ST2* is expressed in goblet cells and is involved in production of sulfated mucins. We also find evidence of associations in or near several genes associated with allergies in the 23andMe cohort, including *ID2*, *LPP*, *TLR1*, and *PTGER4*.

Most genetic associations with asthma and allergy are shared, with similar effect sizes, and identifying risk factors that distinguish between different allergic disease types seems more challenging. We further explore this issue with analyses of the susceptibility loci stratified by disease subgroups, determined by age of onset, triggers, and severity, and with patterns of allergy symptoms.

922T

A genome-wide association study highlights multiple variants associated with Epstein-Barr virus load in the 1000 Genomes and HapMap lymphoblastoid cell lines. *C.J. Houldcroft[1], J.Z. Liu[1], A. Gall[1], D. Frampton[2], C.A. Anderson[1], P. Kellam[1,2].* 1) Wellcome Trust Sanger Institute, Cambridge, Cambs, United Kingdom; 2) UCL/MRC Centre for Medical Molecular Virology, Department of Infection, University College London, Cleveland Street, London W1T 4JF, UK.

Epstein-Barr virus (EBV) infects 95-98% of adults world-wide, persists for life and causes benign infectious mononucleosis in ~50% of young adults upon primary infection. EBV is also linked to more severe conditions such as Burkitt's lymphoma, nasopharyngeal carcinoma and post-transplant lymphoproliferative disorder. Persistent life-long infection can be modelled using lymphoblastoid cell lines (LCLs), human B cells immortalised with EBV. It is unknown to what extent host genetic variants influence EBV load within LCLs and whether variation in EBV load affects gene expression studies of these cell lines.

We measured relative EBV genome load in LCLs from 1000 Genomes and HapMap projects and performed a heritability analysis and genome-wide association study (GWAS) on 899 of these individuals. This combined sequencing data from 1000 Genomes Project Phase 1 with genotype data from Illumina Omni 2.5M and HapMap Phase III. We controlled for population structure using FaST-LMM-Select. After filtering, there were 30M SNPs included in the final analysis.

Estimates of heritability from genome-wide covariance and trio methods were consistently between 30-50%. The top SNP identified in the GWAS was rs182621445 on chromosome 6 (p=5.55E-10), downstream of DAAM2, a gene over-expressed in nasopharyngeal carcinomas. Genome-wide significant results were also seen for SNPs close to or located within genes CD109 (a negative regulator of TGFβ, which has been implicated in immunity to infectious mononucleosis), ZNF839 and WAC. Gene-based association analysis (VEGAS) identified TBXAS1 as most strongly associated with EBV load (p=8.39E-08); followed by a cluster of zinc-finger proteins (ZKSCAN4, ZSCAN9, ZSCAN31) on chromosome 6 (p=1.55E-07). Future work will characterise the frequency of these mutations in a population of UK university students with infectious mononucleosis, as well as functional validation of the role of these variants through gene expression studies, over-expression in lentiviral vectors and RNAi gene knockdown.

923F

Identification of multiple genetic susceptibility loci in Takayasu's arteritis. *T. Hughes[1], G. Saruhan-Direskeneli[2], P. Coit[1], J.M. Guthridge[3], J.A. James[3], P.A Merkel*[4], H. Direskeneli**[5], A.H. Sawalha[1], *on behalf of Vasculitis Clinical Research Consortium;**on behalf of Turkish Takayasu Study Group.* 1) Division of Rheumatology, University of Michigan, Ann Arbor, MI, USA; 2) Department of Physiology, Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey; 3) Arthritis and Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, USA; 4) Division of Rheumatology, University of Pennsylvania, Philadelphia, PA, USA; 5) Department of Rheumatology, Marmara University, Faculty of Medicine, Istanbul, Turkey.

Background: Takayasu's arteritis is a rare inflammatory disease of large arteries. The etiology of Takayasu's arteritis remains poorly understood, but genetic contribution to the disease pathogenesis is supported by the confirmed genetic association with HLAB*52. Genomic studies in Takayasu's arteritis have not been previously performed. Methods: We genotyped ~200,000 genetic variants in two ethnically divergent Takayasu's arteritis cohorts from Turkey (339 patients and 516 controls) and North America (112 patients and 599 controls) using a custom designed genotyping platform (Immunochip). Additional genetic variants and the classical HLA alleles were imputed and analyzed. Results: We identified and confirmed two independent susceptibility loci within the HLA region (r2<0.2): HLA-B/MICA (rs12524487, OR= 3.29, P= 5.57×10^{-16}), and HLADQB1/ HLA-DRB1 (rs113452171, OR= 2.34, P= 3.74×10^{-9}, and rs189754752, OR=2.47, P= 4.22×10^{-9}). In addition, we identified and confirmed a novel genetic association between Takayasu's arteritis and the FCGR2A/FCGR3A locus on chromosome 1 (rs10919543, OR= 1.81, P= 5.89×10^{-12}). The risk allele in this locus results in increased mRNA expression of FCGR2A. We also established the genetic association between IL12B and Takayasu's arteritis (rs56167332, OR= 1.54, P= 2.18×10^{-8}). An association with an additional locus on chromosome 21q22 downstream of PSMG1 did not pass the threshold for genome-wide significance and requires replication (P=4.39×10^{-7}). Conclusion: We established multiple genetic susceptibility loci for Takayasu's arteritis with a genome-wide level of significance including two independent susceptibility loci in the HLA region, and disease susceptibility loci in FCGR2A/FCGR3A and IL12B.

924W

Genome-wide association confirms TCF4 as a major locus for Fuchs Endothelial Corneal Dystrophy and identifies novel loci. *S.K. Iyengar[1,4], N. Afshari[2], R.P. Igo, Jr.[1], Y-J. Li[3], J.L. Lass[4,1], G. Klintworth[5] for the FECD Consortium.* 1) Dept Epid/Biostat, Case Western Reserve Univ, Cleveland, OH; 2) Dept. Ophthalmology, UCSD, San Diego, CA; 3) Department of Biostatistics & Bioinformatics, Duke University Medical Center Center for Human Genetics, Duke University Medical Center, Durham, NC; 4) Department of Ophthalmology and Visual Sciences, Case Western Reserve Univ, Cleveland, OH; 5) Duke Eye Center, Duke University Medical Center Durham, NC.

Background. Fuchs Endothelial Corneal Dystrophy (FECD) is a progressive, age-dependent disease of the corneal endothelium, associated with decreased vision. Women are more commonly affected than men. Histological hallmarks of the disease include decreased endothelial cells, thickened Descemet membrane (DM) due to excessive accumulation of extracellular matrix, and the formation of excresences on DM called corneal guttae. FECD is one of the most common indications for corneal transplants in developed countries, with a prevalence of approximately 4%;, and heritability in the range of 30-40%;. **Methods.** We organized a multi-center consortium, with a large cohort of patients uniformly graded for FECD. We conducted a genome-wide association study in 1452 unrelated cases and 2535 controls using the Illumina Omni 2.5 chip. Primary analyses consisted of association testing via logistic regression, controlling for population structure via six principal components, and covariates age and sex. We also conducted sensitivity analysis for histopathology validated cases, and determined whether female versus male gender showed differences in odds ratios at the best loci. Genetic risk models were built using forward selection and were compared using the area under the receiver operating characteristic (AUC). **Results.** Transcription factor 4 (TCF4) emerged as a major locus for FECD (per-allele odds ratio = 5.78; p= 3.9×10^{-146}, confirming a prior small GWAS (Baratz et al. (2010) NEJM 363, 1016). Besides TCF4, five novel loci on chromosomes 1q and 11p also reached genome-wide significance with minor-allele odds ratios ranging from 0.75 to 1.43; the latter are being validated in independent samples. Sensitivity analysis of histopathology validated cases confirmed all loci. TCF4 shows genome-wide significance in sex-specific analysis. The chr1q and chr11p loci remain strongly significant in the Female subset ($P < 0.001$ with min P= 2.8×10^{-8}), but two loci show promising results in the Male subset ($P< 0.01$, min P=2.6×10^{-6}). Markers at all six loci yielded an AUC of 0.77, but the majority of the predictive value came from TCF4 (AUC=0.75). **Conclusions.** The FECD Genetics Consortium has conducted the largest genome-wide association study to date on FECD, leading to confirmation of the role of TCF4 on FECD. Five novel loci on chromosomes 1 and 11 were identified. Further analyses of these genes should help elucidate different pathways in FECD pathogenesis.

Sub-phenotype Mapping in Systemic Lupus Erythematosus Identifies Multiple Novel Loci Associated with Circulating Interferon Alpha. *S. Kariuki[1], Y. Ghodke-Puranik[2], J. Dorschner[2], B. Chrabot[1], J. Kelly[3], B. Tsao[4], R. Kimberly[5], M. Alarcón-Riquelme[3,6], C. Jacob[7], L. Criswell[8], K. Sivils[3], C. Langefeld[9], J. Harley[10], A. Skol[1], T. Niewold[2].* 1) University of Chicago, Chicago, IL; 2) Mayo Clinic, Rochester, MN; 3) Oklahoma Medical Research Foundation, Oklahoma City, OK; 4) University of California, Los Angeles, CA; 5) University of Alabama, Birmingham, AL; 6) Pfizer - Universidad de Granada - Junta de Andalucia Centre for Genomics and Oncological Research (GENYO), Granada, Spain; 7) University of Southern California, Los Angeles, CA; 8) University of California, San Francisco, CA; 9) Wake Forest University, Winston Salem, NC; 10) Cincinnati Children's Hospital Medical Research Center, Cincinnati, OH.

Systemic Lupus Erythematosus (SLE) is a phenotypically heterogeneous complex disease. Our previous work has documented significant genetic heterogeneity, with some well-validated risk factors demonstrating strong sub-group effects. Approximately 50% of patients have high circulating levels of interferon alpha (IFN-α), and many lines of investigation support IFN-α as a heritable and primary causal factor in human SLE. This study aims to genetically map the serum IFN-α trait in SLE patients, allowing for novel genetic discovery in this heterogeneous disease. GWAS data were obtained from 450 European ancestry SLE cases who were genotyped as part of the Systemic Lupus Erythematosus Genetics (SLEGEN) study. Genotypes were generated on the Illumina Infinium HumanHap300 genotyping platform, and principal component analysis was used to correct for population stratification. Sera were obtained from each of these subjects, and IFN-α activity was measured using a sensitive and specific reporter cell assay. Associations between genome-wide SNP markers and serum IFN-α were detected using logistic regression conditioned on the principal components to control for structure. IFN-α activity was studied as a categorical trait. Patients with IFN-α levels two standard deviations above the mean of healthy controls were designated as high IFN-α, and the remainder as low IFN-α. Top novel associated loci in the GWAS screen include multiple SNPs in the C7orf57, PRKG1, ANKRD44, and PNP loci. Interestingly, three of the five top SNPs are missense SNPs. Strong association signals were also detected in chromosomes 12 and 14. Genome-wide imputation using SNPs from the 1000 Genomes Project did not yield additional significant association signals beyond those identified by the directly genotyped SNPs. These novel loci have not been previously associated with SLE in case-control analyses. This supports the concept that studying pathogenic subgroups within the complex disease SLE will be important in our efforts to fully map disease susceptibility. These loci could provide novel therapeutic targets in the IFN-α pathway and assist in personalizing therapy in this disease.

926F

Presence of genome-wide associations for Parkinson's disease on the X chromosome. *M.F. Keller[1, 2], M.A. Nalls[1], A.B. Singleton[1], International Parkinson's Disease Genomics Consortium (IPDGC).* 1) Laboratory of Neurogenetics, NIH NIA, Bethesda, MD; 2) Department of Biological Anthropology, Temple University, Philadelphia, PA.

GWA studies have identified over 1,200 associations with p-values of < 5x 10-8 for over 200 traits, yet only 7 such associations have been reported on the X chromosome. While a plethora of GWA data is available on the X chromosome, it is currently underutilized. This is largely due to exclusion of X chromosome variants from analyses even though these regions are assayed on many current microarray platforms. Employing genotype and phenotype data from 6 European ancestry cohorts, we imputed the genotypes of 9,511 controls and 8,497 cases to test for genome wide associations to Parkinson's disease status, and to the quantitative trait age of Parkinson's disease onset. Our analyses identified a number of statistically significant SNPs clustered in three regions of the X chromosome, which suggest risk to Parkinson's disease development. Two of these regions contain protein-coding transcripts expressed in the testis, and two contain non-coding micro RNA. Replication is underway in a supplementary cohort containing over 14,000 individuals. In addition to identifying novel genetic variants associated with Parkinson's disease, our results indicate that utilization of X-chromosome GWA data can facilitate a more comprehensive understanding of complex disease architecture in a previously unexplored region of the genome. Continued development of study designs examining the sex chromosomes and disease status are necessary, and our work provides a first step towards documenting the applicability of GWA analyses to complex diseases in the X chromosome.

Feasibility of routine bi- & tri-variate exhaustive analysis of Case-Control GWAS. *A. Kowalczyk[1,2], Q. Wang[1,2], B. Goudey[1,2], H. Ferra[1], D. Rawlinson[1], J. Bedo[1,2], A.C. Kowalczyk[2], G. Abraham[3], F. Shi[1,2], L. Gor[1], R.M. Campbell[1,7], C. Iglesias[1], A. Zarnegar[1,5], E. Kikianty[1,6], G.J. Macintyre[1,2], I. Haviv[1,4], C.S. Ong[1,2], M. Inouye[3].* 1) NICTA, National ICT Australia, Parkville, Victoria, Australia; 2) Computing and Infromation Systems, The University of Melbourne, Australia; 3) Pathology, The University of Melbourne, Australia; 4) Bar Ilan University, Israel; 5) Victorian AgriBioscience Centre, Latrobe University, Australia; 6) University of The Witwatersrand, South Africa; 7) Electrical and Electronic Engineering, The University of Melbourne.

Genome-wide association studies (GWAS) genotype a large number of single nucleotide polymorphisms (SNPs) and attempt to determine their association with a given phenotype. Typically, the follow up data analysis examines the association of each SNP individually. Yet many common diseases have complex aetiologies that involve combinations of SNPs from different genes which may vary within the population of affected individuals. The search for such combinations is hindered by such extreme computational and statistical difficulties, that many researchers have declared that exhaustive search for 3-way interactions in modern human GWAS will not be practical. We show that such pessimism is unfounded. We recently demonstrated a model-free, ROC-based strategy called GWIS (Goudey et. al, BMC Genomics, 2013) that exhaustively searches medium-size GWAS studies for pairwise interactions within minutes. For all seven WTCCC datasets, we detected nearly all top hits reported previously in the literature within a short list of a few thousand candidate pairs. GWIS is freely available as a web service at: bioinformatics.research.nicta.com.au/software/gwis/. We have now extended GWIS to exhaustive search for 3-way interactions. For illustration, an exhaustive 3-way analysis of Celiac disease GWAS from UK containing ~310K SNPs and 2200 samples using a cluster of 200 GPUs requires 7 days of computing time. To our knowledge this is the first time such an analysis has been shown to be practical. The runtime reduces significantly for more targeted analysis, of a specific DNA region or of a preselected set of SNPs. In particular, exhaustive filtering through all triplets in ~2500 SNPs, including the extended MHC region, required <3 minutes on a standard PC with a single GTX470 NVIDIA GPU. Using the above discovery study, we have found hundreds of triplets having statistically significant association with disease, replicating across four independent Celiac cohorts (a second UK, Dutch, Finnish and Italian cohorts of 5603, 1649, 2476 and 1040 samples, respectively). In particular, within the top ten triplets we observed an area under the ROC curve of high 80%'s and variance explained for balanced data up to 50%. Notably, the ranking of genotypes according to relative risk for many of the top triplets was preserved across cohorts. In conclusion, we demonstrate that exhaustive tri-variate search for epistatic interactions is possible with existing computing hardware.

928T

Genetic variants associated with total lung capacity in chronic obstructive pulmonary disease. *J.H. Lee[1,2], G.M. Hunninghake[3], M.N. McDonald[1], M.H. Cho[1,3], M. Hardin[1,3], E.S. Wan[1,3], P.J. Castaldi[1], A. Gulsvik[4], P. Bakke[4], E.K. Silverman[1,3], C.P. Hersh[1,3], The COPDGene and ECLIPSE investigators.* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Department of Internal Medicine, School of Medicine, Ewha Womans University, Seoul, Korea; 3) Pulmonary and Critical Care Division, Brigham and Women's Hospital, Boston, MA; 4) Haukeland University Hospital and Institute of Medicine, University of Bergen, Bergen, Norway.

Background: Chronic obstructive pulmonary disease (COPD) is characterized by expiratory flow limitation, resulting in air trapping and lung hyperinflation. Hyperinflation is closely related to exercise tolerance and quality of life in COPD patients. It could also be used as a distinguishing feature to explain COPD heterogeneity. The aim of this study was to identify genetic variants associated with hyperinflation in COPD. Methods: We performed genome-wide association studies in three cohorts: COPDGene; the Evaluation of COPD Longitudinally to Identify Predictive Surrogate Endpoints (ECLIPSE); and GenKOLS (Bergen, Norway). All subjects were Caucasians and had at least moderate COPD, defined by a ratio of forced expiratory volume in 1 second to forced vital capacity (FEV_1/FVC) <0.7 and FEV_1 <80% predicted in post-bronchodilator spirometry. Total lung capacity (TLC) was used as a marker of hyperinflation and calculated by using volumetric computed tomography scans of the chest. Genotyping in each cohort was performed on the Illumina platforms, with additional markers imputed using 1000 Genomes CEU or EUR reference panels. To find genetic variants associated with TLC, we used linear regression models adjusting for age, sex, pack-years of smoking, height, and principal components for genetic ancestry in PLINK version 1.07, with meta-analysis of the results using METAL. Results: The most significant loci were on 11q24.2 (β= -0.19, p=3.55×10^{-7}), 8p23.2 (β= -0.16, p=4.22×10^{-7}) and 5q23.1 (β= -0.17, p=6.14×10^{-7}) in the COPDGene cohort; 19p13.2 (β= -0.50, p=6.95×10^{-7}), 13q34 (β= -0.95, p=9.34×10^{-7}), and 12q24.33 (β= -1.22, p=9.64×10^{-7}) in the ECLIPSE cohort; and 8p11.21 (β= -2.58, p=2.51×10^{-7}), 3q24 (β= -1.87, p=4.88×10^{-7}) and 9q34.13 (β= -1.97, p=5.05×10^{-7}) in GenKOLS cohort. In a meta-analysis of these three cohorts, the most significant loci were on 17p13.2 (β= -0.17, p=1.82×10^{-7}) and 19p13.12 (β= 0.13, p=2.36×10^{-7}). Conclusions: Although no single genetic variant reached genome-wide significance, there were several suggestive associations with TLC in three COPD cohorts. Expanding to another cohort could improve statistical power to elucidate associations between genetic variants and hyperinflation-related phenotypes. Funding: NIH R01 HL089856 and R01 HL089897.

The genome-wide association analysis and meta-analysis of sciatica in two Finnish populations. *S. Lemmelä[1], S. Solovieva[1], R. Shiri[1], I. Seppälä[2,3], M. Heliövaara[4], M. Kähönen[2,3], M. Juonala[5,6], J. Viikari[5,6], O. Raitakari[5,6], T. Lehtimäki[2,7], E. Viikari-Juntura[1], K. Husgafvel-Pursiainen[1].* 1) Finnish Institute of Occupational Health, Helsinki, Finland; 2) Tampere University Hospital, Tampere, Finland; 3) University of Tampere, Tampere, Finland; 4) National Institute for Health and Welfare, Helsinki, Finland; 5) University of Turku, Turku, Finland; 6) Turku University Hospital, Turku, Finland; 7) Fimlab Laboratories, Tampere, Finland.

Sciatic pain is one of the leading causes of disability in the working age population. A strong genetic component in family and twin studies as well as a multifactorial etiology as documented in epidemiological studies have been shown for sciatica. A genome-wide association study was conducted in two large population-based Finnish cohorts informative for sciatica. In our current study, data containing more than 500 000 genotyped SNPs and several million imputed SNPs as based on 1000 Genomes imputation reference constructed by the IMPUTE program were analysed using PLINK and SNPTEST, respectively. Results were adjusted for age and gender. Finally, meta-analysis using result data of both cohorts was conducted using GWAMA. In summary, our preliminary results revealed novel candidate regions for sciatica. These results, with several highly interesting regions warranting further investigation, will be discussed. The study received financial support from the Academy of Finland (project no 129364, MSDs@Lifecourse, The SALVE Program).

Replication of GWAS results for dental caries in the permanent dentition. *D. Lewis[1], J. Shaffer[1], E. Feingold[1,2], M. Cooper[3], R. Weyant[4], D. McNeil[5], R. Crout[5], S. Reis[8], A. Vieira[4], M. Vanyukov[7], M. Marazita[1,3,6].* 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Department of Biostatistics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 3) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, Pittsburgh, PA; 4) School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 5) Dental Practice and Rural Health, West Virginia University, Morgantown, WV; 6) Clinical and Translational Science, School of Medicine, University of Pittsburgh, Pittsburgh, PA; 7) University of Pittsburgh School of Pharmacy, Pittsburgh PA; 8) Health Policy Institute, University of Pittsburgh, PA.

There is increasing evidence that variation in the risk for dental caries (i.e., tooth decay) includes a genetic component. We previously published several GWAS studies for dental caries in the permanent dentition (adult teeth), primarily based on the dataset from the GENEVA dental caries study. Those publications considered several different phenotypes, including overall number of carious teeth in the mouth(DMFT)and numbers of caries lesions in specific types of tooth surfaces. Interesting nominated genes included BMP4, BCOR, LYZL2, and ABCG2. BMP4 is known to initiate and regulate the repair of carious tissue. Mutations in BCOR cause oculofaciocardiodental syndrome. In the current work, we did follow-up genotyping in suggestive regions in four study populations totaling approximately 2000 individuals in order to replicate and fine-map our original results.

Negative-regulation-of-apoptotic-process identified to be associated with appendicular lean mass through meta-analysis of pathway-based genome-wide association analysis. *J. Li[1], C. Xu[1], YF. Pei[1,2], Q. Tian[1], H-W. Deng[1,2].* 1) Center for Bioinformatics and Genomics, Biostatistics and Bioinformatics, Tulane University, New Orleans, LA, 70112 USA; 2) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China.

Background: Sarcopenia, characterized by degenerative loss of skeletal muscle mass and strength with aging, is a major public health problem. It is a heritable disease with the heritability of muscle mass and strength being estimated as high as ~60%. Body lean mass (LM) and appendicular lean mass (aLM, the total muscle mass in limbs) are often used as measures for sarcopenia. Recent studies, especially, genome-wide association studies (GWAS), had linked a few genes to LM or aLM. However, they only account for a small proportion of the total LM/aLM variation. Two potential approaches for better identification of genes, especially those with relatively small effects, related to LM/aLM are meta-analyses and pathway-based analysis. In this study, we had conducted combined meta-analysis and pathway-based association analysis for LM and aLM. Methods: Using seven population samples with over 10,000 subjects and leveraging on the genomic variant information from 1000 Genomes Project, we performed GWAS on the imputed genotypes within each sample. We then conducted pathway-based analyses on the GWAS results through GenGen, before conducting meta-analysis on the pathway-based analysis results. Results: The negative regulation of apoptotic process (NROAP) pathway was identified to be the most significant pathway associated with aLM (raw p-value 1.06*10-8 for 885 pathways after QC). The pathway had q-value less than 0.05 in the majority of the samples in which aLM measurements were available. Previous studies had indicated that NROAP included genes for negative regulation of muscle cell and mesenchymal cell apoptotic process, potentially affecting the muscle mass changes in the human body. Conclusion: In this study, we identified the potential role of NROAP pathway in human aLM variation and sarcopenia. These results provided new insights into the genetic basis of osteoporosis, and potential targets for further functional analysis.

932F

Cannabis Dependence Is Associated with Genetic Variants in Genes Linked to Schizophrenia. *M. Lohsen[1, 2, 3], R. Sherva[1, 2], R. Koesterer[1], H. Kranzler[4], H. Zhao[5], L. Almasy[6], L. Farrer[1, 2, 3], J. Gelernter[7].* 1) Boston University School of Medicine, Department of Medicine, Section of Biomedical Genetics, Boston, MA; 2) Boston University School of Medicine, Department of Medicine, Graduate Program in Molecular Medicine, Boston, MA; 3) Boston University, Transformative Training Program in Addiction Sciences, Boston, MA; 4) University of Pennsylvania School of Medicine, Department of Psychiatry and VISN4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 5) Yale School of Public Health, New Haven, CT; 6) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 7) Yale University School of Medicine, Departments of Psychiatry, Genetics and Neurobiology, New Haven, CT.

Background: Cannabis dependence (CaD) is a major public health problem, but little is known about the genetic risk factors. A case-control GWAS on a sample of 708 cases and 2346 exposed controls from the Study of Addiction: Genetics and Environment (SAGE) revealed suggestive evidence of association with the *ANKFN1* gene (Agrawal *et al.*, 2011), which were not genome-wide significant (GWS). Our study provides data from a larger sample with a discovery data set and meta-analysis using results from SAGE. **Methods:** To determine potential links between genetic variants and addiction, users of various substances (alcohol, cocaine and opioids) were recruited in multiple U.S. cities. Many had other comorbid substance dependencies as well, including CaD. The Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA) was administered for psychiatric diagnosis. 988,306 autosomal SNPs (889,659 usable after QC) were genotyped on the IlluminaOmni1-Quad microarray. IMPUTE2 was used to impute the subjects' genomes onto the 1K Genomes reference panel and yielded ~30 million SNPs for analysis. A GWAS was performed using the summation of the 7 DSM-IV CaD diagnostic criteria in the discovery and replication samples and combined by meta-analysis. Samples consisted of cannabis-exposed controls, cases meeting 3 or more of the 7 DSM-IV diagnostic criteria and others (unexposed or meeting fewer than 3 criteria). African Americans ((AAs) discovery: N=3318; 895 cases, 1470 controls, 953 others; SAGE: N=1311; 289 cases, 796 controls, 226 others) and European Americans ((EAs) discovery: N=2379, 781 cases, 938 controls, 660 others; SAGE: N=2752; 458 cases, 1589 controls, 705 others) were analyzed separately in each subsample and then combined by meta-analysis. **Results and Discussion:** We identified several GWS and near GWS associations. The most robust finding was with relatively common variants (MAF~10%) in the *PI4K2B* gene for both AAs and EAs (rs313544; p_{meta}=2.93E-08). The direction of effect was the same for all 4 groups (AAs and EAs, both in discovery and SAGE). This gene was associated with schizophrenia (Houlihan *et al.*, 2009). After *NRG1* (Han *et al.*, 2012), this is the second schizophrenia-associated gene we found to be associated with CaD as well. Several other common SNPs approached, but did not reach, GWS, in one or more of the samples. This study presents additional evidence for biological convergence between schizophrenia and substance dependence traits.

933W

Examining genetic risk factors for progression of chronic kidney diseases: genome-wide pathway analysis of PediGFR. *L. Luo[1], P.A. Kanetsky[2], J. Gupta[2], N. Mitra[2], E. Wühl[3], A. Köttgen[4], S.L. Furth[2,5], B.A. Warady[6], F. Schaefer[3], C. Wong[7].* 1) Dept. of Internal Med., Univ. of New Mexico (UNM), Albuquerque, NM, US; 2) Dept. of Biost. and Epi., The Perelman School of Med. at the Univ. of Pennsylvania, Philadelphia, PA, US; 3) Ped. Nephrology Div., University of Heidelberg, Heidelberg, DE; 4) Renal Div., Univ. Med. Center Freiburg, Freiburg, DE; 5) Dept of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, US; 6) Ped. Nephrology Division, Children's Mercy Hospital, Kansas City, MO, US; 7) Ped. Nephrology Div., UNM Children's Hospital, Albuquerque, NM, US.

Background: Chronic kidney disease (CKD) is a worldwide public health issue. The PediGFR study is an international effort to determine genetic factors associated with kidney function decline in children with CKD via the prospective cohorts of the CKiD, ESCAPE and 4C studies. In addition to the classical GWA single SNP analysis, we are performing a complementary pathway analysis to investigate the role of pre-specified biological pathways in pediatric CKD progression. **Methods**: Longitudinal assessments of either measured or estimated Glomerular Filtration Rate (GFR), a measure of kidney function, were determined in the pediatric CKD cohorts. Among those providing consent for genetic testing, DNA was genotyped using the Illumina® Omni 2.5 BeadChip. Principal component analysis was used to assess subjects' genomic ancestry. Linear regression models adjusting for age, sex, baseline GFR, and population stratification were performed to determine SNP associations with GFR slope. We evaluated the enrichment of GFR slope associations for pathways as grouped in multiple databases (GO Term, KEGG, PANTHER, BIOCARTA, INGENUITY and REACTOME) using Meta-Analysis Gene-set Enrichment of variaNT Associations(MAGENTA) method. **Results**: Among the 444 subjects genotyped in the CKiD study and 1006 subjects genotyped in the ESCAPE/4C study, 267 subjects in the CKiD study and 885 subjects in the ESCAPE/4C study with European ancestry were available after QC. Based on the 267 CKiD subjects, we identified 87 pathways that were nominally significantly enriched ($P<0.05$) for genes associated with GFR slope. The enrichment for four pathways (Autophagy, Translational Regulation, Receptor Mediated Endocytosis, Toll Receptor) was robust to different pathway annotations across databases. However, none of the pathways were significant after correcting for multiple comparisons. **Conclusions**: We identified pathways that were enriched for genes associated with CKD progression in the CKiD cohort with modest significance. We are in the process of completing single SNP and pathway analysis based on the GWAS meta-analysis of the CKiD, ESCAPE and 4C studies. The top enriched pathway findings will be tested for replication in the adult Chronic Renal Insufficiency Cohort study. Pathway analysis of PediGFR has the potential to provide insight into the genetic architecture of CKD progression in children by identifying functionally-related biological pathways enriched for multiple genetic risk factors.

Systemic sclerosis and systemic lupus erythematosus pan-meta-GWAS reveals new shared susceptibility loci. *J.E. Martin[1], S. Assassi[2], L.M. Diaz-Gallo[1], J.C. Broen[3], X. Zhou[2], J.D. Reveille[2], O. Gorlova[4], B.P.C. Koeleman[5], T.R.D.J. Radstake[3], T. Vyse[6], M.D. Mayes[2], M.E. Alarcon-Riquelme[7], J. Martin[1], SLEGEN.* 1) Instituto de Parasitologia y Biomedicina Lopez-Neyra, CSIC, Granada, Granada, Spain; 2) The University of Texas Health Science Center-Houston, Houston, Texas, USA; 3) Department of Rheumatology, Clinical Immunology and Translational Immunology, University Utrecht Medical Center, Utrecht, The Netherlands; 4) Department of Epidemiology, M. D. Anderson Cancer Center, Houston, Texas, USA; 5) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 6) Divisions of Genetics and Molecular Medicine and Division of Immunology, Infection and Inflammatory Disease, King's College London, Guy's Hospital, London, UK; 7) Centro de Genómica e Investigación Oncológica (GENYO) Pfizer-Universidad de Granada-Junta de Andalucía, Granada, Spain.

Systemic sclerosis (SSc) and systemic lupus erythematosus (SLE) are two archetypal systemic autoimmune diseases which have been shown to share multiple genetic susceptibility loci. In order to gain insight into the genetic basis of these diseases we performed a pan-meta-analysis of two genome-wide association studies (GWAS) together with a replication stage including additional SSc and SLE cohorts. This increased the sample size to a total of 21,109 (6,835 cases and 14,274 controls). We selected for replication 19 SNPs from the GWAS data. We were able to validate *KIAA0319L* (P = 3.31×10-11, OR = 1.49) as novel susceptibility loci for SSc and SLE. Furthermore, we also determined that the previously described SLE susceptibility loci *PXK* (P = 3.27×10-11, OR = 1.20) and *JAZF1* (P = 1.11×10-8, OR = 1.13) are shared with SSc. Supporting these new discoveries, we observed that *KIAA0319L* was overexpressed in peripheral blood cells of SSc and SLE patients compared to healthy controls. With these, we add three (*KIAA0319L*, *PXK* and *JAZF1*) and one (*KIAA0319L*) new susceptibility loci for SSc and SLE, respectively, increasing significantly the knowledge of the genetic basis of autoimmunity.

935F

Replication Study of Age-Related Macular Degeneration Susceptible Gene Using Large Genome-Wide Association Study of Japanese.
M. Miyake[1,2], K. Yamashiro[1], H. Nakanishi[1,2], I. Nakata[1,2], Y. Akagi-Kurashige[1,2], K. Kumagai[1], M. Oishi[1], A. Oishi[1], N. Gotoh[1], A. Tsujikawa[1], M. Saito[3], Y. Kurimoto[4], T. Kawaguchi[2], CC. Khor[5], CY. Cheng[5], TY. Wong[5], R. Yamada[2], F. Matsuda[2], N. Yoshimura[1], the Nagahama Study Group. 1) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Center for Genomic Medicine/Inserm U.852, Kyoto University Graduate School of Medicine, Kyoto, Japan; 3) Fukushima Medical School. Fukushima, Japan; 4) Kobe City General Hospital, Kobe, Japan; 5) Genome Institute of Singapore, Singapore, Singapore.

Age-related macular degeneration (AMD) is a major cause of progressive, irreversible visual impairment among elderly population in developed countries. To date, more than 10 genome-wide association studies (GWASs) have been conducted on AMD. In 2013, a large international GWAS (≥ 70,000 subjects) have identified 7 novel AMD susceptible genes (The AMD Gene Consortium, Nature Genetics). However, since this study mainly consists of Caucasians (≥ 94%), this result needs to be replicated in other ethnicity. In the current study, we performed GWAS using large cohort of Japanese to look up the results. Case group consists of 1576 wet AMD patients recruited from all over Japan. These samples were genotyped using Illumina HumanOmni2.5M or OmniExpress. For the control group, we used 3248 healthy Japanese individuals recruited from the Nagahama Prospective Genome Cohort for the Comprehensive Human Bioscience (The Nagahama Study) dataset. After our standard quality control, 558,850 SNPs were included. GWAS was conducted with an adjustment for age, sex, and first 7 principal components. Inflation factor lambda of 1.07 suggested that population stratification was well adjusted. ARMS2 and CFH, that are the established disease susceptible genes of AMD, reached genome-wide significance ($P = 4.7\times10^{-22}$, 1.8×10^{-8}, respectively). We screened ±25kb region of the 7 single nucleotide polymorphisms (SNPs) newly reported by The AMD Gene Consortium. Though p-value of ≤0.05 was observed in ADAMTS9 (lowest P-value = 3.5×10^{-2}), COL8A1 (lowest P-value = 2.9×10^{-3}), and SLC16A8 (lowest P-value = 1.8×10^{-2}), only COL8A1 showed significant association after Bon-ferroni correction. Since no SNP was genotyped within ±25kb around rs3130783 which is located between IER3 and DDR1, we screened ±50kb region for this SNP. This analysis revealed significant association of this region (lowest P-value = 3.0×10^{-3}) before multiple comparison correction. However, it was no more significant after Bon-ferroni correction. In conclusion, 4 regions out of 7 regions newly reported by the AMD Gene Consortium might be associated with AMD in Japanese.

936W

Imputation-Based Genomic Coverage Assessments of Current Human Genotyping Arrays.
S.C. Nelson[1], K.F. Doheny[2], E.W. Pugh[2], J.M. Romm[2], H. Ling[2], S.R. Browning[1], B.S. Weir[1], C.C. Laurie[1]. 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Center for Inherited Disease Research, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Microarray SNP genotyping, combined with imputation of untyped variants, has been widely adopted as an efficient means to interrogate variation across the human genome. The total proportion of genomic variation captured by an array, either by direct observation or imputation, is referred to as 'genomic coverage.' We have performed imputation-based genomic coverage assessments of eight current genotyping arrays that assay ~0.3 to ~5 million variants. Coverage was estimated using the 1000 Genomes Project phase 1 release, with 1,092 samples representing 14 populations in four continental ancestry groups. Samples were divided into ten batches, balancing across populations. In each batch, array variants were used to impute the remaining 1000 Genomes variants, with the rest of the samples serving as the imputation reference. The squared correlation between the observed and imputed allelic dosage (imputation r^2) was calculated at each imputed variant over all samples within an ancestry group. The percentage of variants with minor allele frequency (MAF)>0.05 and r^2≥0.8 is >75% for all arrays and ancestry groups except for African ancestry, and up to ~90% in all ancestries for the highest density arrays. The percentage of variants with 0.01<MAF<0.05 and r^2≥0.8 is substantially lower: <40% for low density arrays in all ancestries and 50-80% in high density arrays, depending on ancestry. We calculated genome-wide power to detect variant-trait association in a case-control design, as an average over a grid of MAF by r^2 bins weighted by the number of variants per bin, assuming an additive genetic model, prevalence of 5%, significance level of 5×10^{-8} and with variable sample size (N) and genotype relative risk (GRR). Genome-wide power for array genotyping with imputation was compared with a hypothetical array that would type all variants in 1000 Genomes. These results can be used to estimate cost efficiency of different array choices. For example, for variants with MAF>0.05 and GRR= 1.3, achieving 80% power requires N=8,700 (1000 Genomes), 9,700 (Omni2.5M) or 11,700 (HumanCore) in European ancestry and N=10,100 (1000 Genomes), 11,700 (Omni2.5M) or 19,600 (HumanCore) in African ancestry, where N is the total sample size (including equal numbers of cases and controls). These imputation-based genomic coverage and power analyses are intended as a practical guide to researchers weighing the costs and benefits of current array choices in different ancestry groups.

937T

Understanding of IL28B gene associated with treatment response for HCV patients.
N. Nishida[1,2], Y. Tanaka[3], M. Sugiyama[1], Y. Mawatari[1], M. Ishii[1], C. Haga[1], K. Tokunaga[2], M. Mizokami[1]. 1) Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Chiba, Japan; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Bunkyo-ku, Tokyo, Japan; 3) Department of Virology & Liver unit, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan.

Genome-wide association studies (GWAS) identified single nucleotide polymorphisms (SNPs) near interleukin-28B (IL28B) gene to be associated with response to PEG-IFN-α/RBV therapy for HCV patients (Tanaka et al. Nat Genet 2009, Ge et al. Nature 2009). The SNPs (rs8099917, rs1297860) could predict treatment responses at approximately 80%, however, the remaining 20% of HCV patients would have unrevealed host genetic factors. A recent report showed that a frame-shift mutation (ss469415590), which located upstream of IFNL3 (IL28B), generated a novel gene, designated IFNL4 (Prokunina-Olsson et al. Nat Genet 2013).

To identify novel host genetic factors except for IL28B (rs8099917), we performed a GWAS with increased number of HCV individuals (118 with null virological response (NVR) and 140 with virologic response (VR)). Candidate genetic regions for replication analysis were selected from the result of GWAS by combining the information of gene-gene interactions and genetic pathways. We performed the replication analysis using a total of 895 HCV patients including (321 NVR and 574 VR). A GWAS using Japanese 118 NVR and 140 VR identified the strongest associations of rs8099917 with NVR ($P = 9.6\times10^{-18}$, OR=7.62), and also detected 16 novel candidate genetic regions with P values below 10-4. Moreover, there were 38 additional candidate genetic regions to be selected by gene-gene interactions and genetic pathways.

We found no significant association of candidate genes except for IL28B gene, in a total of 895 samples. The combined p-value for rs8099917 reached $P = 2.5\times10^{-42}$ (OR=6.00). We also determined the LD structure in a genetic region including IL28B in the Japanese population. Two known associated SNPs (rs1297860 and rs8099917) with HCV drug response had a strong LD with the frame-shift mutation (ss469415590).

Further studies following our report of these robust genetic associations to NVR may make it possible to develop a pre-treatment predictor of which individuals are likely to respond to PEG-IFN-α/RBV treatment. This would remove the need for the initial 12-24 weeks of treatment that is currently used as a basis for a clinical decision about whether treatment should be continued.

938F

Association of body mass-associated polymorphisms in *FTO* intron 1 with determination of Sasang constitutional types in Koreans. *A. Park, S. Cha, H. Yu, J. Kim.* Korea Institute of Oriental Medicine, Deajon, South Korea.

Sasang constitutional (SC) medicine, a part of traditional Korean medicine, classifies humans into 4 constitutional types~Tae-Yang, Tae-Eum (TE), So-Yang, and So-Eum (SE)~based on responses to herbal medicine and individual psycho-physiologic characteristics. Interestingly, the constitutional types are inheritable as revealed by twin and family studies. Recently, several genetic polymorphisms have been associated with SC types from 1,222 subjects via genome-wide association (GWA) analysis. However, the association signal appears to be weak due to the small size of the population used, and the associations are not replicated in the following study. Here, we performed a GWA analysis and replication analysis for SC types determined using an SC analytic tool on the basis of top tertile of the probability values for each type, by scaling up the population size into 5,478 subjects (3,798 subjects in the discovery stage and 1,680 subjects in the replication stage). We found that the minor alleles of polymorphisms in intron 1 of fat mass and obesity associated (*FTO*) gene were replicably associated with SE type in 2 populations (a peak polymorphism in combined: odds ratio (OR) = 0.729, p = 1.45E-07). For the other SC types, there were additional associations with the TE type (a peak polymorphism in combined: OR = 1.27, p = 1.45E-05) despite weak association signals in the discovery population, but not with the So-Yang type. Since the minor alleles of the polymorphisms in *FTO* intron 1 have been associated with increased body mass index (BMI), we performed association analyses by controlling BMI. The association signals in SE type remained significant (a peak polymorphism in combined: OR = 0.688, p = 1.28E-04) but not in the TE type. These results corresponded well with bodily characteristics of SE and TE types. That is, the subjects with SE type are known to be the slimmest among SC types, whereas the subjects with TE type tend to gain more body mass than other SC types. In conclusion, the BMI-associated polymorphisms in *FTO* intron 1 were significantly associated with SE type, independent of BMI as per the GWA and replication analyses. Therefore, the minor alleles of the *FTO* polymorphisms appear to be involved in not only body mass increase but also SC type determination.

939W

A genome-wide association study to identify susceptibility loci for bronchiolitis. *A. Pasanen[1], M.K. Karjalainen[1], M. Ruotsalainen[2], E. Piippo-Savolainen[2], E. Goksör[3], G. Wennergren[3], M. Hallman[1], M. Rämet[4], M. Korppi[5].* 1) Department of Pediatrics, Institute of Clinical Medicine, Clinical Research Center, University of Oulu, Oulu, Finland; 2) Kuopio University Hospital, Pediatrics, University of Eastern Finland, Kuopio, Finland; 3) Queen Silvia Children's Hospital, Pediatrics, University of Gothenburg, Gothenburg, Sweden; 4) Institute of Biomedical Technology and BioMediTech, University of Tampere and Department of Pediatrics, Tampere University Hospital, Tampere, Finland; 5) Pediatric Research Center, Tampere University and Tampere University Hospital, Tampere, Finland.

Background: Bronchiolitis is a severe respiratory disease primarily affecting infants less than one year of age. The most common causative agent of bronchiolitis is respiratory syncytial virus. The severity of bronchiolitis varies among healthy infants; therefore genetic factors likely affect the disease outcome. So far, a number of polymorphisms have been associated with severe disease in candidate gene studies conducted mainly on immunity genes. To our knowledge, genome-wide analyses have not been previously published. **Objective:** To identify genetic susceptibility loci predisposing to severe bronchiolitis. **Methods:** Individuals from Finnish and Swedish populations were genotyped with Illumina HumanOmniExpress BeadChip containing approximately 700,000 SNPs. Finnish population consisting of two birth cohorts with a total of 64 cases and 64 controls was collected in Kuopio during 1979-1982 and 1990-1993. Swedish population with 31 cases and 31 controls was collected in Gothenburg during 1981-1982. Statistical analyses were performed using plink v.1.07 and imputation was carried out to boost resolution. Cases and controls were matched based on birth date (± two months). Only individuals of European origin were included in the analyses. The most significant SNPs will be further analyzed in Finnish populations from Tampere (cases n = 160, controls n = 320), Oulu (n = 200) and Seinäjoki (n = 60) regions. **Results:** Several signals suggestive for association with bronchiolitis (p-value $\le 10^{-5}$) were found. Statistically significant signals were not expected with the present small sample sizes. In the next step we will genotype the best associating SNPs in larger, independent populations to identify significant associations. One of the most promising genes showing association was *KLRK1* (killer cell lectin-like receptor subfamily K, member 1), which is centrally involved in natural killer (NK) cell function. **Conclusions:** We found suggestive association signals for several SNPs. Because one of the signals was within the *KLRK1* gene, we hypothesize that an altered NK cell function could affect the susceptibility to bronchiolitis. The most promising associating SNPs will be further analyzed in independent Finnish populations to identify significant association signals. Later, functional studies of relevant candidate genes will be performed.

940T

The contribution of low frequency coding variants to normal variation in adult height and BMI. *D. Pasko[1], K. Stirrups[2], N. Masca[3], L. Southam[4], T.V. Varga[5], H. Zhang[6], R. Mägi[4, 7], D. Thompson[8], W. Zhang[9], A. Mahajan[4], R.A. Scott[10] on behalf of UK ExomeChip Consortium.* 1) Genetics of Complex Traits, University of Exeter Medical School, Exeter, United Kingdom; 2) Wellcome Trust Sanger Institute, Hixton, Cambridge, United Kingdom; 3) Department of Cardiovascular Sciences, University of Leicester, Glenfield Hospital, Leicester, United Kingdom; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 5) Genetic and Molecular Epidemiology Unit, Lund University Diabetes Centerm Malmo, Sweden; 6) Division of Cardiology, Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, Michigan, United States of America; 7) Estonian Genome Center, University of Tartu, Tartu, Estonia; 8) Department of Public Health and Primary Care, Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, United Kingdom; 9) School of Public Health, Imperial College London, London, United Kingdom; 10) MRC Epidemiology Unit, Institute of Metabolic Science, Cambridge, United Kingdom.

The role of rare (MAF<1%) and low frequency (1-5% MAF) protein coding variants in common traits is unknown. We used the HumanExome Beadchip to test the role of low frequency and rare coding variants in 47,224 and 32,733 European-ancestry individuals from up to 20 studies for adult height and BMI respectively. We aimed to identify low frequency large effect (OR>1.5) exonic variants, and test the distribution of the effect sizes that we could exclude and how these compared to the known common signals. We combined summary statistics (single-variant) from up to 190,918 (height) and 187,603 (BMI) autosomal variants across studies by meta-analysis. Fifteen percent of variants were low frequency and 78% were rare. We performed analyses in a discovery sample that left out studies representing 15-20% of the data and looked for directional consistency of the most strongly associated 100 variants in the left out studies across 3 categories of variants: rare and low frequency variants i) within 1Mb of known GWAS signals, ii) further than 1Mb from known GWAS signals and iii) within 1Mb of known monogenic genes. Finally we compared the effect sizes of the 20 most strongly associated variants, regardless of their significance, to the leading known common signals. No rare and low frequency coding variants achieved study wide significance (2.8×10-7) for height or BMI. In contrast, for height, for each of the 100 most strongly associated low frequency or rare variants (all MAF<5%) in the discovery samples that fell within 1Mb of a GWAS signal, further than 1Mb from a GWAS signal, and within 1Mb of a monogenic genes, 63%, 65% and 58% respectively were directionally consistent in the left out studies. For BMI the equivalent figures were 60%, 52% and 53% (p=0.02 for 60% consistency, p=0.003 for 65% consistency). In the left out studies we observed that, of the 100 leading low frequency variants from the discovery data, 28 and 43 were consistent with effect sizes greater than the strongest known common signals for height (HMGA1 0.09 SDs) and BMI (FTO 0.08 SDs) respectively. Our results are consistent with the presence of low frequency coding variants contributing to human anthropometric phenotypes but demonstrate that larger sample sizes will be needed to identify specific variants that contribute effects of similar or greater magnitude to the strongest known common variants such as those in FTO with BMI.

On individual genome-wide association studies and their meta-analysis. *Y. Pei[1,2], L. Zhang[1,2], C. Papasian[3], Y. Wang[2], H. Deng[1,2].* 1) Center of System Biomedical Sciences, University of Shanghai for Science and Technology, Shanghai 200093, P. R. China; 2) Center for Bioinformatics and Genomics, Department of Biostatistics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 3) Department of Basic Medical Science, University of Missouri-Kansas City, Kansas City, MO 64108, USA.

Individual genome-wide association (GWA) studies and their meta-analyses represent two approaches for identifying genetic loci associated with complex diseases/traits. Inconsistent findings and non-replication among/between individual GWA studies and meta-analyses are commonly observed, hence posing the critical question as to how to interpret their respective results properly. In this study, aiming to investigate and compare the statistical properties of the two approaches, we performed simulation studies. Our results show that: 1) As expected, meta-analysis is more powerful than individual GWA studies under the ideal setting of population homogeneity among the individual GWA studies because of enlarged sample sizes; 2) Under the realistic setting of heterogeneity between individual GWA studies included in meta-analyses, detection of heterogeneity is usually difficult and meta-analysis (even with the random-effects model) may introduce elevated false positive and/or negative rates; 3) Even with relatively small sample sizes, well-designed individual GWA studies still have the capacity to identify novel loci for complex traits; 4) Replicability between meta-analysis and independent individual GWA studies or even between different independent meta-analyses is limited, thus the inconsistent findings (even for true positive results) among studies should not be surprising.

942W

Genome-wide association study and admixture mapping reveals new loci associated with total IgE levels in Latinos. *M. Pino-Yanes[1], C.R. Gignoux[2], J.M. Galanter[1,2], A.M. Levin[3], R. Immunoglobulin E (IgE) is key mediator of allergic inflammation and is frequently elevated in allergic disorders, such as asthma. Although IgE levels are influenced by the environment, there is an important genetic contribution with estimates of heritability as high as 80%. IgE varies by race-ethnicity in the United States, with higher levels reported in both Latinos and African Americans. While genome-wide association studies (GWAS) have identified ten genes associated with total serum IgE levels, most have been performed in populations of European descent.

We performed a GWAS and admixture mapping study of total IgE levels in 3,334 Latinos participating in the Genes-environments & Admixture in Latino Americans (GALA II) Study. Our GWAS identified a genome-wide significant association of a common intronic indel in *ZNF365* with total IgE (rs200076616, $p=2.3\times10^{-8}$), which replicated in an independent sample of Latinos (n=216, $p=0.03$). We identified four admixture mapping peaks where significant correlations with IgE were observed with African, European, or Native American ancestry at 6p21-22, 13p22-31, 14q23.2, and 22q13.1; all but 22q13.1 were replicated in an independent sample of Latinos, and two of the peaks replicated in African Americans (6p21-22 and 14q23.2) ($p\leq0.05$). The most significant peak in GALA II was 6p21-22, where Native American ancestry was associated with lower levels of IgE ($\beta=-0.10$, $p=4.95\times10^{-8}$), and African ancestry was associated with higher levels of IgE ($\beta=0.07$, $p=1.6\times10^{-4}$). Fine mapping using imputation and allelic association testing within 6p21-22 identified a genome-wide significant SNP approximately 12 kb 5' of *HLA-DQA1* (rs1846190, $p=3.5\times10^{-8}$) that replicated in Latinos ($p=0.023$). Locus-wide significant SNPs were also identified at 13p22.3 near *MYCBP2* ($p<1\times10^{-5}$). We then tested the generality of these findings across African Americans (n=3,187) and European Americans (n=1,564). Overall our results support the importance of studying diverse, multiethnic populations and the use of admixture mapping to uncover new loci associated with IgE. Future studies are required to identify the causal variation behind these associations.

943T

Sequencing-based GWAS contributes to the refinement of association signals for inflammatory markers in Sardinians. *E. Porcu[1,2,3], C. Sidore[3], M. Steri[3], A. Mulas[3], M. Zoledziewska[3], F. Busonero[3], A. Maschio[1,3], F. Danjou[3], G. Pistis[1,2,3], M.G. Piras[3], M. Dei[3], S. Lai[3], H.M. Kang[1], C. Brennan[4], R. Berutti[2,5], M.F. Urru[5], M. Oppo[5], A. Angius[3,5], D. Schlessinger[6], F. Cucca[2,3], G. Abecasis[1], S. Naitza[3], S. Sanna[3].* 1) Center for Statistical Genetics, Biostatistics Department, University of Michigan, Ann Arbor, MI; 2) Università degli Studi di Sassari, Dip Scienze Biomediche, Sassari, 07100, Italy; 3) Istituto di Ricerca Genetica e Biomedica-CNR, Monserrato (CA), 09044, Italy; 4) DNA Sequencing Core, University of Michigan, Ann Arbor, MI, USA; 5) Center for Advanced Studies, Research and Development in Sardinia - CRS4, Pula, Italy; 6) Laboratory of Genetics, NIA, Baltimore, MD, 21224.

Inflammation is a response of a tissue to injury often caused by invading pathogens. It has also been implicated in the pathogenesis of numerous chronic diseases but we are still far from a full understanding of this complex phenomenon. Identifying the genes that influence levels of pro-inflammatory molecules can help to elucidate the factors and mechanisms underlying inflammation and their consequences on health. Genome-wide association studies have revealed several associated variants, but those are insufficient to explain the estimated heritability. Here, we measured the levels of the key inflammatory biomarkers Adiponectin, the high-sensitivity C-reactive protein (hsCRP), erythrocyte sedimentation rate (ESR), monocyte chemotactic protein-1 (MCP-1) and interlukin-6 (IL-6) in ~6,000 individuals enrolled in the SardiNIA project. Samples were genotyped with four different Illumina genotyping arrays: OmniExpress, ExomeChip, Cardio-MetaboChip and ImmunoChip and in order to increase the genomic resolution, we imputed ~17 million variants using a reference panel derived from whole-genome low-pass sequencing of 2,120 Sardinians. For each trait, we carried out a sequencing-based genome-wide association scan that allowed us to fine map known signals and detect novel loci. The impact of using sequencing data was clear for all traits, with the exception of IL-6, for which no major differences were seen compared to our previous HapMap GWAS. Interestingly, the same genomic resolution was not reached when using the 1000 Genomes reference panel for imputation. For example, with the 1000 Genomes imputation we were unable to detect the association at the HBB gene for erythrocyte sedimentation rate, with the stop codon variant Q40X. This mutation is common in Sardinia (MAF=5%) but very rare elsewhere. It was present in only one haplotype among 1000 Genomes samples, and thus poorly imputed as rare variant ($R^2=0.31$, MAF=0.008%). Association was missed in the 1000 Genomes imputed data set for three other variants. Consequently, when considering the top variants detected with imputation of the Sardinian haplotypes, the explained heritability was higher for four of five traits than when estimated with the top variants observed after 1000 Genomes imputation. Our study proves the importance of population specific reference panels and their value over the base 1000 Genomes reference set.

944F

Genetic variants underlying endometriosis risk: Meta-analysis on eight genome-wide association and replication studies. *N. Rahmioglu[1], D. Nyholt[2], S.A. Missmer[3], G.W. Montgomery[2], K.T. Zondervan[1].* 1) Wellcome Trust Centre for HG, University of Oxford, Oxford, United Kingdom; 2) Queensland Institute of Medical Research, Brisbane, QLD 4029, Australia; 3) Department of Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital and Harvard Medical School, 75 Francis Street, Boston, MA 02115, USA.

Endometriosis is a complex women's disease with heritability estimated at 52%. A meta-analysis of the published Japanese, Australian and UK endometriosis GWASs confirmed three published loci including, CDKNA2-BAS (rs1537377; P=2.4×10^{-9}), intergenic chromosome 7 (rs12700667; P=3.6×10^{-9}), WNT4 (rs7521902; P=3.2×10^{-11}) and provided evidence for a further four (Nyholt 2012). However, since the publication of the meta-analysis, a fourth GWAS in women of European ancestry from the US was published (Albertsen 2013), involving 2019 cases and 14471 controls. In addition, two replication studies in women of European ancestry were published involving: (1) 1129 cases and 831 controls from Belgium (Sundqvist 2013), (2) 305 cases and 2710 controls from Italy (Pagliardini 2013). Some of the replication evidence for locus-specific associations in these recent papers was non-significant and has generated hypotheses of heterogeneity in the genetic loci underlying endometriosis in different clinical studies even within populations of similar-European-ancestry. Here, our aim is to investigate the heterogeneity and consistency of results across all published eight GWAS and replication studies from Australia, Belgium, Italy, Japan, the UK, and the US through fixed and random effect meta-analyses. The results show robust evidence for nine genetic loci associated with endometriosis, including rs12700667 (P=9.8×10^{-11})-of which association with endometriosis was contested in the two published replication studies-and rs7521902 in WNT4 (P=1.4×10^{-12}), with consistent directions of effect across studies and populations and showing no evidence for heterogeneity. Furthermore, six of nine loci are associated with stronger effect sizes among more severe endometriosis cases(rAFS 3/4), implying that they are likely to be implicated only in severe disease. Whilst three variants are in intergenic regions and have unknown functionality, the remainder are in/near genes with known functions with biological relevance to endometriosis. Furthermore, although the results are reassuring in terms of their consistency, they also show that the phenotypic definitions used in the GWAS to date are crude. This emphasises the importance for future studies to include more detailed phenotype data, an objective that forms the basis of the global EPHect initiative aimed at harmonisation of clinical phenotype and biological sample collection in endometriosis research (http://endometriosisfoundation.org/ephect/).

Searching genes for body shape: a genome-wide meta-analysis in >170,000 individuals of the GIANT consortium. *J.S. Ried[1], J.M. Jeff[2], J. van Dongen[3,4], J.E. Huffman[5], J. Bragg-Gresham[6], A.Y. Chu[7], M. Müller-Nurasyid[1,8,9], R.J.F. Loos[2,10,11] on behalf of the GIANT consortium.* 1) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 2) The Charles Bronfman Institute for Personalized Medicine, The Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA; 3) Department of Biological Psychology, VU University Amsterdam, Amsterdam, The Netherlands; 4) EMGO+ Institute for Health and Care Research, VU Medical Centre, Amsterdam, The Netherlands; 5) MRC Human Genetics, MRC IGMM, University of Edinburgh, Edinburgh, Scotland, United Kingdom, EH4 2XU; 6) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI 48109, USA; 7) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA 02215, USA; 8) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Genetic Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 9) Department of Medicine I, University Hospital Grosshadern, Ludwig-Maximilians-Universität, Munich, Germany; 10) The Mindich Child Health and Development Institute,The Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA; 11) MRC Epidemiology Unit, University of Cambridge, Cambridge, UK.

Analyses within the GIANT and other consortia have revealed hundreds of anthropometric trait loci. Although these studies have been successful in identifying loci for one trait at a time, the question remains open if there are genetic variants that affect 'body shape' as a more comprehensive composite phenotype that is represented by multiple anthropometric traits. Therefore, we calculated four average principal components (avPCs) based on six anthropometric traits (body mass index (BMI), height, hip circumference, waist circumference, and waist hip ratio (WHR)) in a standardized manner across studies. The association between ~2.5 million SNPs and each of the four avPCs was meta-analyzed over 43 studies (N>132,000). SNPs in 606 independent loci reached promising associations ($P<5\times10^{-6}$); 93 for avPC1, 328 for avPC2, 133 for avPC3, 52 for avPC4. These loci were followed up in a second stage of 22 studies (N>39,000), revealing 199 loci that reached genome-wide significance. We confirmed many loci that were found previously in GIANT analyses on height, WHR and BMI. The number and type of confirmed loci represented the main body size phenotypes captured by each avPC. Most confirmed loci for the avPC1 were found with BMI and analysis of avPC2 identified many loci known from height. The analyses of avPC3 and avPC4 mainly confirmed loci known from WHR or height analyses. Nevertheless, eight loci had not been previously identified, 2 for avPC1 (nearest gene *FANCL* and *CD47*), 1 for avPC2 (nearest gene *IL17RC*), 2 for avPC3 (*GANAB*, nearest gene *RPS6KA5*) and 3 for avPC4 (*ARL15, PLCE1, CCDC91*). We followed these eight loci in previously published meta-analyses on various traits to unravel potential pleiotropic effects. For example the locus *CD47* was also associated with HDL levels (GLGC, p=3×10^{-3}) as well as fasting insulin (MAGIC, p=1×10^{-3}), HOMA-IR (MAGIC, p=3×10^{-3}) and weakly with HOMA-B (MAGIC, p=0.02) and diabetes (DIAGRAM, p=0.01). Using this alternative approach, we successfully confirmed previously established associations with anthropometric traits while we also identify novel loci that associate with our comprehensive body shape dimensions. This suggested that the avPCs represent body shape phenotypes that are not solely represented by height, WHR and BMI. This work highlights the advantage of using multiple traits to define complex phenotypes for discovery, which are not otherwise captured by single-trait analyses and may shed light onto new pathways.

Metabolomics in Genome-Wide Association Studies: Revealing Gene-Metabolite-Disease Links. *R. Rueedi[1,2], M. Ledda[3], S. Bergmann[1,2], U.K. Genick[3], Z. Kutalik[1,2].* 1) CBG/DGM, Université de Lausanne, Lausanne, VD, Switzerland; 2) Swiss Institute of Bioinformatics, 1015 Lausanne, Switzerland; 3) Department of Food-Consumer Interaction, Nestlé Research Center, Lausanne, Switzerland.

While still in its infancy, the use of metabolic profiles in genome-wide association studies has improved the detection of, and provided biological context to, the sometimes poorly understood effects of genetic variants on clinical phenotypes. We ran a metabolome- and genome-wide association study on 1H-NMR urine profiles from 835 individuals of the Cohorte Lausannoise. We used an untargeted approach, with the NMR signal intensities as the study's phenotypes, thereby carrying all available metabolomic information into the study. We then identified the metabolites underlying significant association using, in addition to manual identification, a newly developed automated identification method. The two novel gene-metabolite associations resulting from this study are of particular interest because both involve metabolites which we also found to associate with clinical phenotypes. These associations thus provide specific, statistically-determined, evidence of the propagation of genetic effect from gene to disease via the metabolome.

A Genome Wide Association Study To Determine the Susceptibility to *Staphylococcus aureus* Infection. *S.K. Shukla, D. Vasco, T. Carter, M.H. Brilliant, S.J. Schrodi.* Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI., USA.

Staphylococcus aureus is a significant opportunistic pathogen capable of causing a wide range of diseases from boil and carbuncle to bacteremia, endocarditis, and osteomyelitis. However, little is known about the role of host genetics to determine the susceptibility to S. aureus infection. The goal of this study was to conduct the first genome-wide association study (GWAS) to identify specific genetic variants that underlie susceptibility to infection from this pathogen. We conducted a case/control GWAS using samples from the Personalized Medicine Research Project (PMRP) at Marshfield Clinic. All 3616 subjects (408 cases/3208 controls) were genotyped at 522,204 SNPs on the 660W-QUAD Illumina platform. All 408 cases were defined as individuals who have at least one laboratory confirmed evidence of S. aureus infection. The remaining individuals who did not have evidence of the infection in their electronic medical record were considered as controls. PLINK was used for the association statistics. Gene-based and pathway analyses were done using VEGAS and GOrilla and DAVID, respectively. Extensive permutation tests were conducted to obtain appropriate P-values for gene-based and pathway-based results. Additionally, we compared results to those generated under the null by randomly sampling from the entire dataset to minimize the likelihood of false positive results. Males were significantly more likely to be cases than females (P=1.50E-06). The avg age of cases mildly exceeded that in controls (Case Avg=75.6 y/Control Avg=73.6 y; P=5.70E-04). Subjects with higher BMI and/or type 2 diabetes were enriched in cases (BMI: Case Avg=31.9/Control Avg=29.5; P=5.44E-09) (T2D: Case freq=22.0%/Control freq=13.0%; P=2.50E-06). Q-Q plots showed no evidence of confounding by population stratification. No individual SNP exceeded genome-wide significance but eight SNPs exceeded the P<10-6 warranting further investigation. The top results in the gene-based analysis highlighted several biologically interesting candidates involved in inflammation including interleukin subunits and an integrin binding molecule gene. Pathway analysis identified potentially critical molecular networks including the protocadherin-gamma pathway and MAPK signalling pathway. We have identified several SNPs that may influence susceptibility to S. aureus infection. Pathway analysis suggests the potential role of adhesion and inflammation pathways.

948W

Uncovering Genetic Modifiers of Sickle Cell Anemia in a Sub-Saharan African Population - A Genome-Wide Association Study of Sickle-Cell Severity. *T. Singh[1], S. Nkya[2], S.E. Cox[2,3], J.C. Barrett[1], J. Makani[2,4].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, UK; 2) Muhimbili Wellcome Programme, Muhimbili University of Health and Allied Sciences, Dar-es-Salaam, Tanzania; 3) MRC International Nutrition Group, London School of Hygiene & Tropical Medicine, London, UK; 4) Nuffield Department of Clinical Medicine, University of Oxford, Oxford, UK.

BACKGROUND: Sickle cell anemia (SCA) is the most common inherited hemoglobinopathy caused by the homozygous inheritance of sickle haemoglobin (HbS) and mostly affects populations of African descent. While the causal variant of the disorder has long been known, SCA results in a heterogeneous set of clinical outcomes affecting all organ systems, and usually includes varying degrees of chronic anemia and episodic acute pain. In our association study, we hope to find common variants that explain the heterogeneity of SCA severity, and in particular, to find further variants that contribute to the heritability of fetal haemoglobin (HbF) levels, which correlate with SCA outcome. This is the largest genome-wide association study analyzing SCA in a population based in Africa, with the widest range of hematological traits and parameters. METHODS: 1167 patients with a phenotype of HbSS or HbSF, based on quantification of hemoglobin fractions using HPLC (Variant I, Beta-thalassaemia short programme, BioRad, Hercules, CA, USA) from the Muhimbili Sickle Cohort in Dar-es-Salaam, Tanzania were genotyped. Following QC and imputation, associations tests were performed on fetal and haemoglobin (HbF) using ~2.4 million SNPs typed on the Illumina Omnichip platform. RESULTS: Despite including only Tanzanian SCA patients in our cohort, substantial population stratification was still observed in our initial association tests. A linear mixed model framework successfully controlled for population stratification, genetic and cryptic relatedness. Our study successfully replicated known associations for HbF in BCL11A (rs1427407, p=4.9e-42) and the HBS1L-MYB intergenic region (rs9494145, p=4.3e-10), while a few novel loci that are genome-wide suggestive were also identified. We will conduct similar regression analyses on additional clinical phenotypes relevant to SCA outcomes with the same dataset, and are in the process of initiating a replication study to verify our results in an independent population with SCA.

949T

Identification of 3 Susceptibility Loci for Crohn's Disease in a Genome-Wide Association Study of a Korean Population. *K. Song[1], S. Yang[2], M. Hong[3], W. Zhao[1], J. Baek[1], I. Liu[3], Y. Jung[1].* 1) Biochem and Molecular Biol, Univ of Ulsan College of Medicin, Seoul, South Korea; 2) Internal Medicine, Univ Ulsan Col Medicine, Seoul, Korea; 3) Genome Institute of Singapore, Singapore.

We have performed a three-stage genome-wide association study in 2,311 Korean patients with Crohn's disease and 2,442 controls. Three new susceptibility loci were identified at genome-wide significance: SNP1 at 4p14 (OR= 1.43, Pcombined = 3.60 × 10-14), SNP2 at 10q25 (OR=1.42, Pcombined = 1.55 × 10-10), and SNP3 at 11q13 (OR=1.46, Pcombined = 7.15 × 10-9). Using data from the International IBD Genetics Consortium, disease associations of SNP1 (P= 0.00024) and SNP2 (P= 5.32 × 10-5) were replicated in Caucasians. We also replicated four previously reported loci of Caucasian population: TNFSF15, IL23R, the major histocompatibility complex (MHC) region, and the RNASET2-FGFR1OP-CCR6 region. Together, the novel and replicated loci accounted for 5.31 % of the total genetic variance for CD risk in Koreans. Our study provides new biological insight to CD and supports the complementary value of genetic studies in different populations.

950F

Genetic burden of common variants in progressive and bout onset multiple sclerosis. *M. Sorosina[1], P. Brambilla[1], F. Clarelli[1], N. Barizzone[2,3], S. Lupoli[4], C. Guaschino[1,5], G. Liberatore[1,5], A.M. Osiceanu[1], V. Martinelli[5], D. Cusi[4], M. Leone[2], G. Comi[5], S. D'Alfonso[2,3], F. Martinelli Boneschi[1,5], International Multiple Sclerosis Genetics Consortium, PROGEMUS, PROGRESSO.* 1) INSPE, San Raffaele Scientific Institute, Milan, MI, Italy; 2) Interdisciplinary Research Center of Autoimmune Disease IRCAD, University of Eastern Piedmont, Novara, Italy; 3) Department of Health Sciences, University of Eastern Piedmont, Novara, Italy; 4) Department of Health Sciences, University of Milan and Genomics & Bioinformatics Unit, c/o Fondazione Filarete, Milan, Italy; 5) Department of Neurology, Institute of Experimental Neurology (INSPE), Division of Neuroscience, San Raffaele Scientific Institute, Milan, Italy.

Multiple sclerosis (MS) is a neurological autoimmune disease in which genetic and environmental risk factors influence the risk to develop the disease. It could be divided in two main clinical courses based on the characteristic of the onset: progressive onset (PrMS) and bout onset (BOMS) MS. The genetic component of MS has been extensively studied and several loci was found to be associated with the susceptibility to the disease, while the contribution of common genetic variants in the risk of developing the different clinical courses is still unclear. We estimated the proportion of variance in disease liability explained by 296,391 autosomal SNPs in a cohort of Italian PrMS and BOMS patients using the genome-wide complex trait analysis (GCTA) tool and we calculated a weighted log-additive genetic risk score (wGRS) based on the known MS genetic risk variants to evaluate and compare the role of common variants in the disease courses of MS. Our results identified that common SNPs explain more phenotypic variance in BOMS (36.5%±10.1%) than in PrMS (20.8%±6.0%), and this difference further increased (14.7%±6.9%) when considering pure primary progressive (PPMS) cases. Similarly, genetic burden measured using wGRS and explained variance by MS-associated SNPs were higher in BOMS than PPMS in males (wGRS: 6.63 vs 6.51, p=0.04; explained variance: 4.8%±1.5% vs 1.7%±0.6%; p=0.05). Our results suggest that the liability of disease is better explained by common genetic variants in BOMS than PrMS cases. Moreover, the absence of superimposed relapses and male gender further increase the difference between clinical courses.

951W

Dissecting genomic architecture through advanced SNP-based heritability analysis. *D. Speed[1], V. Plagnol[1], M. Johnson[2], D. Balding[1].* 1) UCL Genetics Institute, University College London, London, United Kingdom; 2) Division of Brain Sciences, Imperial College London, United Kington.

SNP-based heritability analysis has had a large impact on the study of complex traits in recent years, but we show that extensions of the method can be used to answer many more questions than have been appreciated to date. We develop several such extensions and apply them to make detailed inferences about the genetic architecture of complex traits. We develop a likelihood ratio test to compare the heritability of different sets of SNPs relative to their sizes (measured in terms of genetic variance). Using this approach, we find that for rheumatoid arthritis and type 1 diabetes, the eQTLs have 50 to 100 times higher intensity of heritability than non-eQTL SNPs, but for other traits eQTLs carry little more heritability than expected by chance. We further find that exonic SNPs explain on average 4.5 times the heritability of non-genic SNPs, and that regions flanking exons have significantly inflated contribution up to 30Kb (after allowing for LD). We compare the heritability of SNPs that are, and are not, associated with a second trait, and use this approach to replicate the known concordance between Schizophrenia and bipolar disorder, and to obtain novel evidence of Schizophrenia and type 1 diabetes having a shared genetic architecture. By likelihood-based comparison of different heritability models, we find that although there is a tendency for variants of lower frequency to have greater effect size, this relationship is weaker than commonly assumed. Finally, we find that SNP-based heritability analysis provides a robust method for gene-based analysis, one which is better able to detect causal genes than single-SNP tests of association and that lends itself to subsequent testing of biological pathways. All analyses are facilitated by our software LDAK.

952T

GWAS Identifies Classical HLA Alleles Associated with Susceptibility to Infectious Diseases. *C. Tian, J. Mountain, N. Eriksson, J. Tung, A. Kiefer, D. Hinds.* Research, 23andme, Mountain View, CA.

The human leukocyte antigen (HLA) system is a highly polymorphic region on chromosome 6 that encodes several hundred genes critical for the immune system. HLA has long been known to play an important role in susceptibility and resistance to many infectious diseases and responsiveness to pathogens or vaccines. Many studies have shown significant associations between HLA loci and major infectious diseases, such as HIV/AIDS, hepatitis and malaria etc. However most studies have tested only candidate loci in small samples, and the associations between HLA alleles and many other infectious diseases are not well studied. We conducted genome wide association studies with over 61,000 individuals who were genotyped on the 23andMe platform and asked to report on multiple infectious diseases. We identified single nucleotide polymorphisms in the HLA region that are associated with cold scores, plantar warts, mumps, positive TB test, scarlet_ fever and shingles at a genome-wide-significant level. We did not detect associations between HLA loci and bladder infection, urinary tract infection, measles, intestinal parasite, myringotomy, mononucleosis or rheumatic fever. To explore the relationship between individual HLA alleles and susceptibility to infectious diseases we used HIBAG, a statistical method combining a large database of individuals with known HLA alleles and SNP variation within the MHC region, to impute HLA alleles at key class I and class II loci over all 23andMe customers of European ancestry. We found that HLA-B*18:01 is the HLA allele most significantly (p=5.5e-07) associated, in a protective manner, with cold sores. Individuals with the HLA-DQA1*03:01 allele were less likely to have plantar warts (p=1.7e-08). HLA-A*02:05 is the HLA allele most significantly associated with mumps (p=1.6e-12). Individuals with the HLA-DRB1*01:03 allele are more susceptible to tuberculosis (p= 4.5e-12). Individuals with the HLA-DQB1*03:01 allele are less likely to have scarlet_fever (p=9.0e-09). HLA-B*44:02 allele is an important factor in the resistance to shingles (p=3.4e-11). Although additional studies will be required to separate and validate the association signals in this complex region, combining accurate HLA typing with our knowledge of the function of specific HLA molecules in immune response and with GWAS can be a powerful tool for dissecting infectious disease etiology.

953F

Improving Genome-Wide Association Studies via Markers Decorrelation. *O. Weissbrod[1], D. Geiger[1], N. Zaitlen[2], D. Heckerman[3].* 1) Computer Science Department, Technion - Israel Institute of Technology, Haifa, Israel; 2) Department of Medicine, Lung Biology Center, University of California San Francisco, San Francisco; 3) eScience Group, Microsoft Research, Los Angeles.

Contemporary state of the art genome-wide association studies typically use linear mixed models (LMMs), due to their robustness to false positive results in the presence of population or family structure. It has recently been widely recognized that case-control studies which use covariates are prone to power loss due to ascertainment bias, where the frequency of cases in the study is larger than in the population. Such bias appears in most case-control studies. As we show in this work, LMMs are especially prone to power loss in such cases, because they implicitly treat every single nucleotide polymorphism (SNP) as a covariate. The result is that many risk variants elude detection. We devised a statistical test that bears many similarities to an LMM regarding its ability to properly control the false positive rate, but does not suffer power loss due to ascertainment, thus solving both fundamental problems of association studies. The principal idea behind our method is that true risk variants can be teased apart from false ones via a simple linear (Mahalanobis) transformation for variables decorrelation. After applying the transformation, SNPs that were correlated with the disease due to confounding are no longer correlated. A simple statistical test can then be carried out on the transformed data. We demonstrate that our method outperforms LMMs in ascertained studies of stratified samples via analyses of synthetic and real data. Simulations suggest that our method can have over 40% power gain over LMMs in realistic scenarios, and over 90% power gain under extreme ascertainment, corresponding to diseases with 0.1% prevalence. We used our method for analyses of Crohn's disease, type I diabetes, and Ulcerative colitis from the Wellcome Trust Case Control Consortium, and a highly stratified study of smoking habits from the Genome Analysis Workshop 14 data set. In all cases, our method managed to identify as many or more risk variants than an LMM, with a properly controlled false positive rate. We also verified that our method consistently assigned a statistically significant lower p-value to known risk variants. These results suggest that existing GWAS datasets may be sufficiently powered to reveal dozens of yet undiscovered disease loci.

954W

A group sparse additive model for genome-wide association studies of dynamic complex traits. *J. Yin[1], M. Marchetti-Bowick[2], J. Howrylak[3], E. Xing[1, 2].* 1) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA; 3) Division of Pulmonary and Critical Care Medicine, Penn State, Milton S. Hershey Medical Center, Hershey, PA.

Despite the widespread popularity of using genome-wide association studies (GWAS) to perform genetic mapping of complex traits, most existing GWAS methodologies are still limited to the use of static phenotypes measured at a single time point. In this work, we propose a new method for performing association mapping that considers dynamic phenotypes measured at a sequence of time points. Our approach relies on Group Sparse Additive Models (GroupSpAM) for nonparametric regression. This new technique detects a sparse set of genomic loci that are associated with trait dynamics, while simultaneously learning an explicit representation of the dynamic effects of genetic variants at each such locus. We perform a proof-of-concept analysis for detecting single nucleotide polymorphisms (SNPs) associated with the FEV1 score, a sensitive measure of airway obstruction used to assess asthma severity. We evaluate our method using a set of 1500 SNPs from the TGFB1 gene, which has an established role in asthma pathogenesis and thus serves as a positive control.

955T

Characterizing and redefining clinical subtypes of inflammatory bowel disease (IBD) using genotypes and phenotypes from 47,000 patients.
G. Boucher[1,2] on behalf of the International Inflammatory Bowel Disease Genetics Consortium (IIBDGC). 1) Research Center, Montreal Heart Institute, Montreal, Quebec, Canada; 2) Department of Medicine, Université de Montréal, Montreal, Quebec, Canada.

To date, large-scale genetic studies in IBD have concentrated on the broad clinical diagnoses of Crohn's disease (CD) and ulcerative colitis (UC). However, it is clear that these conditions are clinically heterogenous and encompass a wide range of subtypes, each with its own pattern of disease behaviour, location and outcome. Whether these subtypes of IBD are distinct diseases with different aetiologies and/or parts of a continuum remains open to debate. Recent progress in characterizing the genetic architecture of IBD, including the identification of 163 IBD-associated loci, affords a unique opportunity to address important clinical questions through the application of genetic risk algorithms. The IIBDGC (a multi-site international consortium) cohort is the largest IBD bioresource generated to date comprising data from over 47,000 patients. Clinical and demographic information on over 26,700 CD and 21,000 UC cases including gender, age at diagnosis, disease location and behaviour, duration of follow-up, surgical history and smoking status were collected according to agreed criteria. We conducted genotype-phenotype analyses across >150k variants (Immunochip), using both established and novel statistical methods for analyses of multinomial phenotypes. We confirmed genome-wide significant associations between the NOD2 and MHC loci and multiple CD phenotypes. We also confirmed an association of the MHC region with extensive UC. Moreover, our analyses implicated multiple additional variants in clinically relevant sub-types. Using the 163 validated IBD loci we showed a significant association between both CD and UC risk scores and CD disease location and behaviour. This association remained highly significant (p-value$<10^{-20}$) after removing the HLA and NOD2 signals, confirming a role for many IBD risk loci in CD sub-phenotype. Furthermore, we used risk scores to show that colonic CD (a subtype phenotypically similar to UC) is genetically intermediate between ileal CD and UC. In conclusion, our data demonstrate significant genetic influence on IBD clinical heterogeneity. They support the hypothesis that UC, colonic CD and ileal CD could be considered as part of a continuous spectrum. These findings will enhance our understanding of the underlying pathogenesis of the subtypes within IBD, and will likely facilitate a molecular classification of IBD subtypes - a major step on the pathway to personalized medicine.

956F

Genome wide association in 5 isolated populations give new insight on the genetic bases of food preferences.
N. Pirastu[1], M. Kooyman[2], A. Robino[1], C. van Duijn[2,3], D. Toniolo[4,5], P. Gasparini[1]. 1) Medical Genetics, Institute for Maternal and Child Health - IRCCS 'Burlo Garofolo' - Trieste, Univ, Trieste, Trieste, Italy; 2) Genetic Epidemiology Unit, Department of Epidemiology, Erasmus Medical Center, Rotterdam 3000 CA, the Netherlands; 3) Centre for Medical Systems Biology, Leiden University Medical Center, 2300 RC Leiden, The Netherlands; 4) DGCB, San Raffaele Research Institute, Milano; 5) 5IGM-CNR, Pavia.

Food preferences are the first factor driving food choice and thus nutrition. It involves numerous different senses such as taste and olfaction plus numerous other factors such as personal experiences and hedonistic aspects. It is clear that all of these have a genetic base although up to now very limited studies have been conducted. In this work we aimed at identifying the genes that underlie to food preferences using 5 different isolated populations. We have collected during whole population screening ~5000 samples coming 3 Italian isolated population from the INGI network, 1 Western European isolated population from the Netherlands (Erasmus Rucphen Family (ERF) study)) plus one coming from isolated communities scattered along 8 countries along the silk road (SR). For each participant we collected numerous information regarding life style, health plus, genome wide genotypes using high density SNP arrays and a food preferences questionnaire which included more than 60 common foods such as liver, orange juice and dark chocolate. Since many of the preferences were specific to each population we decided to restrict our analysis to 22 common foods. We run genome wide association on all 5 cohorts using 1000G imputed SNPs. In order to account for relatedness between samples analyses were conducted using GenABEL and MixABEL. Given the reduced sample size analyses were conducted also on non-additive models (dominant, recessive and overdominant) in order to maximize power to detect associations. Metanalysis was then conducted on the European cohorts and SR was used for replication. Overall we found 19 genome wide significant results for liking of Artichokes (4), Eggplant (2), Whole Milk(2), Dark Chocolate(2), Hot Tea(1), Orange Juice(1), Whipped Cream(2), Red Wine(1), White Wine(2), Mushrooms(1) and Ice Cream (1). Since none of the identified significant SNPs was replicated in the SR cohort we decided to replicate with regional association analysis. We defined around each SNP a 10kb region and estimated region wide significance using PCA-LRT as described in Wang and Abbot 2008. If the SNP fell inside a gene the whole gene was also tested. This type of analysis allowed us to replicate 3 loci one for Artichokes, one for Eggplant and one for Whole Milk. This study shows for the first time replicated genome wide loci for liking of common foods and represent a good starting point in understanding the genetic bases of food preferences and consumption in general.

957W

Analysis of Exomic Variation in the Ashkenazi Jewish Population Identifies Novel Associations to Crohn's Disease in LRRK2. *K. Hui[1], W. Zhang[1], T. Haritunians[2], S. Carmi[3], B.M. Bowen[1], S.R. Duerr[16], J.H. Cho[1], I. Peter[11].* 1) Internal Medicine and Genetics, Yale University, New Haven, CT; 2) Genetics, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Computer Science, Columbia University, New York, NY; 4) Medicine, Johns Hopkins University, Baltimore, MD; 5) Medicine, University of Montreal, Montreal, QC, Canada; 6) Medicine, University of Toronto, Toronto, ON, Canada; 7) Medicine, North Shore-Long Island Jewish Health System, Manhasset, NY; 8) Medicine, Harvard University, Boston, MA; 9) Biostatistics, Yale University, New Haven, CT; 10) Medicine, Albert Einstein College of Medicine, New York, NY; 11) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 12) Neurology, Albert Einstein College of Medicine, New York, NY; 13) Pathology and Cell Biology, Columbia University, New York, NY; 14) Psychiatry, Hofstra North Shore-LIJ School of Medicine, Manhasset, NY; 15) Medicine, Cedars-Sinai Medical Center, Los Angeles, CA; 16) Medicine, University of Pittsburgh, Pittsburgh, PA.

Background Crohn's disease (CD) is 4.3-7.7 times more prevalent in the Ashkenazi Jewish (AJ) population compared to non-Jewish European-ancestry populations. The unique demographic history of the AJ population, characterized by an extreme bottleneck, subsequent explosive population growth, and endogamy, has resulted in increased sharing of long haplotypes. We showed previously that common polymorphisms in established CD loci did not account for the AJ population's increased disease prevalence. In this study, we hypothesized that uncommon variation, particularly within protein-coding exons poorly assayed by GWAS, contributes uniquely to CD in the AJ population. Methods and results We performed exome sequencing of 50 AJ individuals with CD and identified 4,277 novel coding polymorphisms of interest, which we combined with markers on the Illumina HumanExome beadchip. Using this custom array, we conducted genotyping in 1,463 CD unrelated cases and 2,770 independent healthy controls, which were genetically validated as having full AJ ancestry. We detected conditionally independent novel AJ-enriched association signals in leucine-rich repeat kinase 2 (*LRRK2*) at the low-frequency coding mutations N2081D and N551K (OR=1.8, $P=1.0\times10^{-11}$ and OR=0.66, $P=2\times10^{-5}$, respectively). This elaborates our prior CD finding of genome-wide significant association in the *LRRK2* region in a large study of European-ancestry individuals, as well as our previously detected linkage peak with a LOD score of 2.08, driven by AJ families. Both mutations were previously linked to Parkinson's disease (PD), with N2081D conferring a 24% increased risk, while N551K showed a 12% decreased risk in at least one population. Interestingly, *LRRK2* G2019S, which is very strongly associated with PD in the AJ population and occurs in the same domain as N2081D, showed no evidence of association with CD. Combined analysis of genotype data from Ashkenazi PD and CD cases, based on AJ population-specific imputation using a reference panel of 128 whole genome-sequenced individuals, suggested additional extensive genetic pleiotropy within the extended LRRK2 locus. Discussion These findings demonstrate the critical role that uncommon alleles play in CD heritability, providing a key link between structure and function. Our results also point towards complex relationships between the genetic risks that can be uncovered by performing a focused study in the Ashkenazi Jewish population.

958T

Genome-wide association analysis of diverse immune-related phenotypes highlights complex overlapping pathways of immune response. *J.Y. Tung, N. Eriksson, A.K. Kiefer, D.A. Hinds.* 23andMe, Inc, Mountain View, CA.

The immune system's defense of the body against assault requires a complex interplay of cell-mediated and humoral immunity including a multitude of cell types, antigen processing and presentation systems, cytokines, and inflammatory factors. As a result, teasing out which components underlie each individual's susceptibility to immunological conditions is a daunting task. Genome-wide analyses studying these conditions can shed light on which pathways play the biggest roles for different types of conditions. We compared the top associations for a diverse set of inflammatory phenotypes including poison oak contact dermatitis, mosquito bite size, and tonsillectomy (as a proxy for chronic tonsillitis) with each other and with published associations with autoimmune, allergic, and infectious conditions. For inflammatory phenotypes, significant hits near *IL21* and *GMCSF2*(mosquito bite size) and *OSM*, *LTBR*, *CXCL13*, *IGFBP3*, and *IKZF1* (tonsillectomy) suggest a more prominent role for cytokines and inflammatory pathways for these conditions than in allergy or infectious disease. There are several overlaps as well. For tonsillectomy, the variant near *IKZF1* is in high linkage disequilibrium with a variant strongly associated with systemic lupus erythematosus, an autoimmune condition. The region near *IL2* and *IL21* associated with mosquito bite size is also associated with allergy, though the respective variants are not closely linked. In addition, like for many autoimmune, allergic, and infectious conditions, the HLA region comes up as an important hit for both mosquito bite size and tonsillectomy. In our data, the same variant between *HLA-B* and *MICA* (rs138099588) associated with tonsillectomy is also strongly associated with psoriasis ($p = 6.57e-52$) and shingles ($p = 2.05e-8$). For poison oak contact dermatitis, we see a hit within a cluster of *CD1* genes on chromosome 1, rather than in the HLA region. CD1 proteins mediate presentation of lipids to T cells (instead of proteins like the major histocompatibility complex molecules). This is consistent with the role of urushiol, the oily substance produced by the poison oak plant, in triggering the dermatitis. These results highlight the myriad of mechanisms used by the immune system, as well as the subtle similarities and differences in those mechanisms, to react to toxic substances and invaders in the environment.

959F

Joint association analysis of genome-wide human and HIV-1 variation. *I. Bartha[1,2,3], J. Carlson[4], P.J. McLaren[1], Z. Brumme[5], Ch. Brumme[6], R. Harrigan[6], A. Rauch[7], H. Günthard[8], M. Background: Joint analysis of human genetic and HIV sequence variation has been largely limited to HLA alleles and viral mutations in corresponding epitopes. We performed an unbiased genome-wide survey of associations between human SNPs and variation across the HIV proteome. We hypothesized that this non-a priori genome-to-genome analysis would identify and map all host selective pressures on the viral genome.

Methods: Human genome-wide genotyping and HIV-1 full-length sequencing data were available for the study. Binary variables were created for each variable amino-acid positions, for every amino acid that was present in at least 3 HIV genomes. Human SNP imputation was performed using 1000 Genomes data as reference. Associations between all SNPs and HIV-1 amino acids were tested by logistic regression under an additive genetic model. For each amino acid that had genome-wide significant association, we searched for independently associated SNPs by iteratively conditioning on the most significant SNP.

Result: A total of 1071 patients of European ancestry from 7 cohorts and 5 countries were included in the study. After imputation 6 889 656 SNPs were tested for association with more than 3000 different HIV residues. Highly significant associations ($p < 1E-11$) were observed between SNPs in the Major Histocompatibility Complex (MHC) and multiple amino acids in several HIV-1 proteins. SNPs tagging HLA class I alleles strongly associated with viral variation in CTL epitopes targeted by the corresponding alleles. No significant signals were identified outside the MHC.

Conclusion: A non a priori genome-to-genome approach maps associations between host SNPs and HIV genomic variation. We confirm the extensive evolutionary effect that MHC exerts on HIV Gag, Pol and Nef and the lack of common variants with strong effects elsewhere in the host genome on within-host viral evolution.

960W

Shared genetic background for Leprosy an Inflammatory Bowel Disease: chinks in the primary defense against pathogens. *E. Festen[1,2,10], A. Kresentia Irwanto[3,4,10], S. Ripke[5,6], D. Ellinghaus[7], R.K. Weersma[2], A. Franke[7], J.J. Liu[3,4,8,9], IIBDGC.* 1) Department of Genetics, University of Groningen and University Medical Center Groningen, Groningen, The Netherlands; 2) Department of Gastroenterology and Hepatology, University of Groningen and University Medical Center Groningen, Groningen, The Netherlands; 3) Human Genetics, Genome Institute of Singapore, Singapore; 4) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 5) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, USA; 6) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 7) Institute of Clinical Molecular Biology, Christian-Albrechts- University, Kiel, Germany; 8) Shandong Provincial Hospital for Skin Diseases, Shandong University, Jinan, China; 9) School of Biological Sciences, Anhui Medical University, Hefei, China; 10) Authors contributed equally to this work.

Introduction: IBD and leprosy are known to have several overlapping genetic risk loci and the histology of the inflammation is similar. The goal of this study is to identify new shared genetic risk variants for inflammatory bowel disease (IBD) and leprosy, which can shed light on shared biology for the diseases. A secondary goal was to discover new risk loci for each of the two diseases.

Methods: We compared 9026 IBD cases and 15256 population controls of European descent to 706 Leprosy cases and 1225 controls of Chinese descent. The cohorts were genotyped on various genome-wide platforms and equalized by imputation with the HapMap 1000-Genomes reference set (feb'12 release) on IMPUTE2. Because the cohorts have different ethnic descent the MANTRA algorithm was used for their meta-analysis. The MANTRA algorithm was especially developed for the meta-analysis of cohorts of different ethnic backgrounds. For replication an IBD cohort of 869 cases and 2023 controls of European descent, and a Leprosy cohort of 545 cases and 700 controls of Chinese descent, are being analyzed.

Results: Eight known shared risk loci for IBD and leprosy were confirmed in this study: *IL23R*, *TNFSF15*, *RIPK2*, *IL12B*, *LACC1*, *HLA-DR/DQ*, *LRRK2*, and *NOD2*. We identified several potentially new shared risk loci that are currently being replicated in independent cohorts: *REL*, *IL3*, *CD6*, *NUCB2*, *NFATC1*, *UBE2L3*, *MST1*, *C11orf30*, *ZNF365*, *IL10* and *JAK2*.

Conclusion: IBD and leprosy share a large number of risk loci. Most shared risk loci point toward an impairment of the innate immune system as the shared biological background of IBD and leprosy.

961T

Novel Genetic Loci Identified for HIV-1 Acquisition: a 1000 Genomes-Imputed Genome-wide Association Study among Injection Drug Users and a Replication. *E.O. Johnson[1], D.B. Hancock[1], N.C. Gaddis[1], J.L. Levy[1], G.P. Page[1], S.P. Novak[1], C. Glasheen[1], N.L. Saccone[2], J.P. Rice[2], Q. Wang[3], M. Moreau[3], K. Doheny[4], J. Romm[4], B. Aouizerat[5], A.I. Brooks[3], L.J. Bierut[2], A.H. Kral[1].* 1) RTI International, Research Triangle Park, NC; 2) School of Medicine, Washington University, St. Louis, MO; 3) Rutgers University Cell and DNA Repository, Piscataway, NJ; 4) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 5) School of Nursing, University of California San Francisco, San Francisco, CA.

Host genetic factors likely influence susceptibility to acquiring HIV-1 upon exposure. However, besides a rare 32-base pair deletion in the CCR5 gene, no replicable genetic associations have been reported. To identify novel genetic factors, we conducted a genome-wide association study (GWAS) of HIV-1 acquisition in 2,004 African Americans and 1,132 European Americans from the Urban Health Study, one of the largest studies of street-recruited injection drug users in North America. Study participants were frequency matched on several important environmental and behavioral risk factors to create an approximate 2:1 ratio of high-risk HIV-negative controls to HIV-positive cases. After genotyping on the Illumina Omni1-Quad BeadChip and applying standard quality control metrics, 1000 Genomes imputation was conducted using IMPUTE2 with reference to the ALL panel, resulting in the availability of ~8 million single nucleotide polymorphisms (SNPs) with minor allele frequency (MAF)>0.5%. Genotyped and imputed SNPs were tested for association with HIV-1 acquisition in the separate ancestral groups using logistic regression models adjusted for age, gender, survey year, behavioral risk class, and 10 eigenvalues. The ancestral-specific GWAS results were then combined via fixed-effects meta-analysis. Eight genetic loci of interest were identified: 1 locus with statistically significant SNP associations ($P<5\times10^{-8}$), 6 loci with nominally significant SNP associations (P between 5×10^{-8} and 1×10^{-6}), and 1 locus with the top genotyped SNP association ($P=1\times10^{-5}$). Across the 8 loci of interest, SNPs with $P<1\times10^{-3}$ were selected for independent replication testing in 1,852 African Americans and 681 European Americans from the Women's Interagency HIV Study. One chromosome 9p13.2 SNP ($P=1.38\times10^{-4}$) exceeded the statistical significance threshold for replication ($P<3.33\times10^{-4}$ based on correction for multiple testing). Several SNPs from 3 other loci on chromosomes 5q31.2, 6p21.32, and 9p24.1 were replicated at nominal significance (minimum P ranging from 1.18×10^{-3} to 3.64×10^{-3}). The GWAS-implicated loci with evidence for replication span genes that have biologically plausible roles in the immune system, some of which have specific functional and regulatory links to protease inhibition and HIV viral DNA integration in host cell DNA. Additional replication testing is underway to further support the statistical evidence for association with HIV-1 acquisition.

962F

Genome-wide discovery of genetic predictors of weight-loss in obese subjects in response to diet and exercise. *C.M. Molony[1], D.F. Reilly[1], H. Zhou[1], S. Heymsfield[3], B. Goldstein[2], M.L. Reitman[4], L. Tacconi[5], N. Thornberry[2].* 1) Merck Research Laboratories,Informatics and Analysis, Merck & Co., Inc., Boston, MA; 2) Merck Research Laboratories, Whitehouse Station, NJ, USA; 3) Pennington Biomedical Research Center, Baton Rouge, LA, USA; 4) NIDDK, National Institutes of Health, Bethesda, MD, USA; 5) Vree Health, a wholly owned subsidiary of Merck and Co., Inc., Whitehouse Station, NJ, USA.

Diet and exercise are the first-line treatments for obesity. Since the probability of successfully achieving long-term (> 12 months) weight-loss is modest, clinicians and patients would benefit from development of robust early biomarkers of weight-loss response. Here we report on the first genome-wide association study in placebo-treated subjects pooled from multiple weight-loss trials in order to identify genetic predictors of long-term weight-loss with diet and exercise intervention. DNA samples were available from 355 placebo-treated subjects who also followed a diet which targeted a 25% caloric restriction and an exercise regimen designed according to increase the patient's current level of physical activity. This cohort had a mean baseline BMI 35.0 (s.d. 4.0) and mean age 49.6 (s.d. 11.9) an overall weight-change of -3.3kg (CI -4.0, -2.7) over the 52 week treatment period. DNA samples were genotyped on the Illumina Human 1M DNA Beadchip and additional marker data were inferred using imputation approaches with the 1000genomes as reference. Depending on the population there were approximately 6 million markers available for analysis after imputation. After adjustments for multiplicity and undetected stratification, the analysis yielded two significant and three suggestive loci in the White population. The largest signal was observed at Chr19p13.1 for the SNP rs147773401 lying intronic to gene LPHN1 with a p-value of 5.88×10-12 and covariate adjusted genotypic means of -2.7kg (CI -3.3,-2), -6.7kg (CI -8.4,-5.1), and -29.8kg (CI -38.9,-20.7). A sensitivity analysis of this marker after removing extreme weight-loss subjects yielded an association signal that still met suggestive thresholds (p-value<5×10-7). Another single nucleotide deletion at chr10.109889967 was also associated with a p-value 5.85×10-8 with a covariate adjusted mean weight-loss of -13.9kg (CI -17.2,-10.5) for the most extreme genotype group. Genetic predictors of large effect may aid in helping to distinguish responders from non-responders in order to make trial designs more efficient and improve benefit/risk/cost ratios in medical practice. However obesity is a multifactorial process and our data suggest that it is unlikely that any single genetic marker will robustly characterize the response to a diet plus exercise intervention for a large segment of the patient population.

Plasma Lipids, Chromosome 11q23.3, and the Risk of Infantile Hypertrophic Pyloric Stenosis. *B. Feenstra[1], F. Geller[1], L. Carstensen[1], P.A. Romitti[2], I. Baranowska Körberg[3], B. Bedell[4], C. Krogh[1], R. Fan[5], A. Svenningsson[3], M. Caggana[6], A. Nordenskjöld[3], J.L. Mills[5], J.C. Murray[4], M. Melbye[1].* 1) Dept. of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Dept. of Epidemiology, University of Iowa, Iowa City, Iowa; 3) Dept. of Women's and Children's Health and Center for Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 4) Dept. of Pediatrics, University of Iowa, Iowa City, Iowa; 5) Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, Maryland, USA; 6) Wadsworth Center, New York State Department of Health, Albany, New York.

Infantile Hypertrophic Pyloric Stenosis (IHPS) is a serious condition in which hypertrophy of the pyloric sphincter muscle layer leads to gastric outlet obstruction. Currently, it is the most common condition requiring surgery among newborns. To search the genome for genetic associations with IHPS, we used reference data from the 1000 Genomes Project for imputation into a genome-wide dataset of 1,001 Danish surgery-confirmed cases and 2,371 disease-free controls. The five most strongly associated loci were tested in replication sets from Denmark, Sweden, and the United States with a total of 1,663 cases and 2,315 controls. We found a novel genome-wide significant locus for IHPS at chromosome 11q23.3 in a region harboring the apolipoprotein (APOA1/C3/A4/A5) gene cluster. The most significant SNP at the locus (odds ratio, 1.59; $P = 1.9\times10^{-10}$) is strongly correlated with SNPs previously found to be associated with levels of circulating cholesterol. For these SNPs, the cholesterol lowering allele consistently conferred increased risk of IHPS. To further investigate the role of lipid levels at birth for IHPS risk, we conducted a functional follow-up study based on umbilical cord blood samples from 46 cases and 189 controls of Danish ancestry sampled from the Danish National Birth Cohort. We found that IHPS risk was inversely associated with total cholesterol levels at birth. There was a 64% (95% confidence interval -83% to -26%; P = 0.005) lower risk per mmol per liter and the 25% of newborns with the lowest levels of total cholesterol were at almost five times higher risk compared with the 25% with the highest levels. In conclusion, low levels of plasma cholesterol, partly genetically-driven, were associated with higher risk of IHPS. This association suggests the possibility that dietary modifications to ensure normal lipid levels could reduce the risk.

964T

Meta-analysis of genome-wide association studies identifies three new susceptibility loci for intracerebral hemorrhage. *G.J. Falcone[1,2,3,4], D. Woo[5], C.D. Langefeld[6], J. Rosand[1,2,3], International Stroke Genetics Consortium.* 1) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 2) Division of Neurocritical Care and Emergency Neurology, Department of Neurology, Massachusetts General Hospital, Boston, MA; 3) Hemorrhagic Stroke Research Group, Massachusetts General Hospital, Boston, MA; 4) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 5) Department of Neurology, University of Cincinnati College of Medicine, Cincinnati, OH; 6) Center for Public Health Genomics and Department of Biostatistical Sciences, Wake Forest University, Winston-Salem, NC.

BACKGROUND: Intracerebral hemorrhage (ICH) is the stroke type with the worst prognosis and has no established treatment. ICH is classified as lobar and nonlobar based on histopathological differences, with genetic variation contributing to risk of both subtypes. We report the first genome wide association study (GWAS) of this condition. **METHODS**: The discovery phase included 6 ICH GWASs that enrolled subjects from European ancestry in the US and Europe. Cases were ascertained by neurologists blinded to genotype data and classified as lobar or nonlobar based on brain computed tomography. ICH-free controls were selected from ambulatory clinics or by random digit dialing, depending on the study. Genotyping was completed in Illumina 610 or Affymetrix 6.0. Standard quality controls filters were applied and principal component analysis was implemented to account for population structure. Unobserved genotypes were inferred by imputation to 1000 genomes references panels, with subsequent filtering of single nucleotide polymorphisms (SNPs) with minor allele frequency (MAF) <1% or low imputation quality. Association testing was carried out using logistic regression assuming additive genetic effects and including age, gender and principal components in the model. Meta-analyses were completed using the inverse normal method, weighting by sample size. Replication of signals with p<5×10E-6 was pursued in an independent multi-ethnic study utilizing direct genotyping. **RESULTS**: The discovery phase included 1545 cases (664 lobar and 881 nonlobar) and 1481 controls and identified 4 possible loci: for lobar ICH, chromosome 12q21.1 (rs11179580: MAF=0.22, odds ratio [OR]=1.54, p=6.7×10E-8) and 8p23.1 (rs1630950: MAF=0.37, OR=1.33, p= 7.1×10E-7); for nonlobar ICH, chromosome 1q22 (rs2984613: MAF=0.31, OR=1.45, p=1.8×10E-8) and 3q13.13 (rs4682240: MAF=0.07, OR=2.04, p= 1.4×10E-06). Replication included 1256 cases (329 whites, 506 blacks and 421 Hispanics) and 760 controls (237 whites, 346 blacks and 177 Hispanics) and confirmed 3 loci: 12q21.1 (p=0.037, meta-analysis p=2.3×10E-8), 1q22 (p=0.009, meta-analysis p=2.0×10E-9) and 3q13.13 (p=0.048, meta-analysis p=6.7×10E-7). Chromosome 8p23.1 did not replicate (p=0.72). **CONCLUSION**: Three susceptibility loci for ICH were identified, all showing subtype-specificity. These results confirm the presence of biological heterogeneity across ICH subtypes and highlight the importance of ascertaining ICH cases accordingly.

965F

Association between Obsessive-Compulsive Disorder (OCD) and Phenotypes in a Genome-Wide Association Study. *G. Zai[1, 2, 3], C. Zai[1, 2], J. Knight[1, 3], J.L. Kennedy[1, 2, 3], M.A. Richter[2, 3, 4].* 1) Neurogenetics Section, CAMH, Univ Toronto, Toronto, ON, Canada; 2) Department of Psychiatry, University of Toronto, ON, Canada; 3) Institute of Medical Science, University of Toronto, ON, Canada; 4) Department of Psychiatry, Sunnybrook Health Science Centre, Toronto, ON, Canada.

Background: Obsessive-compulsive disorder (OCD) is a chronic and debilitating psychiatric disorder with a strong genetic etiology. A recent genome-wide association study (GWAS) reported interesting candidate gene variants with potential susceptibility to developing OCD. Hypothesis: We hypothesized that genetic variation(s) may be associated with OCD symptom severity using the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) severity score and age at onset (AAO). Method: We investigated 357 individuals with OCD and their nuclear families or matched healthy control (age, gender, and ethnicity) for an association of gene variant(s) and phenotypes including Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) severity score and age at onset (AAO) in a GWAS. GWAS was conducted by the OCF Genetic Collaborative Group. Quality control and analyses were conducted using PLINK and R programs. Results: Several suggestive genome-wide association signals were detected with a p-value of 10E-6 on chromosome 3 and 22 for Y-BOCS severity score and chromosome 3 and 9 for AAO. Conclusion: Preliminary findings from our GWAS suggested possible involvement of several regions in OCD symptom severity and age of onset. Further analyses are required to characterize these results.

966W

Genome-wide association analysis in a 23andMe cohort identifies novel associations with uterine fibroids. *A.S. Shmygelska, N.K. Eriksson, J.Y. Tung, J.L. Mountain, U. Francke, A.K. Kiefer, D.A. Hinds.* 23andMe Inc., Mountain View, CA.

Uterine leilomyomata, commonly known as uterine fibroids, are benign tumors derived from smooth muscle and fibrous tissue in the uterus, and are the leading cause of hysterectomy in the United States. The lifetime risk for a woman to develop fibroids has been estimated to be as high as 25%. Fibroids tend to grow under the influence of estrogen and shrink when estrogen levels are reduced. The underlying causes of uterine fibroids are not well understood, but twin studies suggest that approximately 55% of the variation in susceptibility to fibroids is genetic. To investigate the genetic factors underlying uterine fibroids, we conducted a genome-wide association study (GWAS) of over 4,000 cases and 12,000 controls of unrelated individuals with European ancestry from the 23andMe cohort. We imputed genotypes against 1000 Genomes reference haplotypes. Participants reported *via* a web-based survey whether or not they had had uterine fibroids. We report one novel genome-wide association and four suggestive associations. The most significant finding is a variant in the spectrin repeat containing nuclear envelope 1 (SYNE1) gene (rs71575922: odds ratio=1.3, $p = 4.8 \times 10^{-10}$), which is 18 kbp upstream of the ESR1 gene that encodes estrogen receptor alpha. Variants in ESR1 have been previously shown to be associated with breast and endometrial cancer. SYNE1 is expressed in skeletal and smooth muscle, and peripheral blood lymphocytes, and localizes to the nuclear membrane. Other suggestive associations include (1) the lipoprotein(a) (LPA) gene (rs1800769: odds ratio=1.2, p=8.8x 10^{-7}), which has been shown to promote smooth muscle cells proliferation in transgenic rabbits and (2) the rs12789861 variant (odds ratio=0.9, p=6.7x 10^{-7}) 40 kbp downstream of the Wilms tumor protein (WT1), whose product interacts with the estrogen receptor alpha in breast cancer cells, and downstream of the reticulocalbin 1 (RCN1) gene which is involved in muscle development and tumorigenesis. We also detect an association between uterine fibroids and the recoverin (RCVRN) gene (rs6503269: odds ratio=1.2, p=4.4x 10^{-7}) that appears non causal. RCVRN encodes a neuronal calcium sensor that plays role in the phototransduction cascade in the retina and is implicated in endometrial cancer associated retinopathy. In our European cohort we replicate two of the three previously identified associations reported in women of Japanese ancestry, however, not on the genome-wide significance level.

967T

Identification of susceptibility genes of adult asthma in French Canadian women. *J.C. Berube[1], E. Lavoie-Charland[1], N. Gaudreault[1], L. Sbarra[1], C. Henry[1], L.P. Boulet[1], Y. Bosse[1,2].* 1) Institut universitaire de cardiologie et de pneumologie de Québec, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

Introduction: Asthma is a heterogeneous disease in which several susceptibility genes have been identified, but together, those genes explain only a small fraction of the heritability. It was postulated that additional genetic factors may be found by studying subgroups of phenotypically similar asthmatic patients. **Objective:** The goal of this study is to identify single nucleotide polymorphisms (SNPs) associated with asthma in adult women of European ancestry. **Methods:** A pooling-based genome-wide association study was performed in 240 allergic asthmatic women and 120 non-asthmatic allergic women. The genotyping was performed in six replicates for both pools using the Ilumina HumanOmniExpress BeadChip. The 730 525 interrogated SNPs were ranked based on their likelihood of being associated with asthma using the silhouette score calculated by the GenePool software. The top 20 ranked SNPs plus 18 SNPs ranked among the top 2000 and near candidate genes were selected for individual genotyping in an extended cohort of 349 asthmatic women and 261 non-asthmatic women using the Illumina BeadXpress platform. **Results:** 21 of the 38 SNPs tested by individual genotyping showed P values lower than 0.05 for association with asthma. SNPs rs17655581 (P = 8.2 × 10-5) and rs7980829 (P = 2.4 × 10-4) were the most significant. These SNPs are located in intergenic regions uncharacterized for asthma. The third most important genetic signal was found with rs803010 (P = 4.4 × 10-4) located in the promoter of PTGDR, which is a gene previously associated with asthma in individuals of European ancestry. **Conclusion:** This pooling-based GWAS in French Canadian adult women identified new loci associated with asthma. This study also supported the role of PTGDR in this more homogenous subgroup of asthmatic patients. Further validation is required in independent cohorts of adult asthmatic women of European ancestry.

968F

Familial history of chronic rhinosinusitis predicts more severe disease. *L. Mfuna Endam[1], A. Filali-Mouhim[1], P. Boisvert[2], LP. Boulet[3], Y. Bossé[3], M. Desrosiers[1,4].* 1) Department of Otolaryngology, CHUM HOTEL DIEU, CRCHUM, Montreal, PQ, Canada; 2) Department of Otolaryngology, Saint-François d'Assise Hospital, Québec, PQ, Canada; 3) Centre de Recherche, Institut Universitaire de Cardiologie et de Pneumologie de Québec, Québec, PQ, Canada; 4) Department of Otolaryngology-Head and Neck Surgery, Montreal General Hospital, McGill University, Montreal, QC, Canada.

Introduction: Genetic association studies have linked chronic rhinosinusitis (CRS) with a number of biologically-plausible genes. However, effects are often small and account for only a portion of CRS cases. Recent evidence suggested that pathogens contributing to CRS development share similar pathways as those revealed by genetic association studies. Cohorts of individuals with CRS may thus contain individuals with genetically-determined and acquired disease, thereby diluting the strength of the genetic signal. We wished to determine whether CRS populations would be enriched for genetic basis to disease by restricting analysis to the sub-group of subjects with a positive family history of CRS. More specifically we tested whether this sub-group was associated with i) a distinct disease evolution and ii) increased strength of previously identified genetic associations. Methods: An existing population of 198 French-Canadian patients with CRS refractory to medical and surgical treatment were screened for incidence of CRS in relatives and impact on population demographics and previously reported genetic associations. PLINK software was used to perform genetic association tests. Results: 38% of subjects had a family history of CRS. This group had more severe disease as suggested by an earlier age at onset, an earlier age at first endoscopic sinus surgery and a greater number of surgeries. However, analysis of previously reported SNPs did not show a great variation in strength of previously reported genetic associations. Conclusion: Family history of CRS appears to select for a sub-group of patients with more severe disease suggesting a large genetic component. Exclusion of individuals with a lower risk of a genetic component by restricting patient recruitment or analysis to individuals with a family history of CRS may help better identify candidate genes implicated in development of CRS.

Refinement of whole-body bone mineral density measures of children assists the identification of genetic variants associated with skeletal site specificity and bone mass attainment. *J.P Kemp[1,2], C. Medina-Gomez[3,4,5,6], K. Estrada[3,5,6], B. St-Pourcain[1], D.H.M. Heppe[4,5,7], N.J. Timpson[1,2], L. Oei[3,5,6], S.M. Ring[1], C.J. Kruithof[4,5], L.E. Wolber[8], F.M.K. Williams[8], M.C. Zillikens[3,6], A. Hofman[4,5,6], A.G. Uitterlinden[3,4,5,6], G. Davey-Smith[1,2], V.W.V. Jaddoe[4,5,7], J.H. Tobias[9], F. Rivadeneira[3,4,5,6], D.M. Evans[1,2].* 1) MRC Centre for Causal and Translational Epidemiology, University of Bristol, Bristol, United Kingdom; 2) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 3) Department of Internal Medicine, Erasmus University Medical Center, Rotterdam, The Netherlands; 4) The Generation R Study Group, Erasmus University Medical Center, Rotterdam, The Netherlands; 5) Department of Epidemiology, Erasmus University Medical Center, Rotterdam, The Netherlands; 6) Netherlands Genomics Initiative (NGI)-sponsored Netherlands Consortium for Healthy Aging (NCHA), The Netherlands; 7) Department of Paediatrics, Erasmus University Medical Center, Rotterdam, The Netherlands; 8) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 9) School of Clinical Sciences, University of Bristol, Bristol, UK.

The heritability of bone mineral density (BMD) varies across skeletal sites, reflecting different relative contributions of environmental and genetic influences. To quantify the degree to which common genetic variants and environmental factors influence BMD at different sites, we estimated the genetic (r_g) and environmental (r_e) correlations of BMD measured at the upper limbs (UL), lower limbs (LL) and skull (S), using whole-body DXA scans of ~4890 participants recruited by Avon Longitudinal Study of Parents and their Children (ALSPAC). Point estimates of r_g indicated that appendicular sites shared a greater proportion of shared genetic architecture (LL-/UL-BMD r_g= 0.78) when compared to the skull (UL-/S-BMD r_g=0.58 and LL-/S-BMD r_g= 0.43). Likewise, environmental factors influencing BMD at the appendicular sites were broadly similar to each other (r_e=0.55), however they were appreciably different from the factors influencing S-BMD (r_e=0.20 - 0.24). To explore the basis for the observed differenced in r_g and r_e, genome-wide association meta-analyses were performed (n~9395), combining data from ALSPAC and the Generation R study (GEN-R) to identify genetic signals associated across different skeletal regions. Twelve known BMD associated variants differed in the strength of their association and magnitude of effect with each sub-region. In particular, effect sizes of variants situated closest to *EYA4* (6q23.2), *COLEC10* (8q24.12), *LIN7C* (11p14.1) and *TNFRSF11A* (18q21.33) appeared to be largest for S-BMD when compared to UL- and LL-BMD. Furthermore variants at the *WNT16* and *CENPW* showed considerable site-specificity as indicated by very strong levels of association with S-BMD and/or UL-BMD but not with LL-BMD. In addition, we report a novel association between a variant in *RIN3* and LL-BMD (rs754388: β=0.13, SE= 0.02, P=1.4×10^{-10}) and highlight its prior association with Pagets disease. We suggest that different skeletal sites as measured by whole body-DXA are to a certain extent under distinct environmental and genetic influences. Allowing for these differences may help to uncover new genetic influences on BMD, particularly those involved in bone accrual, for which S-BMD appears to be particularly well suited.

970T

GWAS SNPs impact gene expression through inheritance of multiple enhancer variants. *O. Corradin[1], A. Saiakhova[1], B. Akhtar-Zaidi[1], L. Myeroff[2], J. Willis[2,3], S. Markowitz[1,2,4], P.C. Scacheri[1,2].* 1) Department of Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH 44122; 2) Department of Pathology, Case Western Reserve University, Cleveland, OH 44122; 3) Department of Medicine, Case Western Reserve University, Cleveland, OH 44122; 4) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH 44106.

Since 2005 over 1350 genome-wide association studies (GWAS) have been published, identifying thousands of SNPs associated with more than 600 traits. More than 90% of these SNPs are located outside protein coding genes, and are hypothesized to influence gene expression by disrupting the function of non-coding regulatory elements such as enhancers. Consistent with this hypothesis, the ENCODE consortium and other groups have localized thousands of GWAS variants to enhancer elements identified through epigenomic profiling studies. However, the genes whose expression these enhancer variants influence and their effect on target transcript levels often remains unknown. Moreover, because GWAS-loci often contain multiple SNPs in linkage disequilibrium (LD) with the 'lead' SNP, any one of which may be 'causative', pinpointing the culprit is often a major challenge. We provide evidence that for six common autoimmune disorders (rheumatoid arthritis, Crohn's disease, celiac disease, multiple sclerosis, lupus, and ulcerative colitis), the GWAS-association arises from a group of polymorphisms in LD that map to multiple enhancer elements active in the same cell type. This finding suggests that for common traits, there is not necessarily a single disease-causing variant that underlies the association signal, but rather several variants that impact multiple enhancers and cooperatively affect gene expression. We call this the 'multiple enhancer variant' hypothesis. Using a novel method to delineate enhancer-gene interactions, we show that multiple enhancer variants within a given locus typically target the same gene. Using available data from HapMap and B lymphoblasts as a model system, we provide evidence at numerous loci that multiple enhancer variants cooperatively contribute to altered expression of their gene targets. The effects on target transcript levels can be either gain or loss of function, and overall tend to be modest. Overall, the multiple enhancer variant hypothesis offers a new paradigm by which non-coding variants confer susceptibility to common traits.

971F

Novel Genetic Association of Primary Severe Localized Provoked Vulvodynia with TRPV1 and NGF; Possible Common Predisposition with Other Pain Syndromes. *T. Falik-Zaccai[1,2], L. Kalfon[1], A. Azran[3], Y. Farajun[3], E. Tubin[1], O. Hemo[1], L. Abramov[4,6], A. Yeshaya[5,6], J. Bornstein[2,3].* 1) Institute of Human Genetics, Western Galilee Medical Center, Nahariya, Israel; 2) The Galilee Faculty of Medicine, Bar Ilan, Safed, Israel; 3) Department of Obstetrics & Gynecology, Western Galilee Medical Center, Nahariya, Israel; 4) Lis Women's Hospital, Tel Aviv, Israel; 5) Shnaider Women's Hospital, Beilinson Medical Center, Petah-Tikva ,Israel; 6) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Localized Provoked Vulvodynia (LPV) is a multifactorial syndrome affecting 10-16% of women worldwide, causing pain of variable nature and intensity at every attempt to have sexual intercourse. Familial occurrences of LPV suggest genetic susceptibility in the etiology of this condition. We have studied possible associations between LPV and several SNPs in genes previously hypothesized to be involved in the pathophysiology of LPV by coding for proteins involved in mast cells degradation and hyper-innervation in the vestibule of affected women. We have analyzed and compared the prevalence of seven SNPs in each of three genes between 70 women presenting severe primary LPV and 132 healthy, ethnically matched controls. Each participating women have answered a detailed questionnaire, addressing possible familial occurrence of LPV and the existence of pain co-morbidity conditions. SNP analyses were performed for the genes Transient Receptor Potential Vanilloid type-1 (TRPV1), the Nerve Growth Factor (NGF) and the Heparanase (HPSE), using multiplex PCR and SNapShot assay and by restriction fragment length polymorphism. We found a significant difference in familial occurrences of LPV, Temporo mandibular joint (TMJ) symptoms, recurrent vaginitis and irritable bowel syndrome (IBS) between affected women and the healthy controls. Novel statistically significant differences in the prevalence of non-synonymous polymorphism c.945G>C (rs222747) of TRPV1 and a SNP located in the promoter region of NGF (rs11102930) were identified between the affected women especially from Ashkenazi Jewish ancestry and the control group. Data was also analyzed to compare genetic variation with a variety of pain condition among the 202 women. Interestingly, rs222747 minor allele of TRPV1 was found in association with women presenting TMJ and women with recurrent vaginitis, suggesting possible common genetic predisposition to pain co-morbidities. Our results imply possible genetic susceptibility to LPV associated with specific alleles in the genes TRPV1 and NGF, and propose a genetic predisposition for LPV and other pain syndromes through a yet unknown biological pathway involving TRPV1.

Predicting regions associated with complex traits using Multi-kernel Support Vector Machines. *D. Kostka[1], J.A. Capra[2].* 1) Developmental Biology and Computational & Systems, University of Pittsburgh, Pittsburgh, PA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) have identified thousands of genomic loci associated with hundreds of complex traits in different populations. However, these associations likely represent only a fraction of the loci contributing to the genetic basis of most complex traits. To aid the search for additional loci and improve our understanding of known associations, we developed an algorithm to distinguish genomic regions containing SNPs associated with a trait from regions associated with other traits and from the genomic background. For 59 traits with more than 40 unique associated SNPs in the NHGRI GWAS Catalog, we computed a tight linkage disequilibrium (LD) block (using appropriate 1000 Genomes populations) for each trait-associated SNP and then characterized these blocks' evolutionary histories, sequence motif patterns, and overlapping functional genomics data (from ENCODE and Roadmap Epigenomics). We then trained a multiple kernel support vector machine to distinguish regions associated with each trait from those associated with other traits and regions with no known associations. The algorithm obtains strong performance at distinguishing regions for many traits from regions with no associations (ROC AUCs above 0.8), and it performs significantly better than random for all but five traits. Our approach is also able to distinguish among regions associated with different traits; however, there is considerable variation in performance: a maximum ROC AUC of 0.78 for celiac disease and a minimum of 0.50 for adverse metabolic events. Using the trained classifiers for each trait, we predicted thousands of loci across the human genome that resemble known trait-associated regions (at a 5% FDR). The predicted regions for nearly all traits are enriched for nearby annotations and gene expression relevant to the trait. In addition, traits known to share common pathways overlap in their predicted regions more than less related traits. These genome-wide predictions can extend our knowledge of the genetic basis for complex traits. To illustrate this potential, we show how they can aid in prioritization of SNPs with low p-values that do not reach the genome-wide significance level. We also demonstrate the use of our predictions in developing hypotheses about the mechanisms behind these associations by identifying several hundred known enhancers and eQTLs that fall in novel predicted trait-associated regions.

973T

A search for genetic risk factors of age-related macular degeneration informed by the genetics of Alzheimer disease. *M.W. Logue[1,5], M. Schu[1], B.N. Vardarajan[1], J. Farrell[1], K.L. Lunetta[5], G. Jun[1], C.T. Baldwin[1], M. DeAngelis[6], L.A. Farrer[1,2,3,4,5].* 1) Biomedical Genetics, Boston Univ Sch Med, Boston, MA; 2) Dept of Neurology, Boston Univ Sch Med, Boston, MA; 3) Opthalmology, Bost Univ Sch Med, Boston, MA; 4) Epidemiology, Boston Univ Sch of Public Health. Boston, MA; 5) Biostatistics, Boston Univ Sch of Public Health, Boston MA; 6) Moran Eye Center, University of Utah, Salt Lake City, UT.

Background: Several lines of evidence point to overlapping molecular mechanisms between late-onset Alzheimer disease (AD) and age-related macular degeneration (AMD), including the molecular composition of the extra-cellular deposits which are the hallmarks of each, shared cardiovascular risk factors, and significant risk associated with *APOE* in both disorders. **Methods:** We evaluated summary statistics from large-scale genome-wide meta-analyses of AD (Naj et al. 2011) and AMD (Fritsche et al. 2013), treating the AD GWAS as a discovery dataset and the AMD dataset as a replication dataset to focus our search for genetic risk factors of AMD at the SNP, gene (significance based on peak SNP adjusted using the Li and Ji method), and pathway level. Results: First, we examined all SNPs associated with AD at a 10% false discovery rate (FDR) cutoff~excluding regions previously associated with AMD. None of the 226 SNPs tested for association with AMD were significant at the .05/226=.00022 level. Next, we examined all putative AD genes significant at a 10% FDR level (excluding the *APOE* region) for association with AMD. Two of 24 genes examined were significant (p<.05/24=.0021). The gene *PILRA* on chromosome 7q22 (FDR_{AD}=.057) was associated with AMD (p_{gene}=7.0E-6; peak SNP rs7792525, MAF=19%, OR=1.14, p=2.3E-6). Second, the known AD risk gene *ABCA7* (FDR_{AD}=.006) was also associated with AMD (p_{gene}=.0012, peak SNP rs3752228, MAF=5% OR=1.22, p=1.2E-4). The AMD-associated *ABCA7* SNP is not in LD with the previously identified AD risk variants rs3764650 and rs3752246 (r2<.01). Finally, we examined association of AMD with genes in the clathrin-mediated endocytosis signaling pathway (191 genes) and the atherosclerosis signaling pathway (132 genes), which emerged from an INGENUITY canonical pathway analysis of AD risk genes. Multiple genes in these pathways were significantly associated with AMD including several previously established AMD loci. Novel associations for AMD were observed with *HGS* (p_{gene}=7.5E-5, peak SNP rs8070488, MAF=23%, OR=.91, p=1.8E-5), which encodes a protein regulating endosomal sorting, and gene *TNF* (p_{gene}=1.2E-5, peak SNP rs2071590, MAF=34%, OR=.89, p=9.8E-7), a proinflammatory cytokine. LD in the regions around *TNF* and *PILRA* makes it impossible to localize the association to those genes specifically. Conclusions: We identified several novel modest-effect AMD risk variants in genes with a direct or peripheral role in AD pathogenesis.

974F

X-linked genes associated with cleft lip with or without palate in a family-based genome wide association study in Patagonia. *R.F. Fonseca[1], F.M. de Carvalho[1], F. Poletta[2,3], D. Montaner[4], J.C. Mereb[5], M.A.M. Moreira[6], H.N. Seuanez[6], A.R. Vieira[7], E.H. Castilla[8], I.M. Orioli[1].* 1) ECLAMC (Latin American Collaborative Study of Congenital Malformations) INAGEMP (National Institute of Populational Medical Genetics) at Department of Genetics, Institute of Biology, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil;; 2) ECLAMC (Latin American Collaborative Study of Congenital Malformations) at INAGEMP-CNPq (National Institute of Population Medical Genetics), Rio de Janeiro, Brazil;; 3) ECLAMC at Center for Medical Education and Clinical Research (CEMIC-CONICET), Buenos Aires, Argentina;; 4) Bioinformatic Department, Research Center Principe Felipe, Valencia, Spain;; 5) ECLAMC and INAGEMP at Hospital Zonal El Bolsón, El Bolsón, Argentina;; 6) Divisão de Genética, Instituto Nacional de Câncer, Rio de Janeiro, Brazil;; 7) Departments of Oral Biology and Pediatric Dentistry and Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh,; 8) ECLAMC and INAGEMP at Congenital Malformations Epidemiology Laboratory, Oswaldo Cruz Institute, FIOCRUZ, Rio de Janeiro, Brazil.

Cleft lip with or without palate (CL±P) are one of the most common birth defects, worldwide. Its birth prevalence ranges from 1/500 to 1/2000, depending on geographical origin, and ethnic background. The etiology of CL±P is complex and very heterogeneous with multiple genetic and environmental factors playing a role. The identification of genes that participate in the complex etiology of CL±P is an important step considering the morbidity that accompanies this relatively common birth defect. In this scenario, genome wide association studies are important tools in the search for candidates genes associated with complex diseases. Among the candidate genes described to be associated with CL±P some of them are on the X chromosome. Recently two genes (OFD and DMD) were associated with isolated CL±P in Asians and European populations. In this study we selected a CL±P high prevalence population from Patagonia identified by the ECLAMC and 99 individuals were until now ascertained and studied. SNPs from chromosome X were genotyping using the Affymetrix Plataform (Genome-Wide 6.0) and tested (TDT) for association with isolated CL±P in 24 trios, 2 duos, and 23 sibs using PLINK. We found statistical evidence of association with CL±P in 57 SNPs localized in six genes KAL 1 (06), DMD (04), SYN1 (02), CFP (02), TBL1X (01), TLR8 (01), uncharacterized region LOC100873065 (01) and intergenic regions (40) ($P \leq 0.008151$). To assess the role of these 57 SNPs on CL±P phenotype, we performed the haplotypes analysis with Haploview Software. Fourteen haplotypes under $P \leq 0.0068$ were identified whereas the most significant involves the following SNPS rs16988033-rs7055843-rs16997889, all of them in intergenic regions on locus Xp21.3 ($P= 0.0009$). The results for DMD and KAL1 genes are consistent with recent data about the involvement of these genes in the etiology of oral clefts while the other genes were described for the first time. In order to confirm the current association and also to improve our statistical power, it's advisable increase the number of trios affected by CL±P in further studies.

975W

Linkage analysis: genomic regions contributing to the expression of type 1 diabetes microvascular complications. *E.M. Lipner[1], Y. Tomer[2], J.A. Noble[3], M.C. Monti[4], J.T. Lonsdale[5], B. Corso[4], D.A. Greenberg[6].* 1) Department of Epidemiology, Columbia University, New York, NY; 2) Department of Medicine, Mount Sinai Medical Center, New York, New York; 3) Children's Hospital Oakland Research Institute, Oakland, CA; 4) Department of Public Health, Neurosciences, Experimental and Forensic Medicine, University of Pavia, Pavia, Italy; 5) National Disease Research Interchange, Philadelphia, PA; 6) Battelle Center for Mathematical Medicine, Nationwide Children's Hospital, Department of Pediatrics, Wexner Medical Center, Ohio State University, Columbus, Ohio.

We conducted a linkage analysis to identify susceptibility loci for microvascular complications of type 1 diabetes (T1D). We used 415 families from the Human Biological Data Interchange (HBDI) who were diagnosed with T1D before age 30. After finding significant HLA and non-HLA linkage peaks on chromosome 6, we restricted further analyses to that chromosome. Using 402 SNP markers, our analysis used the phenotypes of 1) any microvascular complication, 2) only retinopathy, 3) nephropathy alone, 4) neuropathy alone. When using 'any complication' as the phenotype, we identified two linkage peaks: one located at the HLA region (HLOD=2.90) and another, novel locus telomeric to HLA (HLOD=3.13). These same two peaks were also evident when retinopathy was the phenotype (HLODs of HLA region=2.69, telomeric locus=3.30). We did not find evidence for linkage for nephropathy alone or neuropathy alone We stratified on families whose probands were positive for DRB1*03:01 and DRB1*04:01 because previously published evidence suggest that DRB1 locus alleles affect complications expression. When using 'any complication' as the phenotype and including only DRB1*03:01-positive families, the HLA peak decreased (HLOD=1.82) from the unstratified analysis (HLOD=2.90), and a peak centromeric to HLA appeared (HLOD=1.27). When we stratified on DRB1*04:01-positive families, not only was there was no evidence of heterogeneity (LOD=HLOD) but the linkage evidence for HLA (HLOD=3.83) and the telomeric locus (HLOD=3.69) both went up, despite the drop in sample size with stratification. When using retinopathy as the phenotype, we observed the same increase in linkage peaks (HLOD at HLA region=3.62, telomeric locus=3.76). These observations suggest that DRB1*04:01 interacts with the telomeric locus to produce complications' susceptibility. Simultaneously, the drop in linkage evidence for the DRB1*03:01 confirms a protective effect seen in our previously reported association analysis (Lipner et al, 2013). Based on large differences in the linkage evidence, we argue that the DRB1*03:01-positive and DRB1*04:01-positive groups are genetically distinct, a finding in accordance with the observation that DRB1*03:01 is protective for retinopathy. The evidence also suggests there is an interaction between specific HLA alleles and a locus telomeric to HLA that influences the expression of some complications.

976T

Gene-environment interactions between obesity gene variants and body size in multiple sclerosis. *M.A. Gianfrancesco[1], B. Acuna[2], L. Shen[2], F.B.S. Briggs[1], H. Quach[1], A. Bernstein[3], A.K. Hedstrom[4], I. Kockum[5], L. Alfredsson[4,6], T. Olsson[5], C. Schaefer[2,7], L.F. Barcellos[1,2].* 1) School of Public Health, Dept of Epidemiology, UC Berkeley, Berkeley, CA; 2) Kaiser Permanente Division of Research, Oakland, CA; 3) Palm Drive Hospital, Sebastopol, CA; 4) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 5) Neuroimmunology Unit, Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden; 6) Centre for Occupational and Environmental Medicine, Stockholm County Council, Stockholm, Sweden; 7) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) is a demyelinating autoimmune disease affecting over 2.5 million people worldwide. Although studies have confirmed a strong genetic component for susceptibility, evidence for environmental risk factors, such as childhood and adolescent obesity, has also been reported. We investigated the relationship between early obesity and MS while controlling for effects of several established genetic and environmental risk factors. A gene-environment (GxE) investigation also assessed whether variation within established obesity genes, including APOA2, APOA5, FTO, MC4R, SCG3, TUB, and PCSK1, modifies the MS risk conferred by body size and body mass index (BMI) during various periods of life. Participants included female members of Kaiser Permanente Medical Care Plan, Northern California Region (985 MS cases, 10,000 controls). Common and rare variant data for each candidate gene were obtained for each individual through genome-wide association profiling and imputation. Being overweight at age 10 and 20 were associated with MS onset ($p<0.02$) after adjusting for age, smoking status, education, history of infectious mononucleosis, HLA-DRB1*15:01 and a weighted genetic risk score. Pooled analyses with a secondary dataset from a Swedish cohort indicated strong evidence for dose-effect of BMI at age 20 and MS (N= 1,364 cases and 1,639 controls) ($p=9.6\times10$-4). Results, thus far, show that of 1,212 SNPs across the fat mass and obesity-associated (FTO) gene (chr16q12.2), 7 SNPs were associated with MS risk ($p<0.05$: rs741300, rs9931900, rs2540772, rs8051873, rs7185735, rs2192869, rs708278). Inclusion of carrier status for the common FTO rs9939609 variant in the model did not modify the relationship between body size/BMI and MS at age 10. There was no evidence for interaction between FTO rs9939609 and body size/BMI at various ages. These findings convincingly show that childhood and adolescence obesity are associated with an increased risk of MS after controlling for known genetic and environmental risk factors, as well as obesity-related variants. Obesity is modifiable; therefore, these findings have large clinical and public health implications. Furthermore, MS risk conferred by obesity may be independent of predisposing genetic factors for obesity, suggesting that alternative mechanisms may mediate disease onset.

977F

Genetic linkage analysis using large consanguineous pedigrees from South India suggests new loci for ocular quantitative traits. *B. Fan[1], P. Ferdina Marie Sharmila[2], N. Soumittra[2], S. Sripriya[2], J. Madhavan[2], D.S. Friedman[3], L. Vijaya[4], J.L. Haines[5], R. George[4], J.L. Wiggs[1].* 1) Department of Ophthalmology, Harvard Med Sch, Massachusetts Eye & Ear Infirmary, Boston, MA; 2) Vision Research Foundation, Sankara Nethralaya, Chennai, India; 3) Johns Hopkins Medical School, Wilmer Eye Institute, Baltimore, MD; 4) Medical Research Foundation, Sankara Nethralaya, Chennai, India; 5) Center for Human Genetic Research, Vanderbilt University School of Medicine, Nashville, TN.

Many ocular quantitative traits are highly heritable. Mapping genes contributing to these quantitative traits may effectively identify genetic risk factors predisposing to related complex diseases, such as glaucoma. Compared to outbred pedigrees, consanguineous pedigrees are expected to have more power to identify quantitative trait alleles with additive or subtractive effects. Additionally, inbreeding due to social customs or geographic constraints may reduce genetic heterogeneity. In this study we performed genome-wide linkage analyses for selected ocular quantitative traits using 240 members of 16 consanguineous pedigrees from South India (Chennai). All study participants underwent a comprehensive ophthalmic examination for ocular quantitative traits including axial length (AXL), central corneal thickness (CCT), cup depth (CD) and vertical cup-disc ratio (VCDR). Genotyping was performed using the Illumina HumanOmni2.5-8 platform. Multipoint linkage analysis of 1,223,314 SNPs was performed using the variance components analysis in MERLIN (v1.1.2). All traits were adjusted for age and sex, and inverse-normal transformation of ranks was applied before analysis. Significant novel linkage signals were identified for AXL on 6q24.1-q24.2 (LOD_{max} = 3.45), CD on 12q24.31 (LOD_{max} = 3.92) and VCDR on 14q32.12 (LOD_{max} = 3.62). In addition, suggestive evidence of linkage was identified for CCT on 11q22.3-q23.2 (LOD_{max} = 2.37). Further evaluation of interesting candidate genes located within these linkage intervals is ongoing. This study shows that a relatively small number of consanguineous pedigrees can provide sufficient power to identify quantitative trait loci. Genome-Wide Family-Based Linkage Analysis of Coding Variants and Cardiometabolic Risk. *J.N. Hellwege[1,2,3], N.D. Palmer[2,3,4], L.M. Raffield[1,2,3], M.C.Y. Ng[2,3], G.A. Hawkins[2], J. Long[5], C. Lorenzo[6], J.M. Norris[7], J.I. Rotter[8], C.D. Langefeld[9], L.E. Wagenknecht[9], D.W. Bowden[2,3,4].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Division of Epidemiology, Department of Medicine, Vanderbilt Epidemiology Center, Vanderbilt University School of Medicine, Nashville, TN; 6) Department of Medicine, University of Texas Health Science Center, San Antonio, TX; 7) Department of Epidemiology, Colorado School of Public Health, University of Colorado Denver, Aurora, CO; 8) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, California; 9) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC.

In contrast to Mendelian disorders, family-based linkage analysis of complex traits has had limited success in identifying trait-influencing or disease loci. Recently, however, low frequency coding variants have been shown to be the basis for some biomedical associations. We tested the hypothesis that low frequency coding variants are the basis for linkage peaks identified in the analysis of complex traits from 42 African American (N=586) and 88 Hispanic (N=1270) families in the Insulin Resistance Atherosclerosis Family Study (IRASFS). DNAs were genotyped using the Illumina HumanExome Beadchip. A total of 92,157 variants in African Americans (~34%) and 81,559 (~31%) in Hispanics were polymorphic and passed quality control metrics, including Mendelian error checking. Family-based two-point linkage and conventional association analysis were performed using the Sequential Oligogenic Linkage Analysis Routines (SOLAR) program package. Two-point linkage analyses in families in each ethnic group were performed for 38 cardiometabolic phenotypes. Analyses yielded greater than 3 million LOD scores in each ethnic group. In African Americans, 1127 LOD scores greater than 2 and 77 greater than 3 were observed. The highest LOD score was 4.91 with the *APOE* SNP rs7412 (MAF=0.13) and plasma levels of apolipoprotein B (ApoB). In association analysis, rs7412, one of the SNP determinants of the ApoE ε2/3/4 isoforms, was also powerfully associated with ApoB (p-value= 4×10^{-19}). This *APOE* variant accounts for 16.2% of the variance in ApoB in African Americans. In Hispanic families, 1218 LOD scores were greater than 2 and 104 were greater than 3. Excluding a previously identified linkage peak on chromosome 3 for adiponectin, the strongest evidence of linkage (LOD=4.29) was with rs5882 (MAF=0.46) in *CETP* with HDL levels. Variants in and near *CETP* were strongly associated with HDL levels (p-values= $0.00049\text{-}4.6\times10^{-12}$) accounting for up to 4.5% of the variance in HDL. Both of these loci have previously been shown to have effects on the biomedical traits evaluated in this study. Thus, variants that contribute appreciably to the variance in a trait show evidence of sample-wide linkage. Analysis of individual families provides a powerful approach for identifying additional coding variants linked to complex traits in IRASFS.

979T

Genome-wide screen for self-reported physical disability loci in the oldest-old Amish. *J.E. Hicks[1], J.R. Gilbert[1], L. Caywood[1], L. Reinhart-Mercer[1], D. Fuzzell[2], R. Laux[2], M.A. Pericak-Vance[1], J.L. Haines[2], W.K. Scott[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University, Nashville TN.

As the population ages, age-related disability will increasingly become an important public health concern. However, many objective measures of aging differ from self-reported measures of impairment. To identify patterns of perceived disability in the oldest old, a latent class analysis was performed on four scales assessing perceived disability in 263 cognitively intact participants aged 80 or above. Participants were enrolled through a population-based door-to-door study of community-dwelling Amish individuals aged 65 and older from Indiana and Ohio. Individuals were placed into a 13-generation pedigree using the Anabaptist Genealogy Database. These individuals were assessed with the Activities of Daily Living scale (basic self-care tasks such as dressing and bathing), Instrumental Activities of Daily Living scale (higher-level tasks such as cooking and shopping), the Nagi scale for musculoskeletal function, and the Rosow-Breslau scale for lower-extremity function. Data analysis was performed with the poLCA package in R with age and sex included as covariates. The optimal model identified two classes. The first (n=209) was largely unimpaired on all disability questions, while the second class (n=54) reported some degree of physical disability. Random forest analysis of disability found that the strongest predictor of class was ability to perform heavy housework. A genome-wide screen was performed with Affymetrix Genome-Wide Human SNP Array 6.0. PLINK was used to select a set of 4,966 SNPs in linkage equilibrium (pairwise r2 < 0.16) for linkage analysis. PedCut created 11 subpedigrees suitable for linkage analysis, each containing at least 2 of the 54 physically impaired individuals. Multipoint nonparametric linkage analysis (LOD*) was performed in MERLIN and identified no regions of significant linkage to disability but did find two regions providing suggestive evidence of linkage on chromosomes 1 (LOD*=2.43, 18,922,283 Mb) and 3 (LOD*=2.28, 30,502,223 Mb). While tests of association in the 2-LOD-down support intervals (SI) surrounding these peaks did not identify markers significantly associated with disability after correction for multiple testing ($p<10^{-6}$), the strongest associations were at rs12071805 (p=0.000052) and rs1552391 (p=0.000029). The chromosome 3 SI contains rs11177, which has been previously associated with osteoarthritis (OA). These results suggest that multiple loci may influence disability in these older adults, possibly through OA.

980F

Linkage and association analysis of von Willebrand factor propeptide levels provides mechanistic insight into the genetic control of plasma von Willebrand factor levels. *K.C. Desch[1], A.B. Ozel[2], D. Siemieniak[4], J.Z. Li[2], D. Ginsburg[1,2,3,4].* 1) Pediatrics and Communicable Disease, University of Michigan, Ann Arbor, MI; 2) Human Genetics, University of Michigan, Ann Arbor, MI; 3) Internal Medicine, University of Michigan, Ann Arbor, MI; 4) Howard Hughes Medical Institute, Ann Arbor, MI.

von Willebrand Factor (VWF) is a plasma glycoprotein playing a central role in hemostasis. Common alleles at the ABO locus account for 24.5% of VWF variance and operate through altered VWF clearance rates. The VWF propeptide (VWFpp) is secreted into circulation with mature VWF where unlike VWF, it is rapidly cleared from circulation. Therefore plasma VWFpp levels are largely determined by the rate of synthesis/secretion of VWF. To gain mechanistic insight into genetic determinants of VWF levels, we performed linkage and genome-wide association studies (GWAS) of VWFpp in two healthy cohorts (combined n=3462) and compared the results to our previous analyses of VWF in these cohorts.(Desch et al., 2013) VWFpp levels were determined with monoclonal antibodies in an AlphaLISA assay. 800K SNPs, that were available after extensive QC in our previous study, were used in association studies (PLINK, EMMAX, METAL) and linkage analysis (MERLIN). Heritability (h2) of VWFpp was 74% compared to 65% for VWF. Our previous meta-analysis GWAS of VWF revealed signals at ABO (P=7.9E-139) and VWF (P=5.5E-16). Here, preliminary GWAS for VWFpp in one cohort revealed a single significant SNP rs1800378 (p-value= 8.94E-13) at 12p13, overlying the VWF gene itself. This SNP encodes a His484Arg variant in the VWF propeptide domain. However, interference of His484Arg with antigen detection was suggested after a repeat GWAS in this cohort using VWFpp levels determined with a different set of monoclonal antibodies was performed and did not reveal any significant SNPs at the VWF locus. Meta-analysis GWAS for VWFpp identified a signal in ABO (rs8176746, P=1.01E-12) suggesting that the plasma clearance of VWFpp, like VWF, is weakly altered by ABO glycosylation patterns. Previous linkage analysis of VWF identified a novel locus at 2p12-2q13 (19.2% variance explained) that was not detected by GWAS, strongly suggesting a high level of allelic heterogeneity. Here, linkage analysis for VWFpp did not reveal significant signals suggesting the 2p12-2q13 locus harbors variants affecting VWF clearance rates. In summary, we identify a common non-synonymous SNP in VWFpp domain resulting in a 'false positive' GWAS signal that may have important implications in the analysis of GWAS data for other antibody based quantitative traits. Futhermore, by examining VWFpp, a marker of VWF synthesis/secretion rates, we provide mechanistic insight into a previously identified linkage signal for VWF.

981W

Genetic variants on 17q23.2 and 10q11.21 are associated with variation in telomere length: The Long Life Family Study. *J.H. Lee[1,3], R. Cheng[1], L.S. Honig[1,2], M. Feitosa[4], C. Kammerer[6], M.S. Kang[1], N. Schupf[1,3], R. Lin[4], J.L. Sanders[6], H. Bae[7], T. Druley[5], T. Perls[7], K. Christensen[8], M. Province[4], R. Mayeux[1,2,3].* 1) Sergievsky Ctr/Taub Inst, Columbia Univ, New York, NY; 2) Depts of Neurology and Psychiatry, Columbia University, New York, NY; 3) Dept of Epidemiology, Columbia University, New York, NY; 4) Div of Statistical Genomics, Depr of Genetics, Washington University, St. Louis, MO; 5) Dept of Pediatrics & Genetics, Washington University, St. Louis, MO; 6) Dept of Epidemiology & Center for Aging and Population Health, University of Pittsburgh, Pittsburgh, PA; 7) Div of Geriatrics, Dept of Medicine, Boston University Medical Center, Boston, MA; 8) The Danish Aging Research Center, Epidemiology, University of Southern Denmark, Odense, Denmark.

Telomere length is hypothesized to measure cellular aging in humans, and short telomere length is associated with increased risks of late onset diseases, including cardiovascular disease, dementia, cancer, and other age-related disorders. Many studies have shown that telomere length is a heritable trait, and several candidate genes have been identified, including *TERT, TERC, OBF1*, and *CTC1*. Most studies have focused on genetic causes of chronic diseases such as heart disease and diabetes in relation to telomere length. This investigation involved a genome wide family-based association analyses that identified genetic variants that contribute to variation in telomere length among families with exceptional longevity. From the genome wide association analysis in 4,289 LLFS participants, we identified a novel intergenic SNP rs7680468 near *PAPSS1* on 4q24 (p=4.7E-8). From our linkage analysis, we identified two additional loci with HLOD scores>3, including one at 17q23.2 (HLOD=4.77) and another at 10q11.21 (HLOD= 4.36). Subsequent gene-wise association analysis identified multiple candidate genes from these two regions, including *DCAF7, POLG2, CEP95*, and *SMURF2* at 17q23.2; and *RASGEF1A, HNRNPF, ANF487, CSTF2T,* and *PRKG1* at 10q11.21. Among these genes, we identified one contiguous haplotype in *CEP95* and *SMURF2* that was significantly associated with telomere length. In addition, previously reported genes - *TERC, ARPM1, MYNN, OBFC1*, and *ZNF729* - showed weak to modest association with telomere length variation. Here we report novel genetic variants and confirm previously reported genes that are associated with variation in telomere length. These may reveal additional insight into cellular aging.

982T

Combined genome-wide linkage and association studies of centenarians identifies several new candidate genes for longevity. *P. Sebastiani[1], H. Bae[1], T.T. Perls[2].* 1) Dept Biostatistics, Boston Univ Sch Public Health, Boston, MA; 2) Dept Medicine, Boston University School of Medicine, and Boston Medical Center, Boston MA.

The genetic basis of extreme longevity increases as more extreme lifespans are examined. However, genome-wide association studies (GWAS) of longevity have failed to discover highly significant variants. Several studies have confirmed a role of APOE in lifespan and rs2075650 in TOMM40/APOE is the only single nucleotide polymorphisms(SNP) that reached genome-wide significance in several GWAS of nonagenarians and centenarians. In a GWAS of 801 centenarians (median age at death 104 years) versus population controls, we showed that a set of 281 SNPs that did not reach genome-wide significance could accurately distinguish centenarians from controls, with increasing sensitivity in older and older people. SNPs that failed to reach genome-wide significance but showed consistent effects in different studies have also been published. These findings suggest that the genetic makeup of exceptional longevity is determined by a combination of common and rare variants with modest genetic effects, and that the relatively small sample size of centenarian studies is a serious limitation to their discovery power. We hypothesized that linkage analysis could be used to prioritize variants that reached statistical significance in association studies but failed to reach genome-wide significance. We conducted a non parametric linkage analysis of affected sib-pairs enrolled in 172 families of the New England Centenarian Study (NECS) enrolled between 1995 and 2010. Affected pairs were defined as two siblings with age at death exceeding a fixed percentile survival from sex and birth year matched life table from the US Social Security Administration. Percentile survivals π between 0.25 and 0.001 were used to derive nested sets of sib-pairs that were analyzed in Merlin. Regions in chromosomes 2, 3, 4, 7, 10 and 19 had linkage peaks with LOD score >2.4 for at least one threshold π, or LOD score >2 for more than one threshold π and 1.5LOD support intervals were annotated by significant results from two GWAS of longevity in NECS centenarians. The region under the linkage peak in chromosome 10 includes ADARB2 that we found previously associated with extreme longevity. The region in chromosome 2 includes SNPs in MYTL1 and its regulatory region that is enriched of SNPs associated with insulin resistance, insulin variability and diabetes complications. Three regions in chromosome 19 point to additional genes that are associated with extreme longevity independent of APOE.

983F

Analyzing patterns of IBD sharing in Oceanic Palau to identify genomic regions harboring risk for schizophrenia. *C.A. Bodea[1], F. Middleton[2], L. Klei[3], S.V. Faraone[2], S. Vinogradov[4], J. Tiobech[5], V. Yano[5], S. Kuartei[5], K. Roeder[1], N. Melhem[3], B. Devlin[3], M. Myles-Worsley[2], W. Byerley[4].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Psychiatry, SUNY Upstate Medical University, Syracuse NY; 3) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Department of Psychiatry, University of California San Francisco, Pittsburgh, PA; 5) Palauan Ministry of Health, Republic of Palau, Pittsburgh, PA.

The genetics of schizophrenia is complex and, despite recent successes, it remains challenging to identify individual risk loci. We have been studying the genetics of schizophrenia in Oceanic Palau, an island nation some 500 miles east of the Phillipines. One of the features we have been analyzing is the co-segregation pattern of genetic variation and schizophrenia status to identify regions of the genome shared identical-by-descent (IBD) among related, affected individuals. These IBD segments are shared as haplotypes and we search for inherited haplotypes that increase the risk of developing schizophrenia. A challenge in this small and until recent-generations isolated Oceanic population is that pedigrees are large and even those subjects who do not fall in the same close-knit pedigree are often found to be genetically related to some degree. Motivated by this observation we build a statistical test that can be applied to large pedigrees whose structure need not be known, one that evaluates the association between the extent of IBD sharing within specific genomic regions and the presence of schizophrenia. We first estimate a matrix of pairwise relatedness between subjects by measuring IBD sharing over the entire genome using Germline. This results in a matrix with genetic estimates of kinship amongst all pairs of subjects in the study, but the matrix is noisy. Applying a recently developed algorithm to the kinship matrix -- treelet covariance smoothing -- we reduce the noise by using the information inherent in clusters of individuals with estimated positive kinship coefficients. To form a test, we apply a kernel-based approach that compares local IBD sharing between cases and controls, while controlling for estimated relatedness. Within a given region, every pair of subjects is characterized by the segment-length inherited from a common ancestor (IBD). The statistic seeks to identify regions of the genome where the amount of IBD sharing amongst cases and/or amongst controls is greater than the sharing between cases and controls, because these regions have the potential to harbor mutations that are associated with schizophrenia. Our approach identifies regions of the genome as potentially harboring risk variants and some of those loci harbor known schizophrenia-associated genes, suggesting the results are likely to be meaningful. We continue to explore these data to identify variants affecting risk for schizophrenia.

984W

Cumulative genetic load for known multiple sclerosis risk variants in Sardinia. *A. Hadjixenofontos[1], L. Foco[2], P-A. Gourraud[3], A. Tikka[5], P. Bitti[6], R. Pastorino[2], L. Bernardinelli[2,4], J.L. McCauley[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Public Health, Neurosciences, Experimental and Forensic Medicine, Medical Statistics and Epidemiology Unit, University of Pavia27100 Pavia, Italy; 3) Department of Neurology, School of Medicine, University of California at San Francisco, San Francisco, CA, USA; 4) Statistical Laboratory, Centre for Mathematical Sciences, Wilberforce Road, Cambridge CB3 0WA, UK; 5) Divisione di Neurologia, Ospedale S. Francesco, Nuoro, Italy; 6) Immunohaematology and Blood Transfusion Department, Ospedale S. Francesco, Nuoro, Italy.

Multiple Sclerosis (MS) is an autoimmune, demyelinating disease for which the prevalence rates follow a latitude gradient with the lowest prevalence in countries closest to the equator. Sardinia, in Insular Italy, is an exception to this trend with unenviable prevalence rates that range between 150 and 200 per 100,000 individuals. The geographical isolation of Sardinia presents a valuable opportunity to study a relatively homogeneous population, for which the underlying genetic load is not known. Recent collaborative investigations by the International Multiple Sclerosis Genetics Consortium (IMSGC) have increased the list of MS risk variants to 113 tag SNPs. We use these variants in the calculation of a MS genetic risk score with the goal of assessing the extent to which NE derived variants allow differentiation between Sardinian MS cases and controls. The genotyping data on our dataset of 16 Sardinian families and 94 unrelated Sardinian controls originated from a custom Illumina genotyping chip dubbed the 'Immunochip'. Using Generalized Estimating Equations (GEE) to correct for correlations between relatives, we built a logistic regression model with disease status as the outcome, and the MS risk score, and sex as the predictors. An increase in the NE derived MS risk score was associated with MS case status in our preliminary analysis of 70 Sardinian cases and 244 Sardinian unaffected family members and population controls (OR=1.68, 95% CI=1.33-2.11, P<0.001). This is in contrast to our previous results with a version of the MS risk score that included fewer tag SNPs and which was not associated with affection status. No differences in the MS risk score were detected between MS patients from Sardinian vs. Caucasian population (OR=1.11, 95% CI=0.81-1.58, P= 0.55). In light of our latest results a more extensive analysis is currently underway. These will seek to capitalize on the relatedness in the sample by examining whether variants in the known regions are shared identical by descent (IBD) in cases from each family, and additionally will include information on rare variants from exome sequencing data which may be present in the known regions.

985T

Interaction between Adiponectin and Adiponectin Receptor 1 is Associated with Age-related Hearing Impairment. *C. Wu[1,2], C. Tsai[3], J. Hwang[4], Y. Lu[1,5], Y. Lin[1,6], P. Chen[7], W. Yang[2,7], W. Liao[8], Y. Lee[3,9], T. Liu[1], C. Hsu[1].* 1) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 4) Department of Otolaryngology, Buddhist Dalin Tzu-Chi General Hospital, Chiayi, Taiwan; 5) Institute of Biomedical Engineering, National Taiwan University, Taipei, Taiwan; 6) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 7) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 8) Health Management Center, National Taiwan University Hospital, Taipei, Taiwan; 9) Research Center for Genes, Environment and Human Health, College of Public Health, National Taiwan University, Taipei, Taiwan.

Age-related hearing impairment (ARHI) is a complex disease caused by an interaction between environmental and genetic factors. Recently, several studies confirmed obesity as an independent risk factor for ARHI. In our previous study investigating the underlying mechanisms, we demonstrated that plasma adiponectin might protect peripheral hearing function (Clin Endocrinol. 2011). It has been revealed that polymorphisms of the adiponectin gene, ADIPOQ, might affect plama adiponectin levels; and polymorphisms of both ADIPOQ and its type 1 receptor gene, ADIPOR1, have been related to obesity-related morbidities. Hence, we postulated that genotypes of ADIPOQ and ADIPOR1 might be associated with the development of ARHI. A total of 1682 volunteers (Han Chinese, aged 40 to 80 y) were included in the clinical analyses, and their audiological phenotypes were determined according to the Z scores converted from their original frequency-specific hearing thresholds. By using the database of Chinese Han haplotypes in International HapMap Project and NIEHS, followed by analyses with the Haploview software, 9 tagSNPs and 4 tagSNPs in ADIPOQ and ADIPOR1, respectively, were selected for genotyping. The genotypes were then correlated to the audiological phenotypes under the assumption of various inheritance models. Significant association was identified between certain ADIPOQ tagSNPs and Z scores under dominant, co-dominant, or additive models; whereas no association was identified between the ADIPOR1 tagSNPs and Z scores. Of note, the association between specific ADIPOQ tagSNPs and Z scores appeared to exist in subjects with specific ADIPOR1 genotypes only, indicating a gene-gene interaction between ADIPOQ and ADIPOR1. These findings were then validated on haplotype analyses. Further measurement of plasma adiponectin level in 736 subjects revealed ADIPOQ genotypes might exert their effects on hearing levels through modulating the plasma adiponectin levels. In conclusion, the ADIPOQ genotypes were associated with ARHI, and might exert effects on hearing levels through modulating the plasma adiponectin levels. In contrast, although the ADIPOR1 genotypes were not directly associated with ARHI, the association between ADIPOQ and hearing thresholds were influenced by the ADIPOR1 genotypes. In other words, the development of ARHI might result from an interaction between adiponectin and type 1 adiponectin receptor.

986F

On the use of cis-eQTL analyses to identify novel associations between *OPRM1* polymorphisms and heroin abuse.
D.B. Hancock[1], J.L. Levy[1], N.L. Saccone[2], N.C. Gaddis[1], L.J. Bierut[2], G.P. Page[3], E.O. Johnson[1]. 1) RTI International, Research Triangle Park, NC; 2) Washington University in St. Louis, St. Louis, MO; 3) RTI International, Atlanta, GA.

The *OPRM1* (opioid receptor, mu 1) gene has long been suspected to influence risk of heroin abuse. The 118A>G polymorphism, in particular, has been widely studied for its association with heroin and other addictions and its functional consequences, but the evidence for association is inconsistent. To identify other polymorphisms that may regulate *OPRM1* and in turn influence risk of heroin abuse, we evaluated single nucleotide polymorphism (SNP) associations with *OPRM1* expression to nominate cis-expression quantitative trait loci (cis-eQTL) in the human brain and subsequently tested the nominated SNPs for association with the heroin abuse phenotype. For the cis-eQTL analyses, we utilized SNP genotypes (Illumina Human1M-Duo or HumanHap650Y) and gene expression data from prefrontal cortex samples of normal human subjects in the publically available BrainCloud. Our cis-eQTL analyses used 112 African American and 109 Caucasian subjects from infancy through adulthood (ranging in age from <1 to 78 years old). In each ancestral group, 103 SNPs located within 100kb of *OPRM1* were tested for association with *OPRM1* expression level using linear models that accounted for sex and age within developmental stage (childhood vs. adulthood). Of the 103 SNPs, 14 were nominated as cis-eQTLs based on their association with *OPRM1* expression (P<0.05) in either ancestral group. The 14 SNPs were then tested for association with heroin abuse using cases from the Urban Health Study and public controls (total N=7,095 African Americans and 3,824 Caucasians), who were genotyped on Illumina arrays and imputed using IMPUTE2 with reference to the 1000 Genomes ALL haplotype panel. In each ancestral group, SNP associations with heroin abuse were tested using logistic models accounting for sex and 3 ancestry-specific eigenvectors. Convergence of the SNP association results revealed that 4 of the nominated cis-eQTLs (P ranging from 0.015 to 0.046) were also associated with heroin abuse (P ranging from 6.17×10^{-5} to 3.85×10^{-3} in a meta-analysis combining the ancestry-specific results). The 4 newly identified regulatory SNPs had minor allele frequencies between 16% and 38% and consistent directions of association with heroin abuse across the ancestral groups. Our findings offer new insights into the role that *OPRM1* may play in developing heroin abuse. Further studies are needed to confirm the observed SNP associations in other data sets and to elucidate their mechanisms.

Evidence for a polygenic contribution to androgenetic alopecia.
S. Heilmann[1,2], F.F. Brockschmidt[1,2], A.M. Hillmer[3], S. Hanneken[4], S. Eigelshoven[5], K.U. Ludwig[1,2], C. Herold[6], E. Mangold[1], T. Becker[6,7], R. Kruse[8], M. Knapp[7], M.M. Nöthen[1,2]. 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life & Brain Centre, University of Bonn, Bonn, Germany; 3) Genome Technology and Biology, Genome Institute of Singapore, Singapore, Singapore; 4) Department of Dermatology, University of Düsseldorf, Düsseldorf, Germany; 5) Private Dermatology Practice, Solingen, Germany; 6) German Centre for Neurodegenerative Diseases (DZNE), Bonn, Germany; 7) Institute of Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany; 8) Private Dermatology Practice, Paderborn, Germany.

Male pattern baldness (androgenetic alopecia, AGA) is a highly heritable trait and the most common form of hair loss in humans. Genome-wide association studies (GWASs) including a meta-analysis and large-scale replication study have identified twelve genome-wide significant risk loci for AGA, which explain a major proportion of the genetic risk for AGA. However, the efficiency of contemporary GWASs for detecting disease associations is restricted by the burden of multiple testing due to the large numbers of single nucleotide polymorphisms (SNPs) considered in these analyses. Thus, only highly significant individual disease associations ($P<5\times10^{-8}$) can be detected. It is therefore likely, that additional genetic risk factors with smaller individual effect sizes still await identification. Their sensitivity for detecting individual disease associations is limited but GWAS datasets can be used to analyze whether there is a collective contribution (polygenic contribution) of common SNPs that show disease association above the *P*-value threshold for genome-wide significance ($P>5\times10^{-8}$). Irrespective of their small individual effect sizes, these loci might jointly explain a significant proportion of the overall genetic risk for AGA. Polygenic score analysis is a method for determining this collective contribution. This study used a German case-control sample for AGA, which comprised 581 severely affected patients and 617 controls, to determine the contribution of polygenic variance to genetic risk for AGA. The sample was divided evenly into discovery and test samples. An additive polygenic risk score was calculated from risk alleles with increasingly liberal *P*-values in the discovery dataset, which was then used to test for the enrichment of AGA risk score alleles in the independent test samples. The analysis provided significant evidence for the specific contribution of a polygenic component to AGA where the amount of variance explained was 1.4-4.5%. It is likely that the contribution of a polygenic component and the large number of genes involved reflect the complexity of the AGA associated biological pathways. Further studies are required to progress from evidence for a polygenic contribution to understanding the specific genetic factors that comprise this polygenic component.

Integrated eQTL and Genetic Association Analysis in Smokers with COPD Identifies Disease-Associated eQTL Loci.

P.J. Castaldi[1], M.H. Cho[1,2], W. Qiu[1], B.R. Celli[2], J.H. Riley[3], S.M. Fox[3], D. Singh[4], R. Tal-Singer[5], B.A. Raby[1,2], V.J. Carey[1], E.K. Silverman[1,2], C.P. Hersh[1,2], ECLIPSE Investigators. 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA, USA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 3) GlaxoSmithKline, Uxbridge, UK; 4) Medicines Evaluation Unit, University of Manchester, Manchester, UK; 5) GlaxoSmithKline, King of Prussia, PA, USA.

Background: Recent GWAS have identified novel loci associated with chronic obstructive pulmonary disease (COPD). Two of these loci have been shown to be associated with the expression level of nearby genes. We hypothesized that integrating eQTL and GWAS results from subjects with COPD would allow for the identification of novel COPD-associated loci, and that cis and trans eQTL analysis could characterize transcriptional networks of disease-relevant genes. **Methods:** Gene expression profiles from whole blood and induced sputum samples were generated for 121 subjects with COPD from the ECLIPSE study using the Affymetrix HG-U133 Plus 2.0 GeneChip. Genome-wide identification of cis eQTLs was performed using a cis window of 500kb. Multiple comparison adjustment was performed by controlling the false discovery rate at 10%. eQTL SNPs were tested for association with COPD susceptibility in a meta-analysis of 4 COPD case-control studies (NETT/NAS, ECLIPSE, GenKOLS, COPDGene). Targeted trans-eQTL analysis was performed for significant cis eQTL SNPs that were also associated with COPD. **Results:** Cis eQTL analysis in subjects with COPD identified 42,020 SNPs associated with expression of 7,223 unique genes in whole blood and 18,474 SNPs associated with 4,474 genes in sputum samples. Cis eQTL SNPs were significantly enriched in the top GWAS results (p<0.001 from both sources of expression data). When these SNPs were tested for association with COPD, SNPs associated with expression of 10 unique genes were also associated with COPD susceptibility (9 genes from blood, 2 genes from sputum with one gene present in both). All previously identified COPD GWAS loci harbored a significant cis eQTL. Trans eQTL analysis of these SNPs identified two SNPs associated with the expression of distal genes. rs1828591 was associated in cis with HHIP (q value = 0.09) and in trans with RTN4RL1 (q value = 0.03). rs8034191 was associated in cis with CHRNA3 and IREB2 (q value = 0.0001 and 0.002) and in trans with SLC35E3, GALE, and SLC22A7 (q value = 0.08 for all three genes). **Conclusions:** Using a gene-based eQTL approach in blood and sputum, we identified ten SNP-gene functional units associated with COPD. Some previously described COPD loci are eQTL for more than one gene, and trans eQTL analysis identified that cis eQTL SNP for HHIP and IREB2 are also associated with regulation of genes in trans. Funding: K08HL102265, K08 HL097029, P01 HL105339, R01HL094635, R01NR013377, NCT00292552.

989F

Using an integrative mapping approach to identifiy novel genetic factors contributing to pulmonary arterial hypertension (PAH).

W.C. Nichols[1,5], M.W. Pauciulo[1], D. Koller[2], C. Tolentino[1], T.D. Le Cras[3,5], P. Pastura[3], B. Aronow[4,5], D. Li[2], T. Foroud[2]. 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Medical and Molecular Genetics, Indiana University Medical Center, Indianapolis, IN; 3) Division of Pulmonary Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH.

While mutations in 5 genes have been identified in patients with PAH, data suggest that additional genetic factors contribute. Lacking the necessary large patient cohorts to power genomewide studies, we are using an integrative mapping approach in mice to identify other genetic factors. Mice from 33 strains as well as F_2 animals from 2 parental crosses were housed in hypoxic conditions (10% O2) for 4 weeks. After hypoxia, mice underwent right heart catheterization to measure right ventricular systolic pressure (RVSP). Hearts were dissected to assess the degree of RV hypertrophy. Total RNA was extracted from left lung (LL) and RV of 51 selected animals. Haplotype association mapping (HAM) was performed to identify regions associated with the quantitative traits measured. QTL analysis was performed after genotyping 668 F_2 animals from 2 crosses: PL/J X MRL/MpJ (PM model) and PL/J X FVB/NJ (PF model) using the MUGA panel of 7,851 SNPs. RNASeq was performed using the LL and RV total RNA. A LOD >15 was obtained on chromosome 17 (F_2 threshold LOD = 3.8) for the PM model that accounts for 17% of the total variation in RVSP. There is no convergence of results between the HAM and QTL analyses on this chromosome. The PF model demonstrated no evidence of a QTL for RVSP on chromosome 17. Also, a significant RVSP QTL was identified on chromosome 11 (LOD 5.8) for the PM model. This region on chromosome 11 was identified in the HAM analysis as an association with increases in RVSP after hypoxia. For the PF model, several regions had LOD scores for RVSP above the F_2 threshold LOD (chromosomes 1, 4, 9, and 16). The most significant, LOD of ~7.0, occurred on chromosome 9. HAM analysis of this region approached, but did not reach, the HAM threshold LOD of 5.1. Any overlap between the HAM and QTL analyses for RVSP in the PF model is under investigation. Preliminary RNASeq analyses identified expression differences for 3,232 genes between the high responder PL/J strain and the low responder MRL/MpJ and FVB/NJ strains. Analysis of PL/J at 4 different hypoxia time points identified 1,467 differentially expressed genes clustered into 5 groups with different expression patterns. These different expression patterns can be used to identify genes contributing to PAH when integrated with the HAM and QTL analyses. Identification of additional PAH genes can ideally reveal novel pathways involved in disease pathogenesis that will lead to the development of new patient treatments.

Historically, tests of association between HLA and disease have been conducted with the 'classical' HLA alleles; i.e., polymorphisms that encode differential ability of HLA molecules to bind and present antigens. Association of PD with HLA, however, was discovered in a hypothesis-free GWAS and replicated using SNP-based studies. The original SNP that reached genome-wide significance, rs3129882, is in intron 1 of DRA and the others map to intergenic sequences near DRA, DRB1 and DRB5. Our aim was to determine if these SNPs are tagging specific HLA alleles. We HLA-typed 2000 PD cases and 1986 controls that were used in the original GWAS (PMID:20711177), and 843 cases and 856 controls (phs000126.v1.p1) for replication using two SNP-based imputation algorithms (de Bakker PMID:21051598 and HLA*IMP:02). We also sequenced 194 cases and 204 controls using 454-next-generation-sequencing, and calculated allele-specific sensitivity and specificity for each algorithm. For association studies we used the imputed data to increase sample size, mindful of allele-specific imputation accuracy. We tested association of HLA alleles and haplotypes with PD, and replicated alleles that passed P<0.05 (set low to minimize false negatives). We then conducted conditional and stratified analyses to test interdependence of the classical variants identified here and the SNPs identified before. PD risk was associated positively with B*07:02_C*07:02_DRB5*01_DRB1*15:01_DQA1*01:02_DQB1*06:02 and negatively with B*40:01_C*03:04_DRB4*01_DRB1*04:04_DQA1*03:01_DQB1*03:02 alleles and haplotypes. However, when conditioned on the SNPs, the signals for the risk variants were abolished, but the ones for the protective variants remained nominally significant (Pconditioned≥1E-4). The SNPs, on the other hand, stayed strongly significant when conditioned on classical variants (Pconditioned≥3E-10). With in-silico studies (SCAN, eqtlBrowser, Genevar), we found that PD-associated SNPs rs3129882 (original GWAS PMID:20711177), rs2395163 (US_Meta analysis PMID:22451204) and rs660895 (French study PMID:22807207) are eQTLs for HLA-DR and HLA-DQ (4E-5≥PeQTL≥2E-79). In summary: Classical HLA-alleles do not explain association of PD with non-coding SNPs. The SNPs are likely eQTLs. Whether the protective factor that is embedded in the protective haplotype is a classical variant affecting antigen binding or a regulatory element affecting gene expression levels is unknown.

Identification of candidate psoriasis susceptibility alleles within an HLA-C enhancer element. *R.C. Trembath[1,2], A. Clop[2], A. Bertoni[2], S.L. Spain[2], M.A. Simpson[2], V. Pullabhatla[2], R. Tonda[3], C. Hundhausen[2], P. Di Meglio[2], P. De Jong[4], A. Hayday[5], F.O. Nestle[2], J.N. Barker[2], R.J.A. Bell[6], F. Capon[2].* 1) Barts and the London School of Medicine and Dentistry, Queen Mary University of London, London E1 2AD, United Kingdom; 2) Division of Genetics and Molecular Medicine, King's College London, London SE1 9RT, UK; 3) Centre for Research in Agricultural Genomics (CRAG), Campus Universitat Autònoma de Barcelona, 08193 Cerdanyola del Valles, Spain; 4) BACPAC Resources Centre, Children's Hospital Oakland, Oakland, CA 94609, USA; 5) Division of Immunology, Infection & Inflammatory Diseases, King's College London, London SE1 9RT, UK; 6) Department of Neurosurgery, Helen Diller Family Comprehensive Cancer Center, University of California San Francisco, San Francisco, CA 94115, USA.

Psoriasis is a common inflammatory skin disorder that is inherited as a complex genetic trait. Although genome-wide association scans (GWAS) have uncovered more than 30 disease susceptibility regions, up to 50% of the genetic variance is accounted for by single Major Histocompatibility Complex (MHC) locus, known as *PSORS1*. *HLA-C* is widely regarded as the strongest *PSORS1* candidate gene, since markers tagging *HLA-Cw*0602* consistently generate the most significant association signals in GWAS. However, the question as to whether *HLA-Cw*0602* is the causal *PSORS1* allele has not been resolved, especially as the role of SNPs that may affect its expression has not been investigated. Here, we have undertaken a comprehensive molecular characterization of the *PSORS1* region, with the aim of identifying regulatory variants that may contribute to psoriasis susceptibility. We first analysed high-density SNP data and refined the *PSORS1* locus to a 179kb region encompassing *HLA-C* and the neighbouring *HCG27* pseudogene. Next, we compared multiple MHC sequences spanning the 179kb critical interval and catalogued 144 candidate susceptibility variants, which were unique to Cw*0602-bearing chromosomes. In parallel, we determined the epigenetic profile of the critical *PSORS1* interval, uncovering three enhancer elements likely to be active in T lymphocytes. Finally, we showed that nine candidate susceptibility SNPs map within a *HLA-C* enhancer and that three co-localise with binding sites for immune-related transcriptional activators. These data indicate that SNPs affecting the expression of *HLA-Cw*0602* are likely to contribute to psoriasis susceptibility and highlight the importance of integrating multiple experimental approaches in the genetic analysis of complex genomic regions such as the MHC.

Joint eQTL Analysis in Multiple Tissues, Accounting for Heterogeneity and Incomplete Subject Overlap. *G. Li[1], A.A. Shabalin[2], I. Rusyn[3], F.A. Wright[4], A.B. Nobel[1,4].* 1) Statistics and Operations Research, Univ North Carolina, Chapel Hill, NC., Select a Country; 2) Department of Pharmacotherapy & Outcomes Science, Virginia Commonwealth University; 3) Department of Environmental Sciences and Engineering, University of North Carolina; 4) Department of Biostatistics, University of North Carolina.

The analysis of expression quantitative trait loci (eQTL) aims to identify genetic variants that regulate gene transcription, and help dissect complex transcriptional-based mechanisms of disease. Patterns of transcriptional variation are highly tissue-specific, and identifying common and specific eQTLs among various tissues is of great interest. However, most existing methodologies for multiple-tissue eQTL analysis are based on post-hoc analysis of eQTL from individual tissues, and therefore do not fully utilize the data structure of eQTL datasets consisting of multiple tissues. We propose a hierarchical model for the observed correlations of gene-SNP pairs across the available K tissues in a multi-tissue experiment, with a full specification of all 2^K possible patterns of null vs. alternative outcomes across the K tissues. The model allows for incomplete overlap of subjects across the tissues by fitting a flexible correlation structure for genotype-expression associations. The model is fit using an empirical Bayes approach, and provides interpretable posterior probabilities for eQTLs across the range of tissues, as well as control of the local FDR. Simulations demonstrate the approach is stable and computationally feasible for numerous tissues. We further illustrate using RNA-Seq expression data on 9 tissues and genotypes on 3.4 million SNPs, available in pilot form from the Genotyping-Tissue Expression project (GTEx) Consortium, with sample sizes per tissue ranging from 80-200.

Role of common genetic polymorphisms in transgenerational inheritance of inherent as well as acquired traits in budding yeast. *Z. Zhu, Q. Lu, D. Yuan, Y. Li, X. Man, Y. Zhu, S. Huang.* Central South University, Changsha, China.

Both inherent and acquired traits can be transmitted through multiple generations with some traits more stable than others. But the relationship between the stability of such transgenerational inheritance and the genetic variations in an individual or cell has yet to be explored. We studied the effect of genetic polymorphisms on transgenerational inheritance of yeast segregants that were derived from a cross between a laboratory strain and a wild strain of Saccharomyces cerevisiae. For each of 2835 SNPs analyzed, the parental allele present in less than half of the 124 segregants panel was called the minor allele (MA). We found a nonrandom distribution of MAs in the segregants, indicating natural selection, as segregants with high MA content or amount (MAC) were not enriched with MAs from the parental strain that contributed significantly more to the whole set of MAs. We compared segregants with high MAC relative to those with less and found a more dramatic shortening of the lag phase length for the high MAC group in response to 14 days of ethanol training. Also, the short lag phase as acquired and epigenetically memorized by ethanol training was more dramatically lost after 7 days of recovery in ethanol free medium for the high MAC group. Sodium chloride treatment produced similar observations. Using public datasets, we found MAC linkage to mRNA expression of hundreds of genes. Finally, by analyzing a recently published datasets of 1009 yeast segregants that identified numerous additive QTLs for 46 traits, we found by multivariate regression analysis preferential MAC linkage to traits with high number of known additive QTLs (average 16 for the 5 MAC-linked traits vs 12 for the whole set of 46 traits), suggesting that MAC may affect traits via the additive effects of a large number of minor effect SNPs and may thereby account for the 'missing heritability' in most complex traits. These results provide evidence for the slightly deleterious nature of most MAs and a lower capacity to maintain inheritance of traits in individuals or cells with greater MAC, which have implications for disease prevention and treatment. Individuals with high MAC may be more susceptible to environmental pathogens, but they may also be more treatable if treatment was administered relatively early before the disease has progressed past the threshold of no return, because the acquired disease trait may be less stably maintained in these individuals.

994T

Evidence for a genetic contribution to rotator cuff disease in a new population genealogy at the Veterans Administration. *C.C. Teerlink[1], J.M. Farnham[1], L.J. Meyer[2,3], L.A. Cannon-Albright[1,2].* 1) Dept Internal Medicine, Univ Utah Sch Med, Salt Lake City, UT; 2) George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, UT; 3) Department of Dermatology, University of Utah, Salt Lake City, UT.

The Utah Population Data Base (UPDB) and the Icelandic genealogy resource, combining genealogic and phenotypic data, have proven valuable to genetic studies. We are creating a similar resource including a genealogy of United States residents and their ancestors. We have begun to record link to the national Veteran's Administration (VA) population of 25 million retired service men and women beginning with the genealogy of Utah (UT) and Massachusetts (MA) by obtaining genealogical data from public sources using common published formats. The genealogy currently includes 38 million individuals. We have begun record linking to 11M VA patients using any national VA facility and have currently linked 500,000 (4.5%) of these patients to the genealogy. For genetic analyses we restrict our use to the 52,332 VA patients who link to genealogy data including at least both parents and all 4 grandparents. We can analyze the relationships of patients with phenotypes of interest to define relatedness and relative risks. The recent initiation of the VA Million Veterans Project, which will sample DNA for all Veterans, will soon result in the largest genetic repository in the world. When combined with this VA genealogy, the resource will have unlimited potential to the genetics of health-related phenotypes. As an example, among the 52,332 VA patients who link to genealogy data we identified 1,412 patients with an ICD9 in their medical record consistent with rotator cuff tear. We used the Genealogic Index of Familiality (GIF) statistic to assess the presence of excess familial clustering among these cases compared to 1,000 sets of matched controls (matched on birthplace, age, and sex). The GIF statistic computes the average genetic distance between all pairs of people in a set using the Malecot kinship coefficient. The GIF statistic was computed once for the set of cases and once for each of the 10,000 sets of matched controls. The distribution of the sets of matched controls provides an empirical distribution for a hypothesis test. According to the Gif analysis, rotator cuff tear exhibited strong evidence for excess familial clustering ($p<1E-4$) in the VA genealogy, which further supports prior evidence for a genetic contribution to this phenotype in the Utah Population Database and validates, at least in part, the reliability and utility of the new VA genealogy.

995F

High-dimensional genetic prediction of type-2 diabetes susceptibility. *Y. Klimentidis[1], A. Vazquez[2], G. de los Campos[2], D. Allison[3].* 1) Division of Epidemiology and Biostatistics, University of Arizona, Tucson, AZ; 2) Section on Statistical Genetics, Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 3) Office of Energetics, School of Public Health, University of Alabama at Birmingham, Birmingham, AL.

Recent findings from genome-wide association studies (GWAS) have uncovered approximately 65 loci confidently associated with type-2 diabetes (T2D) risk. However, these loci explain less than ten percent of the expected heritability of T2D, and have limited predictive value. Different statistical methods along with the inclusion of additional variants may increase the utility of genomic information, and ultimately lead to a more confident identification of individuals at highest genetic risk of T2D. In this study, we use genotype information from up to approximately 2.5 million SNPs (single-nucleotide polymorphisms), along with information about each SNP's potential importance in T2D risk, as determined by the summary statistics of a recent meta-analysis of GWAS. We build and test various polygenic prediction models in the context of early-life prediction of T2D susceptibility using 1) G-BLUP (genomic best linear unbiased predictor) and 2) multi-SNP risk scores. Prediction models are developed and tested within the Framingham Heart Study dataset, and the main results are replicated in the ARIC (Atherosclerosis Risk in Communities) dataset. We find that prediction accuracy increases substantially with the inclusion of additional SNPs, from an AUC (area under the receiver operating characteristic curve) of 0.689 for the commonly used 'top hits' genetic risk score, up to 0.814 using a multi-SNP risk score that includes over 3,700 SNPs. Our findings are successfully replicated in the ARIC dataset. We have shown that T2D genetic risk prediction models can be markedly improved with the inclusion of thousands of SNPs, given prior information about relative SNP importance.

996W

Investigating missing heritability and improving risk prediction with maximally free marginal models of phenotype. *N. Zaitlen[1], T. Wingo[2], A. Gusev[3], D.J. Cutler[4].* 1) Department of Medicine, University of California San Francisco, San Francisco, CA; 2) Department of Neurology, Emory University School of Medicine, Atlanta, GA; 3) Department of Genetic Epidemiology, Harvard School of Public Health, Boston, MA; 4) Department of Human Genetics, Emory University School of Medicine, Atlanta, Georgia, United States of America.

Genetic association studies have successfully identified thousands of loci in hundreds of phenotypes. In order to increase power studies typically utilize one degree of freedom statistical tests, making a restrictive additive (or multiplicative) assumption about the underlying genetic basis of the phenotype of interest. In this work we examine the validity of this choice, introducing new methods to determine how much better a given phenotype is modeled with unrestricted effect sizes for zero, one, or two copies of each causal variant. We know from both human and model organism genetics that many variants behave in a dominant, recessive, or over-dominant manner, but the total extent to which these richer marginal models of disease affect complex phenotypes is currently unknown. Our approach is an extension of the recent mixed linear model approaches to estimating the phenotypic variance driven by genotyped variants (Yang et al Nat Gen 2010), which also assume a one degree of freedom model. We propose multi-variance component methods, that estimate the additional phenotypic variance captured by increasingly freer disease models. The variance components are constructed by measuring the genome-wide similarity of individuals according to different encodings of genotypes. The method has a corresponding likelihood ratio test with a null model of additivity, allowing a formal examination of the additive assumption. We show via extensive simulation over real and simulated data that our test statistic has the appropriate type-I error rate and accurately estimates the fraction on phenotypic variance driven by each disease model. We apply our method to phenotypes from the National Finnish Birth Cohort and WTCCC data sets, show several potential sources for bias including ascertained data sets, relatedness, and population structure, and confirm the known dominance structure in Type 1 Diabetes (p-value $< 5e-5$). We derive a BLUP based phenotypic prediction method from our mixed linear model, which will improve our prediction ability over existing additive models for those phenotypes with more complex underlying structure. This work will add to our fundamental understanding of the genetic basis of complex human phenotypes and offer insights into the missing heritability problem.

997T

Life course variations in the heritability of body size. *J. Zhao[1], J.A. Luan[1], S.J. Sharp[1], R. Hardy[2], A. Wong[2], Q. Tan[3], N.J. Wareham[1], D. Kuh[2], K.K. Ong[1,2].* 1) MRC Epidemiology Unit, University of Cambridge, Institute of Metabolic Science, Box 285, Addenbrooke's Hospital, Hills Road, Cambridge CB2 0QQ, UK; 2) 2MRC Unit for Lifelong Health and Ageing, University College London, London WC1B 5JU, UK; 3) Epidemiology and Biostatistics, University of Southern Denmark, J.B. Winslows Vej 9, DK-5000 Odense C, Denmark.

Background: It has been shown recently that whole genome data can facilitate estimation of genetic contributions to a variety of traits via a mixed model framework as implemented in GCTA and R/SAS (Yang et al. Nat Genet 2010, 42:565-9; Zhao & Luan. J Prob Stat 2012, doi 10.1155/2012.485174). Our aim was to use this approach to investigate the life course variations in heritability of body size. Methods: We analysed height, weight and body mass index variables at 11 time-points in 2,452 individuals (1,225 men, 1,227 women) born in 1946 and enrolled in the MRC National Survey of Health and Development (NSHD), with genotypes at 147,949 single nucleotide polymorphisms (SNPs) on Metabochips which were subsequently imputed to 506,255 according to the 1000Genomes project. We obtained genome-wide kinship matrices using genotypes at SNPs on Metabochips and genotypes at all SNPs, which were used in mixed models as implemented in the computer program GCTA. Results were also compared to those obtained using an alternative procedure of kinship estimation in PLINK and mixed models in R. Results: In line with earlier findings that specific genetic variants have variable temporal effects in this cohort (Hardy et al. Hum Mol Genet. 2010; 19:545-552), we observed age-related variations in heritability estimates. Estimates based on genotypes at SNPS on Metabochips and genotypes at all SNPs were comparable but generally lower than recently reported GCTA estimates with mean(range) being 0.09(0-0.50), 0.11(0-0.20), 0.10(0-0.22) for height, weight and body mass index, respectively. Variation in estimates was also seen between alternative procedures. Conclusion: This work supports the utility of large-scale genotype data in heritability estimation and highlights the age-related variability in genetic contributions to body size across the life course. Further work will be to distinguish the effects of established variants and to consider estimates in a unified longitudinal model including contrast with models assuming various degrees of temporal homoscedasticity.

998F

Quantifying missing heritability from known GWAS loci and rare coding variants. *A. Gusev[1,2], B.M. Neale[2], G. Bhatia[1,2], N. Zaitlen[3], B.J. Vilhjalmsson[1,2], D. Diogo[4,2], E.A. Stahl[4,2], P.K. Gregersen[5], J. Worthington[6], L. Klareskog[7], S. Raychaudhuri[4,2], R. Plenge[4,2], B. Pasaniuc[8], P.F. Sullivan[9], A.L. Price[1,2].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, Massachusetts, United States of America; 2) The Broad Institute of Harvard and MIT, Cambridge, Massachusetts, United States of America; 3) Department of Medicine, Lung Biology Center, University of California San Francisco, San Francisco, California, United States of America; 4) Division of Rheumatology, Immunology, and Allergy and Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States of America; 5) The Feinstein Institute for Medical Research, North Shore-Long Island Jewish Health System, Manhasset, New York, United States of America; 6) Arthritis Research UK Epidemiology Unit, Musculoskeletal Research Group, University of Manchester, Manchester Academic Health Sciences Centre, Manchester, United Kingdom, NIHR Manchester Musculoskeletal Biomedical Research Unit, Central Manchester NHS Fou; 7) Rheumatology Unit, Department of Medicine, Karolinska Institute at Karolinska Hospital, Stockholm, Sweden; 8) Interdepartmental Program in Bioinformatics Pathology and Laboratory Medicine, University of California Los Angeles, Los Angeles, California, United States of America; 9) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States of America.

GWAS currently explain only a small fraction of common disease heritability. Possible sources of missing heritability include rare coding variants throughout the genome, or additional causal variants at known GWAS loci, each of which may be poorly tagged by GWAS associations. We describe variance component methods to estimate these components of heritability while adjusting for LD both within and between variant classes, which can bias estimates even when all causal variants are typed. Our simulations on real genotypes show that our methods produce unbiased estimates. We applied the methods to two data sets: a 23,000-sample study of rheumatoid arthritis (RA) with ImmunoChip data from 10 known RA loci (excluding HLA), and a 6,400-sample study of schizophrenia typed on both exome and GWAS chips. For RA, known associations at these loci (including those identified in these data) explained 0.006 of the variance in liability of RA, while including all SNPs at the loci explained 0.014±0.002, increasing further to 0.032±0.003 when including data from 17 known autoimmune loci not previously associated to RA. These findings are consistent with the presence of additional causal variants at previously known loci. In the schizophrenia analysis, we partitioned total heritability explained by all typed SNPs of 0.38±0.04 into 0.09±0.03 from coding SNPs and 0.30±0.03 from noncoding GWAS-chip SNPs, demonstrating significant exonic heritability. However, the contribution of 0.04±0.03 from rare coding SNPs (after adjusting for LD between variants) was non-significant, even after collapsing rare variants to reduce statistical noise. The remaining independent contribution from common coding SNPs was significant but largely tagged by GWAS-chip SNPs. Partitioning the coding variants further by functional classification revealed a 4.6x enrichment in heritability at severe loss-of-function sites (P=0.02 by permutation) but no significant enrichment at other predicted-damaging coding variants. Our results shed light on components of missing heritability for these traits and provide insights into their genetic architecture.

999W

Assessing the Impact of Coding Variants on Lipid Levels with the Exomechip. *K.E. Stirrups[1], N. Masca[2,3], T.V. Varga[4], R. Scott[5], L. Southam[1], W. Zhang[6], D. Pasko[7], A. Mahajan[8], S. Kanoni[1], UK Exomechip Lipids Consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 2) Department of Cardiovascular Sciences, University of Leicester, Leicester, UK; 3) NIHR Leicester Cardiovascular Biomedical Research Unit, Glenfield Hospital, Leicester, UK; 4) Genetic and Molecular Epidemiology Unit, Lund University Diabetes Center, Malmo, Sweden; 5) MRC Epidemiology Unit , Institute of Metabolic Science, Cambridge, UK; 6) School of Public Health, Imperial College London, London, UK; 7) Genetics of Complex Traits, University of Exeter Medical School, Exeter, UK; 8) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Multiple rounds of Genome Wide Association (GWA) meta-analyses have so far implicated mainly common variants underlying the molecular basis of blood lipid levels in humans, explaining only a fraction of the genetic component of these traits. The aim of the Illumina HumanExome chip (247,870 SNPs) was to provide a cost-effective way to assess the genetic contribution of low frequency (minor allele frequency (MAF) < 5%) and rare (MAF < 1%) exonic variants which are likely to be functional. An estimated 97% of nonsynonymous variation and 94% of splice and stop variation detected in an average genome through exome sequencing are covered by the design. The array also includes a scaffold of common tag SNPs, HLA and mitochondrial markers as well as all known GWAS lead SNPs (NHGRI catalogue).

We have set up a collaborative effort to perform an inverse variance weighted meta-analysis in European and South-East Asian cohorts (current analysis includes ~20,000 samples) for high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), triglycerides (TG) and total cholesterol (TC) levels. Genotype calling was performed using GenCall followed by zCall. Meta-analysis (autosomal data) was performed in GWAMA, testing fixed and random effects. We excluded subjects on lipid lowering medication and analysed disease and control cohorts separately.

We implemented additional quality control steps for filtering genotypes obtained for rare variants. In total, ~175,000 variants passed QC criteria. We then examined SNPs which were associated with lipid traits at a significance threshold of P < 1×10-4 after inspection of cluster plots. The majority of these SNPs were located within 500kB of a known lipid locus (~40% of reported loci replicated at nominal significance), though in 5 loci the known association was to a lipid trait other than the one analysed. We identified a coding variant in 12 known loci showing a stronger association than the reported sentinel SNP, these are good functional candidates. Interestingly, for 21 known loci we found a variant which was not in LD with the sentinel SNP and remained significant upon conditional analysis, most of them (76%) were low frequency / rare variants. We are currently pursuing replication approaches for 74 (78% are coding SNPs) putative new signals of which ~64% have MAF <1%.

1000T

Narrowing the gap on heritability of common disease by direct estimation in case-control GWAS. *D. Golan, S. Rosset.* Department of Statistics, Tel-Aviv University, Tel-Aviv , Israel, 69978.

One of the major developments in recent years in the search for missing heritability of human phenotypes is the adoption of linear mixed-effects models (LMMs) to estimate heritability due to genetic variants which are not significantly associated with the phenotype. A variant of the LMM approach has been adapted to case-control studies by Lee et al. (2011) and applied to many major diseases, successfully accounting for a considerable portion of the missing heritability. For example, for Crohn's disease the estimated heritability was 22%, considerably higher than the heritability accounted for by significantly associated SNPs. We propose to estimate heritability of disease directly by regression of phenotype similarities on genotype correlations, corrected to account for ascertainment (the enrichment of cases in the study compared to the population). We refer to this method as genetic correlation regression (GCR). Using GCR we estimate the heritability of Crohn's disease at 34% using the same data as Lee et al., much closer to the estimated heritability of 50-60% obtained from family studies. GCR estimates of heritability are also considerably higher than LMM for bipolar disorder (54% compared to 43%, respectively). To understand the gap between GCR and LMM estimates, we conduct extensive simulations to evaluate the performance of both heritability estimation methods. Contrary to previous simulations conducted in the context of heritability estimation, our simulations are the first to simulate the entire generative process of data collection, including generating genotypes and selecting cases and controls. This realistic simulation scheme captures some essential features of case-control GWASs which were overlooked by previous simulation schemes, for example, when a highly heritable polygenic phenotype is rare, randomly sampled cases tend to be more genetically similar than random controls, even when they are unrelated. Our simulations demonstrate that GCR produces accurate and unbiased estimates of heritability for a wide range of scenarios, while LMM estimates are considerably and consistently negatively biased under ascertainment. We thus conclude that GCR estimates of heritability are more reliable than LMM estimates. Lastly, we develop a heuristic correction to LMM estimates, which can be applied to published LMM results. Applying our heuristic correction increases the estimated heritability of multiple sclerosis from 30% (Lee et al. 2013) to 52.6%.

1001F

GWAS-data based heritability estimation of memory related phenotypes. *C. Vogler[1,2,4], V. Freytag[2], A. Milnik[2], L. Gschwind[2], D. Coynel[3], A. Heck[1,2,4], D. de Quervain[1,3], A. Papassotiropoulos[1,2,4].* 1) Psychiatric University Clinic, University of Basel, Basel, Basel City, Switzerland; 2) Moleuclar Neuroscience, University of Basel, Basel, Basel City, Switzerland; 3) Cognitive Neuroscience, University of Basel, Basel, Basel City, Switzerland; 4) Department Biozentrum, Life Sciences Training Facility, University of Basel, Basel, Switzerland.

Background: Genome-wide association studies provide the means to identify the molecular underpinnings of complex heritable traits. Heritability is a concept that summarizes how much of the phenotypic variation in a trait is attributable to genetic factors. Conventionally, heritability estimates in humans are derived from phenotypic data solely by comparing correlations between relatives. However, those methods imply that the amount of resemblance that is due to shared environment is the same for different degrees of relationship. Further, the genetic identity between sib pairs is assumed to be 50%, whereas it has been shown to vary from ~40 to ~60% (Visscher, 2006). Alternatively, recently developed methods, propose to infer genetic identity from high-throughput SNP data and to correlate these estimates with phenotypic resemblance among unrelated individuals. This allows heritability estimation for any specific GWAS dataset. Here we present genetic marker based heritability estimates for working and episodic memory phenotypes.

Methods: A healthy young Swiss sample comprising a total of N=1789 individuals was subjected to phenotypic assessment with a cognitive testing battery and subsequent genotyping using the Affymetrix SNP Array 6.0. Working memory (WM) performance was measured with the n-back paradigm. Episodic memory was assessed with the International Affective Picture System (IAPS) and lists of semantically unrelated words taken from the collections of Hager and Hasselhorn (Hager and Hasselhorn, 1994). In order to obtain the heritability estimates, we performed restricted maximum likelihood (REML) analyses implemented in the GCTA software package (Yang et al, 2011).

Results: Heritability estimates occupy a range from 26 to 65% with a mean standard error of 19% The average heritability estimate for the attention corrected WM performance is 60% (SE: 19%) and the mean heritability for the different episodic memory tasks is 49% (mean SE: 20%). These estimates are consistent with previously reported heritability for WM (Ando, 2001) and episodic memory (Papassotiropoulos, 2011). As this reflects that heritability for the cognitive phenotypes is represented in the GWAS data, this design can serve to unravel the molecular players that act in concert to form these complex traits.

Polygenic analysis of type II diabetes in the DIAGRAMv3 GWAS meta-analysis, and partitioning of polygenic signal in tissue-specifically active genes. *A.L. Dobbyn[1], B.F. Voight[2], E.E. Kenny[1,3,8,9], J. Jeff[1,3], P. Roussos[1,6,7], O. Gottesman[3], A. Morris[4], R. Loos[1,3], E. Bottinger[3], S. Raychaudhuri[5,6], M. McCarthy[4], E.A. Stahl[1,6,7], the DIAGRAM Consortium.* 1) Institute for Genomics and Multiscale Biology, Department of Genetics and Genomics, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Departments of Pharmacology and Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 5) Partners HealthCare Center for Personalized Genetic Medicine, Brigham & Women's Hospital, Harvard Medical School, Boston, MA; 6) Broad Institute, Cambridge, MA; 7) Division of Psychiatric Genomics, Icahn School of Medicine at Mount Sinai, New York, NY; 8) Center for Statistical Genetics, Icahn School of Medicine at Mount Sinai, New York, NY; 9) Dept. of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

INTRODUCTION: Polygenic risk score analyses have shown that a substantial portion of the missing heritability of common, complex diseases can be explained by weakly associated GWAS SNPs that fail to reach genome-wide significance. Separate analyses have demonstrated that tissue specific chromatin marks can be used to identify causal tissues by enrichment in GWAS associations (Trynka 2013). We combine these approaches, partitioning polygenic scores across liver- and pancreatic islet-specific gene sets, in order to dissect the genetic architecture of type 2 diabetes (T2D), a common metabolic disorder that affects up to 8% of the adult population. METHODS: We first conducted polygenic risk score analysis of T2D using the DIAGRAMv3 GWAS (Morris 2012; 12,171/56,862 European cases/controls). Polygenic risk scores based on LD-pruned SNPs stratified by discovery P_{GWAS} and risk allele frequency (RAF) were tested in either WTCCC1 (1,924/2,938 cases/controls) or the Mount Sinai Biobank (4,095/9,832 multiethnic cases/controls). We then identified MACS-called H3K4me3 ChIP-seq peaks from the NIH Epigenomics Roadmap project (34 tissues) in the promoter regions of Refseq transcripts (TSS +/- 1Kb), and normalized to obtain genic tissue-specificity scores. We have explored distance from transcription start and end, and nearest recombination hotspots, to define SNP sets for partitioned polygenic analyses. RESULTS: Polygenic scores were significantly associated with T2D in the test data, with the strongest score having $P=3\times10^{-29}$ and $R^2=0.035$ (841 SNPs with $P_{GWAS} < 0.001$), and with many additional scores having $P < 0.01$ (SNPs with $P_{GWAS} < 0.1$ and $0.1 < RAF < 0.88$). 761 (1.80%) and 442 transcripts (1.05% of all transcripts) constitute primary liver and pancreatic islet gene sets (specificity score > 0.5), respectively, each corresponding to 3.3% of LD-pruned SNPs (transcripts +/- 100Kb). Top polygenic scores for these SNP sets are significant (liver $P=0.002$, $R^2=0.002$, 28 SNPs with $P_{GWAS} < 10^{-3}$; pancreas $P=0.001$, $R^2=0.001$, 817 SNPs with $P_{GWAS} < 0.05$), and show 1.5- to 2.1-fold greater R^2 than expected for the proportion of SNPs represented. CONCLUSIONS: Tissue-specific compartments of polygenic signal can be derived from gene harboring chromatin marks, and will be applied in further studies of T2D causal mechanisms including the relative roles of liver versus pancreatic islets, and pleiotropy with T1D and cardiac/metabolic phenotypes.

Bivariate analysis of blood pressure traits in Danish and Chinese twins. *S. Li[1], T.A. Kruse[1], K.O. Kyvik[2].* 1) Human Genetics, Institute of Clinical Research, University of Southern Denmark, Odense, Denmark; 2) Institute for Regional Health Research, University of Southern Denmark and Odense Patient Data Explorative Network (OPEN), Odense University Hospital, Odense, Denmark.

Studying the multiplex genetic basis of blood pressure regulation can help with elucidating the etiology of hypertension and related diseases as well as with the development of more efficient prevention and treatment strategies. This study aims at investigating the genetic and environmental backgrounds for blood pressure variation as well as for phenotype correlation between systolic and diastolic blood pressure by fitting bivariate models to Danish and Chinese twins and comparing ethnic difference between the two samples. The Danish sample consists of 756 twin pairs (309 monozygotic or MZ pairs, 447 dizygotic or DZ pairs) and Chinese sample includes a total of 325 pairs of twins (183 MZ twin pairs and 142 DZ twin pairs). Our parameter estimates revealed moderate to high additive genetic and unique environmental influences on both systolic and diastolic blood pressure and on their correlation with an overall pattern of higher genetic regulation in Danish than in Chinese twins while higher contribution by unique environment in Chinese than in Danish twins. The estimated genetic components in blood pressure and in blood pressure correlation could serve to guide new researches aiming at looking for heritable genetic variants that affect systolic and/or diastolic blood pressure. Meanwhile, the estimated high contribution to blood pressure by unique environment suggests that promoting healthy lifestyle could provide an efficient way for the control of hypertension especially in the Chinese population.

The genetic architecture of schizophrenia in the Swedish Schizophrenia Study. *E.A. Stahl[1], S.H. Lee[2], G. Moser[2], S. Ripke[3,4], D.M. Ruderfer[1], S.M. Purcell[1,3,4], P. Sklar[1,4], C. Hultman[5], P.F. Sullivan[6].* 1) Division of Psychiatric Genomics in the Department of Psychiatry, Friedman Brain Institute, and Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, NY, NY 10029; 2) The University of Queensland, Queensland Brain Institute, Brisbane, 4072, Queensland, Australia; 3) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, 02114; 4) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, MA, 02142; 5) Department of Medical Epidemiology, Karolinska Institutet, Stockholm, Sweden; 6) Departments of Genetics, Psychiatry, and Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 27599.

INTRODUCTION: Schizophrenia has long been recognized to be familial, and more recently to be highly polygenic. The substantial contribution to phenotypic variance of SNPs falling short of genome-wide significance in GWAS is well appreciated, particularly in schizophrenia. Here we describe inference analyses of schizophrenia genetic architecture using the comprehensive genomic data collected on Swedish national registry samples. METHODS: We analyzed GWAS data of 5,001 schizophrenia cases and 6,243 healthy controls from the Sweden (imputed to 1000 Genomes, 5.7M SNPs after QC) as test data in polygenic risk score (PRS) analyses with PGC schizophrenia GWAS meta-analysis results for training data. Approximate Bayesian Polygenic Analysis (ABPA) was performed under a mixture model of independent associated and null SNPs (Stahl 2012 PMID 22446960). Linear mixed models of normally distributed effects were fit using GCTA (Yang 2011 PMID 21167468, Lee 2011 PMID 21376301), and LD-based SNP weighting (LDAK, Speed 2013 PMID 23217325) was considered. Results were compared using the actual genotype data, with real and simulated phenotypes under a range of genetic architectures. RESULTS: ABPA yields an estimate of 8,300 independent SNPs (95% CI 6,300-10,200) underlying risk of schizophrenia, almost all common (MAF>0.1), and together accounting for heritability of 52% (95% CI 0.45-0.54). GCTA yielded a somewhat lower estimate, 33% (0.27-0.39), still a majority of heritability estimated in the Swedish national pedigree study (64%, Lichtenstein 2009 PMID 19150704). CONCLUSION: These results answer a question that has been debated most of the past century: the majority of the phenotypic heritability of schizophrenia can be explained by GWAS data, overwhelmingly by common SNPs of small effect. These results strongly suggest that additional GWAS will yield many more genetic discoveries. Furthermore, our results suggest that schizophrenia may be more polygenic than other common, complex diseases.

1005W

Heritability Contribution of Gut Microbiome to Metabolic Traits in Mice. *E. Kostem[1], E. Org[2], B. Parks[2], R. Knight[4,5], J. Lusis[2,3], E. Eskin[1,3].* 1) Computer Science Department, UCLA, LOS ANGELES, CA; 2) Department of Medicine/Division of Cardiology, David Geffen School of Medicine, UCLA, LOS ANGELES, CA; 3) Department of Human Genetics, David Geffen School of Medicine, UCLA, LOS ANGELES, CA; 4) Department of Chemistry and Biochemistry, University of Colorado Boulder, CO; 5) Howard Hughes Medical Institute, Boulder, CO.

Over the last few years, the impact of the gut Microbiome composition in complex traits has received a lot of attention. The gut Microbiome hosts hundreds of bacterial species with a tremendous genetic diversity and has been shown to regulate complex traits in addition to the host genome. Using the Hybrid Mouse Diversity Panel (HMDP) that consists of more than 100 inbred strains of mice, we show that the gut Microbiome composition explains a considerable portion of the variation in metabolic traits. We further partition the heritability of metabolic traits to the contribution of genomic regions and show that these estimates may be different if we account for the gut Microbiome. Our findings suggest that gut Microbiome may be one of the key factors in the missing heritability of complex diseases.

Proteomic and bioinformatics analysis of the endolysosomal pathway: Deciphering the insulin receptor Golgi/endosome subnetwork (IRGEN).
M.B. DJIDJOU[1], C. LANDRY[2], R. Laframboise[1], R. Faure[1]. 1) PEDIATRICS, CHUQ Research Center CRCHUQ (Centre-Mère-Enfant-Soleil)/University Laval, Quebec, QUÉBEC, Canada; 2) Institut de Biologie Intégrative des Systèmes (IBIS), Université Laval, Québec, PQ, Canada.

While insulin resistance can be a heritable trait in lean and obese subjects, it remains unclear which cellular mechanism is the dominant driver that determines insulin sensitivity under baseline conditions. The study of the proteomes of lower organisms recently confirmed that proteins are not randomly connected; most interact with just a few others, whereas a limited number (hubs) interact with many others. This nodular architecture is conserved and provides a robust defense against random alterations, but connected proteins-which tend to play essential roles in organisms-can also make networks vulnerable to environmental attacks that target nodes, suggesting that the study of interactomes in rodent models and human is important to understand complex diseases such as diabetes. It is plausible that changes in insulin receptor (IR) traficking will alter circulating insulin concentrations, which in turn could affect insulin-sensitive tissues thus supressing peripheral insulin action. A proteome of a Golgi/endosomes (G/E) fraction prepared from the mouse liver was previously described by us. Bioinformatics analyses using well documented databases such as MGI, STRING and BIOGRID, completed by powerful analytical algorithms now show that they enriched for specific groups of proteins and depleted for others. Proteins identified in the G/E fraction can be grouped and linked according to their functional and molecular associations in the cell whereby they form tight and interconnected clusters, visualized through Cytoscape software, in a robust scale-free protein-protein interaction network (PPIN) of 927 nodes for 4617 interactions. This represents the G/E network (GEN), having a general vesicle-like topology. A close analysis of the insulin receptor subnetwork (IRGEN) identified physically associated proteins, which are involved in the cell cycle machinery (Cdk2, cyclin E), vacuolar ATPase elements, the de novo purine biosynthetic pathway (ATIC), a putative protein tyrosine phosphatase (PTPLAD1), actin cytoskeleton (β-catenin, CEACAM1), cargos (LRP-1) and kinases (AMPK). These proteins were confirmed to have a role in IR regulation. The results indicate the presence of unanticipated pathways subtending both IR signalling and trafficking favoring the idea that insulin clearance may be a primary event, which could generate hyperinsulinemia that negatively act on insulin-sensitive tissues, thus generating insulin resistance.

Transcriptomics of natural resistance to SIV infection in wild African green monkey populations in Africa.
A. Jasinska[1], D. Ma[2], N. Tran[1], C. Blum[1], P. Turner[3,4], T. Grobler[4], Y. Jung[1], C.A. Schmitt[1], M. Dion[5], M. Antonio[5], G. Coppola[6], I. Pandrea[2], C. Apetrei[2], N. Freimer[1]. 1) UCLA Center for Neurobehavioral Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Canter for Vaccine Research, University of Pittsburgh, Pittsburgh, Pennsylvania USA; 3) Department of Anthropology, University of Wisconsin-Milwaukee, Milwaukee, WI, 53201; 4) Department of Genetics, University of the Free State, Bloemfontein, South Africa,; 5) Medical Research Council, Fajara, The Gambia; 6) Department of Neurology, Univ. of California, Los Angeles.

Resistance to acquiring the human immunodeficiency virus (HIV) infection has been observed in some individuals, who remain uninfected despite their exposure. These people are known as exposed seronegative or exposed uninfected (ESN/EU) individuals. This phenomenon offers a unique opportunity to identify host factors protecting against HIV infection. While this trait is rare in humans, we have recently discovered that it is present at a high frequency (~20%) in wild populations of African green monkeys (AGM, *Chlorocebus*), also called vervets, which are natural hosts of simian immunodeficiency virus (SIV), a virus closely related to HIV. We hypothesized that host genetic factors underlie resistance to acquiring SIV infection among AGMs. In order to identify host genes, which are critical to the evasion of infection in the face of massive exposure among AGMs, we used RNA-seq to analyze blood transcriptomic profiles in 19 ESN, 4 acutely SIV-infected and 26 chronically SIV-infected AGMs from wild *Ch. pygerythrus* and *Ch. sabaeus* populations from South and West Africa, respectively. Transcriptome profiling in the *pygerythrus* population indicated that a large group of genes transiently deregulated during the acute (early) stage of infection encompasses interferon-regulated genes, and genes associated with defense, stress response immunity, and inflammation. We also identified 23 transcripts deregulated between ESNs and individuals chronically infected with SIV (in the later stages of infection), with the strongest statistical evidence for IL1F7 (interleukin-1 family member 7), RPS2 (40S ribosomal protein S2), C4BPA (complement component 4 binding protein, alpha), RAD21L1 (RAD21-like 1), and APOE (Apolipoprotein E). We identified the deregulation of several genes previously linked to the control of HIV infection in humans: RPS2, which codes ribosomal protein regulated by HIV tat expression, APOE, whose common alleles are associated with the accelerated progression to AIDS in humans, and genes from the family of defensins (DEFA1, DEFA1B, and DEFA3), which are natural anti-HIV peptides. Among the deregulated genes in pygerythrus, three genes were also top-ranked in *sabaeus* AGMs: RPS2, APOE, and IFIT1B. Our transcriptomic analysis revealed genes that are deregulated in ESN AGMs and therefore possibly involved in the mechanism of defense against infection. These are candidates for functional follow-up studies and potential targets for preventive therapy.

Knockdown of zebrafish *crispld2* results in craniofacial defects and abnormal NCC migration.
Q. Yuan, E.C. Swindell, J.T. Hecht. Department of Pediatrics, Pediatric Research Center, University of Texas Medical School at Houston, Houston, TX.

We have previously found that variation in the CRISPLD2 (cysteine-rich secretory protein LCCL domain containing 2) gene is associated with nonsyndromic cleft lip and palate (NSCLP) and that mouse Crispld2 is expressed in the developing craniofacies, suggesting that CRISPLD2 may play a role in craniofacial morphogenesis. Crispld2 was first identified in mice (as a gene called Lgl1) and plays a role in early branching morphogenesis of the developing lung and kidney and in epithelial/mesenchymal interaction in lung tissue. Defects in the epithelial to mesenchymal transition in craniofacial tissue are thought to underlie nonsyndromic orofacial clefting. To define the role of CRISPLD2 in zebrafish craniofacial development, antisense morpholinos (MO) directed against the start site (MO3) and exon/intron boundaries for exons 3 and 4 (MO1 and MO2, respectively) of zcrispld2 were injected into early embryos. These embryos showed a range of craniofacial abnormalities involving both the jaw and palate, with the most severe phenotypes resulting from knockdown of MO3. Moreover, several marker genes for neural crest cells (NCCs) show abnormal expression in MO3 injected embryos, suggesting that knockdown of zcrispld2 specifically affects NCCs. These results show that zcrispld2 is involved in palate and jaw morphogenesis. We are now examining the migration of NCCs in live embryos to determine when zcrispld2 plays a role in craniofacial development. RNAseq is being utilized to identify potential downstream effectors of zcrispld2. Importantly, our results demonstrate that genes involved in complex birth defects, such as NSCLP, can be identified in candidate gene studies and functionally assessed in zebrafish to define the biological processes that are the basis for these complex birth defects.

Whole genome analysis in fibromyalgia suggests a role for the central nervous system in disease susceptibility. *E. Docampo[1,2,3], G. Escaramis[1,2,3], M. Gratacos[1,2,3], S. Villatoro[1,2,3], A. Puig[1,2,3], M. Kogevinas[4], A. Collado[5], J. Carbonell[6], J. Rivera[7], J. Vidal[8], J. Alegre[9], R. Rabionet[1,2,3], X. Estivill[1,2,3].* 1) Genetic Causes of Disease Group, Centre for Genomic Regulation (CRG), Barcelona, Spain; 2) Universitat Pompeu Fabra (UPF), Barcelona, Spain; 3) Centro de Investigación Biomédica en Red en Epidemiología y Salud Pública (CIBERESP), Barcelona, Spain; 4) CREAL, Centre de Recerca en Epidemiologia Ambiental, CREAL, Barcelona, Spain; 5) Rheumatology Service, Hospital Clinic, Barcelona, Spain; 6) Rheumatology Service, Hospital del Mar, Barcelona, Spain; 7) Rheumatology Unit, Instituto Provincial de Rehabilitación, Madrid, Spain; 8) Rheumatology Unit, Rheumatology, Guadalajara, Spain; 9) Chronic Fatigue Syndrome Unit, Internal Medicine, Barcelona, Spain.

Fibromyalgia (FM) is a highly disabling syndrome defined by a low pain threshold and a permanent state of pain. The mechanisms explaining this complex disorder remain unclear and its genetic factors have not been identified. The aim of this study was to elucidate genetic susceptibility factors for FM. We used the Illumina 1 million duo array to perform a genomewide association study (GWAS), and Agilent's 2X400K platform for array comparative genomic hybridization (aCGH) to identify regions varying in copy number that could be involved in FM susceptibility. GWAS was performed in 300 FM cases and 203 controls. No SNP reached GWAS significance, but 21 of the most associated SNPs were chosen for replication in over 900 cases and 900 pain free-controls. Four of the strongest associated SNPs selected for replication showed a nominal association in the joint analysis, and one, rs11127292 (MYT1L) was found to be associated to FM with low comorbidities ($p=4.28\times 10^{-5}$, OR (95%CI)=0.58 (0.44-0.75). By aCGH, an intronic deletion in NRXN3 showed to be associated to female cases of FM with low levels of comorbidities (p=0.021, OR (95%CI)= 1.46 (1.05-2.04)). Both GWAS and aCGH results point at a role for the central nervous system in FM genetic susceptibility. If the proposed FM candidate genes are further validated in replication studies, this would highlight a neurocognitive involvement in this disorder, currently considered musculoskeletal and affective. This work was supported by ENGAGE, NOVADIS (EU and Spanish Ministry of Economy and Competitiveness).

1010F

Sex-specific heritability of traits related to human obesity in rhesus macaques. *A. Vinson[1,2], A.D. Mitchell[1], D. Toffey[2], M.J. Raboin[2].* 1) Molecular and Medical Genetics, Oregon Hlth & Sci Univ, Portland, OR; 2) Oregon National Primate Research Center, Oregon Hlth & Sci Univ, Portland, OR.

Obesity is a major component of the metabolic syndrome and is associated with insulin resistance, type 2 diabetes mellitus, and increased risk for cardiovascular disease. Numerous studies in humans have demonstrated a genetic contribution to obesity. Further, obesity is sexually dimorphic in humans, and sex-specific genetic effects on human obesity have also been reported. The goals of this study were to explore the utility of the rhesus macaque as a genetic model for human obesity, by assessing the extent of additive genetic effects on traits related to human obesity and the influence of sex on these genetic effects. We measured weight, body mass index (BMI), abdominal circumference, and waist-to-thigh ratio in 584 Indian-origin rhesus macaques selected from a single 6-generation, 1,289-member pedigree unascertained with respect to phenotype, and designed for statistical power in quantitative trait analysis and gene mapping. Using a maximum likelihood-based variance decomposition approach, after removing mean effects related to housing, age, and sex, we found significant heritability for all traits in the total sample (h^2 range 0.247~0.407, P-value range 7.44×10^{-10}~2.43×10^{-3}). When stratified by sex (N=361 females, 223 males), analyses revealed apparent differences in heritability between males and females for BMI ($h^2 = 0.703$ in males, $P=7.75 \times 10^{-5}$, vs. $h^2 = 0.198$ in females, P=0.07), abdominal circumference ($h^2 = 0.258$ in females, P=0.05, vs. $h^2 = 0.101$ in males, P=0.25), and waist-to-thigh ratio ($h^2 = 0.273$ in females, P=0.03, vs. $h^2 = 0.191$ in males, P=0.06). We conclude that genetic contributions to traits related to human obesity can be detected and measured in rhesus macaques, and that genetic contributions to some traits may differ by sex. Our results are consistent with substantial similarity between macaques and humans in the genetic architecture of obesity, and support the value of the rhesus macaque as a genetic model for this human condition.

1011W

Gene expression changes in response to paraquat and caffeine in a Drosophila model of Parkinson's Disease. *E.M. Hill-Burns[1], P. Ganguly[1], W.T. Wissemann[1], W.J. Wolfgang[2,3], H. Payami[1,3].* 1) Division of Genetics, NY State Department of Health Wadsworth Center, Albany, NY; 2) Division of Infectious Disease, NY State Department of Health Wadsworth Center, Albany, NY; 3) Department of Biomedical Sciences, State University of New York Albany, NY.

Previous studies have established that paraquat exposure can induce Parkinsonism in Drosophila and serve as a model for Parkinson's disease (PD) in humans. Consistent with findings in humans that coffee drinking correlates with lower risk of PD, our lab extended the Drosophila paraquat model, observing that exposure to caffeine can partially rescue paraquat-induced mortality. To better understand the mechanisms at work in these Drosophila models and how they might relate to PD pathology in humans, we attempted to identify genes whose expression changed significantly in response to paraquat and/or caffeine. Flies were kept on food containing either no caffeine or 1mM caffeine for ten days, and then transferred to food containing either no paraquat or 5mM paraquat (in addition to the original concentration of caffeine), for a total of four treatment conditions with 3-4 replicates each of 30 female flies per vial. Fly heads were dissected after six days of paraquat treatment (or no paraquat treatment), RNA was extracted from the pooled tissue of each replicate, and cDNA was synthesized and hybridized onto arrays. Expression (of 18,954 transcripts, using Affymetrix expression arrays) was assayed in dissected heads of untreated flies, flies exposed to paraquat, flies exposed to caffeine, and flies exposed to both paraquat and caffeine. Array data were corrected for background signal and normalized. We tested for differences in expression associating with paraquat (in untreated vs. paraquat-only-treated flies), caffeine (in untreated vs. caffeine-only-treated flies), or for paraquat-caffeine interaction (in all four treatment conditions). We found transcripts of two genes with significantly different expression in response to paraquat exposure: *CG31288* ($P_{unadjusted}$=3E-6; $P_{adjusted}$=0.046) and *sugarbabe* ($P_{unadjusted}$=5E-6; $P_{adjusted}$=0.046). We also found transcripts of two genes with significantly different expression upon caffeine exposure: *Hr38* ($P_{unadjusted}$=3E-6; $P_{adjusted}$=0.04) and *CG3016* ($P_{unadjusted}$=4E-6; $P_{adjusted}$=0.04). No transcripts showed significant evidence for paraquat-caffeine interaction on expression when adjusted for genome-wide tests. Human orthologs for these Drosophila genes include *Nr4a2* (with *Hr38*) and *USP30* (ubiquitin specific peptidase 30, with *CG3016*). Both *Nr4a2* (aka *Nurr1*) and ubiquitin-related genes have been previously linked to PD in humans, making these genes interesting candidates for further study.

Probing the Gaucher/Parkinson Link By Crossing Different Mouse Models. *N. Tayebi, E. Maniwang, R. Tamargo, Y. Blech-Hermoni, N. Moaven, E. Aflaki, B. Berhe, E. Sidransky.* Section on Molecular Neurogenetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Gaucher disease, the most common lysosomal storage disorder, results from mutations in the glucocerebrosidase gene (GBA1) causing pathologic accumulation of glucosylceramide and glucosylsphingosine. Mutations in GBA1 are identified at an increased frequency in patients with Parkinson disease (PD) and Dementia with Lewy Bodies (DLB), although the mechanism for this association is not fully established. Among the heterozygous GBA1 mutations identified in subjects with PD are the loss-of function mutations, c.84dupG and IVS2+1. To explore how loss-of-function mutations on one allele might impact PD pathogenesis, we attempted to model this situation in mice using null allele gba carrier knock-out mice (gba-/wt) crossed with transgenic (Tg) mice over-expressing mutant A53T human alpha-synuclein (α-syn).Wild type (wt/wt) gba-/wt, TgA53Tα-syn/wt and TgA53Tα-syn/Tgα-syn mice were used as controls. The α-syn copy number in the Tg mice was estimated using Real-Time PCR. After breeding, gba and TgA53Tα-syn genotypes were confirmed, and nine sets of mice were followed over two years, monitoring for weight and neurological symptoms. Weight loss was a common initial sign, followed by arched back, impaired axial rotation, and finally lack of any movement. Mice with progressive neurologic deterioration were euthanized with their respective controls, and midbrain, frontal cortex, and spinal cord were collected. Gba expression, glucocerebrosidase (GCase) levels and enzyme activity were determined. Over-expression of α-syn was confirmed by western blot. Levels of RNA expression and GCase protein in the brain samples were similar in all mice studied. However, GCase activity was lower in the gba- /TgA53Tα-syn mice compared to gba-/wt mice. Brain glucosylsphingosine levels and neuropathology are also being evaluated. In a second set of animals with the same genotypes, 12 month old mice were treated with thioglycolate injections intraperitoneally for one week. The mice were then sacrificed and peritoneal macrophages were collected. Here too GCase activity was significantly lower in the gba- /TgA53Tα-syn macrophages compared to those from gba-/wt mice. These results suggest that over-expression of mutant α-syn could impair lysosomal function or interrupt the interaction between GCase and its activator, SAP-C. We postulate that the loss of function of one GBA1 allele may alter lysosomal function, and contribute to neuronal degeneration.

1013F

eQTL mapping of genes differentially expressed in the lung of COPD patients reveals new genes associated with disease susceptibility. *M. Lamontagne[1], C. Couture[1], M. Laviolette[1], Y. Bossé[1,2], The Merck-Laval-UBC-Groningen.* 1) Inst Univ de Cardiologie et de Pneumologie de Québec, Quebec, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

Introduction: COPD is a complex disease characterized by a progressive airflow obstruction that is not fully reversible. Cigarette smoking is responsible for 85 to 90% of COPD cases, but only 15 to 20% of the smokers develop the disease. A genetic component to develop COPD is thus persuasive. Methods: Genome-wide gene expression profiles of 500 non-tumor lung specimens were obtained from patients undergoing lung surgery. Blood-DNA from the same patients were genotyped for 1,2 million SNPs. Following quality control filters, 409 samples were analyzed in three steps. First, analyses were performed to identify transcripts differentially expressed between patients with and without COPD. Second, expression quantitative trait loci (eQTL) mapping was performed on these transcripts. Finally, eQTL SNPs were tested for association with COPD. Results: 33 transcripts mapping 28 unique genes were differently expressed between cases and controls (p-value < 1e-04). 160 eQTLs (145 SNPs) were associated with 19 of the 33 transcripts (p-value < 1e-06). 57 of the 145 eQTL SNPs were nominally associated with COPD (p-value < 0.05). The 57 disease-associated variants were correlated with five differently expressed genes (BRAP, DAAM1, SEPT3, SOST, SPINK5). Disease-associated eQTL SNPs for BRAP, SEPT3, SOST, SPINK5 were trans-acting variants. Conclusion: By combining genome-wide gene expression in the lung, eQTL mapping and genetic association in a case-control series of patients with COPD, we identified five new genes that are likely to play a role in the pathogenesis of COPD. This study confirms the importance of well-powered eQTL mapping design to find disease-related trans variants that cannot be identified by GWAS alone.

1014W

Generation of a cre recombinase-conditional *Nos1ap* overexpression transgenic mouse for modeling QT interval variation. *D.R. Auer[1], P. Sysa-Shah[2], D. Bedja[2], J. Simmers[1], E. Pak[3], A. Dutra[3], R. Cohn[1], K.L. Gabrielson[2], A. Chakravarti[1], A. Kapoor[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Molecular and Comparative Pathobiology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Polymorphic noncoding variation at the *NOS1AP* locus is the major genetic regulator of the human electrocardiographic QT interval explaining ~2% of the phenotypic variation, is associated with the risk for sudden cardiac death (hazard ratio ~ 1.4) and is a potent genetic modifier (increasing risk up to 10X) of cardiac phenotypes in patients with Mendelian long QT syndrome. *in vitro* and *ex vivo* gene targeting studies by our group have indicated that gene expression levels of *NOS1AP* alter cardiac electrophysiology through variation at an enhancer element. To further enhance the understanding of *NOS1AP* function in physiology and cardiac disease, we report here the generation and characterization of cre recombinase conditional *Nos1ap* overexpression transgenic mice (*Nos1ap*^{Tg}). Conditional transgenic mice were generated by pronuclear injection and three independent single site, multiple copy integration event-based founder lines were selected. For heart-restricted overexpression, *Nos1ap*^{Tg} mice were crossed with *Mlc2v-cre* and *Nos1ap*^{Tg}; *Mlc2v-cre* F1 mice were evaluated for transcript levels, electro- and echo-cardiographic parameters. Surface electrocardiographic recordings were performed at baseline and 20 minutes after injection with the sodium channel blocker flecainide acetate at dosages of 20 or 30 milligrams of drug per kilogram body weight. *Nos1ap* transcript over-expression was observed in left ventricles from *Nos1ap*^{Tg}; *Mlc2v-cre* mice. However, no significant difference was observed between *Nos1ap*^{Tg}; *Mlc2v-cre* mice and wild type control littermates in electro- and echocardiographic measurements. Steady-state Nos1ap protein levels, as assessed by Western blotting, in left ventricles from *Nos1ap*^{Tg}; *Mlc2v-cre* mice were similar to those in control wild type mice, indicating that Nos1ap protein levels are tightly regulated, at least in cardiac tissue. We hypothesize that the discordance between *Nos1ap* transcript and protein expression leads to absence of phenotypic consequence in *Nos1ap*^{Tg}; *Mlc2v-cre* mice.

1015T

Generation and characterization of NLGN2 R215H knock-in mice as a model of schizophrenia. *C.H. Chen[1], H.M. Liao[2], C.C. Yeh[3], Y.L. Chao[4].* 1) Dept. of Psychiatry, Chang Gung Memorial Hospital at Linkou, Gueishan, Taiwan; 2) Dept. of Psychiatry, Taiwan University Hospital, Taipei, Taiwan; 3) Graduate Institue of Life Sciences, National Defense Medical Center, Taipei, Taiwan; 4) Dept. of Psychiatry, Tzu-Chi General Hospital, Hualien, Taiwan.

Schizophrenia is a severe chronic mental disorder with a high genetic component in its etiology. Several mutations of synaptic genes have been found to be associated with schizophrenia in the literature, including neuroligin gene family. In our previous study, we identified a rare missense mutation R215H of the neuroligin-2 gene (NLGN2) in a patient with schizophrenia. The missense mutation was shown to be a loss-of-function mutant in inducing GABAergic synaptogenesis in cell-based assay (Hum Mol Genet 201;20(15)3042-51) . To further characterize the pathogenesis of this mutation in schizophrenia in vivo, we generated a line of R215H knock-in mice using homologous recombinant gene transferring technology. Immunohistochemistry and Western blot analysis of the animal showed significant reduction of neuroligin-2 protein in the cerebral cortex, hippocampus, and cerebellum of the transgenic mice. A series of behavioral tests showed that the male transgenic mice had significant increased pre-pulse inhibition (PPI) compared to the wild type animal. This enhanced PPI was not observed in female transgenic mice. Morris water maze test showed no impaired memory in both male and female transgenic animals compared to the wild type animal. Furthermore, enhanced social interaction activities and contact time were observed in both male and female transgenic mice compared to the wild type. The transgenic animals seemed to be resistant to the methamphetamine-induced impaired PPI, but more susceptible to alcohol-induced impaired PPI. Several functional and behavioral characterization tests are under way. Our preliminary data suggest that the R215H transgenic mice may have impaired GABAergic interneuron function in their brain, and the behavioral characteristics of the animal might to some extent mimic the positive symptoms rather than negative symptoms of schizophrenia, which is consistent with the clinical symptoms of the affected patient who carried this mutation.

Identifying pathway-level pleiotropic effects in pancreatic cancer and Crohn's disease. *K. Aquino-Michaels[1], E.R. Gamazon[1], P. Evans[1], V. Trubetskoy[1], F. Innocenti[3], K. Owzar[4], H.K. Im[2], N.J. Cox[1].* 1) Department of Medicine, University of Chicago, Chicago, IL; 2) Department of Health Studies, University of Chicago, Chicago, IL; 3) Institute for Pharmacogenomics and Individualized Therapy, The University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Duke Department of Biostatistics & Bioinformatics, Duke University School of Medicine, Durham, NC.

Inflammation has long been considered the underlying basis to several complex traits and plays well-established roles in elevating risk to various cancer types. Given the clear heritability of complex traits, we hypothesized that there may be pleiotropic loci for both inflammatory diseases and cancer. To test this hypothesis, we used the SNP effects from the Wellcome Trust Case Control Consortium (WTCCC) Crohn's disease (CD) dataset to generate a polygenic CD liability score which we correlated to case control status in a set of 304 CALGB 80303 pancreatic cancer (PC) patients and 1425 controls. We report significant predictive ability of the Crohn's disease liability score in pancreatic cancer (area under the receiver operating characteristic (ROC) curve of 0.63). To better understand the biology driving this inflammatory signature built from CD, we developed SNP-pathways by annotating SNPs from the SCAN Database (scandb.org) and Regulome Database (regulomedb.org) to canonical pathways from the Molecular Signatures Database (broadinstitute.org/gsea/msigdb) based on their association to transcript levels or overlap with transcription factor binding regions. Using this annotation approach, a given SNP-pathway contained typically between 2-8% of the genome-wide SNP set. We computed liability scores (containing only subsets of β-values) for each SNP-pathway and assessed the correlation between a pathway specific score and PC case control status. Top pathways yield comparable area under the curve (AUC) to the full set (0.58-0.60 versus 0.63) and are all characterized as immune mediated.

1017W

Cell-specific enrichment metrics for overlap of signals from GWAS with DNase hypersensitivity sites. *D. Chasman, F. Giulianini on behalf of the CKDGen and BP Metabochip-ICBP consortia.* Division of Preventive Medicine, Brigham & Women's Hospital, Boston, MA.

SNP associations from GWAS are enriched in non-coding regions mapping to chromatin marks. Quantitative characterization of this enrichment by cell type may identify causal SNPs and help reveal the physiologic basis of a phenotype of interest. We propose quantifying enrichment as an odds-ratio (OR) comparing the odds of a phenotype's GWAS SNPs overlapping the chromatin marks of a particular cell with a reference odds. The reference odds may pertain either to reference SNPs mapping to chromatin marks of the same cell or to the same phenotype's SNPs mapping to chromatin marks of a reference cell. We also considered a related notion of specificity quantified by relative entropy (H), the amount of information in bits needed to distinguish the enrichment in chromatin marks of phenotype SNPs compared with reference SNPs. We explored these metrics in publicly available data from 123 cell types, in which 1.1-6.7% of autosomal HapMap SNPs used by GWAS studies map to DNase hypersensitivity sites (DHSs). Applied to the NHGRI GWAS catalog, the enrichment measures were consistent with known biology. For example, across all 123 cell types and using reference SNPs from the GWAS catalog excluding the phenotype of interest, breast cancer SNPs were most enriched in DHSs from mammary ductal carcinoma epithelial cells (62% SNPs, OR= 4.4, p=0.012, H=0.38) while SNPs for celiac disease or rheumatoid arthritis were most enriched in DHSs from T-regulatory cells (67-72% SNPs, OR=3.4-4.9; p=0.002-0.04, H=0.23-0.38). In a new scan of eGFR (i.e. kidney function) among a total of >130,000 samples, genome-wide significant SNPs were most enriched in DHSs from renal proximal tubule and cortical epithelial cells with ORs up to 3.7 -7.1 (45-72% SNPs, p=0.02-0.001, H=0.30-0.64). Similarly, genome-wide significant SNPs from a new combined metabochip+GWAS scan for blood pressure (BP) in up to 201,200 samples were most enriched in DHSs from microvascular endothelial cells with ORs up to 6.8-7.4 (75% SNPs, p=0.01-0.009, H= 0.60-0.66). For both eGFR and BP, SNPs with larger association p-values showed less cell-type specific enrichment in DHSs compared with reference SNPs from the GWAS catalog. This trend may be interpreted as evidence for a lower proportion of true associations or associations with pleiotropic effects shared with other phenotypes among less significant SNPs. The proposed framework may be extended to other choices for reference SNPs or chromatin marks, e.g. H3K4me3 sites.

1018T

Down-regulation of the acetyl CoA metabolic network in visceral and subcutaneous adipose tissue of diabetic but not healthy obese individuals. *H. Dharuri[1], P.A.C. 't Hoen[1,5], J.B. van Klinken[1], P. Henneman[2], J.F.J. Laros[1,4,5], M. Lips[3], H. Pijl[3], K. Willems van Dijk[1,3], V. van Harmelen[1].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, RC, Netherlands; 2) Department of Clinical Genetics, DNA Diagnostics Laboratory, University of Amsterdam, Amsterdam, The Netherlands; 3) Department of Endocrinology, Leiden University Medical Center, Leiden, The Netherlands; 4) Leiden Genome Technology Center, Leiden University Medical Center, Leiden, The Netherlands; 5) Netherlands Bioinformatics Center, Nijmegen, The Netherlands.

Obesity, a growing world-wide epidemic, is associated with decreased life expectancy due to associated metabolic and cardiovascular disorders. The expanded adipose tissue is thought to serve as the pathogenic link between obesity and type-2 diabetes. Furthermore, it has been shown that the accumulation of visceral adipose tissue (VAT) poses a greater metabolic risk than the subcutaneous adipose tissue (SAT). While a majority of obese individuals develop insulin resistance and type-2 diabetes, some remain metabolically healthy. We hypothesize that the biochemical mechanisms that underlie the function of adipose tissue can help explain the difference between healthy and diabetic obese subjects. To address this hypothesis, we utilized RNA-sequencing to analyze the transcriptome of samples extracted from VAT and SAT of obese female subjects undergoing bariatric surgery. A differential gene expression analysis between diabetic and non-diabetic individuals within the cohort pointed to important differences both in the VAT and SAT. Bioinformatic visualization techniques implicated acetyl coA metabolism. A workflow management software called Taverna was used to generate a gene set for acetyl coA reaction network using the KEGG database. Gene set analysis using the global test R package pointed to a statistically significant association with the phenotype. Multiple genes in the immediate vicinity of acetyl coA in the reaction network are down-regulated in diabetic obese subjects. To ascertain if the down-regulation of these genes is correlated to health status, we compared the pre and post-surgery (3 months after) expression levels of these genes in the SAT by qPCR. At this time the majority of diabetic obese women had a significantly improved metabolic health status. We observed a statistically significant up-regulation of acetyl-CoA acetyltransferase 1 (ACAT1), acetyl-CoA carboxylase alpha (ACACA), aldehyde dehydrogenase 6 family, member A1 (ALDH6A1), and methylenetetrahydrofolate dehydrogenase (MTHFD1) post-surgery in diabetic subjects, and the expression level of these genes increased to those observed in non-diabetic subjects. These represent novel loci associated with type-2 diabetes and recovery in the VAT and SAT of obese subjects. Moreover, our data suggest that acetyl coA metabolic dysregulation plays a role in the pathophysiology of type-2 diabetes in obese subjects.

Primary Progressive versus Bout Onset Multiple Sclerosis: GWAS and pathway-network analysis. *G. Giacalone[1], F. Clarelli[1], P. Brambilla[1], A. Osiceanu[1], M. Sorosina[1], V. Martinelli[1], M. Leone[2], S. D'Alfonso[2], G. Comi[1], F. Martinelli Boneschi[1].* 1) San Raffaele Scientific Institute, Milan, Italy; 2) University of Eastern Piedmont, Novara, Italy.

Background: Genetic contribution to the two different Multiple Sclerosis (MS) courses, Primary Progressive MS (PPMS) and Bout Onset MS (BOMS), has previously been hypothesized by epidemiological studies, but so far no single genetic marker association has been found. Aim: to identify single nucleotide polymorphisms (SNPs) associated to MS course by comparing PPMS and BOMS through a genome-wide association study (GWAS) and a pathway-network analysis approach. Methods: a total of 444 PPMS and 541 BOMS patients genotyped on two different platforms were merged on common autosomal SNPs (296,589). After applying standard quality controls, logistic regression analysis was carried out including age, age at onset, gender and the first principal component as covariates. A pipeline of multiple-pathway and network analysis was developed to move from SNPs, through gene-wise p-values (p), to biological enriched terms/networks and potential disease-modifier genes. In the pipeline we used Gene Ontology and KEGG databases and the following bioinformatic tools: proxyGeneLD, MetaCoreTM, GOSTAT, Genecodis, Pathway-Express. Results: ProxyGeneLD program mapped 296,589 SNPs to 16,583 genes according to linkage-disequilibrium structure (HapMap CEU II 23a/hg18) and computed gene-wise adjusted p. Genes with adjusted p <0.05 (n=958) were prioritized for those directly interacting with each other (MetacoreTM protein interactions database) and the final list (n=218) submitted to multiple-pathway and network analysis. The first 3 hubs of the network composed of 218 genes were HIF1A, ETS1, NOTCH1, known to be involved in angiogenesis, immunity and myelination. Multiple-pathway analysis produced 32 significant terms, the majority of which related to immune functions ('B cell mediated immunity', 'T cell receptor signaling', 'Leukocyte transendothelial migration', 'Cytokine production'), 'Canonical Wnt receptor signaling', 'L-glutamate transport'. Network analysis produced 11 significant networks, some of them enriched also in immune functions and Wnt signaling. Conclusions: in the comparison of PPMS vs BOMS patients, pathway and network analyses approach suggest a possible role of genes related to immune functions, Wnt signaling and myelination processes, which should be further investigated in additional studies.

Genome-wide analyses of TCF7L2 DNA occupancy across multiple cell lines point to genetic networks underpinning complex traits. *M.E. Johnson[1], J. Zhao[1], J. Schug[2], S. Deliard[1], Q. Xia[1], V. Guy[1], J. Sainz[3], K.H. Kaestner[2], A.D. Wells[4], S.F.A. Grant[1,2,5].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Genetics and Institute of Diabetes, Obesity and Metabolism, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Institute of Biomedicine and Biotechnology of Cantabria (IBBTEC), Spanish National Research Council (CSIC), Santander, Spain; 4) Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Variation at the *TCF7L2* locus is strongly implicated in the pathogenesis of type 2 diabetes (T2D) and cancer. We previously mapped the genomic regions bound by TCF7L2 using ChIP-seq in the colorectal carcinoma cell line, HCT116, revealing a highly significant over-representation of GWAS loci associated with T2D and cardiovascular disease among the TCF7L2-bound targets. We carried out ChIP-seq in HepG2 hepatoma cells, where TCF7L2 is abundantly expressed, and leveraged these data against six additional cell lines for which genome-wide TCF7L2 binding is now available from ENCODE. Analyzing each cell line in turn, we found strong evidence for enrichment of endocrine (including T2D), cardiovascular and cancer GWAS categories. Ingenuity pathway analysis detected enrichment of the 'T2D mellitus signaling' category in TCF7L2-bound genes in all cell lines except in HepG2 and HEK293, suggesting that neither the liver nor the kidney is the primary site of TCF7L2 influence on type 2 diabetes pathogenesis. In addition, we observed consistent under-representation of factors involved in beta-cell related functions within this 'T2D mellitus signaling' category but over-representation of members of the AKT pathway in other tissues within the same category. Finally, the lists of genes within key pathways that are consistently bound by TCF7L2 across multiple cell lines were also highly significantly enriched for genes implicated by GWAS. As such, our data strongly suggests that knowledge of TCF7L2 occupancy gives us insight in to multiple genetic vulnerabilities in important pathways influencing the risk of several complex diseases.

Pathway analysis reveals new insights to genetic risk for multiple sclerosis among smokers. *H. Quach[1], F.B.S. Briggs[1], L. Shen[2], C. Schaefer[2,3], L.F. Barcellos[1,2].* 1) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA; 3) Research Program in Genes, Environment, and Health (RPGEH), Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) is a complex neuro-inflammatory autoimmune disease. Despite progress through genome-wide association studies (GWAS), identifying the complete heritable risk component has proven challenging. There has been less success determining the environmental contribution, though tobacco smoke (TS) is a definitive risk factor. Collectively, much of the MS risk remains unknown and prior studies have not explored genetic heterogeneity in an environmental exposure context. Therefore, we sought to identify the biological mechanisms mediating pathogenicity among tobacco smokers. A multi-stage investigation was conducted using a large non-Hispanic White MS study in Northern California (1,084 cases, 10,832 controls), genotyped on the Illumina Infinium 660K BeadChip or Affymetrix Axiom array. Detailed TS exposure was available; MS cases who smoked before onset were considered smokers. Two GWAS were conducted: smokers (46% of cases, 40% of controls) and nonsmokers. Stringent quality control was imposed; 4571 and 4543 genes were associated ($p<0.05$) with MS risk among smokers and nonsmokers, compared to control groups, respectively. 2268 genes were specific to risk among smokers, and these loci underwent functional classification (DAVID 6.7). Using Gene Ontology, genes participating in ion transport (fold enrichment [FE]=1.4, p=0.0005) and acute inflammatory response (FE=2, p=0.006) were overrepresented. There was an enrichment of genes in several KEGG and PANTHER pathways: metabotropic glutamate receptor group III (FE=2, p=0.001); complement and coagulation cascades (FE=2, p=0.01); butanoate metabolism (FE= 2.4, p=0.02); nicotinic acetylcholine receptor signaling (FE=1.8, p=0.03) and *WNT* signaling pathway (FE=1.5, p=0.03). These pathways have not been previously implicated in MS, but play a role in physiological responses to TS. For example: TS negatively influences the coagulation cascade and activates thrombi formation; *WNT4* exacerbates TS induced proinflammatory cytokine release in bronchial endothelium. Recent work in MS murine models shows that upon local lung stimulation, autoreactive T cells migrate to the CNS with the aid of *Ninj1* receptors and induce inflammation. Interestingly, a missense *NINJ1* SNP was significantly associated with MS risk among smokers only (rs2275848: OR=1.4, $p<0.01$; PolyPhen: possibly damaging). Thus, our results suggest variation within genes related to physiological response to TS contributes to MS onset among smokers.

1022F

Regulatory networks reveal directed pathways enriched in disease-associated SNVs in complex diseases. *G. Quon[1,2], S. Feizi[1,2,3], D. Marbach[1], M. Mendoza[1,4], M. Kellis[1,2].* 1) CSAIL, MIT, Cambridge, MA; 2) Broad Institute, Cambridge, MA; 3) Research Laboratory of Electronics, MIT, Cambridge, MA; 4) Instituto de Informática, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil.

A major challenge in understanding the role of regulatory variation in human disease is to identify regulatory pathways that may be disrupted by single nucleotide variants (SNVs) located in regulatory elements in the genome. To address this challenge, we have identified candidate regulatory elements and inferred a directed human regulatory network using the ENCODE and Roadmap Epigenomics datasets. We then developed a probabilistic model that takes as input the aforementioned network and regulatory element locations, as well as the SNV association P-values from genome-wide association studies (GWAS). The model identifies SNVs highly ranked (by P-value) whose target genes form surprisingly long, or dense, pathways in the regulatory network, and computes posterior probabilities for disease relevance for each SNV and gene in the network.

We applied our model to two GWAS datasets from dbGaP: type 1 diabetes (T1D) and multiple sclerosis (MS). For T1D, 1276 (0.26%) SNVs and 423 (1.8%) genes were predicted as disease-relevant; for MS, 141 (0.044%) SNVs and 232 (1.0%) genes were predicted as disease-relevant. The disease genes formed five modules in T1D and three modules in MS.

For each disease, the model identified one key regulator that is not in *cis* with any disease-associated SNV, but is predicted to be disease-relevant because it connects the disease gene modules together. The MAZ regulator identified in the T1D dataset is an important regulator of the insulin gene: a variable number tandem repeat (VNTR) sequence several hundred base pairs upstream of the insulin transcription start site contains high-affinity binding sites for MAZ, and specific VNTR alleles have protective effects on T1D risk.

The SP3 regulator connects the disease gene modules identified in the MS dataset. Previous work has identified SP3 as substantially depleted in expression in several immune cell types in MS patients relative to control cell populations, consistent with MS as an autoimmune disease.

These results suggest our probabilistic model is a powerful tool for identifying disease-relevant pathways from GWAS data.

1023W

Currarino syndrome - Searching for factors modifying expression of MNX1. *I. Holm[1], T. Monclair[2], B. Stadheim[1], K.L. Eiklid[1].* 1) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Department of Pediatric Surgery, Oslo University Hospital, Oslo, Norway.

Currarino syndrome (CS), (OMIM#176450) is an autosomal dominantly inherited developmental disorder caused by incomplete rostral separation of the endo- and ectoderm. The condition is characterized by three main findings; a sacral bony abnormality, anal stenosis and a presacral mass. CS is associated with mutations in the MNX1 transcription factor gene (previously known as HLXB9) in familial cases. Penetrance is reduced and expression is variable within families. In sporadic cases less than one third of the patients have detectable MNX1 mutations. Clinical signs and symptoms are similar in familial and sporadic patients. We have detected mutations in MNX1 in all affected members of four Norwegian families, but in none of the six sporadic cases. MNX1 is one of many transcription factors working together in regulation of embryonal development. The transcription factor is expressed early in foetal life and is especially important for pancreatic development and development in the sacral region. It is assumed to play a role in neonatal diabetes (Bonnefond et al., 2013) although patients with CS do not have diabetes. We wanted to examine if transcription factors known to interact with MNX1 could lead to defective expression of MNX1 and thereby causing clinical CS features in the non-familiar cases. We searched for sequence variation in both translated and untranslated regions in the transcription factors already known to interfere with MNX1. We have so far looked at SOX17 (OMIM # 610928), SHH (OMIM # 600725), CDX1 (OMIM # 600746), ISL1 (OMIM # 600366) and PDX1 (OMIM # 600733). Preliminary results show no common SNPs shared by all six sporadic patients. We also searched for sequence variation in the highly conserved region upstream of the MNX1 to see if that could influence expression of MNX1 in non-familiar CS patients. aCGH with SNP-microarray were used to look for other regions with factors or genes explaining the symptoms in non-MNX1 patients. The complete result will be presented in the poster.

1024T

Analysis of GTF2IRD1's role in the craniofacial and neurological features of Williams-Beuren syndrome indicates an epigenetic control function. *S.J. Palmer[1], C.P. Canales[1], P. Carmona-Mora[1], F. Tomasetig[1], J. Widagdo[1], A.C.Y. Wong[2], G.D. Housley[2], P. Kaur[3], I. Smyth[4], A.J. Hannan[5], P.W. Gunning[1], E.C. Hardeman[1].* 1) School of Medical Sciences, Cellular and Genetic Medicine Unit, University of New South Wales, Sydney, Australia; 2) School of Medical Sciences, Department of Physiology and Translational Neuroscience Facility, University of New South Wales, Sydney, Australia; 3) Epithelial Stem Cell Biology Laboratory, Peter MacCallum Cancer Centre, Melbourne, Australia; 4) Department of Biochemistry and Molecular Biology, Monash University, Melbourne, Australia; 5) The Florey Institute of Neuroscience and Mental Health, University of Melbourne, Australia.

Williams-Beuren syndrome (WBS) is a neurodevelopmental disorder resulting from a hemizygous microdeletion within chromosome 7q11.23 involving up to 28 genes. Genotype-phenotype correlations in patients with atypical deletions have mapped the typical craniofacial dysmorphologies and most aspects of the cognitive profile to a pair of genes that encode the evolutionarily-related transcriptional regulators GTF2IRD1 and GTF2I. The gene *GTF2IRD1* was originally cloned and characterized in our laboratory and we have generated *Gtf2ird1* knockout mouse lines that have phenotypes reflecting aspects of the human disease. Similar to WBS patients, knockout mice have large lips and this phenotype correlates with the pattern of *Gtf2ird1* expression in facial tissue during mouse development. RNA-seq analysis of knockout lip tissue suggests defects of proliferation and differentiation that implicates GTF2IRD1 in the control of patterning and development in lip epidermis. *Gtf2ird1* is also expressed in discrete brain regions and sensory organs that correlate with other abnormalities in the knockout mice and WBS patients, including defects of motor coordination, hearing, exploratory drive and anxiety. Gene expression profiling in the corpus striatum of *Gtf2ird1* knockout mice shows changes in the activity of a set of immediate-early genes, indicating possible roles in adult neuron maintenance and the control of experience-induced gene activity. To understand how this may work at the molecular level, our biochemical experiments have shown that GTF2IRD1 negatively auto-regulates its own allele though direct DNA binding and utilizes protein interaction surfaces to cooperate with other DNA binding proteins. GTF2IRD1 also interacts with a specific set of chromatin modifying proteins that would explain its role in gene silencing. The GTF2IRD1 protein is subject to tight control of abundance and activity through SUMOylation and ubiquitin-mediated proteasomal degradation. Together, these data support a role for GTF2IRD1 in the neurological and craniofacial features of WBS and suggest that it regulates gene expression via epigenetic mechanisms.

1025F

A Disease Module Captures Novel Candidate Genes and pathways for Asthma. *A. Sharma[1,2], J. Menche[1,2], S. Ghiassian[1,2], A-L. Barabási[1,2,3].* 1) Center for Complex Networks Research and Department of Physics, Northeastern University, Boston, MA 02115, USA; 2) Center for Cancer Systems Biology, Dana-Farber Cancer Institute, Boston, MA 02115, USA; 3) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA 02115, USA.

To understand various complex disease mechanisms, we not only require cataloging of disease genes by current high-throughput technologies, but detail of cellular components that are influenced by these genes and gene products. Here, we propose a novel concept of disease module that aims to identify the local neighborhood of cellular network for a particular disease phenotype. We illustrate the disease module detection algorithm by identifying the asthma disease module. Further, we validate the module for functional and pathophysiological relevance, using both computational and experimental approaches. Asthma module provides a deeper knowledge of the potential candidate genes and pathways that drive the pathological processes. On one hand, asthma module is enriched with disease-associated variations and on other hand; the impact of asthma specific drug is limited to the disease module. The emergence of GAB1 signaling pathway with both genetics and therapeutics (glucocorticoid) influence establishes the potential of disease module algorithm for dissecting the complex diseases.

1026W

The generation of sex-specific allergy networks: Validation that allergic disease has sexual dimorphic origins. *J. Lasky-Su[1,2], W. Qiu[1,2], V. Carey[1,2], S. Weiss[1,2], B. Raby[1,2], D. DeMeo[1,2].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA.

Childhood allergy affects over 50% of children and has sexually dimorphic features that are evidenced in early childhood and into adolescence, including a higher prevalence of allergy and atopy in boys. A key characteristic of this sex difference is the consistently higher levels of total serum immunoglobulin E (IgE) observed in males. There is growing evidence that a portion of the underlying basis for the observed sexual dimorphism in allergic disorders is molecular, as heritability estimates for allergic phenotypes such as total serum IgE vary significantly for males and females (83% vs. 63%). Previously we examined the relationship between total serum IgE levels and genome-wide gene expression in 223 CAMP individuals and found striking differences by sex: 1) Sex stratified analyses revealed a significant correlation between IL17RB and IgE in males only ($r2 = 0.19$, p value= 8×10^{-8}); 2) There were 873 compared to only 154 transcripts that mapped to gene IDs for males versus females; 3) Pathway enrichment analysis found nominal levels of enrichment in 13 pathways for males and only 5 pathways for females and none of these pathways overlapped. Given these notable differences between males and females, we constructed sex-specific allergy networks using gene expression data from the 223 CAMP individuals and applying Weighted Correlation Network Analysis (WGCNA). We first constructed sex-specific allergy networks using a general co-expression network based on the Pearson correlation coefficient by measuring the concordance of gene expression measures. These correlation measures are used to define an adjacency matrix, which indicates the degree that two expression measures are connected. We then identified important allergy and sex-specific modules within the networks using hierarchical clustering and topological dissimilarity. Once the sex-specific allergy networks were generated, we identified similarities and differences between the networks using preservation methodologies, first by comparing the sex-specific dendograms and second by calculating summary measures of preservation (median rank and Z summary statistic). We found striking differences between the male and female allergy networks, identifying sex-specific biological pathways that contribute to allergy pathogenesis.

1027T

Gene network analysis of candidate loci for human anorectal malformations. *M. Garcia-Barcelo[1,3,4], E.H.M. WONG[2], C.H. NG[1], V.CH. LUI[1,4], M.T. SO[1], S.S. CHERNY[2,3], P.C. SHAM[2,3,4], P.K. TAM[1,4].* 1) Dept Surgery, Univ Hong Kong, Hong Kong, NA, Hong Kong; 2) Dept Psychiatry, Univ Hong Kong, Hong Kong, NA, Hong Kong; 3) Center for Genomic Sciences, Univ Hong Kong, Hong Kong, NA, Hong Kong; 4) 4Centre for Reproduction, Development, and Growth Univ Hong Kong, Hong Kong, NA, Hong Kong.

Anorectal malformations (ARMs) are birth defects that require surgery and carry significant chronic morbidity. Our genome-wide copy number variation (CNV) study had provided a wealth of candidate loci. To find out whether these candidate loci are related to important developmental pathways, we have performed an extensive literature search coupled with currently available bioinformatics tools. This has allowed us to assign both genic and non-genic CNVs to interrelated pathways known to govern the development of the anorectal region. We have linked 11 candidate genes to the WNT signaling pathway and 17 genes to the cytoskeletal network. Interestingly, candidate genes with similar functions are disrupted by the same type of CNV. The gene network we discovered provides evidence that rare mutations in different interrelated genes may lead to similar phenotypes, accounting for genetic heterogeneity in ARMs. Classification of patients according to the affected pathway and lesion type should eventually improve the diagnosis and the identification of common genes/molecules as therapeutics targets.

Comparison of gene expression induced by HIV-1 GAG peptides specific to HLA-A*01:01 and B*07:02 in PBMCs by mRNA-seq analysis. *L.R. Liu[1,2], P. LaCap[1], R. Capina[1], B. Liang[1,2], B. Fristensky[1,3], B. Ball[1,2], F. Plummer[1,2], M. Luo[1,2].* 1) HIV and Human Genetics Division, National Microbiology Laboratory. 1015 Arlington Street. Winnipeg, Manitoba. Canada R3E 3R2; 2) Department of Medical Microbiology, University of Manitoba. 745 Bannatyne Avenue. Winnipeg, Manitoba. R3E 0J9; 3) Department of Plant Sciences, University of Manitoba. 222 Agriculture Building University of Manitoba. Winnipeg, Manitoba. R3T 2N2.

Introduction: A subset of sex workers (CSW) enrolled in the Pumwani cohort in Nairobi, Kenya remain HIV negative despite repeated exposure through high risk sex work. Studies on genetic factors enriched within these highly HIV-1 exposed seronegatives (HESN) suggest this natural resistance to HIV-1 is multi-factorial, and associated with specific alleles of Human Leukocyte Antigens (HLA). HLA-A*01:01 was associated with reduced risk of HIV-1 infection, whereas B*07:02 was associated with increased risk. HLAs initiate cell-mediated immunity (CMI) by presenting antigens to T-cells. Systematic comparison of A*01:01 and B*07:02 HIV-1 Gag epitopes showed that A*01:01 recognized fewer epitopes than B*07:02, and recognition of more Gag epitopes is associated with susceptibility to HIV-1 infection. However, It is unclear whether the A*01:01 or B*07:02 and GAG peptide complex could differently induce downstream gene expression, and lead to differential T cell function. We conducted mRNA-seq analysis and compared gene expression induced by A*01:01 and B*07:02 specific peptide using PBMCs of an individual express both A*01:01 and B*07:02. **Approach:** PBMCs from a single blood draw was split into equal proportions, and stimulated with peptide NSSKVSQNY (A*01:01 specific) or SPRTLNAWV (B*07:02 specific). 8-hours post-stimulation, the PBMCs were harvested for RNA-seq analysis. RSEM (RNAseq by Expectation Maximization) workflow was used for read alignment, and transcript quantification. DESeq was used for differential expression analysis. **Results:** After correction for false-discovery, one gene was significantly differentially expressed, DEQ571357 (FDR P-value = 3.8×10^{-12}), and 190 gene-isoforms (FDR P-value ≤ 0.05). **Implications:** This study aims to inform vaccine design by evaluating host gene expression induced by HLA-specific epitopes. Significant differences were identified however the results need to be validated by qRT-PCR and in other A*01:01 and B*07:02 co-expressed individuals.

Protein altering variants found in ciliary and polarity genes in biliary atresia patients. *E.A. Tsai[1], C.M. Grochowski[2], L.D. Leonard[2], R.P. Matthews[3,4], K.M. Loomes[3,4], B.A. Haber[5], N.B. Spinner[2,6], M. Devoto[3,7,8,9].* 1) Genomics and Computational Biology Graduate Group, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA; 4) Division of Gastroenterology, Hepatology and Nutrition, The Children's Hospital of Philadelphia, Philadelphia, PA; 5) Hepatology, Infectious Diseases Clinical Research Department, Merck Research Laboratories, North Wales, PA; 6) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Perelman School of Medicine, Philadelphia PA; 7) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 8) Department of Biostatistics and Epidemiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 9) Department of Molecular Medicine, University La Sapienza, Rome, Italy.

Biliary atresia (BA) is a bile duct disorder that presents within the first few months of life and causes necroinflammatory obliteration of the extrahepatic biliary tree. Children with BA have severe liver disease, and BA is the most frequent indication for pediatric liver transplantation in the United States. BA is thought to result from a combination of genetic and environmental risk factors, but no specific gene responsible for BA has been identified yet. Absence of immotile cilia on the surface of endothelial cells is apparent upon inspection of intrahepatic as well as remnant extrahepatic bile ducts, suggesting a loss of cell polarity. Manipulation of polarity genes leads to biliary defects in model organisms, and some BA patients demonstrate other anomalies consistent with polarity defects. We compiled a list of genes that participate in the establishment or maintenance of cell polarity (n=280) as well as genes with a role in the composition or function of cilia (n=291). We hypothesize that rare or novel damaging mutations in these genes may contribute to the development of BA. We performed exome sequencing with the Agilent SureSelect All Exon V4+UTR capture kit on 30 Caucasian, isolated BA patients. Variant filtration was performed to analyze only variants with frequency ≤5% in the 1000 Genomes Project Phase I and the NHLBI Exome Sequencing Project (ESP). Notably, one male patient had a nonsense variant in the X-linked polarity gene, *ATP6AP1*. This variant, rs201620814, was not observed in 1000 Genomes, but heterozygous variants in 4/1949 females and a hemizygous variant in 1/1283 males in the ESP cohort (<0.1%) was observed. Additionally, mutations in vacuolar H^+-ATPase subunits have been shown to cause biliary defects in zebrafish. Another patient had two missense variants in trans in *DNAL1*, which encodes for part of the outer dynein arm of cilia. We have identified several other changes in polarity and cilia genes that we suspect are contributing to BA in these patients. Our results support the hypothesis that polarity and cilia genes may be important in BA etiology but also suggest a high level of genetic heterogeneity in this disorder.

Vascular tone pathway in relation to primary open angle: results from the NEIGHBORHOOD consortium. *L. Pasquale[1], S. Loomis[1], J. Kang[2], J. Bailey[3], J. Haines[3], B. Yaspan[3], M. Hauser[4], J. Wiggs[1], NEIGHBORHOOD consortium.* 1) Glaucoma Service, Massachusetts Eye & Ear Infirmary, Boston, MA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA Boston, MA; 3) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 4) Duke University School of Medicine, Durham, NC.

Background: Reduced ocular perfusion pressure and impaired autoregulation of ocular blood flow have been implicated in the pathogenesis of primary open angle glaucoma (POAG). Genome wide association studies (GWAS) of POAG have identified CAV1/CAV2, which codes for caveolins that are involved in vascular regulation. Biologic pathway analyses can enhance the power to discover biologically meaningful genetic markers associated with complex traits. We investigated whether a set of genetic markers of factors involved in setting vascular tone are associated with POAG. Methods: We used Illumina 660W-Quad array platform genotype data and pooled p-values from 3,108 POAG cases and 3,430 controls from the combined the National Eye Institute Glaucoma Human Genetics Collaboration consortium and the Glaucoma Genes and Environment study. We compiled a set of single nucleotide polymorphisms (SNPs) in 186 genes related to vascular tone that were determined with KEGG pathways or previously identified in GWAS for blood pressure. We analyzed the association between these SNPs and POAG using both a pathway- and gene-based approach with the Pathway Analysis by Randomization Incorporating Structure analysis software package, which performs a permutation algorithm to assess the statistical significance of genes and pathways relative to randomly generated genes and pathways of comparable size, structure and linkage patterns. Results: The vascular tone pathway was not associated with POAG overall or the POAG subtypes defined by type of visual field loss (paracentral [n=224 cases] or peripheral loss [n=993 cases]) (permuted $p \geq 0.20$). In addition, results were similarly null in men and women (permuted $p \geq 0.81$). In gene-based analyses, two genes had nominally significant permuted gene p-values <0.05 in almost all analyses by subtype and gender: CAV1/CAV2 (permuted gene $p \leq 0.01$ for all outcomes), PRKAA1 (permuted gene $p \leq 0.05$ for all outcomes); in addition, 4 of the 8 genes that were associated with overall POAG at p<0.001 were those coding for factors that closely interacted with the caveolins. Conclusions: Although the overall vascular tone SNP set did not show significant associations with POAG, the gene-based analyses confirm the previously identified CAV1/CAV2 gene and suggest a possible role of caveolins and related factors in POAG pathogenesis.

1031F

Polygenetic Risk Model Suggests a Protective Effect of Lipid Genes on Plasma Glucose and HbA1c levels. *J. Fu[1], N. Li[2], M. van der Sijder[1], C. Wijmenga[1], H. Snieder[3], M.H. Hofker[2].* 1) Genetics Dept, UMCG, University of Groningen, Groningen, Netherlands; 2) Molecular Genetics, UMCG, University of Groningen, Groningen, Netherlands; 3) Epidemiology Dept, UMCG, University of Groningen, Groningen, Netherlands.

Background and hypothesis: Dyslipidemia is strongly correlated with raised glucose levels and type 2 diabetes (T2D), although the causal nature of the correlation and the role of dyslipidemia genes on T2D are still unclear. The advances made by genome-wide studies are allowing the use of a polygenetic risk score to assess the impact of lipid genes on T2D or related traits. Methods: We studied 95 common genetic variants that were robustly associated with triglyceride (TG), total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C) or high-density lipoprotein cholesterol (HDL-C). We included 13,107 subjects from the LifeLines cohort and calculated the polygenetic scores of blood lipids per individual. We computed the Spearman correlation between each genetic score and fasting plasma glucose and HbA1c levels. Results: Despite the positive correlation between dyslipidemia and HbA1c, surprisingly the individuals carrying a higher triglyceride genetic risk seemed to have lower HbA1c levels (r=-0.025, p=0.009). Conditional on blood lipid levels, this negative correlation became not only stronger for HbA1c (r=-0.043, $p=2.3\times10\text{-}6$) but also significant for fasting glucose level (r=-0.051, $p=8.6\times10\text{-}8$). We also consistently observed that the higher genetic scores of TC and LDL-C were correlated with lower HbA1c levels ($p=7.2\times10\text{-}4$ and p=0.003, respectively). Conclusions: In the Lifelines cohort, our polygenetic risk model suggests that genes associated with dyslipidemia may have weak protective effects on plasma glucose and HbA1c levels. This protective effect is pleotropic and independent of all types of lipid.

1032W

Molecular intermediate phenotype mapping of IL-6 and TNFα levels reveals genes critical for chronic systemic inflammation. *S.J. Schrodi[1], D. David[2], JK. Meece[2], DA. Vasco[1], JJ. Mazza[3], MH. Brilliant[1], JA. Smith[4].* 1) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 2) Core Laboratory, Marshfield Clinic Research Foundation, Marshfield, WI; 3) Clinical Research Center, Marshfield Clinic Research Foundation, Marshfield, WI; 4) Department of Pediatrics, University of Wisconsin-Madison, Madison, WI.

Background Numerous common diseases exhibit an underlying component of chronic systemic inflammation. Discovery of genetic variants that produce susceptibility to these diseases has many pitfalls, not the least of which lies in the clinical definition of disease which may or may not reflect pathological mechanisms at the molecular level. Hence, redefining phenotypes based on molecular characteristics may elicit more robust and lucid genetic association signals. This study uses a composite metric of the circulating levels of two important and correlated inflammatory cytokines, TNFα and IL-6, in the general population as a molecular intermediate phenotype. Both cytokines are important in the immunobiology of proinflammatory processes and have been directly targeted by biological therapeutics to remediate autoimmune conditions. To identify novel genes involved in regulation of TNFα/IL-6-mediated chronic inflammation, we performed a quantitative trait GWAS on TNFα/IL-6 levels in a genetically homogeneous population in Central WI, largely derived from Bavarian immigrants in the late 1800s. **Materials/Methods** Using the Meso-Scale Discovery platform, we measured levels of TNFα and IL-6 in plasma from 1015 individuals not taking immune-modulating therapies or having evidence of acute infection. A small number of genetic background outliers were removed from the sample set. The Illumina 660W-QUAD array was applied to all samples and a linear correlation test was applied for the genotypes at each of >500,000 SNPs to transformed TNFα/IL-6 concentration data. The VEGAS program was applied to individual SNP data to obtain gene-based association P-values. **Results/Conclusions** From roughly 18,000 genes evaluated, two statistically compelling regions emerged from the analysis: 1) the *RXFP3-SLC45A2* region on the short arm of Chr5 (P<1E-06), and 2) the *GPR31-CCR6* region on the long arm of Chr6 (P<1E-06). *RXFP3* encodes for a relaxin/insulin-like receptor, and may wield anti-fibrotic, and anti-inflammatory actions. *SLC45A2* encodes for a melanocyte differentiation antigen and is intimately involved in melanin synthesis (OMIM). Interestingly, Sellick *et al* (2005) mapped the *GPR31-CCR6* region as conferring strong predisposition to small vessel lymphocytic vasculitis within an extended family. Additionally, *CCR6* encodes for a chemokine receptor expressed on lymphocytes. These results may provide unique insight into the molecular mechanisms behind proinflammatory processes.

1033T

Uncovering the genetic architecture of complex traits using network approaches. *J. Choi[1], C. Cotsapas[1,2,3].* 1) Department of Neurology , Yale School of Medicine, New Haven, CT; 2) Department of Genetics, Yale School of Medicine, New Haven, CT; 3) Medical and Population Genetics, the Broad Institute of Harvard and MIT, Cambridge, MA.

Over the last decade, genome wide association studies (GWAS) have uncovered thousands of genetic variants influencing complex traits affecting all organ systems. However, it has proven difficult to infer which genes these variants are perturbing, so the challenge of uncovering underlying biological mechanisms remains elusive. We do not yet understand the genetic architecture of traits: do variants perturb entire pathways or other groups of interacting genes? How big are these groups? Are many distinct pathways involved or is a single molecular system sufficient to alter traits? We have developed a robust and flexible framework to address these questions by detecting groups of interacting genes perturbed by associated variants. We have previously observed that genes encoded in disease risk loci tend to interact, suggesting that risk variants modulate susceptibility by perturbing gene networks representing pathways [Rossin et al PLoS Genetics 2011]. Here, we project GWAS scores onto protein-protein interaction networks and use robust network clustering algorithms to look for regions of the overall interaction network enriched for disease association signal, indicating the presence of an interacting set of genes modulating susceptibility. Within this framework, we investigate several genetic architecture models by simulation: scenarios where either a single or multiple groups of interacting genes modulate risk versus no aggregation of signal in gene groups. We are able to recover both true positive and false negative associations, increasing the heritability explained by GWAS. Surprisingly, we also find that in models of multiple distinct susceptibility pathways, these are detected as a single large connected gene network. This appears to be a property of gene interaction networks and suggests that recent reports of large sets of interacting genes underlying disease susceptibility are in fact capturing multiple biological pathways. In two disease GWAS meta-analyses (Crohn's disease and multiple sclerosis) we find gene networks of size ~100 enriched for genetic risk, consistent with an architecture of cumulative genetic burden on molecular pathways. We also find that subsets of these components are expressed in different tissues, indicating that both diseases involve multiple pathways, not a single large group of genes. We are currently extending this framework to simultaneously consider both diseases and investigate pleiotropic effects in these networks.

Topological analysis of heterogeneous domain knowledge networks prioritizes genes associated with complex diseases. *D.S Himmelstein[1], S.E. Baranzini[1,2].* 1) Biological and Medical Informatics, University of California, San Francisco, San Francisco, CA; 2) Department of Neurology, University of California, San Francisco, San Francisco, CA.

Genome Wide Association Studies (GWAS) remain the preeminent strategy for identifying disease-associated variants, although small effect sizes combined with constraints on expanded sampling limit the pace of discovery. Gene prioritization approaches can increase the power of GWAS by increasing the prior probability of association, but generally only incorporate information from a single biological domain. Here we present a method to prioritize disease-associated genes from a heterogenous network which captures the diversity of biological entities and relationships underlying complex disease pathogenesis. We created a network of 11,249 genes/proteins, 30 tissues, and 44 complex diseases. Using publicly available resources, we connected the three entity types: gene-gene relationships indicate protein-protein interactions, gene-tissue relationships indicate tissue-specific gene expression; tissue-disease relationships represent known pathogenesis; and disease-gene relationships indicate reported associations from published GWAS studies. By adapting an existing algorithm, PathPredict, we provide a framework for computing the probability that a gene-disease pair represents a true association. The method calculates the prevalence of different network topologies connecting genes, tissues, and diseases. A logistic regression model identifies influential topological features and enables prediction of gene-disease pairs with an unknown association status. We assessed the performance of our method on six diseases - rheumatoid arthritis, inflammatory bowel disease, multiple sclerosis (MS), ankylosing spondylitis, psoriasis, and systemic lupus erythematosus - with multiple available large-scale GWAS. Our algorithm scored confirmed associations highly, yielding disease-specific AUC in the range of 0.70-0.79. Using our predictions as prior probabilities, we identified candidate genes that have not been associated to date. Relying on independent GWAS for discovery and validation, we highlight REL, JAK2, and TNFAIP3 as likely candidates in MS. The probability of the observed validation rate occurring by random prior estimates is 0.002, underscoring our ability to uncover novel associations. Integrating information across multiple domains through the use of heterogeneous networks significantly improved performance. Topological analysis of heterogeneous networks provides a potentially powerful new platform for discovery in human genetics.

Novel approach using gene set enrichment based on human genome-wide association study data implicates FXR/RXR activation as a common pathway affecting blood lipids levels and nonalcoholic fatty liver disease. *Y.M. Puentes[1,2], C.C. Powell[1,2], L.M. Yerges-Armstrong[3], M.F. Feitosa[4], L.F. Bielak[5], A.V. Smith[6], T.B. Harris[7], J. Liu[8], S.K. Musani[8], I.B. Borecki[4], P.A. Peyser[5], E.K. Speliotes[1,2], GOLD Consortium.* 1) Department of Bioinformatics and Computational Biology , University of Michigan, Ann Arbor, MI; 2) Department of Internal Medicine, Division of Gastroenterology, University of Michigan, Ann Arbor, Michigan 48109, USA; 3) Division of Endocrinology, Diabetes and Nutrition, Department of Medicine, University of Maryland School of Medicine , Baltimore, Maryland 21201, USA; 4) Division of Statistical Genomics, Department of Genetics, Washington University, Saint Louis, Missouri 63108, USA; 5) Department of Epidemiology, University of Michigan School of Public Health, Ann Arbor Michigan, 48109, USA; 6) Icelandic Heart Association, Kopavogur IS-201, Iceland; 7) Laboratory of Epidemiology, Demography, and Biometry, Intramural Research Program, National Institute on Aging, National Institutes of Health, Bethesda, Maryland 20892, USA; 8) University of Mississippi Medical Center, Jackson, Mississippi, 39213, USA.

Nonalcoholic fatty liver disease (NAFLD) is rapidly increasing in prevalence and will become the number one cause of liver disease worldwide by 2020. NAFLD is associated with high triglycerides (TG), high low-density lipoprotein cholesterol (LDL-C) levels, and low high-density lipoprotein cholesterol (HDL-C) levels. Both NAFLD and blood lipid levels are genetically influenced and may share a common genetic etiology. We aimed to identify genes and pathways enriched for genetic associations with both blood lipids and NAFLD using human genome wide association study (GWAS) data. We examined whether genome wide, significantly associated lipid SNP sets from publicly available HDL-C, LDL-C and TG GWAS analyses (N=99,000) were enriched for associations with NAFLD (N=7,126, Speliotes 2011). We then used gene set enrichment analysis (GSEA) as implemented in MAGENTA to identify pathways enriched in HDL-C, LDL-C, and TG GWAS analyses. These lipid pathways were then tested for enrichment in the NAFLD GWAS (N=7,126) and these enriched pathways were also tested for replication in an independent NAFLD GWAS (N=3,124, Palmer 2013). We found that TG (P=0.004) and LDL-C (P=0.02) but not HDL-C GWA SNP sets were enriched in NAFLD. We identified 58 pathways that were enriched in lipid GWAS data. Three of these were also enriched in the NAFLD GWAS (N=7,126) and one, FXR/RXR activation, also showed significant enrichment in another NAFLD GWAS (N=3,124). None of the three original NAFLD pathways were enriched for associations in control publically available GWAS analyses of diastolic and systolic blood pressure (N=275,000), body mass index (N= 249,796), and waist to hip ratio (N=77,167) suggesting that the enrichment was specific to NAFLD. Genes associated with NAFLD ($P<0.05$) in FXR/RXR activation fell into three functional categories: (1) VLDL Assembly: *MTTP, APOB, APOC3*, (2) Nuclear Related Processes: *PPAR-α, HNF1α, NR0B2/SHP* and (3) Hepatic Transport: *MRP2, AE2, ABCG8, ABCG5, OAT2.* Using a novel approach, we found that human genetic variation in or near genes involved in FXR/RXR activation affects both blood lipids and NAFLD in humans. These results suggest that genes that play a role in lipoprotein assembly, nuclear receptor biology, and hepatic transport when altered may affect NAFLD and thus could provide possible therapeutic targets for NAFLD prevention or treatment.

Identification of disease-relevant pathways among exome variants with a gene network based on the semantic similarity of mouse phenotypes.
F. Honti, C. Webber. MRC Functional Genomics Unit, Dept. of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK.

The identification of a functional association among a set of genes whose variants are implicated in the same disease can suggest cellular processes relevant to the disease mechanism. As the function of many genes is not known and their classification to pathways is scant, functional links between genes are often inferred from large-scale 'omics' data.

We have derived functional associations between human genes from diverse data types and examined their disease relevance. Annotation data were processed in the form of semantic similarity, which is a measure of relatedness between two genes as assessed by the similarity of their annotations. We combined the most informative data sources to form a functional-linkage network, weighting the different data types in proportion to their relative accuracy. Applying our framework, we have examined the network properties of sets of genes with *de novo* substitutions implicated in the same disease by exome sequencing studies.

We found that mouse knockout phenotypes were the most informative predictors of functional links between human genes. Accordingly, genes mutated in the same disease clustered most significantly in a gene network built on mouse phenotypes and in the integrated functional-linkage network, while genes mutated in controls did not form clusters. Combining three sets of genes implicated in autism by recent exome sequencing studies, we have observed distinct functional sub-clusters in the network, suggesting relevant biological pathways.

Functional associations between genes are often inferred from omics data, but the disease relevance of such data types, including protein-protein interactions and gene co-expression networks, has been unclear. The application of semantic similarity has enabled us to compare diverse data types and establish the value of mouse phenotypes. We present a framework for the identification of biological pathways disrupted in complex disorders and demonstrate the ability of this approach to functionally dissect the molecular variants underlying autism.

1037F

Gene-set enrichment analysis of gene expression associations with acute asthma control hints at candidate drug pathways.
D.C. Croteau-Chonka[1], W. Qiu[1], V.J. Carey[1], S.T. Weiss[1,2], B.A. Raby[1,3], Asthma BioRepository for Integrative Genomic Exploration (Asthma BRIDGE) Consortium. 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Maintenance of effective asthma control is critical for preventing exacerbations, or sudden declines in lung function. Loss of control results in considerable economic costs due to chronic treatment, acute hospitalization, and/or absence from work or school. By better understanding the biological underpinnings of acute asthma control (AAC) we can develop improved clinical and pharmaceutical approaches for maintaining effective disease stability.

To understand the relationships of gene expression with AAC, we performed differential expression analyses in a subset of 583 subjects from the Asthma BioRepository for Integrative Genomic Exploration (BRIDGE) cohort (62% male, mean age = 8.9 years) who had genome-wide gene expression data derived from whole blood RNA extracts and measured with the HumanHT-12 v4 Expression BeadChip. AAC was represented by a modified version of the clinically validated Asthma Control Test (mACT) score. After non-specific filtering, 10,701 probes (one per gene) were tested for linear associations with the normally distributed mACT, adjusting for batch effects using the first ten principal components of gene expression. A total of 548 probes were nominally associated with mACT ($P < 0.05$), but none were associated at a false-discovery rate (FDR) < 0.05.

To gain further biological insights, we performed a gene-set enrichment analysis (GSEA) of the ranked associations using the GSEA2 software and the 'C2' collection of 3,112 curated gene sets from the Molecular Signatures Database (MSigDB). We observed significant enrichment (FDR < 0.25) of 288 MSigDB gene sets among genes whose increased expression was associated with below-median mACT and two gene sets associated with above-median mACT. At an FDR < 0.05, the counts were 41 and zero, respectively (mean gene set size = 62). Enriched gene sets included ones related to expression in immune cells (e.g. plasma cells, eosinophils, B lymphocytes) and to changes in expression in response to non-chemotherapeutic drugs (e.g., glucocorticoids, prostaglandin E2, methoxyestradiol).

These preliminary results suggest the mACT phenotype is a biologically meaningful representation of AAC and hint at potential candidate pathways for drug treatment development. This work was supported by NHLBI grants RC2 HL101543, R01 HL086601-6.

Gene set signature of leprosy reversal reaction type 1.
M. Orlova[1], A. Cobat[1, 2], N. Thu Huong[3], N.N. Ba[3], N.V. Thuc[3], J. Spencer[4], Y. Nédélec[5], L. Barreiro[5], V.H. Thai[3], L. Abel[6,7,8], A. Alcaïs[6,7,8,9], E. Schurr[1,2]. 1) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 2) Departments of Human Genetics and Medicine, McGill University, Montreal, Quebec, Canada; 3) Hospital for Dermato-Venereology, Ho Chi Minh City, Vietnam; 4) Department of Microbiology, Immunology and Pathology, College of Veterinary Medicine & Biomedical Sciences, Colorado State University, Fort Collins, CO, 80523-1619, USA; 5) Department of Pediatrics, Sainte-Justine Hospital Research Centre, University of Montreal, Montreal, Quebec, H3T 1C5, Canada; 6) Laboratory of Human Genetics of Infectious Diseases, Necker Branch, Institut National de la Santé et de la Recherche Médicale, U980, Paris, France; 7) University Paris Descartes, Imagine Institute, Paris, 75993, France; 8) St. Giles Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, The Rockefeller University, New York, NY 11065, USA; 9) URC-CIC, Hopital Tarnier, Paris, 75006, France.

BACKGROUND. While effective drug treatment of leprosy is widely available, some leprosy patients suffer from major nerve damage due to leprosy type 1 reversal reactions (T1R). T1R are sudden episodes of exacerbated local delayed-type hypersensitivity to *Mycobacterium leprae* in skin and/or nerves. The incidence of T1R varies widely from 6% to 67% of leprosy patients in different leprosy endemic settings. T1R is effectively treated by corticosteroids, yet neurological impairment persists in about one third to a half of all cases. Thus, early identification of patients at risk of T1R, and consequently at risk of neurological injury, is a major challenge in leprosy care. METHODS. We used whole blood cultures stimulated with high doses of *M. leprae* sonicate to assay transcriptional responses of leprosy patients. To avoid the problem of highly dysregulated inflammatory responses during acute episodes of T1R we enrolled cured leprosy patients who had undergone T1R more than five years before and compared their transcriptional response to *M. leprae* antigens with the one displayed by former leprosy patients that had remained T1R-free (retrospective arm). The gene sets that were preferentially regulated in former T1R patients were then validated in a cohort of 43 newly diagnosed leprosy patients of which 11 developed T1R over a three year follow-up (prospective arm). Transcriptome responses to *M. leprae* antigens at the time of enrolment were compared between patients who developed T1R and those who did not. RESULTS. We defined and replicated prospectively a T1R signature set of 44 differentially regulated genes. Three functional groups represented the majority of the T1R set genes: a) pro-inflammatory regulators; b) arachidonic acid metabolism mediators and c) regulators of anti-inflammation. The validity of the T1R gene set signature in the prospective arm directly demonstrated that T1R patients have an innate defect in the regulation of inflammatory responses to *M. leprae*. The T1R gene set appeared as molecular characteristic of T1R susceptibility and was consistent with a breakdown of communication between pro- and anti-inflammatory responses in T1R patients. The identification of the T1R gene set represents a critical first step towards a genetic profile of leprosy patients who are at increased risk of T1R and concomitant nerve damage.

1039T

Characterizing variation in inter-individual immune response by asthma and allergic disease status in a founder population. *M. Stein[1], C. Hrusch[2], G. Alkorta-Aranburu[1], K.A. Bailey[1], M. Çaliskan[1], C. Igartua[1], C. Kagan[1], K. Ross[1], E.E. Thompson[1], A. Sperling[2], C. Ober[1].* 1) Department of Human Genetics, University of Chicago , Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago IL.

Asthma is a common, heterogeneous disease of the airways, characterized by inflammation and dysregulated immune responses to inhaled allergens and early life environmental exposures. The etiology of asthma and atopy is complex, but involves both genetic and environmental factors, as well as their interactions. In particular, early life exposure to high levels of endotoxin can protect again the subsequent development of asthma and atopy in childhood. We initiated this study to characterize the genetic regulation of transcriptional response to endotoxin (lipopolysaccharide, LPS), a component of the gram-negative bacterial cell wall that stimulates the innate immune system via the TLR4/CD14 pathway. As a first step, we characterized transcriptional responses to LPS using a closed cell culture system in which 1 ml whole blood from each of 40 Hutterite school children (ages 6-14) was exposed to either 0.1/ml ug LPS + media or to media alone (null control). 15% of the children in this study were diagnosed with asthma and 30% were atopic (defined by at least 1 positive specific IgE); 12.5% of children were both asthmatic and atopic. RNA from LPS-treated and untreated samples was hybridized to the Illumina HT12v4 microarray platform. 14,442 probes, corresponding to 11,317 genes, were detected as expressed with $p<0.05$ in at least 20% of samples. At a false discovery rate (FDR) of 10%, we observed significant responses to LPS for 6,021 genes in non-asthmatic children and 909 in asthmatic children. 112 of those genes showed response to LPS only in asthmatic children, and was enriched for genes in the RIG1-like receptor pathway ($p=0.019$) (IPA, Ingenuity Systems, www.ingenuity.com). At the same FDR, we observed significant responses to LPS for 5,441 and 4,034 genes in non-atopic and atopic children, respectively. 841 of those genes showed significant response in atopic children only, and were enriched for genes in immunological disease pathways ($p= 0.0015$), inflammatory response pathways ($p=0.039$), and pathways in pattern recognition receptors of bacteria and viruses ($p=0.025$). Overall, peripheral blood leukocyte response to LPS identified differences in transcriptional response in individuals with asthma or atopy that may underlie some of the clinical features of these conditions. This work was supported by NIH grant HL085197.

Gene Network Analysis with GWAS Data Identifies Novel Lung Function Gene Set. *J. Li[1], B.A. Ong[2,3], J.M. McDonough[2], Z. Wei[4], C. Kim[1], R. Chiavacci[1], F. Mentch[1], J.B. Caboot[5], J. Spergel[6,7], J.L. Allen[2,7], P.M.A. Sleiman[1,7,8], H. Hakonarson[1,7,8].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Pulmonary Medicine and Cystic Fibrosis Center, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Pediatric Pulmonology, Tripler Army Medical Center, 1 Jarrett White Rd, Honolulu, HI; 4) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 5) Division of Pediatric Pulmonology, Madigan Army Medical Center, Tacoma, WA; 6) Center for Pediatric Eosinophilic Disorders, The Children's Hospital of Philadelphia, Philadelphia, PA; 7) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 8) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Pulmonary function reflects various pulmonary conditions and predicts morbidity and mortality in adults. While several studies have already been published on pulmonary function traits, these have mainly been carried out in adults of Caucasian ancestry leaving the genetic determinants of pulmonary function traits in the pediatric population and in African Americans, in particular, relatively unexplored. To identify novel genetic determinants of pediatric lung function, we conducted a genome-wide association study (GWAS) of four pulmonary function traits, including FVC, FEV1 FEV1/FVC and $FEF_{25-75\%}$ in 1556 children. Though no SNP reached genome-wide significance, we identified SNPs with notable trend towards association with the pulmonary function measures in both Caucasian and African American cohorts. We also replicated the previously reported *INTS12* locus association with FEV1 ($p_{meta}= 1.41\times10^{-7}$). We subsequently carried out gene network analysis for each trait using SNPs with P-value of $< 1.0 \times 10^{-3}$ in GWAS. We found that the glycoprotein gene set is associated with all four pulmonary function measures in our pediatric Caucasian cohort and the association was validated in our pediatric African American cohort and two reported adult cohorts. Its meta-analysis p-values range from 6.29×10^{-4} to 2.80×10^{-8} for the four pulmonary function traits tested. In our study, we provide the first comprehensive analysis of pulmonary function traits in pediatric population and African Americans and identified novel pulmonary function specific gene set in that population.

Genetics of the sphingolipid metabolism in hypertension. *M. Fenger[1,2], A. Linneberg[1,3], J. Jeppesen[1,3].* 1) University of Copenhagen, Copenhagen, Denmark; 2) Hvidovre University Hospital, Hvidovre Denmark; 3) Glostrup University Hospital, Glostrup Denmark.

Several attempts to decipher the genetics of essential hypertension have been done, but only a few genes have been identified. Unsolved population heterogeneity and the insufficiency of the prevailing monogenic approach to capture genetic effects in a polygenic condition are the main reasons for the modest results obtained. The physiologically heterogeneity of diastolic and systolic blood pressures was resolved by partition of the study population by combined latent class analysis and structural equation modelling into an ensemble of 14 physiological more homogeneous subpopulations. Two-gene interactions were evaluated for the sphingolipid metabolic network, and he phosphatidate and redox metabolic networks by variance decomposition and by a information theory approach. On average more than 5,000 highly significant interactions were detected by variance decomposition in each of the subpopulations including 160 single nucleotide polymorphisms (SNP) in 82 genes. The number of interactions were reduced to less than 0.5% by only including interactions with significant mutual information. The analysis suggests that acid ceramidase and sphingosine kinase-1 to be functional hubs in blood pressure regulation. Of the 675 interactions with significant weighted mutual information 38 increased the prevalence of hypertension (diastolic and/or systolic), while 27 decreased the prevalence of hypertension in the study population. These interactions included genes from the networks mentioned above in a complex pattern of specific genotypes. Thus, the sphingolipid metabolic network was established to be of significance in regulating the blood pressure by itself and by integrated interaction with the phosphatidate and redox genetic networks.

Characterization of gene expression biomarker signatures for use as an Alopecia Areata Disease Activity Index (ALADIN). *J.E. Cerise[1], A. Jabbari[1], J.C. Chen[2,3], M. Duvic[6], M. Hordinsky[7], D. Norris[8], V. Price[9], J. Mackay-Wiggan[1], R. Clynes[1,4,5], A.M. Christiano[1,2].* 1) Depart of Dermatology, Columbia University, New York, NY; 2) Depart of Genetics & Development, Columbia University, New York, NY; 3) Joint Centers for Systems Biology, Columbia University, New York, NY; 4) Depart of Internal Medicine, Columbia University, New York, NY; 5) Depart of Pathology, Columbia University, New York, NY; 6) Dept of Dermatology, MD Anderson Cancer Center, Houston,TX; 7) Dept of Dermatology, University of Minnesota, Minneapolis,MN; 8) Dept of Dermatology, University of Colorado, Denver, CO; 9) Dept of Dermatology, UCSF, San Francisco, CA.

Alopecia Areata (AA) is a highly prevalent autoimmune disease in which the hair follicle is attacked by cytotoxic T lymphocytes. The accessibility of the target organ within skin biopsies has provided us the opportunity to develop a novel disease activity score based on quantitative composite gene expression signatures. Using both Affymetrix microarrays and RNA-Seq data analyzed using Bioconductor/R and Ingenuity Systems' IPA, we identified three striking gene expression signatures in total skin from both human AA and the C3H-HeJ mouse, namely the IFN response, including IFN-gamma and IFN-inducible chemokines, and a cytotoxic T cell (CTL) signature including CD8 and granzymes, implicating these effectors as the dominant inflammatory cells in AA pathogenesis, as well as a keratin network. To generate a functional biomarker from the AA transcriptome, we developed the Alopecia Areata Disease Activity Index (ALADIN), a multi-dimensional quantitative composite score. ALADIN was derived from expression levels of representative genes from both the IFN and CTL pathways and KRT network to generate a measure of the distance of AA transcriptional levels from a baseline obtained from the skin of healthy individuals. We anticipate that ALADIN will be useful as a dynamic functional biomarker to stratify and longitudinally track patients enrolled in observational and interventional clinical studies. The ALADIN score reduces the complexity of the transcriptome into a tractable multivariate index that can be used to quantitate and monitor patients' disease status and progression. We deployed ALADIN in our studies of mouse AA, and demonstrated that ALADIN scores provide a quantitative measure of observed disease reversal, and 'molecular distance to skin homeostasis' during the course of successful prevention and treatment of disease. ALADIN is currently being assessed in cross-sectional studies to validate its utility in human AA. We anticipate that ALADIN will be useful as a dynamic functional biomarker to stratify and longitudinally track patients enrolled in observational and interventional clinical studies.

Psoriasis susceptibility genes in patient with severe compared with mild phenotype. *P. Nikamo, M. Ståhle.* Department of Medicine, Dermatology Unit, Karolinska Institutet, Stockholm, Sweden.

Psoriasis is usually graded as mild (affecting less than 3% of the body), moderate (affecting 3-10% of the body) or severe (affecting more than 10% of the body). According to National Psoriasis Foundation the distribution of psoriasis severity are 67% mild, 25% moderate and 8% severe (http://www.psoriasis.org/). The degree of severity is generally based on the following factors: the proportion of body surface area affected; disease activity (degree of plaque redness, thickness and scaling); response to previous therapies; and the impact of the disease on the person. Several psoriasis GWAS have been published, but phenotypic stratifications are lacking. Our large patient material with detailed clinical and genotype information allows for different stratification procedures. Healthy controls (n=1750) are compared with patients with mild psoriasis (only topical therapy n=712) and severe psoriasis (systemic therapy n=543). The analysis involves genes known to associate with psoriasis. Major differences are detected, such as only patients with severe psoriasis associate with the IL23R (p=0.0007, OR=1.31, CI 1.12-1.53) and IL23A (p=0.0001, OR=2.04, CI 1.40-2.93) - genes in a key psoriasis pathway (the effective biologic ustekinumab is directed against IL23/IL12). In contrast, HLA-C and its putative functional partner ERAP1 (peptidase involved in trimming MHC Class I peptides) associates more with the mild phenotype. These are novel and rather dramatic data and additional genotypes are now being explored to dissect the differences between these phenotypes. Altogether, these findings indicate that genes participating in IL23 signaling play a significant role in the severity of psoriasis. Conversely, the characterization of non-MHC disease loci has been problematic, owing to the small effects of the underlying genetic variants. This can be overcome by careful phenotyping and characteristics of the material.

1044W

Validating trans-eQTLs using evidence of cis-mediation: a genome-wide analysis among 1,800 South Asians. *B. Pierce[1], L. Tong[1], R. Rahaman[1], L. Chen[1], M. Kibriya[1], M. Argos[1], J. Farzana[1], R. Shantanu[1], R. Paul-Brutus[1], R. Zaman[2], M. Rahman[2], J. Baron[3], H. Ahsan[1].* 1) Health Studies, Univ Chicago, Chicago, IL; 2) UChicago Research Bangladesh, Dhaka, Bangladesh; 3) University of North Carolina, Lineberger Comprehensive Cancer Center, Chapel Hill, NC.

Genome-wide studies of expression quantitative trait loci (eQTLs) indicate that the majority genes in the human genome show evidence of regulation by a cis-eQTL (i.e., cis-eSNP). However, less is known regarding the effects of genetic variants on expression of distant genes (trans-eQTLs), which are difficult to detect in genome-wide analyses for two primary reasons: (1) trans effects, on average, are weaker than cis effects and (2) a huge number of tests must be conducted to comprehensively assess the evidence for trans eQTLs, resulting in the use of stringent significance thresholds. Several large eQTL studies (>1,000 participants) have attempted to identify trans signals, typically using leukocytes as source of RNA. These studies have reported hundreds of 'significant' trans-eQTL signals, but only a fraction of these signals have been identified across multiple studies. While there are many explanations for this lack of consistency for trans findings, this observation highlights the difficulty of identifying true trans signals with confidence. In this work, we use data on genome-wide SNP and mononuclear cell array-based expression data from ~1,800 Bangladeshi individuals to (1) characterize the cis- and trans-eQTL patterns among South Asians and (2) demonstrate how identified trans signals can be validated by assessing evidence for cis-mediation. We first used standard eQTL methods to identify cis and trans signals using a false-discovery rate (FDR) of 0.05. Among the 448 independent putative trans-eSNPs we identified, we could classify 52 of these as cis-eSNPs (defined as r2 >0.8 with the lead eSNP for a cis-eQTL signal). For each of these 52 SNPs showing both cis and trans associations, we estimated the trans association both with and without adjustment for the cis-transcript, a potential mediator of the trans effect. For approximately half of these signals, the magnitude of the trans-eQTL association was drastically reduced (fold change >60%) after adjustment, implying that the trans effect is mediated by a measured cis-transcript. For weaker trans signals that did not surpass the FDR threshold, we show that cis-mediation analysis can identify a subset of these signals that are likely to be true effects. In conclusion, assessing evidence for cis-mediation is a promising and straightforward approach for validating trans signals and enhancing trans-eQTL discovery. This approach may be especially useful when ideal replication data is not available.

Transcriptome analysis of CD4+ lymphocytes in asthmatics with or without depression. *J. He, T. Wang, Z. Liang, X. Xiong, Y. Yang, Y. Ji.* Department of Respiratory, Sichuan University, Chengdu, Sichuan, China.

Rationale: Cumulative studies have shown that asthma is positively associated with depression. The underlying mechanisms are poorly understood. Assuming common pathophysiological mechanisms especially immune mechanisms exist, the aim of this study was to determine the common pathways between asthma and depression using the global gene expression pattern of CD4+ lymphocytes from asthmatics with or without depression. Methods: Four groups of subjects (Non-depressive asthmatic, NDA; Depressive asthmatic, DA; Depression, DE; and Healthy control, HC) consisted of 6 participants in each group were studied. Peripheral CD4+ lymphocytes were isolated and the global transcriptome profile was performed using the Agilent SurePrint G3 Human GE 8x60K Microarray. Experimental data analyses were performed using the software R and Bioconductor. Genes with expression level of at least ± 2.0-fold change and a false discovery rate ≤ 0.05 were defined as statistically significant changes. Functional analysis and pathway enrichment analyses of differentially expressed genes were performed using the Ingenuity Pathway Analysis (IPA). Results: A total of 1145 differentially expressed genes were identified in any of the AS vs. HC, DA vs. HC, or DE vs. HC comparisons after corrected for multiple comparisons. Among these genes, 148 genes were demonstrated as differentially expressed genes only in DA vs. HC. Gene pathway analysis using these 148 genes identified six significant biological processes: Acute Phase Response Signaling, Nicotine Degradation III, Melatonin Degradation I, Superpathway of Melatonin Degradation, Serotonin Degradation and Nicotine Degradation II. Conclusion: The use of microarray analysis to identify genes commonly differentially expressed in CD8 cells in non-depressive asthmatic; depressive asthmatic and depression groups may provide a foundation for further studies on the pathogenesis of co-exist of asthma and depression. The results of this study shed new light on the common molecular mechanisms of asthma and depression and may provide theoretical clues for further pathophysiological and clinical therapeutic studies.

Genetic variation in the ER stress response network in the mouse. *C.Y. Chow, D.D. Riccardi, X. Wang, M.F. Wolfner, A.G. Clark.* Dept Mol Bio & Gen, Cornell Univ, Ithaca, NY.

The endoplasmic reticulum (ER) is responsible for synthesis and maturation of many proteins essential for cellular function. ER dysfunction can have devastating consequences when misfolded proteins accumulate in the ER, resulting in "ER stress" associated with pathogenesis of diseases from diabetes to neurodegeneration. To understand the contribution of ER stress resistance to disease, it is important to determine the extent of natural variation in ER stress resistance. Previous studies in human cell lines and Drosophila demonstrate that there is extensive variation in ER stress response, but comparable data in mouse is conspicuously absent. To characterize the variation in ER stress transcriptional response in mouse, we studied the eight genetically diverse inbred laboratory mouse strains that had been employed in the Collaborative Cross. Mouse embryonic fibroblasts (MEFs) from each strain were exposed to tunicamycin, an ER stress inducing drug. RNA-seq was performed to identify transcriptional changes in response to ER stress by contrasts with RNA-seq runs of cells under drug-free control conditions. Many canonical ER stress genes showed inter-line differences in response, indicating that the core ER stress pathways may be more plastic than previously thought. To partition this regulatory variation into cis and trans effects, we measured ER-stress-induced gene expression by RNA-seq in MEFs from F1 hybrids of the original eight inbred lines, and quantified allele-specific expression across nearly every expressed gene. The results reveal a surprising degree of trans regulatory variation, consistent with the variability lying close to the head of the regulatory cascade. Whether the most important ER stress genes modulating variability in disease risk play these key regulatory roles remains to be demonstrated. But differences in cis vs. trans regulatory architecture of genes in a network such as ER stress may have important implications for effect sizes of allelic variants, the nature of mutation-selection balances, and the prospects for therapies that target single gene products.

Global Metabolite profiling and the Risk of Osteoporotic Fractures: A Systems Biology Approach by Integrating Genomics and Tissue-Specific Gene Expression Profiling, Proteomics and Metabolomics in Postmenopausal Caucasian Women. *YH. Hsu[1,2], S. Reppe[3], CL. Chi[4], D. Karasik[1], J. Brain[5], DP. Kiel[1], K. Gautvik[6].* 1) Hebrew SeniorLife Inst Aging Res and Harvard Medical School, Boston, MA; 2) Molecular and Integrative Physiological Sciences Program, Harvard School of Public Health, Boston, MA; 3) Oslo University Hospital, Ulleval, Norway; 4) Medical Informatics Center, Harvard Medical School, Boston, MA; 5) Dept. Environmental Health, Harvard School of Public Health, Boston, MA; 6) Department of Medical Biochemistry, Oslo University Hospital, Ulleval, Norway.

Metabolomics is the quantitative measurement of dynamic metabolic response to pathophysiologic stimuli or genetic modification making metabolome quintessence of biological processes. To identify metabolite signatures for osteoporotic fractures and to understand its underlying biological implication, we measured ~500 metabolites in bone tissue and serum from osteoporotic hip fracture patients (OP) and age-matched normal-bone mineral density controls. Bone tissues were obtained from trans-iliac biopsies in 84 post-menopausal Caucasian women. Transcriptome profiling of bone biopsies was measured by Affymetrix microchips. GWAS genotyping was done in all samples to identify variants associated with metabolites and gene expression. Metabolites were measured by three types of mass spectrometers (MS). MS signatures of metabolites were matched to a small-molecule library. Age, BMI, estrogen use, cigarette smoking, menopause age and medication were collected and used in statistical analyses. To find metabolite signature, we applied a support vector machine algorithm with a nonlinear classification and identified 12 endogenous metabolites significantly differed between OP and controls. These 12 metabolites are involved in fatty acid amides; lipid oxidation; bile acid metabolism; tryptophan metabolism and redox homeostasis. Among them, significant accumulation of 5 dicarboxylic fatty acids suggests potentially suppressed mitochondrial β-oxidation in OP. Higher levels of the cannabinoid (CB) receptors agonist, oleamide, were observed in OP, indicating a disruption of CB signaling. Serotonin (5HT) was also higher in OP. To further characterize underlying mechanisms, we performed regression analysis between transcriptome and these 12 metabolites, adjusted for covariates described above. The expression of 71 genes was associated with these 12 metabolites at $p < 5\times10^{-5}$. AR, FGF2, PRKAA2 and several G-protein coupled receptors expressions associated with oleamide, providing supportive evidence of the involvement of CB receptors in OP. A pathway enrichment analysis pointed out three distinct cellular functional pathways. In summary, we identified a 'signature' of 12 endogenous metabolites associated with osteoporosis in postmenopausal Caucasian women. We used the transcriptome to further characterize their functional implications. A replication study of metabolite signatures in ~1,000 Framingham Study participants is underway to further validate these findings.

1048T

Integrating Genome-Wide Association Data with a Protein-Protein Interaction Network to Define Chronic Obstructive Pulmonary Disease Gene Modules. *M-L.N. McDonald[1], M. Cho[1,2], M. Matthiesen[3], B. Harshfield[1], T.H. Beaty[4], C.P. Hersh[1,2], C. Lange[5], E.K. Silverman[1,2] on behalf of the COPDGene investigators.* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Aarhus University, Denmark; 4) Johns Hopkins School of Public Health, Baltimore, MD; 5) Harvard School of Public Health, Boston, MA.

Chronic obstructive pulmonary disease (COPD) is currently the third leading cause of death in the United States. Genetic association studies have identified several key genetic loci associated with this complex trait. The majority of SNPs tested in genome-wide association studies (GWAS) do not achieve conventional genome-wide significance but still may provide valuable information. Using systems biology approaches integrating genotype and protein-protein interaction (PPI) data, genes and proteins involved in the same disease have been shown to cluster together when centrality is measured by protein physical interactions. Therefore, we applied dmGWAS (Jia, P et. al. 2011, Bioinformatics, 27:94-102), a method that integrates GWAS results with PPI, to identify COPD modules related to case-control status in the COPDGene Study.

Non-Hispanic White (NHW) (Ncases=2,812, Ncontrols=2,534) and African American (AA) (Ncases=821, Ncontrols=1,749) participants were genotyped on the Illumina Human Omni Express chip. GWAS were performed separately for the NHW and AA participants adjusting for population substructure, smoking history and age of enrollment. Using the smallest P-value per gene (+/- 50kb), dmGWAS identified 11,815 modules for the NHW group and 11,841 modules for AA. The module score is based on the GWAS test statistics for all genes in the module and then normalized by randomly selecting modules with the same number of genes 100,000 times. These normalized module scores ranged from 4.7 (P=1.5E-6) to 11.8 (P<1E-16) in NHW and from for 2.6 (P=0.005) to 8.1 (P=2.2E-16) in AA. The average module size was 10.6 +/- 1.3 genes for the NHW and 9.1 +/- 1.0 for the AA. A total of 110 modules were significant in both NHW and AA analyses when the NHW served as a discovery group. These modules were comprised of 239 distinct genes that were input to Ingenuity Pathway Analysis (IPA®). The top highlighted molecular and cellular function, represented by 111 genes, was cell death and survival (P-value range: 2.1E-16 to 2.8E-4). IPA highlighted 90 different genes for their involvement with neurological disease (P-value range: 1.5E-17 to 2.7E-4), the top disease and disorder category. Future directions for this analysis include additional validation of the top modules using permutation and comparing these results to traditional pathway based analysis. Funding: P01HL105339, R01HL089856, and R01HL089897.

Using genome-wide SNP data, we assessed biologic pathways as annotated in the KEGG database for association with risk of primary open-angle glaucoma (POAG) overall as well as with the normal-tension POAG subgroup with increased susceptibility to optic nerve degeneration. Our pathway analysis included all SNPs in the GWAS to identify meaningful associations that did not meet the genome-wide significance threshold. The PARIS (Pathway Analysis by Randomization Incorporating Structure) algorithm used in this study creates a null distribution of random pathways to mimic the size and structure of the actual pathways. The algorithm uses this null distribution to determine whether statistical associations are due to the biologic properties of the pathway, or instead, its size and structure. We conducted a POAG case-control analysis of 3108 cases and 3430 controls from the GLAUGEN and NEIGHBOR studies genotyped on the Illumina 660W quad platform. We first analyzed each study individually for single-SNP associations using logistic regression models to test for association. A subsequent meta-analysis of the two studies was performed. After multiple testing correction, we found 14 pathways associated with risk of POAG overall (permuted $p<0.001$ for all pathways). These pathways were loosely grouped into three categories: metabolism, cellular adhesion and signaling, and autoimmune disorders. Twelve of these pathways contained the same HLA genes and after removal of these genes, 11 of the pathways were no longer significant, while the HLA gene set was highly significant ($p<0.001$). In the normal tension subgroup analysis 7 pathways were associated with disease risk ($p<0.001$) falling into 5 general categories: metabolism (butanoate and ketone bodies), amino acid synthesis, MAPK signaling; hedgehog signaling and glycosaminoglycan biosynthesis. Only the butanoate metabolism pathway was significant for both POAG overall and the normal-tension subgroup. The butanoate pathway includes enzymes responsible for GABA metabolism, which can influence ganglion cell function in the retina. Overall, these data provide insight into the complex genetic etiology of glaucoma-related optic nerve degeneration and provide hypotheses for future functional studies.

Gene Expression Profile of Synovial Fluid following Meniscal Injury; Osteoarthritis (OA) Markers Found. *D.D. Vance[1,3], L. Wang[2], E. Rampersaud[2], T. Guettouche[2], B.P. Lesniak[3], J.M. Vance[2], M.A. Pericak-Vance[2], L.D. Kaplan[3].* 1) Univ Miami Miller Sch Med, Miami, FL; 2) Hussman Institute for Human Genomics, Miami, FL; 3) UHealth Sports Performance and Wellness Institute, University of Miami, Miller School of Medicine, Miami, FL.

BACKGROUND: Meniscal tears predispose individuals to the development of osteoarthritis (OA). This is due in part to the mechanical changes that occur within the knee joint following meniscal injury. Additionally, molecular differences between arthritic and normal knee joints have been shown. It is, however, not clear when these molecular changes start to develop. We hypothesize that, in addition to the mechanical changes important molecular changes occur within the knee joint soon after the meniscal tear contributing to eventual development of OA. The purpose of this study is to characterize the gene expression profile of synovial fluid (SF) following a meniscal tear; looking for early expression of inflammatory and arthritis-related genetic markers. **METHODS:** SF was collected from 11 patients (<48yrs) undergoing an arthroscopic partial meniscectomy at the time of surgery. RNA was extracted from cell pellets precipitated from the SF. Gene expression analysis was completed using Illumina HumanHT-12 array and Lumi R code (Bioconductor) software. A Heat map identified patterns among gene expression profiles and pathway analysis was performed by Metacore software. T-tests with Bonferroni corrections compared subsets of genes between individuals with recent injury (< 2 months; short duration) versus longer time lapse (long duration) until meniscectomy. **RESULTS:** The top 5% genes expressed across all samples mapped to inflammatory and cytoskeleton remodeling pathways. Included in the most abundant genes; *LAIR 1, TMSB4X, CCR6, IL18 and IL10* all have been associated arthritic conditions previously. Clustering of 3 samples with short duration was observed from the heat map and when compared to those samples with long duration across a subset of 340 genes with previous links to inflammatory or arthritic conditions, the following showed significant differential expression ($p < 1.47\times10^{-4}$); *IL1A, ILF2, NFKB1, IL10RB, IL18, ILF3, IL13RA, BMP2K and IL10*. These data support the inception of changes early in the disease process as well as indicated continued changes in expression profiles over time from injury onset. **CONCLUSION:** Our results support the hypothesis that molecular changes predisposing meniscal injury patients to OA may occur earlier after injury than previously reported. These findings suggest the possibility for early interventional treatments to halt these molecular changes and reduce the susceptibility of patients to OA following a meniscal tear.

Genetic association study of adaptor protein complex 4 with cerebral palsy in Han Chinese population. *Q. Xing[1,2], H. Wang[1,2], T. Li[3], M. Chen[1,2], Q. Shang[4], D. Zhu[3], L. Wang[1,2], Q. Li[1,2], L. He[1,2], C. Zhu[3,5].* 1) Children's Hospital and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 2) Bio-X Institutes, Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders (Ministry of Education), Shanghai Jiao Tong University; Shanghai, China; 3) Department of Pediatrics, the Third Affiliated Hospital of Zhengzhou University; Zhengzhou, China; 4) Department of Pediatrics, Zhengzhou Children's hospital; Zhengzhou, China; 5) Center for Brain Repair and Rehabilitation, University of Gothenburg; Sweden.

Cerebral palsy (CP) is caused by injury or developmental disturbances to the immature brain and leads to substantial motor impairments. Adaptor protein complex 4 (AP-4) plays a key role in vesicle formation, trafficking, and sorting processes, which are critical for brain development and function. AP-4 consists of four subunits encoded by AP4E1, AP4B1, AP4M1 and AP4S1 gene respectively. AP-4 is identified to involve in trafficking of the a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptor. A number of studies have pointed to the involvement of AP-4-mediated vesicular trafficking pathway in the etiology of cerebral palsy, the most notable of which are the causative mutations identified in each of them that have recently been reported in different CP families. We therefore postulated that variations in AP-4 coding genes may exert an important role in the susceptibility to CP. In the present study, sixteen SNPs were geneotyped among 517 CP patients and 502 healthy controls from the Chinese Han population. We systematically analyzed the association of the AP4E1, AP4B1, AP4M1 and AP4S1 genes with CP on the basis of clinical characters. No significant associations were found between these variants and the risk of overall CP. Subgroup analysis showed that rs1217401 of AP4B1 was significantly associated with CP as a sequela of hypoxic-ischemic encephalopathy (HIE) (HIE + CP) (allele: $p=0.042151$; genotype: $p=4.46\times10^{-6}$). The current results indicate that 16 variants studied in four units of AP-4 have no detected effects on the susceptibility to overall CP, but AP4B1 is a susceptible gene for HIE +CP in the Chinese population.

Association analysis of candidate gene polymorphisms in Asthma, Rhinitis and Chronic Bronchitis: preliminary results from the GEIRD study. *C. Bombieri[1], F. Belpinati[1], A. Baldan[1], A.R. Lo Presti[1], G. Malerba[1], S. Accordini[2], L. Calciano[2], M. Ferrari[3], I. Perbellini[4], P.F. Pignatti[1], R. De Marco[2].* 1) Dpt. of Life and Reproduction Sciences, Section of Biology and Genetics, University of Verona, Verona, Italy; 2) Dpt. of Medicine and Public Health, Section of Epidemiology and Medical Statistics, University of Verona, Verona, Italy; 3) Unit of Internal Medicine, University of Verona, Verona, Italy; 4) Unit of Occupational Medicine, University of Verona, Verona, Italy.

Within The Gene Environment Interactions in Respiratory Diseases (GEIRD) study (Int Arch Allergy Immunol 2010;152:255-263), we performed an association analysis, in a large and accurately defined series of Italian subjects, to investigate the genetic involvement in the susceptibility to respiratory diseases. The study population included 1000 subjects (aged 20-66 years) from the general population, enrolled between 2007 and 2010, through a 2-stage screening process (postal questionnaire and clinical examination). Cases and controls were diagnosed on the basis of the answers to a detailed interview, to collect informations about family history for respiratory diseases, individual and ecological exposures, diet, smoking habits, medication, life-styles, and of pre/post bronchodilator spirometry, methacoline challenge, and skin prick tests. According to collected data, subjects were hierarchically classified as follows: 342 asthma, 7 COPD (with no asthma), 112 chronic bronchitis (with neither asthma nor COPD), 205 rhinitis (without asthma, COPD or chronic bronchitis) patients, and 312 controls (subjects without respiratory diseases). Classification was not possible for 22 subjects which did not completely meet diagnostic criteria of neither cases nor controls. A total of 971 subjects were genotyped, by a customized version of the GoldenGate Genotyping assay (Illumina), for a panel of 384 SNPs (Haplotype-Tagging-SNPs), representative of 63 candidate genes with a previous indication of possible association to the studied diseases. COPD subjects (due to the limited number) and unclassified subjects were not considered in the present analysis. A preliminary association analysis based on allele frequency comparison was performed. Presence of association (unadjusted $p<0.001$) was observed between polymorphisms of RAD50-IL13-IL4 region and past-asthma, PDE4D and ever asthma with atopy, PDE4D and chronic bronchitis with atopy, SPINK5 and rhinitis, GPR154 and chronic bronchitis. Moreover, considering only atopic subjects, ADAM33 polymorphisms showed association with ever asthma, total asthma, and rhinitis. Haplotype analysis is going on in order to confirm the association of these genes with the studied diseases.

Extending the population spectrum for nonsyndromic orofacial clefting: Recruitment and genetic analyses in an Arabian population from Yemen. *K.U. Ludwig[1,2], K. Aldurai[3], A.C. Boehmer[1,2], B. Lippke[1,2], N. Daratsianos[4], M.M. Noethen[1,2], A. Jaeger[4], M. Knapp[5], E. Mangold[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life and Brain Center, Bonn, Germany; 3) Faculty of Dentistry, University of Science and Technology, Sana'a, Yemen; 4) Department of Orthodontics, University of Bonn, Bonn, Germany; 5) Institute of Medical Biometry Informatics and Epidemiology, University of Bonn, Germany.

Nonsyndromic orofacial clefting (nsOFC) is a frequent congenital disorder, and has a genetically complex etiology. There are two common subtypes of nsOFC, namely nonsyndromic cleft lip with or without cleft palate (nsCL/P) and nonsyndromic cleft palate only (nsCPO). Research into the genetics of nsCL/P and nsCPO has identified numerous genetic susceptibility loci. The past genetic analyses have predominantly included diverse European and Asian populations. The present study now investigated a large and phenotypically well-characterized sample of Arabian origin from the Yemen population. Individuals included nsOFC patients (n=310), their relatives (n= 107) and unaffected controls (n=423). Patients were recruited within the context of surgical outreach programs that took place in Yemen between 2010 and 2012. Controls were recruited from blood donors of the same ethnic origin in the same area. Blood samples of patients/controls were transferred to the Institute of Human Genetics, Bonn where DNA was extracted. As research into nsCL/P has seen major advances by the recent application of genome-wide association studies (GWAS), we analyzed the genome-wide significant variants that have been previously been identified in European and Asian samples in the nsCL/P (n=252) and the nsCPO group (n=45) of the Yemeni patients. Twenty-four markers (SNPs, single-nucleotide polymorphisms) representing fifteen loci were genotyped using MassArray spectroscopy (n=23) or TaqMan assay (n=1). Loci included the European high-risk locus at 8q24.21 (rs987525) and the IRF6 locus. Statistical analyses using Armitage trend test revealed SNPs at nine of these loci to show nominal significant P-values in nsCL/P, the lowest P-value observed being 2.46×10^{-05} for rs987525, with an relative risk of 1.80 (95% confidence interval (CI): 1.27-2.55) for the heterozygous and 2.45 (95% CI: 1.54-3.90) for the homozygous genotype. In total, markers at three of the loci (8q24.21, 9q22 and 13q31) withstood correction for multiple testing. In the nsCPO group, no nominal significant associations were identified. This observation is consistent with results from other populations and might reflect the fact that there is little genetic overlap between nsCL/P and nsCPO. Our results reveal that a majority of nsCL/P risk loci identified in European and Asian ethnicities are also conferring risk for nsCL/P in the Arabian population.

Further evidence suggesting a role for variation in *ARHGAP29* in nonsyndromic cleft lip/palate. *L. Maili[1], A. Letra[1,2,3], J.B. Mulliken[4], S. Slifer[5], S.H. Blanton[5], J.T. Hecht[1,3].* 1) Department of Pediatrics, Pediatric Research Center, University of Texas Health Science Center Medical School at Houston, Houston, TX; 2) Department of Endodontics, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 3) Center for Craniofacial Research, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 4) Children's Hospital of Boston, Boston, MA; 5) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a common birth defect occurring in approximately 1 in 700 births. The complex etiology of NSCL/P reflects multiple genetic and environmental factors acting individually or in concert. A variety of research approaches, including candidate gene, genome-wide linkage, and genome-wide association studies (GWAS), have been used to identify the etiologic genes contributing to NSCL/P. While numerous genes have been implicated, only a few have been replicated across datasets. *ARHGAP29* was suggested as a candidate gene for NSCL/P for being located in close proximity to *ABCA4* (1p22), a gene previously identified in a GWAS of NSCL/P. Rare, potentially damaging, coding variants in ARHGAP29 were found in NSCL/P cases, and its expression was detected during craniofacial development in mice. Taken together, these findings suggest a role for this gene in NSCL/P. In this study, we investigated if variations in *ARHGAP29* were associated with NSCL/P. Five SNPs flanking and within *ARHGAP29* were genotyped in our NSCL/P datasets consisting of simplex and multiplex families of white NonHispanic (WNH, primarily western European) and Hispanic race/ethnicity. Family-based association tests were performed, stratified by ethnicity and family history of NSCL/P. P-values ≤ 0.01 were considered statistically significant. Results showed strong association of three *ARHGAP29* SNPs with NSCL/P in the WNH families. Two intronic SNPs (rs1541098 and rs3789688) showed association with NSCL/P in all WNH families (p=0.0005 and p=0.0002, respectively), and in the simplex WNH families (p=0.003 for both SNPs). A SNP in the 3' UTR (rs1576593) also showed an association with NSCL/P, in all WNH families (p=0.002) and the multiplex subset (p=0.002). No associations were found between variants in *ARHGAP29* and NSCL/P in the Hispanic datasets. This study further supports *ARHGAP29* as a candidate gene for human NSCL/P in families of Caucasian descent.

Association of GABRG2 rs211307 polymorphism with susceptibility to epilepsy in Asians: a multicentre case control study and meta-analysis.

B.S. Haerian[1], L. Baum[2], P. Kwan[3], S.S. Cherney[4], H.J. Tan[5], A.A. Raymond[5], Z. Mohamed[1]. 1) Pharmacology, University of Malaya, Kuala Lumpur, Malaysia; 2) School of Pharmacy, The Chinese University of Hong Kong, Shatin, Hong Kong, China; 3) Division of Neurology, Department of Medicine and Therapeutics, Prince of Wales Hospital, The Chinese University of Hong Kong, Shatin, Hong Kong, China; 4) Department of Psychiatry and The State Key Laboratory of Brain and Cognitive Sciences, The University of Hong Kong, Hong Kong, China; 5) Department of Medicine, Faculty of Medicine, Universiti Kebangsaan Malaysia, Kuala Lumpur, Malaysia.

The gamma-aminobutyric acid receptor subunit gamma-2 (GABRG2) gene encodes GABR-gamma2 protein, which has been implicated in susceptibility to epilepsy. Several studies have investigated whether the synonymous GABRG2 rs211037 polymorphism is a risk factor for various epilepsy types including febrile seizure (FS), idiopathic generalized epilepsy (IGE) and symptomatic epilepsy (SE), however results have been inconclusive. Therefore, we examined association of this polymorphism in FS, IGE, SE, and cryptogenic epilepsy (CE), through both a multicenter case control study and a meta-analysis. rs211037 was genotyped in Hong Kong Chinese and in Malaysian Chinese, Indian, and Malay participants. Genotypes of 5101 participants, of which 1769 were from Malaysia and 3332 from Hong Kong, were included in this case-control study. Of the 1179 patients, 66 percent; 13 percent;, and 21 percent; were Chinese, Indians, and Malays, respectively. Of the Chinese patients, 37 percent; were from Malaysia and 63 percent; were from Hong Kong. Significant association was observed between rs211037 polymorphism and susceptibility to SE (T vs. C p= 0.000003 and TT vs. CC, p=0.00001) or to epilepsy with FS (T vs. C p= 0.02 and CT vs. CC, p=0.02) in overall Chinese and to IGE in Chinese from Malaysia (TT vs. CC, p=0.01), but not to CE. Meta-analysis revealed a strong association between rs211037 with FS and SE in Asians for alleles (p=0.02, p=0.002 and p<0.00001, respectively) and for all genotype models. Our data suggests that GABRG2 rs211037 polymorphism is a risk factor for susceptibility to SE and FS in Asians, particularly in Chinese.

Asthma is a complex disease characterized by airway inflammation and bronchial smooth muscle contraction. About a dozen loci for asthma susceptibility have been identified by genome-wide association studies (GWAS) but more loci are likely contributing to disease risk. The myosin light chain kinase (*MYLK*) gene, which has been associated with asthma albeit not constituting a GWAS hit, encodes a key cytoskeleton effector that is highly expressed in asthmatic airway smooth muscle cells. Here we aimed to perform a replication of *MYLK* gene association with asthma in unrelated subjects from Spanish (n=3249) and Latino (n=3774) populations. A total of 30 tSNPs of *MYLK* were genotyped using iPLEX Gold assays (Sequenom) and used for imputation in the 1000 Genomes Project, in a sample of 606 asthma cases and 1258 controls from the Genetics of Asthma (GOA) study in the Spanish population (Sample 1). The top ancestry-adjusted associated SNP was followed up for replication in an independent Spanish sample of 320 cases and 250 controls (Sample 2) using TaqMan assays (Life Technologies). This SNP was also tested for replication in two additional study samples with genome-wide genotypes obtained from population-optimized SNP content Axiom arrays (Affymetrix). These studies included 264 cases and 551 controls of Spanish descent (Sample 3) and 1893 cases and 1881 controls of Latino ancestry from the Genes-environments & Admixture in Latino Americans (GALA II) study (Sample 4). Two non-coding SNPs in perfect linkage disequilibrium (r^2=1) were associated in Sample 1 after multiple testing adjustments (rs78442149 and rs77820417, $p=1\times10^{-6}$). The SNP rs77820417 was followed up, which replicated both in Sample 2 (p= 0.004) and Sample 4 (p=0.019), but not in Sample 3 (p=0.598). A random effects meta-analysis of the 7,023 individuals confirmed the strong association of rs77820417 with asthma (OR=1.64, 95% CI=1.01-2.69, $p=3.6\times10^{-7}$). These results support the importance of the *MYLK* gene in asthma susceptibility in Spanish and Latino populations. APOE e2 homozygous individuals are underrepresented among elderly Brazilian population. _M.S. Naslavsky[1], M.L. Lebrao[2], Y.A.O. Duarte[2], E. Amaro Jr[3,4], T.A.B. Mendes[4], A.S. Rodrigues[4], G. Bandeira[1], D. Schlesinger[5], L.T. Grinberg[3,6], C.K. Suemoto[3], R.E.P. Leite[3], R.E.L. Ferretti[3], C.A. Pasqualucci[3], J.M. Farfel[3], R. Nitrini[3], W. Jacob Filho[3], M. Zatz[1]._ 1) Human Genome and Stem Cell Center, University of Sao Paulo (USP), Sao Paulo, SP, Brazil; 2) Public Health Faculty, USP, Sao Paulo, SP, Brazil; 3) Medical School, USP, Sao Paulo, SP, Brazil; 4) Instituto do Cerebro, Hospital Israelita Albert Einstein, Sao Paulo, SP, Brazil; 5) Mendelics Analise Genomica, Sao Paulo, SP, Brazil; 6) Department of Neurology, University of California San Francisco, San Francisco, CA, USA.

The genome variation of healthy individuals undergoing aging has been the focus of worldwide interest and research. In order to enhance our understanding on human genetic variability our group is building a comprehensive collection of data from a cohort of elderly individuals from São Paulo (Brazil) , which has a mixed population of about 12 million inhabitants characterized by a great ethnic variability. Up to now, the cohort is composed by more than 1400 individuals who will be submitted to whole genome analysis. However, a preliminary analysis of apoliprotein E, a key protein in the metabolism and transport of lipoproteins and cholesterol and coded by chromosome 19 _APOE_ gene, has shown unexpected results and called our attention. _APOE_ variants have been highly associated with the physiopathology of late onset Alzheimer's disease (LOAD) and thus genotyping the different alleles became a standard procedure within studies of aging-related cognitive impairment. The main isoforms are _APOE_ e2, _APOE_ e3 and _APOE_ e4. While _APOE_ e4 is thought to increase AD risk, _APOE_ e2 has been considered to be a protective variant. DNA samples from 1447 individuals, 60 years old or older were collected, including cognitively healthy octogenarians. Up to now, 1000 _APOE_ genotypes were obtained by allele-specific amplification. Genotypic and allelic frequencies were derived by direct count. Surprisingly, although allelic frequencies were within the expected frequency according to other population studies, the _APOE_ e2 homozygous genotype was underrepresented and shifted from Hardy-Weinberg Equilibrium (HWE). The same analysis in a subset of 519 samples of individuals deceased from natural causes (aged 50 to 102) obtained from the largest brain bank of São Paulo showed no deviation from HWE. It is suggested that, even considering _APOE_ e2 an LOAD protective allele, carriers of _APOE_ e2 isoform may be at risk for early vascular disorders such as hyperlipoproteinemia. We hypothesize that early vascular disorders may increase the mortality rate of _APOE_ e2 homozygotes and, therefore, be responsible for the decreased frequency of individuals homozygous among older healthy subjects. We are currently increasing the sample size and analyzing the correlation between vascular causes of mortality and expected _APOE_ e2 homozygous frequency. We believe this may bring important contribution to our understanding on the role of _APOE_ e2 polymorphism in LOAD and vascular disorders susceptibility.

1058F

GWAS-nominated variants in homogeneous asthma sub-phenotypes. _E. Lavoie-Charland[1], J.-C. Bérubé[1], M. Laviolette[1], L.-P. Boulet[1], Y. Bossé[1,2]._ 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Québec, Canada; 2) Department of Molecular Medicine, Laval University, Québec, Canada.

Purpose: Asthma is a heterogeneous disease and subgrouping patients with similar clinical characteristics is likely to be important to improve our molecular understanding of this disease. Large-scale genome-wide association studies (GWAS) have identified many single nucleotide polymorphisms (SNPs) robustly associated with asthma. The goal of this study is to test GWAS-nominated SNPs in phenotypically similar asthmatic patients.

Methods: The number of clinical variables was reduced by factor analysis. With selected variables, k-means clustering was applied on 523 asthma patients to produce more homogenous subgroups of patients with asthma. Genotypes from 49 independent SNPs selected from previous GWAS on asthma were then compared between these phenotypically similar subgroups.

Results: Five variables were selected from the factor analysis. From these, four clinical sub-groups were produced: smoking history, low atopy and low lung function, high atopy, and young non-smoking with average atopy. Genotype frequencies of four SNPs were significantly different between sub-groups (p-value<0.05). One is located near IKZF4 and the others within RCBTB1, DPP10 and IL33. The frequency of the asthma risk allele for SNP on DPP10 (rs1435879) was less frequent in the highly allergic sub-group compared with the other sub-groups.

Conclusion: The genotype frequencies of four SNPs were different across homogeneous sub-groups of asthmatic patients. DPP10-rs1435879 was particularly different in a subgroup characterized as highly allergic. Whether SNPs in DPP10 can be used to modify the current asthma classification remains to be validated. Additional studies are needed to identify SNPs differentially distributed within asthma cohorts in order to improve current asthma classification, and ultimately offer targeted therapy.

1059W

Genetic profiles of lipid-associated polymorphisms for lipid-related traits for addressing constitution-based discrepancy in Koreans. _S. Cha, S.K. Chung, H. Yu, A.Y. Park, J.Y. Kim._ Med Res, KIOM, Daejeon, South Korea.

Abnormal lipid concentrations are risk factors for atherosclerosis and cardiovascular disease. Each constitutional type classified by Sasang constitutional medicine, a Korean conventional type of personalized medicine, has shown to have a distinctive pathological characteristic for cardiovascular disease risk. Here, we performed an association analysis between lipid-related traits and genetic variants from several genome-wide association studies according to Sasang constitutional types classified using an integrated diagnostic model consisting of face, body shape, voice, and questionnaire information. We estimated the associations of 26 lipid-associated variants in 20 loci using multiple regression analyses in 2 Korean populations, i.e., 8,597 individuals. Of the 26 variants, 12 were significantly associated with lipid levels, including LDL cholesterol, HDL cholesterol, and triglycerides. In subgroup analysis of Tae-Eum (TE) and non-Tae-Eum (NTE) types (each 2,664 individuals) on the basis of tertiles of probability values from the diagnostic model for TE type harboring predominant cardiovascular risk, the associations of 3 variants near APOA5-APOA4-APOC3-APOA1 (rs6589566 on triglyceride: p = 8.90E-11), APOE-APOC1-APOC4 (rs4420638 on triglyceride: p = 1.63E-05), and LIPG (rs2156552 on HDL cholesterol: p = 0.00428) remained significant in the TE type, while those of 3 variants near ANGPTL3 (rs10889353 on triglyceride: p = 0.00233), APOA5-APOA4-APOC3-APOA1 (rs6589566 on triglyceride and HDL cholesterol: p = 3.09E-06 and 0.000555, respectively), and LPL (rs6586891 on HDL cholesterol: p= 0.000200) remained significant in NTE type. Interestingly, the minor allele effects of the lipid-associated variants in TE type had a harmful influence on lipid risk, whereas those of the variants in NTE type had neutral influences due to a compensating effect among the associated variants. These findings supported that the genetic susceptibility to lipid risk presented by the minor allele effects of the variants may predispose TE type subjects to a high cardiovascular disease risk.

1060T

Pleiotropic effects of three SLE associated functional variants within IFIH1 linked to several autoimmune diseases. _J.E. Molineros, S.K. Nath._ Oklahoma Medical Research Foundation,Arthritis & Clinical Immunology Research Program, 825 Ne 13th, Oklahoma City, OK 73104.

Background Using admixture mapping, we recently identified three functional variants within IFIH1 (Interferon induced helicase 1) associated with Systemic lupus erythematosus (SLE)[Molineros et al. 2013. PLoS Genet 9, e1003222]. These three variants are rs1990760 (A960T), rs10930046 (H460R) and intronic SNP rs13023380. IFIH1 has been related to viral response and apoptosis functions. There is a close correlation between viral response and the development of autoimmune disease (AD). Therefore, ADs are likely to share susceptibility variants/genes, especially those related to viral immune response. In fact, the pleiotropic effect has been reported for IFIH1 missense variants rs1990760 with some ADs. Objective The objective was to extend the analysis of pleiotropic effects to six ADs and 2 non ADs, and to identify other possible novel AD associated variants within IFIH1. **Approach** We performed an imputation based association analysis using publicly available GWAS data from cohorts of European descent with six ADs: Rheumatoid Arthritis (RA, N=1999), Scleroderma(N=833), Psoriasis(N=919), Celiac Disease(CD, N=1716), Vitiligo(N=1089), Type1 diabetes (T1D, N=823), and two non-ADs: Myocardial Infarction (N=2967), Parkinson's disease(N=2000). All were compared with a common set of controls from the HRS(N=8833). Missing genotypes were imputed from 1000 Genomes variants using MACH. Only SNPs with imputation quality (Rsq >0.7) were used for this analysis. **Results** We identified significant associations with all three independent SNPs in all ADs. SNPs were not significant (P>0.05) in non-ADs. The rs1990760 was associated with Vitiligo (P = 8.16×10-5, OR = 0.83) and Psoriasis (P = 1.12×10-4, OR = 0.82); rs10930046 was associated with CD (P = 1.95×10-2, OR=1.40) and T1D (P =9.94×10-3, OR = 0.43); and rs13023380 was associated with Vitiligo (P = 6.17×10-5, OR= 0.83), Psoriasis (P = 7.15×10-3, OR=0.88), and T1D (P = 1.20×10-2, OR=0.88). Nine additional SNPs were identified but were correlated (r2>70%) with either one of these three SNPs. There was no haplotype effect of any combination of these SNPs with any other AD. **Conclusion** IFIH1 plays an important role in autoimmunity through multiple causal variants. In this study we confirmed association of three functional variants common to four ADs. Replication of the same multiple variants association with multiple ADs highlights the importance of IFIH1 for our understanding of the development of autoimmunity.

1061F

Are genes previously associated with schizophrenia also predictive of dimension-specific psychotic experiences in adolescence?
D. Sieradzka[1], R.A. Power[2], F. Dudbridge[3], E.L. Meaburn[1], R. Plomin[2], A. Ronald[1]. 1) Centre for Brain and Cognitive Development, Department of Psychological Sciences, Birkbeck, University of London, London, UK; 2) MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, King's College London, UK; 3) Faculty of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, UK.

Evidence suggests that a considerable amount of variance in schizophrenia liability can be accounted for by common genetic variants. As psychosis can be viewed as a continuum, here we test the hypothesis that these common variants associated with schizophrenia also influence sub-clinical psychotic experiences in adolescence. Our aim was to test whether polygenic risk scores from schizophrenia GWAS and specific single nucleotide polymorphisms (SNPs) previously identified as risk variants for schizophrenia (Bergen & Petryshen, 2012), were associated with dimension-specific psychotic experiences. Six dimension-specific psychotic experiences (self-reported: paranoia, hallucinations, cognitive disorganisation, grandiosity, anhedonia, and parent-rated negative symptoms), as measured by the Specific Psychotic Experiences Questionnaire (SPEQ), were assessed in a community sample of 2,130 16-year-olds. First, polygenic risk scores were calculated using estimates of the logs of odds ratios from the Psychiatric Genomics Consortium (PGC) GWAS mega-analysis of schizophrenia and polygenic risk analyses were conducted. Schizophrenia polygenic risk scores were a significant predictor of anhedonia at pT=.40, pT=.50 and pT=1 (all p-values<.008; corrected) and parent-rated negative symptoms at pT=.01 only (p-value=.004; corrected); however, not in the expected direction. The signal accounted for less than 0.5% of the variance in both dimensions. Second, individual SNP analyses were performed to test for associations between dimension-specific psychotic experiences and 28 SNPs previously associated with schizophrenia. A significant association was found between the SPEQ paranoia dimension and rs17512836 (TCF4; p=.02, post correction). Replication of these individual SNP analyses in an independent sample of 16-year-olds (N=3,427) drawn from the Avon Longitudinal Study of Parents and Children (ALSPAC) and assessed using the Psychotic-Like Symptoms Questionnaire (PLIKS-Q) failed to yield significant results. This study presents the first empirical test of whether aggregated common variants and single SNPs associated with schizophrenia are also predictive of dimension-specific psychotic experiences in adolescence. The results do not provide support for the hypothesis, but due to the limited power for identifying very small genetic effects, further research in larger samples sizes is required.

1062W

Association of *GALNT10* genetic variants with adiposity in African Americans.
M.E. Stromberg[1, 2, 3], J.M. Hester[1, 2, 3], P. Mudgal[1, 2], J. Li[1, 2], P.J. Hicks[1, 2, 4], B.I. Freedman[5], D.W. Bowden[1, 2, 4, 5], M.C.Y. Ng[1, 2]. 1) Center for Diabetes Research, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Molecular Genetics and Genomics Program, Wake Forest University School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC; 5) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Despite the higher prevalence of obesity (35.7%) in African Americans (AAs) compared to non-Hispanic whites (23.7%), genetic contributors to obesity in AAs remain poorly understood. Recent genome-wide association studies identified a region near the *GALNT10* gene as strongly associated with body mass index (BMI) in AAs. *GALNT10* is a member of the N-acetylgalactosaminyltransferase family and is located in the Golgi apparatus. The 20 known members of this family have been reported to have varying expression patterns in different tissues and multiple associations with metabolic traits. *GALNT10* is expressed in the hypothalamus, which regulates hunger. We examined multiple SNPs in the associated linkage disequilibrium (LD) region for association with BMI and other adiposity measures including waist circumference to hip ratio (WHR), visceral adipose tissue (VAT), subcutaneous adipose tissue (SAT) and VAT:SAT ratio (VSR). The 9 common variants tagging the LD block surrounding previous GWAS top hits and 12 exonic variants from the NHLBI ESP GO database were genotyped. Coding SNPs were prioritized for minor allele frequency (MAF) $\leq$0.05 with predicted functionality using the PolyPhen program. Variants were tested for association with BMI, WAIST, WHR, VAT, SAT and VSR in a meta-analysis of African American cohorts totaling up to 4,992 subjects. The most significantly BMI-associated SNPs were common (MAF between 0.32-0.44), noncoding SNPs; the most significantly associated was rs6890277 (β=-0.096(SE=0.02) p=3.64E-06), followed by rs7708584 (p=3.71E-05), rs815611 (p=4.65E-06), rs7719067 (p=6.99E-06), rs2033195 (p=7.26E-06), rs1366219 (p=9.91E-06), and rs4958361 (p=0.001). Associations were seen for BMI, not other adiposity traits. There was minimal evidence for association of coding or rare variants (individually or jointly with sequence kernel association test analysis). Common variants near *GALNT10* are associated with BMI (overall body size), but not other measures of adiposity, and coding variants in the gene do not contribute measurably to the association. Fine mapping of the *GALNT10* gene region will assist in detecting causal variants for BMI in the region.

Investigation of the rs2157719 SNP in the CDKN2B-AS1 gene in a Primary Open-Angle Glaucoma Brazilian population.
H.F. Nunes[1], J.P.C. Vasconcellos[2], V.P. Costa[2], N.I.T. Zanchin[3], M.B. Melo[1]. 1) CBMEG, University of Campinas, Campinas - SP, Brazil; 2) Department of Ophthalmology, Faculty of Medical Sciences, University of Campinas, Campinas - SP, Brazil; 3) Fiocruz, Curitiba - PR, Brazil.

Primary open-angle glaucoma (POAG) is a chronic neurodegenerative disease that leads to progressive damage of retinal ganglion cells resulting in visual field loss. Glaucoma is recognized as the main cause of irreversible blindness worldwide. Although the pathophysiology of glaucoma is not well understood, positive family history is one of the most important risk factors for glaucoma development. Single nucleotide polymorphisms (SNPs) have been widely associated with glaucoma, although their frequencies vary among different populations. CDKN2B-AS1 gene encodes a long noncoding RNA, and it is likely to play a role in regulating the expression of genes at the 9p21 locus through epigenetic mechanisms. CDKN2A encodes 2 proteins, p16INK4A and p14ARF, in different reading frames from alternative splicing of exon 1, whereas CDKN2B encodes p15INK4B. The proteins are cyclin-dependent kinase inhibitors and are involved in cell cycle regulation through the Rb and p53 tumor suppressor pathways. They also seem to be involved in inducing apoptosis in response to stress in terminally differentiated neurons, which is of particular relevance to glaucoma, a disease characterized pathologically by apoptosis of retinal ganglion cells and loss of their axons. The goal of this study was to investigate the distribution of the rs2157719A>G SNP, located in the CDKN2B-AS1 gene as a glaucoma risk or protective factor in a sample of Brazilian POAG patients. A case control study involving the genotyping of 147 POAG patients and 127 control subjects was performed by direct sequencing. The frequency of each of the three possible genotypes of rs2157719 was compared between POAG patients and controls and a significant difference was detected (p=0.00019). The minor allele frequency of rs2157719 (G) in our study group from Brazil was 32% in the POAG patients and 51% in control subjects, suggesting a protective effect previously described in other studies. Significant difference was detected in the allele frequencies between the POAG patients and controls (p=0.0019). However, the mechanism through which alterations in these gene might cause or prevent glaucoma is unknown. Overall, these data and observations imply that the G allele at this locus is possibly associated with protection against glaucoma in this sample of the Brazilian population.

Genetic Testing for Age-Related Macular Degeneration in an Armenian Population.
K.W.S. Small[1 2 3], A.A. Abraamyan[1 2 3], B.Z. Zanke[4], P.R. Ramamoorthy[4]. 1) Molecular Insight Research Foundation, Los Angeles, CA; 2) Cedars-Sinai Regenerative Medicine Institite, Los Angeles, CA; 3) Macula & Retina Institute, Los Angeles, CA; 4) Arctic Dx - Macula Risk; Bonita Springs, FL.

Purpose Age-related macular degeneration (ARMD) has a significant genetic influence, especially in Caucasian groups. The Armenian ethnogenesis dates back at least 3,000 years and is considered to be a genetically isolated population. Additionally, the Armenian genocide created a genetic bottleneck. Because of these demographics, we hypothesized that the genetic involvement in ARMD may be different than that of other Caucasian populations. To our knowledge, this is the first reported evaluation of the genetic contribution of AMRD susceptibility genes in an Armenian population. Methods A retrospective review was performed of 38 Armenian patients with wet (exudative) ARMD who had genetic analysis using the commercially available Macula Risk genotyping method. We obtained buccal cheek swabs which were sent to Advanced Diagnostic Laboratories for routine clinical testing of previously documented ARMD risk alleles: Complement Factor H (CFH) with 5 Single Nucleotide Polymorphisms, Complement Component 3 (C3), Age-Related Maculopathy Susceptibility 2 (ARMS2) and mitochondrially encoded NADH dehydrogenase 2 (MT-ND2). Each genetic component adds to a specific portion of a Macula Risk score, which predicts risk of developing advanced macular degeneration. This was compared to the Macula Risk genetic database of a 786 person Caucasian population with wet ARMD. The data was analyzed using Mann-Whitney U test to show differences in age and Macula Risk score. Chi squared test with two degrees of freedom was used to show differences in the genotypes (except MT-ND2, which only required a 2x2 table). Results The Mann-Whitney U tests showed no statistically significant difference between the Armenian and Caucasian data sets for Macula Risk score. The average age for Armenians (83.6) was higher than Caucasians (79.8), p=0.04. The Chi squared tests show no statistically significant difference between the genotypes. Conclusion In Armenian and Caucasian patients with wet ARMD, there is no difference between genotypes and Macula Risk score. Although we found no statistical significance, our data set is relatively small and may not be sufficiently powered. Additional analysis is necessary to evaluate the reasons contributing to the age difference within these populations. In patients who present with wet ARMD, we can find no genetic difference in the ARMD risk alleles in the Armenian population compared to the Caucasian population.

1065W

Associations of Age-Related Macular Degeneration Susceptibility Genes to Drusen.
K. Yamashiro[1], M. Yoshikawa[1], M. Miyake[1,2], H. Nakanishi[1,2], I. Nakata[1,2], N. Gotoh[1], Y. Kurashige[1,2], K. Kumagai[1], M. Oishi[1], A. Tsujikawa[1], R. Yamada[2], F. Matsuda[2], N. Yoshimura[1]. 1) Ophthalmology, Kyoto Univ Graduate Sch of Med, Kyoto, Japan; 2) Center for Genomic Medicine/Inserm U.852, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Large drusen, typical characteristics of age-related macular degeneration (AMD), is a great risk for developing vision-threatening choroidal neovascularization in the later stage of AMD. Although susceptibility genes for AMD have been indentified in previous studies, genetic background of large drusen is still unclear. We evaluated associations between large drusen and known 19 regions associated with AMD, using Japanese individuals recruited from the Nagahama Prospective Genome Cohort for the Comprehensive Human Bioscience (The Nagahama Study). Among the participants with age ≥50 years old, 1224 were analyzed for their drusen and genotyped using Illumina HumanOmni2.5M or HumanHap610K. After imputation based on 1000 Genomes Project data and our standard quality control, 3,139,805 single nucleotide polymorphisms (SNPs) were included for the analysis. Large drusen was observed in 377 participants, while 837 did not have large drusen in their both eyes. We screened 19 AMD susceptibility regions reported by the AMD Gene Consortium with an adjustment for age and sex. P-value of ≤0.05 was observed in CFH, COL8A, CFI, IER/DDR1, VEGFA, TGFBR1, B3GALTL, RAD51B, LIPC, C3, APOE, TIMP3, and SLC16A8. In contrast to the strongest susceptibility effect of ARMS2/HTRA1 to AMD, SNPs in ARMS2/HTRA1 did not show significant associations to large drusen. Furthermore, SNPs in ADAMTS9, C2/CFB/SKIV2L, COL10A1, TNFRSF10A, and CETP did not show significant associations to large drusen. Stepwise analysis revealed 9 genes associated with large drusen; C3, CFI, CFH, TIMP3, LIPC, APOE, TGFBR1, B3GALTL, and IER3/DDR1. Our findings that some strong susceptibility genes for AMD did not show significant associations to large drusen suggest that roles of AMD susceptibility genes might be different in the early stage of AMD and in the late stage of AMD.

1066T

Positive Associations of ZIC2, RASGRF1, and SHISA6 Gene with High Myopia in Japanese.
M. Yoshikawa[1,2], K. Yamashiro[1], M. Oishi[1,2], M. Miyake[1,2], Y. Akagi-Kurashige[1,2], K. Kumagai[1], I. Nakata[1,2], H. Nakanishi[1,2], A. Oishi[1], N. Gotoh[1], A. Tsujikawa[1], R. Yamada[1], F. Matsuda[2], N. Yoshimura[1], the Nagahama Study Group. 1) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Center for Genomic Medicine Inserm U.852, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Introduction: Myopia is the most common ocular disorder in the world. High myopia, with a prevalence of 1%-2% in the general population, is distinguished from common myopia by excessive increase in axial length of the eye ball and is associated with various ocular complications leading to blindness. Recently, 24 new chromosomal loci associated with refractive error and common myopia were reported in a large scale multi-ethnic genome wide association study (GWAS) and several loci were confirmed by another GWAS dealing myopic patients in Caucasian population. Therefore, we conducted a case-control study to investigate whether these genetic variations, which confer risk of common myopia in Caucasians, were associated with high myopia in Japanese or not. Because choroidal neovascularization (CNV) is the most common cause of visual loss related to high myopia, we also evaluated the contribution of those genetic variations to the occurrence of CNV among the high myopic patients group. Methods: 5 single nucleotide polymorphisms (SNPs) from 5 candidate genes; TOX, RDH5, ZIC2, RASGRF1 and SHISA6 reported in both of the two previous GWASs were genotyped using Taqman assay in a total of 1339 unrelated highly myopic Japanese patients. As a control, the genotype data of 3248 healthy Japanese individuals were obtained from the Nagahama Prospective Genome Cohort for the Comprehensive Human Bioscience dataset. Results: Significant associations of rs8000973 near ZIC2 (P=8.80E-10), rs4778879 in RASGRF1 (P=3.85E-07), and rs2969180 in SHISA6 (P=0.028) with high myopia were observed in this study. The odds ratios (95% confidence intervals) were 1.39 (1.25-1.54) for rs8000973 C allele, 0.78 (0.71-0.86) for rs4778879 A allele, and 1.11 (1.01-1.22) for rs2969180 G allele, respectively. The effect of rs2969180 allele G was in the opposite direction to the previous report, while the other 2 SNPs showed same direction to the original report. The SNPs in RDH5 (rs3138144) nor near TOX (rs7837791) didn't show association with high myopia. A total of 516 high myopic patients with CNV and 823 high myopic patients without CNV were evaluated, but none of 5 SNPs showed significant associations with the presence of CNV among them. Conclusion: This study suggests that ZIC2, RASGRF, and SHISA6 would be susceptibility genes for not only common myopia but also for high myopia.

1067F

A large clinical biorepository linked to de-identified electronic medical records mimics a random sample from the general population. *D.C. Crawford[1], M.D. Ritchie[2], L. Dumitrescu[1], S.A. Pendergrass[2], R. Goodloe[1], J. Boston[1], E. Farber-Eger[1], H.H. Dilks[1], J.L. Haines[1], W.S. Bush[1].* 1) Ctr Human Gen Res, Vanderbilt Univ, Nashville, TN; 2) Ctr Systems Genomics, Depart Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA.

Present day limited resources demand DNA and phenotyping alternatives to the traditional prospective population-based epidemiologic collections. To accelerate genomic discovery with an emphasis on diverse populations, we as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study accessed all non-European American samples available in BioVU, the Vanderbilt University biorepository linked to de-identified medical records, for Metabochip genotyping. BioVU began DNA collection in the Davidson County area in 2007; as of 2011, a total of 15,863 samples were identified for Metabochip genotyping including African Americans (n= 11,521), Hispanics (n=1,714), and Asians (n=1,122). Overall, more than half of the non-European descent patients are female (63.35%) and are young (mean age 37 years). The average number of clinical visits and billing (ICD-9) codes per patient was 81.8 (1 to 1,456) and 147.3 (1 to 3,617), respectively. The most frequent billing codes (collectively >50%) observed among African American adults >18 years reflected known population differences in prevalence and incidence of specific conditions such as hypertension, type 2 diabetes, and end stage renal disease. Despite the clinical origins of these data, comparisons with the population-based National Health and Nutrition Examination Surveys (NHANES) III and 1999-2002 (n=3,458 and 3,950 non-Hispanic blacks and Mexican Americans, respectively) suggest that common health metrics such as body mass index or BMI [African American mean = 27 kg/m2 (EAGLE BioVU) and 27 kg/m2 (NHANES)] and HDL-C [African American mean =50 mg/dL (EAGLE BioVU) and 51 mg/dL (NHANES)] exhibit little bias. Similar observations were made for BMI and HDL-C in EAGLE BioVU Hispanics versus NHANES Mexican Americans: 25.2 versus 27.1 kg/m2 and 46 versus 47 mg/dL, respectively. Differences observed for mean LDL-C between BioVU (African Americans = 99 mg/dL) and NHANES (non-Hispanic blacks = 116 mg/dL) were attributed to well-documented lipid lowering medication usage in clinical populations. Collectively, these data suggest this clinical collection is essentially a random sample of the general population, making this resource more than comparable to traditional epidemiologic collections in the context of genetic association studies.

1068W

Characterization of a Hispanic population from a biorepository linked to de-identified electronic medical records for genetic association and gene-environment studies. *E. Farber-Eger, J. Boston, R. Goodloe, S. Wilson, W.S. Bush, D.C. Crawford.* Ctr Human Genet Res, Vanderbilt University, Nashville, TN.

The rapid accrual of DNA samples offered by biorespositories linked to de-identified electronic medical records (EMRs) such as BioVU in Nashville, Tennessee has the potential to accelerate genomic discovery, particularly in diverse populations such as Hispanics. A major challenge for these clinical-based collections is the extraction of environmental variables suitable for gene-environment (GxE) studies. To contribute towards this massive challenge, we as part of the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study accessed ~15,000 non-European descent samples in BioVU for Metabochip genotyping including 1,714 Hispanics. More than half of EAGLE BioVU Hispanics are female (>63%) and most are young (mean age ~26 years). Despite the clinical origins of these data, the two most frequent billing (ICD9) codes for this population include normal pregnancy for adults (>18 years) and routine infant child health check for children (≤ 18 years). Given that race/ethnicity is administratively assigned in the clinic, we compared the Hispanic label in EAGLE BioVU to genetic ancestry from variants targeted on the Metabochip using STRUCTURE and EIGENSTRAT. Overall, the observed patterns of genetic ancestry among EAGLE BioVU Hispanics were consistent with a complex three-way admixture event. To further characterize this Hispanic sample for GxE studies, we performed automated searches of the clinic notes for acculturation variables 'country of origin' and 'primary language spoken.' A preliminary search of Spanish-speaking countries and their common misspellings was performed in approximately half of the sample; of these, 322 (19%) had a Spanish-speaking country mentioned in the clinical notes. The most frequent country mentioned was Mexico (37%) followed by Puerto Rico (12%), El Salvador (11%), and Guatemala (11%). String searches for 'needs a translator', 'Spanish speaking', and 'does not speak English' among the first half of this Hispanic sample suggest Spanish is the primary language for ~27% of the patients. Further data mining is being conducted to fully characterize the diverse population in EAGLE BioVU for genetic association and GxE studies.

1069T

Mitochondrial genetic effects on proliferative diabetic retinopathy. *D.C. Samuels[1], M.A. Brantley, Jr[2].* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN, USA.

Diabetic retinopathy is the leading cause of vision loss in working-age adults in the US. The most severe form of this disease is Proliferative Diabetic Retinopathy (PDR), which is defined by aberrant blood vessel growth in the retina. The increased glucose level in diabetes causes increased flow of metabolites into the glycolytic pathway, while reactive oxygen species produced by mitochondria modulate the flow of metabolites out of the glycolytic pathway. The combination of these two effects, acting at opposite ends of glycolysis, determines the level of intermediate glycolytic metabolites and the rate at which these metabolites are diverted into alternative cytotoxic pathways, such as the polyol, hexosamine, protein kinase C, and the advanced glycation end products (AGE) pathways. Increased activation of these pathways in diabetes has been suggested to cause cellular damage leading to diabetic retinopathy and other diabetic complications. We hypothesized that mitochondrial genetic variation alters reactive oxygen species production, thus modulating the flow of metabolites through glycolysis and affecting the development and progression of diabetic retinopathy. Using BioVU, the de-identified version of the Vanderbilt Electronic Medical Record, we found that the common European mitochondrial haplogroup H was significantly overrepresented in the PDR cases compared to the Non-Proliferative Diabetic Retinopathy (NPDR) controls (p=0.038, OR= 3.4 [95% CI 1.1-10.7], 21 cases & 54 controls). This result was replicated in a clinical cohort (p = 0.0024, OR = 3.8 [1.6-8.8], 58 cases & 44 controls). In addition, the common haplogroup U(k) was significantly protective against PDR in the combined BioVU and Clinical cohort group (p=0.031, OR = 0.43 [0.20-0.90]), though the association was not significant in the individual groups.

1070F

The association of 9p21.3 with acute myocardial infarction in managed care populations is independent of statin therapy. *P. Erlich[1], D. Carey[1,2], S. Steinhubl[1], C. McCarty[3], D. Cross[4,5].* 1) Center for Health Research, Geisinger Health System, Danville, PA; 2) Weis Center for Research, Geisinger Health System, Danville, PA; 3) Division of Research, Essentia Institute of Rural Health, Duluth, MN; 4) Marshfield Clinic Research Foundation, Marshfield, Wisconsin; 5) Department of Forensic and Investigative Genetics, School of Biomedical Sciences, University of North Texas Health Science Center, Fort Worth, Texas.

Introduction: A locus on 9p21.3 is associated with risk for acute myocardial infarction (AMI) in multiple GWAS and replication studies. Current evidence suggests that 9p21.3 represents a previously-unknown pathway in AMI etiology, which is independent of traditional cardiovascular risk factors. If this hypothesis is true, it follows that the effect of 9p21.3 should not be influenced by the use of statins and that it should add a significant increment of performance to risk factor-based predictive models. **Methods:** This nested case-control study used electronic health records (EHR) linked to population-based biobanking initiatives of two integrated healthcare delivery systems in the US - Geisinger Health System in PA and Marshfield Clinic in WI. A cohort of 18,329 individuals (57% female; 108,400 person-years) aged 40 to 80 was constructed. EHR were scanned to ascertain incident AMI status and covariates. Subjects with prevalent cardiovascular disease at baseline were excluded. A nested sample of 721 incident AMI cases and 722 matched controls was genotyped for a SNP (rs2383206) located in an intron toward the 3' end of the CDKN2B-AS1 transcript. Bivariate and multivariate logistic regression was used to test for association of rs2383206 with incident AMI and examine hypotheses related to effect independence. Receiver operating characteristic-area under the curve (ROC-AUC) was used to discern the net predictive performance of rs2383206 within a model with traditional risk factors. **Results:** The crude AMI incidence in the cohort was 10.8 and 5.0 per 1,000 person-years among males and females, respectively. In the nested sample, rs2383206 was associated with AMI in bivariate analysis (OR per A allele=0.71; 95%CI 0.62, 0.83; p<0.0001) and, with no notable difference in effect magnitude, in multivariate analysis adjusted for traditional risk factors and statin therapy (OR per A allele=0.72; 95%CI 0.61, 0.85; p<0.0001), suggesting an independent effect. The ROC-AUC of the parsimonious predictive model excluding rs2383206 was 70% (95%CI 67%, 73%), and increased by 1.2% upon addition of rs2383206 (95%CI for the increment 1.6%, 2.2%; p=0.02). **Conclusions** A SNP in 9p21.3 is associated with incident AMI in managed care populations independently of traditional risk factors and statin treatment. When added to a risk factor model, the SNP enhanced predictive performance by a small, statistically significant increment.

1071W

Computational resources required to transform bedside data to base-pair research. *W. Bush, J. Boston, E. Farber-Eger, R. Goodloe, D. Crawford.* Ctr Human Gen Research, Vanderbilt Univ, Nashville, TN.

Biorepositories linked to de-identified electronic medical records (EMRs) have enormous potential for disease gene mapping and pharmacogenomics. Tapping this potential, however, requires a range of specialized skills, software, and hardware. To illustrate these needs, we describe here the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) BioVU, a subset of the Vanderbilt University biorepository of ~15,000 DNA samples from non-European Americans representing African Americans (n=11,521), Hispanics (n=1,714), and Asians (n=1,122). EMR data for each patient, including billing (ICD9) codes, procedure codes, medications, labs, problem lists, and clinical notes have been scrubbed of identifiers and are accessible for research in the Synthetic Derivative (SD), the de-identified mirror image of the EMR updated monthly to capture new clinic visits and associated clinical data. To create the EAGLE BioVU resource for genomic analysis, we first captured a static view of the SD records to create a stable data structure or 'data freeze' for subsequent electronic phenotyping. This capture included 2.3 million billing codes, 4.6 million procedure codes, 13 million medication records, 11 million laboratory values, and over 13 billion characters of clinical text, amounting to more than 14 gigabytes of data. Electronic ascertainment for a given study requires a collaborative multidisciplinary team. Genetic epidemiologists and content experts define criteria for electronic phenotyping. Database queries are performed over the entire collection by software, and database developers to define phenotype groups. Laboratory values and longitudinal data are processed by statisticians to assess distribution assumptions and outliers. The final result is a set of samples with well-defined phenotypes for subsequent study. To date, this process has been completed for body mass index, type 2 diabetes and associated traits and conditions, cardiovascular disease and related traits, reproductive traits (ages at menarche and menopause), ocular diseases, peripheral artery disease, and kidney disease and associated labs. While new advances improve the ability to manipulate large datasets, these processes are computationally and labor intensive necessitating the creation of specialized workflows to transform clinical data into usable phenotypes for genomic discovery.

1072T

Hirschsprung Disease Research Collaborative (HDRC): A multidisciplinary partnership to advance Hirschsprung disease research. *C. Berrios[1], F. Abdullah[1], P.K. Frykman[2], R. Kapur[3], J.C. Langer[4], A. Chakravarti[1].* 1) Johns Hopkins University, Baltimore, MD; 2) Cedars-Sinai Medical Center, Los Angeles, CA; 3) Seattle Children's Hospital, Seattle, WA; 4) Hospital for Sick Children, Toronto, Ontario, Canada.

Hirschsprung disease (HSCR) or congenital aganglionosis, a functional intestinal obstruction affecting 1 in 5,000 neonates, is a multifactorial neurodevelopmental genetic disorder with >15 susceptibility genes identified and numerous more becoming evident through exome sequencing. Importantly, rare coding variants, common polymorphisms and chromosomal anomalies, involving both coding and non-coding sequences, are all implicated in HSCR. Demonstrated correlation of variant types with clinical presentation offers promise for translation of genomic findings into prognostic markers. However, these results have been obtained from referrals of exceptional, not random, cases. HSCR is treated surgically, and has a 30% incidence of suboptimal post-operative outcomes. A lack of standardized pathology and surgical approaches has prevented a full understanding of the variability in outcomes, and research is therefore needed using standardized phenotypic data from randomly ascertained patients. The HDRC was formed in 2011, as a partnership of geneticists, pediatric surgeons, pathologists and gastroenterologists, to fill this need. Interest in joining the HDRC has been expressed by clinicians and researchers at 60 sites in 9 countries, with 35 commitments to join. IRB approval for enrollment has been obtained at 10 sites and 2 additional sites refer patients to the Coordinating Center for enrollment. Parent-child trios are enrolled, with collection of detailed, standardized medical/family history from questionnaires and medical records. Blood samples are collected, with plans to include fresh and fixed pathology samples for genomic and histopathological analyses. Over the past year, a growing number of sites have submitted 74 patient and 84 parental samples. The HDRC has already embarked on a pilot retrospective study to correlate genetic and histopathology markers with post-operative outcomes. Each study site contributes a few samples with clinical data, and subsequently benefits from the opportunity to access the pool of HDRC samples and data for IRB-approved studies. While challenges have included coordination of a large number of sites and agreement among IRB approvals and materials transfer contracts, the HDRC is making steady progress toward building a large international biorepository of samples, accompanied by clinical and genomic data, within a multidisciplinary collaboration to facilitate research and improve patient care for children with HSCR.

1073F

Risk assessment of *APOL1* genetic variants on renal function and lipid profile in multiethnic hospital-based population. *M. Udler[1, 2], V. Lotay[3], G. Belbin[2,3], C. Wyatt[1], O. Gottesman[3], E. Bottinger[3], E.E. Kenny[2,3,4,5], I. Peter[2,5].* 1) Dept of Medicine; 2) Dept of Genetics and Genomic Sciences; 3) The Charles Bronfman Institute for Personalized Medicine; 4) The Center for Statistical Genetics; 5) The Institute for Genomics and Multiscale Biology, all at Icahn School of Medicine at Mount Sinai, NY, NY.

Variants in *APOL1* are strongly associated with non-diabetic end-stage renal disease (ESRD) in African Americans (AA), however, the mechanism by which these variants affect renal function is unknown. *APOL1* encodes apolipoprotein L1, a component of high density lipoprotein (HDL) cholesterol. Given that patients with chronic kidney disease are prone to developing dyslipidemia, we investigated whether *APOL1* variants were also associated with lipid levels. Additionally, it was of interest to obtain genetic risk estimates in a diverse, hospital-based population. The Mount Sinai Biobank is a repository of genetic data collected from patients and anonymously linked to their electronic medical records (EMRs). Three coding variants in *APOL1* previously shown to be associated with ESRD in AA (Genovese *et al* 2010) were genotyped in 13,527 Biobank participants (3706 AA, 4465 European Americans (EA), and 5356 Hispanic/Latinos (HL) by self-reported ancestry). MDRD estimated glomerular filtration rate (eGFR) and lipid levels were obtained from the patients' medical records. Associations were analyzed using regression analysis with recessive model and adjustment for global proportion European, African, or AmerIndian ancestry per individual, using Illumina 770K chip data and the ADMIXTURE algorithm. The frequency of homozygous risk alleles at any of the three variants was 7.6% in AAs, 0.7% in HLs, and 0% in EAs. Among non-diabetic patients, harboring two *APOL1* risk alleles at any variant was significantly associated with ESRD in both AA (OR 5.5, 95% CI 2.4-12.5, $P=5\times10^{-5}$) and HL (OR 21.9, 95% CI 2.3-207.2, $P=0.007$). Associations in AA, but not in HL, remained significant with adjustment for age, sex, blood pressure, BMI, and smoking status. The variants were not significantly associated with HDL, low density lipoprotein, triglyceride levels, non-HDL cholesterol, or total cholesterol in patients who were not prescribed lipid-lowering medication (N=2448 AA, 3032 EA, 3099 HL). Nor were the variants associated with being prescribed lipid-lowering medication. Our findings suggest that *APOL1*'s effect on ESRD risk is not mediated through altering lipid levels. This is the largest and most ethnically diverse study to-date to characterize variation at *APOL1* with regard to both eGFR and lipid profile, and demonstrates how Biobanks linked to EMRs can facilitate investigation of genetic associations with multiple phenotypes in diverse ethnic populations.

1074W

Towards a phenome-wide catalog of human clinical traits impacted by genetic ancestry. *L. Dumitrescu[1], R. Goodloe[1], J. Boston[1], E. Farber-Eger[1], W.S. Bush[1,2], D.C. Crawford[1,3].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 3) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Racial/ethnic differences for commonly measured clinical variables, such as cholesterol and blood pressure (BP), are well documented. Although the causes of these observed differences are unclear, it has been postulated that population-specific genetic factors may play a role. The genetic heterogeneity of admixed populations, such as African Americans (AA), provides a unique opportunity to identify genomic regions and variants associated with the clinical variability observed for diseases and traits across populations. To begin a systematic search for these population-specific genomic regions at the phenome-wide scale, we determined the relationship between global genetic ancestry, specifically European ancestry, and clinical variables measured in a population of AA from BioVU, Vanderbilt University's biorepository linked to de-identified electronic medical records (EMR), as part of the Epidemiologic Architecture using Genomics and Epidemiology (EAGLE) study. Through billing (ICD9) codes, procedure codes, labs, and clinical notes, 37 common clinical and laboratory variables were mined from the EMR, including body mass index (BMI), kidney traits, lipid levels, BP, and electrocardiographic measurements. A total of 11,167 DNA samples from AA were genotyped on the Illumina Metabochip containing ~200,000 variants. A subset of Metabochip SNPs (n=75,000) were chosen as ancestry informative markers and percent global European ancestry was estimated using STRUCTURE version 2.3.4 (K=3), with data from 395 HapMap samples (CEU, YRI, and CHB/JPN) included as predefined parental clusters. Linear regression, sex-stratified and sex-combined, was used to examine associations between global ancestry and the phenotype of interest. EAGLE/BioVU AA had a mean percent European ancestry = 17.2±15%. Increased European ancestry was most strongly correlated with an increase in QRS duration (p=6.7E-05, beta(SE)=8.0(2.0), n=837), consistent with previous observations that AA tend to have shorter a QRS duration than European Americans. A nominally significant association was also observed for BMI among AA females (p=3.9E-02, beta(SE)=1.3(0.6), n=5959). However, despite known racial/ethnic disparities in BP, European ancestry was neither associated with diastolic nor systolic BP measurements. Collectively, these results suggest that this clinical population can be used to identify traits in which population differences may be due, in part, to population-specific genetics.

Practical implementation of polygenic risk scores in personalized risk assessment for common cardio-metabolic traits.
K. Fischer[1], K. Läll[2, 1], R. Mägi[1], T. Haller[1], L. Leitsalu[1], T. Esko[1], A. Metspalu[1]. 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Institute of Mathematical Statistics, University of Tartu, Estonia.

Large-scale genome-wide association studies (GWAS) identify an increasing number of genetic variants associated with common complex diseases. Such markers (SNPs) are used to form polygenic risk scores. We will discuss the essential steps needed to translate GWAS results to personalized risk estimates. The process is illustrated using the data of Estonian population-based biobank and polygenic risk scores for Type 2 Diabetes (T2D), Coronary Artery Disease (CAD) and primary hypertension (HTN). The following questions will be addressed: 1)Validity of the genetic risk score in the target population. We will propose some graphical tools that address the question on consistency of published effect estimates (based on meta-analysis of a large number of cohorts) and estimates within the cohort of interest. That is done for each of the individual SNPs, as well as summary risk scores. 2)Conventional (non-genetic) risk factors and adjustment. Typically the GWAS results are obtained using minimal adjustment for other covariates. In practice, one is mainly interested in the added predictive value of a genetic risk score conditional on conventional risk factors. We will study the differences of conditional and unconditional effects, as well as possible heterogeneity across subsets with different baseline risk levels. 3)Number of markers to be included in the risk score. Increasing the number of SNPs does not necessarily lead to improved predictive accuracy in a particular cohort and there is an optimal number of SNPs producing the best results. A graphical tool is proposed to aid marker selection. 4)Population risk estimates from available genotyped samples. Often the genotyped (subsets of) biobank cohorts include a larger proportion of prevalent cases than the underlying population. We will show how the risk estimates can be corrected using external data on population prevalence. 5)Communication of the risk estimates in practice. We will propose some useful graphs that help to interpret the actual meaning of the risk estimate. For the Estonian Biobank cohort we show that the risk score for T2D has a very good discriminatory ability between high-risk and low-risk individuals, especially in those who are overweight, but not extremely obese (BMI 25-35). We will also show that the risk score for CAD should be mainly used to identify individuals at the highest percentiles of risk, whereas the risk score for HTN may be useful in some well-defined subsets of the cohort.

1076F

Optimization of Genetic Coverage and Biomedically Relevant Content of Microarrays for Genotyping in Biobank Cohorts.
J. Schmidt, Y. Zhan, J. Gollub, Y. Lu, G. Hsiao, M. Nitzberg, E. Schell, L. Bellon, T. Webster. Informatics, Affymetrix, Santa Clara, CA.

Growing numbers of biobanks hold large collections of clinically interesting samples. Common trends have emerged in needs for genotyping these large cohorts for biomedical studies, primarily the desire to simultaneously assay rare, potentially causal variants and large panels of common markers for genome wide association studies (GWAS). However, the detailed needs for each biobank or study depend on the ancestry of the cohort as well as the specific study aims. We present a system for optimizing an Affymetrix® Axiom® genotyping microarray for a specific study or biobank, including: (1) a computationally tractable method for selecting space-efficient probes to maximize genetic coverage in the population and allele frequencies of interest for GWAS; and (2) modular sets of markers relevant to specific biological and biomedical questions, which can be further customized for the specific phenotypes and populations of interest. We demonstrate the selection of only 246k markers, with minimal space requirements on the array, to provide 87% imputation-based coverage of the CEU population across 6.7M markers with MAF ≥ 5% in the 1000 Genomes Phase 1 (March, 2012) genotype data. We also describe the selection of smaller sets of markers ('booster panels') to augment the coverage provided by this core 246k set in non-target populations, such as African and Asian populations, or to increase coverage of lower frequency markers. E.g., the addition of only 50k markers can be used to significantly raise imputation coverage of common Yoruban variants (MAF ≥ 5%), or increase coverage at lower minor allele frequencies in the primary target population, or raise coverage in any particular region of interest. Other sets of markers can be added to suit specific study needs, such as ADME or HLA markers, known GWAS hits from previous studies, coding, non-synonymous SNPs and indels or markers with predicted loss-of-function impact, etc. This system for marker selection can improve the efficiency of genotyping in a biobank setting, potentially allowing more and more effective genetic studies in very large cohorts.

1077W

ChIP-seq in alcoholic steatohepatitis and normal liver tissue identifies candidate disease mechanisms suggesting progression to cancer.
C. Wadelius[1], MB. Bysani[1], O. Wallerman[1,5], S. Bornelöv[2], K. Zatloukal[3], J. Komorowski[2,4]. 1) Dept Immun, Gen & Pathol, Uppsala University, Uppsala, Sweden; 2) Department of Cell and Molecular Biology, Uppsala University, Uppsala, Sweden; 3) Institute of Pathology, Medical University of Graz, Austria; 4) Interdisciplinary Centre for Mathematical and Computational Modelling, University of Warsaw, Warszawa, Poland; 5) Current address: Department of Medical Biochemistry and Microbiology, BMC, Uppsala.

Background: Excessive consumption of alcohol may induce accumulation of fat in the liver concurrent with inflammation in a disease called steatohepatitis, which may progress to liver cirrhosis and hepatocellular carcinoma. Its molecular pathogenesis is to a large degree unknown. Histone modifications play a key role in transcriptional regulations as marks for silencing and activation of gene expression and for location of functional elements. Many transcription factors (TFs) are crucial for the control of gene activity and abnormality in their function may lead to disease. **Methods**: We performed ChIP-seq of histone modifications associated with active promoters and enhancers and a candidate transcription factor, in liver tissue from patients with steatohepatitis and normal livers and correlated results to mRNA-expression and genotypes. **Results**: We performed ChIP-seq of the three histone modifications H3K4me1, H3K4me3 and H3K27ac and the TF upstream stimulatory factor 1 (USF1) in tissue from normal liver and from alcoholic steatohepatitis patients. We found many peaks that are differentially enriched between disease and normal tissue, and qRT-PCR results indicated that the expression of the tested genes strongly correlated with ChIP-seq of histone modifications but is independent of USF1 enrichment. By gene ontology analysis of differentially modified genes we found some which had previously been implicated in the etiology of steatohepatitis and others that are candidates to contribute to the disease. Importantly, the genes associated to the strongest histone peaks in the patient were over-represented in cancer specific pathways suggesting that the tissue was on a path to develop to cancer, a common complication to the disease. We also found several novel SNPs and GWAS catalogue SNPs that are candidates to be functional and therefore needs further study. In summary we find that analysis of chromatin features in tissue samples provides insight into disease mechanisms.

1078T

National Biological Sample And Data Repository For WHO Group 1 Pulmonary Arterial Hypertension.
M. Pauciulo[1], A. Reponen[1], K. Lutz[1], C. Winslow[1], A. Walsworth[1], J. Harley[2], M. Barnes[2], L. Martin[1], K. Marsolo[3], W.C. Nichols[1]. 1) Division of Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH; 2) Division of Rheumatology, Cincinnati Children's Hospital, Cincinnati, OH; 3) Division of Biomedical Informatics, Cincinnati Children's Hospital, Cincinnati, OH.

We have established the National Biological Sample and Data Repository for PAH with funding from the National Heart, Lung, & Blood Institute of the National Institutes of Health. Biological samples, clinical data, and genetic data are being collected on approximately 3,000 WHO Group 1 PAH patients from 3/2012 to 2/2017 to create this bio repository. Twenty four pulmonary hypertension centers across the United States have been enlisted to enroll patients, collect peripheral blood samples, and enter clinical data into a web-based eCRF. Many of the patients recruited for the bio repository are already enrolled in a multicenter, observational, U.S.-based Registry of PAH. Efforts are also being made to enroll treatment naïve patients to obtain both pre and post-treatment samples. Serum and plasma are being isolated and banked using the patient blood samples. Additionally, both DNA and RNA are being isolated from a portion of the obtained lymphocytes. Immortalized lymphocyte cell lines are also being established for each patient. Genetic data are being generated for each patient including genotypes for genome wide SNPs (5M) and coding sequence and/or MLPA data for BMPR2, ALK1, ENG, CAV1 and SMAD9. Additional genes can be added for screening as identified. All biological samples, clinical data, as well as the SNP genotype and sequencing/MLPA data for the patients will be made available to the scientific community using a web-based application process. The samples and data will become available for request after the first 500 patients have been enrolled and the data are completed. The National Biological Sample and Data Repository for PAH represents an unparalleled collaboration between pulmonary hypertension centers in the United States to enable the collection of the largest cohort of PAH patients' biological samples in the United States. To date, 600 patients have been enrolled and sampled. This endeavor will provide the PAH research community an opportunity for here to now unprecedented hypothesis-driven studies. Funded by NHLBI HL105333.

Exome sequencing and genome-wide copy number variant mapping reveal novel associations with sensorineural hereditary hearing loss.
R.R. Haraksingh[1], F. Jahaniani Kenari[2], J. Rodriguez-Paris[3], J. Gelernter[4], K. Nadeau[5], J. Oghalai[6], I. Schrijver[3], M. Snyder[2]. 1) Psychiatry, Stanford University, Palo Alto, CA; 2) Genetics, Stanford University, Palo Alto, CA; 3) Department of Pathology, Stanford University School of Medicine, Stanford, California, USA; 4) Department of Psychiatry, Yale University School of Medicine, New Haven, CT, USA; 5) Department of Pediatrics, Stanford University School of Medicine, Stanford, CA 94305, USA; 6) Department of Otolaryngology - Head and Neck Surgery, Stanford University School of Medicine, Stanford, CA 94305, USA.

The genetic basis of hearing loss is not fully understood in terms of the diversity of loci and types of mutations that are responsible. We used multiple approaches, including exome sequencing of families and of probands with hearing loss, as well as copy number variation mapping in a case-control cohort, to identify loci associated with non-syndromic sensorineural hearing loss. Analysis of three distinct families revealed a novel gene candidate, MYH7B, associated with hearing loss in one family, and candidate loci in two other families. MYH7B encodes a Type II myosin, extending the role of cytoskeletal proteins in hearing. High-resolution genome-wide copy number variation analysis of 151 cases and 157 controls further revealed deletions in known hearing genes (e.g. GJB6, OTOA, and STRC, encoding connexin 30, otoancorin, and stereocillin, respectively), indicating that CNVs may be responsible for hearing loss. In addition, we found a novel association with hearing loss of a deletion on chromosome 16 containing the gene PDXDC1 (OR = 3.85, p = 1.45 × 10-7). Overall, our results indicate that a large number of loci, some of which are novel, and distinct types of mutations not typically tested for, may contribute to the etiology of hearing loss in humans.

Mutations in the BMP genetic network in patients with congenital GnRH deficiency.
D. Cassatella[1, 2], J. Liang[3], A. Dwyer[1], G. Sykiotis[1], H. Miraoui[1], C. Xu[1], S. Santini[1], V.A. Hughes[1], X.Z. Liu[3], P.M. Bouloux[5], M. Lang-Muritano[6], R. Quinton[4], J.G. Zhang[3], B.J. Stevenson[2], Y. Sidis[1], N. Pitteloud[1]. 1) Service of Endocrinology, Diabetology and Metabolism - Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 2) Vital-IT - Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) BGI-Shenzen, Shenzen, China; 4) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, UK; 5) Centre for Neuroendocrinology, Royal Free and University College School of Medicine, London, UK; 6) Department of Endocrinology and Diabetology, University Children's Hospital, Zurich, Switzerland.

The hypothalamic secretion of gonadotropin-releasing hormone (GnRH) is well-known as the "pilot light" of reproduction in all mammals. GnRH neurons arise in the olfactory placode during embryonic development and migrate to the preoptic area of the hypothalamus. Mutations in genes involved in GnRH neuron ontogeny, survival and/or function result in GnRH deficiency (congenital hypogonadotropic hypogonadism, CHH), characterized by absent puberty and infertility. The mechanisms controlling GnRH neuron specification are only partially known. Through human genetic studies, Fibroblast growth factor 8 (Fgf8) was identified as a strong morphogen for GnRH neuron specification. Bone morphogenetic protein 4 (Bmp4), which antagonizes Fgf8 signaling in various tissues, is expressed in the olfactory placode at E10.5. Heterozygous BMP4 mutations have been identified in severe myopia, polydactyly, cleft lip/palate, and renal dysplasia, phenotypes that are all associated with CHH. In addition, we identified a duplication of gremlin 2, an inhibitor of BMPs, in a CHH patient. Therefore, we hypothesized that mutations within the BMP genetic network could cause CHH by impairing GnRH neuron specification. After performing whole-exome sequencing in 36 CHH patients, we employed a multi-step bioinformatics strategy incorporating computational prioritization of the candidate genes, protein-protein interaction databases, and in silico functional predictions of variants. We found variants in 17 BMP pathway genes including ligands (BMP2 and BMP4), receptors (BMPR1B and BMPR2), inhibitors (NOG and FST), and enhancers (ENG and FBN1), and selected BMP4 as the best candidate to further study. In vitro studies revealed detrimental effects of BMP4 mutants on cell signaling/protein maturation. To strengthen the evidence that BMP4 is a novel locus for CHH, we are currently examining GnRH neuronal development in Bmp4 deficient mice. Studies of mutations in other BMP pathway genes are ongoing. In conclusion, we have identified mutations in the BMP genetic network among patients with CHH. Impaired BMP signaling may disrupt the cross-talk between FGFs and BMPs in the olfactory placode during a critical stage for GnRH neuron development.

Identifying rare, non-coding DNA variants in Systemic Lupus Erythematosus.
S.J. White[1], S. Cantsilieris[1], E.F. Morand[2]. 1) Monash Institute of Medical Research, Monash University, Australia; 2) Southern Clinical School, Monash University, Australia.

Systemic lupus erythematosus (SLE) is a debilitating multisystem autoimmune disease. Patients with SLE suffer a marked loss of life expectancy, and severe morbidity, due to autoimmune-mediated inflammation of multiple organs. A classic hallmark of SLE is the presence of autoantibodies. This is a clear biological link between SLE and antibody-producing B-lymphocytes (B-cells), strengthened by the clinical efficacy of anti-B cell therapies in certain patients. Genetic studies have associated SLE susceptibility with a number of Single Nucleotide Polymorphisms (SNPs), many of which are found in or near genes with B-cell functions. However, the known SLE SNPs together only account for a small percentage of the genetic contribution to SLE, and as most SNPs are located in non-coding DNA, the mechanism of their effect is often unclear. Several SLE-associated SNPs are located in such DNA elements that control gene regulation, with sequence changes disrupting the binding of specific transcription factors. In 2012 the ENCODE consortium published papers outlining genome-wide studies of open chromatin in a range of cell types. These studies demonstrated that DNaseI hypersensitive sites strongly correlate with known and predicted regulatory sequences. In addition, they are enriched for known and predicted transcription factor binding sites (TFBS). This provides a clear link between sequence variants and functional activity, and rare variants in B-cell regulatory loci (defined by open chromatin in B-cells) would explain genetic susceptibility to SLE in a way not detectable by GWAS. We undertook a pilot study to screen three B-cell regulatory elements previously associated with SLE. We identified a previously undescribed sequence variant in DNA from an SLE patient, predicted to have a significant effect on transcription factor (TF) binding. This finding validates our hypothesis that non-coding regulatory elements will contain private sequence variants affecting TF binding sites and chromatin structure, and may explain part of the 'missing heritability' issue in the post-GWAS era. We are currently performing additional mutation screening of putative B-cell regulatory loci in SLE patients, along with functional validation using reporter constructs and changes in DNaseI-sensitivity.

MTHFS Mutation May Contribute to Cerebral Folate Deficiency Syndrome.
H. Zhu[1], Y. Lei[1], R.H. Finnell[1, 2]. 1) Dell Pediatric Research Instutite, Department of Nutritional Sciences, UT Austin, Austin, TX; 2) Department of Chemistry and Biochemistry, College of Natural Sciences, UT Austin, Austin, Texas.

Cerebral Folate Deficiency (CFD) syndrome is characterized by very low concentration of 5-methyltetrahydrofolate (5-MTHF) in the patient's cerebrospinal fluid (CSF), while folate levels in plasma and red blood cells are within normal limits. Major clinical features of CFD syndrome include unrest, irritability, and insomnia, decelerating head growth, neurodevelopmental delay, regression, hypotonia, ataxia, dyskinesias, spasticity, speech difficulties, and seizures. It has been speculated that the etiology of CFD syndrome may be explained by: disrupted folate transport through the blood brain barrier (BBB), autoantibodies against folate receptor alpha (FOLR1) impeding transport, mutations in folate transport and metabolism genes, as well as mitochondrial deficiency. Folate genes that have been implicated in CFD syndrome include: *FOLR1*, *DHFR* (dihydrofolate reductase) and *PCFT* (proton coupled folate transporter). We performed exome sequencing analysis of the family (proband, parents and a healthy sibling) of a CFD patient, hoping to identify causal mutation(s) that contribute to the patient's conditions. Genomic DNA was extracted from whole blood using the Gentra Puregene Blood Kit (Qiagen). Whole exome libraries were established using Agilent SureSelect Kit v4.0 (3'UTR included) and submitted to sequencing on Illumina HiSeq 2000. Sequencing data was analyzed using NEXTGENe software (Softgenetics). Ninety-nine recessive novel mutations were identified through the exome sequencing, of which 21 were predicted to be damaging by the PolyPhen program. No de novo mutations were detected in the patient. The patient carries a homozygous mutation, c.101G>T (p.R34L, rs200058464), in a folate pathway gene, 5,10-methenyl-tetrahydrofolate synthetase (MTHFS). Both parents are heterozygotes, and the healthy sibling of the patient does not carry the mutant allele. After confirming the mutation using Sanger sequencing, we performed in vitro functional assays by transfecting the wild type and mutant alleles into HEK293T cells. The mutant allele (T) showed more than 50% reduction in luciferase activity, indicating the functional effect of this MTHFS mutation. Our study suggested that exome sequencing analysis of the CFD family is an efficient way to identify potential candidate genes and may lead to the discovery of causal mutation(s) responsible for this clinical disorder. (Supported in part by NIH grants HD067244 and NS076465).

1083W

Pilot whole genome sequencing of germline DNA from 186 breast cancer cases. *P. Kraft[1], J. Allen[2], C. Chen[1], B. Decker[2], J. Figueroa[3], S. Hart[4], S. Lindstrom[1], J. Long[5], M. Yeager[3], S. Chanock[3], F. Couch[6], D. Easton[2], C. Haiman[7], W. Zheng[5], D. Hunter[1].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, UK; 3) Division of Cancer Epidemiology and Genetics, NCI, Rockville, MD; 4) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 5) Division of Epidemiology, Vanderbilt University School of Medicine, Nashville, TN; 6) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 7) Department of Preventive Medicine, USC Keck School of Medicine, Los Angeles, CA.

High coverage whole genome sequencing (WGS) has been proposed to identify rare germline mutations associated with complex traits in both coding and regulatory regions. However, WGS studies present many logistical and analytic challenges, including coordinating variant calling and cleaning across multiple sites, accruing sufficient sample size, and designing and interpreting appropriate statistical analyses. We illustrate some of these challenges using a pilot whole genome sequencing study of 143 European-ancestry (EA), early-onset, family-history-positive breast cancer cases, 21 Asian cases and 25 African-American cases from six studies participating in the DRIVE consortium, an NCI-sponsored post-GWAS initiative. Samples from each study were sequenced separately using Illumina HiSeq to an average depth of 30x and called individually using CASAVA. Preliminary analyses identified a missense *BRCA1* mutation present in three EA cases that was absent in 4,300 EA subjects in the Exome Sequencing Project ($p=6.8\times10^{-5}$). A nonsense variant in another gene was present in 11 cases and 0 ESP subjects ($p=5\times10^{-16}$), but this apparent association was driven by false negative calls in the ESP--the average read depth at this position in the ESP was 1. We describe and present results from a rare-variant burden that uses summary data from individual studies. We discuss future plans, including combined variant calling and analysis of non-coding variants.

1084T

Exome Sequencing in Hodgkin Lymphoma Families. *M. Rotunno, M. McMaster, L. Goldin.* NIH/NCI/DCEG, Bethesda, MD.

Hodgkin lymphoma (HL) shows strong familial aggregation but no major susceptibility genes for HL have been identified to date. Studies based on exome sequencing are promising for identifying disease susceptibility rare genetic variants. The goal of this study was to identify high-penetrance variants in HL-prone families. Using Nimblegen v2.0 and v3.0 exome capture array and the Illumina HiSeq2000 sequencer, we exome sequenced 45 HL cases or obligate carriers from 11 HL-prone families with three or more affected members and 2 families with two HL cases. Reads were aligned using Novoalign v.2.07.14 and variants were called using GATK software. Possible technical sequencing artifacts were eliminated by filtering out variants found in more than 1% of samples from other studies identically processed and sequenced in our laboratory. The Ingenuity Variant Analysis software was used to analyze, annotate and prioritize the resulting exome data. Only rare (<1%; frequency in European populations), non-synonymous variants were kept. According to a dominant segregation model, between 2 and 59 variants were shared by all cases or obligate carriers within each family with 3 or more members. No variants were shared by more than one family. Six variants occurred in 3 genes shared by two families each: FSTL5, SMTNL2, and ZFYVE28. We plan to perform targeted sequencing of these genes in additional HL families. In addition, genes from individual families were also prioritized for further follow-up based on damage prediction and conservation of the shared variant, and literature link to cancer or immune related processed. Further study is needed to determine whether rare variants in the identified genes increase risk for familial HL.

1085F

The burden of coding, non-coding and chromosomal mutations in Hirschsprung disease. *T. Turner[1], K.D. Nguyen[1], N. Krumm[2], S. Chatterjee[1], A. Kapoor[1], Q. Jiang[1], A.Y. Ling[1], M.X. Sosa[1], N. Gupta[3], E.E. Eichler[2], S. Gabriel[3], C. Berrios[1], A. Chakravarti[1].* 1) Center for Complex Disease Genetics, McKusick - Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Genome Sequencing and Analysis Program, Broad Institute of MIT and Harvard, Cambridge, MA.

Hirschsprung Disease (HSCR) affects ~1/5000 live births and is characterized by the failure of gut innervation. This multifactorial neurodevelopmental disorder has variable recurrence risks depending on the proband's sex, familiality and segment length of aganglionosis. 15 genes with rare, deleterious mutations in HSCR, most commonly at the receptor tyrosine kinase gene *RET*, are known. Although common functional variants in two enhancers of *RET* exist in ~90% of HSCR cases and all known rare coding functional variants in ~10% of patients, they cumulatively explain <10% of the risk variation. To understand the total burden of genomic variation, we performed exome capture (Agilent 44Mb) and sequencing on an Illumina platform in 304 patients representing the gamut of HSCR variability. We identified 90,818 high quality coding and splicing single nucleotide variants (SNVs) using GATK, and 146 rare (<1% in ESP) copy number variants (CNVs) using CoNIFER. Our major analyses have focused on 189 unrelated, European ancestry, non-admixed individuals and >361 analogous controls from dbGAP, ESP and 1000 Genomes. We focused on genes with 3 or more putative highly deleterious coding variants (NMD nonsense, donor/acceptor intronic splice, conserved (phyloP≥4) missense) in cases and identified genes, expressed in the gut, for which this distribution was significantly different ($P<10^{-4}$) than in controls. This analysis identified 64 genes with deleterious alleles at significantly higher frequencies as compared to the EVS. Among these, three genes are known to underlie HSCR in humans (*RET*, *EDNRB*, *SEMA3D*), one has dosage effects in patients (*NAV2*), and one causes aganglionosis in the mouse (*PAX3*). The novel genes show significant enrichment of genes in neuronal and/or ubiquitination pathways (22 or 37%) adding these to known HSCR defects in enteric neural crest cell differentiation, mesenchymal function and axonal guidance. We found 11 CNVs, at >10-fold increased frequency, at loci previously identified with recurrent deletion/duplication syndromes, such as 16p11.2, 1q21.1 and 17p11.2, suggesting a broader role for these loci in neuronal disease. Further analysis of these data show that HSCR can be sub-divided into four types arising from the effects of single genes, recurrent deletion/duplication loci, multi-organ syndromes of 'multifactorial' etiology and 'multifactorial' isolated cases, with effects, on average, from ~5 deleterious variants.

1086W

Analyses of WES data in multiplex Syrian non-syndromic oral clefts families. *J. Bailey-Wilson[1], E. Holzinger[1], M. Parker[2], S. Szymczak[1], Q. Li[1], C. Cropp[1], M. Nöthen[3], J. Hetmanski[2], H. Ling[4], E. Pugh[4], P. Duggal[2], M. Taub[5], I. Ruczinski[5], A. Scott[4], M. Marazita[6], H. Albacha-Hejazi[7], E. Mangold[3], T. Beaty[2].* 1) Inherited Disease Res Branch, NIH/NHGRI, Baltimore, MD, USA; 2) Department of Epidemiology, Bloomberg School of Public Health, The Johns Hopkins University, Baltimore, MD, USA; 3) Institute of Human Genetics, University of Bonn, Bonn, Germany; 4) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD, USA; 5) Department of Biostatistics, Bloomberg School of Public Health, The Johns Hopkins University, Baltimore, MD, USA; 6) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 7) Ibn Al-Nafees Hospital, Damascus, Syrian Arab Republic.

Oral clefts (cleft lip, cleft palate and cleft lip & palate) are common birth defects with a complex and heterogeneous etiology. Some genes and chromosomal regions have been associated with risk in genome wide association and linkage studies. This whole exome sequencing (WES) study used 22 affected 2nd degree or more distant relatives drawn from 10 multiplex inbred families (2 families with 3 relatives and 8 families with 2 relatives) initially ascertained in the Syrian Arab Republic for linkage studies. WES was done by the Center for Inherited Disease Research using the Agilent SureSelect v.4 capture reagents & Illumina HiSeq 2000 sequencers. Variants were called for all samples together within this project using Unified Genotyper (2.3-9). Variants were flagged by VQSR annotation using a Gaussian Mixture model for both SNVs and INDELs. Random Forests was used to estimate probability of high versus low quality calls. Results of analyses using the Ingenuity software on these newly recalled data will be presented. Additional sequencing studies of more families and more affected individuals in these families are ongoing to determine which genes segregate with oral clefts in these Syrian families.

1087T

Multigenic inheritance as a cause of familial congenital diaphragmatic hernia.
T.F. Beck[1], P.M. Campeau[1], J.T. Lu[2,3], C. Gonzaga-Jauregi[1], J.R. Lupski[1,4], R.A. Gibbs[2], B.H. Lee[1,5], W. Reardon[6], D.A. Scott[1,7], Centers for Mendelian Genomics. 1) Molec & Human Gen, Baylor College Med, Houston, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Department of Structural and Computational Biology & Molecular Biophysics, Baylor College of Medicine, Houston, TX; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Howard Hughes Medical Institute, Houston, TX; 6) Our Lady's Hospital for Sick Children, Crumlin, Dublin 12, Ireland; 7) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX.

Congenital diaphragmatic hernia (CDH) is a common life-threatening birth defect which can present either alone or as part of a genetic syndrome. Isolated CDH has a low recurrence risk (1 to 2%) with most cases being caused by a combination of genetic and environmental factors. We report a male patient with isolated CDH whose father was also diagnosed with CDH at age 8 and exhibited severe scoliosis, low intellectual achievement, and unusual windswept hands. Both father and son had normal G-banded chromosome analyses. In an effort to identify the cause of CDH in this family, genomic DNA samples from the patient and his father were subjected to whole-exome sequencing analysis. This analysis revealed a frameshift mutation (c.4970_4971insA → p.Cys1658Leufs*29) in the fibrilin 1 gene (*FBN1*) which is associated with Marfan syndrome~a connective tissue disorder with a range of associated phenotypes, including lens dislocation, aortic dilatation, and skeletal anomalies. Sanger sequencing confirmed this mutation in father and son, as well as an asymptomatic male sibling who also shares his father's unusual windswept hands. An ophthalmological evaluation revealed iridodonesis in both father and proband confirming the diagnosis of Marfan syndrome. The father also exhibited phacodonesis. A cardiovascular evaluation has been scheduled. Although CDH has been reported in a handful of Marfan cases, it is unusual for CDH to be the presenting symptom and to reoccur in more than one family member. With this in mind, we looked for mutations in other CDH-related genes which might account for the high prevalence of CDH in this family. Putatively damaging sequence changes were identified in the *FRAS1*-associated extracellular matrix protein 1 (*FREM1*), desmin (*DES*), and hepatocyte growth factor receptor (*HGFR*) genes in both the father and his affected son. These findings underscore the importance of considering the potential influence of deleterious changes in other genes as an explanation for rare and/or unusual phenotypes associated with common genetic syndromes.

Kato[1]. 1) Shinshu University School of Medicine, Matsumoto, Japan; 2) DNA chip institute, Kanagwa, Japan; 3) Toyama Medical University, Toyama, Japan; 4) Hokkaido Medical Univesiry, Sapporo, Japan; 5) Osaka City Medical University, Osaka, Japan; 6) Nagano Prefectual Chilcren's Hospital, Azumino, Japan; 7) Institute for Comprehensive Medical Science, Fujita Health University, Toyoake, Japan; 8) Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA.

[Purpose] Congenital Vertebral Anomalies (cVA) affect 0.5-1/1000 children and show a significant high mortality. Causes of most cVA remain largely unknown. The purpose of this study is to identify genetic abnormalities in Japanese cVA patients. [Methods] We focus on primary cases with cVA that affect more than 1 vertebral body with malformation. Cases with congenital scoliosis with rib malformation, Klippel Feil syndrome, or VACTERL association were included in the patient cohort. We first performed exome sequencing on 8 patients and their 9 unaffected family members using the Agilent SureSelect Human All Exon 50Mb Kit and the illumina HiSeq Sequencer. Reads were mapped to the hg19 reference genome with Burrows-Wheeler Aligner and variant calling was performed by The Genome Analysis Toolkit. We excluded mismatches that did not change amino-acid sequences and known SNPs whose allele frequencies were greater than 1% according to the dbSNP JPT and 1000 Genompe project. Approximately 700 such mismatches were found in each patient. We then confirmed the data by Sanger sequencing. [A summary of results] We have found de novo mutations in the DCLRE1B, AGBL5, PDE2A, OLFML1, and ASB16 genes. All of these mutations are non-synonymous, and there has been no report of any mutations based on dbSNP and 1000 genome databases. DCLRE1B is involved in DNA interstrand cross-link repair; the major role of AGBL5 is tubulin deglutamylation; PDE2A is a phosphodiesterase involved in many signal transduction pathways; the function of OLFML1 is unknown. Although the function of ASB16 is mostly unclear, based on the sequence similarities and its domain structure, ASB16 may be a component of an E3 ubiquitin-protein ligase complex. Interestingly, a possible de novo non-sense mutation was found at a different position of the ASB16 gene in another patient. We are currently performing exome sequencing analyses on additional 4 families. We are also planning to create genetically-modified zebrafish models to understand the in vivo functions of those genes. [Conclusion] These findings suggest that cVA are genetically heterogenous. Our study identified several potentially disease-causing genes of cVA.

1089W

Whole-genome sequencing of individuals from a founder population identifies candidate genes for asthma. *C.D. Campbell[1], K. Mohajeri[1], M. Malig[1], F. Hormozdiari[1], B. Nelson[1], G. Du[2], K. Patterson[2], C. Eng[3], D.G. Torgerson[3], J.X. Chong[2], A. Ko[1], L. Vives[1], B.J. O'Roak[1], M. Abney[2], E.G. Burchard[3], C. Ober[2], E.E. Eichler[1,4].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Genetics, University of Chicago, Chicago, IL; 3) Department of Medicine, University of California San Francisco, San Francisco, CA; 4) Howard Hughes Medical Institute, Seattle, WA.

Asthma is a complex genetic disease caused by a combination of genetic and environmental risk factors. We sought to test classes of genetic variants largely missed by whole-genome association studies (GWAS) by performing whole-genome sequencing of 16 individuals from asthma-enriched and depleted families from an extended 13-generation Hutterite pedigree with reduced genetic heterogeneity due to a small founding gene pool and reduced environmental heterogeneity as a result of a communal lifestyle. We sequenced each individual to an average depth of 13-fold (Illumina HiSeq), generated a comprehensive catalog of genetic variants, and tested for association with asthma in 1200 individuals from the same population. Specifically, we identified and validated 2881 copy number variants (CNVs), 19 gene-disruptive single nucleotide variants (SNVs), and 18 frameshifting insertions or deletions ('indels'). We genotyped 593 of the CNVs in 1199 individuals, including 164 individuals with asthma, 488 controls, and 547 with intermediate phenotypes, from the extended pedigree. We identified a nominally significant association (p=0.03; Odds ratio=3.13) between a 6 kbp deletion in an intron of *NEDD4L* and increased risk of asthma. We genotyped this deletion in 742 cases and 755 controls of Puerto Rican ancestry and observed this variant in two cases and zero controls. Interestingly, *NEDD4L* is an ubiquitin ligase expressed in bronchial epithelial cells, and conditional knockout of this gene in the lung in mice leads to severe inflammation and mucus accumulation. This gene resides under a linkage peak for asthma in the Hutterites making it a plausible candidate. Additionally, this deletion is not in strong linkage disequilibrium with any particular SNP genotyped by the HapMap or 1000 Genomes Projects and would have been missed by GWAS. Of the 37 gene-disruptive SNVs and indels, we observed a nominally significant association with asthma for six variants in the larger cohort, which have allele frequencies between 1-6% in the Hutterites. We have extended these results by resequencing 16 genes in 837 cases and 540 controls of Puerto Rican ancestry in order to test for a burden of rare protein-altering mutations. Our study represents one of the early instances of applying whole-genome sequencing to complex disease with a large environmental component, and we have used these data to assess genetic variation largely untested in GWAS, including CNVs and low-frequency variants.

Cluster detection approaches to identify disease genes in CNVs implicated in psychiatric disorders: applications to whole-exome sequencing studies on autism and schizophrenia. *I. Ionita-Laza[1], B. Xu[2], V. Makarov[1], J. Buxbaum[3], J. Louw Roos[4], J. Gogos[5,6], M. Karayiorgou[2].* 1) Biostatistics, Columbia University, New York, NY; 2) Department of Psychiatry, Columbia University, New York, NY; 3) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY; 4) Weskoppies Hospital, Pretoria, South Africa; 5) Department of Physiology & Cellular Biophysics, Columbia University, New York, New York, USA; 6) Department of Neuroscience, Columbia University, New York, New York, USA.

Advances in next-generation sequencing technologies make possible to exhaustively explore the genetic influence of rare variants, both point and structural, on the risk of developing complex psychiatric and neurodevelopmental disorders. A number of studies have highlighted a significant role for CNVs (both de novo and inherited) as a constant source of pathogenic variation in psychiatric disorders. Most of the identified CNVs span multiple genes and highlight regions in the human genome likely containing susceptibility genes. It is thought that it is the imbalance of several affected genes that determines the overall phenotype associated with a given CNV although one or a few genes may have a greater phenotypic impact. We propose new cluster detection methods based on scan statistics, for both family-based and case-control designs, to identify significant clusters of rare disease risk variants, corresponding to disease susceptibility genes. Unlike conventional gene-based association tests, these cluster detection tests take into consideration the spatial aggregation of risk variants into a small region, e.g. a gene, within a larger CNV. Using simulation studies based on exome-sequencing data, we show that the proposed cluster-detection methods are more powerful than conventional gene-based tests when variants cluster significantly within a gene in a larger CVN. We present results from several exome sequencing studies on autism and schizophrenia, using both family-based and case-control designs, and identify in each case statistically significant associations with rare nonsynonymous variants within genes for several well-known CNVs, including 15q13.3. Notably, the genes involved highlight new mechanisms in these disorders. Furthermore, on these data, only the cluster detection tests allow for robust statistical findings, while the conventional tests result in findings that are not statistically significant after multiple testing adjustment, highlighting the utility of the cluster detection approaches for the identification of susceptibility genes in larger CNVs.

1091F

Identification and characterization of the first OSBPL1A mutations in individuals with low plasma HDL-C levels. *M.M. Motazacker[1], H. Kentala[2], J.A. Kuivenhoven[3], A.W. Schimmel[1], Y. Zhou[2], J. Pirhonen[2,4], E. Ikonen[2,4], G.M. Dallinga-Thie[1], G.K. Hovingh[1], M. Jauhiainen[5], V.M. Olkkonen[2,4].* 1) Department of Vascular Medicine, Academic Medical Center, Amsterdam, Netherlands; 2) Minerva Foundation Institute for Medical Research, , Helsinki, Finland; 3) University Medical Center Groningen, Department of Molecular Genetics; 4) University of Helsinki, Institute of Biomedicine and Anatomy, Helsinki, Finland; 5) National Institute for Health and Welfare, Public Health Genomics Unit, Helsinki, Finland.

Oxysterol-binding protein-like proteins (OSBPLs) have regulatory or sterol-transfer functions in eukaryotic cells from yeast to human. However, the detailed mechanisms of their action and their contribution in human phenotypes have remained elusive thus far. In search of variants involved in extreme HDL-C phenotypes, we sequenced ~200 lipid associated genes including several members of OSBPL gene family in individuals with low or high plasma HDL-C levels. Results: We identified 2 missense (p.R186W and p. Q459P) and 1 indel (p.C39X) variant in OSBPL1A in 3 unrelated individuals with low HDL-C levels. All mutations involved highly conserved nucleotides (PhastCons score =1) and were predicted to be deleterious to protein structure/function. Families of the index patients were expanded and even after excluding index patients, plasma HDL-C levels were significantly lower in carriers of the variants compared to non-carrier relatives ($p<0.05$) while there was no difference in LDL-C, TG or Total cholesterol levels between the two groups. Immunoprecipitation experiments in HuH7 cells showed a lack of binding to Rab7 -GTPase controlling membrane trafficking between early/late endosomes and lysosomes- for the p.C39X variant. We then studied subcellular localization of GFP-tagged OSBPL1A by overexpressing wild-type and mutant proteins in HuH7 cells. Unlike WT protein which was mainly detected on late endosomal compartments, p.C39X variant showed a cytosolic distribution and p.R186W variant showed enhanced association with endoplasmic reticulum and nuclear membrane. The p.Q459P variant was localized on late endosomes however these compartments were smaller in size and more frequent in number compared to WT protein. Conclusions: We have identified the first OSBPL1A mutations in individuals with low plasma HDL-C levels. The variants have deleterious effect on localization of the protein and can potentially influence endosome motility and function. An anticipated relation between disturbed endocytic pathway function, cholesterol transport and low plasma HDL-C levels is currently being investigated.

1092W

Whole exome sequencing to identify variants influencing both pre-diabetic traits and type 2 diabetes mellitus in Pima Indians. *L.J. Baier, K. Huang, A. Nair, Y.L. Muller, M. del Rosario, S. Kobes, R.L. Hanson, W.C. Knowler, C. Bogardus.* PECRB, NIDDK/NIH, Phoenix, AZ.

Genes associated with type 2 diabetes (T2D) have been previously identified, but the causative variant underlying the association and the physiologic mechanism whereby the gene influences T2D risk are often unknown. The goal of this study is to identify coding variation that increases susceptibility to T2D via its effect on a pre-diabetic trait. Exome sequencing was done on 177 Pima Indians and 148,616 variants (11.1% novel) were detected that met our quality control criteria. Of these variants, 15,799 and 15,642 were non-synonymous and synonymous SNPs, respectively. Selected variants (N=360) were genotyped in 555 non-diabetic Pima Indians characterized as inpatients in our Clinical Research Center for % body fat (PFAT), central obesity (waist/thigh), glucose disposal rates (M) during a hyperinsulinemic-euglycemic clamp, acute insulin response (AIR) to intravenous glucose, and 2-hour plasma glucose concentrations (2-hr glucose) during an OGTT. Variants were further assessed for association with BMI and T2D in up to 7,667 subjects who had participated in a longitudinal study of T2D in the Gila River Indian Community. Two SNPs (in the genes *ASXL3* and *CYB5A*) were significantly associated with a pre-diabetic trait after correction for multiple testing (360 SNPs analyzed for 5 traits required a $p<2.7\times10^{-5}$). The SNP in *ASXL3* (rs2282632) was associated with insulin sensitivity (M; $p = 2.0\times10^{-5}$, adjusted for age, sex, PFAT and nuclear family membership) but was not associated with T2D. In contrast, the SNP in *CYB5A* (rs7238987) was associated with PFAT ($p=6.7\times10^{-6}$) in 555 non-diabetic subjects, BMI measured at a non-diabetic exam in 5880 subjects ($p=6.2\times10^{-7}$) and T2D in 7667 subjects (OR=1.14 [1.03-1.14]; $p=9.2\times10^{-3}$). Variants in 5 other genes (*RNF10*, *BBS12*, *ACACB*, *ZNF530* and *HNF4A*) had comparable associations with T2D ($p<9.0\times10^{-3}$), but their associations with pre-diabetic traits were weaker (not significant after adjustment for multiple testing). In summary, *CYB5A* provided the strongest evidence for a pre-diabetic loci. It encodes a membrane bound microsomal hemoprotein which acts as an electron carrier for the stearoyl-CoA-desaturase (SCD) complex facilitating the conversion of saturated fatty acid to mono unsaturated fatty acid. Prior studies have reported that SCD activity is associated with obesity. We conclude that exome sequencing is a viable technique for identifying new loci that increase risk for T2D via an influence on a pre-diabetic trait.

1093T

Whole-exome sequencing of 4,000 samples identifies rare variants strongly associated with type 2 diabetes risk in Mexicans and Latinos. *K. Estrada[1,2,3] for the SIGMA T2D Consortium.* 1) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 3) Harvard Medical School, Boston, MA. USA.

Type 2 diabetes (T2D) is more prevalent in Latino populations than in people of European descent. We investigated the hypothesis that this increased T2D risk in the Latino population may be driven by rare, and possibly population-restricted, protein-coding variants that have remained undetected by previous studies focusing on common genetic variation.

We performed the largest ever whole-exome sequencing project of Mexicans and Latinos totaling 3,946 samples equally distributed between T2D cases and controls.. Samples were selected based on high Native American ancestry from a pool of 9,225 well-characterized individuals who had been genotyped with OMNI 2.5 and ExomeChip arrays. After stringent quality control 3,792 samples were available for analysis and included ~1.2M variants.

The most significant locus identified pointed to a novel common variant in the 5'UTR of SLC16A11 (minor allele frequency [MAF]=36.7%, $P_{EMMAX}=1.7\times10^{-10}$, OR=1.3). Our prior GWAS identified missense variants in this gene associated with T2D (in review). The 5'UTR variant is rare in European and African populations (MAF <2%) but common (MAF = 28%) in Mexicans of the 1000G project.

The second most significant signal pointed to a novel non-synonymous rare variant (control MAF = 0.2%, case MAF = 1%, $P_{EMMAX}=4.4\times10^{-7}$, OR=3.8). This variant seems to be largely private to the Latino population: we only observed 2 carriers in a collection of 26,000 non-Latino exomes of mainly Caucasian ancestry. This variant has previously been reported as dominant causal for a mild version of *maturity-onset diabetes of the young* (MODY) in two cases. However, our data indicate that this variant confers a large-effect (but not fully penetrant) risk for T2D present in 0.2% of our controls with age range of 45-73.

Ongoing work includes 1) imputation of our non-sequenced samples using a reference panel based on those samples with both array and sequence data 2) collapsing and other burden tests and 3) exome analysis of severe Mendelian forms of T2D such as MODY and neonatal diabetes. Our results suggest that previously uncharacterized rare population-specific genetic variants contribute to the high burden of T2D in the Mexican population.

1094F

A test of association of genome-wide coding variation with type 2 diabetes in 13,000 individuals from five ancestry groups. *P. Fontanillas[1], N. Burtt[1], P. Cingolani[2], J. Flannick[1], K. Gaulton[3], H. Highland[4], A. Mahajan[3], A. Morris[3], M. Rivas[3], X. Sim[5], T. Teslovich[5] on behalf of T2D-GENES and GO-T2D Consortia.* 1) Prog Medical & Population Genetics, Broad Institute, Cambridge, MA; 2) McGill University and Génome Québec Innovation Centre, Montréal, Canada; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 4) Human Genetics Center, University of Texas Health Science Center, Texas, USA; 5) Department of Biostatistics and Center for Human Genetics, University of Michigan, Ann Arbor, MI.

We sequenced the coding regions of 18,162 genes in ~13,000 individuals (6,562 cases and 6,459 controls) to evaluate the contribution of coding variation to risk of type 2 diabetes (T2D). To maximize genetic diversity, samples were chosen from five ancestry groups: African American, East Asian, European, Mexican American, and South Asian. Of 3,473,514 SNPs and short INDELs identified, 2,038,377 were in exons and the remainder within 50bp of exons in introns or UTRs. Most variants had low minor allele frequency (MAF) (96%<1% and 88%<0.1%) and were specific to one ancestry group (79%).

We tested for single-variant association under an additive genetic model using meta-analysis. For common variants (MAF>5%), sequencing revealed no new coding variant association signals that were exome-wide significant ($p<2.5\times10^{-6}$). Eight variants in seven genes showed association with T2D at $p<10^{-4}$ [odds ratios (OR) <1.26]. The four known GWAS T2D lead variants located in coding regions (in *MACF1*, *PPARG*, *SLC30A8*, and *KCNJ11*) all had association p>10-4. For low-frequency variants (1% <MAF<5%), we demonstrated T2D association for an ancestry-specific coding variant in *PAX4*, a transcriptional regulator of β-cell development ($p=6.4\times10^{-9}$, OR=1.81 [1.48-2.17]). Three others variants (in genes *ATAT1*, *NT5E*, and *ZNF283*) showed p<10-4 and OR<1.57. For rare variants (0.1%<MAF<1%), 17 variants were observed with $p<10^{-4}$ and 2.16<OR<5.26. A variant in *FES* ($p=1.3\times10^{-5}$, OR=4.24 [2.09-12.04]) was of particular interest because of its location in a known T2D GWAS region (near *FURIN-PCR1*); it may be the transcript mediating the association signal at this locus. Gene-based burden analyses on rare variants (MAF<1%) using collapsing approaches identified few genes with T2D association signals ($p<10^{-4}$), in particular *ASCM3*, an acyl-Co A synthetase, which showed an enrichment of coding deleterious variants in T2D cases.

Our 13,000 sample multi-ancestry design was well-powered (80%) to detect exome-wide significant single variant association for low-frequency (1%<MAF<5%), and medium-large effects (OR>2.5). While some rare variant T2D association signals may emerge from our analyses, the hypothesis that low-frequency variants with large effects could be a main feature of T2D architecture is not supported by our results.

1095W

Whole Genome Sequencing to Identify Variants that Influence Pre-diabetic Traits in American Indians. *K. Huang, P. Piaggi, S. Kobes, R. Hanson, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

To identify genetic variation that influences pre-diabetic traits and thereby increases risk for type 2 diabetes (T2D), we obtained whole genome sequence data on 235 Pima Indians (127 men, age: 24.8±5.4 years, BMI: 33.4±7.4 kg/m2). These individuals had been metabolically characterized for the following traits when they were non-diabetic: BMI, % body fat, central obesity (waist/thigh), insulin-stimulated glucose disposal rate during a hyperinsulinemic-euglycemic clamp, acute insulin response to 25 g intravenous glucose bolus, and 2-hour plasma glucose concentrations during an oral glucose tolerance test. A subset of these subjects had also been profiled for gene expression levels (69 had expression data from a subcutaneous adipose biopsy and 90 had expression data from a skeletal muscle biopsy). Sequencing was performed by Illumina (N=200) and Complete Genomics, Inc (N=35). ~12 million variants were found, including ~10.2 million SNPs, ~1.3 million Indels and 255,802 substitutions. Association analysis between variants and pre-diabetic traits is ongoing, as are association analyses between variants and gene expression data to identify cis-acting variants. Variants with the strongest associations, as well as variants predicted to be damaging that map near candidate genes, will be genotyped in a sample of 555 Pima Indians who also have phenotypic information on pre-diabetic traits. Association with T2D will be assessed by genotyping in up to 7,667 American Indians who are part of a longitudinal study and have data on T2D status and BMI.

1096T

Whole exome sequencing identifies PAX4 nonsynonymous variant as susceptibility loci for type 2 diabetes in Koreans. *S.H. Kwak[1], J.I. Kim[2], K. Kim[3], Y.M. Cho[1], H.S. Jung[1], Y.J. Park[1], K.S. Park[1].* 1) Department of Internal Medicine, Seoul National University Hospital, Seoul, South Korea; 2) Department of Biochemistry and Molecular Biology Seoul National University College of Medicine, Seoul, Korea; 3) Department of Statistics, Sookmyung Women's University, Seoul, Korea.

Type 2 diabetes is a common complex disorder with strong genetic predisposition. Although more than 65 common genetic variants of diabetes have been identified so far, their effect sizes are small and they explain only a limited part of the heritability. In this study we used whole exome sequencing to identify low frequency, functional variants of type 2 diabetes. This was a case-control analysis using 324 confirmed type 2 diabetes patients and 101 carefully selected normal glucose tolerant elderly subjects without family history of diabetes. We limited our diabetes subjects to those who had at least one first degree relative of diabetes in their family. Whole exome capture was prepared using Agilent SureSelect version 4 + UTR and sequencing was performed by Illumina HiSeq 2000. Sequence alignment was done using BWA and Picard software and variant identification was done using GATK software. EPACTS software was used for rare variant association testing. A nonsynonymous variant in PAX4 (rs2233580, R192H) was associated with risk of diabetes in near exome-wide significance of P= 9.66E-05 with minor allele frequency (MAF) in diabetes subjects 0.122 and controls 0.030. We then compared diabetes subjects having the rs2233580T variant of PAX4 gene (N=77) and diabetes subjects not having this variant (N=247). Those with the variant had lower body mass index (23.3±2.5 vs. 24.0±2.5, P=0.037) and waist circumference (83.0±7.3 vs. 84.7±6.7, P= 0.047) with nominal significance. Another variant located in intron of SORBS3 (rs12680280) was significantly associated with risk of diabetes with MAF 0.017 in diabetes subjects compared to 0.099 in control subjects (P=2.15E-08). However, these variants require further replication and we are currently genotyping these variant in another set of 1,387 diabetes cases and controls and 821 gestational diabetes women. In conclusion, we have identified low frequency nonsynonymous variant in PAX4 to be associated with risk of diabetes in Koreans.

1097F

Large-scale exome chip association analysis identifies rare and low-frequency coding variants associated with glycemic traits. *A. Mahajan[1], X. Sim[2], A.K. Manning[3], M.A. Rivas[1], N. Grarup[4], H.K. Im[5], H.M. Highland[6], A.E. Locke[2], P. Fontanillas[3], T.M. Teslovich[2], J. Flannick[3], C. Fuchsberger[2], K. Gaulton[1], H.M. Kang[2], A.P. Morris[1], J.B. Meigs[7], C.M. Lindgren[1] for T2D-GENES and GO-T2D Consortia.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 4) Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, DK; 5) Department of Health Studies, University of Chicago, Chicago, USA; 6) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 7) Massachusetts General Hospital, Boston, Massachusetts, USA.

The extent to which low-frequency (LF; minor allele frequency (MAF) 1-5%) and rare (MAF <1%) coding variants contribute to variability of glycemic traits has not been systematically evaluated to date. To discover novel coding variants associated with fasting plasma glucose (FG) and fasting insulin (FI), and examine whether LF and rare coding alleles could explain established genome-wide association (GWA) signals for these traits, we studied up to 33,553 and 31,149 non-diabetic individuals of European ancestry for association with FG and FI respectively. Samples were genotyped using the Illumina HumanExome Beadchip array, which collectively represents >80% coding variation with >0.5% MAF in European ancestry populations. We tested variants for association with FG and FI using a linear mixed model to account for relatedness. We also carried out gene-based tests using the sequence kernel association optimal (SKAT-o) test. We then combined summary statistics at up to 135,904 high-quality autosomal variants and 14,667 genes across studies by meta-analysis. We identified one rare non-synonymous variant associated with FI at chip-wide significance (P= 3.7×10^{-7}) in a gene not mapping to an established locus: *URB2* (P= 2.75×10^{-7}; 0.1% MAF; E594V). Two novel non-synonymous variants (one rare and one LF) were also associated with FG, approaching chip-wide significance in *TP53BP1* (P=6.08×10^{-7}; 0.2% MAF; T1278I) and *GLP1R* (P=7.64×10^{-7}; 1.5% MAF; A316T). Of these, *GLP1R* encodes glucagon-like-peptide-1 receptor, and therefore transduces incretin signaling in pancreatic beta cells. We also identified multiple rare coding variants in *G6PC2*, that in aggregate were associated with FG (SKAT-o P=5.31×10^{-13}), which reside within an established GWA locus. Furthermore, conditional single variant analysis confirmed the presence of two independent association signals in this gene, one common (P_{COND}=2.28×10^{-15}; 48.2% MAF; V219L) and one rare (P_{COND}=1.23×10^{-9}; 0.8% MAF; H177Y), neither of which can explain the GWA signal at this locus (lead SNP rs560887). They are also independent of nearby promoter variants (r^2<0.2) identified in a recent study to be potentially functional. In conclusion, these results provide evidence that LF and rare coding variants contribute to variability in glycemic traits, and support *G6PC2* as the causal gene at the established FG GWA locus.

1098W

Exome Chip genotyping in 9,000 individuals (type 2 diabetes and controls) in Mexican and Latinos. *J.M. Mercader[1,2], H. Moreno[3], A. Huerta[3], M.J. Gomez[3] for the SIGMA T2D Genetics Consortium.* 1) Medical and Population Genetics Program, Broad Institute of MIT and Harvard, Cambridge, MA., United States of America; 2) Center for Human Genetic Research and Diabetes Research Center (Diabetes Unit), Massachusetts General Hospital, Boston, Massachusetts, United States of America; 3) Instituto Nacional de Ciencias Medicas y Nutricion Salvador Zubiran, Mexico City, Mexico.

Type 2 diabetes (T2D) has become a mounting health problem in Mexico, with an estimated nationwide 25% increment in prevalence over a 7 years period. To date, most genome-wide association studies (GWAS) to identify susceptibility genes for T2D have been carried through common variant genotyping arrays with very comprehensive coverage of European variability, but with lower coverage in other populations. Under the hypothesis that population-specific common and rare coding variants, in Mexicans and Latino-Americans may influence risk of T2D, we genotyped 4,210 T2D cases and 4,786 controls with the Exome Chip. The Exome Chip was designed to capture 235,933 protein-coding variants (mostly non-synonymous, splice-site and stop altering SNPs) that were selected based on ~12,000 sequenced exomes (including hundreds of Mexican American samples), as well as some common variants to control for population stratification and to tag already known GWAS hits. After quality control, based on several metrics and on genotype concordance with OMNI2.5M array in the same samples as well as a subset of 4,000 samples with exome-sequence, 161,676 variants in 8,621 individuals were tested for association using logistic regression adjusting for body mass index, age and ancestry via 10 principal component analysis. Among the top hits, we replicated the previously reported associations of SNPs in or near TCF7L2, and KCNQ1, with similar effect sizes and direction of effects shown in other populations. We also validated those variants identified last year in *SLC16A1* (SIGMA T2D Genetics Consortium, submitted) as well as an association in a splice-site acceptor variant in the *INS-IGF2* gene (OR=0.79; $p=7.0\times10^{-8}$) found through imputation in the same dataset. This variant, not yet replicated, has only been reported in Latin Americans, with its highest frequency in Mexico (MAF=0.17), and East Asian populations (MAF=0.01), according to 1000 Genomes. This study represents a proof of concept of how analyses of rare and common coding variants using a cost-effective methodology, such as the Exome Chip, in diverse populations can allow the identification of novel genes and functional variants involved in the susceptibility of complex diseases, such as T2D. Nonetheless, despite having systematically tested low frequency variants (MAF range of 0.1-5%) in 9,000 samples, we did not observe low frequency variants of larger effect as significantly meeting genome-wide significance for T2D risk.

1099T

A low frequency coding variant (A316T) in the glucagon-like protein receptor 1 (GLP1R) is associated with fasting glucose levels. *D. Waterworth[1], R. Scott[2], L. Li[3], C. Gillson[2], J. Aponte[4], L. Warren[3], S. Chissoe[4], M. Ehm[4], N. Wareham[2].* 1) Genetics, GlaxoSmithKline, King of Prussia, PA; 2) Department of Public Health, University of Cambridge, UK; 3) Statistical Genetics, GlaxoSmithKline, RTP, NC; 4) Genetics, GlaxoSmithKline, RTP, NC.

It has been anticipated that mining of the low frequency spectrum of variation will identify meaningful associations that were not observed with common variation (>5% MAF). With a focus on type 2 diabetes and related traits as well as obesity, we attempted to replicate and extend findings from a large sequencing study of 202 drug-target genes in 4065 subjects phenotyped for cardiovascular and metabolic traits (Nelson 2012). We selected 30 variants to be assessed in up to 46,037 subjects of European origin (cohorts including CoLaus, LOLIPOP, EPIC-Norfolk, Norfolk Diabetes Study, Ely and Fenland). All variants identified in the initial study were also imputed into a subset of these studies where genome-wide data were available (up to 10K individuals). We performed meta-analyses to test for association between these 30 variants and diabetes, insulin, glucose and obesity-related traits. A p value of <3.6e-5 was considered significant (independent tests for 202 genes for a given trait). Imputed and genotyped results of interest included SNPs within the GLP1R gene associated with fasting glucose (p=4e-4), HRH1 gene variants associated with insulin (p=2.7e-5), IL1R1 (p=2e-4) variants associated with 2-hr glucose, CNR2 variants associated with HOMAB in obese subjects (p=3e-4) and NTRKB variants associated with waist (4e-4). These results were not previously identified by genome-wide studies at genome-wide significant levels. Additional results from recently published studies were added to increase the level of evidence. The most compelling result emerging from 11,497 subjects from the CoLaus and LOLIPOP studies was an association between rs10305492 coding for A316T (MAF 0.02) in GLP1R with fasting glucose (adjusted for BMI), the target of the GLP1 agonists. This variant was included in a recent meta-analysis of 38,000 individuals (Manning 2012) , including individuals from the Ely and Fenland studies, and also showed an association with fasting glucose (p=1e-4). We have identified associations with a number of existing drug target genes for diabetes including GLP1R and ILIR1 which can assist in target validation or drug repositioning. Moreover, we provided information on novel targets such as CNR2 and identified a common variant in NTRKB which had previously been identified only as a rare cause of extreme obesity gene in children. Nelson et al, 2012, Science 337;100-4 Manning et al, 2012, Nat Genet 44:659-69.

Whole genome sequencing identifies novel low frequency variant associations in liver function traits. *L. Quaye on behalf of the UK10K Consortium Cohorts Group.* Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom.

1,754 individuals from the TwinsUK cohort were whole genome sequenced (WGS) to average 6.5x coverage using next-generation sequencing technology, as part of UK10K Consortium Cohorts Group. Variants from 1000 Genomes and those discovered through WGS conducted on 3,621 individuals within UK10K were imputed into individuals in the TwinsUK cohort who had been previously genotyped, thereby increasing the sample size for analysis. In a meta-analysis of directly sequenced and imputed variants, we evaluated variants for association with liver function traits (albumin, alkaline phosphatase, total bilirubin and gamma-glutamyl transpeptidase (GGT)) of individuals from the TwinsUK cohort. Association analysis was performed on quantile-normalised abundance of the liver function traits, with adjustments for age and body mass index. 22 previously reported genome-wide significant associations between total bilirubin and the *UGT1A* cluster on chromosome 2 were replicated (P<5E-08). In addition, an association was identified between levels of bilirubin and a variant of *KCNB1* (20q13.2) with a minor allele frequency (MAF) of 0.026 (beta= 0.61, standard error (SE)=0.11, P=6.02E=08). This variant, also associated with height, is a missense mutation within the coding region, resulting in a proline to serine amino acid substitution. This association is being replicated with exome sequencing data and an independent cohort. A further genome-wide significant association was found between GGT and a rare variant not available in HapMap2 reference panels), near *TEX14*, on chromosome 17p13 (MAF= 0.019; beta beta=-0.82842, SE=0.17, P=8.99E-7), which is not available on Hapmap2. A SKAT analysis of 26,367 gene regions using 42,799 non-overlapping windows with maximal 50 coding variants with MAF<5% showed a suggestive association (P=3.1E-5) between KCNB1 and bilirubin. In conclusion, we found novel associations have been found between bilirubin and GGT and variants with MAF<0.05. These promising early results from the UK10K project highlight the value of WGS studies in identifying novel associations and indicate that low frequency variants are likely to contribute to the genetic variance of liver function traits.

Autozygosity Mapping in Pakistani Intellectual Disability Families. *M. Rafiq[1], K. Mittal[1], I.A. Balouch[1,2], A. Noor[1,3], C. Windpassinger[4], A. Mikhailov[1], M. Aslam[5], M. Ayaz[5], A. Mir[6], M. Ansar[7], P. John[2], M. Ayub[5,8], J.B. Vincent[1].* 1) Molecular Neuropsychiatry, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Atta-ur-Rehman School of Applied Biosciences (ASAB), National University of Sciences and Technology (NUST), Islamabad-Pakistan; 3) Dept. of Pathology & Laboratory Medicine, Hospital for Sick Children, Toronto, Canada; 4) Institute of Human Genetics, Medical University of Graz, Austria; 5) Lahore Institute of Research & Development, Lahore, Pakistan; 6) International Islamic University, Islamabad, Pakistan; 7) Dept. of Biochemistry, Quaid-i-Azam University, Islamabad, Pakistan; 8) Division of Developmental Disabilities, Dept. of Psychiatry, Queen's University, Kingston, ON, Canada.

Autosomal recessive causes of intellectual disability (ARID) have, until very recently, been under-researched due to the high degree of genetic heterogeneity. However, now that genome-wide approaches can be applied to single multiplex consanguineous families, identification of genes harboring disease-causing mutations by autozygosity mapping is expanding rapidly. We have ascertained more than 165 multiplex, consanguineous ARID families from Pakistan. These families are selected for lack of obvious syndromic features. Our strategy includes genotyping family members on genome-wide single nucleotide polymorphism microarrays, looking for large regions of shared homozygosity (and haploidentity) between affected individuals (homozygosity-by-descent, or autozygosity). We also screen for potential disease-related CNVs- either as a shared homozygous genotype, or heterozygous as a potential cause of phenocopy. We firstly exclude any known ARID genes in HBD regions, then either select candidates from within the HBD region for mutation screening by Sanger sequencing, or we embark on whole exome sequencing to identify disease mutations. Our successes include a number of new genes for apparent non-syndromic ARID, such as MAN1B1, TRAPPC9, NSUN2, as well as new genes for syndromic forms or ARID, such as Joubert syndrome (CC2D2A and TCTN2), and many known ARID genes (TUSC3, TPO, VPS13B, PEX1, PSPH, PMM2). Here we describe the use of autozygosity mapping and whole exome sequencing to identify an additional 6 new genes for NS-ARID. As more and more genes for ID are identified, using these and other strategies, we are building a picture of the biological pathways that, when perturbed, may lead to intellectual disability.

1102T

Identifying Genetic Variants Associated with Anorexia Nervosa via Exome Sequencing. *S. Yu, E. Pruett, R. Cone, B. Li.* Vanderbilt University, Nashville, TN.

Anorexia nervosa (AN) is a highly heritable psychiatric disease characterized by inability to maintain a minimal normal weight, persistent fear of gaining weight and preoccupation about body shape. It affects 0.5-1% of the population with females 10 times more likely to be affected than males. The estimated heritability of AN is 56-75%; however the genetic basis of AN is largely unknown. Results from previous candidate gene studies are often not replicated and genome wide association studies focusing on common variants (e.g. minor allele frequency >5%) do not reveal convincing association signals. We hypothesize that low frequency and rare variants with relatively higher genetic effects play an important role in the genetic etiology of AN. To identify genes and pathways harboring such high-risk rare variants, we carried out exome sequencing on ~70 AN patients and their relatives selected from multiple-generation pedigrees with high loads of AN and other comorbid psychiatric traits. We followed the best-practice procedure for variant calling and annotated all variants using ANNOVAR. We performed single variant analyses using MQLS to identify variants enriched in AN cases compared to their relatives. Although no variants reached exome-wide significance, we observed 14 genes harboring deleterious variants with p value < 10-3. We further carried out gene- and pathway-based analysis by collapsing multiple rare functional variants (i.e. nonsynonymous, splice and stop variants) predicted to be deleterious by bioinformatics algorithms. Using the KEGG knowledge base we identified pathways that are enriched for genes harboring deleterious functional variants, with the most common pathways identified being involved in neurodevelopment. We will sequence additional samples from an independent cohort to further replicate our initial findings.

1103F

Identifying the genetic architecture of neural tube defects by exome sequencing a multiplex anencephaly family. *K. Soldano, D. Krupp, H. Cope, M. Garrett, A. Ashley-Koch, S. Gregory.* Center for Human Genetics, Duke University, Durham, NC.

Neural tube defects (NTDs) are among the most common of birth defects, occurring in approximately 1 in 1000 live births in the US. Caused by improper closure of the developing neural tube during development, NTDs encompass a broad range of phenotypes that are likely to have a complex etiology with both genetic and environmental factors. The most severe NTD phenotype is anencephaly, an open NTD that results in the partial or complete loss of the brain and skull, and is therefore incompatible with life. While most cases are sporadic, some families have multiple affected offspring and are more likely to harbor a highly penetrant genetic risk factor. We performed exome sequencing on one such family who had three consecutive anencephalic pregnancies and a fourth unaffected pregnancy. We have completed the sequencing and analysis of the parents and the first two affecteds in this multiplex family. While we observed that the second affected sample was contaminated with maternal tissue (likely taken at the time of collection), we were able to correct for this using parental genotypes and allele proportions at each site. Exonic regions were enriched using the Illumina TruSeq Exome Enrichment kit, sequenced 2×100nt on an Illumina HiSeq2000 instrument, and aligned against NCBI build 37. Variants were called using the Genome Analysis Toolkit, and only sites with a minimum read depth of 3, quality score of 50, mapping quality of 45 and quality by depth of 7 were included in analysis. The initial set of 115,066 variants was further filtered by requiring concordant genotypes and the presence of at least one minor allele in both affecteds; 34,701 variants met these criteria. We identified 10 nonsynonymous variants in genes belonging to the Gene Ontology term cilium morphogenesis. All of these variants had deleterious effects as predicted by PolyPhen-2, SIFT, and/or PROVEAN, including a pair of compound heterozygous sites in the gene KIF24. These two variants had minor allele frequencies of 0.8% and 19.1% and were inherited from both the mother and father. Exome sequencing of the third affected and the unaffected sibling are currently underway to refine the putative causal genetic risk factors in this family. We are encouraged that the initial findings have implicated molecular pathways previously associated with NTD risk. Downstream functional analyses will be necessary to fully delineate the role of these polymorphisms in the development of anencephaly.

Whole exome sequencing case-control using 1,000 severe obesity cases identifies putative new loci and replicates previously established loci. *A. Hendricks on behalf of the UK10K Consortium: Obesity.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The UK10K project (www.uk10k.org) has sequenced 10,000 individuals: 4,000 cohort participants using low depth (6x) whole-genome sequencing (WGS) and 6,000 disease cases using high depth (50x) whole-exome sequencing (WES) with the aim of providing a variant resource to the community and identifying new disease loci. Of the 6,000 WES cases, 1,000 are patients from the Severe Childhood Onset Obesity Project (SCOOP). SCOOP consists of UK white patients, with an age of onset below 10, and with a body mass index (BMI) Standard Deviation Score (SDS) > 3, a design that is enriched for rare, highly penetrant causes of obesity. Single-variant and gene-region based case-control analyses, using two different control sets, has confirmed previously known obesity signals as well as identified potentially new variants and gene-regions associated with severe childhood obesity. The single-variant case-control analyses were performed using the low depth WGS UK10K population cohort, and a subset of the other WES UK10K disease cases that had been consented for use as controls. After thorough pre- and post- analysis quality control, the results do not show any apparent systematic bias and produce 27 promising single variant associations (p-value < 1e-5), which we are following-up in additional samples. Amongst these is a single variant association within the ADCY3 region (p=3.6e-06), a gene with an established association with BMI. Finally, we performed gene-region based case-control analysis using SKAT-O using the subset of other WES UK10K disease cases as controls. We find several potentially novel gene-regions associated with obesity and are currently performing targeted resequencing of nearly 3,000 independent SCOOP samples to replicate and add further evidence to these findings. The case-control analyses and replication efforts described here highlight the potential value of case-control using WES data to identify disease-associated loci and will help gain further insight into severe childhood obesity.

1105T

Rare variant association analysis reveals novel associations with lipids in genes within established loci via imputation up to the 1000 Genomes Project reference panel.

Genome-wide association studies (GWAS) have been extremely successful in identifying novel loci contributing genetic effects to plasma concentrations of lipids. These loci are typically characterised by common variant associations, and together account for no more than ~25-30% of the genetic variance of total cholesterol (TC), low- and high-density lipoprotein cholesterol (LDL-C and HDL-C), and triglycerides (TG). The aim of this study was to assess the evidence for association of these traits with rare genetic variation (MAF<1%) within genes through imputation into GWAS genotype data from the ENGAGE Consortium.

We considered 31,853 individuals from 17 GWAS of lipid traits, each imputed up to the Phase I 'all ancestries' 1000 Genomes Project reference panel (November 2011 release). In each study, we tested for association of all traits with accumulations of minor alleles at high-quality rare variants (MAF<1% and imputation quality >0.4) within genes (boundaries defined from the UCSC Human Genome database) using GRANVIL (http://www.well.ox.ac.uk/GRANVIL/index.shtml). Association summary statistics were then combined across studies via fixed-effects Z-score weighted meta-analysis.

We observed genome-wide significant evidence of association (Bonferroni correction for 30,000 genes, $p<1.7\times10^{-6}$) for two lipid traits. Accumulations of minor alleles at rare variants were associated with TG within two genes at the *APOA5* locus: *ZNF259* ($p=1.5 \times 10^{-11}$) and *APOA5* ($p=5.0 \times 10^{-8}$). Common variation at this locus has been associated with lipid traits, and rare mutations in *APOA5* have been implicated in hypertriglyceridemia. By restricting our analysis to non-synonymous changes, accumulations of minor alleles at rare variants were associated with HDL-C within *LIPC* ($p=2.1\times10^{-7}$). This gene encodes hepatic TG lipase, an essential enzyme in HDL-C metabolism, and common variation at this locus has been associated with lipid traits.

We have identified novel rare variant associations with TG and HDL-C within genes in established lipid loci. Our results highlight the potential of imputation into existing GWAS data up to high-density reference panels as a tool for discovering rare variant associations with complex traits, and an alternative to costly re-sequencing experiments.

1106F

Identification of common and rare variants associated with trunk fat mass using whole-genome sequencing in the UK10K project.
L. Paternoster, UK10K Consortium Cohorts Group. MRC Integrative Epidemiology Unit, School of Social & Community Medicine, University of Bristol, Bristol, United Kingdom.

As part of UK10K Consortium, 1867 individuals from the Avon Longitudinal Study of Parents & Children (ALSPAC) were whole genome sequenced (WGS) to ~6.5x coverage. Variants discovered through WGS, along with those from 1000 Genomes were imputed into the full cohort with genome-wide SNP data, increasing the sample size to 5498. Trunk fat mass (a highly accurate measure of central obesity) was derived at age 9yrs using dual energy x-ray absorptiometry (DXA). To investigate common variation, we tested 8.8 million variants (MAF>1%) in a meta-analysis of sequenced and imputed variants for association with trunk fat mass. We found three loci with $p<5\times10^{-8}$. Two of these are in known BMI regions (*ADCY3* & *FTO*). The other locus (7p21.1) has previously shown suggestive evidence for association with BMI z-score change in Hispanic children ($p=7\times10^{-6}$). We also found a modest association signal between this variant and BMI in our data ($p=7\times10^{-4}$), but no association with waist hip ratio (WHR). The GIANT GWAS of BMI showed no association with this variant (p=0.847) which indicates that this signal might be specific to childhood obesity. 25 loci were suggestively associated ($p<1\times10^{-5}$); 17 are novel for weight-related traits and 9 are variants of low frequency (MAF<5%). We are replicating these in the TwinsUK arm of the UK10K project (n=1754 sequenced) and additional child cohorts. For rare variants (in WGS data only) we used SKAT to analyse 26,367 gene regions using 41,692 non-overlapping windows with maximal 50 coding variants with MAF<5%. We found three regions (*IL17RC*, *PPP4R1* & *RP11-1152B5*) associated with trunk fat mass ($p<1\times10^{-5}$). Further investigation of the signals in these regions show that two of these (*IL17RC* & *RP11-1152B5*) are driven by only one variant, whereas the signal for *PPP4R1* appears to be driven by two variants. Two of these genes (*IL17RC* & *PPP4R1*) also showed suggestive evidence for association with BMI (p<0.01), but no association with WHR. We are following these up by genotyping in the whole of the ALSPAC cohort to allow validation and replication. We will also investigate enrichment of hits according to functional annotation. The UK10K large-scale WGS project has identified novel loci for trunk fat mass. Our findings suggest that both rare and common variants contribute to the variance of this trait.

1107W

Statistical dissection of genetic factors influencing antibodies against Epstein-Barr virus nuclear antigen 1 (EBNA-1) using whole-genome sequence data. *R. Rubicz[1], M. Almeida[1], E. Drigalenko[1], T.D. Dyer[1], T.M. Teslovich[2], G. Jun[2], J.M. Peralta[1], C. Fuchsberger[2], A.R. Wood[3], A.R. Manning[4], T.M. Frayling[3], P. Cingolani[5], R. Sladek[6], D.M. Lehman[7], J.W. Kent Jr.[1], J.B. Harley[8], M.A. Carless[1], J.E. Curran[1], M.P. Johnson[1], S.A. Cole[1], L. Almasy[1], E. Kraig[7], G. Abecasis[2], R. Yolken[9], R. Duggirala[1], C.T. Leach[7], J. Blangero[1], H.H.H. Göring[1], T2D-GENES Consortium.* 1) Dept of Genetics, Texas Biomed, San Antonio, TX; 2) University of Michigan, Ann Arbor, MI; 3) University of Exeter, Exeter, United Kingdom; 4) Broad Institute, Boston, MA; 5) McGill University, Montreal, Canada; 6) Montreal Diabetes Research Institute, Montreal, Canada; 7) University of Texas Health Science Center at San Antonio, San Antonio, TX; 8) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 9) Johns Hopkins University School of Medicine, Baltimore, MD.

Infection with Epstein-Barr virus (EBV) is highly prevalent among populations around the world and can cause infectious mononucleosis and more severe diseases including Hodgkin lymphoma, nasopharyngeal lymphoma, and post-transplant lymphoproliferative disorders. We measured IgG antibodies against EBV nuclear antigen 1 (EBNA-1) in extended Mexican American families from San Antonio, Texas. We previously performed association analysis in 1,956 individuals using 1M SNPs and reported significant association in the human leukocyte antigen (HLA) region on chromosome 6. There were at least two independent loci in this region (lowest p-value of 1.4×10^{-15}), with HLA class II genes *HLA-DRB1* and *HLA-DQB1* identified as the best candidates. This region was not associated with antibody titer levels against 13 other pathogens, indicating that the loci are specific to EBV. Whole genome sequences (WGS) were recently generated on a subset of the study participants as part of the T2D Consortium. There were a total of >20M variants with more than 5 minor allele copies. Here we used the available cleaned WGS, including highly accurate imputed data for some relatives, in order to search for additional genomic loci associated with EBNA-1 level and to dissect the HLA region in detail. We did not identify novel loci elsewhere in the genome, aside from suggestive evidence of association for SNP rs16921084 on chromosome 8 ($p = 9.39\times10^{-8}$) near gene *IMPAD1*. Within the HLA region, the most significant result was obtained for SNP rs204999 ($p = 6.97\times10^{-9}$ and $\beta = -0.39$, A→G transition with minor allele frequency of 19.1%), which had previously been included in the 1M SNP panel. This SNP was previously associated with decreased risk of nodular sclerosing Hodgkin lymphoma (NSHL) and with schizophrenia. SNP rs204999 is intergenic between HLA class III genes *FKBPL*, which plays a role in intracellular signalling and has been identified as a potential inhibitor of tumor growth, and *PRRT1*. Other significant HLA SNPs, after correcting for >70k variants in the extended HLA region, included rs9276472 ($p = 4.05\times10^{-7}$; gene *MIR3135B*) and rs204995 ($p = 6.39\times10^{-7}$; gene *PBX2*), also in the HLA III region.

1108T

Whole-exome sequencing in age-related macular degeneration. *P. Whitehead[1], W.K. Scott[1], G. Wang[1], W. Cade[1], M.D. Courtenay[1], S.G. Schwartz[3], J.L. Kovach[3], A. Agarwal[4], J.L. Haines[2,4], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 4) Ophthalmology and Visual Sciences, Vanderbilt University School of Medicine, Nashville, TN.

Genome-wide association meta analysis (GWAMA) has implicated common variations in 19 genes as AMD risk factors. Rare variants (RV) are not well captured by genome wide association studies and may represent some of the unexplained heritability in AMD risk. We used whole exome sequencing (WES) in phenotypically extreme individuals to identify RVs implicating novel AMD genes. The GWAS 19 loci were used to calculate a genetic risk score (summed number of risk alleles weighted by effect sizes) for each individual. We created an 'extreme' case/control sample with the following characteristics: 38 individuals with bilateral neovascular AMD and the lowest calculated genetic risk score, and youngest ages at examination; 37 unaffected controls with no drusen, the highest calculated genetic risk score, and oldest ages at examination. Sequencing Capture was by Agilent SureSelect. Alignment and base calling used the Illumina CASAVA 1.6 pipeline, aligned to hg19 using BWA. Single nucleotide variants (SNV) and insertion-deletion variants (indels) were called by GATK Unified Genotyper with VQSR recalibration. Variants with VQSLOD<-3 and variant genotype likelihoods <99 were excluded. All variants were annotated using SeattleSeq Annotation. Association of individual SNV with AMD was assessed by Fisher's exact test. RVASSOC was used for the gene-based tests considering all variants and just rare (minor allele frequency < 5%), damaging coding variants. The 19 genes used to define genotypic extremes were excluded from the gene-based analysis. No gene-based tests met Bonferroni-corrected significance (2.2×10^{-6}). When considering all variants, 19 genes generated gene based test $p<5\times10^{-4}$. When considering only rare damaging variants, six genes (*KRT26*, *KRT27*, *MOG*, *PLD5*, *CD276*, and *SYT9*) generated gene based test $p<5\times10^{-4}$. *MOG* is close to known AMD gene *IER3*, and the others represent novel loci (*KRT26* and *KRT27* are adjacent genes). No novel variants in the 19 known AMD loci were associated with the extreme phenotype. Initial results of this WES suggest additional genes with multiple rare SNVs may influence AMD.

1109F

Whole Genome Sequencing Association Study for Quantitative Ultrasound of the Calcaneus. *S.G. Wilson* [1,2,3], . on behalf of the UK10K cohorts[4].* 1) Endocrinology & Diabetes, Sir Charles Gairdner Hosp, Nedlands, Australia; 2) Department of Twin Research, King's College London, London, UK; 3) Medicine & Pharmacology, University of Western Australia, Australia; 4) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK.

Aim: To identify genetic variants associated with Quantitative Ultrasound (QUS) of the Calcaneus which is used for evaluation of osteoporosis, we performed an association study using whole genome sequence (WGS) data from the UK10K Consortium.

Methods: 1327 individuals from TwinsUK cohort with QUS phenotypes (broadband ultrasound attenuation (BUA) and velocity of sound (VOS)) and WGS were studied. The BUA and VOS data were adjusted for age, age^2, height and weight. We undertook single variant tests using SNPTEST. Variants with a MAF <0.005 or not in Hardy-Weinberg equilibrium were excluded. Significant and suggestive thresholds were set at 5E-8 and 5E-6 respectively.

Results: In the single variant analysis we identified 2 variants significantly associated with BUA at genome-wide significance and a further 76 showing suggestive association. No variants were associated with VOS at genome-wide significant level, however we observed 94 variants showing suggestive association with the phenotype. For VOS, 9 of the variants showing suggestive association were located in the FSHR gene region which has previously been associated with bone mineral density (BMD) and QUS parameters in postmenopausal women. For BUA, both variants associated at genome-wide significance and 28 of those showing suggestive association were located in the WNT16 gene region which has previously been associated with BMD, cortical bone thickness and osteoporotic fracture. Of the remaining loci identified in the study as provisionally associated, most were located in novel genomic regions not previously implicated in bone metabolism.

Conclusion: In this study of whole genome sequence data for association with QUS traits, 2 variants were identified as associated at genome-wide significance with a further 170 showing suggestive association. We were able to confirm the association of variants in the WNT16 gene with bone structural phenotypes and generated supporting evidence suggesting a role for the FSHR gene region in bone metabolism. We also highlighted many other novel loci and genes for further study. These variants will undergo additional replication through in silico analyses and de-novo genotyping.

Targeted Sequencing, Augmented with Public Resources, Identifies a Rare C3 Allele Associated with Large Risk of Agerelated Macular Degeneration. *X. Zhan[1,2], D. Larson[3,4], R. Fulton[3,4], C. Wang[5], D. Stambolian[6], E. Chew[7], E. Mardis[3,4], A. Swaroop[7], G. Abecasis[1,2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI, United States; 2) Center of Statistical Genetics, University of Michigan, Ann Arbor, MI, United States; 3) The Genome Institute, Washington University, St. Louis, MO, United States; 4) Department of Genetics, Washington University, St. Louis, MO, United States; 5) Department of Biostatistics, Harvard University, Boston, MA, United States; 6) Department of Ophthalmology and Human Genetics, University of Pennsylvania, Philadelphia, PA, United States; 7) National Eye Institute, Bethesda, MD, United States.

Macular degeneration is one of the most common causes of incurable blindness. Common alleles in >19 loci have now been associated with disease. We set out to investigate whether rare variants in the same loci were also associated with disease risk and to compare the relative effect sizes of common and rare variants.

In collaboration with the Genome Institute at Washington University in St. Louis, we designed a sequencing study focused on 8 of the known AMD risk loci (CFH, ARMS2, C3, C2/CFB, CFI, CETP, LIPC and TIMP3/SYN3) and 2 other candidate regions (LPL and ABCA1). We resequenced these regions in 3,124 individuals (2,335 cases and 789 controls) to an average depth of 85x. To augment the number of controls available for analysis, we designed an algorithm to identify previously sequenced samples with good coverage of our regions of interest and similar genetic ancestry. Finally, we investigated association between genetic variation in each locus and risk of disease using both single variant and gene level burden tests.

Across 967 kb of examined sequence, we discovered 41,202 high quality SNP variants in the 3,124 sequenced individuals (34,346 of these were novel, and not previously described in dbSNP). Among these variants, we focused our attention on 1,800 nonsynonymous, stop and splice variants. We estimated the ancestry of our sequenced samples and of samples from the NHLBI exome sequencing project, identifying an ancestry matched set of 2,268 cases and 2,268 controls. Individuals in this matched set had deep (minimum 10x) coverage of coding regions in the 10 targeted loci. Association analysis identified two strongly associated variants, one in the CFH gene (control frequency = 0.02%, exact Pvalue = 2.91×10^{-6}, OR = 23.11) and another in the C3 gene (control frequency = 0.40%, exact Pvalue = 2.73×10^{-4}, OR = 2.68). Replication efforts for these findings are ongoing.

Through targeted sequencing efforts, augmented with publicly available control data, we replicated a previously reported rare variant association in the CFH gene and identified a new rare variant signal in the C3 gene. In both instances, these rare variants are associated with substantially larger odds ratios than common variants in the same regions.

DES is uniquely useful in the identification of multi-gene alterations: Oligogenic findings make up a significant portion of previously undiagnosed patients. *K. Gonzalez, L. Shahmirzadi, E. Chao, S. Gandomi, M. Parra, B. Tippin Davis, W. Zeng, S. Tang.* Ambry Genetics, Aliso Viejo, CA.

Diagnostic exome sequencing (DES) has been instrumental in discovering the pathogenic etiology in patients in whom traditional molecular methods were uninformative. In addition to establishing a molecular diagnosis, enhancing genetic counseling, and aiding in clinical management, DES is uniquely useful in overcoming limitations posed by traditional molecular diagnostic strategies in the identification of multi-gene findings. Often complicating the interpretation of genetic variants are factors such as reduced penetrance and variable expressivity, frequently attributed to the effects of genetic modifiers. Herein, we examined the first 100 reported DES cases with positive gene alteration findings. Among them, 17 (17%) contained mutations in more than one reported gene of either positive or uncertain significance. The majority of the multi-gene cases (15) reported two gene findings, while two cases each reported three gene findings. All reported genes were associated with high penetrance disease as DES does not include the interpretation or reporting of disease-association risk alleles with low penetrance. The clinical spectrum of the patients with multi-gene findings was wide with 23% presenting with multiple congenital anomalies, 19% metabolic disease, 19% musculoskeletal phenotypes, and 15% childhood onset neurological disease. A minority of patients also presented with hematologic, cancer predisposition, cardiologic, and immunologic/infectious phenotypes. Interestingly, oligogenic findings were not identified among the cohort of positive results from patients presenting with autism spectrum disorder, which is typically considered multi-factorial. Virtually all patients had not previously received a clinical diagnosis consistent with our DES results and less than half had been provided with a consistent differential diagnosis. Among the 17 multi-gene cases, 11 (65%) contained at least one alteration classified as a deleterious mutation. If single gene testing had been performed for these patients, the pursuit of further molecular testing in the context of a single deleterious alteration in a well described gene would have been unlikely. Overall, these results reveal that oligogenic findings make up a significant portion of previously undiagnosed patients highlighting the value of DES in providing the most comprehensive molecular diagnosis available. Moreover, these data have significant implications for genetic counseling and clinical management.

1112F

Meta-analysis of rare variant associations for lipids metabolism traits. *D. Liu on behalf of the Global Lipids Genetics Exome Array Consortium.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Plasma lipids including total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, and triglycerides are biomarkers that predict the risk of coronary artery disease. Although many genetic loci have been identified for blood lipids using the genome-wide association approach, these variants collectively explain a modest proportion of overall heritability for these traits. In order to investigate the contribution of rare genetic variants to blood lipid levels, we assembled one of the largest exome-wide dataset to date. We examined array genotype data for ~201,000 protein coding variants in ~85,000 individuals from 34 studies with lipids measurements. Most variants were rare, with ~180,000 (83.5%) variants having a frequency of <1%. For analysis, we developed and implemented a method that uses summary statistics measuring association at each variant and their covariance matrix to reconstruct single variant and gene-level association statistics across the entire sample. At the time of submitting the abstract, we completed first round of association analysis. Overall, 154 coding variants (139 common with MAF>1%, 15 rare with MAF < 1%) were associated with one or more lipid traits at $p < 3\times10^{-7}$. In addition, 25 genes showed significant association with one or more lipid traits at $p < 2.5\times10^{-6}$ using at least one of the three gene level association tests we considered (a simple burden test for variants with frequency < 5%, a variable threshold association test, and sequence kernel association test for variants with frequency <5%).Loci with evidence for association include known and novel loci, such as *ABCA1*, *APOC3*, *APOE*, *LDLR*, *PCSK9*, *CD300LG*, *CELSR2*, *APOH*, and *NPC1L1*. Using this dataset, we are investigating the genetic architecture of lipids traits, to estimate the number and characteristics of rare variants contributing to plasma lipid levels, and quantify the impact of performing deep sequencing and enlarging sample sizes on the power for detecting rare variant associations.

Exome-wide association study of fetal hemoglobin levels in African Americans with sickle cell disease. *S. Lessard[1,2], G. Lettre[1,2].* 1) Montreal Heart Institute, Montréal, Québec, Canada; 2) Université de Montréal, Montréal, Québec, Canada.

INTRODUCTION: Reactivation of fetal hemoglobin (HbF) production in patients suffering from sickle cell disease (SCD) is a promising treatment. To develop such therapy, it is however necessary to understand the genetic mechanisms underlying the regulation of HbF levels. Genome-wide association studies have identified common variants associated with HbF at three loci (BCL11A, HBS1L-MYB and HBB), which altogether explain half of the heritability of the trait. Rare and low-frequency markers are expected to account for a substantial fraction of the unexplained heritability and are not tested using GWAS methodologies. METHODS & RESULTS: To address this issue, 250,000 DNA sequence variants, mostly coding and rare or of low-frequency, were genotyped in 1,495 African Americans with SCD from the Cooperative Study of Sickle Cell Disease (CSSCD) using the Illumina ExomeChip array. After quality control, 132,419 polymorphic markers and 1,301 individuals remained, with genotyping rate >99.9%. Variants with a minor allele frequency (MAF) ≥0.05 were analysed by linear regression against HbF using the software PLINK, accounting for age, sex and the first 10 principal components. The analysis replicated the association of HbF at the BCL11A, HBS1L-MYB and HBB loci. Excluding these loci, the lowest P-values were found at two SNP near the KLF1 gene ($P=9.08\times10^{-6}$ and 1.75×10^{-5}), an erythroid transcription factor implicated in the globin switch and hereditry persistence of fetal hemoglobin. We analyzed missense, nonsense and splice site markers with MAF <0.05 using the Optimal Sequence Kernel Association Test (SKAT-O), but no genes reached exome-wide significance (all $P>2.5\times10^{-6}$). To test if any biological pathways were enriched in the association results, we performed gene-set enrichment analyses using gene-based association results. Preliminary analysis revealed multiple pathways nominally enriched, implicating among others Notch, FGF and SAPK/JNK signalling. CONCLUSION: We genotyped SCD patients with the Exome Chip to identify functional DNA sequence variants associated with HbF levels. The data generated here will be combined with other genetic results along with comprehensive functional data in order to identify new regulators of HbF production and biomarkers of SCD morbidity.

Targeted sequencing identifies loci associated with sarcoidosis in African Americans. *I. Adrianto[1], G.B. Wiley[1], A.M. Levin[2], S.B. Glenn[1], M.C. Iannuzzi[3], B.A. Rybicki[2], P.M. Gaffney[1], C.G. Montgomery[1].* 1) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Department of Public Health Sciences, Henry Ford Health System, Detroit, MI; 3) Department of Medicine, SUNY Upstate Medical University, Syracuse, NY.

Sarcoidosis is a systemic granulomatous disease that primarily affects the lungs, but can manifest in multiple organ systems. While previous genome-wide association studies (GWAS) of both European and African American populations have identified common variants associated with sarcoidosis, rare variants (minor allele frequency<1%-5%) are hypothesized to have large effect sizes and may contribute to sarcoidosis risk. Therefore, we analyzed both common and rare variants to identify loci associated with sarcoidosis. We performed targeted sequencing using the Illumina HiSeq 2000 platform of 5Mb of genomic DNA within the loci identified through linkage, admixture, and GWAS in 187 sarcoidosis cases and 293 healthy controls of African Americans. All samples were sequenced with an average of 75x coverage. Rare variant association tests, which collapse rare variants within a gene of interest, were utilized using PLINK/SEQ. The sequence kernel association test (SKAT) was also applied to analyze both common and rare variants. An advantage of SKAT is its robustness to identify variants with different direction and magnitude of effects. Based on rare variant association tests, we identified 15 significant genes including PPT2 ($p=4.22\times10^{-4}$), FRMD3 ($p=4.46\times10^{-4}$), and ZNF451 ($p=5.66\times10^{-4}$). PPT2 has been associated with pulmonary function. FRMD3 is under-expressed in the lung tumor tissue of lung carcinoma patients suggesting its important role in the origin and progression of lung cancer. ZNF451 may play a role in transcriptional regulation. This gene is near RAB23, a sarcoidosis locus first identified in a German sample. From the SKAT test by taking into account both common and rare variants, we found 5 significant genes including HLA-DQA1 ($p=6.17\times10^{-4}$), AGER ($p=6.30\times10^{-3}$), and NOD2 ($p=4.33\times10^{-3}$). HLA-DQA1 plays a central role in the immune system and has been associated with sarcoidosis and other autoimmune disorders including rheumatoid arthritis, type 1 diabetes, and celiac disease. AGER has been associated with pulmonary function, whereas NOD2 that plays a role in the immune response, has been associated with early-onset sarcoidosis, inflammatory bowel disease, and psoriatic arthritis. This is the first targeted sequencing study to be done in sarcoidosis. We present the association of rare variants within genes in sarcoidosis. Replication and functional studies were required to define those associated genes in the specific pathogenesis of sarcoidosis.

Exome sequencing identifies variants in families with idiopathic scoliosis. *E. Baschal[1], K. Swindle[1], K. Calbart[1], C. Wethey[1], K. Gowan[2], K. Jones[2], N. Miller[1].* 1) Orthopaedics, University of Colorado Denver Anschutz Medical Campus, Aurora, CO; 2) Biochemistry and Molecular Genetics, University of Colorado Denver Anschutz Medical Campus, Aurora, CO.

Idiopathic scoliosis (IS) is the most common disorder of spinal imbalance, which, when progressive, leads to significant morbidity and financial burden to individuals and families. Most cases are strongly suspected to be genetic, arguing for the development of novel approaches to finding causative genes for this disorder. As efforts to find the genetic causations of IS, including GWAS, have not led to major advances in disease understanding, we believe that causal variants may differ among families. To this end, we used exome sequencing to focus on multigenerational families affected with IS.

We completed exome sequencing for 7 multigenerational families with IS, sequencing three affected individuals in each family (average 6 affected per family). Illumina HiSeq reads were mapped to the reference human genome sequence (hg19) with large-scale alignment software (GSNAP). Sequence calls for variants (single-nucleotide polymorphisms, insertions and deletions) were performed using the Broad's Genome Analysis Toolkit (GATK). The program ANNOVAR was used to filter the variants by cross-referencing multiple genetic variation databases (e.g., dbSNP, 1000 genomes database, AVSIFT, etc.). Information was extracted about variant frequency (if previously known) and location within genes. Non-synonymous changes, those that cause an alternate splice site, and/or aberrant stop codon were considered for further analyses. For non-synonymous changes, variants were cross-referenced to the dbNSFP database to determine whether changes to the protein were considered tolerable or damaging. Finally, a segregation filter was applied. Filtering criteria required variants to be present in all three affected individuals in the family. This bioinformatic filtering resulted in the identification of 3 to 26 potential causative variants in each family (minor allele frequency less than 5%). No variants were present in all families. We performed confirmatory Sanger sequencing for select variants in individuals who originally underwent exome sequencing and in additional affected and unaffected family members. These findings suggest that genes with identified variants may contribute to the scoliosis phenotype, a significant step towards determining the genetic etiology of this disorder. Further investigation is needed to validate novel genes for IS by sequencing the genes in an additional familial IS cohort.

1116W

Asthma: An Omics View through Discordant Monozygotic Twins. *R. Chen[1], G.I. Mias[1], S. Runyon[2], J. Li-Pook-Than[1], G. Euskirchen[1], P. Lacroute[1], K.C. Nadeau[2], M. Snyder[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Pediatrics, Stanford University, Stanford, CA.

Asthma is a complex disease that has a clear hereditary component. As a common disease, asthma affects 11% of the population in the United States, or 13% in children under age 18. To determine the contribution of genetic and epigenetic factors for this disease, we performed whole genome, whole transcriptome, and targeted methylome profiling in 20 pairs of monozygotic twins, who are discordant in asthma, using high throughput sequencing. We determined the whole genomes of 12 pairs of monozygotic twins discordant in asthma (as well as 1 pair discordant in allergy and 2 concordant healthy pairs), and sequenced the whole transcriptome of peripheral blood mononuclear cells (PBMCs) from 20 (including the 12 pairs for whole genome sequencing) discordant monozygotic twins pairs. In addition, we also examined DNA methylation differences within each discordant twin pair by targeted methylome enrichment and high throughput sequencing. We observed a spectrum of genomic differences within each pair of monozygotic twin, including single nucleotide variants, insertions/deletions, copy number variants, structural variants, as well as different mobile element insertions, although none seemed to be a significant contributor to the asthma phenotype. Whole transcriptome sequencing revealed surprisingly similar expression patterns in PBMCs within each twin pair, indicating strong genetic determination for gene expression in monozygotic twins. Differentially expressed genes between the discordant twins are enriched in pathways involved in immune response, which is a key feature for symptoms of asthma. In addition, we also observed interesting differential DNA methylation patterns in each monozygotic twin pair using bisulfite sequencing. Our study provides a unique perspective to evaluate genetic and epigenetic factors associated with this complex, common disease of asthma at the omics level.

1117T

Whole genome sequencing identifies genes and non-coding regions as modifiers of chronic Pseudomonas aeruginosa infection in cystic fibrosis. *J.X. Chong[1], M.J. Emond[2], T. Louie[2], R.L. Gibson[1], M.J. Bamshad[1,3], NHLBI GO Exome Sequencing Project.* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

We recently used exome sequencing of phenotype extremes to identify variants in *DCTN4*, *CAV2*, and *TMC6* that are associated with risk for chronic Pseudomonas aeruginosa (Pa) lung infection in individuals with cystic fibrosis (CF). To investigate the contributions of coding variants not captured by existing exome targets and non-coding variation on age of onset of chronic Pa infection, we performed whole genome sequencing on individuals with CF and early-onset (n=44) or late-onset (n=45) chronic Pa. We used SKAT-O with small sample adjustment to test for differences between extremes in the distributions of variants in genes and non-coding elements, down-weighting common variants. In the per-gene analysis, we analyzed non-synonymous, splice, and utr variants. The most significant (naïve p= 6.2×10^{-6}) association was observed with *CD22*. In the non-coding analysis, we used genome segmentation annotations from the ENCODE project to predict regulatory elements such as enhancers and insulators. We identified 44,749 predicted enhancers that were variable in at least five subjects. While current computational methods cannot reliably predict enhancer targets, the top two associations were a region upstream of *ADAM19* and an intronic region in *STAP1*. These genes play roles in host immunity and are thus biologically plausible candidates. Additionally, we used GREAT (Genomic Regions Enrichment of Annotations Tool) to assign enhancers to potential cis-regulatory target genes and identified a 10.7-fold enrichment (FDR q= 6.1×10^{-4}) for inositol phosphate kinase activity among the top 5% of enhancer associations. This signal is attributable to eight predicted enhancers in *ITPK1* and three in/near *ITPKB* (a kinase upstream of *ITPK1* in the inositol phosphate signaling pathway), yet neither gene was significant nor highly ranked by p-value in the per-gene analysis: *ITPK1* (naïve p=0.35) was ranked 6,158th and *ITPKB* (naïve p=0.15) 3,041st out of 15,800 genes. Interestingly, variability in *ITPK1* expression has been previously predicted to influence CF severity and to affect efficacy of CF drugs through regulation of alternative chloride channel activity, suggesting that variants in *ITPK1* enhancers could lead to differences in age of onset of chronic Pa infection. Nevertheless, validation in a replication cohort is a necessary next step. This analysis represents an early attempt to associate non-coding variation discovered by WGS using an extreme phenotype study design.

1118F

Exome chip analysis identifies rare variants associated with primary open angle glaucoma. *M.D. Courtenay[1], R.K. Lee[2], D.L. Budenz[3], J.L. Haines[4], M.A. Pericak-Vance[1], W.K. Scott[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, USA; 2) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL, USA; 3) Department of Ophthalmology, University of North Carolina, Chapel Hill, NC, USA; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Primary open angle glaucoma (POAG) is a complex ocular disorder with heterogeneous etiology comprised of genetic and environmental factors. Family-based linkage studies have identified few genes with rare mutations underlying POAG, and recently the GLAUGEN and NEIGHBOR consortium case-control meta-analysis implicated common variants in the *CDKN2BAS* and *SIX1/SIX6* genes. This study examined the potential effect of rare variants on the risk of developing POAG. Illumina HumanExome-12v1 arrays were used to genotype 112,385 SNPs in 273 Caucasian POAG cases (mean age 73, 75% normotensive POAG) and 795 controls (mean age 74.5). This array includes coding region variants across the genome, with a majority of variants (88%) being rare (minor allele frequency <5%). POAG cases were clinically evaluated and classified using the NEIGHBOR consortium criteria. After quality control, SKAT was used to assess the association between 16,422 genes and case-control status. SKAT's logistic regression analysis was adjusted for population structure using 7 principal components obtained from analysis with Eigenstrat, and SNPs in each gene were inversely weighted by allele frequency. No genes met Bonferroni criteria (P=3 × 10-6) for significant association, but thirteen genes had P values<0.001. None of the top genes have been previously associated with POAG or ocular development. The most significant gene overall (P=3 × 10-4) and in the normotensive POAG only subset (P=1.5 × 10-4) was *RNF216*, a ring finger protein that colocalizes and interacts with *RIP* to inhibit TNF-induced NF-KB activation. Interestingly, glaucoma has been associated with increased NF-KB activation and optineurin, another negative regulator of TNF-induced NF-KB, has also been previously associated with glaucoma. The next most significant overall gene was *JAG2* (P=5 × 10-4). Two rare missense mutations within this gene were more common in POAG cases than controls and contributed to the gene based result. *JAG2* is widely expressed and involved in notch signaling, which is important for embryonic development. *JAG2* was also recently implicated in the growth and dissemination of uveal melanoma. These initial results suggest that additional genes with multiple coding variants (both common and rare) contribute to the complex etiology of POAG.

1119W

Identification of Variants that Confer Susceptibility to Alzheimer Disease in the Amish through Exome Sequencing. *L. D'Aoust[1], A.C. Cummings[1], R. Laux[1], D. Fuzzell[1], L. Caywood[2], L. Reinhart-Mercer[2], W.K. Scott[2], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetic Research, Vanderbilt University, Nashville, TN; 2) Hussman Institute of Human Genomics, Miller School of Medicine, University of Miami, Miami, FL.

Recent studies using genome-wide association study data sets have successfully identified multiple loci harboring common variation conferring susceptibility to late-onset Alzheimer Disease (LOAD). However, these loci individually have modest effect sizes and the majority of the genetic etiology of LOAD remains unknown. Rare variants with larger effects may explain additional unknown genetic risk. The genetically isolated populations of the Amish in Ohio and Indiana are advantageous for detecting rare variants because they will be enriched for any rare variants carried by the founders. We hypothesized that rare variants conferring susceptibility to LOAD in the Amish can be identified by exome sequencing. We performed whole exome sequencing on 162 individuals (53 affected) selected from these Amish populations. After careful quality control, we identified 62,897 variants in or very near genes for analysis. Association analysis was carried out using MQLS, which adjusts for relatedness using kinship coefficients, for the variants identified through sequencing. We focused our analyses on two classes of genes: the first including 15 genes previously implicated in LOAD through GWAS or carrying early-onset mutations; the second including genes in our four previously identified significant genetic linkage regions. The exomes sequenced harbor 131 variants in the fifteen known AD genes. Of these, 120 have rs numbers assigned, 37 and 28 are not present in the current release of 1000 Genomes and the Exome Sequencing Project, respectively. The most significant p-value among these genes is 0.0098 for position 10,054,789 on chromosome 1 in ABCA7. Within the linkage regions, the most significant p-value was 0.00017 on chromosome 3. We also tested the remaining variants outside these regions, with the most significant p-value being 3.94×10^{-6} for position 128,525,253 on chromosome 3. Four additional variants have p-values less than 1×10^{-4}. The most interesting variants from this screen are currently being genotyped in the entire Amish dataset of more than 1,200 samples. Our previous genetic linkage studies suggested the Amish harbor previously unidentified LOAD loci, and these data continue to support that hypothesis. Continued studies of the Amish are necessary to identify the exact variations underlying their LOAD.

1120T

Whole-genome sequencing of an Italian Multiple Sclerosis multiplex family identifies a novel functional variant in GRAMD1B. *F. Martinelli Boneschi[1,2], F. Esposito[1,2], A. Osiceanu[2], A. Zauli[2], D. Cittaro[3], M. Sorosina[2], A. Calabria[4], D. Lazarevic[2], V. Maselli[2], P. Brambilla[2], G. Comi[1,2], E. Stupka[3].* 1) DEPT NEUROLOGY & INSPE, SCIENTIFIC INST SAN RAFFAELE, MILAN, MI, Italy; 2) Laboratory of genetics of neurological complex disorders, INSPE, Scientific Institute San Raffaele, Milan, Italy; 3) Genome Function Unit & Center of Translational Genomics and bioinformatics, Scientific Institute San Raffaele, Milan, Italy; 4) San Raffaele Telethon Institute for Gene Therapy (HSR-TIGET), Scientific Institute San Raffaele, Milan, Italy.

While the role of common genetic variants is clearly established from recent studies on individuals with multiple sclerosis (MS), the contribution of rare variants to the disease susceptibility in multiplex families remains unclear. The aim of this study is to identify rare genetic variants contributing to MS susceptibility in an Italian multiplex family. SNP microarray genotyping and whole-genome sequencing in 4 MS patients and 4 unaffected individuals belonging to an Italian multiplex family descending from a first cousin marriage were performed. The Merlin software was used for the linkage analyses and SNPeff software was applied to prioritize rare variants. We identified 12,938 variants with high or moderate functional impact according to SNPeff software annotation; 5,453 of them are present with at least one copy in all the patients, of which 250 are novel (not present in dbSNP 137) or rare (GMAF <0.02). Six of these 250 variants are located under one of the two LOD peaks (LOD>1.5) identified on chromosome 8p21.2 and 11q23.3. Four of them are homozygous in cases and controls, while the remaining two suggested an autosomal recessive mode of inheritance with incomplete penetrance. The first one (rs201865228) maps to the OR8G5 gene, which is an olfactory receptor gene under positive selection (GERP++ score=-3.33), while the second one falls within the GRAMD1B gene, causing an amino acid substitution (S601P) (GERP++ score=4.72). The second variant is a novel one, and segregates within the family, being homozygote in 3 affected individuals and heterozygote in the remaining MS patient. Sanger sequencing confirmed the above segregation with the disease. Interestingly enough, the heterozygote MS patient carries the highest genetic load of MS risk variants. GRAMD1B is a very conserved gene from yeast to human. It encodes a membrane protein, which is part of the GRAM containing domain family protein. In the mouse it is highly expressed in the central nervous system and in specific immune cell subtypes, like dendritic cells and neutrophils. Transfection experiments and functional studies are ongoing to investigate the role of the gene. on the disease.

1121F

Comprehensive genomic profiling of 66 cardiometabolic phenotypes by whole genome sequencing in 3,621 samples from the UK10K project. *J. Min, The UK10K Consortium Cohorts Group.* School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

As part of UK10K Consortium Cohorts Group, 3,621 individuals from two deeply phenotyped population-based collections - TwinsUK and the Avon Longitudinal Study of Parents and Children (ALSPAC) - have been whole genome sequenced (WGS) to average 6.5x coverage using next-generation sequencing technology. Variants discovered through WGS of the TwinsUK and ALSPAC cohorts along with those known from 1000 Genomes were imputed into the full genomewide association study genotyped cohorts increasing the sample size for single point association analysis to 12,724 subjects. In a meta-analysis of directly sequenced and imputed variants, we tested 8,8 million variants for association with 66 cardiometabolic phenotypes. In single point analysis, we found 30 novel loci with P<5e-8 of which 13 with an effect allele frequency below 5%. In addition, novel low frequency trait associations underlying known loci such as between *LDLR* and LDL and *LIPG* and total cholesterol were found. In WGS data only, we used SKAT to analyse 26,367 gene regions using 41,692 non-overlapping windows with a maximum of 50 coding variants with MAF<5%. We identified 18 regions below a gene-based significance threshold of P<1.9e-6 including known associations such as *ADIPOQ* and Adiponectin (P<3.7E-11) and *PCSK9* and LDL (P =1.8E-7). Novel loci are being validated and replicated. Among the single point associations with common variants (MAF>5%), we showed a consistent pattern of enrichment of exonic and 5'UTR variants using 100,000 permutations matched on TSS and MAF (p<1e-5, r2<0.1). The enrichment of exonic variants was also seen for single point associations with MAF 1-5%. As a substantial proportion of causal alleles may exist beyond the exome, we combined genome-wide maps of functional annotations including DNAseI hypersensitive sites (DHS) from six ENCODE cell types to estimate the pathogenicity of variants in regulatory or conserved regions. We found DHS enrichments of single point associations relative to sites not in DHS peaks, DHS hotspots or exons (p<1e-5, r2<0.1). We will investigate phenotype cell type specificity by comparing enrichments of cell-type specific sites to sites shared among multiple cell-types. Our results provide insights into how large-scale whole-genome sequencing efforts are likely to contribute to the understanding of the genetic architecture of cardiometabolic phenotypes and may therefore significantly increase previous estimates of explained heritability.

Functional annotation combined with evolutionary principles facilitate whole genome sequence analyses of complex traits: the Cohorts for Heart and Aging Research in Genetic Epidemiology (CHARGE) Consortium. *A.C. Morrison[1], F. Yu[2], J. Lu[3], A. Voorman[4], A.D. Johnson[5,6], J. Reid[2], X. Liu[1], D. Muzny[2], A.R. Folsom[7], C.J. O'Donnell[5, 6], B.M. Psaty[8,9], L.A. Cupples[5,10], A. Clark[3], R. Gibbs[2], E. Boerwinkle[1,2], The Cohorts for Heart and Aging Research in Genetic Epidemiology (CHARGE) Consortium.* 1) Human Genetics Center, University of Texas at Houston, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) NHLBI Framingham Heart Study, Framingham, MA; 6) Division of Intramural Research, NHLBI, National Institutes of Health; 7) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 8) Cardiovascular Health Research Unit, Departments of Medicine, Epidemiology, and Health Services, University of Washington, Seattle, WA; 9) Group Health Research Institute, Group Health Cooperative, Seattle, WA; 10) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Joint analysis of functional annotation of genome variation, particularly outside of non-protein coding regions, combined with empirical evidence of natural selection indicating phenotypic consequences should prove to be an efficient approach to analyzing whole genome sequence data. Here we intersect the results of sequencing the whole genomes of 2,700 deeply phenotyped individuals from the CHARGE consortium, annotation using multiple predictive functional genomic resources (e.g. dbNSFP and ENCODE), and application of population genetic measures of variation (e.g. Watterson's ϑ, nucleotide diversity (π), and integrated haplotype score (iHS)) to infer regions of natural selection. Predicted functional domains (e.g. transcription factor binding sites) with significant evidence of natural selection are used as the unit of inference for genotype-phenotype associations. Whole genome analyses of a priori annotated functional domains (e.g. transcription factor binding sites and microRNAs) reveal an abundance of evidence for selection acting on noncoding regions of the genome. Among the regions with the strongest evidence of natural selection, ~60% lie in intergenic regions, 33% in intronic regions, and slightly over 1% in genic regions. Focused analyses stratified by functional classes of noncoding variants detects pervasive purifying selection acting on enhancers, transcription factor binding sites, microRNAs and target sites but not on lincRNA or piRNAs, suggesting different evolutionary constraints for these domains. Plasma lipids, uric acid levels, and hemostatic factors are being analyzed using this approach. In preliminary analyses of the first 1,000 individuals with whole genome sequence, multiple non-protein encoding loci have been identified that show both evidence of natural selection and phenotypic associations. Detailed results will be shown in select regions as examples. In the first example, variants in a piRNA cluster (chr4: 10114931-10157431) upstream of the *SLC2A9* genes have high derived allele frequencies and are significantly associated with serum uric acid levels. In a second example, a CETPβ transcription factor binding site shows both strong evidence of natural selection and a significant effect on plasma lipid levels. These results document the power of combining whole genomic sequence annotation with evolutionary principles to identify functional regions of the genome influencing health and disease.

1123T

Exome sequence variants associated with blood levels of hemostatic factors: The Cohorts for Heart and Aging Research in Genetic Epidemiology (CHARGE) Consortium and the NHLBI Exome Sequencing Project (ESP). *N. Pankratz[1], J. Brody[2], M.H. Chen[3], B. Davis[4], P. Wei[4], J. Reid[5], C.J. O'Donnell[6], N.L. Smith[2], A.C. Morrison[4] on behalf of the CHARGE Hemostasis Working Group and the ESP Hemostasis Working Group.* 1) University of Minnesota, Minneapolis, MN; 2) University of Washington, Seattle, WA; 3) Boston University, Boston, MA; 4) University of Texas Health Science Center at Houston, Houston, TX; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 6) NHLBI's Framingham Heart Study, Framingham, MA.

Perturbed hemostasis, reflected by altered levels of blood coagulation proteins, can lead to morbidity and mortality from arterial and venous thrombosis. Hemostatic factors such as fibrinogen, coagulation factors VII and VIII, and von Willebrand factor (vWF), are intermediate phenotypes that are associated with clinical thrombotic events; thus, it is important to study these traits and identify genetic variants that increase susceptibility to clotting. To identify associations with rare and low frequency variants, we performed exome sequencing in independent samples from CHARGE and ESP. Sequencing in CHARGE was performed in a subset of participants from the Atherosclerosis Risk in Communities Study (ARIC; n=3,173 whites, 2,408 blacks), the Cardiovascular Health Study (CHS; n=741 whites), and the Framingham Heart Study (FHS; n=850 whites). ESP cohorts with available hemostasis measures included ARIC, CHS, FHS, Coronary Artery Risk Development in Young Adults (CARDIA), Multi-Ethnic Study of Atherosclerosis (MESA), and Women's Health Initiative (WHI), for a total of 2,649 EAs and 1,925 AAs. Available measures of fibrinogen, factor VII, factor VIII, and vWF varied across studies and projects. Initial results (n=3,851 whites total) are described for the meta-analysis of ESP and an initial subset of the CHARGE data for these four hemostatic factors using three approaches: 1) single variant test using linear regression for all variants above 5% minor allele frequency (MAF); 2) a 'T5' test where all non-synonymous or splice site variants with a MAF<5% are summed together to generate a gene score; and 3) the SKAT test which analyzes the same variants as the T5 test, but allows for effects to be in either direction and upweights the contribution of rarer variants. We found genome-wide significant associations for fibrinogen (*FGB*, p=4E-7), factor VII (*F7*, p=2E-74), factor VIII (*ABO*, p=1E-11), and vWF (*ABO*, p=6E=15) using the single variant test. These initial exome sequence analyses confirm prior genome-wide association analyses of common variants. The gene-based tests will be fully evaluated in the total combined sample of 6,225 whites and 3,908 blacks across ESP and CHARGE. These efforts represent the largest integration of exome sequence data from two large national projects to identify novel genes and variants associated with inter-individual variation in hemostatic factors.

1124F

Exome sequencing study identifies several candidate variants associated with Kawasaki disease. *Y. Park, J. Kim, J. Lee, Korean Kawasaki Disease Genetics Consortium.* Asan Institute for Life Sciences, University of Ulsan College of Medicine, Seoul, Korea.

Kawasaki disease (KD) is an acute systemic vasculitis of infants and children, manifested by fever and signs of mucocutaneous inflammation. The highly effective and standard treatment for KD is high-dose intravenous immunoglobulin (IVIG) therapy. However, about 20 % of KD patients have persistent or recurrent fever after the initial IVIG treatment, which increases the risk for coronary artery lesions. To identify susceptibility variants for KD, we sequenced whole exomes of 12 patients with KD as well as 17 control exomes. As unique variants to KD compared to control exomes, a total of 43 novel nonsynonymous single-nucleotide polymorphisms (nsSNPs) were detected by exome sequencing and validated by capillary resequencing. To replicate the findings, additional 18 KD patients and 18 healthy controls were analyzed by direct sequencing. We examined the associations between 30 KD patients and 35 controls in the combined data (exome sequencing data and small scale of case-control data) analysis, and identified strong signal of association with KD in 8 loci. Among 8 loci, 4 genes (*PDE3A, TNFSF8, IL16* and *CLEC11*) had variants unique in KD samples only and the other 4 genes (*HLA-DQB1, SNAPC4, MLL* and *HAVCR2*) showed high odds ratio (OR > 4.9). Currently we are investigating whether those 8 nsSNPs are significantly associated with Kawasaki disease in large independent samples of KD case and control. Our initial data suggest that whole exome sequencing can be used for the identification of causal variants of KD.

1125W

On the association of common polygenic variation with body mass index in 7062 Han Chinese women using low pass sequencing: genome-wide association, genetic risk scores, and GCTA. *R.E. The dramatic increase in obesity prevalence among both children and adults in developed countries and the numerous negative consequences associated with elevated body weight warrant additional research into the genetic and environmental contributions to body mass index (BMI). A mega-analysis of genome-wide association studies (GWAS) of BMI in populations of European descent has confirmed robust association with 32 single nucleotide polymorphisms (SNPs). Of these, seven loci demonstrated association with BMI in a meta-analysis of East Asian populations, including *FTO*, *MC4R*, and *BDNF*. The purpose of this study was to potentially discover variants associated with BMI, and to replicate previously identified associations using the CONVERGE (**C**hina, **O**xford a**n**d **V**CU **E**xperimental **R**esearch on **G**enetic **E**pidemiology) project, a study of 6,000 Han Chinese women with recurrent major depression and 6,000 matched controls. Currently, 7062 individuals have been sequenced genome-wide at 1.2x coverage, imputed genotypes estimated, and have BMI information. We investigated the extent to which common polygenic variation accounts for phenotypic variation in BMI in two ways. First, we applied Genome-wide Complex Trait Analysis (GCTA) to estimate, as a random effect, the cumulative genetic effect due to all SNPs genotyped. In aggregate, common SNPs accounted for 10.0% of the variance in BMI (95%CI=[4.1,15.9], p=0.0004) in CONVERGE. Compared to estimates of 17% for European populations using the same method, this suggests population differences in the heritability of BMI. Second, we determined the predictive value of an aggregate genotypic score by randomly dividing the sample into training and testing sets. Using the best linear unbiased prediction (BLUP) method to estimate SNPs effects in the training set, we subsequently tested their predictive value via an aggregate risk score in the testing set. The score was modestly associated with BMI (p= 0.004) accounting for 0.22% of the variance in the testing set. Preliminary GWAS results of ~7.5M SNPs indicated 3 variants reached genome-wide significance. However, we did not find robust association for previously identified BMI-associated variants (p_{FTO}=0.005, p_{MC4R}=0.0004, p_{BDNF}= 0.646). These preliminary results suggest genetic variation associated with BMI may only partially overlap between European and Han Chinese populations, highlighting the importance of studying genetic contributions to complex traits in diverse populations.

Motivation: We sought to identify rare coding variants which influence risk of advanced age-related macular degeneration (AMD), in order to better define disease mechanism. We were motivated by the discovery of the R1210C mutation in CFH by our group. This mutation confers high risk of AMD (OR~20) and causes loss of C-terminal
Methods: To find additional rare coding functional variants we applied next-generation sequencing to target the exons of 681 genes within AMD-associated loci and pathways in 2,493 cases and controls. We only identified one gene, CFI, with a significant burden of rare variants in cases. We observed that 7.8% of AMD cases compared to 2.3% of controls are carriers of rare missense CFI variants in our data (OR=3.6, $p=2\times10^{-8}$). The enrichment for predicted loss of function variants was particularly noteworthy, being seen in 7 cases compared to 0 controls. Many of these mutations are seen in familial forms of atypical hemolytic uremic syndrome. We also observed significant association with rare missense alleles outside CFI. Genotyping in 5,115 independent samples confirmed associations to AMD with a K155Q allele in C3 (replication $p=3.5\times10^{-5}$, OR=2.8; joint $p=5.2\times10^{-9}$, OR=3.8) and a P167S allele in C9 (replication $p=2.4\times10^{-5}$, OR=2.2; joint p=6.5x10-7, OR=2.2). Then, in functional binding studies we demonstrated that the 155Q allele in C3 results in reduced C3 binding to CFH, mirroring the function of the R1210C mutation in CFH. We then demonstrate that this reduced binding results in reduced cleavage and inactivation of 155Q compared to 155K C3 in cofactor assays by CFH and CFI mediated cleavage.
Conclusions: The combination of functional studies, and rare variants of large effect in C9, CFI, CFH, and C3, implicate excessive alternative pathway complement activation in AMD pathogenesis, in particular by dysregulation of C3. This study informs the mechanistic underpinnings of this disorder.

1127F

Exome sequencing in Autism Spectrum Disorder.

To discover rare genetic variants and new genes associated with Autism Spectrum Disorder (ASD), we are performing a detailed genomic analysis in a cohort of 1000 Canadian Families. By combining high resolution microarrays with exome and whole genome sequencing, we aim to investigate the role of *de novo* and rare inherited mutations, incorporating copy number (CNV), single nucleotide (SNV) and insertion/deletion variants.

From the first 700 individuals analysed by exome sequencing with SOLiD 5500xl, we find in the order of 24,000 single nucleotide variants per individual, of which approximately 350 are novel and in coding regions. We have uncovered numerous rare and novel inherited variants that appear to segregate with the phenotype in genes previously associated with ASD such as *NRXN1*, *NLGN4X*, *ARID1B* and *CHD8*, including mutations resulting in likely haploinsufficiency. *De novo* mutations have also been discovered implicating new genes such as *RIMS2*, *NTF3* and *LYPD6B* in the disorders. We have found multiple individuals carrying potentially pathogenic both CNVs and SNVs and in some cases more than one arising *de novo*. Additional incidental findings from our study have also instigated clinical follow-up such as early cancer screening in families with cancer syndromes.

Now, we are pursuing sequencing using semiconductor sequencing on the Ion Proton System. In the first trio family analysed we detected approximately 19,800 coding single nucleotide variants per person. In comparison with whole genome sequencing data from the same individuals, we identified 91% of the known exonic variants with an estimated false positive rate of 9%. Moreover, analyses of these data correctly recognised four known *de novo* mutations including three substitution variants in genes *KIAA1217*, *FAT3*, *STXBP5L* and a single base insertion in *USP54*.

Our data support a multigenic, multifactoral model for Autism susceptibility and highlight the necessity for extensive information of both genotypes and phenotypes to further our understanding of complex disorders.

Exome sequencing in schizophrenia quartets families identifies the patterns and rates of causal mutations and CNVs.
D. Zhou[1], Z. Zhang[1], Y. Liu[2], L. He[1,2]. 1) Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders (Ministry of Education), Bio-X Institutes, Shanghai Jiao Tong University, Shanghai 200030, People's Republic of China; 2) Institutes of Biomedical Sciences, Fudan University, 303 Mingdao Building, 138 Yixueyuan Road, Shanghai 200032, People's Republic of China.

Schizophrenia is known to be a multifactorial disorder with an underlying heritability that is deemed to be around 80%, without totally displaying Mendelian inheritance. Previous studies have commonly thought that many genes (or other functional genomic elements) are involved. However, the common variants and mutations in known genes confer only a limited effect on the phenotype, and these could not explain a substantial fraction of schizophrenia heritability. Here we examined the effects of the novel rare mutations, CNVs on schizophrenia pathogenesis by sequencing the whole exomes of about 300 subjects from 50 schizophrenia quartets families (only one cases in parents, more than two cases in children). We identified the rare mutations or large copy number alternations in each family. We will then use protein-protein interaction (PPI) network to evaluate the connection of the causal genes.

1129T

Identification of low frequency variants associated with albuminuria and kidney function in Danes with and without diabetes through exome-array analysis. *T.S. Ahluwalia[1], J. Bork-Jensen[1], N. Grarup[1], R. Ribel-Madsen[1], J.M. Justesen[1], M.N. Harder[1], T.H. Sparsø[1], T.O. Kilpeläinen[1], T. Skaaby[2], C. Christensen[3], I. Brandslund[4,5], M. Aadahl[2], M.E. Jørgensen[6], A. Pedersen[1,8,11]*. 1) Novo Nordisk Foundation Centre for Basic Metabolic Research, Section of Metabolic Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 2) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 3) Department of Internal Medicine and Endocrinology, Vejle Hospital, Vejle, Denmark; 4) Department of Clinical Biochemistry, Vejle Hospital, Vejle, Denmark; 5) Institute of Regional Health Research, University of Southern Denmark, Odense, Denmark; 6) Steno Diabetes Center, Gentofte, Denmark; 7) School of Public Health, Department of General Practice, University of Aarhus, Aarhus, Denmark; 8) Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 9) Faculty of Medicine, University of Aalborg, Aalborg, Denmark; 10) Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark; 11) Faculty of Health Sciences, University of Aarhus, Aarhus, Denmark.

Type 2 diabetes (T2D) is an increasingly common disease with 347 million people affected worldwide. About 35% of individuals with T2D attain microvascular complications of the kidney which may lead to end stage renal failure and death. Diabetic kidney disease has been shown to be partially caused by a genetic susceptibility component. We therefore sought to identify coding variants associated with kidney function through an exome-array based association study. Five cohorts were investigated: ADDITION-DK ($n_{non\text{-}T2D}$=610, n_{T2D}=1,574), Vejle (n_{T2D}=1,951), Inter99 ($n_{non\text{-}T2D}$=5,555, n_{T2D}=156), Health2006 ($n_{non\text{-}T2D}$=2,637), and Health2008 ($n_{non\text{-}T2D}$=652). Genotyping was performed by the Illumina Infinium HumanExome BeadChip, including 263,894 variants and 16,550 custom-designed single nucleotide polymorphisms (SNPs) selected from an exome sequencing study of 2,000 Danes. After filtering the variants for minor allele frequency (MAF) ≥ 0.1% and genotyping call rate of > 0.90, the final associations were examined in 72,775 remaining variants. Kidney function was estimated by the Cockroft Gault formula, denoted by estimated glomerular filtration rate (eGFR, ml/min/1.73m^2), while albuminuria, by urinary albumin-to-creatinine ratio (UACR), was estimated from baseline measures. UACR measures were available for 13,153 individuals and eGFR measures for 7,402 individuals. Both traits were rank-normalized and analyzed separately by linear models in each cohort. Adjustments for age, sex, and four principal components were made and an additive genetic model was used. Meta-analysis of these results was then performed in three groups: T2D, non-T2D, and one including all individuals, using fixed effects meta-analysis. In a meta-analysis comprising all individuals, the strongest association with UACR (Pmeta=3.3×10^{-6}) occurred at a rare (MAF=0.9%) missense variant in the cubilin gene (*CUBN*), which was not in linkage disequilibrium with previously identified common *CUBN* SNP (r^2=0.001). Although the variant did not reach our study-wise significant threshold of $P<3.4 \times 10^{-7}$ (Bonferroni correction for 72,775 SNPs and 2 traits), it may represent a secondary signal. The *CUBN* gene is involved in the receptor-mediated endocytotic reabsorption of albumin in the kidney. We also replicate 13 GWAS-identified common loci associated with eGFR or UACR (P<0.05). A deeper understanding of the genetic basis of diabetic kidney disease may help to develop novel therapeutic strategies.

Purpose: The common, late onset form of POAG has a substantial hereditary predisposition. The purpose of this study was to identify protein-changing mutations within the human genome that show strong association with POAG. **Methods:** We used the exome-wide association approach by deploying the customized Human Exome Genotyping Bead Chip manufactured by Illumina; this particular array contains ~250,000 *loci* of base content as well as an additional 30,000 protein-changing mutations specific only to individuals of East Asian descent. Through collaborations with investigators from China, Hong Kong, Vietnam, Japan, India, and the USA, we have collected and genotyped total of 3,822 cases and 10,426 controls. All cases were >40 years old and comprised of both Normal Tension Glaucoma (NTG) and High Tension Glaucoma (HTG). After uniform and stringent quality control filters were applied for both individual samples and SNP markers, 3,540 cases and 9,744 controls across 7 independent sample collections (Singapore, China, Hong Kong, Vietnam, Japan, India, USA) remained. We measured the association between SNP genotypes and POAG risk using unconditional logistic regression. Further compensations were made for the top axes of genetic stratification for each independent collection to ensure minimal confounding due to differing ancestries between POAG cases and controls. Meta-analysis summarizing the results across all cases and controls was performed using fixed effects modeling weighted in an inverse-variance manner. **Results:** We have confirmed strong evidence of association with variants of several genes, including *CDKN2BAS* (OR =0.74, $P = 1.27 \times 10^{-9}$) and several novel *loci*. Novel variants underlying POAG are being validated in an additional 4,000 cases and 11,000 controls that have been independently collected. **Conclusions:** We have performed a meta-analysis of a large multi-ethnic and racial dataset that has confirmed the associations between *CDKN2BAS* and POAG. In addition we have identified several novel genetic variants that are in the process of validation at this time. **Grant support:** This work is supported by Biomedical Research Council (BMRC) in Singapore, Ref: BMRC 10/1/35/19/675.

1131W

Rare Variant Association of von Willebrand Factor Levels in a Healthy Young Cohort of European Individuals Using HumanExome BeadChip Data. *A.B. Ozel[1], K. Desch[2], D. Siemieniak[3], D. Ginsburg[1,2], J. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 3) HHMI, University of Michigan, Ann Arbor, MI.

von Willebrand factor (VWF) is an abundant plasma glycoprotein that regulates hemostasis. Plasma levels of VWF are highly variable among healthy people, with 65% of its variance attributable to inherited factors. We previously performed genome-wide association and linkage analyses of WVF in a healthy sibling cohort of 1,152 subjects and a second healthy cohort of 2,310 individuals (Desch et al., 2012). VWF plasma levels showed significant association with variants at the *ABO* locus (p<7.9E-139) and *VWF* locus (p<5.5E-16), consistent with previous reports. Linkage analysis using sibling data identified significant signals at a ~35cM interval on 2q12-2p13 (LOD=5.3), and a ~10cM interval on 9q34 at the *ABO* locus (LOD= 2.9), which explained 19.2% and 24.5% of the variance in VWF levels, respectively. The presence of a strong linkage signal and its absence in association studies suggest a causal locus harboring many genetic variants that are individually rare, but more common in aggregate. To investigate the role of rare variants (MAF<=5%) we collected genotype data on 940 European individuals in the first cohort using the Illumina HumanExome Beadchips. Most of the >240K variants were rare coding variants, with an average call rate of 99.7% after data clean-up. Common variants on the exome chip replicate previous findings of significant association at *ABO* (p<1E50). Preliminary analysis of 211,149 low-frequency variants (MAF<= 5%, HWE<1E-6) in 15,960 genes using the Sequence Kernel Association Test optimal (SKAT-O) gene-burden test showed a gene-wise significant association for 20 rare variants at *SLFNL1* (Schlafen-Like 1) on chromosome 1 (p<2E-6). Schlafen-family genes may have regulatory roles in haematopoiesis due to their increased expression levels during myeloid differentiation. The top signal in the chromosome 2 linkage interval was for 21 variants at the *RETSAT* gene (Retinol Saturase) (p<8E-3), which plays a role in metabolic adaptation and body weight maintenance. Further tests involving other gene-burden tests (e.g., Variable-Threshold (VT), the method by Madsen & Browning) are under way. These analyses of low-frequency variants could provide new insight into the regulation of hemostasis through VWF and reveal novel loci of extensive heterogeneity that may explain a significant portion of the missing heritability for VWF.

1132T

Exome Chip-based Association Analysis Identifies Novel Coding Variants Associated with Adiposity Traits in Hispanic Americans: The IRAS Family Stud. *N. Palmer[1], C. Gao[2], J. Norris[5], J. Rotter[6], L. Wagenknecht[3], D. Bowden[1], E. Speliotes[7], C. Langefeld[4].* 1) Biochemistry Dept, Wake Forest School of Medicine, Winston-Salem, NC; 2) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 3) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Epidemiology, Colorado School of Public Health, Aurora, CO; 6) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 7) Division of Gastroenterology and Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI.

Despite recent successes of genome-wide association studies (GWAS) in identifying genetic variants that affect adiposity traits, a substantial proportion of the heritability remains unexplained. A potential role for low-frequency and rare variants has been proposed. Exome chip genotyping, a cost-effective approach to evaluate coding variation, was performed in 1,414 Hispanic Americans from the Insulin Resistance Atherosclerosis Family Study (IRASFS). Evaluation of 81,560 autosomal variants for the full complement of adiposity-related traits, including body mass index (BMI), waist circumference, waist-to-hip ratio (WHR), computed tomography (CT) measures of visceral (VAT) and subcutaneous (SAT) adipose tissue, and DEXA measured percent body fat, we identified two loci at exome-wide significance (P<0.05/81,560=6.13E-07). A novel coding variant in *IDH1* (rs34218846, V178I, 7% MAF; P=2.51E-07-2.14E-08) obtained genome-wide significance (P<5.0E-08) for BMI, waist and WHR. This gene was further supported by complementary GWAS and imputation data (P=0.019-4.97E-06). *IDH1* encodes cytosolic isocitrate dehydrogenase 1 and is postulated to play an important role in fat and cholesterol biosynthesis as demonstrated in cell and knock-out models. In addition, a rare missense variant in *ALDH1A3* (rs1130737, R15G, 0.01% MAF; P=2.39E-07) was associated with WHR. Although aldehyde dehydrogenase 1 has been examined for its role in sex- and depot-specific fat formation, gender stratification did not improve the observed association (P_{women}=2.72E-03). Analysis of CT measured adiposity identified variants approaching exome-wide significance in *NCF2* (P= 2.30E-05-8.51E-06) with SAT. Burden testing of non-synonymous variation at this locus did not improve evidence of association (P=1.9E-04). No significant signals were observed in the evaluation of percent body fat (P>2.60E-05). These results highlight that examining exonic variation can identify novel variants and genes that influence adiposity. Since the exome chip captures coding variation present predominantly in Europeans and African Americans, a comprehensive assessment of exonic variation through exome sequencing in this Hispanic American population will complement and extend the current findings.

1133F

A tool for co-segregation analysis using Whole Exome Sequencing data. *T. Gambin[1], B. Yuan[1], E. Boerwinkle[2,3], J. Lupski[1,4,5].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 3) The Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Texas Children's Hospital, Houston, TX.

Whole Exome Sequencing (WES) has proved to be a powerful method in studying Mendelian diseases. However, the identification of causative variants remains challenging due to the very large number of variants observed in each individual's exome. To narrow down the original set of variants to a short list of candidate causal mutations, a large number of tools have been developed, most of which are designed for annotating, filtering and prioritizing variants using allele frequencies in control/disease populations and computational predictions of deleteriousness and conservation of sequence variants and indels. Multiple methods are capable of utilizing trio information to detect de novo variants and/or exclude mutations violating expected Mendelian segregation. However, few published and freely available tools address the problem of selection/prioritization of variants that co-segregate in a family with a Mendelian condition under pre-specified inheritance model. All of them have significant limitations, such as low specificity or unavailable source code. Here, we present an open source R package for co-segregation analysis that incorporates genotype data from WES, pedigree structure and phenotypic information about individuals. In the first step, the algorithm filters out all common variants and generates a 'project level VCF' based on the genotype data from all family members, i.e. the file with genotype calls across all samples in pedigree at every variant position called in at least one sample. Next, for each variant, the pattern of co-segregation of genotype and phenotype information is evaluated under different inheritance models. At the same time, variants detected to be likely de novo mutations are distinguished from others. The list of variants observed to be co-segregating with disease can then be filtered/prioritized based on other criteria, such as predicted functional effects, relevant tissue expression and a priori candidate gene. Our algorithm pays particular attention to a low quality genotype calls by being stringent in looking for variants in affected individuals and lenient in checking the presence of the same variants in unaffected ones. The proposed algorithm is context dependent and can 'learn' from early samples and then applied to newly recruited samples. We are successfully applying this algorithm to data from NHGRI's Centers for Mendelian Genetics, and, once published, the code will be freely available.

1134W

Summarizing polygenic relative risks due to risk alleles for common complex diseases for the MedSeq project. *SW. Kong[1], CA. MacRae[2], IH. Lee[1], HL. Rehm[3], P. Kraft[4], J. Krier[2], JL. Vassy[2], RC. Green[2], IS. Kohane[1,5].* 1) Informatics Program, Boston Children's Hospital, Boston, MA; 2) Department of Medicine, Brigham & Women's Hospital, Boston, MA; 3) Department of Pathology, Brigham & Women's Hospital, Boston, MA; 4) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 5) Center for Biomedical Informatics, Harvard Medical School, Boston, MA.

Known disease-causing mutations and loss-of-function variants are of primary interest for personal whole-genome sequencing (WGS) in a clinical context. However, estimating the genetic liability for common complex diseases using known risk alleles would also be informative for clinical sequencing. The recent success of polygenic risk scoring methods for common diseases such as schizophrenia and type 2 diabetes has demonstrated that a larger proportion of the total liability can be explained by hundreds to thousands of risk alleles. Here we present an outline of a clinical WGS report for common risk alleles within the MedSeq Project, a randomized clinical trial that aims to develop standards and procedures for the evaluation and reporting of genome sequencing data. We have developed a novel method for summarizing known risk alleles focused at present on cardiac diseases- the Cardiac Risk Report (CRR). For 8 clinical phenotypes that are known to be prevalent in both primary care and cardiomyopathy populations, we provide multiplicative polygenic risk scores (MPRS) derived from 161 published risk alleles with small or moderate effect size (odds ratio < 1.2, on average). For each clinical phenotype, we used the product of odds ratio of risk allele each raised by its count as the MPRS. We then normalized the MPRS by the population median from the 379 individuals of European ancestry in the 1000 Genomes Project. Interestingly, the distribution of MPRS for type 2 diabetes showed a significant difference between ethnic groups, suggesting that an individual's disease risk from genetic variation should be carefully interpreted in the context of his or her genetic ancestry. In addition to normalized MPRS, the CRR includes contextual data such as the disease prevalence and heritability, all of which are important elements in the interpretation of modern multi-locus disease risk models. Our approach for the MedSeq Project demonstrates how complex trait risk variants from an individual genome can be interpreted and reported in clinical context.

1135T

Whole exome sequencing of families with multiple cases of adolescent idiopathic scoliosis implicate novel mutations in *FBN2*, *MESP2* and *SNTG1*. *A. Sasson[1], J.P. Dormans[2], F.J. Salley[2,3], C.E. Kim[3], S. Deliard[4], J. Talarico[2], J.C. Perin[1], RM. Chiavacci[3], H. Hakonarson[3,4,5], S.F.A. Grant[3,4,5].* 1) Center for Biomedical Informatics, Children's Hospital of Philadelphia Research Institute, Philadelphia, PA; 2) Department of Orthopedic Surgery, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Untreated scoliosis, particularly in more severe cases, has a detrimental influence on health throughout life plus a negative socioeconomic impact with respect to work and marital status. Approximately three quarters of structural scoliosis is clinically classified as idiopathic, which is the most common spine deformity arising during childhood. One of the main sub-forms of the disorder is adolescent idiopathic scoliosis (AIS), which presents in children aged 10 to 16 years old. There is strong evidence for a genetic component to idiopathic scoliosis, widely considered to be polygenic. It often appears in several members of the same family; indeed, one in three cases is familial. Also studies on twins showing that concordance of monozygotic twins is greater than that of dizygotic twins. Classical candidate gene studies and GWAS have only achieved limited success in identifying genetic determinants of idiopathic scoliosis. As such we elected to perform whole exome sequencing of members of five families with multiple cases of AIS on the Illumina HiSeq platform, based on recruitment from the Department of Orthopedic Surgery at the Children's Hospital of Philadelphia. Variants considered in our analyses had to be unique i.e. not reported in public databases, and were common to all cases, but not present in unaffecteds, in each given family. Subsequent filtering with PolyPhen revealed a shortlist of candidate variants in each family. Interestingly, within the respective shortlists for three of the families, we observed a novel variant in a different previously implicated scoliosis-related gene in each setting. In Family 1, where we sequenced three affected and four unaffected members, we observed a L1309F non-synonymous variant in *FBN2* (PolyPhen score=1). In Family 2, where we sequenced three affected and two unaffected members, we observed a K26Q non-synonymous variant in *SNTG1* (PolyPhen score= 0.759). In Family 3, where we sequenced two affected and three unaffected members, we observed a S224F non-synonymous variant in *MESP2* (PolyPhen score=0.906). Efforts are now underway to validate these novel observations further, test in additional sub-forms of idiopathic scoliosis and to investigate their functional role in the pathogenesis of the trait.

1136F

Identification of *de novo* variants contributing to nonsyndromic cleft lip and palate. *E.J. Leslie[1,6], K.M. Steinberg[2], D.C. Koboldt[2], C. Harris[2], D.E. Larson[2], R.S. Fulton[2], G.L. Wehby[3], J.T. Hecht[4], T.H. Beaty[5], A. Scott[5], M.L. Marazita[6], G.W. Weinstock[2], J.C. Murray[1].* 1) Dept. Pediatrics, University of Iowa, Iowa City, IA; 2) The Genome Institute, Washington University, St. Louis, MO; 3) Depart of Health Management and Policy, University of Iowa , Iowa City , Iowa; 4) Dept. Pediatrics, University of Texas Medical School at Houston, Houston, TX; 5) Dept. Epidemiology, Johns Hopkins University, Baltimore, MD; 6) Center for Craniofacial and Dental Genetics, Department of Oral Biology, University of Pittsburgh, Pittsburgh, PA.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a common birth defect, affecting 1/1000 individuals worldwide. The complex inheritance of NSCL/P reflects the combined action of multiple genetic and environmental risk factors. Efforts to identify genetic risk factors have included numerous linkage, candidate gene, and genome-wide association (GWA) studies. To date, there have been four independent GWA studies and a meta-analysis which have collectively identified genome-wide significant associations for at least a dozen loci. Despite this progress, identifying specific, etiologic variants remains a challenge. We selected thirteen regions from previous GWA and candidate gene association studies for targeted capture and deep sequencing to identify common and rare etiologic variants for NSCL/P. We sequenced these regions, totalling 6.7Mb, in 1200 case-parent Asian trios from the Philippines and China plus 400 trios of European descent. Sequencing trios affords us the opportunity to identify *de novo* mutations which may be more deleterious than other rare variants and could contribute to the missing heritability in complex traits. *De novo* variants were called using the software tool Polymutt, which considered relationships between subjects. We identified 135 *de novo* variants absent from dbSNP or the NHLBI Exome Variant Server. These 135 variants included three missense *de novo* variants in *PAX7*, *ABCA4*, and *PIK3R5* and a splice site variant in *IRF6*. Of the remaining noncoding variants, 51 occurred in putative regulatory elements defined by histone modifications, transcription factor ChIP-Seq, and DNaseI hypersensitivity clusters. Notably, two of the *de novo* variants occurred within the same craniofacial enhancer, located 450kb upstream of *IRF6*. These data show that *de novo* variants are likely contributors to the etiology of NSCL/P. Future analysis of these variants may facilitate identification of inherited rare and common causative variants at these targeted regions.

1137W

Exome sequencing to identify de novo and rare recessive mutations in sporadic ALS. *K. Meltz Steinberg[1], D.C. Koboldt[1], D.E. Larson[1], G.E. Sanderson[1], R. Pamphlett[2], E.R. Mardis[1].* 1) The Genome Institute, Washington University, St. Louis, MO; 2) The Stacey Motor Neuron Disease Laboratory, Department of Pathology, The University of Sydney, Sydney, New South Wales, Australia.

Amyotrophic lateral sclerosis (ALS) is characterized by progressive motor neuron degeneration. Five to ten percent of patients have a family history of ALS (FALS), but most cases are sporadic (SALS). While the almost two thirds of FALS cases can be explained by mutations in a few genes, such as *SOD1*, the causes of SALS are still largely unknown. The late onset of disease further complicates efforts to elucidate the genetic causes of SALS using traditional family based studies. To further investigate the genetic contribution to SALS we performed exome capture and sequencing on 45 trios with no family history of ALS. The average age of the patients was 47.5, and two patients were positive for hexanucleotide repeat expansion of *C9orf72*, which is known to contribute to the ALS phenotype. Using the trio-aware genotype caller, Polymutt, we identified 22 high confidence de novo coding mutations, and twelve of these were identified as deleterious or damaging using bioinformatic prediction software. We also identified a splice site mutation and one nonsense mutation. Of note, some of the de novo mutations characterized are in genes involved in axonal guidance and apoptosis. In addition, we identified a de novo start codon mutation in *CHRM1*, a gene that harbors another de novo missense variant from a recently published, independent SALS cohort. Leveraging the trio information, we were also able to identify rare (MAF<0.01) compound heterozygous mutations in 18 different genes that are predicted to be highly damaging and cause a loss of function. We also identified five rare homozygous stop gain mutations and three rare homozygous splice donor/acceptor mutations. These de novo and rare recessive mutations may provide insight into the genetic contribution to SALS.

1138T

Novel intellectual disability genes identified by exome sequencing. *R. Rabionet[1], L. Domenech[1], O. Drechsel[2], M. Viñas[4], A. Puig[1], M. Gehre[1], S. Ossowski[2], I. Madrigal[3], M. Guitart[4], M. Mila[3], X. Estivill[1].* 1) Center Genomic Regulation (CRG), UPF and CIBERESP, Barcelona, Spain; 2) Center Genomic Regulation (CRG) and UPF, Barcelona, Spain; 3) Servei de Genètica, Hospital Clínic de Barcelona, Barcelona, Spain; 4) Laboratori Genètica, UDIAT-Centre Diagnòstic, Corporació Sanitària Parc Taulí, Sabadell, Spain.

Intellectual disability (ID) is a genetically heterogeneous disorder affecting 1-3% of the population. About 30% of cases of ID can be explained by structural variants, and more than 100 genes have been implicated in its pathophysiology. Nevertheless, a large proportion of cases remains unexplained. A recent study has shown that *de novo* point mutations are a frequent cause of ID, making next generation sequencing technologies very powerful tools to identify rare *de novo* genetic causes of ID. We recruited 33 trio cases and 6 sibling pairs affected with idiopathic ID, all of them negative for the fragile X expansion and without cytogenetically visible abnormalities. Exome sequencing was performed, and non-synonymous variants present in the cases were selected and filtered based on their frequency in known databases. Then, *de novo* variants were identified, as well as potential X-linked or recessive genes (carrying homozygous or compound heterozygous variants in the case); the variants' functionality score was predicted (Condel), and they were annotated against a list of known ID-related genes. Novel variants were also filtered for their presence in an in-house database of exome data. We detected an average of 8520 non-synonymous variants in the cases, of which an average of 27 were considered *de novo*. Frequency and functionality based filtering reduced the number of potential candidate ID genes harboring *de novo* variants to 0-10 per case. The presence and *de novo* state of the identified candidate variants was confirmed by Sanger sequencing. In 4 cases we confirmed the presence of a *de novo* variant in previously described ID genes, and in 7 additional families, 9 genes with damaging *de novo* variants were considered as potential novel ID genes. Three cases carried variants in genes for known ID syndromes. Three male cases carried X-linked variants in known ID genes and 2 cases were homozygous or compound heterozygous for rare potentially damaging variants in ID genes. In 6 cases we identified X-linked (2) or recessive (3) candidate novel ID genes; one X-linked gene was mutated in two families. Of the 14 potential novel ID genes, 11 have functions related with neurite outgrowth, gene silencing or epigenetic control of gene expression, making them good candidates for novel ID genes. Further evidence for their involvement in ID will be collected by analysis of interaction networks, brain expression, and by targeted resequencing in additional isolated ID cases.

1139F

Rare coding variant association study of Inflammatory Bowel Diseases. *M.A. Rivas[1,2], T. Green[2], C. Stevens[2], J.H. Cho[3], J.D. Rioux[4], R.J. Xavier[5], M.J. Daly[2,6], NIDDK IBD Genetics Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Broad Institute, Cambridge, MA, USA; 3) Yale School of Medicine, New Haven, Connecticut, USA; 4) Université de Montréal and Research Centre, Montreal Heart Institute, Montreal, Quebec, Canada; 5) Center for Computational & Integrative Biology, Cambridge, MA, USA; 6) Analytical and Translational Genetics Unit Massachusetts General Hospital, Boston, MA, USA.

In a prior pilot study we reported evidence of independent rare coding variants in common variant association study (CVAS) regions associated to inflammatory bowel disease (IBD). In this study we explored the extent to which rare and low frequency variants contribute to susceptibility of IBD through a combined analysis of targeted exon resequencing and exome array data. We performed targeted exon resequencing analysis of 770 genes proximal to CVAS regions in 2495 IBD patients and 1,121 control subjects. We also used the Illumina HumanExome Beadchip array in 3,352 subjects (895 IBD, 2447 controls) to test association of coding variants with IBD. In the exome-chip data we did not find any genes passing exome-wide significance threshold (P<2.5×10-6) when testing putative loss of function (LoF) or protein altering mutations. For genes in CVAS regions we find suggestive evidence of association of putative LoF mutations at *IFIH1* (P=.0075) and *DPP4* (P=.0047). Interestingly, the putative LoF mutations at *IFIH1* in the exome chip data are the same mutations reported in Nejentsev et al. 2009 to confer protection to Type 1 Diabetes, whereas in IBD we find evidence of conferred risk. Furthermore, we find suggestive evidence of protein altering association at *NOD2* (P=4.3×10-6) and *IL23R* (P=4×10-4).

The goal of the targeted exon resequencing experiment was to identify additional rare putative loss of function mutations that in aggregate may highlight signal for association to disease and provide avenues for downstream functional follow-up. We observed a common protein truncating variant mutations driving association of CVAS signal at *FUT2* (p.W154X) and *GSDMB* (c.IVS6-2A>G); furthermore, additional putative loss of function mutations at NOD2 exclusive to cases (3 additional copies, 0 observations in controls and 0 additional observations in the Exome Variant Server from 6500 subjects) supporting that loss of function of NOD2 confers risk to IBD. We identified a premature stop-gain variant p.R381X in *IL23R* at the same site of the common missense protective associated variant p.R381Q exclusive to controls. Similarly, we find a putative loss of function mutation, p.R179X, at *RNF186*, a CVAS region associated to ulcerative colitis, exclusive to control subjects (6 copies). The presence of loss of function alleles exclusive to controls highlights key targets for inhibition.

1140W

Exome Array Identifies Novel Loci and Rare Variants Associated With Age-related Macular Degeneration. *Y. Yu[1], S. Raychaudhuri[2,3,4,5,6], R. Reynolds[1], J.I. Goldstein[4,7], E. Souied[8], M.J. Daly[4,7], J.M. Seddon[1,9].* 1) Ophthalmic Epidemiology and Genetics Service, Department of Ophthalmology, Tufts Medical Center, Boston, MA; 2) Division of Genetics, Brigham and Women's Hospital, Boston, Massachusetts, USA; 3) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Boston, Massachusetts, USA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 5) Partners HealthCare Center for Personalized Genetic Medicine, Boston, Massachusetts, USA; 6) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK; 7) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 8) Hôpital Intercommunal de Créteil, Hôpital Henri Mondor, Université Paris Est Créteil, Créteil, France; 9) Department of Ophthalmology, Tufts University School of Medicine, Boston, Massachusetts, USA.

Meta-analysis of Genome-wide association studies (GWAS) has identified 19 common variants for age-related macular degeneration (AMD), however, a large proportion of the heritability of AMD is still unexplained and the functional consequences of these variants are still unclear. To fine-map candidate loci and examine the association of rare functional variants to AMD, we genotyped 3693 cases and 3942 controls of European ancestry using Illumina Human ExomeBeadchip with custom content. We confirmed rare AMD causal mutations in several alternative complement pathway genes recently reported by our group, including R1210C in *CFH* ($P = 3.8 \times 10^{-7}$, OR =19.3), K155Q in *C3* ($P = 1.6 \times 10^{-10}$, OR =3.4) and P167S in *C9* ($P = 5.0 \times 10^{-7}$, OR =2.0). In addition, we identified a novel common SNP on chromosome 16 significantly associated with the risk of AMD, and a new rare non-synonymous variant in a gene related to the innate immune pathway for which no common variants have been associated with AMD previously. This study supports the involvement of both common and rare variants in AMD pathogenesis. Additional variants in the low-frequency spectrum are likely to explain the missing heritability of AMD.

1141T

Exome sequencing in children with severe viral respiratory infections.
S. Asgari, P. McLaren, J. Fellay. School of Life Sciences, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland.

Background: Human genetic variation plays a key role in determining individual responses after exposure to infectious agents. Respiratory viruses are the most common pathogens leading to hospitalization in children under the age of 5. Infections are usually mild and self-limiting, however, 0.1-0.2% of all children require admission to Intensive Care Unit (ICU). The majority of these children are previously healthy without known risk factor. Here, we use exome sequencing to search for genetic variants conferring unusual susceptibility to viral respiratory infection in the pediatric population. Methods: Study participant are recruited since 2011 in Swiss and Australian pediatric ICU. Inclusion criteria are age 0-3, ICU admission due to viral respiratory infection, mechanical ventilation, and absence of known risk factor or co-morbidity. So far, we captured and sequenced the exome of 10 patients using the Agilent SureSelect 50Mb enrichment kit and the Illumina HiSeq2000. Paired-end, 120 bp reads were aligned to the hg19 reference genome using BWA. Quality control and variant calling were performed using GATK. We used VAAST to run a case-control analysis of genetic variation between our exomes and data from the 1000 Genomes Project. Finally, we used DAVID for pathway analysis. Results and discussion: Samples were sequenced at high coverage (72x on average). After filtering for high quality variants based on the QC metrics given by GATK, we observed an average of 8434 synonymous-coding, 7889 non synonymous-coding, 71 splice-site, 81 stop-gain and 7 stop-loss variants per sample. Using a VAAST score threshold of 30, the case-control analysis resulted in the identification of 288 genes enriched for potentially deleterious variants in cases. From this list, we filtered out 38 highly variable genes (HLA, mucins, olfactory receptors, T-cell receptors and zinc fingers) as well as an additional set of 73 genes that systematically obtained high VAAST scores in permutation analysis, resulting in a final number of 177 candidate genes. Functional classification of these candidates using DAVID showed enrichment for innate immunity genes. Our ongoing recruitment and sequencing effort will allow us to explore candidate variants, genes and pathways in a larger study population.

1142F

Testing rare coding variation for an impact on HIV-1 viral load through exome sequencing.
P.J. McLaren[1,2], P.R. Shea[3], D.B. Goldstein[3], J. Fellay[1,2]. 1) School of Life Science, EPFL, Lausanne, Vaud, Switzerland; 2) Institute of Microbiology, University Hospital Lausanne, Lausanne, Vaud, Switzerland; 3) Center for Human Genome Variation, Duke University School of Medicine, Durham, NC, USA.

Background: Common variants (maf>5%) in the MHC and CCR5 regions are known to influence set point HIV-1 viral load (spVL) yet explain only a portion of the total trait variance. The impact of rare coding variation on HIV-1 disease progression has not been as thoroughly investigated. Here we utilize exome sequencing in 391 HIV-1 infected individuals with stable spVL to look for rare and functional variants that mediate control of HIV-1 infection.

Methods: Set point HIV-1 viral load was calculated as the average of at least 3 measurements obtained during the chronic phase of infection. We captured and sequenced all coding exons to high coverage (>70x) in 391 HIV-1 infected individuals of the Swiss HIV Cohort Study using the Illumina Truseq 65Mb enrichment kit and the Illumina HiSeq2000. Paired-end, 120 bp reads were aligned using the Burrows-Wheeler Aligner (BWA). Quality control and variant calling were performed using the GATK. Variant functional annotation was performed using snpEff version 2.1. Individual variants were tested for association using linear regression. Gene and gene network burden testing was performed using SCORE-Seq and SKAT.

Results: Individual variant testing showed strong evidence for association in the MHC region. Conditional regression demonstrated that this signal is explained by two independent SNPs, rs1057151 (p=6.7e-11) in HLA-B and rs3207555 (p=4.0e-10) in HLA-C. Accounting for these two SNPs, no other variants show evidence for association. Testing for a relationship between burden of rare variants (maf<5%) and spVL in 16,839 genes individually did not uncover significant associations. Similarly, there was no evidence for enrichment of rare variants affecting spVL across a network of 2,971 genes identified as interacting with HIV-1 in biochemical screens.

Conclusions: Outside of the MHC, no significant impact of rare variation on spVL was detected by exome sequencing in 391 individuals. Larger samples are likely required to fully explore the role of rare coding variation on this phenotype. Additional classes of variation not detected by GWAS or current sequencing technologies may also contribute to host HIV-1 control.

1143W

Exome sequencing reveals a novel putative risk mutation for meningococcal disease.
A. Ndungu[1], K.S. Elliott[1], T.C. Mills[1], A. Rautanen[1], P. Hutton[4], C. Garrard[3], A. Gordon[5], C.J. Hinds[2], A.V.S Hill[1], S.J. Chapman[1,6], GAinS Investigators. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Intensive Care Unit, Barts and The London Queen Mary School of Medicine and Dentistry, London; 3) Intensive Care Unit, John Radcliffe Hospital, Oxford; 4) John Radcliffe Hospital, Oxford; 5) Imperial College, London; 6) Respiratory Medicine, Churchill Hospital Site, Oxford Radcliffe Hospital, Oxford, UK.

Meningococcal disease is a major cause of meningitis and sepsis worldwide and follows invasive infection with the Gram-negative bacteria *Neisseria meningitidis*. Asymptomatic nasopharyngeal carriage of *N. meningitidis* is relatively common in the general population (approximately 5-10% in adults), yet in a small minority of individuals the pathogen is able to penetrate mucosal surfaces and invade the bloodstream leading to life-threatening disease. Host genetic variation is increasingly recognised as playing an important role in determining susceptibility to infectious agents, and common polymorphisms in the gene encoding complement factor H have previously been described at the genome-wide level to associate with a small increase in the risk of meningococcal disease in children. Meningococcal disease is an extreme phenotype which may be enriched for large-effect genetic variants of low frequency. To investigate this possibility further, we performed whole exome sequencing on 13 adults from the UK with well-defined invasive meningococcal disease that were recruited as part of the GAinS (Genomic Advances in Sepsis) project. One further case was excluded from sequencing because of a known primary immunodeficiency resulting from a complement pathway mutation. All cases were critically ill and admitted to a UK intensive care unit with sepsis. Over 84,000 mutations were identified as missense, nonsense, splice site variants or variants occurring in UTRs. These accounted for 17% of total variants while synonymous, intergenic and intronic variants accounted for the rest. From these, we identified a homozygous novel missense mutation (predicted to be deleterious by PolyPhen) in a complement pathway protein in one individual. Validation of this result via functional assays will further understanding of the genetic basis of meningococcal disease. Overall,taking into account the sequenced individuals and excluded patient, two of 14 critically ill adult patients with meningococcal sepsis in this study were found to have predicted deleterious mutations in complement pathway components. This finding raises the possibility that a significant proportion of severe bacterial disease may occur in association with unique large-effect mutations and provides proof-of-principle to support the use of next generation sequencing to study these phenotypes.

Staphylococcus aureus bacteremia (SAB) is a serious, common infection. Both host and bacterial genetic variation likely influence development of complications in SAB patients. Studies of common single nucleotide variants (SNV) have failed to detect significant, reproducible associations with SAB complications. Because such studies may miss the impact of rare coding SNV due to weak linkage disequilibrium (LD), we used whole-exome sequencing to determine if the cumulative effect of common and rare coding SNV influences risk of complicated SAB. To reduce the effect of bacterial strain, we analyzed patients infected with *S. aureus* clonal complexes 5 or 30. In the first phase of the 200-sample study, 35 white cases of complicated SAB were compared to 35 age- (within deciles) and sex-matched white SAB controls without complications. After DNA capture with the Agilent SureSelect 72Mb exome/UTRs kit, samples were sequenced 3 per lane on the Illumina HiSeq 2000. DNA sequences were aligned with BWA and genotypes called with GATK and VQSR recalibration. SNV with VQSLOD>-2 and quality score of 99 were analyzed. Genotypes with read depth<8 and probability<99 were removed before analysis. Association of genes with complicated SAB was tested by Cochran-Armitage (CA) -Sum and -Max tests using RVASSOC software. CA-Sum sums individual SNV chi-square test statistics across the gene and evaluates significance by permutation. CA-Max considers only the SNV with the largest chi-square statistic. While no gene was significantly associated with complicated SAB after Bonferroni correction ($p=0.05/17{,}830$ genes$=2.8\times10^{-6}$), the most significant genes ($p<10^{-4}$ on both tests) were *TLR6* (CA-Sum $p=1.7\times10^{-5}$, CA-Max p=7.9×10-5) and *ENG* (CA-Sum $p=2.9\times10^{-5}$, CA-Max $p=4.9\times10^{-5}$). The similarity in CA-Sum and CA-Max results suggests that the associations are driven by one SNV in each gene; the most significant are common synonymous SNV in *TLR6* (T361T and K421K, in strong LD) and *ENG* (L69L). Although the biological significance of these SNV is unclear, these genes are plausible risk factors for complicated SAB. *TLR6* (dimerized with *TLR2*) recognizes *S. aureus* cell surface proteins, activating innate immune responses. Mutations in *ENG*, a cell surface receptor involved in TGF-beta signaling, cause hereditary hemorrhagic telangiectasia, in which SAB is a common comorbidity. These results suggest that coding SNV in genes underlying the immune response may influence development of complicated SAB.

Implication of *CDH1* in two familial cases of nonsyndromic cleft lip with or without cleft palate.
L.A. Brito, G. Yamamoto, M. Aguena, M.R. Passos-Bueno. Department of Genetics, Institute of Biosciences, University of São Paulo, São Paulo, Brazil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P) is a complex trait and the most common craniofacial birth defect. Familial cases account for 20-30% of the cases, mostly presenting non-mendelian pattern of inheritance. Association of common variants has been reported, but they are far from explaining the whole heritability of the disease. In this sense, rare variants might help to bridge the missing heritability gap. We carried out the exome sequencing of 4 affected individuals (HiScan SQ - Illumina Inc; mean coverage of 100x) of a large Brazilian family segregating NSCL/P in an autosomal dominant and incompletely penetrant fashion (family 1), and identified a nonsense mutation in the exon 6 (c.G760A:p.D254N) of E-cadherin gene (*CDH1*), which had never been described in any population. This mutation is located in a conserved region (LJB-PhyloP conservation score = 0.99) and is predicted to damage the protein function (LJB-SIFT score = 1; LJB-Polyphen score = 0.99 [scores ranging from 0 to 1, where 1 is the most deleterious prediction]). We screened, by Sanger method, 222 unrelated controls and 263 unrelated patients, and found the same mutation in only one patient. This patient belongs to a family with multiple affected members, from a region geographically close to that of family 1, raising the possibility of founder effect. Considering both families, we estimated the penetrance at 53%. CDH1 is largely known to be involved with familial diffuse gastric cancer, and it has also been implicated in breast, ovarian, endometrial and prostate cancer. A few authors have reported the presence of cleft lip and/or palate in individuals belonging to families segregating familial diffuse gastric cancer, suggesting a partially common etiology between these traits. Our families do not report any case of gastric cancer, which, in turn, suggests that *CDH1* might also be implicated with NSCL/P. Recently, one group described potentially deleterious mutations in CDH1 in NSCL/P individuals from European descent without known history of gastric cancer in their families. In conclusion, we describe the impact of a rare mutation underlying two familial cases of NSCL/P, in a gene which had never been implicated by common-variant association studies. In addition, our results support the involvement of CDH1 in NSCL/P etiology and encourage the mutational screening of this gene in familial cases of NSCL/P. FAPESP, CNPq.

Rare variants and risk for asthma in 7,224 individuals from ethnically diverse populations.
C. Igartua[1], RA. Myers[1], C. Ober[1], DL. Nicolae[1, 2, 3], The Eve Consortium. 1) Human Genetics, University of Washingon, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL.

Asthma is a chronic respiratory disease characterized by inflammation and obstruction of the airways, with heritability estimates between 20-80%. Although many common risk alleles have been identified for asthma, together they explain very little of the heritability. Because the genetic architecture of asthma likely involves a combination of common and rare alleles, we evaluated the role of rare variants on asthma risk in subjects of European, African, and Latino ancestry that are part of the EVE Consortium, a multi-center sample that includes 5,523 case-control and 567 parent-child trios. Subjects were genotyped using the Illlumina Infinium Human-Exome Chip array, which contains ~250k variants enriched for rare coding variants that are predicted to affect protein function. A gene-based association test for each gene on the exome chip that had at least 2 functional SNPs (nonsynonymous, stop or splicing) was performed using the optimized SNP-set Kernel Association Test (SKAT-O), and applying the first 2 principal components to adjust for population stratification. We considered a total of 142,744 variants in 13,727 genes in each study sample. Only the *PGLYRP4* gene (10 variants) in the African Caribbean sample was significant after multiple testing correction (p=2.04×10-6). When functional variants were weighted based on their allele frequencies (rarer variants weighted more), 3 genes approached genome-wide significance in African Americans: *RAPGEF6* (6 variants; p=1.1×10-5), *CUL7* (19 variants; p=1.2×10-5) and *SLC22A5* (12 variants; p=4.9×10-5). We also investigated genes near reported asthma GWAS SNPs and found only one instance (*SLC22A5*) where the association was driven by exonic variation. No genes were significant in the other ethnic groups or in the combined sample. These results indicate that rare variants may contribute more significantly to asthma in individuals of African ancestry, possibly due to the larger number of rare alleles in those populations. Our study, which was limited to variants present on the Human Exome array and conducted in relatively small samples, does not provide evidence for large-effect functional low-frequency exonic variants in the etiology of asthma.
