We apply a powerful haplotype-based model (described in Lawson *et al*. 2012) to infer the population history of 410 individuals from ~50 Native American groups, using data interrogated at >470,000 genome-wide autosomal Single-Nucleotide-Polymorphisms (SNPs). The model matches haplotype patterns among individuals' chromosomes to infer which individuals share recent common ancestry at each location of the genome, an approach that has previously been demonstrated to increase power substantially over widely-used alternative approaches that consider SNPs independently. We apply this methodology to 1861 samples described in Reich *et al*. (2012), incorporating 263 additional samples from 32 relevant world-wide regions collated from other publicly available resources and currently unavailable data. We utilize these methodology and data in two ways. First, we infer intermixing (i.e. "admixture") events among different Native American groups by identifying the groups that share the most haplotype segments. Using additional unpublished techniques, we determine the dates of these intermixing events, the proportions of DNA contributed, and the precise genetic make-up of the groups involved. These unique characteristics set this methodology apart from all presently available software, allowing us to place these mixing events into a clear historical context and thus identify the factors (e.g. the rise or fall of various Native American empires) that have contributed most to the genetic architecture of present-day Native American groups. Second, we match DNA patterns from each Native American group to a set of over 30 populations from Siberia and East Asia, describing each Native American group as a mixture of DNA from these regions. This enables us to shed light on the widely debated number of distinct migrations into the Americas during the initial colonization across the Bering Strait, comparing our results to previous inference from the literature. Our application demonstrates the power gained by using rich haplotype information relative to approaches that ignore this information.

1952W

Diversity of the Mexican Mestizo population using 18 X-STR. *E. Ortiz[1], G. Noris[2], C. Santana[2], M.A. Meraz[3], R. Gómez[1].* 1) Dep. de Toxicología, Cinvestav-IPN, Mexico City, Mexico; 2) Laboratorio BIMODI, Querétaro, Qro., Mexico; 3) Dep. de Biomedicina Molecular, Cinvestav-IPN, Mexico City, Mexico.

The use of the X chromosome STRs (X-STR) in population genetics, forensic studies and kinship testing have been amply used in recent years. The X-STRs shows intrinsic characteristics as lower mutation and recombination rates, and faster genetic drift due to smaller effective population size. In addition, population history and demographic factors have a deep impact on the population stratification. Previous studies have indeed highlighted the particularly complex genetic composition of the Mexican-mestizo population using Y chromosome STRs and mitochondrial DNA, however the population genetic studies using X-STR are still very limited. In order to assess the population stratification of the Mexican mestizo population we genotyped 200 unrelated women from central states of Mexico using 18 X-STR. Our results showed DXS10011 (k=32, PIC=0.94), DXS10134 (k=17, PIC=0.83), DXS10146 (k=22, PIC=0.84), and DXS10101 (k=21, PIC=0.90) were the most informative markers. Hardy-Weinberg departure was found in six out of eighteen loci studied (DXS7132: FIS=0.17061, P=0.001; DXS6809: FIS = -0.25683, P=0.001; DXS10134: FIS = -0.01425, P=0.0036; DXS10146: FIS = 0.14370, P=0.009; DXS10101: FIS =0.08344, P=0.001; DXS10079: FIS = 0.1204, P=0.0048). Gametic association was tested for all pairs of loci, however only three pairs of loci show P values below the significant level of 0.0027 (obtained after Bonferroni correction): DXS6809-DXS10134 (P= 0.00146), DXS6809-DXS8378 (P=0.00183), DXS10134-DXS10101 (P= 0.00245). The degree of population subdivision assessed using a hierarchical analysis of molecular variance (AMOVA) showed 91.59% variation within populations. In addition principal component analysis (PCA) suggest high population stratification. Our results established the first database for X-STR markers diversity for Mexican-mestizos. The relatively high number of allele encountered proved that these markers could be considered as highly informative and an important tool for human identification purposes and general anthropological research.

1953T

Native American, European and African ancestry from genotype by sequencing in Argentinean populations. *M. Muzzio[1,2,3], J.M.B. Motti[2,3], T. Cooke[1], L.S. Jurado-Medina[2], M.C. Yee[4], A. Adams[1], J. Beltramo[2], R. Santos[2,3], V. Ramallo[5], M. Schawb[2], O. Cornejo[1], G. Bailliet[2], E.E. Kenny[6,7,8,9], C.M. Bravi[2,3], C.D. Bustamante[1].* 1) Stanford University School of Medicine, Stanford, CA; 2) IMBICE CCT-La Plata CONICET- CICPBA, Argentina; 3) Facultad de Ciencias Naturales y Museo, Universidad Nacional de La Plata, Argentina; 4) Carnegie Institution for Science, Stanford, CA; 5) Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 6) Department of Genetics & Genomic Sciences, Icahn School of Medicine at Mount Sinai, NY; 7) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, NY; 8) The Center for Statistical Genetics, Icahn School of Medicine at Mount Sinai, NY; 9) The Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, NY.

In this work we aim to describe the demographic history and population structure of Argentina, by analyzing a collection of 2904 DNA samples from 15 dispersed regions in Argentina, from the Andean populations in the Northwest to the river lands of the Northeast. Argentina has history of broad cultural diversity, which included hunter-gatherers and agro-pastoralists to the expansion of the Inca Empire, the Spanish arrival, slave trade from Africa and the European migration between the mid XIXth and XXth centuries. Thus far, we have 390 genotypes defined from the Illumina Exome Array 250K and 89 genome-wide sequences from a genotype-by-sequencing strategy we developed, which covers 1.5% of the genome. We will continue to sequence more samples from our collection of 2904 participants from 15 Argentinean populations. From our preliminary data, we have identified proportions and patterns of European, African and Indigenous American ancestry in the Argentinean cohort via local ancestry inference and found a correlation between latitude and proportion of Native American ancestry, where the highest proportion corresponds to the northernmost populations, (where it averages 75.06%) descending towards the center of Argentina (averaging 34.02%). We will focus on our sequencing data and compare it to full genomes of Native Americans, studying the genomic tracts of Native American ancestry for fine-scale examination of sub-continental structure.

1954F

The Genetics of Craniofacial Morphometry in Latin America. *K. Adhikari, A. Ruiz-Linares.* Dept. of Genetics, Evolution and Environment, University College London, London, United Kingdom.

Craniofacial morphometry has been one of the classical components of human physical anthropology. Recently there have been several studies on constructing 3-d models of the face and performing genetic associations. In this project, we bridge the two aspects of facial morphology and obtain interesting patterns with genetic ancestry.

The CANDELA (Consortium for the Analysis of the Diversity and Evolution of Latin America) project is exploring the effect of European-Native American admixture on several thousand subjects from five different countries (Brazil, Chile, Colombia, Mexico and Peru). From photographs, we construct a 3-d model of their faces with 36 landmarks. We also construct symmetrized distances, left-right deviations, and principal components of shape from these landmarks, each covering a different aspect of facial morphometry. We observe these to be strongly correlated with ancestry. In general, European ancestry contributes to a larger facial shape, just as it contributes to taller height in our subjects. The noses and the lips show the largest amount of variation according to ancestry.

Following the style of classical anthropology, we independently phenotype our subjects on various traits using ordinal categories, such as the presence of epicanthic fold or mono-brow. We match these phenotypes with the quantitative distance measurements, and they show similar associations with European ancestry, with nose and lip traits again being the strongest.

Finally, we genotype some of our Colombian samples on an Illumina 730K chip and perform a genome-wide association study on the traits. The GWAS implicates several genes such as NPAS2 and PSD3. As we genotype more samples from the other countries, we will be able to replicate the findings and probably find other associated genes as the sample size increases.

1955W

The Centenarians of Nicoya, Costa Rica: a genomic evolutionary approach. *J. Azofeifa[1], E.A. Ruiz-Narvaez[2], A. Leal[1], L. Rosero-Bixby[3, 4].* 1) Escuela de Biologia, Universidad de Costa Rica, San Pedro, San Jose, Costa Rica; 2) Slone Epidemiology Center and Department of Epidemiology, Boston University; 3) Central American Population Center, University of Costa Rica; 4) Department of Demography, University of California, Berkeley.

The disclosure of the genetic contribution to longevity through polymorphisms that delay the rates of progression of senescence has proven to be elusive partially due to the fact that most of current approaches lack an evolutionary perspective. We propose an approach based on both the antagonist pleiotropy theory, and the mutation accumulation theory to explain senescence, and consequently, longevity. Both theories allow formulating predictions that can be explored by genomic screenings. We present results of a population genetics study derived from a demographic program on healthy aging in Costa Rica (CRELES). We concentrated on the population of Nicoya, in the Costa Rican province of Guanacaste, which is characterized by an extreme longevity (according to the demographic results of CRELES, the Nicoyan nonagenarian males could have the highest life expectancy in the world). We performed a pilot genome-wide association study (GWAS) using a sample of 20 of the oldest old (99-105 years old, 11 males and 9 females), from the Nicoya region, and their respective controls (60-65 years old, 11 males and 9 females) using the Illumina Human Omni Express array (~700,000 markers). No SNP reached genome-wide significance. We then proceeded to estimate individual genetic ancestry based on 464 ancestral informative markers included in the Illumina array to assess its relationship with longevity. Amerindian ancestry was higher in centenarians compared to non-centenarians (43.3% vs. 36.0, $p = 0.027$). We estimated that by each 5% increment of Amerindian ancestry was associated with a 49% higher probability of being a centenarian, OR (95% CI) = 1.49 (1.01-2.23), $p = 0.04$. These results suggest the existence of Amerindian-specific alleles that are associated with extreme longevity, and offer evidence in favor of the mutation accumulation theory, which has lacked support because it is difficult to test empirically. An explanation could be that negative effects of recessive late-acting alleles, accumulated in different populations through long periods of genetic isolation, are masked by heterozygosity. The importance of ancestry and the historical and geographical origin of parental populations have, to our knowledge, never been considered in the context of the origins of senescence and longevity. More research is needed in larger sample sizes to advance the promising results of this pilot study.

1956T

Population Structure and Genetic Diversity in a Population of 15,000 Patients from East Harlem, NY. *G. Belbin[1], D. Ruderfer[2,3,4], E.A. Stahl[2,3,5,6], J. Jeff[5], Y. Lu[5], R.J.F. Loos[5,7], O. Gottesman[5], S. Purcell[2,3,4,5], E. Bottinger[5], E.E. Kenny[1,4,5,6].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Broad Institute, Cambridge, MA; 3) Division of Psychiatric Genomics, Icahn School of Medicine at Mt Sinai, New York, NY; 4) Center for Statistical Genetics, Icahn School of Medicine at Mt Sinai, New York, NY; 5) Institute for Personalized Medicine, Icahn School of Medicine at Mt Sinai, New York NY; 6) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mt Sinai, New York, NY; 7) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mt Sinai, New York, NY.

New York City has historically been a significant point of entry for immigration into the United States and as a consequence is today peopled by a highly structured and ethnically diverse population. Census ethnic labeling reveals some of this diversity, but does not fully capture the variety of cultural groups, with complex and diverse demographic origins, foods and traditions, living in New York. Using genome-wide data, it is possible to detect such population structure which can both inform population history inference and result in better outcomes for medical genetics studies. We present a diversity of approaches for the analysis of fine-scale population structure in a population of 29,093 patients enrolled in the Icahn School of Medicine BioMe Biobank Cohort (BioMe), of which ~13,500 have available Illumnia Omni Express and Exome Chip data (~900K SNPs). BioMe comprises 34%, 47% and 19% participants with self-reported African-American (AA), Hispanic-Latino (HL) and European-American (EA), respectively, and is representative of the population of Northern Manhattan. We combined these data with both data generated from the 1000 genomes project and an additional unique database of genomic variation in over 4,000 individuals from diverse European, Middle Eastern, East Asian, African and Native American populations. Population genetic analysis using standard Principle Component Analysis (PCA) and ADMIXTURE, and a novel ancestry-specific PCA method using Native American, European and African local ancestry haplotypes from AA and HL genomes, reveals diverse sub-continental structure in the BioMe cohort. In particular, we detect a large proportion of Ashkenazi Jewish and Eastern European ancestry in the BioMe EAs. We also performed identity-by-descent (IBD) analysis and detect elevated cryptic relatedness in the AAs and HLs, which results in increased genetic tract sharing compared to EAs. For example, analysis of IBD haplotype sharing between any two less-than-fourth-degree relatives in our cohort indicates a larger percent of their genome is shared (~0.4% and 3.72%, for AA and HL, respectively), compared with the same analysis in EA (~0.12%).

1957F

Ultra fast and sample-aware local ancestry inference using population specific variants. *R.P. Brown[1], B. Pasaniuc[1,2].* 1) Bioinformatics, UCLA, Los Angeles, CA; 2) Pathology and Laboratory Medicine, Geffen School of Medicine, Los Angeles, CA.

Inferring the ancestry at each genomic locus of recently admixed individuals (e.g. Latino Americans) plays a key role in medical and population genetic inferences from finding disease risk loci to inferring recombination rates. Current local ancestry methods are designed for genotyping arrays without utilizing the full spectrum of data available from sequencing and are very computationally expensive. In addition, existing methods do not make use of all the admixed samples when calling ancestry for a given individual and only rely on external reference panels used as proxies for the true ancestral populations. We present a fast and accurate method using population specific variants (PSVs) (i.e. variants identified by sequencing to be present in only one continental population) to infer local ancestry in sequenced admixed genomes. We use the real 1000 Genomes data to find an abundance of such PSVs (e.g. an average of ~13.6 informative PSVs per Mb in Europeans, 109 in Africans) and model them within standard Hidden Markov Models for local ancestry inference to achieve an ultra-fast and accurate approach. Our method includes an iterative framework that rebuilds its reference panels from the confidently called ancestry segments in the admixed individuals themselves to further boost accuracy while reducing bias introduced by the reference panels. Using simulations of Puerto Ricans (Mexicans) from the 1000 Genomes, we show that our method achieves an accuracy of 0.93 (0.91) (quantified by the average r2 between inferred and simulated ancestry) as compared to 0.91 (0.90) achieved by existing methods. Most importantly, our approach is orders of magnitude faster than existing methods for full sequencing data (e.g. our method can infer local ancestry in 10,000 individuals in ~18 CPU days as compared to ~8 CPU years for existing methods). We also explore whether similar results can be attained in real data and show that our approach yields comparable local ancestry to the provided calls in the real Puerto Rican and Mexican individuals from 1000 Genomes. We extend our approach to low coverage sequencing and show that accurate local ancestry inference is attained at low coverage (e.g. r2 of 0.73 in our Puerto Ricans simulations at 4x coverage). Finally, we extend our method to GWAS-array genotyped individuals using a PSV tagging procedure that achieves accuracy similar to when full sequence data is available (e.g. 0.94 in African American simulations).

1958W

Y chromosomes in surname samples: insights into surname frequency and origin. *F. Calafell, N. Solé-Morata, J. Bertranpetit, D. Comas.* Institut de Biologia Evolutiva (CSIC-Universitat Pompeu Fabra), Barcelona, Barcelona, Spain.

In most societies, surnames are inherited through the paternal line, exactly as Y chromosomes are, with the exceptions of adoption, false paternity, and the inheritance of the maternal surname (as in the case of single mothers). The well-established phylogeography of the Y chromosome and the existence of fast-evolving STR markers implies that genotyping the Y chromosomes in samples of men bearing the same surname allows to i) count the number of founders of a surname and the frequency of their descendant in the current population and ii) pinpoint the remote origins of the founder of a surname. We have collected >2,500 samples from volunteers bearing one of 50 different Catalan surnames (http:// http://cognoms.upf.edu/), in which we are genotyping 17 Y-chromosome STRs and a custom-designed set of 64 SNPs (typed in a single reaction with the OpenArray™ Real-Time PCRplatform), with the following objectives: i)Discover and quantify the processes that drive surname frequency. Surname polyphiletism (which can be measured from the number of founders detected from the Y chromosome diversity) can drive surname frequency, as was found in a sample of English surnames, but drift and natural selection (associated with high-status surnames) may also have a role. 2) Were the founders of surnames that are linguistically Arab or Hebrew North Africans or Jews themselves? 3) Were the founders of Germanic patronymic surnames of a different genetic origin form the rest of the population? In Catalonia, as in France, a frequent source of surnames are former first names of Germanic origin (*Albert*, *Robert*, *Grau*,...). We will compare some of those to patronymic surnames of Latin origin (*Oriol*, *Pons*,...). Haplogroup frequency differences between Germany and Catalonia provide sufficient power for this comparison. 4) Does an ethnonymic surname indicate a foreign origin? Some Catalan surnames (*Alemany*, *Danés*, *Guasch*) denote geographic origin (they mean *German*, *Dane*, *Gascon*, respectively). We have completed this objective and we have found that haplogroups that are more frequent in Germany or Gascoigne than in Catalonia were not overrepresented in the founders of the *Alemany* and *Guasch* surnames. Thus, these surnames may have originated as bynames not necessarily linked with the origins of the founders.

1959T

The Population Genetics of Sub-Saharan African Populations. *M. Capredon[1], J. Hussin[1,2], J. Quinlan[1,3], Y. Idaghdour[1], T. de Malliard[1], JC. Grenier[1], V. Bruat[1], E. Gbeha[1], L. Barreiro[1], P. Awadalla[1].* 1) Pediatrics, CHU Sainte Justine, Fac Med, Univ Montreal, Montreal, Quebec, Canada; 2) Biochemistry, Faculty of medicine, , University of Montreal, Montreal, Quebec, Canada; 3) School of public health, Faculty of medicine, University of Montreal, Montreal, Quebec, Canada.

Characterizing genetic diversity in African populations is critical for population genetics and personalized medical-genetic studies. We describe 14 populations, including four novel African datasets, two Western Africa (Cotonou and Zinvie) populations that are geographically very close, and two from Eastern Africa (Batwa pygmies and Kiga from Uganda). We compared these populations to ten published datasets from Africa Hapmap phase 3 (YRI, LWK, MKK) and HGDP (Bantu from Kenya, Bantu from South Africa, Biaka, Mandenka, Mbuti, San and Yoruba) across Africa. We also used a European dataset (Hapmap phase 3 CEU) as controls. Population structure analysis (PCA and admixture), revealed that the Kiga population is genetically very close to the LWK and to the Bantus from HGDP, while populations from Cotonou and Zinvie are clustering closely with the Yoruban and the Mandenka. Although the Zinvie population is geographically very close to Cotonou, clear differentiation was highlighted. Finally, the Batwa pygmies are substantially differentiated genetically from other populations. We observed that variability exists in recombination rates among African populations; sometimes this variability was associated with a geographic cline in Africa, but also was observed among more closely related populations (Yorubans from Nigeria versus Yorubans from Benin).

1960F

A scalable and effective local ancestry deconvolution algorithm for Latinos. *G. Genovese[1,2], A.L. Williams[2], S.A. McCarroll[1,2].* 1) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 2) Department of Genetics, Harvard Medical School, Boston, MA 02115, USA.

Genomes of admixed individuals are a mosaic of genetic segments inherited from different ancestral populations. Local ancestry deconvolution is the process of statistically inferring the ancestral source population of all sites in the genome of admixed individuals. Most local ancestry deconvolution algorithms are designed to work with SNP array genotype data and require reference panel data that are good representatives of each ancestral population. Obtaining reference panels may be especially challenging for Native American groups, and small or inaccurate panels have the potential to bias current methods. We developed a new algorithm (LATOOLS) for Latino local ancestry deconvolution which utilizes whole genome sequence data and does not require reference panels. The algorithm works in two steps. The first step identifies what we termed signature alleles: alleles that are present to an appreciable frequency in at least one ancestral population, but not in all ancestral populations for which the local ancestry deconvolution is computed. The second step uses these signature alleles to infer local ancestry in a given genome. Thus only sites that are fully informative for ancestry are incorporated into the model. While this method does not utilize all available information in its inference, our experimental results demonstrate that this approach is effective for Latinos. Furthermore, because of its relative simplicity, the algorithm is fast and scalable: its run time is linear in signature alleles count and cohort size. We show that in Latino samples from the 1000 Genomes project we are able to achieve, once several potential sources of sequencing biases are carefully removed, over 90% concordance with ancestry calls obtained using more sophisticated algorithms. Finally, we briefly show an application of the obtained local ancestry deconvolutions for the problem of admixture mapping the missing pieces of the human genome reference.

1961W

A two-sex model for the admixture history of a hybrid population: the X-chromosome. *A. Goldberg[1], P. Verdu[2], N.A. Rosenberg[1].* 1) Biology, Stanford University, Stanford, CA; 2) CNRS-MNHN, UMR7206 Eco-Anthropology and Ethno-Biology, Paris France.

Complex social practices such as residence and descent rules, polygyny, and dominance relationships can produce sex-biased demographic histories in admixed human populations. Genetic signatures of sex-biased admixture have been empirically detected in samples from a variety of human populations throughout the world, usually without mechanistically modeling the full complexity of the sex-specific history. Expanding on the model of Verdu & Rosenberg (2011), we developed a model that mechanistically considers sex-specific admixture histories for autosomal DNA. Here, we extend our model to the sex chromosomes, allowing multiple source populations to contribute to the admixed population, potentially with varying contributions from male and female lineages across generations. Under the model, the X-chromosome is particularly informative about sex-biased admixture, as, unlike the autosomes, it can be used to identify which sex has a greater contribution to the admixed population. With no sex bias, the ratio of the expected X-chromosomal ancestry fraction to the expected autosomal ancestry fraction is one, but this ratio deviates from one with increasingly sex-biased admixture. The variance of the ancestry fraction is larger for a random X-chromosome sampled from a male from the admixed population rather than from a random female X-chromosome, in line with the decreased X-chromosomal population size for males compared to females. For admixture processes that are constant in time, we perform approximate Bayesian computation to infer sex-specific contributions from each source population. Considering autosomal DNA and the X-chromosome together, our approach can contribute to methods for inference of complex sex-biased admixture histories.

1962T

Is Genetic Ancestry Associated with Sleep? *I. Halder[1], M. Hall[2], D. Buysse[2], S.E. Reis[1], K. Matthews[2].* 1) Dept. of Medicine, Univ Pittsburgh, Pittsburgh, PA; 2) Dept. of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Background: Sleep characteristics vary by race. Compared to Whites, African Americans (AA) take longer to fall asleep, have lower sleep efficiency, lesser sleep duration and spend less time in the restorative slow wave sleep stage. The causes underlying these differences are not fully known but substantial heritability of sleep suggests some genetic underpinnings. We hypothesized that an overall genetic effect on sleep might be observed in AAs who have varying proportions of African genetic ancestry. We tested whether sleep phenotypes show an association with objectively measured individual genetic ancestry. **Methods:** The sleep of 101 Whites and 71 AA adults (mean age 58 ± 6 years; 57% female) was examined as part of the University of Pittsburgh SleepSCORE project. Polysomnography was used to assess average sleep duration, efficiency, Apnea-hypopnea index (AHI) and slow wave sleep (delta band of spectral EEG analyses). The Pittsburgh Sleep Quality Index (PSQI) was used to measure sleep quality. Biometric, psychosocial factors, health behaviors, and environmental factors were measured in all subjects. 1600 ancestry informative genetic markers were genotyped in all AAs which were used to infer overall individual African ancestry (IAA) by a maximum likelihood method. Multivariate tests were used to compare sleep phenotypes between Whites and AAs. Next, in AAs only, hierarchical linear regression was used to test whether IAA predicts sleep duration, efficiency, quality, architecture and AHI. Age, gender and BMI, education, income, use of sleep medication and antidepressants were used as covariates. All covarites were entered in step one, AHI (when not tested as the outcome) was entered in step two and IAA was entered in step three of the model. **Results:** Sleep duration, efficiency and architecture differed significantly between Races. In AAs, IAA ranged from 10%-88% with a mean of 67%. Higher African genetic ancestry was associated with lower slow wave sleep in AAs (β (SE) = -4.6 (1.5); P = 0.002). This association persisted after all covariate adjustment. After adjusting for all relevant covariates individual African genetic ancestry explains 11% of the variation in slow wave sleep in AAs. Sleep duration, efficiency, quality or AHI was not associated with African genetic ancestry. **Conclusion:** Racial differences in slow wave sleep (but not other sleep phenotypes) appear to be explained partly by genetic variation related to continental ancestry in AAs.

1963F

Evidence of social marginalisation leading to strong genetic differentiation among the Ari of Ethiopia. *G. Hellenthal[1], L. van Dorp[1], S. Myers[2], L. Pagani[3], C. Tyler-Smith[3], E. Bekele[4], A. Tarekegn[4], M. Thomas[1], N. Bradman[5], D. Balding[1].* 1) Genetics, Evolution, and Environment, University College London, London, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom; 3) The Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 4) Addis Ababa University, Addis Ababa, Ethiopia; 5) Henry Stewart Talks Ltd, London, United Kingdom.

A major debate among population geneticists is whether the large amount of observed genetic diversity among human groups (e.g. from Africa) is primarily attributable to ancient substructure or to more recent inter-mixing or drift events. A specific example involves the caste-like occupational groups within the Ari of Ethiopia, which include the Cultivators and socially marginalized Blacksmiths. There are two competing theories about the origins of the Ari Blacksmiths as (i) remnants of an ancient hunter-gatherer population that inhabited Ethiopia prior to the arrival of agriculturists (e.g. Cultivators) during the Neolithic period, versus (ii) relatively recently related to the Cultivators but presently marginalized in the community due to their craft skills. A recent paper by Pagani et al (2012) collected and analysed genome-wide DNA from samples of Ari Blacksmiths and Cultivators, observing genetic differentiation between these two occupational groups (F_{ST} = 0.04) at a similar level to that observed across multiple ethnic groups sampled throughout Ethiopia (F_{ST} range 0.02 - 0.06). Furthermore, an analysis using the clustering algorithm ADMIXTURE assigned the Ari Blacksmiths almost entirely to a single genetically homogeneous cluster, with other Ethiopian groups -- including the Cultivators -- displaying varying levels of genetic similarity to this unique cluster. The authors noted these patterns were consistent with model (i), with subsequent assimilation of the indigenous hunter-gatherers into the expanding agriculturalist community. We analysed the same samples using a novel haplotype-based approach to test this hypothesis, comparing strings of DNA patterns among different Ethiopian groups and to various groups outside of Ethiopia. Importantly, this new model is able to distinguish genetic structure attributable to allelic drift within a population from that attributable to shared ancestry with outside groups. Using this technique, we provide compelling evidence that the genetic differences among Ari Blacksmiths and Cultivators are entirely attributable to recent social marginalisation, i.e. hypothesis (ii). This finding serves as both a cautionary tale about interpreting results from the widely popular program ADMIXTURE, and a clear demonstration of how social constructions can contribute directly to genetic differentiation among previously similar groups.

1964W

Pinpointing the Indian origin and revealing the Caucasus chapter in the genetic ancestry of the European Roma. *M. Karmin[1], M. Baldovič[2], N. Jeran[3], M. Reidla[1], S. Cvjetan[4], S. Rootsi[1], T. Šaric[3], J. Šarac[3], M. Cenanovic[5], T. Haller[6], A. Raidvee[7], R. Mägi[6], A. Leskovac[8], L. Kovacevic[5], D. Marjanovic[5], H.D. Auguštin[3], N. Novokmet[3], A. Ficek[2], G. Chaubey[1], P. Rudan[3], V. Ferak[2], E. Metspalu[1], M.D.M. Behar[1,9], M. Metspalu[1], R. Villems[1].* 1) Intitute of Molecular and Cellular Biology, University of Tartu and Estonian Biocenter, Tartu, Estonia; 2) Department of Molecular Biology, Faculty of Natural Sciences, Comenius University, Bratislava, Slovakia; 3) Institute for Anthropological Research, Zagreb, Croatia; 4) Mediterranean Institute for Life Sciences, Split, Croatia; 5) Institute for Genetic Engineering and Biotechnology, Sarajevo, Bosnia and Herzegovina; 6) Estonian Genome Center, University of Tartu, Tartu, Estonia; 7) University of Tartu, Faculty of Social Sciences and Education, Department of Psychology, Tartu, Estonia; 8) Vinca Institute of Nuclear Sciences , Belgrade, Serbia; 9) Molecular Medicine Laboratory, Rambam Health Care Campus, Haifa, Israel.

According to linguistic evidence, the Indian exodus of the ancestors of the European Roma most probably took place around the end of the first millennium. By the 13th - 15th centuries, different groups of the Roma had spread throughout Europe. A virtual lack of written records prior to their arrival to Europe has left us with scarce knowledge about their historical migratory routes. Therefore, valuable insight comes from genetic studies. The origin of the maternal (mitochondrial DNA - mtDNA) and paternal lineages (Y chromosome - NRY) of the European Roma can be broadly classified as South Asian and West Eurasian. Out of the nearly 600 mtDNAs and 340 NRY lineages studied here, about 30% of the gene pool of both maternal and paternal lineages of the European Roma were classified as South Asian. To analyze the genetic ancestry of the Roma on the genome-wide level we genotyped ca 650 000 SNPs in 30 Roma individuals from six European countries with Illumina genotyping arrays. STRUCTURE-like analyses and principal component analyses (PCA) were performed in the context of Eurasian populations (N=1219). These analyses showed that in general the European Roma have a three-part genetic ancestry, with components from South Asia, the Caucasus area and Europe. Notably, on average, 38% of each Roma genome comprises the genetic component currently most abundant among populations in the Caucasus region, revealing a genetic legacy that has not received much attention until now. To further pinpoint the Indian origin of the Roma we used two methods based on haplotype data and a pre-defined reference population. 1) With the local ancestry deconvolution method we assigned the parts of genome with South Asian ancestry, and further used information only from those parts for PCA. 2) We used a novel in-house method assigning best-fit ancestry proportions for individuals as amalgamates of ancestral populations. The Roma formed a cluster bordering and overlapping with individuals from Uttar Pradesh and several South Indian states on PCA results, and the best-fit method revealed that the Indian ancestry of the Roma comes primarily from the Southern Indian populations. Thus, our results reveal a substantial amount of ancestry shared with populations from the Caucasus and several lines of evidence suggest a more southern origin of the Roma within India than previously thought.

Reconstructing Austronesian population history. *M. Lipson[1], P.-R. Loh[1], N. Patterson[2], P. Moorjani[2,3], Y.-C. Ko[4], M. Stoneking[5], B. Berger[1,2], D. Reich[2,3].* 1) Department of Mathematics and Computer Science and Artificial Intelligence Laboratory, Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute, Cambridge, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Graduate Institute of Clinical Medical Science, China Medical University, Taichung, Taiwan; 5) Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

Present-day populations that speak Austronesian languages are spread across half the globe, from Easter Island in the Pacific Ocean to Madagascar in the Indian Ocean. Evidence from linguistics and archaeology suggests that the "Austronesian expansion," a vast cultural and linguistic dispersal that began 4--5 thousand years ago, had its origin in Taiwan. However, genetic studies of Austronesian ancestry have been inconclusive, with some finding affinities with aboriginal Taiwanese, others advancing an autochthonous origin within Island Southeast Asia, and others proposing a model involving multiple waves of migration from Asia. Here, we analyze genome-wide data from a diverse set of 31 Austronesian-speaking and 25 other groups typed at 18,412 overlapping single nucleotide polymorphisms (SNPs) to trace the genetic origins of Austronesians. We use a recently developed computational tool for building phylogenetic models of population relationships incorporating the possibility of admixture, which allows us to infer ancestry proportions and sources of genetic material for 26 admixed Austronesian-speaking populations. Our analysis provides strong confirmation of widespread ancestry of Taiwanese origin: at least a quarter of the genetic material in all Austronesian-speaking populations that we studied---including all of the Asian ancestry in populations from eastern Indonesia and Oceania---is more closely related to aboriginal Taiwanese than to any populations we sampled from the mainland. Surprisingly, we also show that western Austronesian-speaking populations have inherited substantial proportions of their Asian ancestry from a source that falls within the variation of present-day Austro-Asiatic populations in Southeast Asia. No Austro-Asiatic languages are spoken in Island Southeast Asia today, although there are some linguistic and archaeological suggestions of an early connection between mainland and island populations. The most plausible explanation for these findings, in light of the historical evidence, is that western Island Southeast Asia was settled by Austronesian groups who had previously mixed with Austro-Asiatic speakers on the mainland.

1966F

Patterns of genetic variation in populations of African ancestry observed in whole genome sequencing of 691 individuals from CAAPA.
R. Mathias[1], L. Huang[1], T.D. O'Connor[2,3], C. Vergara[1], M. Taub[1], A. Deshpande[4], C.R. Gignoux[5], N. Rafaels[1], S. Shringarpure[6], R. Torres[5], J. Galanter[5], R. Hernandez[5], E.E. Kenny[7], D. Locke[4], W. Grus[4], K. Gietzen[8], I. Ruczinski[1], K.C. Barnes[1], CAAPA Consortium. 1) Johns Hopkins University, Baltimore, MD; 2) University of Washington, Seattle, WA; 3) University of Maryland, Baltimore, MD; 4) Knome, Inc., Cambridge, MA; 5) University of California at San Francisco, San Francisco, CA; 6) Stanford University School of Medicine, Palo Alto, CA; 7) Icahn School of Medicine at Mount Sinai, New York, NY; 8) Illumina, Inc., San Diego, CA.

The **C**onsortium on **A**sthma among **A**frican-ancestry **P**opulations in the **A**mericas (CAAPA) includes high coverage whole genome sequence (WGS) data (~30x depth) on 1,005 subjects of African ancestry and extends the patterns of variation catalogued in the Thousand Genomes Project (TGP) and Exome Sequencing Project (ESP) to a spectrum of populations representing a wide range of African ancestry. An interim data freeze (N=691) of CAAPA includes: 329 African Americans from 8 sites in the United States (Chicago, Atlanta, Baltimore/Washington, Nashville, New York City, Detroit, San Francisco, and Winston-Salem); 125 African Caribbeans from three sites (Barbados, Jamaica and Honduras); 212 African ancestry samples with a notable Latino component sampled from 5 Central and South American sites (Cartagena, Conde and Salvador in Brazil, Dominican Republic, and Puerto Rico); and 25 samples from Nigeria. The average Yoruba (YRI) component in CAAPA is 58%, ranging from <40% in the Puerto Rican samples to >80% in the Jamaican samples. Principal components and FST analysis reveals minimal differences between the 8 African American sites. Of the 47.4 million (M) variants observed in CAAPA, a little more than half (~24M) are unique to CAAPA and not observed in TGP sequence data. 68.7% (~33M) have an MAF≤1%, 13.8% (~6.6M) have an MAF 1-5% and only 17.5% (~8.4M) are common (MAF>5%). A dramatic 37% (~18M) sites represent private variation. Per genome, we observe ~4.1M variant sites and observe strong correlation between variation per genome with level of African ancestry (r=0.97 with YRI content). Exome variation in CAAPA is similar to observations in the ESP. Relying on transcription factor binding motifs, DNase-seq, FAIRE-seq, and CHIP-seq data from ENCODE, we annotated each CAAPA genome and observe ~31K variants mapping to CTCF enriched elements, ~23K predicted enhancer site variants, ~3K sites in predicted promoter flanking regions, ~407K sites in predicted transcribed regions, ~13K sites in predicted promoter regions including TSS, and ~12K sites in predicted weak enhancer or open chromatin cis regulatory elements per genome. WGS data from CAAPA will provide an expansive understanding of genetic variation in populations of African ancestry and will be available as a public resource to the scientific community to improve our understanding of the role of genetic variation in complex disease.

1967W

Correlation of Native American Ancestry with Body Mass Index in an Admixed Community.
T.M. Norden-Krichmar[1], I.R. Gizer[2], O. Libiger[1], K.C. Wilhelmsen[3], C.L. Ehlers[4], N.J. Schork[1]. 1) Scripps Translational Science Institute, The Scripps Research Institute, La Jolla, CA; 2) Department of Psychological Sciences, University of Missouri, Columbia, MO; 3) Department of Genetics and Neurology, University of North Carolina, Chapel Hill, NC; 4) Department of Molecular and Integrative Neurosciences, The Scripps Research Institute, La Jolla, CA.

Obesity is highly prevalent in Native Americans (NAs). Because of this, the analysis of ancestral background is essential in association studies of obesity phenotypes in genetic studies of admixed populations with NA ancestry because population stratification can confound the results. In addition, there might be a set of polygenes present in the NA ancestral population that contributes to gradations in obesity phenotypes among admixed individuals with different levels of admixture. We explored the relationship between genetic admixture, cultural and socioeconomic factors, and body mass index (BMI) in a community sample of Native Americans with a high prevalence of obesity (n=822). We estimated genetic admixture by self-report as well as genetic marker-based supervised and unsupervised algorithms determined by: 1) Illumina low-coverage (3X to 20X) whole genome sequencing (WGS) and 2) genotype data from an Affymetrix Exome1A chip. The ancestry estimates from the different genotyping methods had a very high Pearson's correlation of 0.9. Linear regression was performed between the morphological phenotypes of BMI, height, and weight and the estimated percent Native American ancestry. BMI and weight showed a significant positive correlation with Native American ancestry, whereas height showed a negative correlation. Age was also strongly associated with BMI, while gender and socioeconomic measures, such as education and income, were not. Two different cultural identity measures were also used to test for correlation with BMI: the Orthogonal Cultural Identification Scale (OCIS) and the Indian Culture Scale (ICS). The Indian Culture Scale (ICS) showed a positive correlation with BMI , but the Orthogonal Cultural Identification Scale (OCIS) showed no significant correlation. Heritability (h2) estimates for BMI were also calculated from linkage analysis and from the genotyping data to be between 0.38 - 0.49, suggesting a high heritability of this phenotype. These results suggest that genetic and cultural environmental factors influence BMI in this population. Additionally, this study suggests that admixture-mapping may be a successful approach in uncovering genetic variants associated with obesity and obesity-related illnesses in this population.

1968T

Deep coverage Bedouin genomes reveal Bedouin haplotypes shared among worldwide populations in the 1000 Genomes Project.
J.L. Rodriguez-Flores[1,2], K. Fakhro[3], F. Agosto-Perez[2], A. Robay[3], R.G. Crystal[1], J.G. Mezey[1,2]. 1) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 3) Department of Genetic Medicine Weill Cornell Medical College - Qatar, Doha, Qatar.

The 1000 Genomes Project (1000G) has sampled and sequenced over 2500 genomes that are representative of the genetic diversity in populations worldwide. The Arabian Peninsula has not been previously included in 1000G, hence the connections between genetic variation in the indigenous Bedouin people and worldwide populations is unknown. We have sampled genomes from Bedouin individuals in the nation of Qatar as a window into the genetic variation in this understudied region. Our goal was to use this sample to assess the hypothesis that there is detectable shared ancestry between Bedouin and Southern European populations resulting from the history of empires that spanned both the Mediterranean and Arabian regions and the hypothesis that there is shared ancestry between Bedouin and contemporary Latin American populations, since the majority of European settlers in Latin America from the past half millennia are primarily from Southern European countries. We selected 60 Qataris with over 95% Bedouin ancestry and at least 3 generations of ancestry in Qatar for deep coverage genome sequencing. Genomes were sequenced by the Illumina Genome Network using TruSeq DNA PCR-free sample preparation, generating over 120 gigabases of paired-end 100 base pair reads per genome on a HiSeq 2500, yielding over 30x depth and genotypes for >96% of the genome using both the ELAND/CASAVA and BWA/GATK pipelines. Using these genotypes, we inferred haplotypes using SHAPEIT for Bedouin Qataris and for 1000G populations on a set of sites polymorphic in both 1000G and Bedouins. We used admixture analysis to assess shared ancestry between our Bedouin sample and 1000G populations using the ancestry deconvolution method SUPPORTMIX. Given the lack of appropriate ancestral populations, we conducted a leave-one-out approach, where for each population (1000G + Bedouin = n), we removed the population and used the remaining n-1 populations as an ancestral reference panel. Using this approach, we observed up to 15% Bedouin ancestry in European, South Asian, and American populations. Likewise, we observed ancestry from Europe, South Asia, and America in the Bedouin. For individuals from the Americas, the analysis identified a considerable number of segments shared with Bedouins previously classified as European ancestry.

1969F

Fossil free sequencing of archaic hominin metagenomes. *B. Vernot, JM. Akey.* Department of Genome Sciences, University of Washington, Seattle, WA.

To date, the genetic analysis of extinct archaic hominins has required the isolation and sequencing of ancient DNA obtained from fossilized remains, which is technologically challenging and limited by the number of available specimens. Here, we describe an alternative, fossil free paradigm, to sequence archaic genomes. The rationale of this approach is that ~3% of non-African genomes are estimated to have been inherited from Neanderthal ancestors. However, the precise introgressed sequences will vary among individuals. Thus, if enough individuals are analyzed, the various haplotypes of archaic sequence can be identified and stitched together to generate what we refer to as an 'archaic metagenome', as it consists of lineages from multiple archaic ancestors. To enable fossil free sequencing of archaic metagenomes, we developed a novel and computationally efficient statistic to identify introgressed DNA sequences, which is agnostic to the availability of an archaic reference sequence and can therefore facilitate the discovery of previously unknown archaic hominins, if such groups exchanged genes with modern humans. We rigorously evaluated the power and false discovery rate of our method through extensive coalescent simulations under a wide variety of demographic models and admixture scenarios. We applied our method to 379 European whole genome sequences, and identified a total of 5.2 Gb of putatively introgressed sequence, covering 1.1 Gb of the genome. These sequences are significantly enriched for matches to the high-coverage Neanderthal genome, supporting the hypothesis that they were inherited from admixture events with Neanderthal ancestors. Moreover, they are significantly depleted among coding regions, suggesting a fitness cost to hybridization. The recovered sequences also enable a variety of population genetics inferences to be made, such as effective population sizes, time of introgression, and number of archaic ancestors. In summary, we find that approximately 1/3 of the Neanderthal genome survives in modern humans and we anticipate that fossil free sequencing of archaic genomes will be a significant advance for the burgeoning field of paleogenomics, allowing genetic analyses that have heretofore not been possible.

Rosenberg[12].* 1) Evolutionary Biology, Estonian Biocentre & Tartu Univ, Tartu, Estonia; 2) Molecular Medicine Laboratory, Rambam Health Care Campus, Haifa 31096, Israel; 3) The Blavatnik School of Computer Science, Tel Aviv University, Tel-Aviv 69978, Israel; 4) Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv 69978, Israel; 5) Porter School of Environmental Studies, Department of Zoology, Tel Aviv University, Tel Aviv 69978, Israel; 6) Institute of Biochemistry and Genetics, Ufa Research Center, Russian Academy of Sciences, Ufa 450054, Russia; 7) ARL Division of Biotechnology, University of Arizona, Tucson, Arizona 85721, USA; 8) Department of Molecular Microbiology and Biotechnology, George Wise Faculty of Life Science, Tel-Aviv University, Tel-Aviv 69978, Israel; 9) International Computer Science Institute, Berkeley, California 94704, USA; 10) Ruth and Bruce Rappaport Faculty of Medicine and Research Institute, Technion-Israel Institute of Technology, Haifa 31096, Israel; 11) Estonian Academy of Sciences, Tallinn 10130, Estonia; 12) Department of Biology, Stanford University, Stanford, California 94305, USA; 13) Department of Integrative Biology, University of California Berkeley, 94720, USA; 14) these authors contributed equally.

The origin and history of the Ashkenazi Jewish population have long been of great interest. Most studies have concluded that the population derives its genetic ancestry from both Europe and the Middle East, and that it retains high genetic similarity to other Jewish groups such as the Sephardi Jews in Europe and Jewish communities in Northern Africa. It has recently been claimed, however, that a large part of the ancestry of the Ashkenazi population originates with the Khazars, a conglomerate of multi-ethnic, mostly Turkic-speaking tribes who consolidated into a powerful state just north of the Caucasus mountains between ca. 1,400 to 1,000 years ago. It has been difficult to explicitly test for Khazar contributions into Ashkenazi Jews, because it is not clear which extant populations can be used to represent modern descendants of the Khazars, and because the proximity of the southern Caucasus region to the Middle East makes it difficult to attribute any potential signal of Caucasus ancestry to Khazars rather than Middle Eastern populations. Here, we assemble the largest sample set available to date for assessment of Ashkenazi Jewish genetic origins, containing genome-wide single-nucleotide polymorphism data in 1,774 samples from 107 Jewish and non-Jewish populations that span the possible regions of potential Ashkenazi Jewish ancestry: Europe, the Middle East, and 15 populations from the region historically associated with the Khazar kingdom at its peak. Employing a variety of standard techniques for the analysis of population structure, we find that Ashkenazi Jewish samples share the greatest genetic ancestry with other Jewish populations, and among non-Jewish populations, with groups from Mediterranean Europe and the Middle East, and that they have no particular signal of genetic sharing with populations from the Caucasus. Thus, analysis of the most comprehensive set of Jewish and other Middle Eastern and European populations together with a large sample from the region of the Khazar kingdom does not support the hypothesis of a significant contribution of the elusive Khazars into the gene pool of the Ashkenazi Jews.

The Brazilian EPIGEN Initiative: admixture, history and epidemiology at high resolution. *A.C. Pereira[1], M.L. Barreto[2], B.L. Horta[3], M.F. Lima-Costa[4], A. Horimoto[1], N. Esteban[1], F.S.G. Kehdy[5], W.C.S. Magalhães[5], M.R. Rodrigues[5], M. Gouveia[5], M. Machado[5], R. Moreira[5], J.M. Sanches[1], H. Santos[1], F. Soares[1], G.B. Soares-Souza[5], T. Muniz[5], H. SantAnna[5], E. Tarazona-Santos[5], The Brazilian EPIGEN Consortium.* 1) INCOR, Universidade de São Paulo, Brazil; 2) Universidade Federal da Bahia, Brazil; 3) Universidade de Pelotas, Brazil; 4) Fundacão Oswaldo Cruz, Centro de Pesquisa René Rachou, Brazil; 5) Universidade Federal de Minas Gerais, Brazil.

As part of the largest Latin American initiative in population genomics and genetic epidemiology, we studied three Brazilian longitudinal populational cohorts: Salvador (n=1309), Bambui (n=1442) and Pelotas (n=3736) from Northeast, Southeast and Southern Brazil respectively. We genotyped the Omni 2.5 M Illumina array for the 6487 individuals, the Omni 5.0 M Illumina array for 265 individuals and sequenced 30 complete genomes (average coverage: 42X). EPIGEN individuals show a very large extent of individual variability in ancestry proportions. While Native American ancestry was low (5-7% at population level, with no individual with > 30% of this ancestry), the three populations showed individuals with all possible combinations of African and European ancestry. At population level, African ancestry ranged from 14-15% in Pelotas and Bambui to 51% in Bahia. Our unprecedented high resolution analysis of population structure of Brazilians in the context of worldwide variation shows that African and European ancestral subcomponents of Brazilians differ from African-Americans, reflecting the prevalent contribution from Mediterranean countries and African immigration from different geographic areas such as Mozambique and Angola. Our large and highly admixed dataset gives us high power to make inferences based on the distribution of local chromosome ancestry. We are currently inferring the dynamics of the demographic admixture process in different parts of Brazil, as well as the time and mode of arrival to Brazil of clinically relevant mutations. We are also identifying regions with significant excess/deficit of European, African or Native American ancestry, to identify candidate regions to be affected by Post-Columbian natural selection. Moreover, our high-quality sequencing data allowed us to identify between 3.6 M and 4.4 M of autosomal SNPs per each whole-genome sequenced individual, and the high levels of diversity and admixture of the Brazilian population allowed us to identify around 2.3 M of new autosomal SNPs, most of them rare. We are separating the African, European and Native American constituents of the 30 complete genomes to analyze the distributions of different class of variants in function of their ancestry. The EPIGEN Initiative is also performing several GWAS and admixture mapping studies on different complex traits, including longitudinal data. Funding: Brazilian Ministry of Health/FINEP.

1972F

The Genetic Structure and Admixture Analysis of Brazilian Populations: The Brazilian EPIGEN Initiative. *H.C. Santos[1], A. Horimoto[1], A.C. Pereira[1], E. Tarazona-Santos[2], M.L. Barreto[3], B.L. Horta[4], M.F. Lima-Costa[5], M. Gouveia[2], M. Machado[2], F. Soares[2], T.M. Silva[3], J.M. Sanches[1], N. Esteban[1], W.C.S. Magalhaes[2], M.R. Rodrigues[2], F.S.G. Kehdy[2], The Brazilian EPIGEN Consortium.* 1) Laboratory of Genetics and Molecular Cardiology, Heart Institute, Medical School of University of São Paulo; 2) General Biology Department, Federal University of Minas Gerais, Brazil; 3) Instituto de Saúde Coletiva, Federal University of Bahia, Brazil; 4) Universidade Federal de Pelotas, Brasil; 5) Centro de Pesquisas René Rachou, Fundação Oswaldo Cruz, Belo Horizonte, Minas Gerais, Brazil.

Brazilians form one of the most heterogeneous populations in the world, the result of interethnic crosses between peoples from three continents: the European colonizers, African slaves and the autochthonous Native Americans. To analyze patterns of human genetic variation in Brazilian populations, we used data from 370,539 shared SNPs between EPIGEN-BRAZIL Project genotyped by Omni2.5 Illumina array (6,487 individuals from three Brazilian cohorts: Pelotas, Southern Brazil, 3,736 individuals, Minas Gerais, South East Brazil, 1,442 individuals and Bahia, north east Brazil, 1,309 individuals), 688 individuals from 6 populations from HapMap Project (CEU, YRI, ASW, TSI, MEX and LWK) and 95 individuals from 4 Native American populations from HGDP (Karitiana, Surui, Pima and Maya). Principal components and individual admixture analysis (by ADMIXTURE software) were performed to these populations to identify structure, ancestry percentages and a minimum set of SNPs needed to capture the admixture components of Brazilian populations. As expected, Brazilian samples fell between Africans, Europeans and Mexicans. Furthermore, the mean percentage of individual European, African and Native American ancestry, respectively were 0.773, 0.155 and 0.072 for Pelotas cohort, 0.798, 0.142 and 0.060 for Minas Gerais cohort and 0.435, 0.505 and 0.060 for Bahia cohort. From 370,539 analyzed SNPs, we found a minimum number of 256 SNPs able to capture 91%, 93% and 78% of respectively African, European and Native American ancestries components. Our results confirm the highly admixed character of Brazilian populations suggest this population as a good tool for admixture mapping studies. More studies about intracontinental components that contributed to the Brazilian population formation are needed and will be performed. Funding: Brazilian Ministry of Health/FINEP.

1973W

Population stratification detection and correction in rare variant collapsing methods using principal component analysis. *J.R. Wallace[1], C.B. Moore[1,2], A.T. Frase[1], M.D. Ritchie[1].* 1) Center for Systems Genomics, The Pennsylvania State University, University Park, PA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Principal Component Analysis (PCA) has often been used in genome-wide association studies (GWAS) correct for population stratification and prevent increased type I errors. With the proliferation of Next Generation Sequencing (NGS) technology, rare variant collapsing methods have gained popularity. However, applying PCA to rare variant collapsing methods has not been well studied, and the effectiveness of adjusting for population stratification using principal components (PCs) on rare variants is largely unknown. To explore population stratification correction in rare variant data, we collapsed the low frequency (< 5% MAF) variants in the 1000 Genomes Project Phase 1 data based on Entrez gene boundaries using BioBin, a bioinformatics tool for automatically binning rare variants into biologically relevant bins (genes, pathways, regulatory regions, etc.) based on prior biological knowledge gleaned from various public data sources such as Entrez, Gene Ontology (GO), and Protein Families database (PFAM). These bins can then be evaluated with any number of popular rare variant collapsing statistical methods.

We analyzed the data for each pairwise combination of the 14 populations available in the 1000 Genomes data and found dramatic stratification and natural clustering of populations into continental groups. We then examined multiple approaches to construct PCs using different subsets of the genetic data. To compare approaches, we defined a normalized distance metric between sets of PCs as well as notions of correctness for a given stratification and predictive power without given stratification. We illustrate these concepts with respect to the 1000 Genomes data and show how similar concepts can be applied to a natural dataset in the course of analysis. We found that for populations close in ancestral history, rare variants should be excluded from PCA, and we developed a method for increasing the sensitivity of PCA, though this method may disguise other hidden stratification. Identifying and properly correcting for stratification remains an important issue; using the techniques described, we demonstrate solutions that identify and correct the ancestry stratification as well as stratification along sequencing technology.

1974T

Surveying European and West African Population Structure Using >2,300 Samples with Spatial Information. *Y. Wang, K. Noto, J.B. Byrnes, R.E. Curtis, N.M. Myres, M.J. Barber, J.M. Granka, C.A. Ball, K.G. Chahine.* AncestryDNA, San Francisco, CA.

Population structure arises as a consequence of the interplay between geography, genetic drift, and gene flow. Knowledge of human population structure is fundamental to understanding how demographic history has shaped human genetic diversity. In this work, we investigated the genetic structure of European and West African populations using high-density SNP data. First, we analyzed ~2000 European individuals genotyped at >700,000 SNPs using principal component analysis (PCA), spatial ancestry analysis (SPA), and admixture-model-based method (ADMIXTURE). Despite an overall high level of genetic similarity, we observed significant patterns of genetic variation among European populations, ranging from the regional level (e.g., Northern European vs. Southern European and Eastern European vs. Western European) to the local level (e.g., Iberian vs. Italian and English vs. Irish). We then conducted similar analyses on ~330 individuals sampled from nine West African countries (Senegal, Mali, Ivory Coast, Ghana, Benin, Togo, Nigeria, Cameroon and Congo). Our results revealed strikingly significant structure at the country level, despite geographical proximity. Comparing the three approaches, we found that SPA has better power in predicting the population of single origin individuals, given an accurate reference panel of reasonable size. We further applied SPA to identify SNPs showing large gradients in allele frequency, which can be used to tag candidate regions under natural selection. In addition, we selected two sets of ancestry informative markers (AIMs) that carry substructure information for European and West African populations, respectively. Lastly, we investigated the pattern of genetic variation in African Americans using a large cohort (>5,000) of African American individuals and the European and West African reference panels. Our results shed new light on the population and migration history of African Americans.

1975F

Using evolutionary profiles to better-inform model organism selection for human disease research. *A.D. Baxevanis, E.K. Maxwell, C.E. Schnitzler, A.D. Nguyen, R.T. Moreland.* Genome Technology Branch, Division of Intramural Research, National Human Genome Research Institute, NIH, Bethesda, MD.

While the standardization of methods for studying human diseases in traditional animal models has yielded many clinically actionable results, it has effectively narrowed the breadth of species in which we choose to look for insights. The recent expansion of whole-genome sequence data available from a diverse array of animal lineages provides an opportunity to investigate the feasibility of using non-traditional model organisms to advance human disease research. Cases in which traditional animal models have led to conclusions that are not applicable to humans are becoming more commonplace, and the concern that this may be a growing problem calls for a re-evaluation of how appropriate models are selected for different disease classes. To that end, we have used a comparative genomics approach that encompasses a wide range of animals across the metazoan tree to determine which organisms could serve as viable models for studying various classes of human diseases. We show that some emerging non-bilaterian model organisms have surprisingly high proportions of human disease gene homologs despite their great evolutionary distance from humans; these organisms may confer advantages as animal models in terms of their ease of use, short generation times and cost-effectiveness. Conversely, while it has been previously shown that the genes implicated in the causation of most human diseases are of ancient origin, our results indicate that some disease classes involve a significantly large proportion of genes that appear to have emerged relatively recently within the Metazoa. These disease classes, having a more recent evolutionary history, may be difficult to replicate phenotypically outside of our closest animal relatives. Taken together, these findings demonstrate why model organism selection should be done on a disease-by-disease basis, with evolutionary profiles in mind.

1976W

A Model-Based Analysis of GC-Biased Gene Conversion in the Human and Chimpanzee Genomes. *J.A. Capra[1], M.J. Hubisz[2], D. Kostka[3], K.S. Pollard[4], A. Siepel[2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 3) Developmental Biology and Computational & Systems Biology, University of Pittsburgh, Pittsburgh, PA; 4) Institute for Human Genetics and Division of Biostatistics, University of California, San Francisco, CA.

GC-biased gene conversion (gBGC) is a recombination-associated process that favors the fixation of G/C alleles over A/T alleles. In mammals, gBGC is hypothesized to contribute to variation in GC content, rapidly evolving sequences, and the fixation of deleterious mutations, but its prevalence and general functional consequences remain poorly understood. gBGC is difficult to incorporate into models of molecular evolution and so far has primarily been studied using summary statistics from genomic comparisons. Here, we introduce a new probabilistic model that captures the joint effects of natural selection and gBGC on nucleotide substitution patterns, while allowing for correlations along the genome in these effects. We implemented our model in a computer program, called phastBias, that can accurately detect gBGC tracts ~1 kilobase or longer in simulated sequence alignments. When applied to real primate genome sequences, phastBias predicts gBGC tracts that cover roughly 0.3% of the human and chimpanzee genomes and account for 1.2% of human-chimpanzee nucleotide differences. These tracts fall in clusters, particularly in subtelomeric regions; they are enriched for recombination hotspots and fast-evolving sequences; and they display an ongoing fixation preference for G and C alleles. They are also significantly enriched for disease-associated polymorphisms, suggesting that they contribute to the fixation of deleterious alleles. The gBGC tracts provide a unique window into historical recombination processes along the human and chimpanzee lineages. They supply additional evidence of long-term conservation of megabase-scale recombination rates accompanied by rapid turnover of hotspots. Together, these findings shed new light on the evolutionary, functional, and disease implications of gBGC. The phastBias program and our predicted tracts are freely available.

In order to test whether evolutionary conservation of combinatorial protein-DNA interactions gives insight into human gene regulatory function and disease, we experimentally determined transcription factor (TF) binding locations of four master regulatory TFs (ONECUT1/HNF6, FOXA1/HNF3A, HNF4A, and CEBPA) in the livers of human, macaque, mouse, rat and dog. Approximately two thirds of the TF binding events for these four TFs resided in heterotypic clusters, which we designated as cis-regulatory modules (CRMs). Less than half of the identified human liver CRMs could be detected in orthologous regions from one or more of our study species. We found that CRMs conserved in human and at least one non-primate to be disproportionately found in regulatory regions implicated in rare liver-related genetic diseases including those affecting blood coagulation and lipid homeostasis. For example, several of the promoter regions in the blood coagulation cascade contain highly conserved CRMs that are recurrently mutated in bleeding disorders. In comparison, primate or rodent-specific CRMs indicated more lineage-specific pathways involving drug detoxification. Deeply conserved CRMs were also found in close proximity to liver and blood lipid-disease loci identified by genome-wide association studies (GWAS). Together, our data demonstrates how the rapid evolution of human combinatorial transcription factor binding can be used to identify and prioritize the functional study of pathologic regulatory mutations.

Functional characterization of Toll-like receptor signaling pathways in primates. *J.F. Brinkworth[1,2], J.N. Kohn[3,4], J. Boulais[1,5], J.C. Grenier[1], R.E. Lanford[6], Z.P. Johnson[3], L.B. Barreiro[1,2,5].* 1) Centre Hospitalier Universitaire Sainte-Justine Hospital Centre de Recherche; 2) Department of Pediatrics, University of Montreal, Quebec, Canada; 3) Yerkes National Primate Research Center, Atlanta, GA, United States; 4) Graduate Program in Neuroscience, Emory University, Atlanta, Georgia, United States; 5) Department of Biochemistry, University of Montreal, Quebec, Canada; 6) Department of Virology and Immunology, Texas Biomedical Research Institute, San Antonio, Texas, United States.

Despite close genetic relatedness, humans, apes and monkeys exhibit inter-species differences in susceptibility to certain pathogenic infections that are major causes of severe disease in humans. For example, humans are highly susceptible to Gram-negative bacterial sepsis, HIV/AIDS, and tuberculosis, while some monkey and ape species remain resistant or progress very rapidly. Such differences between humans and other primates are thought to result, at least in part, to inter-species differences in immune response to infection. However, due to the lack of comparative functional data across species, it remains unclear in what ways the immune systems of humans and other primates differ. Here we report a genome-wide comparative study of immune responses among primates, specifically focusing on Toll-Like receptor (TLR) signaling pathways. To examine if human and nonhuman primate TLR pathway activity differs, we stimulated leukocytes from humans, common chimpanzees and rhesus macaques with TLR2, 4 and 7 -detected bacterial and viral ligands (LPS from *Escherichia coli*, Lipomannan from *Mycobacterium smegmatis*, single-stranded RNA viral mimetic Gardiquimod). Blood was stimulated for 4 and 24 hours and innate immune response was assessed via global expression profiling of total blood leukocytes using RNA sequencing. Inter-species differences in gene expression were noted across many immune gene families, with humans manifesting many unique gene expression profiles in response to both bacterial and viral ligands. These observations suggest that innate immune responses of human and non-human primates have evolutionary diverged, lending support to the notion that human-specific immune responses might account for some of the known differences in susceptibility to infectious diseases between humans and our closest evolutionary relatives. This study was supported by National Science and Engineering Council of Canada (# grant number LBB) Réseau de Médecine Génétique Appliquée (RMGA), the Fonds de Recherche du Québec - Santé (FRQS) and the Canadian Institutes of Health Research (CIHR, Grant # TGF-96109) (JFB).

1979W

Accelerated evolution of primate-specific microRNAs in the human genome. *M. Lopez-Valenzuela[1], N. Petit-Marty[1], A. Navarro[1,2,3], Y. Espinosa-Parrilla[1].* 1) Institut de Biologia Evolutiva (IBE, Universitat Pompeu Fabra-CSIC), Barcelona, Catalonia, Spain; 2) Instituto Nacional de Bioinformática (INB), Barcelona, Catalonia, Spain; 3) Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Catalonia, Spain.

MicroRNAs (miRNAs) are a class of small non-coding RNAs with a prominent role on gene regulatory networks. miRNA genes are continuously being added to metazoan genomes allowing the creation of lineage-specific miRNAs. The differential regulation provided by these lineage-specific miRNAs may contribute to shape different phenotypes in species with genomes of similar protein-coding content. The rise of primate lineage is marked by an outstanding emergence of new miRNA families, but how natural selection has acted on them is still not known. We studied the action of natural selection on human miRNAs applying a likelihood ratio test based in comparing substitution rates in the sequences of the miRNAs themselves with those in ancestral repeat (AR) sequences that are used as the reference for neutrality. The test can detect positive selection acting upon a small number of sites and distinguish it from relaxation of purifying selection. Primate PhyloP scores for each nucleotide in the studied miRNAs were also calculated as a complementary and alternative method. Comparison of 1,523 known human precursor miRNA sequences (miRBase release 18) with the reference genomes of chimpanzee and rhesus macaque showed nucleotide differences for 555 human miRNAs. The great majority of these miRNAs did not reach significance in the likelihood ratio test indicating that most sites in human miRNAs are either conserved or evolving neutraly. Nevertheless two miRNAs, hsa-mir-518a-1 and hsa-mir-3939, escaped markedly this tendency and presented the signature of accelerated evolution by positive selection. Interestingly, the primate-specific fraction of the analyzed miRNAs (79%) presented a higher proportion of significant nucleotides than the rest of miRNAs (p=0.00001) and showed lower average conservation index in the PhyloP analysis indicating that this group of primate-specific miRNAs could constitute a group of fast evolving miRNAs. We also found that, according to the TargetScan algorithm, these accelerated miRNAs tend to have less targets and that functions related to their target genes are similar to those of genes targeted by the set of more conserved miRNAs suggesting a redundant role for the recently emerged primate-specific miRNAs. Our results shed light on the evolution and function of human miRNAs and the way they might participate in the diversification of the primate lineage.

Addiction Drugs Cluster Functionally in the Genome with Concomitant Variation in Human Populations. *L. Jackson[1], Y. Liu[2], A. Tozeren[1].* 1) Biomedical Engineering, Science, and Health System, Drexel University, Philadelphia, PA., USA; 2) Department of Epidemiology and Biostatistics, University of Pennsylvania-Perelman School of Medicine, Philadelphia, PA, USA.

Understanding the common genetic mechanisms that underlie dopamine, opiate, and GABA addiction is of significant interest to human geneticists. We seek to use biologically relevant addiction genes as the starting pool to identify whether genes involved in addiction cluster together into loci of functional addiction control. We ask whether genes involved in addiction physically cluster in the genome, if there is a functional pattern to this clustering and whether such clusters show polymorphic variation in HapMap populations. Genes with biological relevance related to addiction (N=587) were gathered using NCBI Gene and then physically mapped onto the human genome using computational tools. Clusters of genes were identified using specific threshold criteria. These clusters were then surveyed to determine their drug addiction class membership. Polymorphisms in each of these regions were identified for each of the 11 HapMap populations. To test for deviations from neutral demographic expectations, we used neutrally evolving autosomal comparison regions and mapped within-cluster variation. Our analyses found nine addiction gene clusters with three clusters containing GABA specific addiction genes and six clusters containing addiction genes involved with all surveyed classes. Furthermore, analysis of the polymorphism underlying these clusters show patterns consistent with non-neutral GABA specific evolution in Chinese populations (sampled in either Beijing or Denver), and with non-neutral evolution at generalist addiction genes in African ancestry populations (Luhya, Masaai, African American, and Yoruba). Of particular interest are two polymorphisms (rs9467667 and rs9379817) which sit in the regulatory region of the HIST1H complex in a GABA specific addiction cluster, which show high derived variant frequencies in Chinese populations but which is nearly fixed for the ancestral variant in African and European ancestry populations. These variants may play a role in epigenetic histone regulation of alcohol sensitivity behavior.

1981F

Critical Assessment of Coalescent DNA Simulators in Modeling Recombination Hotspots. *T. Yang, H.W. Deng, T. Niu*.* Dept of Biostatistics and Bioinformatics, Tulane University, New Orleans, LA.

Coalescent-based simulation plays a pivotal role in understanding population evolutionary models and demographic histories, as well as in developing new analytical methods for genetic association studies. A plethora of coalescent simulators are developed, but it often remains challenging to select the most appropriate program. We extensively compared performances of five most-widely used ones - Hudson's ms, msHOT, MaCS, Simcoal2, and fastsimcoal, to provide a practical guide considering three crucial factors: (i) speed, (ii) scalability and (iii) hotspots position accuracy. Hudson's ms, the most popular simulator has very robust performance under standard coalescent but lacks the ability to simulate sequences with recombination hotspots. We highly recommend ms in absence of hotspots. msHOT has compensated the deficiency of ms incorporating crossover and gene conversion hotspots at arbitrary location and intensity. Simcoal2, based on discrete-generation coalescent, could simulate more complex demographic scenarios, but is comparatively slow. MaCS and fastsimcoal, both adopting a fast sequential Markov coalescent model to approximate standard coalescent, are much more computationally efficient whilst keeping salient features of msHOT and Simcoal2, respectively. Our extensive simulations demonstrated that MaCS and fastsimcoal have significant advantages over other programs for a spectrum of demographic scenarios. We also evaluated accuracy of hotspot positions of the simulated data by LDhat 2.2 rhomap package, sequenceLDhot and haploview. We found that fastsimcoal has the best performance. In conclusion, while ms remains an excellent choice for general scenarios, MaCS and fastsimcoal are much more scalable and flexible in simulating many different demographic histories and diverse DNA sequence structures. *Corresponding Author.

The genome-wide distribution of gene conversion, cross-overs, and de novo mutations events in Western Chimpanzees. *O. Venn[1], I. Turner[2], I. Mathieson[1,2], N. de Groot[3], G. McVean[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) University of Oxford, Department of Statistics, Oxford, OX1 3TG, United Kingdom; 3) Biomedical Primate Research Centre, Department of Comparative Genetics and Refinement, Rijswijk, 2288, Netherlands.

A wide spectrum of processes including cross-over, gene conversion, mutation and DNA repair impact genomes from the level of single nucleotide changes to multiple megabases. Inter-species comparisons of their genome-wide distributions may potentially be informative about the relative impact of each process and their evolution. The analysis of genetic variation measured through high-throughput population sequencing is a potentially powerful approach to study such processes. However, a major challenge in interpreting this information is the detection of erroneous, mis-assembled, or incorrectly genotyped genetic variants.

To characterize the spectrum of genome changes occurring in Western chimpanzees (*Pan troglodytes verus*) we sequenced an extended three-generation pedigree (3 founders, 3 F1, 3 F2) to ~30x across individuals. This family structure maximizes transmission information for the detection of rare events: 7/8 of the founder genomes is transmitted at least once, events arising in the F1 parent are naturally validated in the F2s, detected events can be assigned parental origin, and 99.2% of segregating sites can be phased unambiguously. At fine-scales, we describe the properties of de novo mutation events with respect to paternal age and the impact of local sequence. We estimate a sex-averaged de novo mutation rate of 1.38×10^{-8} bp per meiosis. To characterize meiotic recombination, we infer ~400 events for each cross-over and gene-conversion class, at median resolution of 835 bp, and compare these with historical LD-based cross-over hotspots. We find, human and chimpanzee share a male to female cross-over ratio of 0.6 and have an almost identical sex-averaged total genetic distance.

1983T

Moving backwards in time from present-day sequences: the paradox of sequential founder events. *M. Jeanpierre.* Department of genetics, Hôpital Cochin, Paris, France.

It is difficult to unravel the history of ancient populations, and events identified as single founder migrations may actually turn out to be a sequential series of founder events, with a small number of initial settlers gradually joined by an increasing number of related individuals of the same origin. The modeling of sequential founder events is an important issue, because each genetic variant is studied as a member of a sequence, and it is only possible to filter out these adjacent variations if we know the distribution of identical-by-descent segments. When modeling of the decay of haplotype sharing, simple geometric structures that can be described unambiguously in mathematical terms can provide an algebraic framework for analyses of the forces shaping the genealogy of a single allele. The challenge is to develop simplifications with a minimal loss of information, because the precision of the reconstruction depends on the dimensionality of the graph. The definition of blocks as physical entities, with clear borders, as for objects in the physical world, results in an apparent simplification, but is not really helpful because segments identical by descent are statistical entities with an ephemeral existence. Paradoxically, a hierarchical model, in which clusters are considered as border-less elements, gives a better representation of ancestral sequences, its precision steadily increasing with sample size. Large samples are not uncommon, with some containing more than 100,000 individuals, so this relationship between sample size and precision matters. The weakness of low-dimensional contingency tables may be one of several explanations for the poor reproducibility of association studies. This theoretical approach may be illustrated by the non random distribution of genetic variants for adult size. The clustering of variations defining ephemeral units of selection makes sense from a genetic point of view, because selection operates on visible physical characters, not on numerous, infinitesimally small genetic elements.

1984F

Effective population size - recombination, gene conversion and linkage disequilibrium. *D. Labuda, J.F. Lefebvre, C. Moreau.* Dept Ped, CHU Sainte-Justine, Univ Montreal, Montreal, PQ, Canada.

The genetic diversity of a population reflects the rate of mutation (μ) creating new alleles, and recombination events (c) that redistribute these alleles among homologous chromosomes to form a variety of haplotypes. Importantly, genetic diversity also reflects the historical effective size (Ne) of a population, since in larger populations more diversity may arise every generation and surviving variants persist for longer, thus resulting in greater population diversity. Quantitatively, the population parameters Θ=4Neμ and ρ=4Nec define the mutational and recombinational diversity, respectively. Combining different Θ estimates that reveal different aspects of population genealogies has led to statistical tests that are sensitive to selection events and/or demographic history. Here, by computer simulations, we explore different estimates of ρ and compare their sensitivity to detect recombination and gene conversion under a standard neutral population model at constant population size, as well as following population bottleneck and demographic growth. We compare ρ estimates obtained from counting past recombinations (R) with those evaluated from the extent of linkage disequilibrium (LD) along the genomic sequence. While ρLD is practically insensitive to gene conversions, thus monitoring only reciprocal crossover events, ρR monitors both recombination and gene conversion. Interestingly, following a population bottleneck these ρ estimates recover at different rates, as observed with different Θ such as Tajima's and Watterson's estimates. Both ρ estimates were also computed for the autosomes of all HapMap3 populations. An excellent correlation was observed when individual chromosomal estimates were compared, not only between our two methods, but also with LdHat as well as with recent pedigree estimates of the recombination rates. We expect that combining different recombinational diversity estimates and, especially, in combination with different mutational diversity estimates, should open up new ways to infer demographic as well as population genetic history, including events of natural selection.

1985W

Analysis of linkage disequilibrium associated with Southeast Asian Ovalocytosis (SAO). *M.K. Thompson, J.A. Wilder.* Northern Arizona University, Flagstaff, AZ.

Southeast Asian Ovalocytosis (SAO) is a type of hereditary elliptocytosis that confers protection from malaria-causing parasites, including both *Plasmodium falciparum* and *P. vivax*. This trait is caused by a 27-base pair deletion, or a 9 amino acid deletion, in the Band 3-encoding *SLC4A1* gene. While SAO provides protection from severe manifestations of malarial parasitism when heterozygous, the trait is lethal when homozygous. This pattern suggests it is maintained as a balanced polymorphism. Previous studies have found substantial short-range decay in linkage disequilibrium (LD) associated with the SAO-causal mutation, suggesting a relatively ancient age of the trait. Here we extend this analysis by targeted resequencing of loci that span 500 kilobases around the causal mutation in 52 SAO-carriers from Indonesia and Thailand. These data will allow us estimate the decay of LD over a relatively large chromosomal region, spanning a highly heterogeneous recombination environment. These results will refine our understanding of the evolutionary history of Southeast Asian Ovalocytosis.

1986T

Meiotic gene conversion in humans: rate, sex ratio and GC bias. *A.L. Williams[1], G. Genovese[1], T. Dyer[2], N. Patterson[1], J. Blangero[2], D. Reich[1,3], the T2D-GENES Consortium.* 1) Broad Institute, Cambridge, MA; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) Harvard Medical School, Boston, MA.

Gene conversions are short, 20-300 bp segments copied from one homologous chromosome to another during meiosis. While related to crossover, gene conversions are distinct in that they affect a much shorter region, are more frequent, and show bias towards G or C allele transmissions. To date, there has been no genome-wide study of *de novo* gene conversion and no direct inferences about their localization, sex differences, and the impact of GC bias on the genome.

We examined SNP array data from 190 individuals in 16 three-generation pedigrees that are informative for 42 meioses (21 paternal, 21 maternal) and 4.15×10^6 sites. Our study design uses three-generation pedigrees and requires that a gene conversion received by a second generation child is also transmitted to a third generation grandchild. This ensures that the identified gene conversions are either real or the result of at least two genotyping errors at the same site.

We identified 33 putative gene conversions and obtained a genome-wide *de novo* gene conversion rate estimate of 8.0×10^{-6} per bp per generation~a rate consistent with sperm typing and LD-based studies. We validated these gene conversions using whole genome sequence data for a subset of the genotyped samples, with genotype calls available for 19 of the 33 sites. Of these 19 sites, 18 had genotypes consistent with the SNP chip data. The single mismatching site is ambiguous as to the error source and appears to be a sequencing artifact. These results suggest a low false-positive rate and validate our study.

The gene conversions are significantly enriched in recombination hot spots, with 10/33 events in regions with recombination rate ≥10 cM/Mb (P= 1.1×10^{-8}). Male gene conversions predominantly localized to telomeres while females transmitted 1.54x more gene conversions than males. These results further validate our methodology and are consistent with the mechanism for forming gene conversions being similar to that of crossovers.

We observed extreme GC bias in allelic transmissions, with 23/31 sites heterozygous for AT and GC alleles transmitting a G or C allele (P=5.3×10^{-3}). This 3-fold enrichment of GC transmissions suggests that gene conversion substantially alters the allelic make up of the genome. We are examining a 2-fold larger dataset to further validate this and other findings.

1987F

Linkage disequilibrium and haplotype blocks determined by the analysis of 250K SNPs in three quilombo remnants communities.
E.S. Andrade[1], D.M. Salvanha[2], R.Z.N. Vêncio[2], L.M. Garrido[3], H. Krieger[3], A.L. Simões[1], C.T. Mendes-Junior[4]. 1) Departamento de Genética, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14049-900, Ribeirão Preto-SP, Brazil; 2) Departamento de Matemática e Computação, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, 14040-901, Ribeirão Preto-SP, Brazil; 3) Departamento de Parasitologia, Instituto de Ciências Biomédicas, Universidade de São Paulo, 05508-000, São Paulo-SP, Brazil; 4) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, 14040-901, Ribeirão Preto-SP, Brazil.

The non-random association between alleles of different loci characterizes what is called linkage disequilibrium (LD) between them. The LD extent in human populations can be influenced by many factors, such as recombination rate, demographic features and evolutionary events. The aim of this study was to describe the LD patterns of four Brazilian populations and correlate these patterns with their respective demographic histories. Samples from three quilombo remnants populations of the Piauí State, Gaucinha (GAU, n = 14), Mimbó (MIB, n = 15) and Sítio Velho (STV, n = 15) and the urban population of Teresina, Piauí (TES, n = 15), and seven population samples from the HapMap Project (CEU, CHB, JPT, ASW, LWK, MKK, YRI, all with n = 15) were analyzed. More than 250 thousand SNPs (Single Nucleotide Polymorphisms) were genotyped using the GeneChip ® Human Mapping 250K Nsp Array I - Affymetrix® in the samples of the four Brazilian populations. Raw data of the HapMap population samples for this array were obtained from the HapMap homepage. Genotypes for all samples were determined by CRLMM algorithm. LD analyzes and determination of haplotype blocks were performed using the Haploview software. Considering the number of haplotype blocks detected in each population, a consistent pattern was observed for all autosomes. The European population (CEU) and the two Asian populations (CHB and JPT) of the HapMap showed the highest numbers of blocks, while the lowest numbers were observed in the GAU and MIB quilombos and in the TES population. The African populations, LWK, MKK and YRI, and the African-American ASW exhibited intermediate values and the African-Brazilian population STV, presented a number of blocks just smaller than that observed for CEU, CHB and JPT. The great African contribution in the GAU and MIB quilombos may explain their lower LD. On the other hand, the lower LD in TES is probably due to its foundation that involved a larger number of individuals and was followed by a fast growth. A possible explanation for the higher LD observed in STV consists in its particular demographic history: admixture at the time of its foundation, slow growth and low differentiation. Thus, it was shown how the demographic events of each population influence their respective LD patterns. FINANCIAL SUPPORT: FAEPA-HCFMRP-USP/Brazil (Grant 1394/2011).

A recombination map of Latino populations inferred using local ancestry.
S. Shringarpure[1], S. Gravel[2], C. Gignoux[3], A. Moreno[1], C. Eng[3], S. Huntsman[3], D. Torgerson[3], E. Burchard[3], C. Bustamante[1]. 1) Genetics, Stanford University, Stanford, CA, 94305; 2) McGill University, Human Genetics, Montreal, H3A 1B1, Canada; 3) University of California, San Francisco, Bioengineering, San Francisco, CA, 94158.

Recombination maps have traditionally been inferred in populations using information about recombination events in pedigrees. Recent work (Hinch et al., Wegmann et al.) has demonstrated how knowledge of local ancestry can be used to infer relative recombination rates in admixed populations. We apply similar techniques to admixed Latino American populations to infer a high-resolution map of relative recombination rates. We present a method for inferring relative recombination rates in Latino populations by using signals from the admixture events in their evolutionary history. We used 2001 Latino individuals of Mexican and Puerto Rican ancestry from the GALA study, including 551 trios, for our analysis. Local ancestry inference was performed using software RFMix to infer tracts of African, European and Native American ancestry in the study individuals. The inferred ancestry switch points were then used to perform statistical inference and infer recombination rate variation along the genome. We used the statistical framework of Dirichlet Process Mixture Models to correct for the biases of local ancestry inference and estimate underlying rates of ancestry switches. We validated our method on data simulated from an admixture model of the evolutionary history of Latino populations, with admixture parameters from literature. Simulations show that our method can accurately resolve ancestry switch points to within a distance of 400 kb with 80% accuracy. Our analysis of the Latino dataset shows evidence of differentiation in recombination rates between populations. We also compare the recombination rates in the different admixed and nonadmixed populations and interpret the results in light of the PRDM9 variants observed in each. De novo genes in evolution: Apcdd1, a novel dual Wnt and Bmp inhibitor.
V. Luria[1,3], S.G. Oh[1], A.H. O'Donnell[2], A.M. Christiano[3]. 1) Systems Biology, Harvard Medical School, Boston, MA; 2) Children's Hospital Boston, Harvard Medical School, Boston, MA; 3) Genetics & Development, Columbia University Medical Center, New York, NY.

The dynamic instability of biological circuits enables them to decide between alternatives. In genetic circuits transducing signals to cells, circuit components can surprisingly be new genes, raising the question of how these arise evolutionarily and integrate into existing, ancient circuits. A new signal transduction component, Apcdd1, encodes a 514 amino-acid membrane-anchored extracellular protein that, intriguingly, has no significant similarity to any protein. Expressed in neurons, germline and ectodermal appendages, it can be induced by Wnts and, when mutated, causes a form of human hair loss. We showed APCDD1 inhibits Wnt signaling in chick, frog and humans (Shimomura*, Luria* et al., Nature 2010). We now show APCDD1 inhibits Bmp signaling using biochemistry, single-cell imaging and in vivo experiments in chick, frog and zebrafish. The position of APCDD1 at the intersection of Wnt/Bmp pathways may enable it to coordinate pathway activation dynamics. To determine whether Apcdd1 is a de novo gene, we asked when Apcdd1 appeared in evolution, and interrogated the likelihood of gene emergence by coopting random sequences. We found Apcdd1 appeared in Eumetazoa, has no homologues, and that most APCDD1 amino acid sequence is relatively disordered with no recognizable protein domain, suggesting Apcdd1 is a de novo gene. To determine the frequency and content of de novo genes, combining bioinformatics and mathematical modeling, we investigated how de novo genes may arise as a function of gene, genome and population parameters, and the protein structure content of de novo proteins. Surprisingly, we find de novo genes may arise more frequently than previously predicted, may be more disordered than ancient proteins, and that even random proteins have substantial secondary structure. Since de novo genes like Apcdd1 can acquire genetic partners and biochemical functions, the next challenge will be understanding what fraction are maintained in genomes that continuously generate and destroy new genes.

1990F

Detecting evolutionary strata on the human X chromosome in the absence of gametologous Y-linked sequences. *M. Wilson Sayres[1], R. Shanker Pandey[2], R. Azad[2,3].* 1) Integrative Biology, University of California, Berkeley, Berkeley, CA; 2) Biological Sciences, University of North Texas, Denton, TX; 3) Mathematics, University of North Texas, Denton, TX.

Mammalian sex chromosomes arose from a pair of homologous autosomes that differentiated into the X and Y chromosomes following a series of recombination suppressions that likely happened due to serial inversions on the Y. The stepwise recombination suppressions from the distal long arm to the distal short arm of the chromosomes are reflected as regions with distinct X-Y divergence, referred to as evolutionary strata on the X. Identifying evolutionary strata is central to understanding the history and dynamics of sex chromosome evolution. All current methods of stratum detection depend on X-Y comparisons but are severely limited by the paucity of X-Y gametologs. We have developed an integrative method that combines a top down, recursive segmentation algorithm with a bottom up, agglomerative clustering algorithm to decipher compositionally distinct regions on the X, which reflect regions of unique X-Y divergence. In application to human X chromosome, our method correctly classified a concatenated set of 35 previously assayed X-linked gene sequences by evolutionary strata. We then extended our analysis, applying this method to the entire sequence of the human X chromosome, in an effort to define specific stratum boundaries. The boundaries of more recently formed strata, 4 and 5, have been defined by previous studies, and are recapitulated with our method. The older strata, 1-3, have remained poorly resolved due to paucity of X-Y gametologs. By analyzing the entire X sequence, our method identified seven evolutionary strata in these ancient regions, where only three could previously be assayed. Through this study, we present a method for fine scale detection of evolutionary strata across the entire human X chromosome, independent of information about gametologous Y-linked sequences. Our study also provides information about the contribution of repetitive elements in shaping the compositional landscape of the human X chromosome following the suppression of X-Y recombination.

1991W

***NANOGP8*: Evolution of a Human-Specific Cancer-Promoting Retrogene.** *D.J. Fairbanks[1], T.H. Ogden[1], A.D. Fairbanks[1], G.J. Parker[1], P.J. Maughan[2].* 1) Department of Biology, Utah Valley Univ, Orem, UT; 2) Department of Plant and Wildlife Sciences, Brigham Young University, Provo, UT.

NANOGP8 is a human (*Homo sapiens*) retrogene, expressed predominantly in cancer cells where its protein product is tumorigenic. It arose through retrotransposition from its parent gene, *NANOG*, which is expressed predominantly in embryonic stem cells. Based on identification of fixed and polymorphic variants in a genetically diverse set of human *NANOG* and *NANOGP8* sequences, we estimated the evolutionary origin of *NANOGP8* at approximately 0.9 to 2.5 million years ago, more recent than previously estimated. We also discovered that *NANOGP8* arose from a derived variant allele of *NANOG* containing a 22-nucleotide pair deletion in the 3' UTR, which has remained polymorphic in modern humans. Evidence from our experiments indicates that *NANOGP8* is fixed in modern humans even though its parent allele is polymorphic. The presence of *NANOGP8*-specific sequences in Neanderthal reads provided definitive evidence that *NANOGP8* is also present in the Neanderthal genome. Some variants between the reference sequences of *NANOG* and *NANOGP8* utilized in cancer research to distinguish RT-PCR products are polymorphic within *NANOG* or *NANOGP8* and thus are not universally reliable as distinguishing features. *NANOGP8* was inserted in reverse orientation into the LTR region of an SVA retroelement that arose in a human-chimpanzee-gorilla common ancestor after divergence of the orangutan ancestral lineage. Transcription factor binding sites within and beyond this LTR may promote expression of *NANOGP8* in cancer cells, although current evidence is inferential. The fact that *NANOGP8* is a human-specific retro-oncogene may partially explain the higher genetic predisposition for cancer in humans compared with other primates.

1992T

Characterizing bias in population genetic inferences from uncertain genotype data. *E. Han[1], J. Sinsheimer[1], J. Novembre[1,2].* 1) Biostatistics, UCLA, Los Angeles, CA; 2) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA.

The site frequency spectrum (SFS) is of primary interest in population genetic studies, because the SFS compresses variation data into a simple summary from which many population genetic inferences can proceed. However, inferring the SFS from sequencing data is challenging because genotype calls from sequencing data are often inaccurate due to high error rates and if not accounted for, this genotype uncertainty can lead to serious bias in downstream analysis based on the inferred SFS. In our work, we compare two types of approaches to estimate the SFS from sequencing data by detailed simulations: one method that infers individual genotypes from aligned sequencing reads and then estimate the SFS based on the inferred genotypes (two-stage approach) and another method that directly estimates the SFS from aligned sequencing reads by maximizing a likelihood of the SFS (direct estimation approach). We find that the SFS by the direct estimation approach is unbiased even at low coverage, whereas those by the two-stage approach become biased as coverage decreases and most deviations come from the sites with rare variants. Interestingly, the bias by the two-stage approach is in opposite directions depending on the pipeline to infer genotypes: estimating genotypes by pooling individuals in a sample (multi-sample calling) results in underestimation of the number of rare variants, whereas estimating genotypes in each individual and merging them later (single-sample calling) leads to overestimation of rare variants. We characterize the impact of these biases on downstream analyses, such as demographic parameter estimation and rank-based genome-wide selection scans. We observe that at low coverage, the estimated growth rate based on the directly inferred SFS is almost unbiased, whereas using the SFS inferred by a two-stage approach is biased upwards using the single-sample calling and biased downwards using the multi-sample calling. In contrast, bias is less problematic for rank-based genome-wide selection scans because the rank ordering of genomic regions is more robust to genotype errors and biases in the inferred SFS. Our works highlight that depending on the pipeline to infer the SFS from sequencing data one might reach different conclusions in population genetic inferences with the same data set and care is vital for these analyses.

1993F

The evolutionary impact of GC-biased gene conversion on human populations. *J. Lachance, S. Tishkoff.* Dept Genetics, Univ Pennsylvania, Philadelphia, PA.

Gene conversion refers to the non-reciprocal transfer of genetic information between two recombining sequences, and there is evidence that this process is biased towards G and C alleles. Biased gene conversion influences both standing genetic variation and the probability of fixation of new mutants. Using high-coverage whole genome sequences of African hunter-gatherers (including 5 West African Pygmy, 5 Hadza, and 5 Sandawe genomes), other global human populations, and primate outgroups we quantify the effects of GC-biased gene conversion on population genetic data. Gene conversion results in modified allele frequency distributions, particularly when the ancestral allele is A or T and the derived allele is G or C. These shifted allele frequency distributions yield modified values of Tajima's D and Fay and Wu's H, potentially leading to false inferences of natural selection and population size changes. These effects vary across the recombination landscape of the human genome, and are more pronounced in high recombination regions. In addition, biased gene conversion can at least partly explain the two-fold difference in mutation rates estimated from human-chimp comparisons and pedigree data. Because molecular clock estimates depend on accurate estimates of mutation rates, incorporating gene conversion leads to more accurate inference of demographic history. Taken together, our findings reveal that molecular genetic phenomena like GC-biased gene conversion have important population genetic implications.

1994W

Characterization and evolution of LAVA elements in gibbons. *M.K. Konkel[1], J.A. Walker[1], B. Ullmer[2], T.J. Meyer[3], A. Damert[4], R. Hubley[5], A.F.A. Smit[5], L. Carbone[3], M.A. Batzer[1] for the Gibbon Genome Sequencing and Analysis Consortium.* 1) Dept. of Biological Sciences, Louisiana State University, Baton Rouge, LA; 2) School of Electrical Engineering and Computer Science, Center for Computation and Technology, Louisiana State University, Baton Rouge, LA; 3) Dept. of Behavioral Neuroscience, Oregon Health & Science University, Beaverton, OR; 4) Molecular Biology Center, Babes-Bolyai University, Cluj-Napoca, Cluj, Romania; 5) Institute for Systems Biology, Seattle, WA.

We have recently discovered a novel retrotransposon called 'LAVA' in the gibbon lineage. LAVA represents a composite element closely related to the hominoid-specific SVA element. Both share the VA part (VNTR (variable number of tandem repeat region) and *Alu*-like sequence). However, instead of the SVA-specific SINE-R region, LAVA elements contain unique sequence sections as well as ancient *Alu* and L1 sequence. In our investigations of this element, we first analyzed LAVA insertions to confirm that they harbor hallmarks of non-LTR (long terminal repeat) retrotransposons. We conclude that LAVAs most likely rely on the enzymatic machinery of L1 (long interspersed element 1) for their propagation. Next, we investigated the tempo and mode of LAVA expansion in the gibbon lineage leading to *Nomascus leucogenys* (NLE). Computational reconstruction followed by manual curation of the LAVA subfamily structure revealed 23 distinct full-length subfamilies in the NLE draft genome assembly [Nleu 1.1]. We identified >2500 LAVA elements since the origin of gibbons in the NLE genome. Based on the LAVA subfamily structure, activity of some subfamilies peaked prior to the radiation of gibbons, while other subfamilies show evidence for continued propagation until (at least) very recently. To better understand the expansion dynamics of LAVA elements and to investigate the still unresolved gibbon phylogeny, we selected 200 loci for our phylogenetic PCR analyses. We selected LAVA elements based on their divergence from their respective consensus sequence. PCR analyses were performed on a primate DNA panel containing 13 gibbon species from all four genera, with four great apes and green monkey as outgroups. Our wet-bench results confirmed our computational findings that several of the oldest appearing subfamilies ceased activity prior to the radiation of gibbons; while some subfamilies provide evidence for very recent retrotransposition. Even though mobile elements represent a marker system with advantages such as identity by descent and near-absence of homoplasy, we were not able to determine the radiation order of the four gibbon genera due to extended incomplete lineage sorting. This indicates rapid speciation and/or historically recurring hybridization events. Furthermore, our results show an expansion of LAVA elements in gibbons, provide evidence for ongoing LAVA propagation, and highlights that primate lineages evolve uniquely.

1995T

Genetic architecture of variants affecting splicing in human populations. *Y. Lee[1], E. Gamazon[1], H. Im[2], W. Hernandez[1], N. Cox[1].* 1) Department of Medicine, University of Chicago, Chicago, IL; 2) Department of Health Studies, University of Chicago, Chicago, IL.

Alternative splicing (AS) is a crucial mechanism producing unstable proteins in various human pathologies. Transcript isoforms due to differential splicing can occur with different frequencies in different human populations. We hypothesize that SNPs affecting splicing through Splicing Regulatory Elements (SRE) may show evidence for a signature of natural selection including potential evidence for population differentiation in allele frequency. We previously identified splicing-affecting SNPs within splicing regulatory element (SRE) sites which result in skipping of the adjacent exon. In this study, we have investigated SNPs in SREs considered to be silent genic variants (intronic and synonymous SNPs) to gain insight into their contribution to population differentiation by using population-pairwise *Fst* estimates and derived allele frequencies among four populations, resulting in six pairs of comparisons (AFR and AMR, AFR and ASN, AFR and EUR, AMR and ASN, AMER and EUR, and ASN and EUR). We found intronic SNPs in SREs have significantly higher *Fst* values than intronic SNPs not located in SREs; this was true across the allele frequency spectrum. Results are similar for synonymous SNPs in SREs when compared with synonymous SNPs not located in SREs. We also found that for both intronic and synonymous SNPs in SREs, the derived allele frequencies increase as the population differentiation (*Fst*) increases. These findings were observed across all study populations. Our study suggests that SNPs in SREs maybe be commonly subject to natural selection and that this class of functional variation may contribute to population differentiation in disease risk and phenotypes.

1996F

From mouse to human: evolutionary genomics analysis of human orthologs of essential genes. *B. Georgi, B.F. Voight, M. Bucan.* University of Pennsylvania, Philadelphia, PA.

Understanding the core set of genes that are necessary for basic developmental functions is one of the central goals in biology. Studies in model organisms identified a significant fraction of essential genes through the analysis of null-mutations that lead to lethality. Recent large-scale next-generation sequencing efforts have provided unprecedented data on genetic variation in human. However, evolutionary and genomic characteristics of human essential genes have never been directly studied on a genome-wide scale.

In this study we used detailed phenotypic resources available for the mouse and deep genomics sequencing data from human populations to characterize patterns of genetic variation and mutational burden in a set of 2,472 human orthologs of known mouse essential genes. Using the 1000 Genomes Phase 1 dataset we compared the genomic characteristics of these genes with all protein-coding genes, as well as a set of 3,811 genes with non-lethal mouse phenotypes. Consistent with the action of strong, purifying selection, the essential genes exhibit significantly reduced levels of sequence variation (Wilcoxon $P=1.66\times10^{-180}$), skew in allele frequency towards more rare (Wilcoxon $P=3.12\times10^{-35}$), and increased conservation across the primate and rodent lineages (Wilcoxon $P=1.28\times10^{-75}$). In individual genomes we observed ~12 rare mutations within essential genes predicted to be damaging. Consistent with the hypothesis that mutations in essential genes are risk factors for neurodevelopmental disease, we show that de novo variants in patients with Autism Spectrum Disorder (ASD) are significantly more likely to occur in this collection of genes ($P=2.7\times10^{-4}$ by gene permutation). Within a core set of 179 essential genes with de novo events exclusively in ASD cases, we show an enrichment of protein connectivity (P=0.0019 based on 1000 DAPPLE permutations).

In currently ongoing work, we are expanding on the role of essential genes in Schizophrenia and bipolar disorder based on previously reported de novo variants, as well as inherited variants identified in family-based association studies.While incomplete, our set of human orthologs shows characteristics fully consistent with essential function in human and thus provides a resource to inform and facilitate interpretation of sequence data in studies of human disease.

1997W

Exploring the Relationship Between Immune System Related Genetic Variants and Complex Traits and Disease Through a Phenome-Wide Association Study (PheWAS). *A. Verma[1], H. Kuivaniemi[2], G. Tromp[2], D.J. Carey[2], G.S. Gerhard[1,2], J.E. Crowe Jr.[3], M.D. Ritchie[1], S.A. Pendergrass[1].* 1) Center for Systems Genomics, The Pennsylvania State University, State College, PA; 2) Geisinger Health System, Danville, PA; 3) Vanderbilt University, Nashville, TN.

Exploring the relationship between immune-system related genetic loci and a wide array of traits and outcomes provides a way to elucidate interrelationships among the immune system and diagnoses, as well as identify pleiotropic loci. To explore these connections further and identify novel associations and pleiotropy, we selected 132,467 single nucleotide variants (SNPs) with allele frequency > 0.01 that were previously associated with autoimmunity and the immune system to perform a Phenome-Wide Association Study (PheWAS). We calculated associations between the SNPs and 480 clinical diagnoses. To define case-control status we used ICD9 diagnosis codes from 3,035 subjects using de-identified electronic medical records (EMRs) from the Geisinger Clinic MyCode biorepository. We required ≥10 case subjects for ICD9 code inclusion, and used logistic regression for all associations, adjusting models for age and sex. With an exploratory P-value cutoff < 0.001 we found a total of 7,910 SNP-diagnosis associations, and 420 SNPs associated with more than one diagnosis. The most significant novel association was the *GLRB* SNP rs17035787 and the diagnosis of 'hemorrhagic disorder due to circulating anticoagulants' (P = 4.78×10-9; 29 cases, 3,007 controls). Additional novel associations included *CAMTA1* SNP rs79204895 and 'chronic sinusitis' (P =3.5×10-8; 19 cases, 3,017 controls) and the SNP rs11842088 and 'syncope and collapse' (P = 4.29×10-8; 106 cases, 2,930 controls). We found replication of previously reported GWAS results, including the second most significant result of this study, the *F5* SNP rs6025 associated with the diagnosis of 'venous thrombosis' (P = 3.5×10-8; 55 cases, 2,981 controls). Potential pleiotropy was identified, such as the SNP rs79268593 associated with three diagnoses: 'chest swelling, mass, or lump'; 'malignant neoplasm of the bladder'; and 'hypertensive chronic kidney disease'. Further, we found a series of SNPs previously reported to be associated with Crohn's disease and inflammatory bowel disease, that were associated with rheumatoid arthritis in our study. In total, our results showed intriguing relationships between loci and diagnoses, including autoimmune and direct immune system associations. Further work will include seeking replication of the results of this study in an independent EMR-based dataset through the Vanderbilt University Medical Center BioVU repository.

1998T

Bayesian co-estimation of selfing rate and locus-specific mutation rates for a partially selfing population. *B.D. Redelings, M.K. Uyenoyama.* Biology Dept., Duke University, Durham, NC.

We present a novel Bayesian method for inferring the inbreeding rate and locus-specific mutation rates for populations reproducing by partial selfing. We extend the Ewens Sampling Formula (ESF) under the infinite-alleles model to accommodate inbreeding. Our method uses the ESF to determine the likelihood for diploid samples comprising data from patches throughout the genome, accounting explicitly for multi-locus identity disequilibrium generated by inbreeding. Each locus draws a mutation rate from a common mutation rate distribution, which is itself estimated from the data. We construct an MCMC algorithm and apply it to the analysis of androdioecious, gynodioecious, and pure hermaphroditic populations, jointly inferring the frequencies of each reproductive class and rates of inbreeding and locus-specific mutation.

1999F

Geographic structure of an allele associated with blond hair color in western Island Melanesia. *H. Norton, E. Correa.* Department of Anthropology, University of Cincinnati, Cincinnati, OH.

Here we report on the frequency and distribution of an allele in the *TYRP1* gene associated with blond hair color in several populations from across western Island Melanesia. This mutation and its association with hair color were originally discovered by Kenney et al. (2013) in populations from the Solomon Islands, where the blond-hair associated allele occurs at an average frequency of 0.26. However, knowing that the blondism phenotype in Melanesia extends further to the east, we typed this mutation in 515 individuals from several different islands throughout the Bismarck Archipelago. The mean frequency of the blondism allele in the region is much lower (0.125) than observed in Solomon Island populations, although it varies dramatically from island to island, ranging from a frequency of 0.015 on the island of New Britain to a frequency of 0.260 on the island of New Ireland. Linear regression using a recessive model was used to test for an association between genotype at this SNP and quantitatively assessed skin and hair pigmentation (measured as the M index). Associations were tested for in the total sample as well as on three islands separately (New Britain, n = 235; New Ireland, n =152, New Hanover, n = 88). Using age and island as covariates, we demonstrate that genotype at the R932 SNP can explain 8.8% of the variance in hair color ($p < 0.0001$) in the full dataset. A significant association between the R932C genotype and hair M index was only observed on the island of New Ireland ($p < 0.01$), but this may be due in part to reduced power to detect these associations in the smaller island subsamples. We do not observe a significant association between skin pigmentation and R932C genotype in the full dataset or the three islands individually, confirming previous observations (Kenny et al., 2013) that this allele affects hair pigmentation independent of skin pigmentation. The geographic heterogeneity of the blondism allele in western Island Melanesia is consistent with extensive population substructure in the region.

2000W

Test of synergistic interactions among deleterious alleles in humans. *M. Sohail[1], A. Kondrashov[2], P.I.W de Bakker[3], S. Sunyaev[4], GoNL Consortium.* 1) Systems Biology PhD Program, Harvard University, Boston, MA; 2) University of Michigan, Ann Arbor, MI; 3) University Medical Center Utrecht, Utrecht, Netherlands; 4) Brigham and Women's Hospital, Boston, MA.

Understanding the nature of epistatic interactions is crucial to obtaining a complete picture of genetic variation underlying phenotypic diversity. The role of epistatic interactions in the genetic architecture of human complex phenotypes has been widely debated. In evolutionary genetics, epistatic selection may be an important force shaping DNA sequence variation with implications for the adaptive value of sex and reproduction. We developed a new statistical method to detect epistasis in sequencing data, based on testing for variance depletion in the distribution of deleterious mutations. Our statistical test is suitable for performing phenotype-focused studies in medical genetics and addressing key questions in evolutionary theory. We applied our test to detect if synergistic epistasis is the predominant mode of genetic interaction with respect to fitness in human populations. Synergistic interactions mean that multiple mutations have a larger cost on fitness than expected from their individual effects. The mutational deterministic hypothesis for the maintenance of sex postulates that sex is an adaptation to purge the genome of deleterious mutations, and requires synergistic epistasis. We had access to a unique sequencing dataset for this study. The Genome of the Netherlands (GoNL) is an effort to characterize genomic variation in the Dutch population through whole-genome sequencing of 250 families (231 trios, 19 twin quartets) at 12x using Illumina HiSeq. In the GoNL data, we observed that spouses are correlated in the number of private variants for all functional classes of variants, but that the variation of this measure can be primarily attributed to the province of origin, suggesting subtle population substructure within the Netherlands. Indeed, we detected a north-south gradient of increasing heterozygosity due to private variants. After correcting for this structure, our results indicate that the variance in the number of private variants in a specific category decreases with the potential functional importance of the allelic class. However, in the current dataset the variance depletion is not significant compared to the theoretical expectation. This may be due to additional sources of variance inflation, or absence of predominant synergistic epistasis in fitness. We complement our analysis with simulations and analytical approaches to characterize the strength of the variance depletion due to synergistic epistasis as a function of selection.

2001T

Genetic Diversity is a Predictor of Survival in Humans. *N.A. Bihlmeyer[1,2], A. Scaria[3], M. Nalls[4], M. Garcia[5], K.L. Lunetta[6,7], J.M. Murabito[7], D.R. Weir[8], J.A. Smith[9], G. With the advent of genome-wide association studies (GWAS), and more recently whole-exome and whole-genome sequencing, remarkable progress has been made in elucidating the genetics of complex traits, with numerous genetic variants each explaining a small fraction of the variance. The presence of numerous segregating small effect alleles that influence traits that directly impact health raises the question as to whether global measures of genomic variation are themselves associated with human health and disease. Indeed, increased fitness has been associated with the increase of genetic diversity across many organisms, and is often referred to as Positive Heterozygosity Fitness Correlations (HFCs). Two general mechanisms that act at a genome level to influence fitness have been proposed. The first is compensation for recessive deleterious mutations, whereas the second is a specific advantage of the heterozygous state over either homozygous state (overdominance/heterozygous advantage). In this study, heterozygosity was measured as the sum of all heterozygous loci divided by the expected state given the allele frequency under Hardy Weinberg Equilibrium. To test for the effect of genome-wide heterozygosity on survival, we performed a meta-analysis of 16 cohorts (12 European ancestry, 4 African American ancestry) followed prospectively, with a combined sample size of 45,704 individuals, including a total of 14,785 deaths. Using Stouffer's method to combine Z-scores, weighted by the number of deaths in each cohort, we find a significant association between increased heterozygosity and survival (P=0.03). There was no evidence for heterogeneity across studies, and a direct comparison of European Ancestry to African European ancestry cohorts showed no significant difference in effect estimates (P=0.83). Similarly, no evidence for heterogeneity between sexes (P=0.67) or between causes of death was seen (Cancer, CVD and Other; P=0.85). In summary, this study provides evidence that the protective effect of increased heterozygosity seen in lower organisms functions in humans as well.

2002F

A study on genetic diversity of ADME genes in ethnic groups in Northwestern China. *J. Li, S. Xu.* CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

Genetic polymorphisms in many genes related to drug absorption, distribution, metabolism and excretion (ADME) contribute to the high heterogeneity of drug responses in humans. The minority ethnic groups of northwestern China showed significant anthropological and genetic admixture characteristics with ancestry contribution from both European and East Asian populations. Therefore, the genetic diversity of ADME genes might also show high differentiation between those ethnic groups that could cause the potential clinical risk of drug safety. Here, we investigated the genetic diversity pattern of 285 ADME genes from five Northwestern Chinese minority populations, i.e. Tajik, Uyghur, Kazakh, Kirgiz, and Hui. By integrating the genotyping information of CEU and CHB from Hapmap 3 dataset, we found that the complexities of genetic diversity, such as haplotype diversity, of admixed populations are generally higher than their representative parental populations, i.e. CEU and CHB. Especially, this pattern was apparent in some functional important genes which might be shaped by the natural selection occurred in their ancestral populations. Additionally, we analyze the genetic differentiation associated with clinically relevant, functional polymorphic SNPs, which is important for evaluating potential among-population heterogeneity in drug treatment effects.

2003W

Diversity of lactase persistence alleles in Ethiopia; signature of a soft selective sweep. *D.M. Swallow[1], B.L. Jones[1], T.O. Raga[2], A. Liebert[1], P. Zmarz[1], E. Bekele[2], E.T. Danielson[3], A.K. Olsen[3], N. Bradman[1,4], J.T. Troelsen[3].* 1) Genetics Evolution & Environment, University College London, London WC1E6BT, United Kingdom; 2) Department of Biology, University of Addis Ababa, PO Box 32597, Ethiopia; 3) Department of Science, Systems and Models, Roskilde University, DK 4000 Roskilde, Denmark; 4) Henry Stewart Group, 28/30 Little Russell Street, London WC1A 2HN, United Kingdom.

The persistent expression of lactase into adulthood in humans is a recent genetic adaptation that allows the consumption of milk from other mammals after weaning. In Europe, a single allele (*-13910*T*, rs4988235), located in an upstream enhancer of the lactase gene, *LCT*, increases lactase expression in promoter constructs *in vitro* and is responsible for lactase persistence. The widespread occurrence of this allele on a very extended haplotype suggests strong directional selection in the last 5000 years. In Africa and the Middle East, the situation is more complicated and at least three other alleles (*-13907*G*, rs41525747; *13915*G*, rs41380347; *-14010*C*, rs145946881) in the same *LCT* enhancer region can cause continued lactase expression. We have now examined the *LCT* enhancer sequence in a lactose tolerance tested Ethiopian cohort of more than 350 individuals. We show that a further SNP, *-14009 T>G* is significantly associated with lactose digester status and *in vitro* functional tests confirm that the 14009*G allele also increases expression of an *LCT* promoter construct. Other rarer SNPs are either more frequent in non-digesters or not frequent enough to assess for association. The various derived alleles in the *LCT* enhancer region are spread through several ethnic groups in Ethiopia, and we report a greater genetic diversity in lactose digesters than non-digesters. By examining flanking markers to control for the effects of mutation and demography, we further describe, from empirical evidence, the signature of a soft selective sweep. These observations are of relevance to genome wide disease association studies since such parallel selection of functionally equivalent alleles could potentially hide causal gene regions.

2004T

Characterization of private and highly diverged variants among human populations from the analysis of exome sequencing. *L.R. Botigué[1], D.M. Bobo[1], D. Twigg[2], C.D. Bustamante[3], J.M. Kidd[2,4], B.M. Henn[1].* 1) Ecology and Evolution, Stony Brook, Stony Brook, NY; 2) Human Genetics, University of Michigan, Ann Arbor, MI; 3) Genetics, Stanford University, Stanford, CA; 4) Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI.

Previous analysis of human genomic variation revealed an excess of private variants present at very low frequencies in Eurasian populations, and that variants in Europeans are enriched for possibly damaging functional effects. These patterns have been related to the Out-of-Africa bottleneck and the exponential growth of European populations over the last 200 generations. However, a recent analogous study found no significant differences between African-American and European populations regarding the burden of potentially deleterious mutations. Here, we analyze exome data from ten populations with different ancient and recent demographic histories (sequences include publically available 1000 Genomes Project data and samples from the Human Genome Diversity Panel). By contrasting populations with and without explosive growth or severe bottlenecks we are able to assess the effect of demography and zygosity on the distribution of potentially damaging alleles. Additionally, we focus on variants showing high frequency differences between populations, and ask whether specific functional categories are driving differentiation among human populations, with the ultimate goal of understanding the relative importance of demography and natural selection as drivers of population divergence.

2005F

Identification of known genes in a novel gene discovery project: Experience of the FORGE Canada Consortium. *S.L. Sawyer[1], C.L. Beaulieu[1], D.E. Bulman[1], F.P. Bernier[2], K.M. Boycott[1] FORGE Canada Consortium.* 1) Medical Genetics, Children's hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 2) Medical Genetics, Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada.

The primary objective of the FORGE (Finding Of Rare disease GEnes) Canada project was the identification of novel disease-causing genes. Over 200 rare diseases with pediatric onset were studied over a 2-year period using whole exome sequencing (WES) and one of three approaches: (1) cohorts of patients with the same rare disease; (2) consanguineous or dominant families with mapping data; and, (3) affected sib-pairs born to unrelated parents. In approximately 1/3 of the 200 FORGE projects analyzed, known genes previously associated with disease were identified as causative for the phenotype despite careful selection of projects prior to WES to enrich for those more likely to identify a novel disease gene. Review of the characteristics of the approximately 60 projects that identified known disease genes highlighted several factors that likely influenced this outcome including: (1) overall significant rarity of the syndrome (ultrarare); (2) disease presentations with high levels of genetic heterogeneity; (3) limited access to exclusionary genetic testing prior to enrollment in the study; and, (4) atypical clinical presentations. Further stratification of our results based on types of clinical presentation indicated that the likelihood of identifying a mutation in a known disease gene in a patient presenting with cerebellar ataxia, for example, was approximately 40%, while the chance of making a molecular diagnosis in a patient with neuropathy was significantly lower. Autosomal recessive inheritance of the disease was the most significant factor positively influencing success in these projects. Given that half of the 120 projects solved through the FORGE Canada initiative were known disease genes we have gained significant insight into the clinical utility of WES and potentially the depth of rare disease.

2006W

Genic Intolerance to Functional Variation and the Interpretation of Personal Genomes. *S. Petrovski[1,2], Q. Wang[1], E.L. Heinzen[1], A.S. Allen[1,3], D.B. Goldstein[1].* 1) Center for Human Genome Variation, School of Medicine, Duke University, Durham, NC; 2) Departments of Medicine, Austin Health and Royal Melbourne Hospital, University of Melbourne, Australia; 3) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC.

Using empirical polymorphism data from the NHLBI Exome Sequencing Project we introduce a genome-wide scoring system that ranks human genes in terms of their intolerances to functional genetic variation in the human population. We name this score the Residual Variation Intolerance Score (RVIS). It is often inferred that genes carrying relatively fewer common functional variants in healthy individuals may be judged more likely to cause certain kinds of disease. We show that this 'intolerance score' correlates remarkably with genes already known to cause Mendelian diseases (P=10-27). Equally striking, however, are the differences in the relationship between standing genetic variation and disease causing genes for different disease types. Considering disorder classes defined by Goh et al (2007) human disease network, we show a nearly opposite pattern for genes linked to developmental disorders and those linked to immunological disorders, with the former being preferentially caused by genes that do not tolerate functional variation and the latter caused by genes with an excess of common functional variation. We conclude by showing that use of an exome-wide intolerance ranking framework can facilitate interpreting personal genomes and can facilitate identifying high impact mutations through the gene in which they occur.

Application on OMIM disease genes

	OMIM disease genes	OMIM recessive	OMIM Haploinsufficiency	OMIM de novo	OMIM Haploinsufficiency and de novo	Essential Gene List (Georgi et al (2013))

Analysis of nucleotide changes in miRNAs genes along primate evolution.
I. Balcells[1], M. Mele[2], T. Marques-Bonet[1,3], Y. Espinosa-Parilla[1]. 1) Institut de Biologia Evolutiva (UPF-CSIC), Barcelona, Spain; 2) Centre for Genomic Regulation (CRG), Barcelona, Spain; 3) Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

MicroRNAs (miRNAs) are important regulators of gene expression at post-transcriptional level. Although lineage-specific miRNAs may contribute to shape primate evolution; how it happens and what are the specific miRNA changes that contribute to this process is not well understood yet. Using genomic data, we have compared the 1,595 precursor miRNAs (pre-miRNAs) described in humans (miRBase v19) in several Great Ape populations including humans (n=9), bonobos (n=13), chimpanzees (n= 25), gorillas (n= 27) and orangutans (n=14). Our data showed that a total of 1,782 single nucleotide variants (SNV) occurred in pre-miRNA; 590 in the mature miRNAs and 198 in the miRNA seed region. Surprisingly, although it has been described that miRNA seeds are highly constrained, in this study, SNV densities (SNVD) do not differ between the seed region (SNVD= 0.023), the mature miRNA (SNVD=0.022) and all pre-miRNA (SNVD=0.024). And, interestingly, the distribution of nucleotide changes was seen not to be uniform. They are accumulated in 734 (65.4%) pre-miRNAs, 429 (28.9%) mature miRNAs and 170 (11.9%) seed miRNAs. In the branch going from the chimpanzee-human ancestor to humans, 23 substitutions have been fixed in the seed region of miRNAs. These changes could affect directly miRNA function by modifying the number and spectrum of target genes. Some of these nucleotide changes are predicted to provoke important gain or losses of human miRNA targets according to TargetScan prediction. Nevertheless, expression patterns for these miRNAs and their target genes should be further analyzed to decipher their function. On the other hand, 84 nucleotide changes affected mature miRNAs in the human lineage. Out of them, twenty are expressed in specific regions of the human brain. These nucleotide changes could affect miRNA expression levels and thus, the fine-tuning of brain molecular regulatory networks could be altered. Overall, our work describes that many nucleotide changes have been accumulated during Great Ape evolution in different functional regions of miRNAs. However, the great challenge now is to understand which are the functional implications of these changes.

Mitochondrial haplogroup B and oxidative stress associations with antiretroviral-associated peripheral neuropathy in Thai individuals.
R. Levinson[1], T. Hulgan[2], M. Gerschenson[4], N. Phanuphak[3, 5], J. Ananworanich[3,4,5,6], A. Baker[2], V. Valcour[7], D.E. LiButti[4], T. Jadwattanakul[8], D. Murdock[1], J. McArthur[9], C. Shikuma[4], D.C. Samuels[1], the SEARCH 003 Study Team. 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Vanderbilt University, Nashville, TN; 3) South East Asia Research Collaboration with Hawaii, Bangkok, Thailand; 4) University of Hawaii, Honolulu, Hawaii, USA; 5) Thai Red Cross AIDS Research Centre, Bangkok, Thailand; 6) HIV-NAT, Bangkok, Thailand; 7) University of California- San Francisco, San Francisco, CA; 8) Queen Savang Vadhana Memorial Hospital, Chonburi, Thailand; 9) The Johns Hopkins University, Baltimore, MD.

SEARCH 003 was a randomized clinical trial in Thailand designed to evaluate mitochondrial (mt) toxicity of first-line antiretroviral (ARV) regimens in HIV-infected persons. mtDNA sequencing from PBMC was performed on 149 subjects with the AffymetrixGeneChip Human Mitochondrial Resequencing Array 2.0. The SEARCH 003 population fell into 3 mitochondrial haplogroup clades, B (15%), M (43%), and F (21%) determined by Phylotree; the remainder were categorized as 'other'. Participants had epidermal nerve fiber density (ENFD) assessed by distal leg skin biopsy at weeks 0 and 24 as a measure of peripheral neuropathy, an ARV-associated mt toxicity. MtDNA levels were measured by RT-PCR. MtDNA oxidative damage was measured by the gene specific repair assay for 8-oxo-deoxyguanine (8-oxo-dG). Analyses included Wilcoxon rank-sum test and logistic regression. Baseline mtDNA levels, ENFD, and treatment arm were not significantly different by mtDNA haplogroup. Haplogroup B individuals had an increase in median ENFD over 24 weeks compared to non-B individuals (p=0.02). Median 24-week PBMC 8-oxo-dG change also increased in haplogroup B individuals compared to non-B individuals (p=0.02). In a logistic regression model, haplogroup B was significantly associated with an increase in ENFD over 24 weeks (OR= 24.3, 95%CI = [4.95, 168]). In this model, other significant covariates were baseline CD4 count, age, and ENFD. These data show that haplogroup B individuals gained ENFD over the first 24 weeks of ARV treatment. However, for individuals with ENFD data the frequency of peripheral neuropathy was significantly higher in the haplogroup B individuals (p= 0.04), though the number of cases was small (N=6). In conjunction with increased mt oxidative damage in haplogroup B, this leads us to hypothesize that the gain in ENFD may be a compensatory response to mt damage. Follow up studies are needed to validate these associations and elucidate mechanisms by which mtDNA variation influences response to therapy. Most haplogroup B individuals in our study were subgroup B5, though any role of subgroup in these responses remains unclear. Haplogroups are closely related to continental origin and their global distribution follows historical human migrations. Haplogroup B is found in individuals of East Asian descent and Native American lineages, including in about 15% of Hispanics. Follow up studies in Southeast-Asian and Hispanic HIV/AIDS populations would be worthwhile.

Defects in the autophagy pathway contribute to glaucoma caused by mutant myocilin accumulation. *X. Lin[1,2], G. Zode[1,2], C.C Searby[1,2], V.C Sheffield[1,2].* 1) Pediatrics, The University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute, MD.

Autophagy is a cellular degradation pathway that involves the delivery of unnecessary or dysfunctional cellular components to the lysosome. Autophagy is often upregulated in circumstances that result in protein aggregate accumulation. Autophagy plays a role in the clearance of aggregate-prone mutant proteins associated with several neurodegenerative diseases in which accumulation of unfolded protein is the major characteristic. Early reports demonstrated that autophagy contributed to the pathogenesis of Alzheimer disease, Parkinson disease and Huntington disease. However, little is known about autophagy in glaucoma, including glaucoma caused by myocilin mutations. It is well documented that mutant myocilin accumulates in the ER of the trabecular meshwork and leads to an increase in intraocular pressure, which is associated with retina gangalion cell degeneration. We have investigated the role of autophagy in clearing mutant myocilin aggregates. We generated stable HEK 293T cell lines expressing mutant and wild-type myocilin. We confirmed that mutant myocilin accumulates and leads to increased ER stress, while wild type myocilin does not accumulate or result in ER stress. In addition, mutant myocilin leads to increased LC3-I levels compared to wild type myocilin and control cells. We also observed increased levels of p-Akt, beclin-1, (responsible for vesicle elongation), and Atg-4 (pivotal to autophagsome membrane formation) in mutant myocilin cells, while no change was observed in p-mTOR (negative regulator of autophagy), Atg 5 (involved in autophagosome formation), or Atg 3 (involved in LC3-I conjugation). When treated with chloroquine, a lysosome basifying agent which blocks the fusion of autophagosomes with lysosomes, we observed exacerbation of myocilin accumulation only in mutant myocilin cells, but an increase in LC3-II/LC3I ratios only in control cells. Increased LC3-I levels in mutant myocilin cells compared to cells expressing WT myocilin indicate that these cells sense increased myocilin aggragate levels, but that autophagosomes could not form properly. These data indicate that autophagy plays a role in the clearance of mutant myocilin, but is ineffective.

2010T

Modeling Mutation Events for Complex Variants in Human Genome. *M. Bhuyan, I. Pe'er.* Columbia University, New York City, NY.

Background: Availability of whole genome sequences paves the way to observing sites that harbor complex, multi-allelic variation. Such sites may be considered as candidates for genetic association studies. By definition, complex variants (CVs) require the occurrence of multiple mutation events, often including indels and repeats besides single nucleotide substitutions. In this study we focus on cataloging and categorizing CVs, modeling implied mutation events, and reconstructing ancestry among alleles. Methods: We use variant information from a cohort of 69 individuals from 12 different ethnicities made publicly available by Complete Genomics. Specific quality control steps were taken to ensure the vast majority of observed complex variants are genuine. We classify CVs into categories guided by likely types of mutation events. We define a probabilistic model for ancestral mutation events, assigning each type a rate of occurrence. We estimate the parameters of this model along with local trees that describe the history of all the alleles associated with corresponding CVs. This is achieved by iteratively finding a minimum weight local trees and updating the model from the mutation events across edges of all local trees. The trees are rooted by alignment to the chimpanzee sequence, aided by an efficient ad hoc procedure to resolve repeat boundaries. Results: The observed frequency of CVs is considerably higher than expected by chance. We identify several common categories of CVs, each providing evidence for particular types of mutation events. (i) Simple repeat regions with variable count of their repeat unit make up most CVs. These include homopolymers (~36% of CVs) as well as microsatellites (~6%). (ii) Short CVs, all of whose aligned alleles are ≤3bp in length. These include tri/tetra-allelic SNPs (~7%) di/tri-nucleotide polymorphisms (~24%). (iii) Block polymorphisms (~1%) can be expressed as combinations of two or more SNPs, usually linked. Mutation events in our model include, in addition to point substitutions and point indels, specific types for period indels, block indels, and more specifically, block indels at the end of the allele sequence. Mutation rates depend on context of mutated and flanking single nucleotides, and are fit to the data as a matrix.

2011F

Modeling variability in the population mutation rate using 1000 Genomes data for discovery and interpretation of rare variation. *V. Aggarwala, B. Voight.* Genomics and Computational Biology, University of Pennsylvania, Philadelphia, PA.

An emerging, major challenge is the identification of pathogenic, rare mutations contributing to complex disease, as this class of alleles offers great potential to accelerate our understanding of mechanisms and disease etiology. Despite the increasing evidence of the role of noncoding variation in disease, few computational approaches are designed to aid the interpretation of mutations in this large fraction of the genome. New computational approaches design to understand the biological features that govern where mutations occur, how many occur, and how they persistence over time (i.e., selection) in human populations at broad and fine scales will be essential to the disease discovery and interpretation process. To address this shortcoming, we propose a statistical framework to model and assess the variability in the population mutation rate at broad and fine scales. The generalized statistical model is Bayesian in nature, and uses repeated sampling from standard distributions to predict the mutation spectrum and also assign confidence interval to different types of mutations, in any number of individuals from different populations. Based on fundamental population genetics quantities, we provide a framework to hypothesis test and incorporate new biological features and annotations like DNase hypersensitivity, differential selection, epigenetic marks etc. that have been measured empirically or speculated. As a proof-of-concept, using data from Phase I of the 1000 Genomes Project, we demonstrate that sequencing context is a major feature that explains the variability in the population mutation rate at all genomic scales ($P<2.2E-308$), and confirm expected population-size reductions on the X chromosome ($P<7.3E-182$) and in comparisons of between African and non-African population ($P<5.7E-204$). Furthermore, we show that our analysis framework facilitates discovery of previously unknown features influencing the spectrum of observed genetic variation. Our findings suggest that this basic framework can be used to model and predict the genetic variant spectrum in any region of the genome, information which is critical to building appropriately calibrated rare variant association tests in the non-coding (and coding) genome for complex disease.

Neanderthal Introgression at Chromosome 3p21.31 was Under Positive Natural Selection in East Asians. *Q. Ding[1], Y. Hu[1], S. Xu[2], J. Wang[1], L. Jin[1,2].* 1) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai 200433, China; 2) CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China.

Studies on Neanderthal and Denisovan genomes demonstrate archaic hominin introgression in modern Eurasians. In the current study, we present evidence of Neanderthal introgression at 3p21.31 region. Frequency of introgressed haplotypes was high in East Asians, ranging from 49.4% to 66.5%, and was low in Europeans. Signal of strong positive selection was detected in this region only in East Asians. Expansion of the introgressed haplotypes started at 37.4 KYA, suggesting the starting point of selection. We showed that rs12488302-T or its associated alleles might be the candidate targets of selection, among which four are non-synonymous, including rs35455589-G of in *HYAL2*, a gene related to cellular response to UV-B. Furthermore, suggestive evidence supports latitude-dependent selection, implicating the role of UV-B. Interestingly, the distribution of rs35455589-G suggests that this allele was lost during the exodus of modern human from Africa, and reintroduced to Eurasians from Neanderthals.

Homozygous losses of human-specific neural *SRGAP2C* gene discovered in patients with intellectual disability. *X. Nuttle[1], K. Witherspoon[1], C. Baker[1], B. Coe[1], M. Fichera[2, 3], J. Schuurs-Hoeijmakers[4], R. Bernier[5], J. Gecz[6, 7], B.B.A. de Vries[4], C. Romano[2], J. Shendure[1], E. Eichler[1, 8].* 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA 98195, USA; 2) Regional Center for Genetic Rare Diseases with Intellectual Disability or Brain Aging, IRCCS Associazione Oasi Maria Santissima, Via Conte Ruggero, 73, 94018 Troina, Italy; 3) Medical Genetics, University of Catania, Catania, Italy; 4) Department of Human Genetics, Radboud University, Nijmegen, Netherlands; 5) Department of Psychiatry, University of Washington, Seattle, WA 98195, USA; 6) Department of Paediatrics, The University of Adelaide, Adelaide, Australia; 7) Genetics and Molecular Pathology, and South Australian Pathology at Women's and Children's Hospital, Adelaide, Australia; 8) Howard Hughes Medical Institute, University of Washington School of Medicine, Seattle, WA 98195, USA.

Incomplete duplications of *SRGAP2*, a gene involved in regulating neuronal migration and development of dendritic spines, are hypothesized to have played an important role in human brain evolution. Several observations support this hypothesis, including the evolutionary emergence of the duplicate genes at the onset of *Homo* encephalization (~2-3 million years ago), fixation of one duplicate (*SRGAP2C*) in the human population, its expression in fetal brain, and striking effects on neuronal development when introduced into mice. Nevertheless, no direct genetic evidence in humans has yet linked disruptive mutations of these human-specific paralogs with neurodevelopmental disease phenotypes. We recently developed a novel high-throughput method using molecular inversion probes to accurately genotype duplicated genes previously intractable to large-scale genetic analysis, such as *SRGAP2*. We surveyed copy number and sequence variation in *SRGAP2* genes in a diversity panel of 1,056 humans and discovered a rare ~38 kbp deletion in *SRGAP2C* observed exclusively in populations of European descent (~2% allele frequency). Using this approach, we genotyped all *SRGAP2* paralogs in 3,153 individuals with intellectual disability and 715 ethnically-matched controls. We identified five individuals having intellectual disability with complete loss of *SRGAP2C* due to frameshifts~four with the same ~38 kbp deletion including exon 2 and one individual with a single base deletion in exon 3. All five individuals are homozygous, likely due to increased consanguinity, and are predicted to have completely lost the human-specific *SRGAP2C*. In contrast, we never observed homozygous loss of *SRGAP2C* in controls. Three individuals with the homozygous exon 2 *SRGAP2C* deletion additionally exhibit microcephaly, consistent with the gene's function in neuronal migration and increasing dendrite density. We are continuing our large-scale genotyping efforts to confirm the pathogenicity of complete *SRGAP2C* loss and gain further insight into phenotypes accompanying it. These results provide further support for the importance of this new human gene for the evolution of unique aspects of human brain development.

2014F

Most Autosomal Recessive Diseases Have No Frequent Mutations that Reflect Increased Carrier Fitness or Mutation Hotspots. *M.AH. Gener, R.V. Lebo.* Pathology, Akron Children's Hospital , Akron, Oh.

Heterozygous advantage results when the carrier of a mutant gene has an increased reproductive fitness over a noncarrier. Then the relative frequency of initially occurring mutant alleles increase more rapidly in subsequent generations than the frequency of subsequently mutated alleles. Increased frequencies of specific mutant alleles have been reported in diseases exhibiting increased carrier fitness as well as in a disease gene with mutation hotspots. Carriers of one cystic fibrosis (CFTR) mutant allele are reported to exhibit increased fitness over noncarriers when infected with diseases like cholera. Carriers of the sickle cell anemia allele and related α-and β-thalassemia alleles survive malarial infection more readily in regions cultivating rice. This selective advantage explains why the ΔF508 mutation comprises ~70% of cystic fibrosis alleles and the sickle cell mutation βs comprises ~90% of sickle cell alleles. Alternatively, spontaneous mutations in the MECP2 Rett syndrome gene occur at mutation hotspots related to specific de novo, lethal gene sequences.(Lebo et al, 2001) The 34 listed autosomal recessive disorders with frequencies exceeding 1 in 100,000 worldwide patients were identified through GeneReviews and further studied through the Human Gene Mutation Database and Online Mendelian Inheritance in Man websites. No evidence of substantial selection was found for any of these disorders that had between 34 mutations in Kyphoscoliotic Ehlers-Danlos Syndrome and 1009 mutations in Leber Congenital Amaurosis. In contrast, hemochromatosis reported in the large northern European Caucasian regional population results from the Cys282Ty mutation in >90% of known alleles, possibly reflecting an as yet unreported selective carrier survival advantage. Furthermore, allelic selection could readily explain the 10% of all individuals who carry the 5T CFTR allele which decreases CFTR gene expression. 5T/5T alleles are found in patients with CBAVD. The lack of common alleles in most diseases makes analysis of multiple disease genes in the worldwide population more complex. In conclusion, inherited heterozygote carrier frequencies in very large patient populations typically reflect the length of time the mutation existed since its occurrence in the human population and whether a founder allele has been selected. Very frequent single mutations are not anticipated in the absence of heterozygous advantage or mutation hotspots.

2015W

Multiple LD-independent signals of extreme sub-population variation at a region associated with type-2 diabetes suggests a non-neutral evolutionary history. *P.L. Babb[1], B.F. Voight[1, 2].* 1) Pharmacology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 2) Genetics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

Type-2 diabetes (T2D) is a complex metabolic disease affecting over 280 million people worldwide. Although >70 loci have been associated with T2D susceptibility, we are only beginning to understand the range of T2D allelic variation across global populations at those loci, which gene(s) and processes are functionally modulated, and how they ultimately contribute to T2D pathogenesis. Furthermore, the evolutionary history of established T2D-associated variation has not been fully evaluated. Recent work has suggested that T2D variants harbor extreme levels of population differentiation (1), consistent with the hypothesis that T2D susceptibility alleles may have once been advantageous for regulating metabolic load in early human populations. In order to comprehensively test this hypothesis using all established loci for T2D, and to elucidate global distribution of risk alleles at T2D-associated loci, we computed Weir and Cockerham's (1984) formulation of F_{ST} for 69 LD-independent T2D loci ($p<5\times10$-8) in 1088 unrelated healthy individuals from 14 populations studied by the 1000 Genomes Project (Phase I). We used different combinations of sub-population membership to calculate global F_{ST} (AFRxAMRxASNxEUR), intra-continental F_{ST} (e.g. intra-ASN: CHBxCHSxJPT), and pairwise-continental F_{ST} (e.g. AFRxEUR) for each SNP. We computed the empirical distribution of F_{ST} (from 3.6 M HapMap SNPs) for all individuals in each type of F_{ST} comparison to examine whether any of the T2D loci fell within the tail of the F_{ST} distribution. In contrast to previous observations, our results suggest that as a group, the 69 T2D loci do not have greater F_{ST} values than a matched-sampling of SNPs (10,000 random draws) from the rest of the genome (Welch 2-sample t-test, p=0.97). However, upon closer examination of individual T2D loci, we noted one locus showing extreme F_{ST} scores across all population comparisons ($p<0.01$), and exhibiting complex patterns of F_{ST} and LD within 1 Mb of the associated SNP nearby the *PRC1* locus. In particular, our investigation revealed at least three LD-independent clusters of high F_{ST}, all within the $p<0.05$ significance cutoff of empirical distribution in the genome (global $F_{ST}>0.26$). We postulate that by triangulating the signals of such LD-independent F_{ST} clusters derived from non-coding disease-associated SNPs, we can help identify the causal gene(s) functionally involved in the manifestation of T2D. 1. Chen, et al., *PLoS Genetics*, 2012.

2016T

Analysis of type 2 diabetes and obesity variants in Mexican Pima Indians: the Maycoba Project. *R.L. Hanson[1], L.O. Schulz[2], P.H. Bennett[1], S. Kobes[1], R.C. Williams[1], M.E. Valencia[3], J. Esparza-Romero[3], R. Urquidez-Romero[3], L.S. Chaudhari[2], E. Ravussin[4], W.C. Knowler[1], L.J. Baier[1].* 1) Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ; 2) Northern Arizona University, Flagstaff, AZ; 3) Centro de Investigación en Alimentación y Desarrollo, Hermosillo, Sonora, Mexico; 4) Pennington Biomedical Research Center, Baton Rouge, LA.

The Pima Indians of Arizona have a very high prevalence of type 2 diabetes mellitus (T2DM) and obesity, while Mexican Pima Indians from Maycoba, Sonora, have a much lower prevalence of these disorders. While there are differences in environment between populations, the extent to which they differ at genetic loci for T2DM and obesity is unknown. We genotyped representative population samples of 175 Pimas from Maycoba and 402 from Arizona at 253 putative and established T2DM and obesity variants, along with 96 randomly selected single nucleotide polymorphisms (SNPs). Genetic distance between Mexican and Arizona Pimas, estimated from F_{ST} across the random markers, was 0.031 (95% confidence interval 0.019-0.048). Distance across 46 established T2DM variants or across 32 established obesity variants did not differ significantly from that across random markers (F_{ST}=0.038, p=0.53, and F_{ST}=0.054, p=0.36, respectively). Adjustment for a multiallelic score that sums number of risk alleles across established T2DM variants did not attenuate the increased risk for T2DM in Arizona Pimas, nor did a similar score for obesity attenuate the population difference in body mass index. To identify individual variants that differ between populations, absolute value in allele frequency difference (δf) was calculated and statistical significance was assessed with genomic control, calculated over the random markers, to account for expected differences. Five markers showed significant (false discovery rate<0.05) differences in frequency: 4 in *HLA-DRB1* (δf=0.56-0.75) and one (rs117619140, δf=0.40, $p=3.8\times10^{-4}$) in *TREH*. The largest difference was at the *HLA-DRB1* variant rs9271720 (δf=0.75, $p=1.3\times10^{-7}$). Analysis of data from the Human Genome Diversity Project suggests that this magnitude of allele frequency difference is unusual between human populations of comparable genetic distance: among 55,304,216 allele frequency differences analyzed across 101 pairs of populations with F_{ST} 0.019-0.048, the proportion with δf≥0.75 was 4.0×10^{-7}. These analyses show that established T2DM and obesity-associated genetic variants explain little of the difference in risk between Mexican and Arizona Pimas, and in general do not show greater divergence than expected based on genetic distance. However, variants at *TREH* and *HLA-DRB1*, genes which have previously been associated with T2DM in Arizona Pimas, have greater allele frequency differences than expected, perhaps reflecting effects of selection.

2017F

Evolution, adaptation and disease perspectives of Indian populations. *S. Nizamuddin[1], LVKS. Bhaskar[2], P.B. Gai[3], BG. Venkatesh[2], M. Jyotsna[2], K. Thangaraj[1].* 1) Center for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India; 2) Sri Ramachandra University, Porur, Chennai - 600 116, India; 3) Department of Studies in Applied Genetics, Karnataka University, Dharwad-580003, India.

India has been a major corridor for the first modern human, who have migrated out-of-Africa. Since India is inhabited by more than 4,500 anthropologically well-defined populations, who follow strict endogamy marriage practice, they harbors unique genetic architecture compare to populations from rest of the world. India is known not only for its diversity, in terms of social structure, language and culture but also its varied eco-geographical conditions, such as high altitude (Himalayan region: Changkpa population in Ladakh - 5294 meter), sea level (Lakshadweep island: Minicoy population - 10 meter; Andaman and Nicobar: Onge), extreme cold (Himalayan region: Kashmiri Pandit, Changkpa) and moderately warm temperature (Andhra Pradesh: Mala, Madiga, Vysya). In addition, some populations are living in islands while others are in mainland. Since the Indian populations are inhabited in these geographical regions for tens of thousands of years, we hypothesize these populations might have different selective advantages for certain genetic markers. To fetch signal of natural selection in these population, we have genotyped 134 individual on Affymetrix 6.0 platform and did phasing with Beagle software. Further, we calculated XP-CLR and XP-EHH values, and found novel signal. Interestingly, SFRP1, HIRA, HTR2B, ADD1, FGF1, SIM1, SLC7A10, CEBPA, FASLG and ZFPM2 genes are some examples, which are having importance in survival and genetic fitness for continuing progeny. In addition, we have also found novel genetic factors for many diseases, including cleft palate, breast cancer, etc. Details of these finding would be made available during the presentation.

Whole genome sequencing reveals past population history and signature of natural selection in a Japanese population. *A. Fujimoto[1], T. Abe[1], K. Boroevich[1], K. Nakano[1], A. Sasaki[1], R. Kitada[1], H. Tanaka[2], Y. Nakamura[1], S. Miyano[2], M. Kubo[1], H. Nakagawa[1], T. Tsunoda[1].* 1) Ctr for Integrative Medical Sciences, Riken, Yokohama, Kanagawa, Japan; 2) Human Genome Ctr, The Institute of Medical Science, The University of Tokyo, Japan.

We performed whole genome sequencing of 164 Japanese individuals with 30X coverage, and identified single nucleotide variants, insertions and deletions, copy number variations and rearrangements. We analyzed the pattern of genetic variations and estimated the past population history. Our analysis identified two bottleneck events and a population expansion after the last glacial period. The analysis of the frequency spectrum and the linkage disequilibrium detected signatures of recent positive selection. Significantly higher genetic variation was observed in the HLA and olfactory receptor regions. Our analyses showed the past population history of the Japanese population and identified the signature of adaptation in the local environment of East Asia.

Integrated natural selection and genome-wide association scan for cholera resistance in Bangladesh. *E.K. Karlsson[1,2], S. Tabrizi[1,2], I. Shylakhter[1,2], F. Qadri[3], J.B. Harris[4,5], R.C. LaRocque[4,6], P.C. Sabeti[1,2,7].* 1) Broad Institute, Cambridge, MA; 2) Center for Systems Biology, Harvard Univ, Cambridge, MA; 3) International Centre for Diarrhoeal Disease Research, Dhaka, Bangladesh; 4) Div. of Infectious Diseases, Massachusetts General Hospital, Boston, MA; 5) Dept of Pediatrics, Harvard Medical School, Boston, MA; 6) Dept of Medicine, Harvard Medical School, Boston, MA; 7) Dept of Immunology and Infectious Disease, Harvard School of Public Health, Boston, MA.

As an ancient disease with high fatality, cholera has exerted strong selective pressure on affected human populations, particularly in the Ganges River Delta, where the disease is endemic. This history of selective pressure makes it easier to identify host variants associated with cholera susceptibility and severity. We previously developed a method, the Composite of Multiple Signals (CMS), which combines different tests for natural selection to provide 20-100x better positional resolution than any individual signal. CMS scores each variant, allowing precise identification of the top functional candidates. We have now combined CMS with genome-wide association to identify selected variants associated with cholera resistance in Bangladesh. We initially performed a genome-wide study of natural selection in a population from the Ganges River Delta and identified 305 candidate selected regions using CMS. The regions were enriched for potassium channel genes involved in cyclic AMP-mediated chloride secretion and for components of the innate immune system involved in NF-κB signaling. Testing the top selected regions in two independent Bengali cohorts found the strongest association with cholera susceptibility in the top region of selection, peaking in the gene SNRNP200. We used these results to develop a model of the human innate immune signaling pathways that respond to V. cholerae infection and have been selected in the Bengali population. In this model, inflammasome activation and the NF-κB signaling pathway play an integrated role in TLR4-mediated sensing of V. cholera - consistent with our in vitro data. We have now expanded this work by combining a genome-wide association scan for cholera susceptibility with a denser selection scan using full genome sequences for the Bengali population provided by the 1000 genomes project, and have identified new host immune factors likely influencing cholera resistance. Our work shows that using publically available genetic datasets to incorporate tests for natural selection into GWAS analyses can help pinpoint functional variants, an approach applicable to other historically prevalent infectious diseases, such as Lassa fever, tuberculosis, leishmaniasis and malaria, and to complex, common diseases, such as inflammatory bowel disease, for which the associated genes may have been historically selected.

2020F

Targeted analysis of immunogenetic diversity in pre-Columbian Central Andean populations. *B. Llamas, G. Valverde-Garnica, A. Cooper, W. Haak.* Australian Centre for Ancient DNA, School of Earth and Environmental Sciences, University of Adelaide, SA 5005, Australia.

Historic accounts estimate that the South American indigenous population size declined by up to 95% between the period of initial contact with Europeans and the beginning of recovery. Most archaeologists and epidemiologists agree that Old World diseases played a major role in this abrupt population collapse. We used advanced ancient DNA techniques to characterize the genetic diversity of loci involved in immune response in pre-Contact Central Andean populations. We have created immortalized ancient DNA libraries using human remains from various periods ranging from the Archaic Period to the Late Horizon. Results from shotgun sequencing showed that nuclear information and complete mitochondrial genomes could be retrieved from well-preserved samples. We then used a customized targeted enrichment protocol and Next Generation Sequencing to genotype thousands of immunogenetic markers to generate a unique genetic dataset. By contrasting this major genetic survey of pre-Columbian immunogenetic diversity with modern-day populations, which harbour a low (immuno-) genetic diversity, we can test whether indigenous populations were immunologically 'naïve' to Old World diseases, and as a consequence suffered very high levels of mortality.

2021W

Learning Natural Selection from the Site Frequency Spectrum. *R. Ronen[1], N. Udpa[1], E. Halperin[2,3,4], V. Bafna[5].* 1) Bioinformatics and Systems Biology, University of California at San Diego, La Jolla, CA; 2) The Blavatnik School of Computer Science, Tel-Aviv University, Tel-Aviv, Israel; 3) International Computer Science Institute, Berkeley, CA, USA; 4) Department of Molecular Microbiology & Biotechnology, Tel-Aviv University, Tel-Aviv, Israel; 5) Department of Computer Science & Engineering, University of California, San Diego, CA, USA.

Genetic adaptation to external stimuli occurs through the combined action of mutation and selection. A central problem in genetics is to identify loci responsive to specific selective constraints. Many tests have been proposed to identify the genomic signatures of natural selection by quantifying the skew in the the site frequency spectrum (SFS) under selection relative to neutrality. We build upon recent work that connects many of these tests under a common framework, by describing how selective sweeps impact the scaled SFS. We show that the specific skew depends on many attributes of the sweep, including the selection coefficient and the time under selection. Using supervised learning on extensive simulated data, we characterize the features of the scaled SFS that best separate different types of selective sweeps from neutrality. We develop a test, SFselect, that consistently outperforms many existing tests over a wide range of selective sweeps. We applied SFselect to polymorphism data from a laboratory evolution experiment in which populations of Drosophila melanogaster adapted to hypoxia over hundreds of generations. As a result, we identified loci that support the role of the Notch pathway in hypoxia tolerance. Importantly, several of these Notch-related loci (including the Notch gene region itself) were missed by a previous study. We further applied our test to whole genome sequence data from two human populations. We identified many regions evolving under positive selection, some of which are in agreement with earlier studies, but many of which are novel.

2022T

Reconstructing bacterial phylogeny using whole-genome deep-sequencing data. *Y. Lo[1], L. Zhang[2], B. Foxman[2], S. Zöllner[1,3].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Epidemiology, University of Michigan, Ann Arbor, MI; 3) Psychiatry, University of Michigan, Ann Arbor, MI.

Studying the genetic variation among bacterial strains from the human biome gives insight into the origins and transmission of bacterial infections in human communities, and the emergence and spread of virulence and antibiotic resistance in bacterial populations. While sparse genetic data are sufficient to confidently cluster strains into a 'global' phylogeny, a single tree does not fully describe bacterial evolutionary relationships. Ancestries of individual bacterial genes can differ substantially from the global ancestries because of horizontal gene transfer (HGT) and homologous recombination. Comparisons of individual gene trees to the global tree give signals of HGT. Next-generation sequencing methods allow examination of entire bacterial genomes at high resolution and reasonable cost. However, individual gene tree construction often relies on few variant sites on the gene and hence still suffers from lack of data resolution. Here we propose a method to accurately construct and make inferences from gene trees using whole-genome deep-sequencing data of a set of bacterial strains. First we generate the posterior distribution of the global tree using standard Bayesian phylogenetic methods. This global tree posterior distribution serves as prior information for each gene tree. We describe a novel algorithm combining this prior distribution with the likelihood of each gene tree calculated from gene-specific variant calls. Comparing each most probable gene tree to the global tree gives an estimate of the concordance proportion. Bayes factor between each gene tree and the global tree provides a metric for identifying gene phylogenies significantly different from the global phylogeny. We apply the method to a sample of uropathogenic and commensal *Escherichia coli* strains obtained from human patients with urinary tract infections, each sequenced whole genome at >190x. After constructing global and gene trees, we quantify the proportion of the genes having consistent trees with the global tree. Most known virulence genes are not present in all strains. Comparing the gene-trees of these virulence genes to the global tree gives evidence of how often HGT occurs in the sample. Our method provides a novel approach for constructing high confidence gene trees. The results suggest an ongoing circulation of pathogenic genes, and multiple genetic origins of uropathogenic strains in a small geographic region.

2023F

The adaptive variant EDARV370A is associated with straight hair in East Asians. *J. Tan[1], Y. Yang[1], K. Tang[2], P. Sabeti[3,4], L. Jin[1], S. Wang[2,3,4].* 1) Fudan University, Shanghai, China; 2) Chinese Academy of Sciences-Max Planck Partner Institute for Computational Biology, Shanghai, China; 3) The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 4) Center for Systems Biology, Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA, USA.

Hair straightness/curliness is a highly heritable trait among human populations. Previous studies have reported European specific genetic variants influencing hair straightness, but the genetic variants influencing hair straightness in East Asians remain unknown. One promising candidate is a derived coding variant of the ectodysplasin A receptor (*EDAR*), *EDARV370A* (*370A*), associated with several phenotypic changes of epidermal appendages. One of the strongest signals of natural selection in human genomes, *370A* has risen to high prevalence in East Asian and Native American populations, while being almost absent in Europeans and Africans. This striking frequency distribution and the pleiotropic nature of *370A* led us to pursue if hair straightness, another epidermal appendage-related phenotype, is affected by this variant. By studying 1,718 individuals from four distinctive East Asian populations (Han, Tibetan, Mongolian, and Li), we found a significant association between *370A* and the straight hair type in the Han ($p = 2.90\times10^{-6}$), Tibetan ($p = 3.07\times10^{-2}$), and Mongolian ($p = 1.03\times10^{-5}$) populations. Combining all the samples, the association is even stronger ($p = 5.18\times10^{-10}$). The effect of *370A* on hair straightness is additive, with an odds ratio of 2.05. The results indicate very different biological mechanisms of straight hair in Europe and Asia, and also present a more comprehensive picture of the phenotypic consequences of *370A*, providing important clues into the potential adaptive forces shaping the evolution of this extraordinary genetic variant.

2024W

Macrophages from African and European populations respond differently to bacterial infection. *Y. Nédélec[1,2], A. Pagé Sabourin[1,2], V. Yotova[1], J.C. Grenier[1], N. Cotta[1], L.B. Barreiro[1,2]*. 1) Research Center, CHU Sainte-Justine, Montréal, Canada; 2) University of Montreal, Montréal, Canada.

Infectious diseases have always been a major health problem throughout the world, imposing strong selective pressure on the human genome. Geographically distinct human populations are postulated to have differing histories of pathogen exposure. Indeed, previous studies demonstrate that people of African and European ancestry differ in their susceptibility to certain infectious diseases like tuberculosis, malaria and sepsis. Differences in infection progression between African and European populations suggest inter-population variation in the immune response, possibly caused by the adaptation of Africans and Europeans to the pathogens of their environment. For the first time, we characterize the immune response of people of African and European ancestry to bacterial infections. We infected monocyte-derived macrophages from 24 African Americans and 24 European Americans with the intracellular pathogens Listeria monocytogenes and Salmonella typhimurium for 4 hours and measured whole genome gene expression of infected and non-infected cells by RNA-sequencing. We assessed macrophage control of bacterial infection at 1 hour and 24 hours by culturing infected cell lysate and counting colony-forming units to approximate the rate of bacterial survival. We found that macrophages derived from people of African ancestry presented fewer intracellular bacteria after 24 hours than people from European ancestry, suggesting that the African Americans better control intracellular bacterial infections. Concordantly with this observation we identified inter-population differences in immune gene pathway expression that might explain this pattern of increased infection control in African American macrophages. Interestingly, multiple genes up-regulated by bacterial infection in people of European ancestry were found to be already highly expressed in the non-infected cells of people from African ancestry. We show that several of these genes appear to have been subject to recent selection, which may explain between population disparities in their expression. Our study identifies multiple candidate genes that may affect the course of L. monocytogenes and S. typhimurium infection in humans. Importantly, our findings suggest that the clinical differences in bacterial infectious disease progression observed in populations of African and European ancestry may be outcome of natural selection.

2025T

Co-evolution of HLA class I with killer cell immunoglobulin-like receptors in a sub-Saharan African population. *P.J. Norman[1], J.A. Hollenbach[2], N. Nemat-Gorgani1[1], L.A. Guethlein[1], H.G. Hilton[1], M.J. Pando[3], K. Koram[4], E.M. Riley[5], L. Abi-Rached[1,6], P. Parham[1]*. 1) Department of Structural Biology, Stanford University School of Medicine, Stanford, CA; 2) Center for Genetics, Children's Hospital Oakland Research Institute, Oakland, CA; 3) Department of Pathology, Stanford University School of Medicine, Stanford; 4) Noguchi Memorial Institute for Medical Research, University of Ghana, Legon, Ghana; 5) Department of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, UK; 6) Centre National de la Recherche Scientifique, Laboratoire d'Analyse, Topologie, Probabilités, Equipe ATIP, Aix-Marseille Université, Marseille, France.

Human natural killer (NK) cell and cytotoxic T cell responses to pathogens, and the role of NK cells in reproduction, are controlled by diverse receptors that interact with highly polymorphic HLA class I molecules. Although T-cell receptor (TCR) variation is generated somatically with little genetic determination, killer cell immunoglobulin-like receptors (KIR) are highly polymorphic and polygenic and specific combinations of HLA class I and KIR alleles are differentially associated with numerous disease susceptibilities and therapeutic outcomes. Extensive *KIR* gene-content variation is observed between human populations. However, high-resolution analysis of *KIR* allele and haplotype diversity has focused on Asian and Amerindian populations having limited genetic diversity and the more heterozygous sub-Saharan African populations have remained under-represented. We studied KIR and HLA variation in 235 individuals, including 104 mother-child pairs from the Ga-Adangbe ethnic group of Ghana in West Africa. This population has a rich diversity of 175 *KIR* variants that form 208 *KIR* haplotypes and 81 *HLA-A*, *-B* and *-C* variants that form 190 *HLA class I* haplotypes. Balancing selection has maintained this exceptional polymorphism and diversified interaction of HLA class I with KIR, with evidence for their ongoing co-evolution in the Ga-Adangbe. Highlighting the critical role in countering pathogen diversity, every individual studied (N=188) has a unique compound genotype of *KIR* and *HLA class I*. Nevertheless, comparison of the observed frequencies with those simulated under a model of balancing selection revealed the impact of positive selection that has reduced the diversity of functionally interacting sites. Whereas the centromeric region of the Ga-Adangbe *KIR* locus is exceptionally diverse, the telomeric region lacks diversity due to the low frequencies of *Tel B KIR* genes and alleles and correspondingly high frequencies of *Tel A KIR* genes and alleles. As a consequence of the high frequency of HLA-B*53, -B*35 and related allotypes in the Ga-Adangbe, diversity is reduced at residues in the α1 domain of HLA-B that interact with the variable region of T-cell receptor β chains. These features of KIR and HLA-B are consistent with selection by a pathogen endemic to West Africa. The previously reported association of HLA-B*53 with severe malaria and the high prevalence of malaria in the Ga-Adange population strongly suggest *Plasmodium falciparum* as a candidate.

Lassa virus has the unique status of being both one of the world's deadliest pathogens, designated bio-safety level 4 (BL-4), and a public health crisis, endemic in large parts of West Africa. It is estimated to have originated over 1000 years ago in Nigeria, and a genome-wide survey of human variation identified the gene *LARGE*, biologically linked to Lassa virus infection, as among the strongest signals of natural selection in the Yoruba population of Nigeria. We pursued the hypothesis that Lassa virus is an ancient selective force, driving the rise of genetic resistance, by conducting a genome-wide association study (GWAS) of Lassa fever cases and controls in Nigeria and Sierra Leone. We report a signal of association at *LARGE*, and show that it overlaps with the previously reported signal of selection. This suggests recent evolution of resistance to Lassa fever in West Africa, making it one of only a handful of known loci under positive selection elucidated to be involved in resistance to infectious disease. Population genetics analysis provides further insights into the origins and spread of the resistance variant in *LARGE*. We show that the same putatively protective haplotype under selection in the Yoruba is also present in the Esan population of Nigeria and the Mende population of Sierra Leone. We find that the frequency is highest in the Yoruba (30%), lower in the Esan (21%) and the Mende (10%), and absent in East African and non-African populations (where Lassa fever is also absent). This is consistent with results from our sequencing of the Lassa genome showing that the virus is oldest in Nigeria and appeared only recently in Sierra Leone, and helps to explain higher fatality rates and greater disease severity in Sierra Leone. Beyond *LARGE*, our other top GWAS signals fall at genes involved in the immune system, including *PTPRE*, which modulates expression of cytokines involved in host response to viral infection, and *IFRD1*, involved in the activation of neutrophils in innate immune response. We also examine signals of adaptation in the Esan and Mende populations and discover numerous novel candidate loci under positive selection, providing new insights into human diversity in West Africa. This work is one of only a few surveys of genetic diversity in West Africa, a region underrepresented in GWA studies. It is also the first ever GWAS on a BL-4 agent, and demonstrates a novel genomics approach to understanding the world's deadliest pathogens.

2027W

Characterizing positive natural selection in Asian urban and indigenous populations. *X. Liu[1], R.TH. Ong[2], W.Y. Saw[3], A. Mohammad[2], Y.Y. Teo[2,3,4,5], HUGO Pan-Asian SNP Consortium.* 1) NUS Graduate School, National University of Singapore, Singapore, Singapore 117456; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore 117597; 3) Life Sciences Institute, National University of Singapore, Singapore 117456; 4) Department of Statistics and Applied Probability, National University of Singapore, Singapore 117546; 5) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore 138672.

The Pan-Asia SNP consortium is a collaborative work with genetic data from most countries of Asia, and contains data from not only the urbanized populations, but also ethnic minorities and a number of indigenous groups. The indigenous populations represent great diversity of cultural traditions, linguistics, and may possess unique demographic history. However, local adaptations of Asian indigenous groups were not systematically investigated in previous studies. Indigenous people's specific habitant and cultures make them subject to distinct selective pressures. Therefore, we expect to see distinct features of positive selection signals in the indigenous populations, as compared to other Asian urbanized populations. In this study, we aim to find positive natural selection signals in Asian population groups from PanAsia SNP consortium using HaploPS, iHS and XPEHH. We evaluated the power loss of selection methods and phasing accuracy resulting from low SNP coverage of genotyping data. A number of selection signals related to infectious disease and diet were found in 73 Asian population groups. The clustering analysis showed that the sharing of positive selection signals was affected by latitude. Populations residing near the equator tend to share the same positive selection signal, and the populations from further north ie Malaysia, Thailand, China etc also share similar signals. Indigenous populations are enriched with low frequency selection signals, whereas the urban populations have more medium to high frequency selection signals. This observation indicated that the indigenous populations may still undergo strong positive selection pressures and result in recent positive selection events.

2028T

Sensitivity of haplotype signatures of negative selection under different demographic scenarios. *D. Ortega Del Vecchyo[1], M. Ehm[2], M. Nelson[2], S. Zollner[3], K. Lohmueller[1, 4], J. Novembre[5].* 1) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, CA; 2) Department of Quantitative Sciences, GlaxoSmithKline, Research Triangle Park, NC; 3) Department of Biostatistics, University of Michigan-Ann Arbor, MI; 4) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA; 5) Department of Human Genetics, University of Chicago, IL.

As documented by recent studies, haplotypic signatures can help distinguish a group of deleterious variants from a set of neutral variants. Differences in haplotype patterns are observed because deleterious variants are expected to have a younger age compared to neutral variants. Here, we explore the sensitivity of haplotypic signatures to distinguish between neutral and deleterious variants under different realistic human demographic scenarios. In order to do this, we developed a novel algorithm based on importance-sampling that allows us to efficiently simulate large numbers of rare variant haplotypes from arbitrary demographic scenarios. We show that the utility of haplotypic signatures is highly dependent on the demographic scenario being simulated. The reason for this is that the ages of deleterious and neutral alleles are also dependent on demography. We present a power analysis to quantify how many variants are necessary to differentiate deleterious variants with different selective coefficients from neutral variants. Additionally, we explore which summary statistics, such as iHS and r^2, provide highest sensitivity. We use those findings to identify deleterious variants in 202 genes analyzed in a large number of samples from Europe (n=12,514, Nelson et al., 2002). The size of the dataset enables us to resolve the haplotypic signatures of a large number of variants that are either putatively neutral or deleterious. We show how we can use these results to identify gene categories that have an enrichment of deleterious variants and hence are stronger candidates for contributing to disease. We also suggest how our results can be used to infer the distribution of selective coefficients.

2029F

Identification of regions under positive selection in the Gullah African American population of South Carolina. *P.S. Ramos[1], S.P. Sajuthi[2], J. Divers[2], Y. Huang[3], U. Nayak[3], W.M. Chen[3], K.J. Hunt[1], D.L. Kamen[1], G.S. Gilkeson[1], J.K. Frenandes[1], I.J. Spruill[1], C.D. Langefeld[2], W.T. Garvey[4], M.M. Sale[3].* 1) Medical University of South Carolina, Charleston, SC; 2) Wake Forest School of Medicine, Winston-Salem, NC; 3) University of Virginia, Charlottesville, VA; 4) University of Alabama, Birmingham, AL.

The Gullahs form a unique population of African ancestry in the U.S. In addition to their relative genetic and environmental homogeneity and low European admixture (less than 11% on average) a shorter genetic distance between the Gullah and Sierra Leonean tribes has also been reported, suggesting that population genetic signals, such as regions under recent selection, may be more easily detected in the Gullah than in other African American (AA) populations. Given the increased prevalence of some complex diseases in AA and the increasing evidence of selection at loci associated with human diseases, identification of alleles under selection may provide insight into disease susceptibility. Since population-specific selection may cause allele frequency differences, the goal of this study was to identify regions with minor allele frequency (MAF) differences between Gullah and Sierra Leoneans. We had available 277 Gullah and 400 Sierra Leonean samples genotyped on the Affymetrix Genome-Wide Human SNP Array 6.0. After stringent QC, 679,513 SNPs with MAF>5% were used to compute the significance of the MAF differences between the two populations. The European component was adjusted for via inclusion of the HapMap CEU principal component in the logistic regression model. In order to exclude spurious MAF differences, only regions where at least two SNPs in LD showed suggestive (P<10-05) MAF differences were considered. The region showing the most significant MAF differences between the Gullah and Sierra Leoneans was at 20q13.13, where multiple SNPs in LD showed higher MAFs in the Gullah and P-values between E-03 and E-07. As shown in the Haplotter and HGDP Selection Browsers, this region shows evidence for selection (|iHS|>2.5) in the YRI HapMap data, as well as in Africans in the HGDP data. Interestingly, the highest iHS and XP-EHH test results in African populations were identified in the Mandenka, who are geographically the closest to Sierra Leone. In summary, we have identified a ~500 kb region at 20q13.13 with significant allele frequency differences between the Gullah and Sierra Leoneans, suggesting that population-specific selective pressures may be operating at this locus. Given the increased prevalence of several complex traits in AA and the homogeneity of the Gullah, identification of these regions in the Gullahs has the potential to elucidate complex disease risks in AA.

2030W

Identification of a Tibetan-specific mutation in the hypoxic gene EGLN1 and its contribution to high-altitude adaptation. *B. Su[1], K. Xiang[1,6], NA. Ouzhuluobu[2], Y. Peng[1], Z. Yang[1,6], X. Zhang[1,6], C. Cui[2], H. Zhang[1], M. Li[1,6], Y. Zhang[1], NA. Bianba[2], NA. Gonggalanzi[2], NA. Basang[4], NA. Ciwangsangbu[4], T. Wu[3], H. Chen[5], H. Shi[1], X. Qi[1].* 1) State Key Laboratory of Genetic Resources and Evolution, Kunming Inst Zoology, Chinese Academy Sci, Kunming, Yunnan, China; 2) High Altitude Medical Research Center, School of Medicine, Tibetan University, Lhasa, China; 3) National Key Laboratory of High Altitude Medicine, High Altitude Medical Research Institute, Xining, China; 4) People's Hospital of Dangxiong County, Dangxiong, China; 5) Department of Epidemiology and Biostatistics, Harvard School of Public Health, Boston, USA; 6) University of Chinese Academy of Sciences, Beijing, China.

Tibetans are well adapted to high-altitude hypoxic conditions, and in recent genome-wide scans, many candidate genes have been reported involved in the physiological response to hypoxic conditions. However, the limited sequence variations analyzed in previous studies would not be sufficient to identify causal mutations. Here we conducted re-sequencing of the entire genomic region (59.4 kb) of the hypoxic gene EGLN1 (one of the top candidates from the genome-wide scans) in Tibetans, and identified 185 sequence variations including 13 novel variations (12 substitutions and one in-del). There is a non-synonymous mutation (rs186996510, D4E) showing surprisingly deep divergence between Tibetans and lowlander populations (FST = 0.709 between Tibetans and Han Chinese). It is highly prevalent in Tibetans (70.9% on average), but extremely rare in Han Chinese, Japanese, Europeans and Africans (0.56%-2.27%), suggesting that it might be the causal mutation of EGLN1 contributing to high-altitude hypoxic adaptation. Neutrality test confirmed the signal of Darwinian positive selection on EGLN1 in Tibetans. Haplotype network analysis revealed a Tibetan-specific haplotype, which is absent in other world populations. The estimated selective intensity (0.029 for the C allele of rs186996510) puts EGLN1 among the known genes undergone the strongest selection in human populations, and the onset of selection was estimated to have started at the early Neolithic (~8,400 years ago). Finally, we detected a significant association between rs186996510 and hemoglobin levels in Tibetans, suggesting that EGLN1 contributes to the adaptively low hemoglobin level of Tibetans compared to acclimatized lowlanders at high altitude.

2031T

Fluctuating And Geographically Specific Selection Characterize Rapid Evolution Of The Human Killer Immunoglobulin-Like Receptor (KIR) Locus. *J.A. Hollenbach[1], P.J. Norman[2], J.I. Rotter[3], E.A. Trachtenberg[1], P. Parham[2], K.D. Taylor[3].* 1) Center for Genetics, Children's Hospital Oakland Research Institute, Oakland, CA; 2) Departments of Structural Biology and Microbiology & Immunology, Stanford University School of Medicine, Stanford, CA; 3) Medical Genetics Institute, Cedars Sinai Medical Center, Los Angeles, CA.

Killer cell immunoglobulin-like receptors (KIR) are expressed on human natural killer (NK) cells and a small percentage of cytotoxic T-cells, and regulate immune responses during infection. Diversity of KIR is known to impact NK and T cell function and has been associated with infectious and autoimmune diseases, as well as cancer and transplant outcome. The KIR gene complex of human chromosome 19q13.4 displays extensive allelic and gene-content variability, with between 7-14 highly polymorphic genes. To examine KIR evolution in the context of the entire human genome, gene-content diversity and 125 SNPs in the KIR and flanking regions were compared to >650,000 genome-wide SNPs in 852 individuals from 52 populations of the human genome diversity panel (HGDP). KIR allelic diversity was further examined in a subset of 60 individuals. In both African and Oceanic populations, SNP diversity and linkage disequilibrium (LD) patterns in the telomeric segment of the KIR region show strong evidence for purifying selection in response to local pressures. Prior to emergence of modern humans, KIR3DL1/S1 diverged into three linages that encode high and low expressing inhibitory or activating receptors, respectively. In Africa, ongoing selection specifically favors the highly expressing inhibitory receptors. In contrast, in Oceanic populations there is evidence of strong and recent selection for the activating form of the receptor. In the centromeric segment of the KIR region, high diversity worldwide is consistent with balancing selection, particularly in Oceania. Highlighting the considerable fluctuation of selection pressures, East Asians exhibit ongoing purifying selection on the centromeric KIR that began before divergence of Amerindians; populations in which centromeric KIR diversity subsequently rebounded under balancing selection. In all populations exons 7-9 of KIR3DL3 and KIR3DL2 mark the centromeric and telomeric boundaries of LD within the KIR region. Contrasting with the instability of the centromeric and telomeric KIR regions is a segment of strong LD that extends from 40kb 5' of the KIR locus to intron 5 of KIR3DL3 that remains relatively conserved worldwide. We show that this segment is likely maintained by epistatic selection to maintain co-inheritance of functionally dependent polymorphisms. In conclusion, we find strong evidence of fluctuating and geographically specific selection in the KIR region that is independent of demographic history.

2032F

Inference of Natural Selection and Demographic History for African Pygmy Hunter-Gatherers. *P.H. Hsieh[1], K.R. Veeramah[2], J. Lachance[4], S.A. Tishkoff[4], J.D. Wall[5], M.F. Hammer[1,2], R.N. Gutenkunst[1,3].* 1) Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 2) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, AZ; 3) Department of Molecular and Cellular Biology, University of Arizona, AZ; 4) Department of Biology and Genetics, University of Pennsylvania, Philadelphia, PA; 5) Institute for Human Genetics, University of California, San Francisco, CA.

African Pygmies are hunter-gatherers primarily inhabiting the Central African rainforests, where they are exposed to high temperatures, high humidity, and a pathogen and parasite-enriched woody habitat. These factors undoubtedly influenced their evolutionary history as they adapted to this environment. Many Pygmy populations have historically been in socio-economic contact with neighboring Niger-Kordofanian speaking farmer populations, particularly since the agriculture expansion in sub-Saharan Africa that began five thousand years ago (kya). To look for the true signatures of adaptation to the rainforest habitat of pygmies we must control for this complex demographic history. We sequenced and combined 40x whole genome sequence data from 3 Baka pygmies from Cameroon, 4 Biaka pygmies from the Central African Republic, and 9 Niger-Kordofanian speaking Yoruba farmers from Nigeria. We used ∂a∂i, a model-based demographic inference tool, to infer the history of these populations. Our best-fit model suggests that the ancestors of the farmer and pygmy populations diverged 150 kya and remained isolated from each other until 40 kya. This divergence is more ancient than estimated by previous studies that included fewer loci, but is consistent with a PSMC analysis, a separate inference tool that uses different aspects of the genomic data than ∂a∂i. Interestingly, our analysis shows that models with bi-directional asymmetric gene flow between farmers and pygmies are statistically better supported than previously suggested models with a single wave of uni-directional migration from farmers to pygmies. To identify possible targets of positive selection, we conducted a genomic scan using complementary methods, including the frequency-spectrum based G2D test, the population differentiation based XP-CLR test, and the haplotype based iHS test. We performed 10,000 simulations based on the above best-fit demographic model in order to assign statistical significance to each reported target of natural selection. Our results reveal that genes involved in cell adhesion, cellular signaling, olfactory perception, and immunity were likely targeted by natural selection in the pygmies or their recent ancestors. Our analysis also shows that genes involved in the function of lipid binding are enriched in highly differentiated non-synonymous mutations, suggesting that this function may have acted differently on the Pygmies and farmers after their divergence from their common ancestor.

2033W

Forward simulations of recurrent selection and demographics with rescaled parameters. *L.H. Uricchio[1], R.D. Hernandez[2].* 1) Bioengineering Graduate Group, UC Berkeley & UCSF, San Francisco, CA; 2) Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA.

It is well known that positive selection impacts patterns of diversity in linked regions of a genome. When a population experiences frequent positive selection, the resulting patterns of genetic variation in linked regions can be quite skewed, but theoretical treatments of this process (often referred to as 'recurrent hitchhiking') are mostly limited to simple models. Forward simulation can provide insights into more sophisticated models that include arbitrary demographic scenarios, rates of selection, and distributions of selection coefficients, but the computational burden of forward simulation is often prohibitive. A remedy to this computational challenge is to rescale the relevant parameters (e.g., population size) in a way that conserves the underlying dynamics. However, *ad hoc* approaches to parameter scaling in recurrent hitchhiking may not always provide sufficiently accurate dynamics, potentially skewing patterns of diversity in simulated DNA sequences. Here, we perform a detailed theoretical analysis of the recurrent hitchhiking model that relaxes some simplifying assumptions, and present a simple method for parameter rescaling under the model. We thoroughly test the robustness of rescaling across the parameter space, and describe the conditions under which rescaling provides accurate results. We find that our approach enables us to perform large-scale simulations in a fraction of the computational time. We apply this rescaling method to simulations of interference among selected sites as well as demographic models of growth and contraction.

2034T

Variation in Bone Mineral Density (BMD) in Children of Different Ethnic Backgrounds is Explained By Genetic Profiling: The Generation R Study. *M. Medina Gomez[1,2,3], D.H.M. Heppe[2,3,4], K. Estrada[1,2,5,6,7], L. Oei[1,2], A. Hofman[1,2,3], M. Kayser[8], A.G. Uitterlinden[1,2,3], V.W. Jaddoe[2,3,4], O. Lao[8], F. Rivadeneira[1,2,3].* 1) Internal Medicine, Erasmus MC University, Rotterdam, Netherlands; 2) Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 3) The Generation R Study Group, Erasmus Medical Center, Rotterdam, The Netherlands; 4) Pediatrics, Erasmus Medical Center, Rotterdam, The Netherlands; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 6) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 7) Harvard Medical School, Boston, MA. USA; 8) Forensic Molecular Biology, Erasmus Medical Center, Rotterdam, The Netherlands.

Aim: To study genetically-determined differences in BMD in children across ethnicities, we constructed a genetic score (GS) of BMD SNPs in children from multiple ethnic background and tested for association with total-body (TB-) BMD. **Methods:** We included 4,009 children from The Generation R study, a single-center prospective multiethnic birth cohort in Rotterdam, The Netherlands, with GWAS data and TB-BMD measured by DXA at a mean age of 6.2 years. The admixed population includes a wide spectrum of ethnic origins including blends between continental groups. Clustering based on genetic data (using ADMIXTURE) was employed assigning children to one of three transcontinental ancestral groups: predominantly, Caucasian (n=3,513), Asian (n=159) and African (n=337). Differences in TB-BMD were assessed by least-squares means using the Caucasian population as reference and adjusting for age, sex, height, fat and lean mass. The GS consisted of the sum of BMD-increasing alleles (0,1,2) in 63 genetic variants (from 56 BMD loci identified in adults) and was analyzed across quintiles. **Results:** Children of African descent had higher TB-BMD (0.585 g/cm2) than those of Asian (0.559 g/cm2; P=2E-6) and Caucasian descent (0.552 g/cm2; P=1E-6). The GS explained 5.2% of the variance in BMD and 2.6% after principal component correction. As compared to children in the GS middle quintile (54% of the population; n=2,179), individuals in the GS highest quintile (2.6% of the population; n=106) had 0.69 SDs higher BMD (P<1E-6), while those in the GS lowest quintile (1.9% of the population; n=77) had 0.53 SDs (P=4E-6) lower BMD. The number of children of African descent were overly represented (P=3E-104) in the two highest quintiles of the GS with 65.6%, as compared to 18.8% in children of Caucasian and 15.7% in those of Asian descent. Positive differences of >10% in BMD-increasing allele frequencies were seen between children of African and Caucasian descent for 21 variants and differences of > 5% for 34 variants of the score. Data from the Human Genome Diversity panel also indicated higher frequency of BMD-increasing alleles in African populations, with South-west Bantuans displaying the highest frequencies. **Conclusions:** Genetic ancestry of African descent is correlated with a higher frequency of BMD-increasing alleles. Ethnic differences in bone accrual are already evident at childhood and are partially explained by allele frequency differences in variants from known BMD loci.

2035F

Non-Random Geospatial Distributions of HLA-Haplotypes in the United States. *N.P. Leahy[1], A. Chatterjee[2], M. Albrecht[1], M. Maiers[1].* 1) Bioinformatics Research, Be The Match, Minneapolis, MN; 2) School of Statistics, University of Minnesota, Minneapolis, MN.

A key predictor of hematopoietic cell transplantation success is using a donor with a fully HLA-matched donor for the patient. Donor registries such as the Be The Match® require knowledge of human population structure to target recruitment to subpopulations with rare variants. We used data from the Be The Match® registry to test for spatial heterogeneity within self-identified race and ethnic groups (SIRE). In total there were four broad SIRE groups (African-American, Asian/Pacific Islander, Caucasian, Hispanic) and 18 subcategories of the broad SIRE groups. The high genetic variability at HLA and low haplotype frequencies presented challenges for traditional analysis methods. Therefore, we opted for a permutation methodology to establish heterogeneity. For each of the SIRE groups, we generated a matrix, ***H***, of the occurrences of the top 100 haplotypes in 50 US states, District of Columbia, and Puerto Rico. Our metric was the maximum eigenvalue for the variance-covariance matrix, λ_{max}. To test for spatial heterogeneity in our data, we performed 10,000 permutations of the data to generate a probability distribution of λ_{max}. Significance was determined by the position of the metric to the distribution. This was repeated for the top 1000 haplotypes for 1000 permutations. The permutation analysis found for the 100 most common haplotypes, Asian/Pacific Islander ($p < 0.0001$) and Hispanic ($p = 0.0036$) had significant special heterogeneity and Caucasian was marginally insignificant. When the analysis was repeated with the 1000 most common haplotypes, Caucasian was not significant ($p < 0.0001$) and Hispanic was no longer significant ($p = 0.412$). Outcomes of the subcategories mostly reflected those of the broad SIRE groups. African-American was not significant. These results were consistent with historical founder events. That not all SIREs can be treated as homogenous subpopulations has implications for recruitment strategies of donor registries. To better serve patients, it is necessary to resolve the patterns within spatially heterogeneous SIRE groups to maximize diversity within registries. That increasing the number of haplotypes shifted some SIRE groups from significant to non-significant is problematic. The expectation was adding additional genetic information should have provided better resolution of population structure, requiring a more nuanced hypothesis.

2036W

Proportion of African ancestry in *Helicobacter pylori* is associated with increased severity of gastric lesions in human hosts with high Amerindian ancestry. *N. Kodaman[1], A. Pazos[2,8], B.G. Schneider[2], R. Sobota[1], M.B. Piazuelo[2], C.L. Shaffer[3], J. Romero-Gallo[2], T. de Sablet[2,7], L.E. Bravo[4], K. Wilson[2,5,7], T. Cover[3,6,7], S.M. Williams[9], P. Correa[2].* 1) CHGR, Vanderbilt University, Nashville, TN; 2) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Pathology, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Pathology, Universidad del Valle School of Medicine, Cali, Colombia; 5) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN; 6) Division of Infectious Diseases, Vanderbilt University Medical Center, Nashville, TN; 7) Veterans Affairs Tennessee Valley Healthcare System, Nashville, TN; 8) Universidad de Nariño, Pasto, Colombia; 9) Department of Genetics, Dartmouth University, Hanover, NH.

Helicobacter pylori is the principal cause of gastric cancer, the second leading cause of cancer mortality worldwide. In certain Colombian populations, over 90% of individuals are infected with *H. pylori*, but infection rate does not generally predict cancer prevalence. In particular, residents of the Andean mountain region are 25 times more likely to develop gastric cancer than their coastal counterparts, despite similar rates of infection. We determined the ancestry of *H. pylori* isolates from the gastric biopsies of 275 Colombian subjects from both the mountain and coastal regions. Most isolates contained genomic regions from four ancestral *H. pylori* populations: Africa1 (AA1), Europe1 (AE1), Europe2 (AE2), and East Asia (AEA), but these proportions varied with geography. The AA1 cluster was more common in coastal samples (mean=47.9%), and AE2 in mountain samples (mean= 50.7%). The human ancestry of the biopsied individuals also varied with geography, with mean proportions of 57.9% African, 22.6% Amerindian, and 19.5% European ancestry in the coastal region, and 67% Amerindian and 30.4% European ancestry in the mountain region. All pairwise correlations between *H. pylori* ancestry and human host ancestry were significant. While African *H. pylori* ancestry correlated negatively with Amerindian human ancestry ($r=-0.60$), the interaction between the two had a strongly deleterious effect on histopathology. In a multivariate linear model, the marginal effect of Amerindian ancestry on histopathology became non-significant ($p=0.63$) when the interaction was included, indicating that Amerindian ancestry *per se* was not responsible for the increased severity of the lesions. Importantly, region of origin (coast or mountain) was also not significant when added as a covariate to the multivariate model ($p=0.89$). Our findings indicate that AA1 ancestry is relatively benign in humans of African ancestry, but potentially deleterious in Amerindians, making the interaction between human and *H. pylori* ancestry a potential confounder of univariate analyses on histopathology. Co-evolution has likely modulated disease risk, and the disruption of this relationship may account for the risk discrepancy in Colombian populations.

2037T

Principal component analysis reveals the 1000 Genomes Project does not sufficiently cover the human genetic diversity in Asia. *D. Lu, S. Xu.* Partner institute for Computational Biology, Shanghai, China.

The 1000 Genomes Project (1KG) aims to provide a comprehensive resource on human genetic variations. With an effort of sequencing 2,500 individuals, 1KG is expected to cover the majority of the human genetic diversities worldwide. In this study, using analysis of population structure based on genome-wide single nucleotide polymorphisms (SNPs) data, we examined and evaluated the coverage of genetic diversity of 1KG samples with the available genome-wide SNP data of 3,831 individuals representing 140 population samples worldwide. We developed a method to quantitatively measure and evaluate the genetic diversity revealed by population structure analysis. Our results showed that the 1KG does not have sufficient coverage of the human genetic diversity in Asia, especially in Southeast Asia. We suggested a good coverage of Southeast Asian populations be considered in 1KG or a regional effort be initialized to provide a more comprehensive characterization of the human genetic diversity in Asia, which is important for both evolutionary and medical studies in the future.

2038F

The Iranian Genomes Project. *R. Daneshjou[1], M. Ronaghi[2], C.D. Bustamante[1], P.C. Sabeti[3], R.B. Altman[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Illumina Inc., San Diego, CA; 3) Department of Human Evolutionary Biology, Harvard University, Cambridge, MA.

While large-scale full-genome studies, such as the 1000 Genomes Project, have examined genetic variation for many of the world's populations, Middle Eastern populations have remained little studied. This group's unique history and geographic location, at the presumed bottleneck of the out of Africa migration, make them an important population to investigate. Here, we present the Iranian Genome Project, an effort to deeply sequence (at 30x coverage) over 50 individuals of Iranian descent. Our cohort includes conserved and understudied sub-populations from Iran, such as Zoroastrian, Bakhtiari, and Jewish populations. We explore the relationship between the Iranian population to other 1000 Genomes populations and the relationships between the Iranian sub-populations using EIGENSOFT software and the HAPMIX algorithm to compute FST and Principle Components Analysis (PCA). We further identify variants that are unique to the Iranian population and predict the functional impact of these variants. Because ancestry is an important consideration in clinical genetics, we identify the frequency of known or predicted damaging mutations in genes identified by the recent American College of Medical Genetics and Genomics (ACMG) guidelines on incidental findings in genome sequencing. Additionally, we calculate frequencies for important known clinical pharmacogenetic variants and identify new variants in known pharmacogenetic genes, which may play an important role in this population. Given the importance of diverse reference sequences for both population and clinical genetics, the Iranian Genome Project serves to fill in the gap by providing deeply sequenced genomes from a key but unexplored Middle Eastern population.

2039W

Morphometric and ancient DNA study of human skeletal remanants in Indian Subcontinent. *N. Rai[1], M. Mirazon Lahr[2], L. Singh[1], K. Thangaraj[1].* 1) Evolutionary and Medical Genetics, Centre for Cellular and Molecular Biology, Hyderabad, India; 2) Leverhulme Centre for Human Evolutionary Studies, University of Cambridge, U.K.

Recovery and sequencing of mtDNA from ancient human remnants is a daunting task but provides valuable information about human migrations and evolution. Our present study is the first to recover, amplify and sequence (HVR and coding regions of mtDNA) inadequately preserved and highly degraded (1.5 Ky to ≤1.0 Ky ago) hominids mitochondrial DNA of three most intriguing and indigenous ancient population of South and South-East Asia (Myanmar=20 Buried individuals, Nicobar Islands=15 and Andaman Island=6). Following all parameters and to avoid the chance of contamination we independently extracted and sequenced the DNA in two different labs and measured the cranial variability in all hominid skulls using 128 cranial landmarks, compiled 3D morphometrics, genetic data of ancient DNA samples and analyzed the admixture and genetic affinities of above three populations. Results showed the predominant frequency of F1a1 and complete absence of 9bp deletion in ancient Nicobarese. Unlike in previous reports on modern Nicobarese, the high frequency of F1a1 haplogroup in ancient Nicobarese show the probable migration of Nicobarese from South East Asia and the complete absence of 9bp deletion suggests the different events of settlement. This study failed to detect genetic affinities of Burmese with Nicolbarese even though their phenotype and language appears to be same. We first time report any kind of population study on Burmese populations and with the genetic affinity of Burmese with East Asian, East Indian (Including Gadhwal region of Himalaya) and Bangladeshi populations, we found significant admixture with West Eurasians. Our study strongly supports the West Eurasian and East Asian route of migration and settlement of early Burmese population. The three populations in the present study are quite different in their genetic structure but 3D morphometric study using huge number of landmarks explains a close homology among these populations and this can be explained by the role of climatic signature on these populations.

2040T

No significant differences in the accumulation of deleterious mutations across diverse human populations. *R. Do[1,2], D. Balick[1,3], I. Adzhubey[1,3], S. Sunyaev[1,3], D. Reich[1,4].* 1) Broad Institute of Harvard and MIT, Cambridge, Massachusetts, 02142; 2) Center for Human Genetics Research, Massachusetts General Hospital, Boston, Massachusetts, 02114; 3) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, Massachusetts, 02115; 4) Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115.

Differences in demographic history across populations are expected to cause differences in the accumulation of deleterious mutations because natural selection works less efficiently when population sizes are small. Surprisingly, however, the relative burden of deleterious mutations has never been directly measured across human populations on a per-haploid genome basis, despite the fact that this is what matters biologically in the absence of dominance and epistasis. Here we empirically measure the relative accumulation of deleterious mutations in 13 diverse populations (Yoruba, Mandenka, San, Mbuti, Dinka, Australian, French, Sardinian, Han, Dai, Mixe, Karitiana and Papuan) along with one archaic population (Denisova). All the present-day populations have statistically indistinguishable accumulations of coding mutations. We highlight two examples. First, we find no evidence for a lower mutational load in West Africans than in Europeans despite the approximately 30% higher genetic diversity in West Africans: the accumulation of nonsynonymous mutations in West Africans is 1.01±0.02 times that in Europeans, and for 'probably damaging' mutations, the ratio is 1.03±0.04. Second, we find no evidence for a lower mutational load in populations that have experienced agriculture-related expansions over the last 10,000 years and those that have not: the ratio in Chinese to Karitiana hunter gatherers from Brazil is 0.99±0.07. We determined that these null results are not an artifact of insensitivity of our method to differences in demographic history. As a positive control, we also analyzed archaic Denisovans who are known to have had a small population size for hundreds of thousands of years since separation from modern humans. We show that the Denisovan lineage has accumulated 'probably damaging' mutations 1.33±0.06 times more rapidly than modern humans since they split. These analyses are important because of the new constraints they place on the distribution of selection coefficients in humans. Given the currently estimated demographic histories of West Africans and Europeans, combined with the fact that we do not detect a lower accumulation of deleterious mutations in West Africans than Europeans, we can conclude that only a small proportion of nonsynonymous mutations have selection coefficients in the range s=-0.01 to -0.001, which is the range of selection coefficients which would be expected to show a lower accumulation in West Africans than in Africans.

2041F

Y chromosomes of ancient Hunnu people and its implication on the phylogeny of East Asian linguistic families. *LL. Kang[1,2], TB. Jin[1], F. Wu[1,2], X. Ao[2], SQ. Wen[2], CC. Wang[2], YZ. Huang[2], XL. Li[1,2], H. Li[1,2].* 1) Key Laboratory of High Altitude Environment and Gene Related to Disease of Tibet Ministry of Education,School of Medicine, Tibet University for Nationalities, Xianyang, Shaanxi, China; 2) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China.

The Hunnu (Xiongnu) people, also called Huns in Europe, were the largest ethnic group to the north of Han Chinese until the 5th century. The ethnolinguistic affiliation of the Hunnu is controversial among Yeniseian, Altaic, Uralic, and Indo-European. Ancient DNA analyses on the remains of the Hunnu people had shown some clues to this problem. Y chromosome haplogroups of Hunnu remains included Q-M242, N-Tat, C-M130, and R1a1. Recently, we analyzed three samples of Hunnu from Barköl, Xinjiang, China, and determined Q-M3 haplogroup. Therefore, most Y chromosomes of the Hunnu samples examined by multiple studies are belonging to the Q haplogroup. Q-M3 is mostly found in Yeniseian and American Indian peoples, suggesting that Hunnu should be in the Yeniseian family. The Y chromosome diversity is well associated with linguistic families in East Asia. According to the similarity in the Y chromosome profiles, there are four pairs of congenetic families, i.e., Austronesian and Tai-Kadai, Mon-Khmer and Hmong-Mien, Sino-Tibetan and Uralic, Yeniseian and Palaesiberian. Between 4,000-2,000 years before present, Tai-Kadai, Hmong-Mien, Sino-Tibetan, and Yeniseian languages transformed into toned analytic languages, becoming quite different from the rest four. Since Hunnu was in the Yeniseian family, all these four toned families were distributed in the inland of China during the transformations. There must be some social or biological factors induced the transformations at that time, which is worth doing more linguistic and genetic researches.

2042W

Admixture in the Pre-Columbian Caribbean. *J.C. Martinez-Cruzado[1], E.P. Tascón-Peñaranda[1], F. Curbelo-Canabal[1], T. Porrata-Doria[1], C. Eng[2], E.G. Burchard[2].* 1) Department of Biology, University of Puerto Rico at Mayagüez, Mayagüez, Puerto Rico; 2) Department of Bioengineering and Therapeutic Sciences, University of California at San Francisco, San Francisco, California.

The biological origin of the Caribbean aborigines that greeted Columbus is one of the most controversial issues regarding the population history of this region. Genome studies suggest an Equatorial-Tucanoan origin, consistent with the Arawakan language spoken by most natives of the region. However, the archaeological evidence suggests an early arrival from Mesoamerica, and their admixture with the more recent Arawak-speaking group stemming from the Amazon remains a possibility. The lineages comprehending most Puerto Rican samples belonging to haplogroups B1 and C1, which in turn encompass 44% of all Native American mtDNAs in the island, have an unambiguous South American origin. However, none of those belonging to haplogroup A2, encompassing 52% of all Native American mtDNAs, have been related to South America or any other continental region. To augment the scarce data from Mesoamerican countries other than Mexico, we present the complete mtDNA sequence of 6 Honduran samples belonging to distinct control region lineages in addition to 3 from the Dominican Republic and 3 from Puerto Rico. Interestingly, maximum likelihood phylogenetic reconstruction including 40 published haplogroup A2 sequence haplotypes from Mesoamerica, Central America and South America clusters 8 out of 10 Mesoamerican and Andean haplotypes in a deep rooted group, separate from, and excluding all Costa Rican, Panamian and Brasilian haplotypes, suggesting a relatively recent origin for Chibchan-Paezan and Amazonian groups. Furthermore, 4 of the 5 Greater Antillean A2 haplotypes are included in the deeply rooted Mesoamerican-Andean cluster. Moreover, the only Cuban haplotype in the literature and the remaining A2 haplotype from the Dominican Republic form even more deeply rooted private branches. Similarly, the only haplogroup C1d sample sequenced from the Dominican Republic forms a private branch with the deepest root in a maximum likelihood tree containing 19 additional C1d haplotypes from Mexico to Brasil plus the CRS. In conclusion, our preliminary results suggest that a substantial proportion of the Native American mtDNA lineages from the Greater Antilles do not share an Amazonian origin with the language their people spoke in 1492. Furthermore, the position of two Dominican lineages at the earliest split in both their respective trees suggests an early origin that could be explained by extensive lineage extinctions in Mesoamerica and the Andes or an origin in North America.

2043T

Resquencing of Australian Aboriginal mtDNA and Y chromosomes. *Y. Xue[1], M. Cerezo Fernandez[1], Y. Chen[1], S. McCarthy[1], MO. Pollard[1], Q. Ayub[1], N. Nagle[2], P. McAllister[3], RJ. Mitchell[2], C. Tyler-Smith[1].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Genetics, La Trobe University, Melbourne, Australia; 3) Griffith University, Gold Coast, Queensland, Australia.

Modern humans originated in Africa and spread across the rest of the globe 50-70 thousand years ago. The first identified divergence outside Africa was between the ancestors of the Australian Aborigines and some nearby populations on the one hand, and the ancestors of Asians, Europeans and other non-Africans on the other hand. The genetic characterization of this divergence and subsequent events in Australian Aboriginal history before the colonial era remain poorly described. Seven Australian Aboriginal males requested sequencing of their mitochondrial DNA (mtDNA) and Y chromosomes, and we generated high depth Illumina 100 bp paired-end sequence data. The average coverage is ~15-20x for Y chromosome and ~3000x for mtDNA. The mtDNAs of the samples belong to new branches of haplogroups P (5 individuals), M (1 individual) and O (1 individual). These haplogroups are known from Australia, but the many new variants illustrate their diversity and distinct origins. The Y chromosomes belong to haplogroups C (3 individuals), K* (3 individuals), both previously known from Australia, and M (1 individual). This last haplogroup has a restricted geographical distribution centred on Papua New Guinea, and illustrates a genetic link between Australia and that region. The ~3,000 new Y-SNPs present in these samples are permitting refined estimates of the ancient coalescence times between Australian lineages and those in the rest of the world, and re-examination of the hypothesis of more recent links between Australia and South Asia, originally based on Y-chromosomal similarities.

2044F

The possible role of social selection in the distribution of the "Proto-Mongolian" haplotype in Kazakhs, Kyrgyz, Mongols and other Eurasian populations. *M. Zhabagin[1,2], P. Tarlykov[3], Zh. Sabitov[4], H. Dibirova[5], A. Bogunova[6], I. Tazhigulova[7], S. Frolova[5], Zh. Isakova[8], A. Nimadava[9], I. Zakharov[2], O. Balanovsky[2,5].* 1) Center for Life Sciences, Nazarbayev University (Astana, Kazakhstan); 2) Vavilov Institute of General Genetics RAS (Moscow, Russia); 3) Research Centre of Medical Genetics RAMS (Moscow, Russia); 4) Gumilyov Eurasian National University (Astana, Kazakhstan); 5) The Komsomolsk-on-Amur State University (Komsomolsk-on-Amur, Russia); 6) National Center for Biotechnology (Astana, Kazakhstan); 7) Forensic science centre of the Ministry of Justice of the Republic of Kazakhstan (Astana, Kazakhstan); 8) Research Institute of Molecular Biology and Medicine (Bishkek, Kyrgyz); 9) Mongolian Academy of Sciences (Ulan Bator, Mongolia).

Social factors may be important contributors to reproductive success and determination of the selective survival of individuals. Therefore, social selection and other social factors are important for understanding population structure and its formation. The role of social selection on the distribution and formation of Y-chromosomal gene pool has been studied. There is a strong connection between social selection and birth rate of the descendants, whose fathers had achieved high social status during the expansion of the Mongol Empire and associated historical events. A total of 783 haplotypes, including 687 newly obtained and 96 retrieved from the literature were assigned to the haplogroup C3*-M217 (xM48) based on genotyping 17 Y-chromosomal STR markers. These haplotypes represent 11 populations of Eurasia: Kazakhs, Mongols, Kyrgyz, Telengits, Circassians, Balkar, Temirgoys, Karachai, Evenki, Kizhi and the Pashtuns. As the result, a major haplotype 13-16-25-15-16-18-14-10-22-11-10-11-13-10-21 (DYS389a-DYS389b-DYS390-DYS456-DYS19-DYS458-DYS437-DYS438-DYS448-GATA4-DYS391-DYS392-DYS393-DYS439-DYS635, N=94) was found to have 12.00% frequency within haplogroup C3*. This haplotype includes and extends the previously described 'star-cluster' haplotype. Noteworthy, the frequency of this major haplotype within haplogroup C3* was 16.80% in Kazakhs, 10.13% in Mongols and 2.63% in Kirgiz who are not considered as direct descendants of Genghis Khan. 35.10% of the major haplotype was represented by Kazakh tribe Ashamayly-Kerey, 17.02% by the Khalkh Mongols and 7.44% by the Barguts. Therefore, we suppose this major ancestral haplotype to be the "proto-Mongolian haplotype", inherited by Genghis Khan and his descendants. It is important to mention that Temujin belongs to Kiyat-Borjigin tribe that in turn is a branch of the bigger Borjigin tribe, part of the Khalkh Mongols. Thus, Genghis Khan might be considered as a carrier rather than founder of the star-cluster haplotype. He and his descendants are the ones who contributed to a positive effect of social selection in the distribution of this haplotype. Other examples are the Barguts, who had Genghis Khan's credit and were granted with a number of privileges, or the Kerey, based on the fact that Temujin had been brought up at the court of the Togrul Khan, belonging to the Kerey tribe.

2045W

Y-chromosome diversity in Mayan, Ch'ol, and Chontal populations from Campeche and Tabasco. *A. Quinto[2], M.A. Meraz[2], R. Camacho[1], T. Schurr[3], M. Vilar[3], G. Noris[4], C. Santana[4], J.B. Gaieski[3], A.C. Owings[3], R. Gómez[1].* 1) Dep. de Toxicología, Cinvestav-IPN, Mexico City, Mexico; 2) Dep. de Biomedicina Molecular, Cinvestav-IPN, Mexico City, Mexico; 3) Dept. Anthropology, Univ. Pennsylvania, Philadelphia, PA; 4) Laboratorio BIMODY, Querétaro, Qro., Mexico.

Mayan populations are the descendants of a Mesoamerican civilization that survived the Classic period collapse, the arrival of Spanish conquerors, and the European colonization of the Americas. Today, Mayan speakers (≈1.3 million inhabitants) present one of the two largest indigenous populations in Mexico, the other being the Náhua (≈1.6 millions inhabitants). The Mayan language family includes fourteen languages that are spoken in seven states of Mexico (Chiapas, Tabasco, Yucatán, Quintana Roo, Campeche, San Luis Potosí, and Veracruz). Although archeologically well understood, this complex cultural and linguistic region remains genetically understudied. Therefore, to assess the genetic diversity in Mayan populations and reconstruct historic patterns of interactions among Mesoamerican groups, we genotyped 112 males from 16 communities in the states of Tabasco (Ch'ol and Chontal) and Campeche (Mayans). The pattern of Y-chromosome haplogroup diversity in these populations was analyzed using published SNP and Y-STR genotyping methods, and the results compared with data from others Native American populations. Our Y-chromosome analysis revealed high haplotypic diversity in the study populations, with Mayans being the most diverse (0.9905 ± 0.0083), followed by Ch'ol (0.9316 ± 0.0386) and Chontal (0.9291 ± 0.0230). Haplogroup Q-M3 was the most frequent paternal lineage in all groups, suggesting a common ancestral origin for them. However Mayan populations also had significant European (~32%) admixture represented by haplogroups R1a, R1b, E1b1b, and T. In addition, Chontal and Ch'ol populations showed some admixture with Europeans with the presence of haplogroups E1b1b (11%) and J2 (5%), respectively. Our results suggest the Mayans of Campeche have experienced greater European admixture, whereas Chontal and Ch'ol populations have a much higher frequency of Amerindian Y-chromosomes.

2046T

Juxtapositions of short IBD blocks can cause biased estimation in inferences based on the length of IBD blocks.
C.W.K. Chiang[1], *J. Novembre*[2]. 1) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA; 2) Human Genetics, University of Chicago, Chicago, IL.

Blocks of identity-by-descent (IBD) play an important role in many modern genetic applications, including long-range phasing, imputation, genetic mapping, detection of natural selection, and demographic inferences. One commonly used definition of IBD blocks is that they are contiguous segments of the genome inherited from a recent shared common ancestor without intervening recombination. With programs like Beagle's fastibd, long IBD blocks (>1cM) can be efficiently detected using high-density SNP array data of a population sample. However, all programs detect IBD based on contiguous segments of identity-by-state (IBS). As such, detected IBD blocks could often be due to the juxtaposition of smaller IBD blocks inherited from different common ancestors. Here, we show the juxtaposition of small IBD blocks leads to an error in estimating the length distribution of IBD blocks and can affect downstream inferences. To demonstrate the prevalence of subsegment juxtapositions, we used coalescent simulations where we know the precise genealogy of the sample and found that >35% of the detected IBD segments of 1cM or longer are composed of at least two subsegments. In particular, 11% of the detectable segments consist of at least 1 other subsegment >25% of the total length, and this effect was more pronounced for detectable segments between 1 to 2cM long, compared to segments >2cM long. To demonstrate that the juxtaposition can lead to practical problems, we investigated the impact on a novel estimator of the de novo mutation rate using IBD blocks. We observed accurate estimates of the input mutation rate when true IBD blocks are used, but overestimates of the mutation rate by ~15 fold using inferred IBD blocks. When the effect of juxtaposition on the estimated age of the block was modeled, the mutation rate estimate improved greatly. Our results suggest that identifying IBD blocks based on extended IBS can inflate the length of IBD blocks, and in this case results in an inflated estimate of the de novo mutation rate, unless properly accounted for. This effect should be carefully considered as methods to detect shorter IBD blocks using sequencing data are being developed.

Improved detection of ancient hominin admixture in modern humans.
S.R. Browning[1], *B. Vernot*[2], *B.L. Browning*[1,2,3], *J.M. Akey*[2]. 1) Biostatistics, University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA; 3) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA.

The S* statistic [1] detects genomic segments with variants in unusually strong linkage disequilibrium (LD) indicative of ancient admixture with now-extinct hominins such as Neandertals. The detected introgressed haplotypes can be used to reconstruct archaic genomes which will facilitate the inference of important population genetics characteristics such as the effective population sizes of archaic populations, timing and parameters of introgression, and phylogenetic relationships of archaic groups.

S* looks for near complete LD between a subset of SNPs in a region, with penalties incurred when small numbers of haplotypes enter or leave the introgressed state [1]. Recombination events in humans since admixture are inherited which results in groups of haplotypes entering or leaving the introgressed state together. Instead of counting haplotypes, we count haplotype clusters in the Beagle model [2]. The haplotype cluster approach is particularly advantageous when the number of individuals being analyzed is large, because a large number of haplotypes entering/leaving the introgressed state may reflect a single recombination event that is represented by one haplotype cluster. A single recombination event should be penalized lightly, whereas multiple recombination events should be penalized heavily in the statistic.

To evaluate our method, we simulated sequence data using the model of [3]. In the simulated data, we find that haplotype clusters correlate closely with introgression status. Each haplotype cluster typically represents only introgressed or only non-introgressed haplotypes, even when haplotype phase information is not known a priori. In simulated data with 100 African reference samples and 500 European samples, we find 20% more introgressed regions using our haplotype clustering approach than with the standard S* approach, for the same false discovery rate. Incorporation of haplotype clustering into an S*-type statistic is useful for exploiting the increasing numbers of sequenced human genomes to find introgressed haplotypes.

2048W

The theoretical accuracy of deterministic approximations to coalescent formulas.
E.M. Jewett, N.A. Rosenberg. Biology, Stanford University, Stanford, CA.

Many coalescent distributions and expectations can be derived by conditioning on the number, n_t, of alleles at time t in the past that are ancestral to a data set of n_0 alleles sampled in the present. However, summing over the conditional distribution of n_t, given n_0, can be computationally challenging when n_0 is large. Thus, such formulas can be difficult to evaluate on modern genomic datasets with hundreds or thousands of sampled lineages. One alternative to conditioning on all possible values of n_t is to use an approximation in which n_t is assumed to equal its expected value $E[n_t]$ with probability one (Slatkin, 2000). This approximation greatly reduces the number of terms in conditional expressions, significantly reducing their computational complexity. However, despite the utility of the approximation, its theoretical accuracy is not known. Instead, the accuracy of any given version of the approximation must be evaluated empirically by comparing it with the true distribution. As a result, the accuracy of a given approximation cannot be known outside the range of parameter values over which the true distribution can be computed. Here, we show that approximate distributions converge uniformly to the true distributions under certain simple assumptions, and we derive an expression for the asymptotic approximation error. Our results provide a theoretical basis for understanding the ranges of parameter values over which any given approximation is accurate, facilitating the application of the approximation $n_t = E[n_t]$ to reduce the complexity of computing coalescent formulas on large genomic data sets.

2049T

DNA-based detection of Glucose 6-Phosphate Dehydrogenase (G6PD) deficiency alleles in an Eastern Caribbean population.
C. Gupta, L. Deschênes, C. Headland, I. McIntosh. American University of the Caribbean School of Medicine, Cupecoy, St. Maarten.

G6PD deficiency is the most common enzyme deficiency worldwide (~400 million cases) with highest prevalence in populations where malaria is endemic. G6PD is required to produce NADPH and maintain glutathione in the reduced state in red blood cells, and deficiency predisposes to haemolytic anaemia and neonatal jaundice in hemizygous males. The frequencies of deficiency alleles have been reported as 0.05 - 0.25 in African populations but have not been assessed in the Eastern Caribbean. We developed a noninvasive method to detect the major deficiency alleles through extraction of DNA from buccal cells, PCR amplification and identification of the deficiency alleles via restriction endonuclease digestion and gel electrophoresis. In a cohort self-reporting as African or Afro-Caribbean we identified two hemizygous males and two heterozygous females giving an overall G6PD deficiency allele frequency of 0.048. This result is at the lower end of the range reported previously for which we propose two possible explanations: (1) admixture in the population introducing European & Amerindian alleles (of note, the incidence of Hb-S and Hb-C alleles in this cohort was 0.086 c.f. 0.13 in previous studies of this population); (2) mutation-specific analysis would not detect other deficiency alleles which may be more common in this population.

Insights on the evolutionary history of Tibetans from whole-genome sequence data.
H. Hu[1], T. Simonson[2], G. Glusman[3], J. Roach[3], G. Cavalleri[4], M. Brunkow[3], M. McCormack[4], N. Petousi[5], P. Lorenzo[6], R. Gelinas[3], L. Jorde[7], J. Prchal[6], P. Robbins[5], C. Huff[1]. 1) Department of Epidemiology, UT MD Anderson Cancer Center, Houston, TX; 2) University of California, San Diego La Jolla, Division of Physiology, San Diego, CA; 3) Institute for Systems Biology, Family Genomics Group, Seattle, WA; 4) Royal College of Surgeons in Ireland, Molecular and Cellular Therapeutics, St Stephen's Green, Dublin 2, Ireland; 5) University of Oxford, Department of Physiology, Anatomy and Genetics, Oxford, OX1 3PT, United Kingdom; 6) University of Utah, Hematology, Salt Lake City, UT; 7) University of Utah, Department of Human Genetics, Salt Lake City, UT.

The Tibetan people inhabit the world's highest plateau, with an average altitude exceeding 4,500 meters. Over thousands of years Tibetans have evolved unique adaptations to this extreme environment, such as low oxygen levels. Here we report the first study of Tibetan evolutionary history from whole-genome sequence data. Using high-coverage whole-genome sequence data from 17 Tibetan and 9 Han Chinese individuals, we characterize recent admixture events and ancient demographic history of Tibetans from SNV allele frequency spectra data in the context of the Out of Africa and European/Asian divergence events. We restrict this analysis to genomic regions at least 10 kb away from exons or conserved regions to minimize the confounding effects of natural selection. Our results indicate that the Tibetan population diverged from the Han Chinese population much earlier than previously estimated from exome sequence analysis. We also detect evidence of an ancient admixture event from Han Chinese to Tibetans around 25,000 years ago, as well as substantial subsequent gene flow between Tibetan and Han Chinese populations. We utilize this demographic model to detect genomic signals of recent positive selection using the Composite of Multiple Signals (CMS) test. The CMS test identifies several genes previously implicated in Tibetan high-altitude adaptation, including EGLN1 and EPAS1. Our results provide a high-resolution map of the potential functional targets of recent positive selection in Tibetan genomes.

2051W

Identification of signals of recent selection in the Sea Island Gullah African Americans.
S.P. Sajuthi[1], J. Divers[1], Y. Huang[3], U. Nayak[3], W. Chen[3], K.J. Hunt[2], D.L. Kamen[2], G.S. Gilkeson[2], J.K. Fernandes[2], I.J. Spruill[2], C.D. Langefeld[1], W.T. Garvey[4], M.M. Sale[3], P.S. Ramos[2]. 1) Wake Forest University Health Sciences, Winston-Salem, NC; 2) Medical University of South Carolina, Charleston, SC; 3) University of Virginia, Charlottesville, VA; 4) University of Alabama, Birmingham, AL.

PURPOSE: Many common diseases are more prevalent in specific ethnic groups. Given the growing number of disease-associated loci in regions that show evidence of selection, identification of alleles under selection may provide insight into disease susceptibility. Relative to other African-Americans (AA), the AA Gullah population has lower European admixture and higher ancestral homogeneity from the Sierra Leone area in West-West Africa. We sought to capitalize upon the relative closeness between the Gullah and Sierra Leoneans to identify regions that differentiate both populations and may hence be under recent population-specific selective pressures. METHODS: We computed a linear regression model of the HapMap YRI principal component (PC2) as a quantitative outcome, using 277 Gullah and 400 Sierra Leonean samples genotyped on the Affymetrix Genome-Wide Human SNP Array 6.0. We adjusted for European admixture via inclusion of the CEU component (PC1) as a covariate. In total, 679,513 SNPs with MAF>5% were used in this analysis. In order to exclude spurious loci, only regions where at least one SNP met genome-wide significance (P<5E-10) and a second significant SNP (P<1E-07) in LD with it were considered. RESULTS: Nine regions met our criteria as those that best differentiate the Gullah from the Sierra Leonean. The most significant was a ~2 Mb region at Xq22.2-q22.3 around the IL1RAPL2 gene, where 4 SNPs had P<5E-10. Other regions included 3q12.3, 4q35.1, 6p23, the extended HLA at 6p22.1-21.32, 7p15.3, 10q11.22, 10q25.1, and 14q24.2. Four additional regions with at least 3 SNPs in LD with P<1E-07 within 1 Mb were identified. Consistent with the literature, our scan identified the HLA and other regions harboring multiple immune-related genes. CONCLUSION: We have identified several regions that differentiate the Gullah from the Sierra Leoneans, suggesting that recent selection may be operating at these loci. Given the relative homogeneity of the Gullah and their genetic proximity to Africans from Sierra Leone, identification of regions that might be under selection in the Gullah has the potential to elucidate disease risks in AA.

2052T

Population structure and selection pressures: short indels and structural variants from NGS in 250 Dutch trios.

While microarray data have contributed much to population genetics, the higher resolution of whole-genome sequence data is expected to yield new insights about population stratification, population history, the prevalence of selection pressures, and the identification of functional variants under selection. Ancestry differences in the Netherlands show clear geographic distributions, as previously mapped using principal component analysis (PCA) on microarray SNPs. Ancestry-informative PCs can reveal the consequences of population history, and can also be used to detect selection pressures and traces of migration (Abdellaoui et al, 2013). The Genome of the Netherlands (GoNL: http://www.nlgenome.nl/) is a whole-genome-sequencing project in a representative sample consisting of 250 family trios from all provinces in the Netherlands. Sequencing was done on the Illumina HiSeq 2000 platform at the Beijing Genomics Institute (BGI) on blood-derived DNA from uncultured cells and accomplished coverage was 14-15x. Several methodologies (read depth, read pair, de novo assembly, split-read alignment, and combined approaches) were applied for detection of short indels and different types and size ranges of structural variants (SVs), including deletions, large insertions, tandem duplications, inversions, mobile element insertions and translocations. PCA on short common indels revealed two PCs that show regional differences that were not previously observed, in addition to two PCs showing regional differences previously captured with microarray SNPs (differentiating between North and South, and between East and West). Functional variants under selection (and thus with important phenotypic consequences) can be identified by comparing the distribution of alleles between the subpopulations identified by the PCs. Similar analyses are currently being undertaken for additional types of rare and common SVs as well as a combined set of short indels and SVs. The old tripartite linguistic subdivision of Native Americans into three major groups has been revived by recently reported patterns of nuclear genome diversity indicating that Native Americans descend from three streams of Asian/Beringian gene flow. Although this scenario was suggested by early mitochondrial DNA (mtDNA) data, neither this model, nor the alternative scenarios have been fully evaluated by employing entire mitochondrial genomes. In this study we focused our attention on two North American mtDNA haplogroups, known as A2a and B2a. Analyses of B2a mitogenomes, which are absent in Eskimo-Aleut- and northern Na-Dene-speakers, revealed that this haplogroup arose in North America ≈11-13 thousand years (ka) ago from one of the founder Paleo-Indian B2 mitogenomes. In contrast, haplogroup A2a, which is typically found among Eskimo-Aleuts and Na-Dene, but also present in the easternmost Siberian groups, originated only 4-7 ka ago in Alaska, led to the first Paleo-Eskimo settlement of northern Canada and Greenland, and contributed to the formation of the Na-Dene gene pool. However, mitogenomes also show that Amerindians from northern North America, without distinction between Na-Dene and non-Na-Dene, were heavily affected by an additional and distinctive Beringian genetic input. In conclusion, most of the contemporary mtDNA variation observed along the double-continent stems from the first wave that from Beringia followed the Pacific coastal route and is dated to ≈15-18 ka ago based on the 16 mitogenome founders identified so far. This was accompanied or followed by a second inland migratory event, marked by haplogroups X2a and C4c, which affected all Amerindian groups of Northern North America. Considerably later, the ancestral A2a carriers spread from Alaska undertaking both a westward migration to Asia and an eastward expansion into the circumpolar regions of Canada. Thus, the First American founders left the greatest genetic mark but the original maternal makeup of North American Natives was subsequently reshaped by additional inputs and local population dynamics, making even a three-wave view too simplistic.

2054W

Data from extended 1000 Genomes phase I populations refine comparison of X-linked and autosomal population genetic patterns. *L. Arbiza[1], S. Gottipati[1], A. Siepel[1], A.G. Clark[1,2], A. Keinan[1].* 1) Dept. of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Dept. of Molecular Biology and Genetics, Cornell University, Ithaca, NY.

Contrasting the patterns of variability on human chromosome X and the autosomes has grown in power and informativeness with the rapid expansion of whole-genome sequence data. Such a comparison can shed light on demographic processes, differences in the histories of males and females, and the past action of natural selection. Previous studies were based on either genotyping data sets, a small set of resequenced loci in six populations, or genomic sequencing data from at most two populations. These studies leave several open questions. Most notably, to what extent do genome-wide patterns generalize to additional populations? Previous studies also differed in their approaches and population genetic measures, which has led to apparent discrepancies among results. For example, estimates of population differentiation (F_{ST}) reflect more recent patterns of variation ~since the time of split of the specific populations compared~ than nucleotide diversity (π), which captures more ancient epochs. To address these questions and extend our previous results, we capitalized on the 1000 Genomes phase I data, consisting of 14 populations from four ancestry-based continental groups. We improved on our methodology for normalizing X-linked and autosomal π by genetic divergence from different outgroups. To obtain refined resolution of different epochs and disentangle previous results, we also estimated F_{ST} between each pair of populations and compared the level of differentiation of X-linked and autosomal SNPs along each branch in the population tree. These analyses point to three results: (1) While less sensitive to more recent demographic events than estimates of population differentiation, estimates of π support a reduction of the ratio of X-linked to autosomal effective population size (X/A) in non-African compared to African populations. (2) A wide array of models of human demographic history compiled from the literature only partially predict the magnitude of this observed X/A reduction, supporting the need to invoke additional factors such as sex-biased events during the out-of-Africa dispersal. (3) F_{ST} results provide further evidence and accentuate these observations, additionally pointing to variability across different branches, and suggesting changes in mating patterns through human history. Finally, beyond demographic inference, we characterize the relative effect of selection on X and A in different epochs by studying F_{ST} as a function of distance from genes.

2055T

Population differentiation of two Brazilian populations inferred from non-genic Alu insertions and microsatellites of the Class I Major Histocompatibility Complex. *A.C. Arcanjo[1], H.A. Sakata[3], R.C.P. Toledo[1], E.C. Castelli[2], H.R. Magaldi[5], J.A. Peña[4], S.F. Oliveira[1,3].* 1) Biologia Animal Post-Graduate Program, Institute of Biology, University of Brasília, Brasilia, Distrito Federal, Brazil; 2) Department of Pathology, School of Medicine of Botucatu, University of the State of Sao Paulo, Botucatu, Sao Paulo, Brazil; 3) Department of Genetics and Morphology, Institute of Biology, University of Brasilia, Brasilia, Distrito Federal, Brazil; 4) Department of Genetics, Physical Anthropology and Animal Physiology, Faculty of Science and Technology, University of the Basque Country, Bilbao, Spain; 5) Biologia Molecular Post-Graduate Program, Institute of Biology, University of Brasilia, Brasilia, Distrito Federal, Brazil.

Genetic markers located in important genomic regions, such as genes or regulatory sequences, are most commonly affected by natural selection and thereby behave very differently from neutral regions of the human genome. The human MHC (6p23.1) is a region of great importance due to the presence of genes related to action and regulation of the human immune system. Several studies have reported that natural selection might be acting upon its genes, but few have reported the behavior of non-genic elements in such region. Aiming to infer whether this region is under selection, and not solely its genes, this study intended to evaluate the behavior of the Class I MHC region based on Alu insertions and STR markers located nearby but not within the genes in two Brazilian populations. These populations have shown to be very different regarding neutral markers of the genome. 122 samples from two distinct populations, an urban admixed population (Brasília, 65 samples) and an afro-derived rural population (Kalunga, 57 individuals) were studied for the loci AluMICB, AluTF, AluHJ AluHG e AluHF and D6S272, D6S2690, D6S2705, D6S478 and D6S2707. The fragments were amplified by PCR and statistics based on allelic frequencies were obtained with the Arlequin 3.5 and Genepop 4.1 softwares. Deviations from neutrality were inferred with the Slatkin's Implementation of Ewens-Waterson Neutrality Test within the PyPop 0.7.0 software. Both populations showed deviations from Hardy-Weinberg's Equilibrium for the locus D6S2705, probably due to the biggest quantity of missing data for this locus. AluHG showed heterozygote excess even in accordance with HWE, which may indicate influence of evolutionary mechanisms due to its proximity to HLA-G gene. Even considering the different rates of mutation among microsatellites and Alu insertions, both sets of markers indicate that the populations are similar and show little population divergence, in contrast to previous studies regarding neutral markers and Class III MHC microsatellites. The Ewens-Watterson Neutrality test indicated that the D6S478 and D6S2707 loci do not behave neutrally when analyzed and this could be due to the proximity of HLA-G gene, which has already shown deviations from neutrality. These results indicate that the Class I MHC is probably under selection and the genetic markers studied behave very differently than neutral markers of the genome in the studied populations.

2056F

Y chromosomal sequences from southern Africa allow direct comparison of paternal and maternal prehistories. *C. Barbieri[1], S. Lippold[1], R. Schröder[1], S.W. Mpoloka[2], M. Stoneking[1], B. Pakendorf[3].* 1) Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany; 2) Department of Biological Sciences, University of Botswana, Gaborone, Botswana; 3) Laboratoire Dynamique du Langage, UMR5596, CNRS and Université Lyon Lumière 2, Lyon, France.

Comparisons of mtDNA and non-recombining Y-chromosome (NRY) variation can be quite informative about sex-biased differences in human demographic history such as population size variation, unbalanced gene flow after contact, and different origins and migration routes; yet NRY analyses are hampered by the common use of ascertained haplogroup defining SNPs, which precludes the possibility to perform many demographic analyses of NRY variation. Recently we developed a capture-based method for enriching Illumina sequencing libraries for about ~500 kb of NRY sequence which overcomes limitations of SNP-based typing of NRY variation and allows direct comparisons to complete mtDNA genome sequences. We applied this method to a broad DNA collection of ~300 southern African samples predominantly centered on the so-called Khoisan, which was previously analyzed for complete mtDNA genome sequences as well as for autosomal SNPs. Preliminary results show a high level of NRY variation and the presence of highly divergent haplotypes. Our dataset will be compared to the complete mtDNA genome sequences from the same dataset as well as to comparable Y chromosome sequence data generated for other African populations of the CEPH panel, to frame the variability of Khoisan groups within the continent. In particular, we will investigate the extent of sex-biased admixture among groups, the potential contribution of East African pastoralists to southern African groups, and the comparative demographic history of maternal and paternal lineages in southern Africa.

2057W

Population structure in five Mennonite communities. *K.G. Beaty[1], P.E. Melton[2], M.J. Mosher[3], M.H. Crawford[1].* 1) Department of Anthropology, University of Kansas, Lawrence, KS; 2) Center for Genetic Origins of Health and Disease, University of Western Australia, Perth, Australia; 3) Department of Anthropology, Western Washington University, Bellingham, WA.

Mennonites are a branch of the Anabaptists religious groups that formed in Europe during the time of the Reformation. Those who followed Menno Simmons, the Dutch-North German branch, were later known as Mennonites, and this group later fled from the Netherlands and Germany during the 16th Century to Prussia, and in the 1850s came to the United States. The movement and genealogical history of this group has been well documented and indicate population fissions along familial lines after arrival in the United States. This project examines Y-STR profiles consisting of 17 loci from 94 males from the Kansas Mennonite communities of Alexanderwohl (n=13), Lonetree (n=20), Gardenview (n=15), and Meridian (n=25), as well as a community of Mennonites from Henderson, Nebraska (n=21). The most prevalent haplotype in all communities was R1b, which represented 56% of the lineages in the entire sample, with other haplogroups represented in frequencies below 10% including E1b, G2a, I1, I2, J2, L, Q, and R1a. There are no shared Y-STR haplotypes between the communities and haplogroup frequencies vary considerably between populations, supporting the historical evidence that original migrating groups split along familial, and specifically, paternal lines upon arrival to the United States. The Alexanderwohl and Henderson communities, which spilt off from group that migrated from the Ukraine in 1874, are the only two communities with Haplogroups G2a and J2a1. The Meridian community, a heterogenous group believed to be an amalgamation of Swiss, German, and Dutch Mennonites as well as Amish, is represented by 8 haplgroups, including haplogroups L found only in Meridian and a high frequency of E1b1b (12%) when compared to the other populations. It also has a mean number of pairwise differences of 9.3090 (+/- 4.2857) and gene diversity of 0.9621 (+/- 0.0007), higher than any other Mennonite community. Lonetree, differs from the other communities in its high frequency of haplogroups R1a (20%), while Gardenview differs from the other communities with a high frequency of haplgroup I2a (33.4%). Overall, the Y-STR profiles of these groups support the documented movement, fission, and in the case of Meridian, fusion, of Mennonite communities after their arrival to the United States.

2058T

Identity by descent segment detection in sequence data. *B.L. Browning[1,2,3], S.R. Browning[2].* 1) Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 2) Biostatistics, University of Washington, Seattle, WA; 3) Genome Sciences, University of Washington, Seattle, WA.

Chromosome segments shared by inheritance from a recent ancestor without recombination are said to be identical by descent. Segments of identity by descent (IBD) are ubiquitous in population samples. Detection of these segments is useful for a variety of applications including analysis of fine-scale population structure and inference of recent effective population size. Existing methods for IBD segment detection were designed for SNP array data. Sequence data can differ strongly from SNP array data in density of variants, allele frequency spectrum and genotype error rates. We investigate the performance of IBD detection methods with sequence data; we present a new IBD detection method, IBDseq, that is specifically designed for sequence data; and we apply IBDseq to autosomal whole genome sequence data for 2400 individuals from the UK10K project.

With IBDseq we do not model LD or haplotype phase, but instead thin variants to eliminate strong inter-variant LD. This is because much of the information for IBD detection in sequence data comes from the large number of low frequency variants which are difficult to phase and tend not to be in high linkage disequilibrium (LD) with other variants. Genotype error is explicitly modeled in IBDseq because current sequence data can have relatively high error rates compared to SNP array data, and because recent mutations can disrupt allelic identity in IBD segments. To reduce computation time, IBDseq calculates maximal subsequence scores rather than employing a full hidden Markov model, and it uses multi-threading to take advantage of multi-core compute nodes. We compare IBDseq to Refined IBD, Germline and PLINK on realistic simulated sequence data. IBDseq has higher power than the other methods, particularly for detection of very short (<1 cM) segments. In UK10K project sequence data on 2400 individuals, IBDseq finds 444 million IBD segments with a median length of 0.49 cM.

2059F

Synthesizing genetic and genealogical data to trace historical waves of European and African immigration to the United States. *J.K. Byrnes[1], J.M. Granka[1], K. Noto[1], R.E. Curtis[2], Y. Wang[1], M.J. Barber[1], N.M. Myres[2], C.A. Ball[1], K.G. Chahine[2].* 1) Ancestry.com DNA L.L.C., 153 Townsend St., Ste. 800, San Francisco, CA; 2) Ancestry.com DNA L.L.C., 360 West 4800 North, Provo, UT.

Census data can reveal waves of immigration, with immigrants from a single source population migrating to roughly the same U.S. locations within a short period of time. A refinement of the timings and locations of migratory waves using genetic and genealogical data would be useful not only for understanding the peopling of the U.S., but also for understanding patterns of genetic disease risk. To examine migratory waves using genealogical and genetic data, we first identify 'IBD-enriched groups': groups of U.S. AncestryDNA customers who share elevated amounts of DNA identity-by-descent (IBD) with a reference panel of individuals with known deep ancestry from a single location. Elevated IBD with individuals from one location could indicate a source population from which ancestors of a customer originated. As a proof of principle, for individuals in a group that is IBD-enriched for a particular location, we search for an enrichment of ancestors born in this location across the collection of their pedigrees. Then, for each IBD-enriched group, we search the collection of pedigrees for enrichment of more recent birth locations, representing migratory destinations within the U.S. Among over 100,000 U.S. AncestryDNA customer samples, we identify IBD-enriched groups who have elevated IBD with more than 20 European countries and seven West African population groups. For each IBD-enriched group, we present maps showing patterns of ancestor birth location enrichment through time. As expected, customers in an IBD-enriched group to a particular location have an enrichment of ancestor births in that location, though this enrichment is dependent on pedigree completeness (e.g. it is rare for African Americans to have known ancestors from West Africa in their pedigrees). For some punctuated migratory waves, such as the arrival of Norwegian immigrants in the Midwest during the 19th century, clear signals of both source and migratory destinations are visible. These locations are temporally ordered, with ancestors from the migratory destination appearing more recently in the pedigrees than ancestors from the source location. Finally, we are able to pinpoint the age and origin of particular haplotypes defining IBD-enriched groups. With our approach, we demonstrate that we can estimate individual ancestral origins and detail human migratory history by jointly studying estimates of genetic relatedness along with genealogical data.

Population demography and maternal history of Oceania. *A.T. Duggan[1], B. Evans[2], M. Kayser[3], R.J. Trent[4], D.A. Merriwether[5], G. Koki[6], F.R. Friedlaender[7], J.S. Friedlaender[7], M. Stoneking[1].* 1) Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig, Sachsen, Germany; 2) College of Asia and the Pacific, Australian National University, Canberra, Australia; 3) Department of Forensic Molecular Biology, Erasmus MC - University Medical Center Rotterdam, The Netherlands; 4) Sydney Medical School, University of Sydney, Sydney, NSW, Australia; 5) Department of Anthropology Binghamton University Binghamton, NY, USA; 6) Institute for Medical Research, Goroka, EHP, Papua New Guinea; 7) Department of Anthropology, Temple University, Philadelphia, PA, USA.

We present a large-scale study of mtDNA diversity across Near and Remote Oceania with whole-genome mtDNA sequencing and a sample collection of more than 1,300 individuals spanning from the Bismarck Archipelago in the west to the Cook Islands in the east. As the location of at least two major migration events (initial colonization over 40,000 years ago, followed by an expansion of Austronesian-speaking migrants around 3,500 years ago), Oceania provides a unique opportunity to study the effects of population admixture. Our results support the idea of sex-biased admixture between the resident populations and the migrants of the Austronesian expansion. We find that haplogroups of putative Asian origin which are thought to have spread with the Austronesian expansion are found at high frequency in all but two populations and, in general, we see little evidence of distinction between Papuan and Austronesian speaking populations. Santa Cruz, which is part of the Solomon Islands but geographically distinct from the main island chain and considered part of Remote Oceania, has long been considered a linguistic oddity and is now accepted to represent a very deep branch in the Oceanic language family. We find that it is also a genetic outlier, with potential direct connections to the Bismarck Archipelago not evident in the main Solomon Islands chain. In this expanded dataset, we find additional evidence of instability and increased heteroplasmy at the 'Polynesian motif' position 16247, further confirming previous findings restricted to the Solomon Islands.

2061T

The Saudi Arabian Genome Reveals a Two Step Out-of-Africa Migration. *J.J. Farrell[1], A.K. Al-Ali[2], L.A. Farrer[1], A.N. Al-Nafaie[3], A.M. Al-Rubaish[4], E. Melista[1], Z. Naserullah[5], A. Alsuliman[6], P. Sebastiani[7], M.H. Steinberg[1], C.T. Baldwin[1].* 1) Department of Medicine, Boston University School of Medicine, Boston, MA; 2) Department of Clinical Biochemistry, College of Medicine, University of Dammam, Dammam, Kingdom of Saudi Arabia; 3) Department of Hematology, College of Medicine, University of Dammam, Dammam, Kingdom of Saudi Arabia; 4) Department of Internal Medicine, College of Medicine, University of Dammam Dammam, Kingdom of Saudi Arabia; 5) Department of Pediatrics, Maternity & Child Hospital, Dammam, Kingdom of Saudi Arabia; 6) Department of Hematology, King Fahd Hospital, Hafof, Al-Ahsa, Kingdom of Saudi Arabia; 7) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Here we present the first high-coverage whole genome sequences from a Middle Eastern population consisting of 14 Eastern Province Saudi Arabians. Genomes from this region are of interest to further answer questions regarding 'Out-of-Africa' human migration. Applying a pairwise sequentially Markovian coalescent model (PSMC), we inferred the history of population sizes between 10,000 years and 1,000,000 years before present (YBP) for the Saudi genomes and an additional 11 high-coverage whole genome sequences from Africa, Asia and Europe.

The model estimated the initial separation from Africans at approximately 110,000 YBP. This intermediate population then underwent a long period of decreasing population size culminating in a bottleneck 50,000 YBP followed by an expansion into Asia and Europe. The split and subsequent bottleneck were thus two distinct events separated by a long intermediate period of genetic drift in the Middle East. The two most frequent mitochondria haplogroups (30% each) were the Middle Eastern U7a and the African L. The presence of the L haplogroup common in Africa was unexpected given the clustering of the Saudis with Europeans in the phylogenetic tree and suggests some recent African admixture. To examine this further, we performed formal tests for a history of admixture and found no evidence of African admixture in the Saudi after the split. Taken together, these analyses suggest that the L3 haplogroup found in the Saudi were present before the bottleneck 50,000 YBP. Given the TMRCA estimates for the L3 haplogroup of approximately 70,000 YBP and the timing of the Out-of-Africa split, these analyses suggest that L3 haplogroup arose in the Middle East with a subsequent back migration and expansion into Africa over the Horn-of-Africa during the lower sea levels found during the glacial period bottleneck.

These results are consistent with the hypothesis that modern humans populated the Middle East before a split 110,000 YBP, underwent genetic drift for 60,000 years before expanding to Asia and Europe as well as back-migration into Africa. Examination of genetic variants discovered by Saudi whole genome sequencing in ancestral African populations and European/Asian populations will contribute to the understanding human migration patterns and the origin of genetic variation in modern humans.

The CARTaGENE Genomics Project : Population structure, local ancestry contributions and relatedness analysis of the French Canadian founder population. *H. Gauvin[1,2], Y. Idaghdour[1], J. Hussin[1], J.-P. Goulet[1], J.-C. Grenier[1], M. Capredon[1], A. Hodgkinson[1], T. de Malliard[1], V. Bruat[1], E. Gbeha[1], E. Hip-Ki[1], P. Awadalla[1,3].* 1) Sainte-Justine Hospital Research Center, Université de Montréal, Montreal, Canada; 2) Department of Social and Preventive Medicine, Université de Montréal, Montreal, Canada; 3) Department of Pediatrics, Université de Montréal, Montreal, Canada.

The province of Quebec was colonized four hundred years ago by settlers coming from France. In the early settlement of Quebec, some First Nations populations were allied to French settlers and exchanged genetic material as the result of mixed unions between an aboriginal mother and a French father. After the British Conquest, the rapidly expanding French Canadian population generally grew in relative isolation with limited exchange with British, and other incoming populations such as Acadians and Loyalists. The colonization of the territory took place in successive waves leading to regional founder effects contributing to the uniqueness of the French Canadian population. Today, about 80% of the province's 8 million inhabitants are French speaking. Starting in 2010, over 30,000 people from the province of Quebec were recruited to be a part of the CARTaGENE project. Genotyping data (Illumina Omni2.5M) was generated for ~1000 participants sampled in three distinct regions of the province: the Montreal area, the Quebec City area and the Saguenay region. We use the genotypes to study regional differentiation due to demographic history, admixture and migration patterns within Quebec. We analyze identity by descent (IBD) segments to infer relatedness between participants and trace back regional populations flow inside Quebec. Inferred IBD segments are also analyzed to attest their ancestral origin and their breakpoints are compared to recent and ancestral recombination breakpoints across the genome. We also investigate local ancestry of participants with a panel consisting of Native American and European populations. Specifically, we (i) identify regions of the genome shared between individuals and inherited from common ancestors; (ii) characterize IBD tracts in relation to recombination map and (iii) infer local ancestry across the genome to quantify the relative contributions of the different populations. This work refines previous analysis of population structure in Quebec, provides a more accurate picture of how the different populations contributed to the actual French Canadian genetic pool and gives insight on how their contribution is linked to mutations causing differences in disease prevalence throughout regions of Quebec.

2063W

Reconstruction of Ancestral Human Genomes from Genome-Wide DNA Matches. *J.M. Granka[1], R.E. Curtis[2], J.K. Byrnes[1], M.J. Barber[1], N.M. Myres[2], K. Noto[1], Y. Wang[1], C.A. Ball[1], K.G. Chahine[2].* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Provo, UT.

Individuals who lived long ago may still have much or all of their genome present in modern populations. The genomes of these individuals exist in small segments broken down by recombination and inherited in part by his or her descendants. If such an individual had many children, leading to a large number of descendants today, much of the ancestral genome will be present in modern populations. For the pairs of descendants with the 'target' ancestor as their most recent common ancestor (MRCA), any region of their genomes shared identical-by-descent (IBD) most likely represents the corresponding region of the ancestor's genome. Given a set of pairs of individuals linked to the same MRCA, we develop a novel computational approach to reconstruct the haplotypes of the MRCA from the IBD segments and haplotypes of the descendants. With simulated data we assess the performance of our method, affected by factors such as quality of genealogical trees used to infer the MRCA, reliability of inferred IBD, coverage of IBD segments, number of descendants of the MRCA, and number of sampled descendants. To demonstrate the utility of our method, we examine over 125,000 individuals in the AncestryDNA database with phased genome-wide single nucleotide polymorphism data and detailed genealogical information. After first identifying regions of the genome shared IBD between all individuals, we selected one group of several hundred individuals with an 18th century couple as a known MRCA. Using our method to tile together these individuals' IBD segments, we are able to reliably construct the ancestral couple's four haplotypes in large genomic regions with high coverage of IBD segments. In regions of the genome with lower IBD coverage, we are unable to identify and construct all haplotypes with certainty. Our study demonstrates the possibility of reconstructing the genomes of human ancestors, with large family sizes and a large number of living descendants, who lived one to even 12 generations ago. The ability to reconstruct the genomes of human ancestors using genetic and genealogical data has exciting implications in the fields of population genetics, medical genetics, and genealogy research.

The population history of African and Caribbean vervet monkeys inferred from 130 whole-genome-sequenced samples. *Y. Huang[1], H. Svardal[2], C.A. Schmitt[1], A.J. Jasinska[1], J. Wasserscheid[3], N. Juretic[3], Y.J. Jung[1], M. Muller-Trutwin[4], B. Jacquelin[4], M. Antonio[5], M. Dione[5], J.P. Grobler[6], R.K. Wilson[7], K. Dewar[3], W. Warren[7], G. Weinstock[7], T.R. Turner[6,8], M. Nordborg[2], N.B. Freimer[1], First two authors contributed equally.* 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 2) Gregor Mendel Institute, Austrian Academy of Sciences, Vienna, Austria; 3) McGill University and Genome Quebec Innovation Centre, Montréal, Canada; 4) Virology Department, Institut Pasteur, Paris, France; 5) Medical Research Council, Fajara, The Gambia; 6) Department of Genetics, University of the Free State, Bloemfontein, South Africa; 7) The Genome Institute at Washington University in St. Louis, St. Louis, MO, 63108; 8) Department of Anthropology, University of Wisconsin-Milwaukee, Milwaukee, WI, 53201.

Vervet monkeys (genus *Chlorocebus*; African green monkey) are Old World monkeys widely distributed in sub-Saharan Africa and subsequently introduced to the Caribbean. Vervets are broadly used in biomedical research, but there has been relatively few genetic studies and their taxonomy is disputed. Understanding their population genetic history, including genetic relationship among vervet subspecies, is essential for designing association studies of quantitative traits and for elucidating host-pathogen relationships, e.g., with simian immunodeficiency virus (SIV). To investigate vervet population genetics, we have carried out whole genome sequencing of 130 monkeys representing five African subspecies and three Caribbean populations. Our results, from both global ancestry analysis and comparisons of allele frequencies are concordant with the historical literature, in suggesting that the Caribbean populations derive from West African *sabaeus* monkeys. The significantly slower decay in linkage disequilibrium in the Caribbean samples, compared to those from their presumed ancestral population (from the Gambia), support the hypothesis that currently large Caribbean populations experienced a severe bottleneck at the time of their founding. On the African continent, as predicted by the isolation by distance model, the global ancestry result using whole-genome polymorphism data revealed a pattern of relatedness between vervet subspecies that reflects their current geographic distribution. In the classification of the subspecies *cynosuros*, the genetic data suggest a differing phylogeny from that proposed by most standard taxonomies. Additionally, these data indicate patterns of genetic clustering between monkeys sampled at different locations corresponding closely to patterns of variation in SIV sequences observed in samples from the same monkeys, suggesting longstanding co-evolution between host and pathogen. Past population size changes of the subspecies, inferred from the time to the most recent common ancestor distribution along the autosomes, suggested that they started to diverge from each other ~500,000 - 2,000,000 years ago. The results improve our understanding of vervet population history, providing a foundation for investigation of biomedically important traits.

2065F

The Sherpa and Tibetans share a common genetic history and adaptations to high-altitude. *C. Jeong[1], D.B. Witonsky[1], G. Alkorta-Aranburu[1], B. Basnyat[2], M. Neupane[2], J.K. Pritchard[1,3], C.M. Beall[4], A. Di Rienzo[1].* 1) Department of Human Genetics, University of Chicago, Chicago, Illinois, United States of America; 2) Nepal International Clinic, Kathmandu, Nepal; 3) Howard Hughes Medical Institute, Chevy Chase, Maryland, United States of America; 4) Department of Anthropology, Case Western Research University, Cleveland, Ohio, United States of America.

The Sherpa are an ethnic group in Nepal, traditionally living in high-altitude (HA) regions of the Himalayas. Linguistic and historical evidence indicates a close relationship with Tibetans. Furthermore, they share with Tibetans a low concentration of hemoglobin, a key physiological adaptation to HA hypoxia. These findings suggest that the Sherpa and Tibetans constitute closely related branches of the East Asian (EA) populations sharing phenotypic HA adaptations. To develop this idea further, we studied the genetic history of the Sherpa in relation to other Asian populations. First, we asked if the Sherpa are genetically distinct by comparing genome-wide genotyping data of 69 Sherpa native residents at 3800m with the Human Genome Diversity Panel data using principal component analysis (PCA) and ADMIXTURE. These show that the Sherpa genome contains a large portion of a genetic component clearly distinguishable from lowland EA populations. Sherpa individuals have neither South nor Central Asian genetic components and they are tightly clustered with other EA individuals in the global PCA plot. Second, we inferred a past population size change of the Sherpa by applying the pairwise sequential Markovian coalescence method to whole genome sequences (27-30x) of two males. We compared the Sherpa results with those of Han and Dai individuals, which were sequenced at similar depth (Meyer et al, 2012). This comparison suggests an early split of the Sherpa and lowland EA populations about 20,000-30,000 years ago and no evidence for the recent population expansion that characterizes the history of other EA populations. We estimate the effective population size of the Sherpa after the split at about 4,000 individuals. Third, a maximum-likelihood tree of EA populations supports a branch consisting of the Sherpa and Tibetans (from Yunnan Province of China; Beall et al, 2010). Last, we found that 21 of 36 EPAS1 (endothelial PAS domain-containing protein 1) gene SNPs with a significant association with hemoglobin level in a previous study of Tibetans (Beall et al, 2010) also show an association with nominal $p < 0.05$, all of which have the same direction of allelic effect as in Tibetans. The estimated effect sizes also match the Tibetan results. To summarize, our findings support a shared genetic history and genetic adaptation to HA of the Sherpa and Tibetans.

2066W

The Genetic Architecture Of Skin Pigmentation In Southern Africa. *A.R. Martin[1], J.M. Granka[2], C.R. Gignoux[3], M. Möller[4], C.J. Werely[4], J.M. Kidd[5], M.W. Feldman[6], E.G. Hoal[4], C.D. Bustamante[1], B.M. Henn[7].* 1) Stanford University, Genetics Department, Stanford, CA; 2) Ancestry.com, San Francisco, CA; 3) University of California, Pharmaceutical Sciences, San Francisco, CA; 4) Stellenbosch University, Health Sciences, Tygerberg, South Africa; 5) University of Michigan, Department of Human Genetics, Ann Arbor, MI; 6) Stanford University, Department of Biological Sciences, Stanford, CA; 7) SUNY, Deptartment of Ecology and Evolution, Stony Brook, NY.

Skin pigmentation is one of the most recognizably diverse phenotypes in humans across the globe, but its highly genetic basis has mainly been studied in northern European and Asian populations. The Eurasian pigmentation alleles are among the most differentiated variants in the genome, suggesting strong positive selection for light skin pigmentation. Light skin pigmentation is also observed in the far southern latitudes of Africa, among KhoeSan hunter-gatherers of the Kalahari Desert and other populations. The KhoeSan hunter-gatherers, believed to have diverged from other populations 100,000 years ago, maintain extraordinary levels of genetic diversity, but it is unknown whether light skin pigmentation represents convergent evolution or the ancestral human phenotype. We have collected saliva samples, ethnographic information, and pigmentation phenotypes from 123 individuals in the ≠Khomani San from the Kalahari. To understand the genetic basis for light skin pigmentation, we have genotyped and exome sequenced 91 ≠Khomani San individuals to high coverage, generating one of the largest indigenous African exome datasets sequenced outside of 1000 Genomes. Because linkage disequilibrium decay is rapid in this population, we have assessed parameters influencing phasing and imputation accuracy since ideal reference panels do not exist. We have also pursued multiple genotype/phenotype mapping methods, including a mixed model approach, admixture mapping, and linkage mapping. After controlling for admixture from European and Bantu-speaking populations, we find that globally common variants are not significantly associated with pigmentation. Rather, our results indicate that there are a multitude of rare variants in known pigmentation genes, and suggest that previously unidentified genes acting in canonical pigmentation pathways may be involved. Our results highlight the strength of diverse population studies to explain phenotypic variation in the context of human evolutionary history.

2067T

A Novel Likelihood Ratio Test for Sex-Bias and the Effect of Cryptic Sex-Bias on the Estimation of Demographic Parameters. *S. Musharoff[1], S. Shringarpure[1], C.D. Bustamante[1], S. Ramachandran[2].* 1) Genetics, Stanford Univ Sch Medicine, Stanford, CA; 2) Ecology and Evolutionary Biology, Brown University, Providence, RI.

Sex-bias is defined as an unequal number of breeding males and females in a population. This can be caused by variance in reproductive success, demographic events involving unequal numbers of males and females, and/or differential selection at sex-linked genomic loci. We present a novel likelihood ratio test for sex-bias in a single population based on the Poisson random field model. Our test has more power to detect a sex-biased demographic event from unlinked or partially linked sites than the commonly-used test statistic Q (the ratio of neutral genetic diversity estimated from the X chromosome to that estimated from the autosomes). We further develop a test for homogeneity of sex-bias in a set of populations and compare its power to the test statistic Q (here, defined in terms of Fst). We apply our tests for sex-bias to whole-genome, exome, and SNP data from globally distributed human populations and compare our results to those from previous studies. In addition to being of fundamental interest, the presence of sex-bias affects demographic inference. Sex-bias, either in the male or female direction, decreases the effective population size of the X chromosome as well as the autosomes of a population. If this reduction in effective population size is not accounted for, demographic parameters estimates (e.g., bottleneck times or divergence times) will be inflated. We assess the effect of cryptic sex-bias on the estimation of demographic parameters using simulated genomic data. We then estimate demographic parameters jointly from the X chromosome and the autosomes from the dataset described above and compare the parameter estimates to those obtained from autosomes alone. These analyses give us a more complete picture of the presence and effect of human sex-biased demography.

2068F

Y-chromosomal variation in native South Americans: bright dots on a gray canvas. *M. Nothnagel[1,2], L. Roewer[3], L. Gusmão[4,5], V. Gomes[4], M. González[4], D. Corach[6], A. Sala[6], E. While human populations in Europe and Asia have often been reported to reveal a concordance between their extant genetic structure and the prevailing regional pattern of geography and language, such evidence is lacking for native South Americans. In the largest study of South American natives to date, we examined the relationship between Y-chromosomal genotype on the one hand, and male geographic origin and linguistic affiliation on the other. We observed virtually no structure for the extant Y-chromosomal genetic variation of South American males that could sensibly be related to their inter-tribal geographic and linguistic relationships, augmented by locally confined Y-STR autocorrelation. Analysis of repeatedly taken random subsamples from Europe adhering to the same sampling scheme excluded the possibility that this finding was due to our specific scheme. Furthermore, for the first time, we identified a distinct geographical cluster of Y-SNP lineages C-M217 (C3*) in South America, which are virtually absent from North and Central America, but occur at high frequency in Asia. Our data suggest a late introduction of C3* into South America no more than 6,000 years ago and low levels of migration between the ancestor populations of C3* carrier and non-carriers. Our findings are consistent with a rapid peopling of the continent, followed by long periods of isolation in small groups, and highlight the fact that a pronounced correlation between genetic and geographic/cultural structure can only be expected under very specific conditions.

2069W

Analysis of haplotype sharing and recent demographic history in the Netherlands. *P. Palamara, I. Pe'er, The Genome of Netherlands Consortium.* Columbia University, New York City, NY.

Chromosomal segments that are identical by descent (IBD) were recently shown to convey information about population-level features such as demography, natural selection and heritability of common traits. In a recent work [1], we have developed analytical models for the relationship between haplotype sharing and demography, and shown that IBD sharing provides an effective way for reconstructing demographic events of the recent millennia, where classical methods are typically underpowered. We now extend the developed models to accommodate the simultaneous analysis of multiple demes, providing insight into recent migration rates as well as population size fluctuations. Using this approach we analyzed sequencing data for 498 unrelated individuals from 11 Dutch provinces (the Genome of Netherlands Project). Pairs of individuals from all the analyzed provinces are found to share several IBD segments of length greater than 1 centimorgan (cM), suggesting recent common ancestry of these groups. We observe a north-to-south gradient of declining IBD sharing frequency. While the chance of sharing long (>7 CM), extremely recent IBD segments correlates with modern-day geographic distance, shorter segments are more frequently shared with individuals currently residing in the north of the country, regardless of the individuals' modern location. Using the developed analytical methods, we reconstruct coalescent distributions and migration rates across the analyzed provinces. In all cases we find evidence for recent exponential growth at different rates for different provinces, with substantial recent gene flow between these demes. Using the retrieved model, we estimate the average haploid pair of Dutch individuals in the studied dataset to find a common ancestor ~1600 years before present, with earlier common ancestors typically found in northern provinces and variation that depends on modern geographic location.

2070T

Limitations to determining genetic history in the recombinant genome and connection to demographic events from samples of modern populations. *D. Platt, F. Utro, L. Parida.* IBM T. J. Watson Research Center, Yorktown Heights, NY.

We report on our study of the reconstructable genetic history and connections to demographic events impacting genetic history in the recombinant genome derived from modern population samples. We used COSI, which allows for specification of demographic events, such as the out-of-Africa migrations, glacial isolation, and post glacial and agricultural expansions, along with parameterizations for African, European, Asian, and African-American populations, and which allows for the stochastic construction of multiple population histories consistent with these populations' demographic parameters. In prior work, we constructed Ancestral Recombination Graphs (ARGS) to represent the full genetic history of these multiple simulations of these populations. We mathematically defined and characterized Minimal Descriptor (MD) ARGs capturing the essential substructure of an ARG which preserves the genetic landscape of the extant samples, including the topology and edge lengths of the marginal trees. As such, these MDs derived from full COSI output, contain the largest amount of information uniquely specified by extant samples. We identified a measure of 'history' as the number of nodes in a MD due to recombination and coalescence in the minimal descriptor, and measured the number of nodes within any given epoch that were reconstructable from the entire modern population. We showed that coalescence causes the loss of information defining the recombination history, which information loss can include which genome segments had evolved together. This information loss is similar to that observed for equivalent SNPs in non-recombinant phylogenies, where the order in which the SNPs accumulated is lost. Up to 35% of the reconstructable nodes are lost. Further, the reconstructable histories consistently revealed underlying demographic events, even across radically different histories. Here we report, for a given specific history, the reconstructability of the genetic record from samples drawn from the modern population. We generated a representative history, and resampled with varying sample sizes, seeking to quantify how many of the historical nodes were reconstructable from each of the samples, giving a representation of how much of the history could be expected to be recovered from any given sample. We have found the older ARG nodes are broadly supported across multiple resamplings, while more detail in recent events become available with larger sample sizes.

Analyses of exome variants suggest enrichment for functionally-important variants during human expansion into the Americas. *S. Ramachandran[1,2], J.J. Yang[3].* 1) Ecology & Evolutionary Biol, Brown Univ, Providence, RI; 2) Center for Computational Molecular Biology, Brown Univ, Providence, RI; 3) Department of Pharmaceutical Sciences, St. Jude Children's Research Hospital, Memphis, TN.

Genetic variation bears signatures of demographic processes such as population divergences, and a modest number of non-coding variants is adequate to classify human individuals into clusters corresponding to their ancestry. In contrast, the population structure of coding variants has not been well characterized, due to (1) low sampling of non-European individuals for exome- and whole-genome studies and (2) controlling for ancestry in genome-wide association (GWA) studies to avoid spurious correlations. However, controlling for ancestry overlooks the fact that haplotypic and allelic diversity decreases with genetic distance from Africa, meaning derived alleles and variants with functional importance may be particularly enriched on East Asian and Native American ancestral backgrounds. We set out to comprehensively examine the relationships between genetic ancestry and coding variant frequency in admixed US Hispanic populations. In a preliminary analysis of 60 unrelated Mexican individuals from the 1000 Genomes (MXL), we evaluated associations between East Asian, African, Native American, and European ancestry coefficients with the number of copies of the reference allele at polymorphisms on the Illumina Exome chip. African and East Asian ancestry is least often associated (<5%) with number of copies of the reference allele. In contrast, the proportion of SNPs associated with levels of Native American ancestry is 10.3%, slightly lower than those associated with European ancestry (11.2%), and Native American ancestry is significantly correlated with copies of the non-reference allele (and the derived allele) in almost all of these cases. The differences observed in allele frequencies at exome SNPs on different ancestral backgrounds suggests that phenotypically-important variants are enriched on Native American backgrounds, which may explain differential incidence in certain diseases ~ such as acute lymphoblastic leukemia (Xu et al. JNCI 2013) ~ for individuals with >10% Native American ancestry.

2072W

Whole exome sequencing of 126 Northeast Asian individuals including Korean, Chinese, Japanese, and Mongolian ethnicities. *A. Rhie[1,2,3], S. Lee[1,2,3], W. Roh[1], J. Shin[1], J.I. Kim[1,2,3], J.S. Seo[1,2,3,4].* 1) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul 110-799, Korea; 2) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul 110-799, Korea; 3) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul 110-799, Korea; 4) Macrogen Inc., Seoul 153-023, Korea.

Along with the development of massively parallel sequencing method, human DNA sequencing data have been accumulated at a very rapid rate these days. However, most of them were to focus on target diseases or phenotypes, and genomic information of normal individuals has not been sufficient so far for each population. Here we provide the sequence information of Northeast Asian exomes, along with some sequence-level and population-level analyses. We sequenced 126 exomes of Asian individuals; 37 Koreans, 25 Chinese, 25 Japanese, and 39 Mongolians. Variations including single nucleotide polymorphism (SNP), insertion/deletion, and copy number variation were called for these samples, and the genotype frequencies of sequenced bases were provided including wild type bases (http://asap.gmi.-ac.kr). The bases with low genotype qualities were explored genome-wide, and bases with ≥50% low quality genotypes were found to be largely overlapped with segmental duplications (37.99%), which include several genes such as NBPF10, FLG, FRG1, MUC6, and TBC1D3C. In addition, we tried to identify genetic diversity and population structure of the Northeast Asians and reconstruct the demographic history of these populations. As a result, we showed evidences of the Northern route migration in the East Asia and suggested some Mongolian-specific functional loci (rs1453544: OR4D6, rs1453547: OR5A2, rs148138101: ARHGAP3, rs202130413: ARSB, etc.). In this study, we provided the exomic sequence information of the Northeast Asian populations. We hope that our data provide fundamental information to those studying on Asian populations in genetic or medical research fields.

2073T

The impact of background selection on fine-scale population structure in humans. *R. Torres[1,3], RD. Hernandez[2,3].* 1) Biomedical Sciences Graduate Program; 2) Department of Bioengineering and Therapeutic Sciences,; 3) UCSF, San Francisco, CA.

Patterns of observed genetic polymorphism across human populations have provided great insight about those populations' respective demographic histories and their underlying population structure. Due to geographic and cultural barriers, reduced gene flow has resulted in different distributions of allele frequencies between human populations through the process of genetic drift. Population genetics methods and measures, such as principle components analysis (PCA) and Fst, have uncovered the genetic structure that exists between human populations, especially at the intercontinental scale. However, because of the processes of natural selection and recombination, we should not expect that the effective population size of an individual will be homogenous across the entire genome. Rather, diversity-reducing selection (e.g., genetic hitchhiking and background selection) near functional loci has resulted in a mosaic of different effective population sizes across the human genome. Population genetics theory predicts that the strength of drift is a function of both effective population size and time. Leveraging this fact, we have demonstrated through PCA that loci contributing to principle components of populations across European populations of the POPRES dataset are strongly correlated with background selection in 7 of the top 10 PCs (Kendall's tau, significance assessed by permutation). Similar patterns were replicated with respect to Fst as a function of background selection across the same populations. By controlling for conservation, we will present new analysis to demonstrate that such patterns are not the result of direct selection at each site but due to linkage to selected sites. Our findings will highlight the fine-scale population structure that exists at the intra-continential scale and will illuminate valuable targets for the modeling of subtle population demographic histories.

2074F

Evaluating the impact of sex-biased demography and selection on genomic patterns of human diversity. *A. Walia[1], W. Fu[2], S. Ramachandran[1,3].* 1) Ecology & Evolutionary Biology, Brown University, Providence, RI 02912, USA; 2) Department of Genome Sciences, University of Washington, Seattle, Washington 98195, USA; 3) Centre for Computational and Molecular Biology, Brown University, RI 02912 USA.

Disentangling the effects, and relative roles, of demography and selection is central to human population genetics. Due to its mode of transmission, the X chromosome is an ideal system with which to gain insight into both natural selection and sex-biased demographic processes in the human lineage. Recessive deleterious mutations on the X are exposed to selection in males, and the smaller effective population size of the X means the X chromosome experiences drift more strongly than do the autosomes. The ratio of the genetic diversity normalized by divergence between the X chromosome and the autosomes (π_x/π_{Aut}) is expected to be 0.75 . However, past studies (Hammer et al. 2009, Keinan et al. 2009, Hammer et al. 2010, Gottipati et al. 2011) report equivocal estimates for this ratio, and offer different explanations for observed deviations from (π_x/π_{Aut})=0.75. Here, we analyze whole genome data of 567 female individuals from 14 populations, genotyped in Phase 1 of the 1000 Genomes Project. To study the effect of selection on observed genetic diversity, we partition polymorphisms by distance to their nearest gene. We then calculate the ratio of genetic diversity normalized by divergence on the X chromosome to that on the autosomes in different distance intervals to the nearest gene. We compare the (π_x/π_{Aut}) ratio for all pairs of 1000 Genomes populations. Gottipati et al. 2011 suggest that male-biased migration out-of-Africa led to a smaller effective population size of females in non-African populations based on their observation of $(\pi_x/\pi_{Aut})_{CEU}/(\pi_x/\pi_{Aut})_{YRI}$ <1. Their analysis focused on Utah Residents from the CEPH panel with Northern and Western European ancestry(CEU) and Yoruba in Ibadan, Nigeria(YRI). We analyze all 1000 Genomes Phase 1 populations to identify genomic signatures of sex-biased demographic events and social structures in human evolutionary history. This study allows us to examine the relative impact of locally- acting selection and sex-biased demographic processes on human genome-wide variation.

2075W

Estimation of Effective Population Size and Divergence Time of Modern Human Populations Suggest Recent Gene Flow between European and African Populations. *S. Xu, P. Qin, D. Lu, L. Zhao.* Max Planck Independent Research Group on Population Genomics, Chinese Academy of Sciences and Max Planck Society Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China.

Effective population size (Ne) and population divergence time (TD) are two fundamental parameters to understand demographical history of modern human populations. Taking advantage of genome-wide high density single nucleotide polymorphism (SNP) data, we estimated Ne and TD in 53 populations worldwide based on linkage disequilibrium (LD) information across genome. The estimation by LD-based approach makes use of large number of closely linked markers and makes it possible to show changes of Ne traced over time. Our results revealed the stable African populations and the expansion of non-African populations. We further used two independent approaches to estimate the divergence time between populations, which gave consistent estimation. Interestingly, our estimation of divergence time between European and African was much lower than that between Asian and African, suggesting more gene flow between European and African populations since the initial population divergence. The results in this study will advance our understanding of population demographical history, especially, the "out of Africa" model in the early history of human migration and recent interaction between populations since the initial divergence.

Spatial Localization At Each Locus In the Genome. *W. Yang[1], A. Platt[2], C. Chiang[2], E. Eskin[1,3,4], J. Novembre[5,], B. Pasaniuc[3,6].* 1) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA; 2) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, Los Angeles, CA; 3) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, Los Angeles, CA; 4) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 5) Department of Human Genetics, University of Chicago; 6) Department of Pathology and Laboratory Medicine, Geffen School of Medicine at University of California, Los Angeles, Los Angeles, CA.

Ancestry analysis plays an important role in studies of human disease and evolution. Traditionally, ancestry inference from genetic data has been focused on modeling populations as discrete sources. As a result, ancestry prediction at each locus in the genome of any given individual can only be performed in terms of discrete population assignments or ancestry proportions. We have recently proposed methods for ancestry inference in a geographic continuum, by explicitly modeling the spatial distribution of each allele at any locus in the genome as a continuous function of geographic space (Yang et al Nat Genet 2012, Baran et al AJHG 2013). A major drawback of these approaches is that they only model individuals as having ancestry from one or at most two geographical locations (whereas, for example, 20% of the individuals collected in the POPRES data have recent ancestors from at least two country origins). In this work we propose approaches for continuous localization from genetic data for individuals that have recent ancestors from multiple geographical locations. That is, our methods seek to localize on a continuous map the ancestry of the recent ancestors (parents, grandparents and in general all ancestors up to several generations) using the genetic data of a given individual. In addition, we leverage the inheritance pattern to assign geographical locations for each segment in the genome according to the location of its ancestors. We devise an efficient Expectation Maximization approach within hidden Markov models of ancestry in conjunction with forward-backward algorithm that assigns continuous local ancestry for a given individual efficiently (e.g. an average of 2 minutes per individual). We use real data from POPRES as well as admixed individuals of Latino ancestry to show that our method yields high accuracy in ancestor localization as well as in assigning continuous ancestry at each locus in the genome. In simulations starting from POPRES data, our method accurately infers the locations of the 2 grandparents of a given individual's phased haplotype within an average of around 400Km of their true location and assigns continuous local ancestry within around 400Km of the true location at each segment in the genome. Software package implementing our methods is freely available in our website http://genetics.cs.ucla.edu/spa.

Separation of the largest eigenvalues in eigenanalysis of genotype data from discrete subpopulations. *K. Bryc[1], W. Bryc[2], J.W. Silverstein[3].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Department of Mathematical Sciences, University of Cincinnati, Cinciinati, OH; 3) Department of Mathematics, North Carolina State University, Raleigh, NC.

Principal component analysis (PCA) has been a powerful and efficient method for analyzing large datasets in population genetics since its early applications by Cavalli-Sforza and others. In particular, PCA of single nucleotide polymorphism genotype data can be used to illuminate population structure. We present a mathematical model, and the corresponding mathematical analysis, that justifies and quantifies the use of principal component analysis of biallelic genetic marker data for a set of individuals to detect the number of subpopulations represented in the data. A good estimate for the number of populations, K, is needed in Bayesian clustering algorithms such as STRUCTURE (Falush et al. 2003) or ADMIXTURE (Alexander et al. 2009), where one must specify a priori the number of clusters in the data, which affects the inferred relationships among individuals. In contrast to previous work, our results describe behavior of the eigenvalues of the sample covariance matrix without centering or normalization, taking into account both the number of individuals and the number of markers. The raw unprocessed covariance matrix is more amenable to mathematical analysis, and the singular values of such raw data exhibit quantifiable properties that can be used directly to determine the number of populations in the data in an almost deterministic fashion, at least when the number of individuals in the study is sufficiently large. We show that for large data sets of individuals from K well-differentiated subpopulations, with overwhelming probability the un-centered sample covariance matrix has K large eigenvalues. We demonstrate in two proof-of-principle simulations that we are able to obtain evidence of population structure when the number of individuals is large enough. We indicate that the power of the technique relies more on the number of individuals genotyped than on the number of markers.

2078W

Detection of Identity-by-Descent in Whole-Exome Sequencing Data. *W. Fu, M.J. Bamshad, D.A. Nickerson, J.M. Akey, NHLBI Exome Sequencing Project.* Department of Genome Sciences, University of Washington, Seattle, WA.

The distribution of genomic regions that are shared Identical by Descent (IBD) among individuals can provide insight into population history, facilitate the identification of adaptively evolving loci, and is an important tool in disease gene mapping. Next-generation sequencing technology has enabled the creation of large exome sequencing datasets from thousands of individuals. However, accurately inferring IBD segments from exome data is difficult because of the sparsity of the data. Here, we describe an accurate and robust computational framework to detect IBD in exome data, which we evaluated through comprehensive simulations. The key insight of our approach is to identify and exclude exomic loci that are refractory to accurate IBD calling because of insufficient exon density. We applied this computational framework to detect IBD segments in high-coverage exome sequences from 4,298 European-American individuals studied as part of the NHLBI Exome Sequencing Project. Patterns of IBD sharing reveal significant evidence for cryptic and spatial population structure, and allow us to infer the average number of meiosis that separate two randomly selected European-American individuals. Overall, our results enable the power of IBD analyses to be applied to exome data and reveal novel insights into the genetic structure of European-Americans in the United States.

2079T

The timing and history of Neandertal gene flow into modern humans. *S. Sankararaman[1,2], N. Patterson[2], S. Pääbo[3], D. Reich[1,2].* 1) Harvard Medical School, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Max Planck Institute for Evolutionary Anthropology, Leipzig.

Previous analyses of modern human variation in conjunction with the Neandertal genome have revealed that Neandertals contributed 1-4% of the genes of non-Africans with the time of last gene flow dated to 37,000-86,000 years before present. Nevertheless, many aspects of the joint demographic history of modern humans and Neandertals are unclear. We present multiple analyses that reveal details of the early history of modern humans since their dispersal out of Africa.

1.We analyze the difference between two allele frequency spectra in non-Africans: the spectrum conditioned on Neandertals carrying a derived allele while Denisovans carry the ancestral allele and the spectrum conditioned on Denisovans carrying a derived allele while Neandertals carry the ancestral allele. This difference spectrum allows us to study the drift since Neandertal gene flow under a simple model of neutral evolution in a panmictic population even when other details of the history before gene flow are unknown. Applying this procedure to the genotypes called in the 1000 Genomes Project data, we estimate the drift since admixture in Europeans of about 0.065 and about 0.105 in East Asians. These estimates are quite close to those in the European and East Asian populations since they diverged, implying that the Neandertal gene flow occurred close to the time of split of the ancestral populations.

2.Assuming only one Neandertal gene flow event in the common ancestry of Europeans and East Asians, we estimate the drift since gene flow in the common ancestral population. We show that an upper bound on this shared drift is 0.018. Because this is far less than the drift associated with the out-of-Africa bottleneck of all non-African populations, this shows that the Neandertal gene flow occurred after the out-of-Africa bottleneck.

3.We use the genetic drift shared between Europeans and East Asians, in conjunction with the observation of large regions deficient in Neandertal ancestry obtained from a map of Neandertal ancestry in Eurasians, to estimate the number of generations and effective population size in the period immediately after gene flow. These analyses suggest that only a few dozen Neandertals may have contributed to the majority of Neandertal ancestry in non-Africans today.

2080F

A method for computing the exact distribution of the genealogical history of a sample derived from a structured population. *M. Uyenoyama, S. Kumagai.* Biology, Duke Univ, Durham, NC.

Likelihood-based inference methods designed to analyze variation in genes sampled from structured populations require a means of accommodating changes in rates of evolutionary processes, particularly coalescence and migration. Population structure increases the dimensions of the genealogy of a sample, and migration modifies the subsets of lineages among which coalescence can occur. Some inference methods require detailed simulation of migration events to accommodate such changes. Here, we present a simple method for determining the probability of a gene genealogy under a specified model. This probability requires specification of the probability of all possible states of ancestral lineages corresponding to the nodes in a gene genealogy and the density of the time interval between nodes. We describe the qualitative features of the distribution of gene genealogies, including factors that influence the geographical location of the most recent common ancestor and the nature of the distribution of internode lengths.

Rare Variant Stratification in small geographic areas. *S. Zöllner[1,2], M. Mueller-Nurasyid[3,4,5], M. Zawistowski[1], M. Reppell[1], J. Novembre[6], K. Wolf[7], A. Peters[7], H. Grallert[8], K. Strauch[4,5].* 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Psychiatry, Univ Michigan, Ann Arbor, MI; 3) Dept of Medicine I, LMU, Munich; 4) Chair of Genetic Epidemiology, LMU, Munich; 5) Institute of Genetic Epidemiology, Helmholtz Zentrum München Germany; 6) Dept Human Genetics, Univ Chicago, IL; 7) Institute of Epidemiology II, Helmholtz Zentrum München Germany; 8) Research Unit of Molecular Epidemiology, Helmholtz Zentrum München Germany.

The geographic distribution of rare variants provides important insights into human population history and evolutionary forces affecting our genome. Moreover, differences in rare variant counts may affect population-based association studies of rare variants; accumulation tests that jointly analyze multiple rare variants are vulnerable to confounding by very subtle population stratification. Population genetic theory suggests that rare variants are affected by small differences in migratory patterns, such as the differences between urban and rural human populations. However, little data is available to assess the degree of population differentiation in small geographic areas. To explore this question, we analyze samples from the KORA study collecting ~2400 individuals of German ancestry from the German city of Augsburg and 16 surrounding sampling locations. The sampling locations are towns and villages with census sizes between 3.000 and 30.000 located in a geographic region of ~ 1,200 sqkm. We evaluate the genetic differentiation between sampling locations using allele sharing, the normalized probability that two individuals sharing an allele come from a different sampling location. We show that for common and uncommon variants (minor allele frequency >0.005), allele sharing in the study area is near 1, indicating that genotype frequencies do not differ between sampling locations. However, for rare variants, some of the same sampling locations differ from all other sampling locations and the level of differentiation does not depend on the geographic distance between sampling locations. Instead, the average allele sharing is clearly correlated with the census size of a sampling location; locations with small census size are more genetically differentiated than locations with large census size. The degree of population differentiation observed in this sample is predicted to be sufficient to generate inflated Type I error rate in accumulation tests. Tests that model causal and protective variants are especially susceptible to this type of population differentiation. Moreover, we explore the ability of typical correction strategies such as PCA and case-control matching to correct for the observed stratification.

2082T

Response of carrier frequency to a population bottleneck can quantify the amount of recessive variation. *D.J. Balick[1,2], R. Do[2,3], D.E. Reich[2,4], S.R. Sunyaev[1,2].* 1) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, Massachusetts, 02115; 2) Broad Institute of Harvard and MIT, Cambridge, Massachusetts, 02142; 3) 2 Center for Human Genetics Research, Massachusetts General Hospital, Boston, Massachusetts, 02114; 4) Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115.

Given the rich demographic history of humans, understanding the population dynamics in light of these differences has often been a confounding factor in identifying human evolutionary parameters, such as the strength and mode of selection. Here we present a rare example in which we can exploit disparate population histories to extract a detailed understanding of crucial evolutionary parameters. In the presence of a recent bottleneck and subsequent re-expansion, the founder's effect responds differently to distinct modes of selection, for example equilibrating more quickly from an increased additive burden than a comparable recessive burden. The genetic variation in the pre-bottleneck equilibrated population, as measured by the average number of deleterious alleles per individual, is exceeded by the bottlenecked population when all deleterious mutations act additively, but exhibits a relative depletion under recessive selection. As a result, one can extract the dominant form of selection by comparing an easily measurable feature of a population. We introduce a methodology for probing the fraction of polymorphic alleles in a population that act recessively. We analyze the transient dynamics of the site frequency spectrum of a population in response to a bottleneck, and find a qualitative distinction between additive and recessively acting alleles. By comparing the average number of polymorphic mutations per individual subjected to a founder event to the same statistic in an equilibrium population, we are able to determine the fraction of the variation that acts recessively. The transient dynamics in response to a bottleneck are explored in detail, and a crossover is identified in the recessive fraction as a function of the dominance coefficient and the strength of selection. Under the simplest model with no additional epistasis, we determine bounds on this ratio. This provides a simple statistical test for the presence of recessive variation on the whole genome level, or among a collection of functionally or medically relevant loci, and can be used to parse the mode of selection among existing regional variation on the local level.

2083F

Whole genome sequencing informs genealogy and the search for genetic modifiers in a PSEN1 E280A early-onset familial Alzheimer's disease cohort. *H.C. Cox[1], M. Lalli[2, 3], D.E. Mauldin[1], H. Li[1], M. Brunkow[1], M.L. Arcilia[2, 4], G. Garcia[4], L. Madrigal[5], S. Moreno[5], K.S. Kosik[2, 3, 4], L. Hood[1], J. Roach[1], G. Glusman[1], F. Lopera[5].* 1) Institute for Systems Biology, 401 Terry Ave N, Seattle WA 98109, USA; 2) Neuroscience Research Institute, University of California at Santa Barbara, CA, USA; 3) Program in Biomolecular Science and Engineering, University of California at Santa Barbara, Santa Barbara, California; 4) University of California at Santa Barbara, Department of Molecular, Cellular, and Developmental Biology, Santa Barbara, California; 5) Grupo de Neurociencias de Antioquia, Universidad de Antioquia, Medellín, Colombia.

Mutations in the presenilin-1 gene (PSEN1) can promote progressive cerebral deposition of APP, resulting in Alzheimer's disease (AD). In particular, carriers of the 'Pasia mutation', a fully penetrant and dominantly inherited amino acid change (p.Glu280Ala) in PSEN1, suffer early-onset familial AD. This mutation is highly prevalent in Antioquia, Colombia, where over 1000 carriers have been identified. The mean age of onset of mild cognitive decline and dementia in carriers is 44 and 49 years, respectively. The variation in these traits implicates additional genetic factors influencing disease progression. This population provides a unique opportunity to identify genetic modifiers underlying AD. The origin of this mutation is believed to be a single early 17th century male founder during Spanish colonization of Colombia. A comprehensive genealogy with over 3000 descendents of this male founder has been previously described. The genealogy is characterized by geographic isolation, consanguinity and admixture of native Amerindian woman with Spanish Conquistadors and individuals of native African ancestry due to the Atlantic slave trade. We have obtained whole-genome sequences for 102 individuals [from this isolated population, including 74 carriers]. We are analyzing these using custom workflows and the Ingenuity Variant Analysis platform (www.ingenuity.com/variants). We computed pairwise relationships among all sequenced individuals. We determined mitochondrial haplotypes for all individuals and Y-chromosome haplotypes for all males. We observed mitochondrial haplogroups A, B, C, L and T, which are frequent in South and Central America, Africa and Eastern Europe. We used these lines of evidence to reconstruct the extended genealogy and characterize ancestry. This study provides a unique opportunity to investigate the etiology of AD in one of the largest known AD kindreds. The reconstruction of the founder genealogy provides a comprehensive and powerful resource for whole genome sequence analysis that will inform the search for modifiers of early-onset AD. [Funding: Université du Luxembourg, wwwen.uni.lu/lcsb].

2084W

Integration of low coverage whole genome sequence from the Kuusamo Finnish isolate with 1000 Genomes Project data provides an improved population reference panel. *AP. Sarin[1,2], K. Palin[3], I. Zara[4], K. Rehnstrom[1,4], M. Perola[1,2,5], V. Salomaa[6], A. Palotie[1,4,7], S. Ripatti[1,2,4,8], R. Durbin[4].* 1) Institute for Molecular Medicine Finland, Helsinki, Finland; 2) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 3) Genome-Scale Biology Program, University of Helsinki, 00014 Helsinki, Finland; 4) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge CB10 1SA, UK; 5) Estonian Genome Center, University of Tartu, Estonia; 6) Department of Chronic Disease Prevention, National Institute for Health and Welfare, Finland; 7) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 8) Hjelt Institute, University of Helsinki, Helsinki, Finland.

Understanding the genetic variation in population isolates is a valuable resource for genetic studies aiming to map rare and common variation associated to complex traits and common diseases. The reduced genetic complexity in such populations leads to better genotype imputation accuracy when using a population-specific reference panel and the presence of variants rare in the general population and pushed to higher frequency by genetic drift in the isolate offers the opportunity to better represent those variants in reference panels. With the aim of evaluating the potential for imputation of including samples from an isolated sub-population in a more general population reference panel, we sequenced the whole genome of 400 healthy individuals and the whole exome of 24 additional individuals from Kuusamo, a population sub-isolate founded roughly 350 years ago in northeastern Finland. The Kuusamo population was settled by 34 families in 1680s, and reached the present-day populations size of ~20,000 individuals without significant immigration until recently. Our simulations suggested that 400 individuals cover over 97% of all chromosomes in Kuusamo. Whole genome sequencing (WGS) was done at 4.8x on average with 100bp paired end protocol with the Illumina platform, and whole exome sequencing was done at ~37x coverage on average with the Agilent Sure Select Enrichment Kit at the Wellcome Trust Sanger Institute. Of 9,719 coding variants found in the median exome sequence, 9,595 (98.5%) are present in 1000 Genomes phase 1 (1000GP), and 98 (1.0%) more in the 400 WGS call set. Fst between Kuusamo and Finnish and between Kuusamo and Europeans from 1000GP are 0.006 and 0.013 respectively. We also evaluated the proportion of IBD segments shared across individuals and the percentage of individuals with at least one surrogate parent, as described in Kong at. al, Nature Genetics 2008, using the Systematic Long Range Phasing (SLRP) software (Palin et al, Genetic Epidemiology 2011). We evaluated imputation quality of 41 additional Kuusamo samples and 40 Helsinki samples using IMPUTE2. In general imputation is better into the Kuusamo samples than the Helsinki samples. Moreover, in Kuusamo samples a combined reference panel with both Kuusamo and 1000GP haplotypes provides the best performance. Our study demonstrates the value of combining outbred, isolated and sub-isolated population data to increase the amount of variability captured through imputation.

2085T

Genealogical evidence of allele frequency shuffling explains regional genetic structure in a founder population. *C. Bherer[1], L. Excoffier[2,3], M.H. Roy-Gagnon[4], J. Hussin[1], H. Vézina[5], D. Labuda[1,6].* 1) Centre de recherche du Centre Hospitalier Universitaire Sainte-Justine, Université de Montréal, Québec, Canada; 2) CMPG, Institute of Ecology and Evolution, University of Bern 6, Baltzerstrasse, CH-3012 Bern, Switzerland; 3) Swiss Institute of Bioinformatics, 1015 Lausanne, Switzerland; 4) Department of Epidemiology and Community Medecine, University of Ottawa, Ontario, Canada; 5) BALSAC Project, Université du Québec à Chicoutimi, Québec, Canada; 6) Department of Pediatrics, Université de Montréal, Québec, Canada.

Founding events promote allele frequency changes, and even deleterious alleles may rise in frequency by chance. Founder effects may thus account for the greater prevalence of some rare monogenic diseases, like among the French Canadians of Quebec, who are a prime example of founder population. Here we ask whether the demographic history of Quebec is responsible for the increase in frequency of rare disease-causing variants, and if this demography has affected the site frequency spectrum (SFS). By simulating the Mendelian transmission of alleles in the Quebec population genealogy, we studied allele frequency changes following the initial founding settlement and its subsequent regional spatial expansion. We used ascending genealogies of 2,221 individuals representing eight Quebec regions. The total genealogy includes 153,447 ancestors linked to 8,834 founders. Allele dropping (AD) simulations, starting from an equilibrium SFS among founders, led to significant loss for alleles below 1%, but no changes for the larger frequency classes. Using Tajima's D equilibrium test, a significant deficit of rare alleles was found in the whole Quebec sample, in the North-Eastern and Eastern regions, whereas an excess of rare alleles was observed in the western regions, suggesting that regional demographic histories had opposite effects. FST analysis showed significant genetic structuring of the regional populations. We further quantified frequency changes for different initial allele frequencies among founders. For both rare and common alleles, the variance in frequency changes was significantly different between regions, demonstrating differential shuffling effect of allele frequencies among regional populations. We observed extensive variance in genetic contribution among founders. In the North-Western, North-Eastern and Eastern regions, we find that a unique allele carried by a single founder could have increased in frequency up to 5% until now, thus potentially explaining the clinical founder effect of specific Mendelian disorders observed in the North-East. Our results demonstrate that regional demographic histories resulted in regional founder effects and genetic structure over a very short evolutionary time.

2086F

Genetic characterisation of two Greek population isolates. *K. Hatzikotoulas[1], K. Panoutsopoulou[1], I. Tachmazidou[1], L. Southam[1,3], D. Xifara[3,4], L. Moutsianas[3], A. Farmaki[2], A. Matchan[1], N.W. Rayner[1,3], Ch. Kiagiadaki[5], E. Tsafantakis[5], I. Ntalla[2,7], M. Karaleftheri[6], G. Dedoussis[2], E. Zeggini[1].* 1) Human Gentetics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Harokopio University Athens, Athens, Greece; 3) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 4) Department of Statistics, Oxford, United Kingdom; 5) Anogia Medical Centre, Anogia, Greece; 6) Echinos Medical Center, Xanthi, Greece; 7) Department of Health Sciences, University of Leicester, Leicester, United Kingdom.

Genetic association studies of low-frequency and rare variants can be empowered by focusing on isolated populations. It is important to genetically characterize population isolates for substructure and recent admixture events as these may give rise to spurious associations. Under the auspices of the HELlenic Isolated Cohorts study (HELIC; www.helic.org) we have collected >3,000 samples from two isolated populations in Greece: the Pomak villages (HELIC Pomak), a set of religiously-isolated mountainous villages in the North of Greece; and Anogia and surrounding mountainous villages on Crete (HELIC MANOLIS). All samples have information on anthropometric, cardiometabolic, biochemical, haematological and diet-related traits. 1,500 individuals from each population isolate have been typed on the Illumina OmniExpress and Human Exome Beadchip platforms. Multidimensional scaling analysis with the 1000 Genomes Project data shows similarities of the two population isolates with Mediterranean populations such as the Tuscans from Italy and Iberians from Spain. We also observe evidence for structure within the isolates, with the Kentavros village in the Pomak strand demonstrating high levels of differentiation. To characterise the degree of isolatedness in these populations we estimated the proportion of individuals with at least one 'surrogate parent' (using only the subset of samples with pairwise pi-hat<0.2) and compared this to an outbred Greek population from the TEENAGE study, which comprises 707 unrelated adolescents from the Attica district. We find that for random regions in the genome the proportion of individuals with at least one surrogate parent in the MANOLIS isolate is >60% and in the Pomak isolate is >65% compared to ~1% in the outbred Greek population. Our results establish these populations as isolates and provide some insights into the genomic architecture of Greek populations, which have not been previously characterised.

2087W

Risks for Mendelian Disorders in the Bronx. *K. Upadhyay[1], H. Ostrer[1,2], C. Oddoux[2].* 1) Pathology, Albert Einstein College of Medicine, Bronx, NY; 2) Pathology, Montefiore Medical Center, Bronx, NY.

The Bronx, a borough of 1.4 million people, is the third most genetically diverse county in the United States. Of the current residents, 51% are Hispanic-Latino (of whom Puerto Ricans and Dominicans are the largest ethnic groups) and 35% are African-American. To understand the risks of Mendelian disorders among these populations, Affymetrix Axiom Exome 319K arrays were analyzed for 192 members of each group, followed by variant calling using Affymetrix Genotyping Console software. Following quality control, calls were made for 305,519 probes. The called probes were mapped for annotated variants by cross-referencing to Online Mendelian Inheritance in Man, resulting in 1440 known alleles, of which 818 were polymorphic and 338 were pathogenic for Mendelian disorders. These alleles were also cross referenced against 14 other World populations, including an independent set of Puerto Ricans (demonstrated to overlap with Bronx Puerto Ricans by PCA analysis) Among these alleles, 157 were shared among all 3 populations, 32 were shared by Puerto Ricans and Dominicans, 22 were shared by Puerto Ricans and African Americans and 12 were shared by Dominicans and African Americans. In singleton populations, 37 were found only in Puerto Ricans, 45 were found only in Dominicans and 30 were found only African Americans. Among the conditions previously described in these populations were prostate cancer susceptibility and progression (EPHB2 p.A279S), hemochromatosis (HFE p.C282Y), and hereditary amyloidosis (TTR p.I112V). Among the conditions with allele frequencies ≥1% in at least one population were cystic fibrosis (CFTR p.D1270N), spastic paraplegia 44 (GJC2 p.I36M), susceptibility to diffuse gastric cancer (CDH1 p.A617T), Usher syndrome 1C (USH1C p.V130I), cone-rod dystrophy 3 (ABCA4 p.L1201R), fructose intolerance (ALDOB p.A150P), Fuchs endothelial 6 corneal dystrophy (ZEB1 p.G841P) and susceptibility to intestinal carcinoid tumors (SDHD p.H50R). Thus, these studies provide insights into previously unrecognized mutations for Mendelian disorders among the populations of the Bronx.

2088T

***MAK* gene Alu element insertion: high carrier frequency among Ashkenazi Jews most likely due to founder effect.** *L. Shi, M. Luo, L. Edelmann, R. Kornreich.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Background and Purpose: Retinitis pigmentosa (RP) is a group of highly heterogeneous inherited disorders characterized by abnormalities of the photoreceptors of the retina which lead to progressive visual loss. It is estimated to have an incidence of 1 in 3,500 to 1 in 4,000 in the United States and Europe. Whole exome sequencing identified *male germ cell-associated kinase* (*MAK*) (OMIM 154235) as a novel RP disease-cause gene (RP62, OMIM 614181) (Turker *et al. PNAS* 2011). A recurrent homozygous Alu insertion in *MAK* exon9 was identified in 21 unrelated Jewish RP patients, which accounted for approximately 1.2% of 1,798 unrelated RP individuals (Ozgul *et al. Am J Hum Genet* 2011). Population screening of this Alu insertion among Ashkenazi Jewish (AJ) individuals revealed a carrier frequency of 1/55 (Stone *et al. IOVS* 2011). The purpose of this study was to further investigate the carrier frequency of the *MAK* Alu element insertion in the New York metropolitan AJ population and perform haplotype analysis to see if this mutation exhibited a founder effect. Methods: We screened 1,494 unrelated AJ individuals for the Alu insertion by polymerase chain reaction (PCR) amplification of *MAK* gene exon9 and agarose gel electrophoresis. All positive samples identified were confirmed by Sanger sequencing from both directions. Genetic markers flanking the *MAK* gene were analyzed by capillary electrophoresis and haplotype construction was performed by PHASE software. Results: Among our 1,494 AJ samples, 52 showed an extra PCR band of increased size, suggesting a population carrier frequency of 1 in 29 (95% confidence interval 1 in 44 to 1 in 21). Sequencing this extra band identified an identical insertion sequence of an Alu element plus a 13-bp genomic sequence duplication in exon 9 of *MAK* gene among all 52 individuals. Flanking markers revealed a shared haplotype in over 85% of the carriers suggesting a founder effect. Conclusion: *MAK* gene exon 9 Alu element insertion has a carrier frequency of 1 in 29 among Ashkenazi Jews from the NY metropolitan area, most likely from a founder effect. Genetic screening may be appropriate for this mutation in the AJ population due to its high prevalence, however as this form of RP is adult onset with slow progression, it may not be appropriate for prenatal screening.

2089F

Whole-exome sequencing reveals a rapid change in the frequency of rare functional variants in a founding population of humans.

A. Hodgkinson[1], F. Casals[1], J. Hussin[1], Y. Idaghdour[1], V. Bruat[1], T. de Malliard[1], JC. Grenier[1], E. Gbeha[1], F. Hamdan[1], S. Girard[2], JF. Spinella[1], M. Lariviere[1], V. Saillour[1], J. Healy[1], I. Fernandez[1], D. Sinnett[1], J. Michaud[1], G. Rouleau[1], E. Haddad[1], F. Le Deist[1], P. Awadalla[1]. 1) Sainte-Justine Research Centre, University of Montreal, Montreal, Quebec, Canada; 2) Centre d'Excellence en Neuromique de l'Université de Montréal, Centre de Recherche du Centre Hospitalier de l'Université de Montréal, Montréal, Québec, Canada.

Whole-exome or gene targeted resequencing in hundreds to thousands of individuals has shown that the majority of genetic variants are at low frequency in human populations. Rare variants are enriched for functional mutations and are expected to explain an important fraction of the genetic etiology of human disease, therefore having a potential medical interest. In this work, we analyze the whole-exome sequences of French-Canadian individuals, a founder population with a unique demographic history that includes an original population bottleneck less than 20 generations ago, followed by a demographic explosion, and the whole exomes of French individuals sampled from France. We show that in less than 20 generations of genetic isolation from the French population, the genetic pool of French-Canadians shows reduced levels of diversity, higher homozygosity, and an excess of rare variants with low variant sharing with Europeans. Furthermore, the French Canadian population has accumulated a large number of putative damaging functional variants, that may impact upon the fitness of the population and could partially explain the increased incidence of genetic disease in the province. Our results highlight the impact of population demography on genetic fitness and the contribution of rare variants to the human genetic variation landscape, emphasizing the need for deep cataloguing of genetic variants by resequencing worldwide human populations in order to truly assess disease risk.

Whole exome sequencing in families with rare perinatal onset immunodysregulatory diseases present with fever and systemic inflammation.

Z. Deng, Y. Liu, A. Almeida de Jesus, H. Sun, M. Gadina, R. Goldbach-Mansky. Intramural Research Program, NIAMS, National Institute of Health, Bethesda, MD.

WES (Whole Exome Sequencing) has increasingly become the tool of choice in translational research, providing molecular diagnosis in Mendelian diseases and identifying important genes in key biological pathways. Here we report using WES to investigate the molecular basis of a group of rare immunodysregulatory diseases that are characterized by perinatal onset fever and systemic inflammation. We have developed a bioinformatics pipeline to process WES data and an integrated workflow to analyze variants in family trios or quartets. Using the pipeline, we were able to assess the quality of WES data and identify discrepancies in sample gender and family relatedness. The number of coding variants per sample in our WES studies ranged from 19,000 to 25,000, correlating with exome coverage and sample ethnicity. The Transition to Transversion ratio (Ti/Tv) varied from 2.98 to 3.27 with a median of 3.15 after excluding a poorly performed batch. Other QC metrics such as heterozygous to homozygous ratio, synonymous to nonsynonymous ratio and indel percentage were all within expected ranges for WES. Amongst 19 parent-child trios, the Mendelian Inheritance Error (MIE) rates varied from 0.68% to 3.71% with a median of 1.69%. Concordance in two pairs of technical replicates and one pair of identical twins were from 97.25% to 97.82%. On average, the novel variants (defined as not present in dbSNP137) accounted for about 2% of all variants in each sample. The variant annotation, analysis and filtering workflow has allowed us to successfully identify *de novo* mutations in 5 trios. All of the mutations were confirmed by Sanger sequencing, along with a number of other variants in biologically interesting genes. In two of the trios, the mutations were located in genes (PSMB8, NLRP3) known to be responsible for the diseases (CANDLE, NOMID). Functional studies are currently underway in the other families to confirm the pathogenicity of the mutations in these families. Our results suggest that WES can be used as an effective tool in translational research of rare immunodysregulatory diseases.

2091T

The impact of population demography and selection on the genetic architecture of complex traits.

K.E. Lohmueller. Ecology and Evolutionary Biology, University of California, Los Angeles, CA.

The medical genetics community is moving into an era of using exome sequencing to identify low-frequency (<1%) coding region variants associated with complex traits. At the design stage of such experiments, it is critical to understand how many and which individuals to sequence. One important factor that has not been explored fully in previous studies is the demographic history of the sequenced population. Recent studies of thousands of individuals have found evidence of extreme recent population growth in several populations. Here I investigate the effect of this growth on the power to identify low-frequency variants associated with complex disease. In particular, I perform forward simulations using realistic demographic models for different human populations that take into account various levels of recent population growth. The simulations also include a distribution of selective effects for deleterious mutations. Phenotypes are simulated using a liability threshold model where a mutation's effect on the phenotype is proportional to its effect on fitness. First, my simulations show that recent population growth leads to a proportional increase in deleterious amino acid changing polymorphisms, especially if the growth occurred so recently that purifying selection has not had sufficient time to remove the deleterious mutations. Second, if a mutation's effect on fitness is correlated with its effect on the trait, then rare variants account for more of the additive genetic variance of the trait in a recently expanded population than in a population that did not expand. Third, in line with the previous result, I show that recent population growth can increase the genetic heterogeneity of disease. Specifically, a sample of diseased individuals from a population that has undergone recent growth is expected to contain more distinct causal mutations than a sample of the same number of cases from a population that has not expanded. If the causal mutations are scattered across many distinct genes, this increased heterogeneity due to population growth will reduce the power of commonly used gene-based rare variant association tests. These findings suggest that careful consideration of recent population history is essential for designing optimal medical sequencing studies.

2092F

Regional rare allele sharing in a homogeneous, geographically clustered population.

S.L. Pulit[1,2], A. Menelaou[1], C.C. Elbers[1], L.C. Francioli[1], P.I.W. de Bakker[1,2], The Genome of the Netherlands Consortium. 1) University Medical Center Utrecht, Utrecht, The Netherlands; 2) Medical and Population Genetics Program, Broad Institute, Boston, MA, USA.

Next-generation sequencing has yielded unprecedented cataloguing of variants across the frequency spectrum. Although population structure in common variation (CV) is well studied, the exploration of population structure due to rare variants (RVs) has only just begun. Some studies suggest that RV structure is distinct from that of CV while others have found that it can be captured by principal components (PCs) calculated using common SNPs. A broader understanding of population structure is needed as we increasingly focus on the role of RVs in complex traits.To elucidate the architecture of RVs, we used Genome of the Netherlands (GoNL) data of 250 Dutch trios sequenced at 14x coverage. We specifically analyzed f_2 variants, mutations appearing exactly twice in GoNL (N=330 unrelateds evenly sampled from 11 provinces). Since f_2s are rare and likely to be newer mutations, they can illuminate demographic history. We annotated f_2 allele carriers and their province of birth and found that within-province sharing was strongest; on average, both f_2 alleles were 1.46x more likely to be found in the same province. After dividing the Netherlands into northern, central, and southern regions, we tested if within-region sharing of f_2s was stronger in the north or south, areas with historically less migration, compared to the central provinces, areas with more migratory populations, the country's largest city (Amsterdam) and biggest seaport (Rotterdam). We observed strong sharing in the northern vs. central regions ($p<10^{-200}$), but no excess sharing for the southern vs. central regions (p=0.11). These observations are consistent with Dutch history: for centuries, flooding in the northern regions prevented migration into or out of the north and populations primarily settled in the more prosperous central regions.We also explored to what extent CV and RV structure overlap by projecting the samples onto CV PCs. While PC1 captures a North-South cline, the northern samples (with much stronger f_2 sharing) are no more tightly clustered in PC space (mean distance between samples=0.072) than the central (mean dist=0.065, p=0.93) or southern samples (mean dist=0.069, p=0.99). Our results suggest that RV structure, even in a homogeneous population from a small geographic area (41,000 km2), is not fully captured by PCs, which has important implications for RV disease studies such as those employing the exome chip.

Estimation of Migration Rates and Patterns Based on Distributions of Rare Variants.
R. Rothwell[1], M. Ehm[2], P. St. Jean[2], M. Nelson[2], J. Novembre[3], S. Zöllner[1]. 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Quantitative Sciences, GlaxoSmithKline, RTP, NC; 3) Human Genetics, University of Chicago, Chicago, IL.

Careful modeling of the relationships between populations is essential to our understanding of population diversity. Most current models, however, ignore historical changes in migration rate, modeling gene flow as a constant parameter. The growing availability of sequencing data allows estimating temporal changes in these relationships. Identifying such changes may quantify the impact of historical events on human diversity. In this study, we develop a method for using rare variants to identify changing migration patterns. The distribution of rare alleles among multiple populations depends on the migration rate between those populations in the historic time since the mutation event that generated the variant. Rare variants that arose recently are only affected by recent migration events and thus allow an estimate of the migration rate in the recent past. Common variants that arose further in the past allow an estimate of the average migration rate over the time since they arose. Using this intuition, we develop a likelihood function based on the distribution of alleles, where we obtain one estimate of the migration rate each from all variants with a given minor allele count. By comparing different estimates of migration across variants with different minor allele count, we generate a temporal outline of migration rate over time. We evaluate the performance of our method on simulated data of populations with changing migration patterns. For changes as recent as 20 generations in the past, our algorithm identifies a clear temporal pattern. We also show that this methodology can be adjusted to model population characteristics including changes in effective population size and is robust to minor model misspecifications. We apply this methodology to sequence data from the exons and flanking regions of 202 target genes (2220 exons total), generated from European and African American samples. In the African American population, we observe sharply increased migration in recent years from European populations, reflecting a pattern consistent with the transatlantic slave trade. In the European populations, we find generally high gene flow with slightly lower migration rates from the more geographically distant populations. In the Nordic-Baltic regions, we observe temporal trends indicating widespread Scandinavian expansion across Europe and subsequent reduction in migration. In Central and Western Europe, we find increasing European movement in recent years.

2094T

Exome sequencing revealing unique genetic profile of Quebec Nunavik Inuit population.
S. Zhou[1], L. Xiong[1,2], A. Ambalavanan[1,3], A. Dionne-Laporte[1], D. Spiegelman[1], E. Henrion[1], O. Diallo[1], C. Bourassa[1], N. Dupré[4], M.-P. Dubé[5], P. Dion[1], G. Rouleau[1,6]. 1) Centre of Excellence in Neuroscience of Université de Montréal(CENUM), CHUM Research Center and the Department of Medicine, Montréal; 2) Centre de recherche Fernand-Seguin, HÔpital Louis H. Lafontaine, Montréal; 3) Department of Human Genetics, McGill University; 4) Department of Neurology, Université Laval, Québec; 5) Pharmacogenomics Centre, Montreal Heart Institute, Université de Montréal, Montréal; 6) Montreal Neurological Institute and Hospital, McGill University, Montréal.

Background: Nunavik comprises the northern part of Quebec, with 90% of its inhabitants being Inuit. The modern Inuit of Nunavik came from the Thule people which originated from coastal Alaska around 1000 AD and traveled eastward along the Arctic tree line, toward the Northwest Territories (NWT), Nunavut, Greenland, and reached Nunavik around 1500 AD as they became the ancestors of current Inuit residents. In our study, we chose to use a high throughput parallel sequencing approach to generate the specific genetic profile of the Inuit population for the first time. **Materials and Methods:** We performed exome sequencing on 101 Nunavik Inuit from 11 out of 15 villages in Nunavik, using Agilent SureSelect V4 capture kit and Illumina HiSeq platform. Standardized data processing is used to extract all exonic variants. **Results:** We performed preliminary analysis in order to identify Inuit specific novel or rare nonsynonymous variants. The analysis yielded 62 protein changing variants which have allele frequency over 0.5 in Inuit while less than 0.01 in other populations. Among these, a variant p.P479L in the *Carnitine Palmitoyltransferase 1A* (*CPT1A*) gene is the most prominent one. 88 individuals from our Inuit cohort carry the homozygote, and with the lack of homozygous wild-type, the p.P479L allele frequency in Nunavik reaches 0.94. This frequency appears to be the highest when compared to other Inuit populations: 0.43 in Alaska native newborns, 0.44 in NWT Inuit, 0.77 in Nunavaut and 0.73 in Greenland Inuit. Interestingly, the increasing frequency of this variant from Alaska to Greenland and the northeast of Canada seems to correlate with the migration pattern of Inuit over the course of a thousand years. **Discussion:** CPT1A is a key regulator of fatty acid metabolism, and the p.P479L allele is known to be only present in Inuit populations. This variant has been reported to be associated with impaired fasting tolerance in Alaska, and increased risk of sudden infant death (SIDS) in Nunavut. However, in Greenland Inuit the p.P479L allele is linked with higher levels of HDL-cholesterol and apoA-I, which are considered to be a protective allele against cardiovascular risk and infection. The interesting diverse phenotypic variation associated with this allele and its high frequency among older Nunavik adults (mean age 52) suggest the same variant may contribute to different physiological activities in Inuit during different life stages and from different environments.

Inference of population structure using sequence data. *G. Bhatia[1,2], A. Gusev[2,3,4], N. Zaitlen[5], B.J. Vilhjalmsson[2,3,4], D. Diogo[2,6,7], P.K. Gregersen[8], J. Worthington[9], L. Padyukov[10], S. Raychaudhuri[2,6,7,9], R.M. Plenge[2,6,7], B. Pasaniuc[11], A.L. Price[2,3,4].* 1) Harvard-MIT Division of Health Science and Technology, Boston, MA; 2) Medical and Population Genetics Program, Broad Institute, Cambridge, Massachusetts, United States of America; 3) Department of Epidemiology, Harvard School of Public Health, Boston, Massachusetts, United States of America; 4) Department of Biostatistics, Harvard School of Public Health, Boston, Massachusetts, United States of America; 5) Department of Medicine Lung Biology Center, University of California San Francisco, San Francisco, California, United States of America; 6) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States of America; 7) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States of America; 8) The Feinstein Institute for Medical Research, North Shore-Long Island Jewish Health System, Manhasset, New York, United States of America; 9) Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester Academic Health Sciences Centre, Manchester, UK; 10) Rheumatology Unit, Department of Medicine, Karolinska Institutet and Karolinska University Hospital Solna, Stockholm, Sweden; 11) Department of Pathology and Laboratory Medicine, Geen School of Medicine at UCLA, Los Angeles, California, United States of America.

Application of standard principal components analysis (PCA) methods to sequence data does not perform well because of (1) pervasive linkage disequilibrium (LD) and (2) large numbers of rare variants. When applied to 0.78 Mb of targeted sequence data from 918 individuals of European ancestry (Nelson et al. 2012 Science), the top 5 PCs explained only a small proportion of the variance in true population labels ($r^2 = 0.023$). To improve the performance of ancestry inference, we examined the effectiveness of several methods to correct for LD and handle rare variants. To correct for LD, we considered LD pruning, LD shrinkage (reweighting by LD to surrounding SNPs) or LD regression (regressing out surrounding SNPs from each SNP). All of these methods improved results, with LD regression performing best. To handle rare variants, we considered exclusion of rare variants, exclusion of singletons only, or a rare variant reweighting approach (motivated by our theoretical derivations) that imposes an upper bound on the standard weight of 1/p(1-p). Rare variant reweighting and exclusion of singletons both performed well ($r^2 = 0.56$ when used in conjunction with LD regression), whereas the standard strategy of excluding rare variants was suboptimal ($r^2 = 0.44$). These results are consistent with results obtained from coalescent simulations, and suggest that rare variants can improve the performance of ancestry inference from sequence data. We also applied these techniques to ImmunoChip data from 186 loci and 2283 individuals of either Northern or Southern European ancestry (Eyre et al. 2012 Nat Genet). Running standard PCA on data with MAF < 0.01 variants removed, the top 5 PCs explained a moderate proportion of the variance in true population labels ($r^2 = 0.86$). Application of LD correction and inclusion of rare variants resulted in far greater accuracy ($r^2 = 0.99$), sufficient to correct for population stratification in association analysis. Overall, our results suggest that effective ancestry inference from targeted sequence data or targeted high-density genotyping data requires appropriate treatment of LD and rare variants. In particular, rare variants can improve ancestry inference, and should not be universally removed.

2096W

Population-specific variants in whole exome sequencing of American Indians: the Strong Heart Family Study. *S.A. Cole[1], P.E. Melton[2], K. Haack[1], C. Bizon[3], J.K. Sailsbery[3], K.C. Wilhelmsen[4], E.T. Lee[5], L.G. Best[6], L.A. Almasy[1], N. Franceschini[4].* 1) Dept Gen, Texas Biomedical Research Inst, San Antonio, TX; 2) Centre for Genetic Origins of Health and Disease, University of Western Australia, Crawley; 3) Renaissance Computing Institute, University of North Carolina, Chapel Hill, NC; 4) University of North Carolina, Chapel Hill, NC; 5) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 6) Missouri Breaks Research Industries, Inc, Timber Lake, SD.

Sequencing of the human exome has successfully identified novel variants in genes underlying monogenic disorders as well as complex diseases. Exome sequencing has shown that rare variants represent most of the genetic variation in human populations, and because they are of relatively recent origin, tend to be population-specific. Hence, disparities in disease prevalence are likely due to alleles that must be discovered though population-targeted sequencing. To characterize genetic variation in American Indians (AI) residing in the U.S., who are under-represented in 1000 Genome project (1000G) and Exome Sequencing Project (ESP) data, and who suffer disproportionately from diseases such as heart disease and type 2 diabetes, we performed whole exome sequencing of 94 AI samples selected from unrelated founders of large pedigrees of the Strong Heart Family Study Arizona and Oklahoma Centers. Sequence data were aligned to the Human Genome Reference version 37.1 (hg19). Variants were called and recalibrated, and QC metrics were calculated, using the Genome Analysis Toolkits (GATK Unified Genotyper version 2.1). Annotation was provided by SeattleSeq. For the 94 samples, an average of 97.2% of sequences mapped to the reference genome. A total of 250,320 autosomal, non-monomorphic variants passed QC, of which 226,887 were single nucleotide variants (SNVs) and 23,433 were indels. The mean call rate was 0.98, mean transition/transversion ratio (Ti/Tv) was 2.50 and mean variant read depth was 37x. Based on comparison with dbSNP, 1000G and ESP data, 45,602 variants were novel SNVs and 9,776 were novel indels. As expected, most of the novel SNVs were singletons (71%; n=32,350), but we observed several low frequency and common SNVs in exome and putative regulatory regions. Approximately 20% of novel SNVs have predicted functionality (n= 9,374, including frameshift, stop-gain/loss and missense/nonsense), and in 2,700 of those (28%) the minor allele was observed at least twice (minor allele count ≥2). The presence of population-specific exonic SNVs of functional potential may have significant biological implications as the novel variants may account for some of the increased disease burden present in American Indians.

2097T

Forward-in-time Simulation of Recombination, Quantitative Traits, and Selection. *D. Kessner[1], J. Novembre[2,3,1].* 1) Bioinformatics, UCLA, Los Angeles, CA; 2) Human Genetics, University of Chicago, Chicago, IL; 3) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA.

Simulations have a long history in population genetics, both for verifying analytical results and for exploring population models that are mathematically intractable. In a typical forward-in-time simulation, individual fitness is parameterized by fixed per-genotype selection coefficients for a subset of loci in the simulation. While this approach is adequate for simulation scenarios involving simple traits where genetic loci have a constant effect on fitness, it is not flexible enough to handle more complicated scenarios involving polygenic quantitative traits. In addition, while individual haplotype sequences are typically output at the end of a simulation, information about the recombination events that occurred during the simulation has been lost. Recombination information is particularly useful when exploring the haplotype patterns that emerge in scenarios where substantial evolutionary change has taken place in a small number of generations due to recombination and/or selection -- for instance, during recent admixture between isolated populations, or artificial selection experiments. Motivated by such examples, we present a new forward-in-time simulation approach that, instead of tracking single-site variants, tracks individual haplotype chunks as they recombine over multiple generations. This design allows for fast simulation of chromosomal-scale regions, with very efficient memory usage, and also retains recombination information. The simulator uses a modular architecture to allow the user to specify recombination maps, mutation rates, demographic models, quantitative traits and fitness functions. With this modular approach, complicated scenarios are feasible to simulate, including as an example, selection for optimal values of a polygenic quantitative trait in multiple connected populations, where the optimal value may change depending on the population and generation. The simulation program (forqs) is implemented in C++ and is freely available.

2098F

A low frequency of copy number polymorphism for the *NPEPPS*, *POLR2J4*, and *PCDHB13* genes in a sample of admixed Brazilian population. *D. Jimenez[1], T. Lins[2], P. Taveira[1], R. Pereira[1,2].* 1) Universidade Catolica de Brasilia, Brasilia, DF, Brazil; 2) Patologia Molecular, Universidade de Brasília, Brasília, DF, Brasil.

Copy number variants (CNV) represent an important source of variation in the human genome, with some embedded genes differently distributed among human population groups. Therefore, it is necessary to understand the distribution of CNV within and between populations, especially those with admixed ancestry, such as the Brazilians. The aim of the study was to investigate the variability of a set of CNV-embedded genes in a sample of the Brazilian population. The CNV-embedded genes were chosen based on previous published data showing that they have differential copy variation distribution between population samples from Africa and Europe. Three genes (*NPEPPS*, *POLR2J4*, and *PCDHB13*) were investigated by real-time qPCR using TaqMan® assays (Applied Biosystems, Foster city, CA) in a sample of 96 Brazilian individuals previously classified by genetic ancestry informative markers. A low variability in the selected genes was identified, showing 2 copies in frequency of 0.927, 0.990 and 0.979, respectively. Mean distribution ± standard deviation of ancestry according to European, African and Native American proportion was, respectively, 0.702 ± 0.232, 0.189 ± 0.158 and 0.109 ± 0.147, for overall sample. Due to low variability, the genomic ancestry was correlated to copy number (diploid = 2 copies versus non-diploid) only in *NPEPPS* gene, but no correlation was observed (p= 0.257, 0.188 and 0.498, respectively for ancestry estimates). In conclusion, the results provided an overview of the corresponding frequency of gene copy number variation in a sample of the Brazilian population, serving as reference for further population studies, which may correlate these polymorphisms with other phenotypic differences. Nevertheless there is a need for upcoming research to revise these data by using more assays nearby the genes to search for specific breakpoints or use other specific methods, such as high-resolution technologies and second generation sequencing, to confirm and validate the copy number polymorphisms.

2099W

Amylase gene copy number polymorphism in ethnically admixed sample from Brazil. *T. Lins[1], D. Jimenez[2], P. Taveira[2], R. Pereira[1,2].* 1) Patologia Molecular, Universidade de Brasilia, Brasilia, DF, Brazil; 2) Ciencias Genomicas e Biotecnologia, Universidade Catolica de Brasilia, Brasilia, DF, Brazil.

Salivary amylase gene (*AMY1*) copy number variation (CNV) represent a significant variation among individuals and evolved independently in different human population groups worldwide. The *AMY1* genetic variation seems to be related with eating habits and dietary consumption of starch as the *AMY1* gene copy number, the concentration and activity of salivary amylase enzyme are positively correlated to the starch content diet (high or low starch diet). Therefore, it is necessary to understand the distribution of CNV within and between populations, especially those with admixed ancestry, such as the Brazilians. The aim of the study was to investigate the variability of the *AMY1* gene in a sample of 96 Brazilian individuals previously classified by genetic ancestry informative markers. The polymorphism was investigated by real-time qPCR using Taqman® assay (Applied Biosystems, Foster city, CA). The mean *AMY1* copy number was 2.8 with a range of 1 to 8 copies. The major copy number was identified for 2 copies (47.9%), followed by 3 copies (20.8%) and 4 copies (18.8%). Mean distribution ± standard deviation of ancestry according to European, African and Native American proportion was, respectively, 0.702 ± 0.232, 0.189 ± 0.158 and 0.109 ± 0.147, for overall sample. A T-test was performed to compare estimated genomic ancestry proportion among 2 copies and gain of copies (≥3 copies), but no statistical correlation was observed (p = 0.449; 0.494; 0.412, respectively). Despite the low copy number compared to other worldwide populations, the correlation of the polymorphisms with other phenotypic differences must be investigated, such as salivary amylase enzyme concentration and activity, as well as the nutritional status and starch content diet. Since the *AMY1* is highly variable, an increased number of individuals in the Brazilian population should be further evaluated to screen a wider range of variation. The results provided an overview of the corresponding frequency of *AMY1* gene copy number variation in a sample of the Brazilian population serving as reference for further population and nutrigenomic studies.

2100T

Mitochondrial Genome Database for Saudi Community. *I. Alabdulkareem[1], M. Albalwi[1,2], M. Alharbi[1], A. Alghamdi[1], B. Alhamad[1], M. Aljumah[1].* 1) KAIMRC, National Guard Health Affairs, Riyadh, Riyadh, Saudi Arabia; 2) King Abdulaziz Medical City for National Guard, Pathology Department, Riyadh, Saudi Arabia.

This study is aiming to create an electronic database for all Non Mendelian inheritance among Saudi populations that is will be available for all researchers and health providers at the country. Phase one of this investigations is focusing on the establishment of the mitochondria genome sequencing in healthy (mtDNA). mtDNA as extracellular components that do not subdue to Mendelian inheritance mode that is genetically considered as complete different in terms of evolutionary origin since many of the evaluation scientists thought that mtDNA may be derivative from the circular genomes of the bacteria that were engulfed by the early ancestors (endosymbiotic hypothesis). mtDNA was sequenced using the solid 5500™ and validate by Ion Personal Genome Machine® [PGM™] System. Studies showed that the Arab assembled mitochondrial genome contains 16,570 bp as compared to GenBank reference genome with 16,571 bp. Further analysis in mitochondrial genome detected 46 differences, with almost single point mutations and only a deletion of length one. Homology studies on 3,132 known mitochondrial sequences from NCBI with sequence length between 16,000 and 17,000 bp revealed more than 90% matches sequence to accession number EF184636 sequence. Reported single nucleotide polymorphisms (SNPs) are rs3927813 rs3928312 rs1599988 rs3021088 rs3929989, rs1978028 rs121434446, rs1981459, rs3902407, rs3915952, rs3926883, rs3899498 rs2835780, rs3135031, rs34799580. More subjects from healthy and diseased will be included in this investigation that will facilitate more understanding of many unexplained chronic diseases among the populations.

Evolutionary insights into genetic and environmental factors for Crohn's disease in Ryuku and Northern Kyushu. *S. Nakagome[1], H. Chinen[2], H. Said[3], W. Suda[3], A. Iraha[2], A. Hokama[4], F. Kinjo[4], J. Fujita[4], Y. Takeyama[5], S. Sakisaka[5], T. Matsui[6], J. Kidd[7], K. Kidd[7], S. Kawamura[2], T. Hanihara[8], R. Kimura[4], H. Ishida[4], H. Morita[9], M. Hattori[3], S. Mano[1], H. Oota[8].* 1) The Institute of Statistical Mathematics, Tokyo, Japan; 2) University Hospital, Faculty of Medicine, University of the Ryukyus, Okinawa, Japan; 3) Graduate School of Frontier Sciences, University of Tokyo, Chiba, Japan; 4) Graduate School of Medicine, University of the Ryukyus, Okinawa, Japan; 5) Fukuoka University Faculty of Medicine, Fukuoka, Japan; 6) Fukuoka University Chikushi Hospital, Fukuoka, Japan; 7) Yale University School of Medicine, New Haven, CT; 8) Kitasato University School of Medicine, Kanagawa, Japan; 9) Azabu University, Kanagawa, Japan.

Crohn's disease (CD) involves a chronic inflammation in the intestinal tracts, which are caused by complex interaction between multiple genetic and environmental factors. More than seventy loci have been reported as susceptibility genes for CD in Europeans. However, these susceptibilities are different between Japanese and Europeans. Here, we hypothesize that there is the population-specific susceptibility even among Japanese populations. Then, we focus on the TNFSF15 locus whose association with CD has been shown in the Honshu Japanese, and investigate the susceptibility in the Ryukyu and the Northern Kyushu Japanese. The allelic association of TNFSF15 with CD was shown in both of the populations, while the genotype relative risk was different between the Ryukyu (recessive) and the Northern Kyushu (dominant) Japanese. Further, we found that the frequencies of the risk alleles were significantly higher in the Ryukyu Japanese than in the Northern Kyushu and the Honshu Japanese, as well as in the Korean population. These results suggest that the geographic distribution of risk alleles in the TNFSF15 locus can be explained by the demographic effects under the dual-structure model of Japanese populations, and the susceptibility to CD is determined by environmental factors.

2102W

The demographic and genetic dynamics of the human sex ratio from conception to birth. *S. Orzack.* Fresh Pond Research Institute, Cambridge, MA.

We describe the demographic and genetic trajectory of the human sex ratio from conception to birth by analyzing data from 1) three-day-old embryos, 2) induced abortions, 3) chorionic-villus sampling, 4) amniocentesis, and 5) fetal deaths and live births. Our data set is the most comprehensive and largest ever assembled to estimate the sex ratio at conception and the sex ratio trajectory and is the first to include all of these types of data. Our estimate of the sex ratio at conception is 0.5 (proportion male), which contradicts the common belief that the sex ratio at conception is male-biased. The sex ratio among abnormal embryos is male-biased and the sex ratio among normal embryos is female-biased. These biases are associated with the abnormal/normal state of the sex chromosomes, chromosome 15, and chromosome 17. The sex ratio of a cohort of conceptions increases for at least 10 to 15 weeks after conception. The sex ratio levels off after approximately 20 weeks and then declines slowly from 28 weeks to 35 weeks, when it declines markedly and becomes female-biased. This trajectory indicates that there is an early excess of female mortality during pregnancy followed by a later excess of male mortality, with net female mortality during pregnancy exceeding male mortality; this is a fundamental new insight into early human development.

2103T

Critical illness from pandemic influenza A/H1N1 and Streptococcus pneumonia co-infection in Nuevo León, Mexico. *B. Silva[1], A. Padrón-Rocha[1,3], D. Reséndez-Pérez[4], M. Bermúdez-de León[2].* 1) Departamento Inmunogenética, CIBIN-IMSS, Monterrey, Nuevo León, Mexico; 2) Departamento Biología Molecular, CIBIN-IMSS, Monterrey, Nuevo León; 3) FCB-UANL; 4) Departamento de Virología e Inmunología, FCB-UANL.

The influenza A/H1N1 virus pandemic of 2009 started in Mexico and then spread worldwide. Bacterial infection associated with influenza is a common cause of death on seasonal and pandemic influenza. Streptococcus pneumoniae is the major bacterial pathogen associated with the influenza in the 1918 Spanish pandemic. The contribution of bacterial coinfection to critical illness associated with influenza A/H1N1 virus infection remains uncertain. The objective of this study was to determine the association of the influenza pandemic of 2009 with S pneumoniae and its contribution to critical illness. Design: Retrospective cohort study Patients: We examined nasopharyngeal swab samples (NPS) of three hundred five patients who were confirmed for all samples with the WHO approved Real Time PCR influenza A/H1N1 virus pandemic of 2009 essays. Autolysin, encoded by (lytA) gene is required for S. pneumoniae pathogenesis and well-characterized virulence marker. Real-time PCR with sequence- specific primers and fluorescent TaqMan probes were selected to direct detection from NPS. Demographic data, comorbid conditions, illness progression and clinical outcomes were collected. Results: S pneumoniae Co-infection was identified in 10.49% of patients with severe influenza A/H1N1 virus infection. Patients with co-infection were young (median 24.5 [range, 0-76] years) .Co-infection was associated with increased ICU admission (75% patients). Hospital mortality was 16.23% in bacterial co-infection. The presence of S pneumonia was correlated with severe disease. Complex viral, bacterial and host factors contribute to pathogenesis of co- infection. Reductions in morbidity and mortality are dependent on prevention with available vaccines as well as early diagnosis and treatment.

2104F

Quantitative genetic analysis of reactivity to three distinct behavioral challenges in an infant primate model of susceptibility to anxiety disorders and depression. *G.L. Fawcett[1], A.M. Dettmer[2], D. Kay[3], M. Raveendran[1], J.D. Higley[4], N.D. Ryan[5], J.L. Cameron[5,6], J. Rogers[1].* 1) Department of Molecular & Human Genetics, Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 3) Department of Clinical & Health Psychology, University of Florida, Gainesville, FL; 4) Department of Psychology, Brigham Young University, Provo, UT; 5) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA; 6) Oregon National Primate Research Center, Oregon Health & Science University, Beaverton, OR.

Prior data clearly show that susceptibility to anxiety disorders and depression is strongly influenced by genetic differences between individuals. Studies of human children in response to novel stressful environments have revealed moderate additive genetic heritability ($h^2 \approx 0.3$) of anxious temperament, a risk factor for later adult mood disorders. Rhesus macaques (*Macaca mulatta*) are the most commonly used non-human primate in biomedical research, including use as models for studies of alcoholism and drug addiction, response to stress and basic aspects of neurodevelopment. Given the significance of developmental experience as well as genetics in forming temperament later in life, we conducted a behavioral genetic analysis of a large (n=428) set of pedigreed infants raised in large social groups that mimic species-typical social organization and interaction. In order to reveal individual differences in underlying temperament, we challenged infant monkeys (aged 40-158 days) with a series of standardized behavioral tests. Each of these conditions varied the environment so as to alter the mildly stressful challenge conferred to the infant: (1) novel environment without threatening stimulus with the mother sedated but present (Freeplay test), (2) novel environment without threatening stimulus without the mother present (Human Intruder Test (HIT)-Alone), and (3) novel environment with exposure to a mildly threatening stimulus (i.e., human staring at monkey) without the mother present (HIT-Stare). We observed significant heritability for willingness to move away from the sedated mother to examine a novel environment ($h^2=0.25\pm0.13$; $p=0.003$). Infants showed heritable variation in a range of behaviors in response to separation stress or threat when the mother was not present ($h^2=0.29$-0.32, $p=1.5\times10^{-3}$-2.1×10^{-4}). By examining these different testing paradigms, we are able to identify genetic influences on reactivity to different environmental challenges. Future analyses will explore genetic correlations among these different reactions and test for genetic associations between different aspects of behavioral variation and a series of specific candidate genetic pathways.

2105W

Genetic and environmental variables contribute to genome-wide methylation variation in geographically diverse Africans. *S. Soi[1,2], L.B. Scheinfeldt[1], D. Diep[3,4], W. Beggs[1], N. Plongthongkum[3], S.A. Tishkoff[1,5], K. Zhang[3].* 1) Dept. Genetics, Univ. Pennsylvania, Philadelphia, PA; 2) Genomics and Computational Biology Graduate Program, Univ. Pennsylvania, Philadelphia, PA; 3) Dept. Bioengineering, Univ. California-San Diego, San Diego, CA; 4) Bioinformatics and Systems Biology Graduate Program, Univ. California-San Diego, San Diego, CA; 5) Dept. of Biology, Univ. of Pennsylvania, Philadelphia, PA.

DNA methylation varies temporally across cell types in an individual, regulating gene expression crucial to biological processes. While methylation is reprogrammed during early development, it also has a heritable component and recent work has shown that this trans-generational inheritance is influenced both by genetic variation as well as environmental factors such as diet. Here we have employed a targeted padlock probe bisulfite sequencing method to characterize DNA methylation in white blood cell samples obtained from a culturally diverse set of sub-Saharan Africa individuals practicing agricultural, pastoralism, agro-pastorialism and hunting-gathering. Using a dimension reduction approach, we demonstrate that the methylation profile of the West African Pygmy population samples is distinct from other Africans even after controlling for covariates such as age and sex. We find that the methylation sites contributing to this signal are enriched near genes that play a role in growth and immunity. In addition, after adjusting methylation frequencies for variation in nearby SNPs, or methylation quantitative trait loci (methQTL), we find that this Pygmy-specific signal still persists, suggesting an environmental component to differences in genome-wide methylation patterns of Pygmy individuals.

2106W

The myocardial infarction-associated gene PHACTR1 is controlled by MEF2. *M. Beaudoin[1], S. Langlois[1], KS. Lo[1], A. N'Diaye[1], JC. Tardif[1,2], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Université de Montreal, Montreal, Quebec, Canada.

Myocardial infarction (MI) is a leading cause of death and disability worldwide. Genetic factors play an important role in the pathogenesis of MI and coronary heart disease (CAD). To characterize the genetic causes of MI in French Canadians, we genotyped SNPs previously associated with MI or CAD in 1176 MI cases and 1996 controls selected from the Montreal Heart Institute (MHI) Biobank. Of the 45 SNPs that we genotyped successfully, 35 had an odds ratio (OR) consistent with the literature (binomial $P=3\times10^{-5}$ and 10 of these 35 SNPs were nominally significant (one-tailed $P<0.05$, binomial $P=4\times10^{-4}$). The strongest genetic association with MI risk that we observed was with rs12526453, a SNP located in the third intron of PHACTR1 (G-allele OR=0.79, $P=8.4\times10^{-4}$). To further characterize the genetic association between the PHACTR1 locus and MI risk, we performed fine-mapping using exon resequencing and imputation. The strongest association with MI was with a genotyped SNP, rs9349379, located ~24 kb downstream of rs12526453 but still in intron 3 of PHACTR1. This SNP was previously reported to associate with CAD, coronary artery calcification and hemodynamic indexes. When we conditioned on genotypes at rs9349379, no additional DNA markers were significantly associated with MI at the PHACTR1 locus ($P>0.10$). Finally, we tested association between genotypes at PHACTR1 rs9349379 and several risk factors for MI in the MHI Biobank samples: hypertension, blood pressure, type 2 diabetes, LDL- and HDL-cholesterol levels and smoking. After accounting for the number of phenotypes tested, none of the associations were significant. This suggests that genetic variation at the PHACTR1 locus influences MI risk through a less appreciated risk factor. We observed a strong correlation between genotypes at rs9349379 and PHACTR1 expression levels in human right coronary arteries ($r^2=0.52$, $P=0.008$). This result indicates that rs9349379 is an expression quantitative trait locus (eQTL) for PHACTR1 in human coronary arteries, providing a strong argument in favor of PHACTR1 being at least one of the genes at the locus implicated in MI. Finally, using electromobility shift assay (EMSA), we demonstrated that this SNP abolish a MEF2 (myocyte enhancer factor-2) consensus binding site. Those results offer mechanistic insights: since the G-allele at rs9349379 is associated with MI risk and low PHACTR1 expression, it suggests that low PHACTR1 expression level is a risk factor for MI.

2107T

Association of Variants in Inflammatory Genes with Disease Severity in Familial Cerebral Cavernous Malformations Type 1. *H. Choquet[1], L. Pawlikowska[1], J. Nelson[1], C.E. McCulloch[1], A. Akers[2], B. Baca[3], B. Hart[4], L. Morrison[3], H. Kim[1], Brain Vascular Malformation Consortium (BVMC).* 1) Center for Cerebrovascular Research, Department of Anesthesia and Perioperative Care, University of California, San Francisco, CA; 2) Angioma Alliance, Durham, NC; 3) Department of Neurology and Pediatrics, University of New Mexico, Albuquerque, NM; 4) Department of Radiology, University of New Mexico, Albuquerque, NM.

Objective: Inflammation may exacerbate disease severity in familial Cerebral Cavernous Malformations (CCM), an autosomal dominant disease characterized by multiple lesions consisting of thin leaky capillaries. The purpose of this study was to investigate whether common variants in inflammatory genes are associated with increased disease severity, as manifested by greater lesion count in familial CCM type 1 (CCM1). **Methods**: 178 Hispanic CCM1 subjects who all carry the same founder Common Hispanic mutation (Q455X in *KRIT1* gene, named CHM) were recruited as part of the Brain Vascular Malformation Consortium (BVMC) study. Lesions were counted by a neuroradiologist on magnetic resonance imaging including susceptibility-weighted imaging performed at enrollment. Samples were genotyped on the Affymetrix Axiom Genome-Wide LAT1 Human Array. Ten candidate genes (*CD14*, *IL1A*, *IL1B*, *IL6*, *IL6R*, *IL10*, *NFKB1*, *TGFB1*, *TNF* and *TLR4*) involved in inflammatory pathways and implicated in vascular diseases or angiogenesis were selected, including 71 variants. Disease severity was quantified as residuals of log-transformed lesion count adjusting for age at enrollment and gender. Linear regression analysis was conducted for each variant assuming an additive genetic model; empirical *p*-values were generated by permutation to account for family structure. **Results**: Lesion count (range: 0-713; mean ± SD: 60.5 ± 116.3) was highly variable and positively correlated with age ($R^2=0.45$, $P<0.001$). The minor alleles of variants in *CD14* (rs2563298, $P=0.005$) and *IL6R* (rs114660934, $P=0.007$ and rs114879247, $P=0.044$) were associated with increased lesion count, although these associations did not pass Bonferroni correction for multiple testing. Variants in *IL1A*, *IL1B*, *IL6*, *IL10*, *NFKB1*, *TGFB*, *TNF* and *TLR4* genes were not associated with lesion count. **Conclusions**: Common variants in inflammatory genes *CD14* and *IL6R* explain additional variability in lesion count independent of age and gender in familial CCM1-CHM cases; however, larger studies are needed to confirm these findings. CD14 and IL6R may have clinical importance as biomarkers of CCM disease severity and progression.

2108F

Are loci associated with low density lipoprotein cholesterol (LDL-C) in non-diabetics similarly associated with LDL-C in type 1 diabetes (T1D)? *K.M. Eny[1], L. Sun[2,3], A.J. Canty[4], S.B. Bull[2,5], A.P. Boright[6], S.M. Hosseini[1], P.A. Cleary[7], J.M. Lachin[7], A.D. Paterson[1,2], DCCT/EDIC Research Group.* 1) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 3) Department of Statistical Sciences, University of Toronto, Canada; 4) Department of Mathematics and Statistics, McMaster University, Hamilton, Ontario, Canada; 5) Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Prosserman Centre for Health Research, Toronto, Canada; 6) Department of Medicine, University of Toronto, Toronto, Canada; 7) The Biostatistics Center, The George Washington University, Rockville, Maryland.

Elevated LDL-C is a risk factor for cardiovascular disease, a leading cause of death in T1D. Randomization to intensive therapy, aimed at achieving glycemic control in the non-diabetic range, was associated with lower LDL-C in comparison to conventionally treated subjects in the Diabetes Control and Complications Trial (DCCT). The largest genome-wide association study of lipids to date identified 37 loci associated with LDL-C using over 95,000 primarily non-diabetic subjects (Teslovich et al., 2010). Given higher glycemia in T1D, it is unknown whether these loci are similarly associated with LDL-C in T1D. Therefore, to test this hypothesis, we used longitudinal measures of LDL-C from 1304 white participants with T1D from the DCCT. Association results from linear mixed models adjusted for time, randomized treatment group and other covariates showed that the directions for the SNP effect at 35 of the 37 loci were consistent with those reported by Teslovich et al., far exceeding the null expectation of 18.5 (p<10-7). Individually, 17 loci showed evidence of association at p<0.05, but after correcting for multiple testing only 5 (LDLR, APOE-C1-C2, SORT1, ABCG5/8, APOB) remained statistically significant (p≤0.001), suggesting a larger sample is needed to confirm the other locus-specific associations. To test the hypothesis that these 37 loci jointly contribute to susceptibility of higher LDL-C in an additive fashion, we then considered the polygenic risk score method. Risk allele was defined based on the Teslovich et al sample, and risk scores were calculated for each person by multiplying the number of risk alleles by the beta estimate from Teslovich et al for each SNP and summing the product across all 37 loci. Results of this weighted polygenic risk score analysis showed a significant additive genetic effect (p<10-38). To ensure that the result was not driven by the top 5 loci in DCCT, we repeated the analysis focusing on the remaining 32 loci. The strength of the association was attenuated as expected but remained significant (p<10-15). We also tested for a SNP by TREATMENT interaction at each locus but observed only suggestive evidence for interaction at ABO (p=0.01) and ST3GAL4 (p= 0.03). In conclusion, loci ascertained in non-diabetics are similarly associated with lipids in T1D and appear to follow a polygenic additive model. Identifying such loci in T1D can ultimately help target who may benefit from more aggressive lipid management approaches.

2109W

Sequencing candidate genes associated with conotruncal heart defects. *K. Osoegawa[1], C. Parodi[1], N. Mohammed[1], K. Schultz[1], D. Noonan[1], M. Ladner[1], G. Shaw[2], E. Trachtenberg[1], E. Lammer[1].* 1) CHORI, Oakland, CA; 2) Stanford University School of Medicine, Stanford, CA.

Congenital heart defects are the most common malformations, and foremost causes of mortality in the first year of life. Among congenital heart defects, conotruncal defects represent about 20% and are severe malformations with significant morbidity. Conotruncal defects may arise from faulty development of the second heart field cells or from abnormal contributions of cranial neural crest cells. From a population base of 974,579 births during 1999-2004, we identified 389 California infants with tetralogy of Fallot or d-transposition of the great arteries (d-TGA). We isolated DNA from newborn blood spots of these 389 children and used this DNA for sequencing of candidate genes. We chose 15 candidate genes that are either expressed in secondary heart field, for which mutations have been reported in infants with conotruncal defects, or identified via array comparative genomic hybridization (array-CGH). We amplified exons of these genes using the Access Array system (Fluidigm) and generated sequences using the GS FLX+ instrument (Roche 454). DNA sequences were aligned against reference human DNA sequences, and potential novel variations or single nucleotide polymorphisms (SNPs) were identified within protein coding sequences using SeqNext software (JSI Medical Systems). Variations were confirmed by Sanger DNA sequencing. We found 10 novel variants that were not found in the 1000 Genome project and NHLBI Exome Sequencing Project (ESP) databases, in addition to 5 extremely rare SNPs that may be associated with conotruncal heart defects. We assessed the functional consequences using PolyPhen-2, SNAP, PROVEAN and SIFT programs. All four programs predicted that L394P and C392Y substitutions in GATA5 have deleterious effects. Three programs calculated that A459T and P555A in GATA6 and G164R in ZFPM2 are damaging properties.

2110T

Identification of sequence variants of hepatic lipase (LIPC) gene in individuals with extreme HDL-C/TG levels. *D. Pirim[1], F.Y. Demirci[1], X. Wang[1], J.E. Hokanson[2], R.F. Hamman[2], C.H. Bunker[3], M.M. Barmada[1], M.I. Kamboh[1].* 1) Human Genetics, University of Pittsburgh, GSPH, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO; 3) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA.

The hepatic lipase gene (LIPC) encodes hepatic lipase (HL), which is one of the key lipolytic enzymes in HDL metabolism that regulate plasma triglyceride (TG) and HDL-C levels. Common genetic variation in lipid genes is associated with plasma lipid variation and the risk of coronary heart disease (CHD). We hypothesized that in addition to LIPC common polymorphisms influencing plasma lipid levels, undiscovered uncommon (rare and low frequency) LIPC variants would also contribute to the lipid phenotype. In order to discover rare and low frequency variants, the entire LIPC gene (except for the very large intron 1 which is ~30 kb) was sequenced in individuals with extreme HDL-C/TG levels (95 Whites, 95 Blacks) selected from a non-Hispanic White (NHW) population from the U.S. and a Black population from Nigeria. A total of 411 variants were identified; 128 variants were shared in both populations, 53 were unique to NHWs and 230 were unique to Blacks. One hundred and eighty nine of the observed variants were novel; of which 152 were present only in Blacks and 37 were seen only in NHWs. Two novel variants were located in exons and both were synonymous; others were either intronic or located in flanking regions. In NHWs, 88 of 181 variants were common (MAF≥0.05) and 93 were low frequency or rare variants (MAF<0.05). We found 79 rare variants that are unique to either high HDL-C/low TG or low HDL-C/high TG group. In Blacks, 68 of 358 variants were common and 290 were low frequency or rare; of which 97 were present either in high HDL-C/low TG group or low HDL-C/high TG group. Several variants showed allele frequency differences between the two extreme HDL-C/TG groups in both populations, supporting the previous associations of the LIPC polymorphisms with TG and HDL-C levels. In summary, sequencing LIPC in a relatively small number of individuals with extreme HDL-C/TG levels identified a large number of novel low and rare frequency variants, with the number in blacks approximately 5X that in NHWs. Selected uncommon variants and common tag SNPs are currently being genotyped in our entire sample sets of NHWs (n=623) and Blacks (n=788) for validation and genotype-phenotype association analyses.

2111F

Replication of Hypertension Risk Score in Two Hispanic Populations. *G. Beecham[1], A. Beecham[1], N. Vasudeva[1], L. Wang[1], Z. Liu[1], T. Rundek[2], P. Goldschmidt[3], M. Pericak-Vance[1], D. Seo[2], R.L. Sacco[1,2], S. Blanton[1,2].* 1) Dr. John T. Macdonald Foundation Dept. of Human Genetics, Hussman Inst.for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurology, University of Miami, Miami, FL; 3) Division of Cardiology, University of Miami, Miami, FL.

Hypertension is an important risk factor for coronary artery disease and stroke. Although elevated blood pressure (BP) is associated with environmental factors such as diet and exercise, it is also under genetic influence. Several genome-wide association studies (GWAS) of hypertension have been conducted. In a recent meta-analysis of GWAS data from individuals of European descent the International Consortium for Blood Pressure (ICBP) has identified 29 SNPs that are genome-wide significant. A genetic risk score computed using the 29 SNPs has been replicated in Asian and African populations. Given the sparse data in Hispanics, we sought to evaluate the 29 SNPs and the risk score in Hispanics. We utilized two datasets: one with subjects ascertained through cardiac catheterization labs(the Miami Cardiovascular Registry: MCR); the other with subjects drawn from the community-based Northern Manhattan Study (NOMAS). Both sets are predominantly Hispanic in ethnicity. Only Hispanic samples were used in this study (MCR: N=1063, predominantly Cuban; NOMAS: N=931, 68% Dominican). Genotyping was performed in both sets using the Affymetrix 6.0 array; extensive quality control tests were performed to ensure data integrity. We added 10mmHg and 5mmHg for systolic blood pressure (SBP) and diastolic blood pressure (DBP), respectively, when the subject took antihypertensive medication. Linear regression was performed using the PLINK software, assuming an additive genetic model with age, age^2, and gender included as covariates. Principal components from Eigenstrat were used to control for population substructure. The risk score was computed as described by the ICBP. While confirmation at individual SNPs was marginal, the composite effect of multiple loci was replicated (SBP p=7E-4; DBP p=2E-03), supporting the importance of these genetic variants in influencing BP in Hispanics. Of note, the effect size of the risk score in the MCR was much larger than that in the NOMAS (β=1.27 vs 0.65), with the MCR effect approaching that in European population (β=1.65) and the NOMAS effect approaching that in the African American (β=0.41). The effect size difference in the two Hispanic samples is consistent with the population substructure analysis demonstrating more European ancestry in the MCR. This suggests that, while overall the risk score replicates, the underlying population substructure is relevant to the utility of the risk score.

2112W

Role of the rs1704 HLA-G and rs2227631 PAI-1 polymorphisms in acute coronary syndrome. *I.J. Garcia-Gonzalez[1], Y. Valle[2], F. Rivas[3], LE. Figuera-Villanueva[4], JF. Muñoz-Valle[5], F. Ortega-Gutiérrez[6], BE. Gutiérrez-Amavizca[1], NO. Dávalos-Rodríguez[7], JR. Padilla-Gutiérrez[2].* 1) Doctorado en Genética Humana, CUCS, UdeG, Guadalajara, Mexico; 2) Departamento de Clínicas Médicas, CUCS UdeG; 3) Secretaria de Salud Jalisco; 4) CIBO, IMSS; Centro de investigación Biomédica de Occidente; 5) Departamento de Biología Molecular, CUCS UdeG; 6) CMNO, IMSS; Centro Médico Nacional de Occidente; 7) Instituto de Investigación en Genética Humana, CUCS UdeG.

Introduction: Acute coronary syndrome (ACS) is an important cause of morbidity and mortality. The pathogenesis is linked to immunologic and thrombotic process[1], in which the HLA-G[2] and PAI-1[3] could be involved. The rs1704 is a del/ins of 14 bp at +2960 position in exon 8 of HLA-G, that has been associated with an alternative splicing with changes in the stability of the mRNA[2]. The rs2227631 is a G>A variation in the promoter sequence -844 in PAI-1 gene, the A allele has been related with gene expression changes[3]. We evaluate the participation of rs1704 and rs2227631 polymorphisms in patients with ACS. **Methods**: Were recruited 86 patients with ACS according to American College of Cardiology and 150 healthy subjects age-matched. The study was made in accordance to the Declaration of Helsinki, with acceptance to participate and with an informed written consent. Ethical approval was obtained by the CUCS, UdeG (C.I. 069-2012). The rs1704 polymorphism was identified by conventional PCR and the rs2227631 polymorphism by PCR-RFLP. Fragments were separated in polyacrylamide gel electrophoresis. The genotype and allele differences were estimated by Fisher's exact test. The association measure was evaluated by OR and 95% of confidence intervals. The significance level was p<0.05. **Results**: Both polymorphisms were on Hardy-Weinberg equilibrium expectations. The allele and genotype distributions showed no significant differences between groups. The most common ACS diagnostic and related risk was STEMI and high blood pressure, respectively. The risk factors by genotype were similar among patients. **Conclusion**: The rs1704 HLA-G and rs2227631 PAI-1 polymorphisms are not genetic susceptibility markers to Acute Coronary Syndrome in Western Mexico population. FLNA mutations found in patients with aortic aneurysm/dissections.
H. Morisaki[1], I. Yamanaka[1], A. Yoshida[1], R. Sultana[1], K. Minatoya[2], I. Shiraishi[3], H. Ichikawa[4], T. Kosho[5], H. Sonoda[6], T. Morisaki[1,7]. 1) Dept Bioscience & Genetics, NCVC Res Inst, Suita, Osaka, Japan; 2) Dept Cardiovasc Surgery, NCVC, Suita, Osaka, Japan; 3) Dept Pediatric Cardiol, NCVC, Suita, Osaka, Japan; 4) Dept Pediatric Cardiovasc Surgery, NCVC, Suita, Osaka, Japan; 5) Dept Med Genetics, Shinshu U Grad Sch Med, Matsumoto, Nagano, Japan; 6) Dept Cardiovasc Surgery, Kyushu U Grad Sch Med Sci, Fukuoka, Fukuoka, Japan; 7) Dept Mol Pathophysiol, Osaka U Grad Sch Pharm Sci, Suita, Osaka, Japan.

Thoracic aortic aneurysm /dissections (TAAD) often result from genetic predisposition, since about 10 to 20 % of these patients have a first degree relative with TAAD. To find disease-causing gene mutations for TAAD, we generated exome sequence from 213 individuals with young-onset or familial TAAD and/or related connective tissue disorders, who were confirmed not to have any pathogenic mutation in *FBN1*, *TGFBR1*, *TGFBR2*, *ACTA2* or *SMAD3*. Sequence data was interrogated for sequence changes, compared with the data base of 1000 Genomes. While pathogenic mutations in several genes potentially related to aortopathy emerged from this screening, *FLNA* mutations were recurrently identified in 4 probands. Three females (20-54 years old) were heterozygotes for nonsense or frame-shift mutations and 1 male (22 years old) was a hemizygote for missense mutation in the X-linked *FLNA* gene, encoding filamin A. Family study revealed a mother of the male patient carried the same *FLNA* mutation as her son, and she also had dilated cardiomyopathy with severe mitral valve insufficiency. Brain MRI study exhibited periventricular nodular heterotopias (PNH) in all 5 patients. Further studies on the clinical features showed several cardiovascular events including aortic surgery in 2, severe mitral valve insufficiency in 3, aortic valve insufficiency in 3, severe orthostatic hypotension in 2 and patent ductus arteriosus in 1. Also, several features related to connective tissue disorders, including joint hypermobility in 4, inguinal hernia in 3, thoracic deformity in 3 and venous thrombosis in 2, were observed. Regarding neurological features, all had normal intelligence although two patients were diagnosed as adult-onset epilepsy. *FLNA* was shown as a responsible gene for X-linked PNH. Also, several distinct genetic disorders, including otopalatodigital syndrome, frontometaphyseal dysplasia, Melnick-Needles syndrome and Ehlers-Danlos syndrome, were caused by *FLNA* mutation. The major clinical features of our cases were aortic disorder with some connective tissue involvement. Based on these results and literature reviews, we suggest that it is advisable to screen PNH in patients with young-onset or familial TAAD of unknown etiology, even if there are no neurological findings, since individuals with *FLNA* mutation can exhibit cardiovascular phenotype dominantly. Conversely, we propose to screen cardiovascular manifestations in individuals with X-linked PNH.

2114F

Arrhythmogenic Right Ventricular Cardiomyopathy-Molecular Analysis.
P. Nallari. Dept. of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India.

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an autosomal dominant inherited disease with incomplete penetrance and variable expression. It is a leading cause of sudden cardiac death in the ≤35-year age group. The aim of this study was to highlight the genetic basis of Arrhythmogenic right ventricular cardiomyopathy in Indian origin. Blood sample from 100 control individuals and 40 probands with clinical data was obtained. The ARVC diagnosis was established based on Task Force Criteria (TFC) set by the ESC. Mutational screening of two desmosomal genes Plakophilin-2 (PKP-2), Desmoplakin (DSP) and two non-desmosomal genes Ryanodine receptor-2 (RyR-2) and Transforming growth factor β -3 (TGFβ -3) was carried out. Variant band pattern were confirmed on commercial sequencing and insilico analysis was carried out. The study revealed 23.529% of patients had mutations in desmosomal genes where as 14.705% of patients had mutations in non-desmosomal genes. 44.1% familial cases clearly establishing the genetic basis of ARVC. The total percentage of mutations reported is 33.3%. Three different mutations in PKP-2 gene CT deletion, P244L and G>A transition in intronic region of exon 4 and an insertion in intronic region of exon 28 of RYR-2 and an amino acid substitution in DSP (I305F) gene/s were observed . Novel SNPs were also reported in RYR-2(A>C, A>G and A>C) and DSP (deletionG) gene/s. The potentials of pathogenecity and functionality of the above results are carried out by In-silico analysis.

2115W

A Variant in the 5-Hydroxytryptamine Receptor 1 A (HTR1A) Gene Is Associated with Platelet Reactivity and Incident Cardiovascular Events.
S.H. Shah[1,2], M.A. Babyak[3], E.R. Hauser[2], D. Craig[2], M. Chryst-Ladd[2], C. Haynes[2], B. Brumett[3], W.E. Kraus[1,2], R. Becker[1], R.B. Williams[3]. 1) Division of Cardiology, Department of Medicine, Duke University Medical Center, Durham, NC; 2) Duke Institute for Molecular Physiology, Durham, NC; 3) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC.

Background. Variation in the 5-hydroxytryptamine receptor 1 A (HTR1A) gene has been associated with psychiatric phenotypes. Given that depression has been linked to cardiovascular disease (CVD) events, we hypothesized that HTR1A SNP rs1364043 is associated with platelet reactivity (an intermediate phenotype for CVD events), and is associated with CVD event endpoints. Methods. Rs1364043 in HTR1A was genotyped using an ABI Taqman assay in 8697 participants in the CATHGEN biorepository of patients referred to Duke University for cardiac catheterization for evaluation of CVD. Incident events were defined as all-cause death and/or myocardial infarction (MI) after enrollment. Race-stratified Cox proportional hazards modeling was used to test for association with time-to-event in two models (death and death or MI), adjusted for age, sex, hypertension, diabetes, ejection fraction, CAD, dyslipidemia, smoking, and BMI. Expression quantitative trait loci (eQTL) analyses were used to test for cis and trans effects of SNP on RNA expression using additive multivariable linear regression. Association between rs1364043 and platelet reactivity was tested in N= 410 healthy individuals, defined as a binary trait of hyperreactivity (>60% aggregation to epinephrine [2 μM] and serotonin [10 μM]), using generalized linear models adjusted for age, sex and race. Results. In whites, the C allele of rs1364043 was associated with time to death in additive (hazard ratio [HR] 1.09, 95% CI [1.0-2-1.12], p=0.04) and dominant models (HR 1.11 [1.0001-1.24], p=0.05), and with time to death/MI (HR 1.10 [1.02-1.19], p= 0.02 for additive and HR 1.13 [1.03-1.25], p=0.02 for dominant model). eQTL analyses identified no cis effects. The top trans transcripts associated with rs1364043 including several genes involved in cell cycle processes, protein synthesis and stability including CDKN1a, RPL32, ASNS, DDHD2, MED27 and STOML2 (p=0.002-0.0003). Platelet reactivity studies showed a trend for higher proportion of individuals with high platelet reactivity in rs1364043 C allele homozygotes as compared with heterozygotes or wildtype (73.7% vs. 58.0% vs. 52.0%, p=0.04, dominant model). Conclusions. Genetic variants associated with intermediate traits may themselves serve as disease risk variants. We have shown that a variant in HTR1A, previously associated with intermediate psychosocial traits, is also associated with platelet hyperreactivity and predicts CVD events, with an up to 13% increased risk.

Exome sequencing identifies BAG3 gene mutation in dilated cardiomyopathy.
M. Taylor[1], R.L. Begay[1], V.D. Myers[2], S.L. Graw[1], D. Slavov[1], P. Boyer[1], L. Mestroni[1], A. Feldman[2]. 1) Adult Med Gen Prog, University of Colorado - CU Cardiovascular Institute, Aurora, CO; 2) Temple University School of Medicine, Philadelphia, PA.

Background: Recently BAG3 has been identified as a cause of genetic forms of dilated cardiomyopathy. The consequences of BAG3 mutations on cardiac pathology and the role of BAG3 in heart failure are not known. Methods: Whole exome DNA analysis was performed on a multi-generational family affected with dilated cardiomyopathy. Prior studies including linkage analysis, candidate gene analysis, and SNP array analysis had failed to locate the pathogenic mutation. Exome capture was achieved using the Agilent SureSelect Exome capture system and sequencing was completed on an Illumina HiSeq2000. Analysis of explanted human heart tissue from one mutation carrier was performed and BAG3 levels in control and failing hearts were assayed by Western blot analysis. Results and Conclusions: A 10-nucleotide deletion in exon 4 of the BAG3 gene was identified through exome sequencing from distantly affected family members. The mutation was present in seven affected family members and absent in eight healthy relatives. Standard histology of a BAG3 mutation carrier's explanted heart revealed mild to moderate myocyte hypertrophy and patchy mild to moderate interstitial fibrosis; changes more prominent in the left ventricle and septum than the right ventricle. Also, electron microscopy suggested increased glycogen deposition, possibly related to the role of BAG3 protein in autophagy and cellular trafficking. BAG3 levels were markedly depressed without evidence of truncated BAG3 protein in the explanted heart specimen, consistent with haploinsufficiency. Conclusions: Exome sequencing is increasingly useful in identifying pathogenic mutations in cardiomyopathy families where distant relatives are available for segregation analysis. The microscopic evaluation identified notable features of BAG3 heart biopsy due to apparent haploinsufficiency of BAG3, suggesting that modulation of BAG3 levels could represent a novel avenue for therapeutic exploration.

2117F

Haploinsufficiency of *RERE* contributes to cardiovascular defects associated with 1p36 deletions. *H. Zaveri[1], B.J. Kim[1], A. Hernandez-Garcia[1], T.F. Beck[1], O.A. Shchelochkov[2], M. Justice[1], B. Lee[1], S.R. Lalani[1], D.A. Scott[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Dept of Pediatrics, The University of Iowa, Iowa City, IA.

Terminal deletions of chromosome 1p36 affect 1 in 5000 newborns and cause a clinically recognizable syndrome characterized by cognitive impairment, eye/vision problems, hearing loss, facial clefting, cardiovascular malformations and cardiomyopathy. Although cardiovascular anomalies and/or cardiomyopathy affect 71% of individuals with 1p36 deletions, and are the most common cause of morbidity and mortality in the newborn stage,the genes that contribute to these phenotypes have yet to be identified. Using a clinical and molecular cytogenetic data from individuals with terminal and interstitial deletions, we have created a deletion/phenotype map of the 1p36 region. This map includes five non-overlapping critical regions for cardiovascular defects and two non-overlapping critical regions for cardiomyopathy. The majority of these regions contain positional candidate genes which have been shown to cause cardiovascular malformation and/or cardiomyopathy in mice. These genes include *DVL1*, *SKI*, *PRDM16*, *UBE4B*, *PDPN*, *SPEN*, *HSPG2*, *CDC42*, and *LUZP1*. The arginine-glutamic acid dipeptide repeats gene (*RERE*) encodes a nuclear receptor coregulator and is located in a critical region for both cardiovascular malformations and cardiomyopathy on 1p36 and is required for normal retinoic acid signaling. Since perturbations in retinoic acid signaling can cause cardiovascular malformations, and retinoic acid signaling suppresses myocardial hypertrophy and cardiac fibrosis, we hypothesized that RERE deficiency contributes to the cardiac phenotypes seen in individuals with terminal and interstitial 1p36 deletions that include *RERE*. To test this hypothesis, we generated an allelic series of RERE-deficient mice using an *Rere* null-allele and a hypomorphic *Rere* allele (*eyes3*) identified in our laboratory. A portion of *Rere*$^{+/-}$ mice had aortic arch anomalies. *Rere*$^{-/eyes3}$ mice had more serious cardiac defects which included aortic arch, conotruncal, and septal defects. In absence of structural cardiac defects, these mice spontaneously developed cardiac fibrosis and cardiomegaly. *Rere* null mice (*Rere*$^{-/-}$) had unlooped hearts and died of cardiac failure at E9.5. Cardiac defects were also documented in mice in which *Rere* was conditionally ablated in the first and second heart fields. We conclude that RERE functions in a cell autonomous manner to direct cardiac development and that deletion of *RERE* contributes to the cardiac malformations and cardiomyopathy associated with 1p36 deletions.

Analysis of Common and Coding Variants with Cardiovascular Disease in the Diabetes Heart Study. *J.N. Adams[1,2,3], L.M. Raffield[1,2,3], B.I. Freeman[4], C.D. Langefeld[5], M.C.Y. NG[2,3], J.J. Carr[6], A.J. Cox[2,3,7], D.W. Bowden[2,3,7].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston-Salem, NC; 5) Division of Public Health Sciences, Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Radiologic Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 7) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC.

Type 2 diabetes (T2D) affects ≈8% of the US population. T2D is a major risk factor for cardiovascular disease (CVD). Up to 65% of T2D deaths are CVD-related. Identification of genetic risk factors for CVD is important to understand individual disease risk. Recent GWAS meta-analyses in the CHARGE consortium identified loci associated with coronary artery calcification (CAC), myocardial infarction (MI), carotid intima media thickness (IMT), and/or carotid plaque. CAC and IMT are clinically relevant measures of subclinical CVD and strongly predict mortality. We examined if prior associations from the population-based CHARGE study were applicable in the Diabetes Heart Study (DHS), a family-based cohort (n=1220) with >80% T2D affected subjects. SNPs (n=36) from CHARGE were evaluated in GWAS data from the DHS. Phenotypes including vascular calcification and conventional CVD risk factors were tested. No SNPs were significantly associated after correction for multiple comparisons ($p<0.0014$), although multiple SNPs showed nominal significance: rs599839 in *PSRC1* (β=-0.315, p=0.0084) and rs646776 in *CELSR2* (β=-0.380, p=0.0099) were associated with CAC; rs17398575 in *PIK3G* was associated with aortic calcification (AACP) (β=11.0, p=0.0054). Additional SNPs at *COL4A2* and *CXCL12* were nominally associated with all-cause or CVD-mortality. Genes implicated by CHARGE were investigated further by examining exonic variants. 209 coding variants were investigated using Illumina HumanExome BeadChip genotype data from the DHS; rs61730407 in *OR2G3* was significantly associated with AACP (β=85.4, $p=7.1\times 10^{-5}$). Additional SNPs were nominally associated with multiple lipid measures and subclinical CVD (CAC, AACP, and IMT) ($0.00026<p<0.0097$). Genetic risk scores (GRS) were calculated to evaluate multiple variants from the CHARGE study. We constructed a GRS containing CHARGE SNPs (n=12) associated with CAC. A second GRS was calculated containing SNPs associated with both CAC and MI (n=8). GRS associations with mortality, CVD events and vascular calcified plaque were examined. The GRS containing CAC SNPs was associated with history of CVD events (p=0.033; OR=1.09). The CAC/MI GRS was associated with history of MI (p=0.026; OR=1.15). We found that genetic risk factors for subclinical CVD in the general population (CHARGE) were, in part, associated with T2D-related risk factors and outcomes.

***VKORC1* and *CALU* eQTLs and susceptibility to venous thromboembolism among African Americans.**
W. Hernandez[1], E.R. Gamazon[1], A. Konkashbaev[1], K. Aquino-Michaels[1], T.J. O'Brien[2], A.F. Harralson[2], R.A. Kittles[3], A. Barbour[4], M. Tuck[5], S.D. McIntosh[4,5], J.N. Douglas[5], L.H. Cavallari[6], M.A. Perera[1]. 1) Department of Medicine, Section of Genetic Medicine, University of Chicago, Chicago, IL; 2) The George Washington University, Department of Pharmacology and Physiology Washington, DC; 3) University of Illinois, Department of Medicine, Institute of Human Genetics, Chicago, IL; 4) The George Washington University, Department of Medicine, Washington, DC; 5) Uniformed Services University of the Health Sciences, Department of Veterans Affairs, Washington, DC; 6) University of Illinois, Chicago, Department of Pharmacy, Chicago, IL.

Venous thromboembolism (VTE) is a complex disease encompassing deep vein thrombosis (DVT), pulmonary embolism (PE), or a combination of both. In the US, each year over 900,000 individuals are hospitalized due to VTE and over 300,000 patients die. African Americans (AAs) have the highest incidence and mortality rates of DVT and PE. Warfarin is used to treat and prevent DVT and/or PE. However, warfarin dose requirement has been shown to be higher among AAs as well as DVT/PE patients. In this study, we aimed to investigate the role between *VKORC1* and *CALU* expression quantitative trait loci (eQTLs) and DVT/PE susceptibility. As subtle differences in plasma levels of proteins involved in the coagulation pathway may be risk factors, eQTLs may yield novel insights into the genetic risk of DVT/PE. Using publicly available liver eQTL data, we identified both cis and trans eQTLs for *VKORC1* and *CALU* genes known to be associated with warfarin dose. 72 SNP eQTLs were genotyped in a study population of 462 AAs on stable warfarin dose; of which 256 individuals were treated with warfarin due to DVT/PE (cases) and the remaining due to a variety of other conditions including atrial fibrillation (controls). We found a significant decrease in risk of DVT/PE for carriers of the minor allele of two *VKORC1* eQTLs and one *CALU* eQTL (rs9925964, OR=0.53, P=0.01; rs12597511, OR=0.48. P=0.02; and rs11054879, OR=0.61, P=0.03 respectively). We also found our DVT/PE patients had a higher percentage of West African ancestry and were younger compared to controls (t=-1.991, p=0.04 and t= 2.720, p=0.007 respectively). Interestingly, the frequency of these protective alleles were approximately 10% in our study population and significantly higher in the HapMap European Americans (CEU) at approximately 40% but lower among Yorubans (YRI) at 5%. The lower frequency of these protective alleles among populations of African descent compared to European Americans (EAs) is particularly interesting as the risk of DVT/PE is lower among EAs than AAs. In this study, we also observed *VKORC1* -1639 is highly associated with warfarin dose requirement (β=-0.42 and P=6.79E-12) but not to DVT/PE susceptibility (OR=0.79 and P=0.32). By investigating eQTLs for genes known to contribute to warfarin dose requirement we have uncovered novel disease loci involved in the coagulation cascade and risk of DVT/PE. These findings may help explain the increased risk of DVT/PE seen in the African American population.

Multi-allelic Haplotype Association Identifies a new Protective Haplotype in the KCNN3 Gene for Post-Operative Atrial Fibrillation.
M. Heydarpour[1], C. Collard[2], A. Fox[1], J. Muehlschlegel[1], M. Sigurdsson[1], S. Shernan[1], S. Body[1]. 1) Department of Anesthesiology, Preoperative and Pain Medicine, Brigham and Women's Hospital, Boston, MA; 2) Division of Cardiovascular Anesthesia, Texas Heart Institute, Houston, TX.

Atrial fibrillation (AF) is the most common arrhythmia after cardiac surgery. Two regions have been associated with AF in ambulatory populations (KCNN3, ZFHX3), but not yet associated with AF in cardiac surgical populations. Candidate single nucleotide polymorphisms (SNPs) that describe risk haplotypes for AF in ambulatory populations were genotyped in this study. The objective was to replicate findings of AF-associated loci while accounting for previous association of 4q25 with postoperative AF (poAF). Using a case-control association study of 325 Caucasian patients with poAF and 727 Caucasian controls, we examined 488 SNPs in three regions (1q21.3, 4q25 and 16q22.3) for SNP and haplotype association analysis using logistic regression analysis while accounting for age, gender, prior AF and other clinical variables, and an additive genetic model. Maximum likelihood hierarchical clustering methods were used for haplotype clustering analysis. Permutation testing was used to assess statistical significance. Significant association was identified between SNPs rs6683557 (1q21.3, OR=0.70, P= 0.00051), rs3853445 (4q25, OR=0.68, P=0.0016), and rs67402452 (16q22.3, OR=1.45, P=0.0033) and poAF after adjusting for prior association of SNPs in 4q25 and for clinical variables. We identified a 1q21.3 haplotype, AAAAG which conferred significant protection against poAF (OR=0.564, P= 0.0011). All five SNPs in this haplotype were intronic to KCNN3, which encodes a potassium channel protein involved in atrial repolarization. The rs3853445 in 4q25 region as a protective variant against AF has been reported by Lubitz et al., 2010, (OR=0.71, P=4.1×10-5) which is confirmed by this study. Two other susceptible markers (rs2200733 & rs13143308) are identified in 4q25 for risk of poAF which previously reported by Body et al. 2009 to predict poAF after coronary artery bypass graft (CABG). These results suggest that a common haplotype AAAAG of KCNN3 gene confers a significant protective effect on the development of poAF. Our results confirmed the role of these two regions variants for AF risk in previous studies (Body et al. 2009, Benjamin et al. 2009, Ellinor et al. 2012) for European-descent population. Consideration of multiple susceptibility signals at these regions identifies individuals in high risk of AF or protective against AF and they may localize regulatory elements at the locus with biological relevance in the pathogenesis of AF.

2121W

Elucidating the role of genes encoding sarcomeric structural proteins in modulating cardiac hypertrophy in Hypertrophic Cardiomyopathy.
C.J. Kinnear[1], L. Bloem[1], L. van der Merwe[2], M. Revera[3], M. Heradien[4], A. Goosen[4], PA. Brink[4], JC. Moolman-Smook[1]. 1) University of Stellenbosch/ Medical Research Council (US/MRC) Centre for Molecular and Cellular Biology, Department of Biomedical Sciences, Stellenbosch University, South Africa; 2) Biostatistics Unit, Medical Research Council of South Africa; 3) Department of Cardiology, IRCCS San Matteo Hospital, Pavia, Italy; 4) Department of Medicine, Faculty of Health Sciences, University of Stellenbosch, South Africa.

Hypertrophic cardiomyopathy (HCM) is an autosomal dominantly inherited cardiac muscle disease clinically defined by unexplained left ventricular hypertrophy (LVH). The degree and location of the LVH in HCM patients is extremely variable, even in patients carrying the same HCM-causing mutations. Phenotypic expression of HCM is therefore dependant on the disease-causing mutation as well as additional determinants including environmental factors and modifier genes. Many investigations aimed at identifying modifier genes in HCM have focused on genes that are relatively far removed from the primary disease-causing genes. We hypothesise that since most HCM-causing mutations are found in genes encoding proteins of the cardiac sarcomere, factors that closely interact with defective sarcomeric proteins, will have a greater capacity to modulate them and thus modulate the LVH phenotype. Therefore genes encoding sarcomeric structural proteins as well as those encoding enzymes that function in sarcomere-based energetics may be considered plausible modifier genes of LVH in HCM. In the present study we focused on genes encoding sarcomeric structural proteins as candidate modifiers of LVH. A total of 24 single nucleotide polymorphisms (SNPs) in 9 genes (ACTC1, TNNT2, TNNI3, TPM1, ACTN3, MYL3, MYH7, MYL2 and MyBPC3) were investigated for association with cardiac hypertrophy traits in a familial HCM-cohort. A total of 388 individuals from 27 HCM South African HCM families in which one of three HCM founder mutations segregates (R92WTNNT2, R403WMYH7 and A797MYH7) were genotyped by validated Taqman® SNP genotyping assays. All participants provided written informed consent and was conducted in accordance with the ethical guidelines as set out in the 'Declaration of Helsinki', 2008. We identified a modifying role in the development of hypertrophy in HCM for each of the candidate genes investigated in the present study. More specifically, single variant association analyses identified a modifying role for variants within MYH7, TPM1 and MYL2, while Haplotype-based association analyses identified combined modifying effects for variants within ACTC, TPM1, MYL2, MYL3 and MYBPC3. The data presented here indicates that variations sarcomeric structural genes may act as modifiers of cardiac hypertrophy in HCM. These findings further enhance our understanding of genotype/ phenotype correlations in HCM and could potentially improve patient risk stratification and management.

Analysis of Coding Variants in C1q/TNF Superfamily Genes in the Diabetes Heart Study.
L.M. Raffield[1,2,3], A.J. Cox[2,3,4], C.D. Langefeld[5], M.C.Y. Ng[2,3], J.J. Carr[6], B.I. Freedman[7], D.W. Bowden[2,3,4]. 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC, USA; 2) Center for Human Genomics, Wake Forest University Health Sciences, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC, USA; 5) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC, USA; 6) Department of Radiologic Sciences, Wake Forest School of Medicine, Winston-Salem, NC, USA; 7) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston-Salem, NC, USA.

Members of the C1q/tumor necrosis factor (TNF) superfamily have a variety of roles in inflammation and metabolism and have been associated with cardiovascular disease (CVD) and type 2 diabetes (T2D). Previously, we have shown that coding variants in the collagen domain of the C1q family member adiponectin dramatically lower serum adiponectin levels and impede multimerization. We hypothesized that coding variants influencing multimerization or other protein-protein interactions in C1q/TNF superfamily members and their binding partners/ receptors could impact CVD- and T2D-related phenotypes. This analysis was performed in 1190 European American individuals from 468 families in the Diabetes Heart Study (DHS). In the DHS cohort, 83.7% of participants were affected by T2D with average disease duration of 10.5 ± 7.2 years. Genotyping was completed using the Illumina Infinium HumanExome BeadChip array. 464 coding variants in 97 C1q/TNF related genes were analyzed for associations with CVD- and T2D-related phenotypes, including measures of vascular calcified plaque, glucose control, dyslipidemia, inflammation, renal function, bone density, and adiposity. Single variant association analyses were performed using a variance components based approach in SOLAR, while analyses of all variants in a given genetic locus were performed using the rare variant Sequence Kernel Association Test program for family data (famSKAT). These analyses were adjusted for age, sex, and T2D status. While significant associations with mutations in domains important for multimerization were rare, several associations were observed in binding partners/receptors, including a variant in cadherin 13 (Asn39Ser, MAF= 0.006) associated with abdominal aortic calcification (p= 6.23×10^{-6}) and a variant in calreticulin (Glu381Ala, MAF= 0.001) associated with CRP levels (p= 1.80×10^{-5}). Adiponectin can bind both cadherin 13 and calreticulin, and these loci have been previously associated with CVD-related phenotypes and prevention of systemic inflammation, respectively. The 8 variants in the cadherin 13 locus were also cumulatively associated with abdominal aortic calcification (p= 2.52×10^{-5}) in analysis using famSKAT. Replication of these uncommon coding variants in additional cohorts will be necessary, but these results suggest important roles for C1q/TNF superfamily members in CVD- and T2D-related phenotypes which can be revealed by analysis of exonic variants.

2123F

Cross-sectional and Longitudinal Replication Analyses of Genome-wide Association Loci of Type 2 Diabetes in Han Chinese Populations.
Q. Zhao[1], X. Kong[2], J. Hong[2], X. Zhang[2], J. He[1], W. Yang[2]. 1) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 2) Department of Endocrinology, China-Japan Friendship Hospital, Beijing, China.

Most of the genetic loci for type 2 diabetes (T2D) identified by genome-wide association studies (GWAS) in populations of European ancestry are still controversial about their associations with T2D of East Asians. The purpose of our study is to examine recently GWAS-identified loci for their associations with T2D and quantitative glycemic traits and their effects on longitudinal changes in fasting plasma glucose (FPG) and T2D development in Han Chinese populations. Single nucleotide polymorphisms (SNP) from 26 loci were genotyped in 10,001 Chinese Hans (5,338 T2D cases and 4,663 controls). Eight SNPs in or near *WFS1*, *CDKAL1*, *CDKN2A/2B*, *CDC123*, *HHEX*, *TCF7L2*, *KCNQ1*, and *MTNR1B* showed significant associations with T2D ($P < 0.05$). The most significant SNP, rs10811661 near *CDKN2A/2B* ($P = 1.11 \times 10^{-8}$), were also associated with glucose level of 2-h post an oral glucose tolerance test ($P = 9.11 \times 10^{-3}$) and insulinogenic index ($P = 2.71 \times 10^{-2}$). A total of 16 SNPs showed consistent association directions with the reported T2D GWAS meta-analysis results of the Asian Genetic Epidemiology Network (AGEN) (6,952 cases and 11,865 controls). Twelve SNPs of the 16 aforementioned SNPs reached the significance of 0.05 in a combined analysis of AGEN and the current study (including 28,818 subjects), and most of them had similar effect sizes to those seen in European populations. In a cohort of 1,881 Chinese Hans without T2D at baseline, individuals carrying more risk alleles of the replicated SNPs in the combined analysis had greater FPG increase and T2D incidence over a 7.5-year follow-up period, with each quartile increase in the number of risk alleles being associated with a 0.06 mmol/l greater increase in FPG ($P = 0.03$) and 19.0% higher odds for developing T2D ($P = 0.058$). Our results indicate that some of GWAS-identified loci for T2D in Europeans are associated with T2D and glycemic traits and may also predict risk for T2D development in the Chinese population.

Sex-specific genetic variants on 11p15 influence high density-lipoprotein cholesterol levels in long-lived subjects: The Long Life Study Family (LLFS). *M.F. Feitosa[1], M.K. Wojczynski[1], C.M. Kammerer[2], W. Daw[1], R.J. Straka[3], J.H. Lee[4], K. Christensen[5], A.B. Newman[6], M.A. Province[1], I.B. Borecki[1].* 1) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 2) Department of Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 3) Department of Experimental and Clinical Pharmacology, College of Pharmacy, University of Minnesota, Minneapolis, MN; 4) Sergievsky Center and Taub Institute, College of Physicians and Surgeons, Columbia University, New York, NY; 5) Institute of Public Health at the University of Southern Denmark, Denmark; 6) Department of Epidemiology, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA.

Studies have shown that high levels of high-density lipoprotein cholesterol (HDL-C) have protective effects on atherosclerosis and cardiovascular disease, and also have been associated with longevity. Some of the common variants, which have been identified by genome-wide association (GWA) studies, appear to have sex-specific effects. However, while GWA is suited for interrogation of common variation in the genome, rare variants will likely be missed and may account for some degree of the missing heritability. In order to identify regions of the genome that are likely to harbor collections of rare variants influencing HDL-C, we returned to classical linkage analysis, using data from 2,256 women and in 1,858 men from 534 healthy-eldest families participating in the LLFS. A linkage marker panel was created by estimating haplotypes across the genome comprised of sets of up to 5 SNPs within a 0.5 cM interval from the GWA panel, resulting in markers with high polymorphic information content. The proportion of alleles shared Identical-by-descent over all such loci was estimated for all relative pairs using LOKI, and linkage analysis was carried out using SOLAR. For subjects taking lowering-lipid medications, a constant was added to their measured HDL-C levels specific to the reported class of medication. HDL-C was then adjusted for age effects and principal components for stratification using stepwise regression, within sex. Significant linkage was found on 11p15 for HDL-C in women (LOD=4.2) at 19 cM, but not in men (LOD=0.5) or in sex-combined data (LOD=2.2). To test whether common variants from GWA explained this linkage peak, we further adjusted HDL-C for the effects of our GWA SNPs with p <1e-4 and repeated the linkage analysis. Despite the decrease in LOD from 4.2 to 3.0, evidence of linkage remained, suggesting that other variants in the region influence HDL-C, and these may be rare variants. Because it is likely that different variants are segregating in different families, we aggregated the 277 families (1,065 women) supporting linkage to this region with Heterogeneity LOD=20.9. The strong evidence of genetic effects in these families were within 5-11 Mb region. Chromosome regions thus detected can be prioritized for sequencing to identify the specific rare variants influencing HDL-C in these healthy-longevous families.

Influence of genetic determinants and lifestyle factors on blood lipid traits: 10-year follow-up of the GLACIER Study. *T.V. Varga[1], D. Shungin[1,2,3], R.W. Koivula[1], G. Hallmans[2], I. Johansson[3], I. Barroso[4,5,6], F. Renström[1], P.W. Franks[1,2,7].* 1) Department of Clinical Sciences, Genetic and Molecular Epidemiology Unit, Skåne University Hospital Malmö, SE-205 02, Malmö, Sweden; 2) Department of Public Health & Clinical Medicine, Umeå University Hospital, Umeå, Sweden; 3) Department of Odontology, Umeå University, Umeå, Sweden; 4) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, UK; 5) NIHR Cambridge Biomedical Research Centre, Institute of Metabolic Science, Addenbrooke's Hospital Cambridge, UK; 6) University of Cambridge Metabolic Research Laboratories, Institute of Metabolic Science, Addenbrooke's Hospital Cambridge, UK; 7) Department of Nutrition, Harvard School of Public Health, Boston, USA.

Background - Recently, a genome-wide meta-analysis identified 95 loci associated with lipid traits (Teslovich *et al.*, Nature, 2010), here we attempted to test whether these loci associate (singly and in trait-specific genetic risk scores (GRS)) with longitudinal changes in total cholesterol (TC) and triglyceride (TG) levels in a population-based prospective cohort from Northern Sweden, the GLACIER Study. We also investigated the extent to which reducing extraneous model variance by adjusting for lifestyle factors (e.g. diet, physical activity, socio-economic position) affects the ability to detect associations. **Methods and Results** - A total of 6,064 participants of the GLACIER Study were genotyped with the MetaboChip array. Up to 3,495 had longitudinal (10-yr follow-up) data available. The TC- and TG-specific GRSs were strongly associated with change in lipid levels over the 10-yr period (β=0.02 mmol/l per effect allele, P=1.98/10^{-11} for TC; β=0.02 mmol/l per effect allele, P=0.0005 for TG). One TC locus, rs4420638 in *APOE* (β=0.12 mmol/l per effect allele, P=2/10^{-5}) and one TG locus, rs2954029 in *TRIB1* (β=0.09 mmol/l per effect allele, P=8.5/10^{-4}) remained significantly associated with longitudinal changes in the respective traits after correction for multiple testing, results which we are currently replicating. Additionally adjusting for lifestyle factors in the analyses did not materially change these results. **Conclusion** - In conclusion, in both cross-sectional and longitudinal analysis, the trait-specific GRSs were significantly associated with TC and TG levels. Furthermore, two SNPs were individually associated with changes in lipid levels over the 10-year follow-up period.

2126F

HAPLOTYPES OF CYTOKINE GENE POLYMORPHISMS IN DILATED CARDIOMYOPATHY. *M.L. Satyanarayana[1], V. Viswamitra[1], N. Swapna[2], N. Pratibha[1].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Department of Cardiology, CARE Hospitals, Hyderabad, Andhra Pradesh, India.

Dilated cardiomyopathy is characterized by left ventricular dilatation, impaired systolic function, reduced myocardial contractility and inefficient pumping of the heart. The symptoms include tachycardia, palpitations, syncope and a risk for sudden cardiac death, culminating into heart failure or premature deaths in children and adults. Myocarditis, systemic diseases and myocardial toxins have been identified as causative factors for DCM. Elevated levels of inflammatory cytokines have been reported in patients with DCM. However, inflammation is an important component and one of the possible mechanisms in cardiomyopathy. Hence present study is designed to study the role of polymorphisms associated with cytokines like IL-1β (-31C/T, -511C/T) and TNF-α (-308G/A). The study includes 200 healthy individuals and 105 DCM cases. IL-1β (-31C/T, -511C/T) genotyping was done by PCR based RFLP method and TNF-α by allele-specific PCR. Allelic and genotypic frequencies were estimated and control groups and appropriate statistical tests were employed. A significant association of CT genotype (C-31T) with an odds ratio of 1.69, (95% CI 1.03 - 2.77, p= 0.04) was observed in DCM. However, no significant association was observed with respect to other two polymorphisms studied. The loci combinations C-31T:C-511T and C-511T:G-308A were in perfect LD (D' = 0.99) highlighting the synergistic role of these polymorphisms in the pathology of the disease. On haplotype analysis TTA haplotype was found to exhibit 1.5 folds increased risk for DCM compared to the controls (OR 1.50, 95% CI 1.02 - 2.25, p=0.05), whereas the haplotypes CTG and CTA were found to exhibit protective effect (OR 0.47, 95% CI 0.27 - 0.83, P=0.009; OR 0.28, 95% CI 0.13 -0.60, P=0.001). The T allele of C-31T polymorphism could be the risk allele for DCM and TTA haplotype could be the risk haplotype for DCM, whereas CTG and CTA haplotypes could be protective haplotypes.

2127W

Multi-ethnic case-control studies of Moyamoya disease by high-depth exome sequencing of unrelated affected individuals and matched controls. *M. Clark[1], L. Shoemaker[2,3], A. Patwardhan[1], R. Chen[1], G. Chandratillake[1], S. Garcia[1], N. Leng[1], S. Chervitz[1], M. Pratt[1], H. Lam[1], D. Newburger[1], S. Kirk[1], C. Haudenschild[1], J. West[1], R. Chen[1], G. Steinberg[2,3].* 1) Personalis, Inc., Menlo Park, CA; 2) Department of Neurosurgery, Stanford University School of Medicine, Stanford, CA; 3) Stanford Institute for Neuro-Innovation & Translational Neurosciences, Stanford University, Stanford, CA.

Moyamoya disease (MMD) is a rare cerebrovascular disorder characterized by stenosis/occlusion of the internal carotid artery and proliferation of microvessels. Symptoms include stroke, seizures, aphasia and cognitive impairments. It exhibits low penetrance autosomal dominant inheritance. To determine genetic associations with MMD, 125 ethnically diverse unrelated patients were matched based on gender and broad ethnic categories to 125 controls obtained from the 1000 Genomes Project. All case and control samples were exome sequenced to high depth and analyzed together using the Personalis Pipeline. Rather than using public 1000 Genomes data, case and control exomes were resequenced on the same platform and analyzed together to reduce experimental biases. Case-control analyses were performed within broad ethnic subsets (70 Asian, 136 Caucasian) to identify enriched variants. In order to investigate associations with MMD among cases in which the known founder RNF213 mutation was absent, an additional matched case-control analysis using only samples without the mutation was conducted. Variants were collapsed into genes to identify genes enriched for mutations in these MMD cases. The most highly enriched variant in Asian cases, R4810K (p=6.01×10-5), confirmed a known founder mutation in the gene RNF213 in the Asian population. Notably, this mutation was highly enriched in East Asians, but not Southeast Asian or Pacific Islander samples (p=9.52×10-4). A second variant (R4810G) was identified at the same locus as the East Asian founder mutation in one self-identified Filipino sample. Frameshift, nonsense, and splice site mutations were not observed in RNF213 in any of the case and control samples, suggesting that severe loss of function mutations in RNF213 may not be tolerated. In the Caucasian subset, the most highly enriched variant was P562L in the ZXDC gene (p=7.93×10-4), but no strong founder mutation was identified. Among cases without the RNF213 founder mutation, the collapsing method ranked OBSCN as the gene most enriched for variants (p=5.31×10-5). Our analyses leveraged high-depth exome sequencing, an internally re-sequenced multi-ethnic control set, and an analysis pipeline that identified disease-associations despite limited samples sizes. We independently confirmed the RNF213 founder mutation for MMD in the East Asian population, found it absent in other ethnicities, and identified new candidate genes via collapsing methods.

Digenic inheritance of mutations in ITGA7 and MYH7B results in congenital myopathy with left ventricular non compact cardiomyopathy.

T. Esposito[1], S. Sampaolo[2], G. Limongelli[3], A. Varone[4], D. Formicola[1,2], D. Diodato[2], O. Farina[2], F. Napolitano[1], G. Pacileo[3], F. Gianfrancesco[1], G. Di Iorio[2]. 1) Inst Gen & Biophysics, Italian Natl Res Council, Naples, Italy; 2) Department of Medical Sciences, Surgery, Neurological, Metabolic and Aging, Second University of Naples, Italy; 3) Department of Cardiological Sciences, Second University of Naples, Italy; 4) Department of Neuro-sciences, 'Santobono-Pausilipon' Hospital, Naples, Italy.

We describe an unusual association between congenital fiber type disproportion (CFTD) and left ventricular non compaction cardiomyopathy (LVNC) in the proband of an Italian family. The CFTD myopathy is a genetically heterogeneous disorder characterized by relative hypotrophy of type 1 muscle fibers compared to type 2 fibers on skeletal muscle biopsy. The hallmark features of LVNC include prominent trabeculations and deep endocardial recesses associated with arrhythmias, thromboembolic events, and heart failure. Clinical and instrumental analysis of the family members identified the LVNC phenotype also in the mother, the sister and the first-degree cousin of the proband suggesting a dominant mode of inheritance with high phenotype heterogeneity and reduced penetrance. Recessive mode of inheritance was assumed for the CFTD phenotype which is characteristic of the proband. The study was focused at the identification of the responsible gene/s through whole exome sequencing approach. Two homozygous missense mutations in two genes, the myosin heavy chain 7B (MYH7B) and the integrin alpha 7 (ITGA7) were identified. Both genes are expressed in heart and muscle tissues and both mutations were predicted as deleterious and were not found in healthy population. The R890C mutation in the MYH7B gene segregates with the LVNC phenotype in the examined family, and was also found in one not related patient affected by LVNC. The arginine at position 890 of the MYH7B gene is highly conserved in all species and this region is also conserved in MYH7 gene in which when mutated causes LVNC. The E882K mutation in ITGA7 gene, a key component of the basal lamina of muscle fibers, was found only in the proband. The glutamic acid at position 882 is highly conserved in all species and bioinformatics tools predict that when the 882E is substituted with the lysine the secondary structure of the protein changes. This study identifies two novel disease genes. Mutation in MYH7B cause a classical LVNC cardiomyopathy and further support the concept that sarcomere genes are associated with LVNC, whereas, mutation in ITGA7 gene cause CFTD. Both phenotypes represent alteration of skeletal and cardiac muscle maturation and are usually not severe. The severe phenotype of the proband is probably due to a synergic effect of these two mutations. This study provides new insights into the genetics underlying Mendelian traits showing a role for digenic inheritance in complex phenotypes.

2129F

Genetic variants associated with C-reactive protein in African Americans: a MetaboChip analysis in the Population Architecture using Genomics and Epidemiology (PAGE) study.

J.M. Kocarnik[1], C.L. Carty[1], A. Reiner[1], C.L. Avery[2], C.M. Ballantyne[3], J. Haessler[1], A. LaCroix[1], A. Young[1], T.L. Assimes[4], M. Barbalic[5], W. Tang[6], L.G. Best[7], J.L. Introduction: Inflammation is an important health outcome related to many common complex diseases, several of which have differential disease burden by ethnicity. C-reactive protein (CRP) is a circulating biomarker indicative of systemic inflammation. Genome-wide association studies (GWAS) have successfully identified susceptibility loci important to inflammation and inflammation-related diseases, though discovered primarily in populations of European ancestry. To test if genetic variants associated with inflammation generalize to populations of African ancestry, we evaluated the association between serum CRP levels and the large number of single nucleotide polymorphisms (SNPs) on the MetaboChip array. Methods: We analyzed 9,648 African American participants from three studies~Atherosclerosis Risk in Communities (ARIC), Multiethnic Cohort (MEC), and Women's Health Initiative (WHI)~participating in the Population Architecture using Genomics and Epidemiology (PAGE) study or the SNP Health Association Resource (SHARe) project. Participants had serum high-sensitivity CRP measurements and genotype information for the 196,725 SNPs on the MetaboChip, a customized Illumina iSelect array targeting 257 regions identified by GWAS for metabolic, atherosclerotic and cardiovascular endpoints. Fixed-effect meta-analyses combined study-specific linear regression estimates to evaluate the association between each SNP and log-transformed CRP. Additive genetic models adjusted for age, sex, top 4 principal components of genetic ancestry, and study-specific factors. Results: 28 SNPs in 5 regions reached a Bonferroni-corrected p-value cutoff of $p<3.3e-7$: CRP (10 SNPs below the correction threshold; rs3091244 had the lowest p-value at $p=4.2e-76$), TOMM40-APOE-APOC1 (8 SNPs; rs446037 $p=2.9e-16$), NOS1AP-OLFML2B (5 SNPs; rs6676438 $p=3.7e-10$), HNF1A (4 SNPs; rs7979473 $p=4.8e-10$), and LEPR (rs4655779 $p=2.6e-7$). Discussion: We identified five genetic regions that were associated with CRP levels in an African American population. One of these regions, NOS1AP-OLFML2B, has not previously been associated with CRP and may represent a novel risk locus for CRP levels. SNPs in this region were included on the MetaboChip because of previous associations with QT interval. Future analyses will further evaluate these associations in other race/ethnicity groups, compare LD patterns in these regions between these groups, and use conditional analyses to identify independent loci.

2130W

Predictive Profile for the early detection of metabolic syndrome in a pediatric Turkish cohort. *M.J. White[1,2], M. Agirbasli[3], F. Eren[4], D. Agirbasli[5], S.M. Williams[1,2].* 1) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Department of Genetics, Institute for Quantitative Biomedical Sciences, Dartmouth College, Hanover, NH; 3) Department of Cardiology, Marmara University School of Medicine, Istanbul, Turkey; 4) Department of Medical Biology, Marmara University School of Medicine, Istanbul, Turkey; 5) Department of Medical Biology, Acibadem University School of Medicine, Istanbul, Turkey.

Metabolic syndrome (MetS) is characterized by the presence of three or more cardiovascular disease (CVD) risk factors, including abnormalities in lipid profiles. The presence of MetS increases CVD risk by approximately two-fold and is also associated with increased mortality in adults. Recent evidence of childhood MetS underscores the impact of the global childhood obesity burden and its potential impact on long-term health. MetS prevalence rates are as high as 60 percent in some overweight pediatric/adolescent populations and autopsy studies in children and adolescents have revealed that the presence of MetS is related to the early stages of atherosclerosis. These data indicate that CVD morbidity and mortality may be increased through childhood MetS. We investigated the impact of genetic variation (single nucleotide polymorphisms - SNPs) in six candidate genes known to influence lipid profiles and circulating sex hormone levels in adults, as well as known CVD risk factors, on susceptibility to MetS in a pediatric Turkish cohort (n=360). Turkish children and adolescents have lipid profiles characterized by lower high-density lipoprotein cholesterol, elevated triglyceride levels (two hallmarks of MetS), and lower prevalence of obesity than American pediatric populations. This unique lipid profile makes Turkish children and adolescents an at risk population for MetS. Logistic regression analysis revealed that a SNP in *SHBG* (rs1799941) was significantly associated with MetS (p=0.010) after adjustment for known CVD risk factors, suggesting an independent genetic effect. Exploratory single and multi-locus analysis was performed using multi-factor dimensionality reduction (MDR) to determine the genetic and metabolic profile most predictive of MetS. MDR identified rs1799941, high triglycerides, BMI, and insulin resistance as the most predictive model (Testing balance accuracy=0.7965, p<0.001). In conclusion, our study identifies a positive association between rs1799941 and MetS, and presents a predictive model for the early detection of MetS in an at risk pediatric population. This result has the potential for future clinical use.

2131T

Investigation of functional variants of eight SNPs in lipid level modifier genes in healthy Roma and Hungarian population. *B. Melegh[1,2], K. Sumegi[1,2], L. Jaromi[1,2], L. Magyari[1,2], E. Kovesdi[1,2], B. Duga[1], R. Szalai[1], P. Matyas[1], Zs. Banfai[1], A. Szabo[1], J. Bene[1].* 1) Department of Medical Genetics, University of Pecs, Pecs, Hungary; 2) Szentagothai Research Centre, University of Pecs, Pecs, Hungary.

Purpose: Investigation of the role of triglyceride metabolism in various diseases, such as cardiovascular or cerebrovascular diseases is still in the focus of numerous studies. Genome-wide association studies reported a number of polymorphisms associated with plasma lipid level changes. The aim of our study was to investigate the distribution of eight variants: rs12130333 at the ANGPTL3, rs16996148 at the CILP2, rs17321515 at the TRIB1, rs17145738 and rs3812316 of the MLXIPL, rs4846914 at GALNT2, rs1260326 and rs780094 residing at the GCKR loci.

Methods: A total of 399 Roma (Gypsy) and 404 Hungarian population samples were genotyped using PCR-RFLP method.

Results: Significant differences were found between Roma and Hungarian population samples in the allele frequencies of GALNT2 variant (G allele frequency of rs4846914: 46.6% in Romas vs. 54.5% in Hungarians, p<0.05), of ANGPTL3 variant (T allele frequency of rs1213033: 12.2% in Romas vs. 18.5% in Hungarians, p<0.05) and of both MLXIPL variants (C allele frequency of rs17145738: 94.1% vs. 85.6%, C allele frequency of rs3812316: 94.2% in Romas vs. 86.8% in Hungarians, p<0.05), while no differences could be verified in the remaining SNPs and the known minor alleles showed no correlation with triglyceride levels in any population samples.

Conclusions: Our results may be presented as risk factors for metabolic or cardio-cerebrovascular diseases in different population samples. The current study revealed fundamental differences of known triglyceride modifying SNPs in Roma populations, however no association with triglyceride levels could be established.

2132F

Arterial Tortuosity in Patients with Vascular Abnormalities due to Mutation in Filamin A. *E. Reinstein[1], S. Morris[3], D. Rimoin[2], R. Lacro[4].* 1) Medical Genetics Inst, Rambam Health Care, Haifa, Israel; 2) Medical Genetics Inst, Cedars Sinai Medical Center, LA, CA, USA; 3) Texas Children's Hospital / Baylor College of Medicine TX, USA; 4) Boston Children's Hospital, MA, USA.

Introduction: Arterial tortuosity of the head and neck vessels, as measured by the Vertebral Artery Tortuosity Index (VTI), was recently demonstrated to be elevated in patients with Loeys-Dietz and Marfan syndromes, and correlated with adverse cardiovascular outcomes in those patients. Mutations in the Filamin A (FLNA) locus give rise to several disorders including the otopalatodigital syndrome (OPD; a bone dysplasia), X-Linked Periventricular Heterotopia (XL-PH; a disorder of abnormal neuronal migration), and Cardiac Valvular Dystrophy (CVD). Previous reports also linked mutations in FLNA to a connective tissue disorder characterized by joint, skin and vascular abnormalities, primarily aneurysms of the thoracic aorta. Methods: In this study, we evaluated a mother-daughter pair because of vascular aneurysms due to mutation in the FLNA gene. Calculation of arterial tortuosity following magnetic resonance angiography analysis was performed. Results and Discussion: Significant expansion of aortic aneurysm was seen in the mother despite normal VTI, culminating in an early aortic replacement surgery. In the daughter, a slight expansion in the size of a subclavian artery aneurysm has been observed and surgery is pending. These findings suggest that vascular surveillance is warranted in patients with arterial aneurysms due to FLNA mutations despite the presence of normal vascular turtuosity.

2133W

Phenotype, Genotype and Natural History of Arrhythmogenic Dilated Cardiomyopathy. *A. Spezzacatene[1,2], G. Sinagra[2], M. Merlo[2], G. Barbati[2], D. Slavov[1], A. Di Lenarda[2], X. Zhu[1], S. Graw[1], E. Salcedo[1], M. Taylor[1], L. Mestroni[1].* 1) Cardiovascular Institute, University of Colorado, Colorado; 2) Cardiovascular Department, Hospital and University of Trieste, Italy.

BACKGROUND Arrhythmogenic dilated cardiomyopathy (aDCM) is a form of dilated cardiomyopathy (DCM) frequently encountered in clinical practice and characterized by severe ventricular arrhythmias. The purpose of this study was to determine the prevalence, genotype-phenotype correlations and long-term outcome predictors of aDCM, to implement current criteria for risk-stratification. **METHODS** From February 1979 to November 2012, we studied 461 patients (364 families) with DCM enrolled in the Familial Cardiomyopathy Registry. Criteria for aDCM were DCM with VT, SD, AICD shock, syncope, cardiac arrest, PVC>1000/24h. A subgroup of patients was tested for DCM genes (MYH6, MYH7, MYBPC3, TNNT2, TTN, LMNA, LAP2, SCN5A, DES). For survival analysis, endpoints were: 1) death or heart transplant, 2) death, heart transplant or malignant ventricular arrhythmias (MVA), 3) MVA. **RESULTS** Over a follow-up of 96±82 months (up to 20 years), we identified 211 patients (45.8%) with aDCM: among them 72 (15.6% of the total DCM population) experienced MVA during follow-up. When compared to DCM patients, aDCM patients had worse survival (endpoint 1: P=0.006; endpoint 2: P<0.001). Independent risk factors for endpoint 1 in the aDCM population were LVEF<34% and the presence of QRS>110 ms in V1-V3. There was a cumulative risk for death or heart transplant per additional risk factor. Predictors of MVA in the aDCM population were the presence of QRS>110 ms in V1-V3 and family history of MVA. aDCM was most frequent among LMNA (70.6%), TTN (54.5%) and SCN5A variant carriers (50%). Furthermore, nuclear envelope (LMNA and LAP2) variant carriers had worse NYHA (P=0.030) in spite of smaller LVEDD at baseline (P=0.003), and experienced more heart transplants (P=0.010). TTN carriers had worse event-free survival for endpoint 2 (P=0.037). Finally, SCN5A mutation carriers were younger at enrollment (P=0.004) compared to noncarriers, had prevalence of males (P=0.029) and epsilon waves (P=0.030). **CONCLUSIONS** In a large and extensively studied DCM cohort, we define a novel subpopulation characterized by prominent ventricular arrhythmia and different prognosis. Our results suggest that aDCM may benefit from more aggressive therapeutic interventions including modified ICD criteria.

2134T

Advancing Genomic Research on Congenital Cardiac Malformations in Africa. *P. Kruszka[1], M. Muenke[1], B. Solomon[1], P. Lwabi[2], L. Harris[3], A. Beaton[4], C. Sable[4], B. Lanpher[3].* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Uganda Heart Institute, Kampala, Uganda; 3) Department of Genetics and Metabolism, Children's National Medical Center, Washington, D.C; 4) Department of Cardiology, Children's National Medical Center, Washington, D.C.

Background: Congenital heart disease (CHD) is the most common birth defect and is the leading cause of mortality among congenital malformations. Many types of CHD are associated with syndromes; some isolated genes have been identified in non-African populations. Previously, we have identified mutations in several CHD-related genes: CFC1, GDF1, and FOXH1. However, many causes of CHD remain unknown. Our study will harness emerging genomic technologies to better understand the etiology of CHD in African and other populations. Also, genotype-phenotype analyses will characterize syndromes with known genetic etiologies that have yet to be characterized in African populations. Methods: Using comprehensive medical genetic/family history, dysmorphology exam, and echocardiogram, CHD patients were phenotyped and assigned clinical diagnoses when possible. In the future, we will conduct trio-based high-throughput genomic investigation (including exome/genome sequencing and copy number analyses). Results: From 2012-2013 we clinically evaluated 211 Ugandan patients with CHD. Forty-eight (22.7%) were clinically diagnosed with a known syndrome. Of these 48, 20 (41.7%) were suspected to have 22q11 deletion syndrome, 15 (31.3%) had convincing signs of aneuploidy, and 9 (18.8%) were diagnosed with Noonan syndrome or related Rasopathies. Other syndromes recognized included Williams, Holt-Oram, and Kabuki. Notably, truncus arterious was more frequent (2.8%) than expected from known prevalence in other populations. Conclusions: This study is anticipated to advance our understanding of CHD, both by characterizing known syndromes in this understudied population as well as revealing novel disease loci in the African cohort. Through this international collaboration, we will pilot the practice of clinically-oriented genomic medicine in a resource-limited setting, the ultimate goal of which is to assist local clinicians and researchers in their management of this complex cohort of patients.

Advantages of Next Generation Sequencing in the diagnosis of diseases associated with sudden cardiac death. *D. Cantalapiedra[1], A. Romera[1], L. Pérez-Cabornero[1], V. Felipe[1], D. Valero[1], G. Hernández[1], C. Buades[1], A. Arilla[1], C. Rodríguez[1], C. Collado[1], V. Fernández-Pedrosa[1], O. Rodríguez[1], J. Durbán[1], JC. Triviño[1], S. Zúñiga[1], A. Ballester[1], R. Miñambres[1], M. Gil[1], A. Forteza-Gil[2], M. Martínez-Atienza[3], MF. Márquez-Murillo[4], S. Santillán[1].* 1) Medical Genetics Unit, Siatemas Genómicos, SL, Paterna, Valencia, Spain; 2) Marfan Unit, Hospital Universitario 12 de Octubre, Madrid, Spain; 3) Servicio de Genética, Hospital Virgen de las Nieves, Granada, Spain; 4) Instituto Nacional de Cardiología "Ignacio Chávez", Mexico DF, Mexico.

OBJECTIVE: Genetic characterization of patients with hereditary diseases associated with sudden cardiac death, in a quick, comprehensive and cost-effective manner, using NGS resequencing panels. METHODS: We studied 172 patients (72 cases of cardiomyopathy, 21 of arrhythmogenic right ventricular dysplasia/cardiomyopathy, 27 cases of heart rhythm disorders, 37 of isolated and syndromic thoracic aortic aneurysm, 7 of idiopathic sudden death, and 8 with a family history of sudden death. Up to 90 genes associated with sudden cardiac death, were resequenced (exons, splicing junctions, 5' and 3' UTR). These regions were captured (SureSelect) and sequenced on a high-capacity NGS platform (SOLiD 5500xl). The results were confirmed by Sanger sequencing. RESULTS: We identified a total of 42 mutations (24.4% cases), which can be considered as pathogenic. The percentage of characterized cases by pathology, varies between 0% and 100% depending on the genetic heterogeneity of the condition, the degree of phenotypic overlap among pathologies, and in some cases, chance (if the number of samples is small). In 8 cases (4.6%) we identified mutations that could be considered as pathogenic, associated to a different disease than the one being stated in the clinical diagnosis of the patient. CONCLUSIONS: NGS sequencing: 1) Confirms the diagnosis. Contributes to the knowledge of new genetic mechanisms, by the identification of mutations in genes that would not have been studied by conventional techniques. 2) Identifies modifier genes that explain the intra- and interfamilial variable expressivity. 3) Helps to identify patients who require preventive measures against the risk of sudden death. 4) Helps to identify family members at risk, so that monitoring and prevention measures can be established, as well as those family members who are not at risk of sudden death. 5) Optimizes health resources, as preventive measures are offered to the actual population at risk. 6) It allows an adequate familial genetic counseling, with specific reproductive choices.

Dilated Cardiomyopathy - An updated Gene Database. *S.Justin Carlus, KM. Al Harbi.* Centre for Genetics and Inherited Diseases (CGID), Taibah University, Madinah, Saudi Arabia.

Cardiomyopathy is a rare and severe disease of the heart muscle. Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy and accounts for more than half of all cardiac transplantations in children. Mutations in 41 genes have been found to be associated with DCM and accounting for only 5- 25% genetic causes; etiologies of a larger percentage of DCM still remain unknown. To date most of the research data show only a limited number of gene tests like TTN, LMNA, MYH7, TNNT2, SCN5A, DES, MYBPC3, TNNI3, TPMI, ACTC, PLN, LDB3 and TAZ are routinely used for DCM. This is because of the lack of a comprehensive gene database available for DCM. Here, for the first time, the present gene database provides an account of 104 currently known genes, which are either directly or indirectly implicated in DCM. This updated information would help the cardiologists and the researchers to analyze more genes to screen the causative mutations in the DCM cases for early detection. The updated gene database for dilated cardiomyopathy would be available at the time of presentation.

Clinical consequences of CNVs detection in Congenital Heart Disease. *L. Kulikowski[1,2], E. Zanardo[1,2], F. Piazzon[1,2], R. Dutra[1,2], A. Dias[1,2], M. Montenegro[1,2], G. Novo-Filho[1,2], M. Basso[1,2], T. Costa[1,2], A. Nascimento[1,2], M. Grassi[2], M. Carneiro-Sampaio[2], C. Kim[2].* 1) Pathology Division- Cytogemonics Lab - LIM 03, University de Sao Paulo, São Paulo, SP,Brazil; 2) Departament of Pediatrics, The Children Institute, University de Sao Paulo, SP,Brazil.

Despite recent medical and surgical advances, congenital heart disease (CHD) remains mostly deadly birth defect, affecting nearly 1% of all newborns. And although new cytogenomics methods allowed the molecular investigation of the cardiac malformations, a limited number of studies have established the relevance of copy number variations (CNVs) in the etiology of CHD. We prospectively studied a cohort of 107 patients with CHD and concomitant no-cardiac anomalies such as facila dysmorphisms and/or developmental delay using distinct MLPA (Holland) kits and arrays (HumanCytoSNP-12, Illumina). Unexpected our analysis identified duplications (8,4%) as well as deletions (17,8%) associated with 22q11.2 region, and smaller atypical CNVs (19,6%) that implicated *IL17RA, CECR1, PEX26, PRODH, CLDN5, SHANK3, ACR* deletions. Additional genomic changes were located at 1p36, 4p16.3, 4q35.2, 5q35.3, 7p21.3, 7q36.3, 8p23.3, 9q34, 10p12.3, 11q13, 11q24, 15q11.2, 16p13.3, 17p11, 19p13.3 and 20q13.3 regions. Some of these alterations comprise genes (e.g. *CREBBP, RAI1, NKX2.5,NOTCH1,GATA4*) known for causing syndromic or isolated CHD suggesting that these CNVs are pathogenic and consistent with a model where imbalance of multiple genes associated with contributes to congenital heart disease. Also our findings showed that at least 10% of cases can be attributed to novel CNVs and that further investigation of these loci can be of great prognostic value. Application of new technologies contributes to better understanding of the role of CNVs and their effect on congenital heart phenotype. Support CNPq401910/2010-5 and FAPESP 53105/9.

Sequence variants in the mitochondrial D-loop region are associated with ventricular arrhythmias and appropriate ICD-therapy. *H. Tao, S. Rosenberg, J. wingrove.* CardioDx, Palo Alto, CA94043, CA.

Background: Sudden death from cardiac ventricular arrhythmias is a leading cause of mortality in the industrialized world. Mitochondrial dysfunction has been implicated in both heart failure and arrhythmias. Mitochondrial sequence was evaluated in a primary prevention heart failure (HF) population with implantable cardioverter-defibrillators (ICDs).

Materials and Methods: Mitochondria DNA (mtDNA) was analyzed in subjects enrolled in DISCERN, a multi-center clinical trial (www.clinicaltrials.-gov; NCT00500708) designed to identify markers associated with ventricular tachycardia or fibrillation (VT or VF). Cases were defined as subjects with adjudicated ICD therapy; controls were subjects with no documented ICD therapy for ≥ 2 years. MtDNA was initially sequenced in pooled case/control samples (Set 1; 19 subjects/pool) using the Ion Torrent PGM; the mitochondrial D-loop region was subsequently re-sequenced in individual Set 1 subjects plus an additional 40 subjects (Set 2). Melting temperatures (Tm) in candidate regions was assessed by SYBR Green RT-PCR across Sets 1, 2 and a larger set of 260 subjects (Set 3).

Results: A region within the D-loop, spanning 160-280 bp of the mitochondrial genome, showed significant sequence variant enrichment in the control pool (p=0.007). The Tm of this region was significantly elevated in individual Set 1 control samples (p=0.016); this increase was validated in two additional independent sets of subjects (Set 2: n=40, p=0.007; Set 3: n=260; p=0.0025). Sequencing of the entire D-loop region in individual Set 1 and 2 subjects showed increased sequence variant enrichment in control samples (n=78, p=0.0025); this increase was also significantly associated with lower 7s DNA copy number (p=0.004).

Conclusion: The number of variants in the mitochondrial D-loop is associated with ventricular arrhythmias and appropriate ICD therapy, and may affect D-loop formation and mitochondrial function.

Relative contributions of gene expression, genetics, and clinical factors for diagnosis of obstructive coronary artery disease. *J. Wingrove, A. Johnson, H. Tao, S. Rosenberg.* CardioDx, Palo Alto, CA.

Background - Several genetic models for predicting coronary artery disease (CAD) risk have recently been published. We previously validated a whole-blood gene expression score (GES) for obstructive CAD in patients from PREDICT, a population clinically referred for angiography. The performance of the genetic models in the PREDICT population were evaluated independently and in the context of clinical risk factors and GES.

Methods - 20 SNPs derived from 3 published models (Elosua, Kathiresan, Wells) were genotyped across 955 subjects from PREDICT (37% cases; case = ≥ 50% occlusion in ≥1 major artery by QCA). Genetic risk scores were calculated using published methods; expression levels of the 23 genes in the GES were measured and score calculated. A clinical risk score was constructed by logistic regression using age, sex, hypertension, dyslipidemia, and smoking as covariates. A model including all 20 SNPs was constructed and included in logistic regression models combining all pairs of variables as well as combining 3 variables into a single model. Genetic models, GES, and clinical risk scores were compared by AUC to assess performance. Interactions between the 20 SNPs and gene-expression levels were examined.

Results - The AUC for the published genetic models ranged from 0.55-0.59, consistent with previous data. The AUC for the GES and clinical models were similar, 0.750 (95%; CI 0.723-0.776) and 0.747 (95%; CI 0.717-0.768), respectively. The AUC increased in all models combining data types, with the highest AUC observed in the 20 SNP/GES/clinical model (AUC 0.798, 95%; CI 0.766-0.833). This model had a significantly increased AUC compared to any of the baseline models of SNPs, GES or risk factors alone (p < 0.001, each comparison). Multiple trans-acting interactions were observed between SNPs and gene expression levels.

Conclusions - The performance of 3 published genetic models for CAD risk was consistent with that previously reported. The addition of genetics to clinical factors and gene expression significantly increased the ability to detect obstructive CAD by AUC analysis.

Functional Assessment of Potential Splice Site Variants in Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy. *D. Dooijes[1], J.A. Groeneweg[2, 3], A.S. Ummels[1], M.J. Mulder[1], H. Bikker[4], J.J. van der Smagt[1], J. Post[1], J.F. van der Heijden[2], A.C. Houweling[5], J.D.H. Jongbloed[6], A.A.M. Wilde[7], J.P. van Tintelen[6], R.N. Hauer[2, 3].* 1) Dept. Medical Genetics, University Medical Center Utrecht, Utrecht, Utrecht, The Netherlands; 2) Dept. Cardiology, University Medical Center Utrecht, Utrecht, Utrecht, The Netherlands; 3) Interuniversity Cardiology Institute of the Netherlands, Utrecht, The Netherlands; 4) Dept. Clinical Genetics, Academic Medical Center, Amsterdam, The Netherlands; 5) Dept. Clinical Genetics, VU Medical Center, Amsterdam, The Netherlands; 6) Dept. Clinical Genetics, University Medical Center Groningen, Groningen, The Netherlands; 7) Dept. Cardiology, Academic Medical Center, Amsterdam, The Netherlands.

Introduction: Interpretation of genetic screening results in Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy (ARVD/C) is often difficult. Pathogenicity of variants with uncertain significance may be predicted by software algorithms. However, functional assessment can unambiguously demonstrate the effect of such variants. **Aim**: Functional analysis of putative splice site variants identified in ARVD/C patients. **Methods**: Eleven variants in desmosomal (PKP2, JUP, DSG2, DSC2) and non-desmosomal (TMEM43) genes with potential RNA splicing effect (predicted by SpliceSiteFinder-like, MaxEntScan, NNSPLICE, GeneSplicer, and Human Splicing Finder) were analyzed. The variants were found in patients with ARVD/C (fulfilment of 2010 Task Force Criteria) or suspected ARVD/C (3 patients: DSC2 c.1350A>G, JUP, TMEM43 variant). Total RNA was isolated from fresh blood samples and subjected to rtPCR. Obtained cDNA products were amplified by PCR with exonic primers specific for fragments of interest. All cDNA fragments were separated according to size using gel electrophoresis. PCR fragments were subjected to direct sequence analysis. **Results**: Of the 11 variants, 6 were intronic and 5 exonic. Eight variants, including 2 missense variants, had a functionally deleterious effect on mRNA splicing by causing exon skipping, generating new splice sites, or activating cryptic sites. All 6 intronic variants tested affected mRNA splicing. Two of 5 exonic variants severely impaired pre-mRNA processing. The remaining 3 exonic variants had no detectable effect on splicing, heterozygous presence in mRNA confirmed biallelic expression in these cases. **Conclusion**: Eight variants of uncertain significance had a functional effect on mRNA splicing, indicative of being ARVD/C related pathogenic splice site mutations. This highlights the importance of functional assessment of potential splice site variants to enhance patient care and facilitate cascade screening.

Functional analysis of collagen VI variants and their contribution to atrioventricular septal defect in Down syndrome. *C. Ackerman[1], P. Holden[2], J. Fitzgerald[2], C. Maslen[1].* 1) Knight Cardiovascular Institute, Oregon Health & Science University, Portland, OR; 2) Department of Orthopedics & Rehabilitation, School of Medicine, Oregon Health & Science University, Portland, OR.

Atrioventricular septal defect (AVSD) is a common heart defect frequently associated with Down syndrome (DS). Children with DS have a 2000-fold increased risk of the defect, yet many have a normal heart indicating that trisomy 21 alone is insufficient to cause AVSD. We conducted a candidate gene study to test if rare variants in genes involved in heart development contribute to the risk of AVSD in DS. We discovered a significant excess of potentially damaging rare variants in children with DS-associated AVSD compared to children with DS and no heart defect, including mutations in the genes encoding the α1 and α2 chains of collagen VI. We hypothesized that AVSD-associated variants in *COL6A1* and *COL6A2* impact collagen VI biosynthesis disrupting microfibril formation in the extracellular matrix in the developing heart that leads to AVSD. To determine if rare variants play a pathogenic role in AVSD we analyzed the biosynthesis and trafficking of proteins expressed by three missense variants in *COL6A1* (V117A, Q786H, and R872W) and two variants in *COL6A2* (p.E106K and p.R853Q). Immunoblot analysis showed that the α1 protein expressed by the *COL6A1* variant p.R872W was undetectable in the media, and α2 proteins for both *COL6A2* variants, p.E106K and p.R853Q, were observed in reduced amounts in the media compared to wildtype (WT). In addition, the α2 protein expressed by the R853Q variant was retained in the cell, compared to WT. To test if the α1 chains produced by missense variants were triggering cellular processes activated by endoplasmic reticulum (ER) stress, we analyzed expression of HERPUD, which directs misfolded proteins to the proteosome for degradation, and CHOP, a pro-apoptotic transcription factor activated by ER stress. We found that the cells expressing α1 p.V117A, p.Q768H, and p.R872W variants expressed significantly increased levels of HERPUD than WT α1. Cells expressing α1 p.Q768H and p.R872W variants also expressed significantly higher levels of CHOP compared to WT. Our results indicate that rare variants in *COL6A1* and *COL6A2* associated with AVSD cause defective protein secretion and intracellular retention of protein chains that form collagen VI microfibrils. In addition, these variants are coupled with increased expression of proteosomal degradation and pro-apoptotic genes as a result of ER stress. Further analysis of these variants will provide mechanistic insight into how collagen VI contributes to heart defects during development.

2142W

Epigenomic regulation in the promoter of miR-210 gene affects HIFa1 binding and vascular diseases. *S.H Juo[1], K.C. Chen[1], Y.S. Wang[1], Y.C. Liao[2,3].* 1) Genome Medicine, Kaohsiung Medical Univ, Kaohsiung City, Taiwan; 2) Taichung Veterans General Hospital, Taichung, Taiwan;; 3) Department of Neurology, National Yang-Ming University School of Medicine, Taipei, Taiwan;.

microRNAs are short non-coding RNAs that can regulate gene expression by inhibiting target mRNAs. Therefore, microRNAs are considered to play a regulatory role for gene expression. However, the regulation of microRNA expression is mainly unknown. In this study, we presented the data to indicate DNA methylation can control microRNA expression. microRNA-210 (miR-210) has been reported to be involved in hypoxia-related events. Several studies suggested that miR-210 expression can be regulated by hypoxia-inducible transcription factors-1αα (HIF-1αα) during hypoxia. Furthermore, by using the bioinformatics analysis, the promoter of the miR-210 gene contains several CpG-rich regions. However, there are no reports about epigenetic regulation of miR-210 gene. We investigated the role and mechanism of miR-210 in the cardiovascular system. We first found miR-210 gene was upregulated in vascular smooth muscle cells (VSMC) and human umbilical venous endothelial cells (HUVEC) when they were exposed to oxidized low-density lipoprotein (oxLDL). By combining with 5-Aza-2'-deoxycytidine treatment or DNA methyltransferase 3b knockdown, we found that miR-210 gene expression could be epigenetically regulated by oxLDL. By using the bisulfite sequencing assay, the decreased methylation levels of miR-210 gene was identified in vitro and in vivo. This methylation change could affect the HIF-1αα-regulated miR-210 gene expression. Furthermore, over-expression or knockdown of miR-210 influenced the ability of oxLDL-mediated VSMCs and HUVECs migration. According to the bioinformatic prediction, SPRED2 (an inhibition regulator in ERK activation) could be a major miR-210's target gene involved in cell migration. Our reporter assays using wild-type and mutant 3' UTR of SPRED2 gene confirmed that SPRED2 was a novel direct target of miR-210. Over-expression or knockdown of SPRED2 affected oxLDL-mediated ERK/c-Fos/MMPs pathways in cell migration. Altogether, the data suggest that epigenetic regulation of miR-210 gene and its effect on cell migration are involved in the cardiovascular diseases formation.

2143T

Distribution of hepatic lipase C-514T and G-250A polymorphisms and their association with plasma lipid profile in young Jordanians. *O. Khabour, M. Alomari, K. Alzoubi, M. Gharaibeh, F. Alhashimi.* Medical Laboratory Sciences, Jordan Univercity of Science and Technology, Irbid, Jordan.

Hepatic lipase is an enzyme involved in the metabolism and regulation of the plasma lipoproteins. Variants in the HL gene (LIPC) may influence plasma lipoproteins levels. In this study, distribution of LIPC C-514T and G-250A polymorphisms and their associations with plasma lipid profile in young Jordanians was investigated. Genotyping of the polymorphisms in 348 young Jordanian adults was performed using polymerase chain reaction-restriction fragment length polymorphism technique. The G-250 and C-514 alleles are abundant in the Jordanian population with frequencies of 79% and 80%, respectively. However, no significant difference in lipid-lipoprotein profile (total cholesterol, triglycerides, LDL and HDL) between the different genotype groups of either C-514T or G-250A polymorphisms even when males and females were examined separately ($P > 0.05$). Thus, in young Jordanian adults, the examined LIPC polymorphisms seem to play a limited role in determination of plasma lipoprotein levels.

2144F

Novel mutation in PRKAG2 gene highlights the allosteric site of AMPK. *C. Phornphutkul[1], A. Gray[2], K. Rotondo[1], J. Padbury[3], Y. Tseng[3], D.G. Hardie[2].* 1) Pediatrics, Rhode Island Hosp, Providence, RI; 2) College of Life Sciences, University of Dundee, Dundee, Scotland, UK; 3) Pediatrics, Women and Infants' Hospital, Providence, RI.

Mutations in PRKAG2 have been implicated in hypertrophy cardiomyopathy (HCM). PRKAG2 encodes a (γ2)isoform of the nucleotide-binding regulatory subunit of AMP-activated protein kinase (AMPK), a heterotrimeric enzyme with major roles in regulation of energy metabolism in response to cellular stress. Twelve different heterozygous point mutations within the nucleotide-binding domains have been reported. De novo mutations (R531Q and R384T) were associated with severe disease and death during infancy. Case study: An abnormal 27-week prenatal ultrasound, consistent with HCM, was noted. At birth, the cardiac echo confirmed HCM. Parents had normal cardiac evaluation. Molecular testing for HCM panel was conducted and a de novo novel mutation in the PRKAG2 gene [Lys475Glu (K475E) likely disease causing] was identified in the child. At three years of age, the child has modest HCM but clinically is doing well on supportive medications. Unlike the previous cases with R531Q and R384T mutations, this case appears to have a better clinical course. To investigate the significance of the K475E mutation on AMPK complex, functional studies were performed. Method: HEK-293 stably expressing wild type (WT) or K475E FLAG-tagged γ2 from a tetracycline-inducible promoter were established. AMPK complexes containing the WT or K475E mutant γ2 were immunoprecipitated using anti-FLAG antibodies and their activities determined at varying AMP concentrations. We also compared the effects of metabolic stress induced using phenformin. Results: Our molecular studies show that the K475E mutation has three effects on the regulation of the AMPK complex: (i) markedly increasing the basal phosphorylation of Thr-172 and associated kinase activity; (ii) reducing the sensitivity to AMP in allosteric activation; (iii) preventing the increased Thr-172 phosphorylation and activity observed in response to the metabolic stressor, phenformin, in intact cells. Conclusions: K475 is conserved in γ1 and γ2 isoforms of all species, and examination of crystal structures shows that its side chain could form electrostatic interactions with the phosphate groups of AMP, ADP or ATP bound in site 1. The mutation almost abolishes allosteric activation by AMP, but also increases the basal Thr-172 phosphorylation and activity and prevents further activation by metabolic stress. Ongoing studies of the effect of these changes on downstream pathways are underway in patient fibroblasts.

2145W

Systematic cell-based functional screening for novel cardiovascular risk genes. *H. Runz[1,3,4], C. Schuberth[1,3], P. Blattmann[2,3], G. Domschke[1], A. Thormaehlen[1,3], S. Kathiresan[4], R. Pepperkok[2,3].* 1) Institute of Human Genetics, University of Heidelberg, Heidelberg, Germany; 2) European Molecular Biological Laboratories (EMBL), Heidelberg, Germany; 3) Molecular Medicine Partnership Unit (MMPU), Heidelberg, Germany; 4) Center for Human Genetic Research, Massachusetts General Hospital, Boston, USA.

Elevated levels of plasma low-density lipoprotein cholesterol (LDL-C) are a causal, heritable risk factor for myocardial infarction (MI), and strategies to reduce LDL-C efficiently lower MI-risk. Sequencing and genotyping of large population cohorts are uncovering numerous genes and genetic variants with putative relevance for blood LDL-C levels and predisposition to disease. However, discovery of novel disease genes and improvement of therapies is challenged by the fact that 1) most candidate genes harbor vast numbers of potentially relevant, yet rare and often neutral variants that reduce the power of association testing; and 2) a modest mechanistic understanding if and how genes and variants therein impact on relevant phenotypes. To address these limitations, we have established technology that complements human genetics by systematic, quantitative phenotypic analyses of gene and variant function in cultured human cell models. Our unbiased, scalable functional genomics strategy is based on reducing (by RNAi-interference), increasing (by cDNA-overexpression) or complementing cellular levels of candidate genes, high-throughput functional assays, automated microscopy and multiparametric image analysis. We will present data on how we are applying this technology to systematically characterize >100 candidate genes suggested as likely associated with blood lipid levels, coronary artery disease and/or myocardial infarction for functions in regulating LDL-C uptake and turnover in cells. We will provide mechanistic insight how several genes without previously known lipid-regulatory roles may affect levels and function of the LDL-receptor and provide hypotheses how variation in these genes could predispose to disease. Our study proposes that the combination of genetics with systematically-acquired functional data in cells can pinpoint new genes responsible for altered LDL-C and MI-risk.

2146T

Using Genetic Information to Analyse and Define the Complex Aetiology of Blood Pressure. *K.H. Wade, N.J. Timpson, G. Davey Smith.* School of Social and Community Medicine, University of Bristol, Bristol, Bristol, United Kingdom.

Blood pressure (BP) is an important phenotype that has had its study hampered by complexity. The discovery of 29 SNPs, robustly associated with BP, has provided an opportunity to examine the aetiology of BP through SNP-based associations to further understand the mechanisms that maintain and alter BP at different stages of development. We aimed to assess the contribution of 29 SNPs (individually and in a weighted score) reported in the International Blood Pressure Consortium GWAS on BP in children (mean age 3-18 years). The Avon Longitudinal Study of Parents and their Children is a geographically-based birth cohort investigating factors influencing health and development of children. After data cleaning, 8,361 unrelated individuals had genome-wide information and at least one systolic and diastolic BP (SBP and DBP, respectively) measured at 11 times (mean ages: 3- 5, 8, 10-15, and 18). We examined the associations between SNPs and BP at different ages in the same samples cross-sectionally and longitudinally, and assessed whether the overall contribution of SNPs changed with age. Cross-sectionally, the score was associated with SBP at ages 8-15 years and with DBP at ages 8-18 years. For example, the score was associated with a 12.67mmHg increase (95%CI: 4.88, 20.46; p=0.001) in SBP at age 11 and an 18.87mmHg (95%CI: 8.18, 29.56; p=0.001) increase in SBP at age 15. Individually, few SNPs showed associations with BP cross-sectionally. At age 11, rs7129220 was associated with a 0.68mmHg (95%CI: 0.12, 1.25; p=0.018) increase in SBP and rs1799945 was associated with a -0.51mmHg change (95%CI: -0.99, -0.04; p=0.035). Longitudinally, age was strongly associated with a 0.0377mmHg (95%CI: 0.0372, 0.0382; p<0.0001) increase in SBP and a 0.0138mmHg (95%CI: 0.0134, 0.0142; p<0.0001) increase in DBP, with no evidence of interaction between score (separated into centiles) and age (p=0.890 for SBP, p=0.223 for DBP). However, there was evidence of interaction between 6 SNPs and age (p=0.031 for rs419076; 0.048 for rs805303 and DBP; 0.011/0.04 for rs932764 and SBP/DBP, respectively; 0.036 for rs1327235 and SBP; 0.016 for rs3774372 and SBP; 0.032 for rs17249754 and SBP; and 0.02 for rs12940887 and SBP). We have replicated the association between 29 SNPs and BP in a large sample of children aged 3-18 years. We aim to further assess the patterns of association and whether these conform to biologically relevant groups, where the complexity of BP aetiology may be explained.

Sale[1,16,17].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Cardiovascular Research Center, University of Virginia, Charlottesville, VA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 4) The Framingham Heart Study, Framingham, MA; 5) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 6) Department of Biology, East Carolina University, Greenville, NC; 7) Center for Health Disparities Research, East Carolina University, Greenville, NC; 8) Jean Mayer USDA Human Nutrition Research Center on Aging and Friedman School of Nutrition Science and Policy, Tufts University, Boston, MA; 9) Department of Neurology, Boston University School of Medicine, Boston, MA; 10) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 11) 11Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic College of Medicine, Rochester, MN; 12) National Human Genome Research Institute, 5635 Fishers Lane, Bethesda, MD; 13) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 14) Department of Biostatistics, University of Washington, Seattle, WA; 15) Department of Neurology University of Virginia, Charlottesville, VA,; 16) Department of Medicine, University of Virginia, Charlottesville, VA; 17) Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA.

Circulating homocysteine levels (Hcy), a product of the folate one carbon metabolism pathway (FOCM), are heritable and have been associated with an increased risk of stroke and dementia. However, the genetic determinants of elevated Hcy, hyperhomocysteinemia, are poorly understood. Variants located in genes involved in the FOCM have been consistently linked to stroke risk but the underlying biological processes remain unclear. We conducted independent genome wide association studies and a meta-analysis of methionine metabolism, characterize by post-methionine load test Hcy levels(ΔPOST), in 2710 participants from the Framingham Heart Study (FHS) and 2100 participants from the Vitamin Intervention for Stroke Prevention (VISP) clinical trial, and then examined the association of the identified loci with incident stroke. Five genes in the FOCM pathway (*GNMT* [1.60×10^{-63}], *CBS* [3.15×10^{-26}], *CPS1* [9.10×10^{-13}], *ALDH1L1* [7.3×10^{-13}] and *PSPH* [1.17×10^{-16}) were associated with the difference between pre- and post-methionine load test tHcy levels (ΔPOST). *GNMT*, the Glycein N-Methyltransferase gene, is responsible for the demethylation of of S-adenosyl-L-methionine to give rise to S-adenosyl-L-homocysteine. This step affects the availability of all methyl groups to the cell and may have a major impact on the epigenetic state of the whole genome. Additionally, one variant in the *ALDH1L1* locus, rs2364368, was also associated with incident ischemic stroke in FHS (p = 0.02). Analysis indicates that circulating homocysteine levels do not correlate well with POST or ΔPOST, demonstrating the need for investigation of the true measure each test explains. Haplotype differences indicate that the 5' *GNMT* regulatory region may play a major role in differential methionine metabolism. Followup promoter analyses and pyrosequencing of the *GNMT* gene reveal genetic and epigenetic mechanisms that explain *GNMT* transcription differences and likely impact methionine metabolism. Finally, a risk-score consisting of the 5 loci, explains 13% of the variance of ΔPOST in FHS and 6% of the variance in VISP. Association between variants in FOCM genes with ΔPOST suggest a novel mechanism, altered transcriptional regulation, by which variation in methionine metabolism occurs affecting parallel pathways and stroke risk. These data emphasize the importance of a concerted effort to understand regulators of one carbon metabolism in future studies and their potential as therapeutic targets.

Analysis of vWA and TPOX loci reveals a highly associated relationship with thrombosis disease in Mexican Mestizo population. *R. Camacho[1], A. Majluf[2], G. Noris[3], C. Santana[3], M.A. Meraz[4], J. Hernández[2], R. Gómez[1].* 1) Departamento de Toxicologia, Cinvestav-IPN, México D.F; 2) Unidad de Investigación Médica en Trombosis y Aterogénesis, Instituto Mexicano del Seguro Social, México D.F; 3) Laboratorio BIMODI (Biología Molecular Diagnóstica), Querétaro, Qro; 4) Departamento de Biomedicina Molecular, Cinvestav-IPN, México D.F.

Thrombosis disease is an important target for biomedical research due to its high morbidity and mortality around the world. Thrombosis is a complex disease and several risk factors are evolved (age, trauma, hormonal alterations, immobility, obesity, diabetes type 2, and hypertension) as well as environmental factors. In addition, genetic factors are strongly associated with this disease. Recent studies suggest that ethnicity is considered an important risk factor in thromboembolism incidence, showing a variable frequency of the disease among different ancestries. In this study we identify truly genetic biomarkers, type short tandem repeat (STRs), associated with thrombosis in a population with multiethnic backgrounds from Mexico. Genotypes were obtained using a validated method of genotyping from patients (n=177) with venous thrombosis. The allelic frequencies were compared with non-related healthy individuals (n=531). Bayesian methods were used to correct population stratification in order to avoid spurious associations due to admixture. We found that vWA-18 (OR=1.5), TPOX-9 (OR=17), and TPOX-12 (OR=2.3) alleles were significantly associated with thrombosis disease, showing accurate confident intervals. This association remains after admixture correction, confirming a strong genetic association (P<0.0001). In addition, the combination of allele 18 (vWA) with allele 12 (TPOX), shows a significant difference (P<0.05) with high accurate CI95% (1.02 - 3.64), suggesting that this combination could be associated with an increase of two times of the thrombosis risk. In summary, our data propose that vWA and TPOX are good biomarkers, which may improve in the diagnostic methods reducing significantly treatment costs by providing preventive and personalized medicine.

2149T

GALNT2, a HDL cholesterol and triglyceride candidate gene, regulates lipoprotein metabolism in vivo. *S. Khetarpal[1], A. Edmondson[1], A. Raghavan[1], S. Kathiresan[2], D. Rader[1].* 1) Dept Med, Univ Pennsylvania, Philadelphia, PA; 2) Broad Institute and Massachusetts General Hospital, Boston, MA.

Several genome-wide association studies (GWAS) for blood lipids have uncovered novel genomic loci influencing these traits. One such locus associated with high-density lipoprotein cholesterol (HDL-C) and triglycerides (TG) is that harboring GALNT2 on chromosome 1q42. GALNT2 encodes GalNAc-T2, an enzyme catalyzing the initiation of O-glycosylation of specific protein targets. We previously demonstrated an in vivo role for GALNT2 in lipoprotein metabolism through GALNT2 overexpression and knockdown in mice using adeno-associated virus vectors. To further study the mechanism through which GALNT2 regulates plasma lipids, we have generated whole-body and liver-specific GALNT2 knockout (KO) mice. Whole-body GALNT2 deficiency resulted in elevated VLDL-TG levels compared with wild-type and a moderate reduction in HDL-C (20%, P < 0.05). GALNT2 KO mice did not exhibit differences in post-prandial TG clearance or VLDL-TG secretion. Liver-specific deletion of GALNT2 reduced HDL-C (26% decrease relative to WT, P < 0.01), and reduced numbers of HDL particles (19% decrease relative to WT, P < 0.01) with minimal changes in plasma TG or dietary TG clearance. Our data further implicate GALNT2 as an important regulator of plasma lipoprotein metabolism with tissue-specific regulatory roles in vivo.

Disease-relevant pathways modulate a cis-regulatory element at the TCF21 coronary heart disease locus. *C. Miller[1], D. Anderson[1], R. Kundu[1], A. Raiesdana[1], S. Nürnberg[1], R. Diaz[1], N. Leeper[1], E. Schadt[3], C. Hsiung[2], T. Assimes[1], T. Quertermous[1].* 1) Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA; 2) Division of Biostatistics and Bioinformatics, National Health Research Institutes, Zhunan, Taiwan; 3) Institute for Genomics and Multiscale Biology, Mount Sinai School of Medicine, New York, NY.

Coronary heart disease (CHD) is the leading cause of mortality in both developed and developing countries worldwide. Genome-wide association studies (GWAS) have now identified 46 independent susceptibility loci for CHD, however the biological and disease-relevant mechanisms for these associations remain elusive. The large-scale meta-analysis of GWAS recently identified in Caucasians a CHD-associated locus at chromosome 6q23.2, a region containing the transcription factor TCF21 gene. TCF21 (Capsulin/Pod1/Epicardin) is a member of the basic-helix-loop-helix (bHLH) transcription factor family, and regulates cell fate decisions and differentiation in the developing coronary vasculature. Herein, we characterize a cis-regulatory mechanism by which the lead polymorphism rs12190287 disrupts an atypical activator protein 1 (AP-1) element, as demonstrated by allele-specific transcriptional regulation, transcription factor binding, and chromatin organization. Further, this element is shown to mediate signaling through platelet-derived growth factor receptor beta (PDGFR-β) and Wilms tumor 1 (WT1) pathways. A second disease allele identified in East Asians also appears to disrupt an AP-1-like element. Thus, both disease-related growth factor and embryonic signaling pathways may regulate CHD risk through two independent alleles at TCF21.

2151W

A functional polymorphism that affects the *APOA5* gene expression determines plasma triglyceride levels conferring coronary atherosclerosis risk in Han Chinese Population. *W. Shou[1], F. Xie[1], Y. Wang[1], B. Wang[1], Z. Wang[1], J. Shi[1], W. Huang[1,2].* 1) Department of Genetics, Shanghai-MOST Key Laboratory of Health and Disease Genomics, Chinese National Human Genome Center, Shanghai, China; 2) Rui Jin Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China.

Elevated plasma triglyceride (TG) level has been established as an independent risk factor for multiple cardiovascular diseases. Thus, it is clinically important to identify genetic determinants of plasma TG levels. *APOA5* in 11q23.3-q23 gene cluster, the top hit of the TG-associated loci, encodes an apolipoprotein APOA5, which promotes lipoprotein lipase mediated plasma TG hydrolysis. A polymorphism rs2266788 in 3' untranslated region of the *APOA5* gene was identified significantly associated TG levels, but was underrepresented compared to the lead variants in genome-wide association studies. So, we investigated the association between rs2266788 and plasma TG regulation, and between rs2266788 and coronary artery disease (CAD) incidence in Han Chinese population. rs2266788 was genotyped in 3222 unrelated subjects consisting of 2,062 CAD cases and 1,160 matched controls. *APOA5* mRNA expression level and allelic expression imbalance (AEI) was measured in 89 normal liver specimens. Luciferase assays were conducted in BEL-7402, BEL-7405, Huh7 and HepG2 cell lines to compare transcription activity of two alleles. Through multiple linear regression analysis, a significant association was observed between rs2266788 and plasma TG levels in the total cohort ($P = 1.02 \times 10^{-13}$), and the association remained strong ($P = 5.17 \times 10^{-13}$) even after adjustment for age, sex and CAD status. Plasma TG levels were higher in samples with C allele than T allele. In stratified analyses, the association was all significant in controls, in cases, in females and in males. In logistic regression analyses adjusted for age and sex, rs2266788 was significantly associated with CAD in total samples (OR = 1.151, 95% CI =1.012-1.309, $P = 0.033$), and in females (OR = 1.397, 95% CI =1.139-1.714, $P = 0.001$). The C allele conferred an increased risk for CAD development. Analyses of the mRNA expression levels among different genotypes and AEI of *APOA5* in the liver samples showed C allele had a significantly lower transcription activity than T allele. Concordantly, the mean transcription activity of C allele in different cell lines was 70% that of T allele in luciferase assays. We provided strong evidence that functional rs2266788 was significantly associated with plasma TG levels conferring CAD risk in Han Chinese population due to its *cis*-acting effect to the gene expression.

2152T

Use of allele-specific FAIRE for identification of functional variants at cardiometabolic loci. *A.J.P. Smith[1], J. Palmen[1], E. Romeo[1], F. Drenos[1], P. Howard[1], A.D. Hingorani[2], P.J. Talmud[1], S.E. Humphries[1].* 1) Cardiovascular Genetics, University College London, London, United Kingdom; 2) Genetic Epidemiology, University College London, London, United Kingdom.

GWAS for cardiometabolic diseases have identified many novel loci for further analyses, although identification of functional, non-coding variants at the majority of these loci remains limited. Using FAIRE followed by allele-specific analysis with the Cardiometabochip array, we have examined GWAS loci for effects on chromatin accessibility as a marker of regulatory potential, to differentiate functional variant/s from non-functional variants in strong LD. Using this methodology, we have localised functional SNPs at several loci. We confirm the functionality of two variants at the 9p21 locus, previously implicated in coronary artery disease and type 2 diabetes susceptibility, and describe their effects on protein-DNA interactions, reporter gene expression and biomarkers.

2153F

Identification and characterization of patients with autosomal dominant hypercholesterolemia caused by gain-of-function mutations in proprotein convertase subtilisin/kexin type 9 and comparison with patients with Familial Hypercholesterolemia (FH) and Familial Defective apolipoprotein B (FDB). *G.D. Swergold[1], S.W. Fouchier[2], B. Sjouke[2], J. Mendoza[1], S. Mellis[1], S. Hamon[3], J.C. Defesche[2] on behalf of the PCSK9 Natural History Study (NHS) Group.* 1) Regeneron Pharmaceuticals, Inc., Tarrytown, NY, USA; 2) Department of Vascular Medicine of the Academic Medical Center at the University of Amsterdam, The Netherlands; 3) Statistical and Genetic Consulting, LLC, Darien, CT, USA.

Autosomal Dominant Hypercholesterolemia (ADH) is a common disorder of lipid metabolism characterized by high levels of serum LDL cholesterol (LDLC), and early onset cardiovascular disease. The most frequent mutations causing ADH are found in the LDL receptor (LDLR; FH) or its ligand apolipoprotein B (ApoB; FDB). Gain-of-function mutations (GoFm) in proprotein convertase subtilisin/kexin type 9 (PCSK9), a potent modulator of LDLR on hepatocytes, appear in ~2% of patients with ADH. To date, relatively few patients with PCSK9 GoFm have been described, and their clinical syndrome incompletely characterized. To better understand the geographic and familial distribution of PCSK9 GoFm, their clinical manifestations, and their comparison to FH and FDB we conducted a retrospective, cross-sectional parallel-group observational cohort study. Patients with PCSK9 GoFm confirmed by molecular testing were matched for age and sex with patients with molecularly proven FH and FDB. Data collected included baseline and on-treatment lipid profiles, the presence of xanthoma, xanthelasma, and corneal arcus, and the occurrence and age of onset of CVD. We initiated 200 site contacts and collected data on 164 PCSK9 GoFm patients (83 men, 81 women) from 12 sites in France, Japan, Norway, Portugal, South Africa, The Netherlands, the UK, and the USA. We matched these patients with 2126 patients with FH and 470 with FDB. We characterized the LDLR mutations as "defective" (missense, small in-frame indel, synonymous with added splice site) or "deficient" (large or frame-shifting indel, nonsense, splice site, promoter snp) and compared their lipid profiles. In general, individual PCSK9 GoFm appeared to have restricted geographic distributions and to be concentrated within a small number of pedigrees. Examples include 22 patients with R215H found only in 2 pedigrees in Norway, and 12 patients with V4I and 30 patients with E32K found only in Japan. These data support a similar (recent origin) history for PCSK9 GoFm and LDLR FH mutations that is distinct from ApoB FDB mutations. Mean baseline LDLC was highest in patients with PCSK9 GoFm and lowest in those with FDB. Of the patients with PCSK9 for whom data were available, 53% had evidence of xanthoma, and 33% had a history of CAD. Index patients with either FH or FDB had higher baseline LDLC levels than family members and patients with deficient LDLR mutations had higher baseline LDLC than those with defective mutations.

2154W

***GATA4* is implicated in the pathogenesis of neonatal and childhood-onset diabetes.** *E. De Franco[1], C. Shaw-Smith[1], H. Lango Allen[1], S. Flanagan[1], M. Borowiec[2], W. Mlynarski[2], M. Batlle[3], J. Ferrer[3], A. Hattersley[1], S. Ellard[1].* 1) University of Exeter Medical School, Exeter, United Kingdom; 2) Department of Paediatrics, Oncology, Haematology and Diabetology, Medical University of Lodz, Lodz 91-738, Poland; 3) Genomic Programming of Beta-cells Laboratory, Institut d'Investigacions August Pi i Sunyer (IDIBAPS), Barcelona, Spain.

Recent studies have shown that GATA6 haploinsufficiency is the most common cause of pancreatic agenesis and can also result in diabetes diagnosed outside the neonatal period. GATA4 is a transcription factor closely related to GATA6 and is known to be involved in the first stages of pancreatic development in mouse models: conditional knock-out of Gata4 in mouse embryos causes agenesis of the ventral pancreas. In humans GATA4 has been long regarded as a candidate regulator of pancreatic development but the evidence reported so far has been inconclusive. A single patient with a congenital heart defect and pancreatic agenesis harboring a GATA4 missense mutation has been reported, but causality was not proven. Similarly to GATA6, GATA4 mutations and deletions are a known cause of congenital heart defects.

We report four patients with diabetes, congenital heart malformations, and deletions including the GATA4 gene locus. In three cases diabetes presented in the neonatal period (age at diagnosis: 1-7 days) and the fourth case was diagnosed at 13 years. In addition we identified a fifth patient with a de novo GATA4 missense mutation (p.Asn273Lys) with complete absence of the pancreas confirmed post mortem. This mutation affects a highly conserved residue located in the second zinc finger domain of the GATA4 protein. Functional in vitro studies showed reduced DNA binding and transactivational activity of the mutant protein.

These results suggest that GATA4 haploinsufficiency is a cause of neonatal or childhood-onset diabetes with or without pancreatic exocrine insufficiency. GATA4 mutation testing should therefore be considered in patients with neonatal/childhood onset diabetes and congenital heart defects in whom no GATA6 mutation has been identified.

2155T

SMAD3 haploinsufficiency has a causative role in development of TAAD. *L. Gong[1], X. Duan[1], P. Yang[2], X.F Wang[2], O.A Moffitt[1], D.M Milewicz[1].* 1) Department of Internal Medicine, University of Texas Health Science Center at Houston, 6431 Fannin, MSB 6.100, Houston, TX 77030, USA; 2) Department of Pharmacology and Cancer Biology, Duke University, Durham, North Carolina, USA.

Thoracic aortic aneurysms leading to acute aortic dissections (TAAD) can be inherited in families in an autosomal dominant manner with reduced penetrance and variable clinical expression. Mutations in genes in the TGF-beta signaling pathway are believed as the causes of the disease in these families. The majority of these mutations are predicted to decrease TGF-beta signaling but there is evidence of increased signaling based on phosphorylated Smad2 (pSmad2) in aortic tissue of patients with these mutations. SMCs were explanted from a patient with SMAD3 R279K and Smad3-/- mice to investigate TGF-beta signaling. After exposure to TGFbeta1, the patient's SMCs showed decreased phosphorylation of Smad3 but increased pSmad2 compared with wild-type (WT) SMCs and the Smad3-/- SMCs also increased and sustained pSmad2 signaling with exposure to TGF-beta1. When treated with SB-431542, a small molecule inhibitor of the type I TGF-beta receptor, the pSmad2 signaling on Smad3-/- SMCs was reduced. Both Smad3-/- and SMAD3R279K SMCs also had reduced expression of SMC contractile proteins compared with WT SMCs, along with decreased expression of other genes known to be dependent on Smad3 signaling, including Col1A1 and Col3A1. The expression of DCN in the patient's SMCs was increased. Based on transfection of mutant SMAD3R279K, WT with SMAD4, it was determined that the mutant Smad3 could not complex with Smad4 but smad3 WT could. In both the transfected and SMAD3 R279K SMCs, SMAD3 remained in the cytoplasm 1 hour after exposure to TGFbeta1, but with WT transected or WT SMC, SMAD 3 was in the nucleus. The increased tgfbr3, which increases tgfr1 signaling, may be responsible for the increased smad2 signaling. Therefore, SMAD3 mutations disrupt Smad3 signaling in SMCs thus disrupting expression of contractile proteins and collagens. At the same time, SMCs have increased signaling through smad2, including increased proteoglycan production. Further studies will determine if the aortic disease results from loss of Smad3 signaling or increased Smad2 signaling.

Tnfaip8 is Involved in Host Response to _Staphylococcus aureus_ Infection in Mice and Humans. *Q. Yan[1], S.H. Ahn[2], B.K. Sharma-Kuinkel[1], C.L. Nelson[3], W.K. Scott[4,5], A.S. Allen[3,6], T.H. Rude[1], V.G. Fowler Jr[1,3].* 1) Department of Medicine, Duke University Medical Center, Durham, NC; 2) Department of Biochemistry School of Dentistry, Chonnam National University, Bukgu, Gwangju, Korea; 3) Duke Clinical Research Institute, Duke university Medical Center, Durham, NC; 4) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 5) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 6) Department of Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC.

Background: We previously showed that *Tnfaip8* was associated with susceptibility to *S. aureus* infection in susceptible (A/J) but not resistant (C57BL/6J) mice (Ahn, PLOS Pathogens 2010). However, the role of *Tnfaip8* in host response to *S. aureus* is unknown. **Methods:** RNA and protein expression profiles of both variants of *Tnfaip8* in both *S. aureus*-susceptible (A/J) and resistant (C57BL/6J) mice were evaluated by real-time PCR and western blot. Expression profiles of *Tnfaip8* in patients with bloodstream infection (BSI) due to *S. aureus* (n=32) or *E. coli* (n= 19) or healthy subjects (n=44) were evaluated with whole genome expression data. **Results:** Levels of *Tnfaip8* RNA were respectively 34% (variant 1) and 13% (variant 2) lower in susceptible vs. resistant mice blood (n=6). By western blot lower levels of TNFAIP8 protein was confirmed in A/J mice, but the protein signal was predominated in immune-related tissues (e.g., kidney, spleen, lymph node) in both mouse strains. Both variants of *Tnfaip8* were highly expressed in both susceptible and resistant mice blood. However, when challenged with *S. aureus* or *E. coli*, whole blood expression of *Tnfaip8* variant 1 decreased to non-detectable level in susceptible mice but had more than 40% increase in resistant mice (n=6). Expression of *Tnfaip8* variant 2 decreased about 15% in susceptible A/J mice blood, but increased more than 11% in resistant C57BL/6J mice (n=6). Similarly, susceptible patients with *S. aureus* BSI had 15% decrease (p=0.0005) of expression, while *E. coli* BSI exhibited 18% ($p<0.001$) decrease of *Tnfaip8* as compared to healthy human subjects. **Conclusions:** These findings further support the importance of *Tnfaip8* in immune response to *S. aureus*, and suggest that both variants of *Tnfaip8* may participate in this function.

2157W

Association of eNOS 4 a/b polymorphism in Mexican patients with coronary artery disease. *M. Gallegos Jr[1], RP. Mariaud[2], LE. Figuera[3], AM. Puebla[4], GM. Zúñiga[5].* 1) Dept Med Molec, Guadalajara, CIBO, IMSS, Jalisco, Mexico; 2) Departamento de Clínicas Odontológicas Integrales, Centro Universitario de Ciencias de la Salud, Universidad Guadalajara; 3) Division de Genética, CIBO, IMSS; 4) Laboratorio de Inmunofarmacología, CUCEI, Universidad de Guadalajara; 5) Laboratorio de mutagénesis,-CIBO, IMSS.

Coronary artery disease (CAD) is a major cause of illness and death, affecting more than 7 million people in the world, their behavior is multifactorial with genetic and environmental predisposition possible. Several polymorphisms in the gene for endothelial nitric oxide synthase (eNOS) have been associated with the development of CAD, one of the most studied has been the 4a/ b, and however the results have been contradiction in different parts of the world. The aim of this study was to determine the association of eNOS 4a /b polymorphism in CAD patients with stenosis coronary positive. Were Included 114 patients with CAD and stenosed coronary and 116 controls from the general population, by the PCR was amplified the intron 4 of the eNOS gene. The allele identification was performance by polyacrylamide gel electrophoresis after staining with silver nitrate. The observed genotype frequencies for controls and CAD patients with stenosis coronary positive were 1% and 17% for a/a, 15% and 42% for a/b, 1% for b/c only control group, and finally 83% and 41% for b/b respectively. The frequencies of the eNOS 4 a/b polymorphism showed statistically significant differences when comparing the study groups ($p < .05$). We conclude that the genotypes a/a-a/b of the eNOS 4 a/b polymorphism contribute significantly to CAD patients with stenosis coronary positive susceptibility in the analyzed sample from the Mexican population.

2158T

KLF15 regulates circadian cardiac susceptibility to ischemia reperfusion injury. *L. Zhang[1], D. Prosdocimo[2,3], M. Jain[2,3].* 1) Dept Med/Human Gen, Case Western Univ SOM, Cleveland, OH; 2) CVRI, Case Western Univ SOM, Cleveland, OH; 3) HHVI, Univ Hosp Case Med Ctr, Cleveland, OH.

It is well recognized that heart attacks have a diurnal variation in their incidence and severity. However, molecular mechanism of the regulation of circadian susceptibility to ischemia/reperfusion (I/R) injury is largely unknown thus preventing effective intervention. Kruppel-like-factors (KLFs) are zinc finger transcriptional factors that serve key roles in cardiovascular biology, in particular, we have previously identified that in multiple cardiovascular diseases, including astherosclerosis and heart failure, *KLF15* expression is reduced. Interestingly, its expression also oscillates in a circadian fashion under the direct regulation of core clock gene, *BMAL1*. Reactive oxygen species (ROS) have long been recognized as a major insult in I/R injury, however, antioxidants have been disappointing in multiple clinical trials. We hypothesize that cellular activities that generates ROS, such as metabolism need to be meticulously coordinated with that dispose ROS in a temporal fashion, so that homeostasis can be maintained despite the dynamic activities of the organism in a 24 hour period. We demonstrate that Klf15 deficiency leads to increased cellular oxidative stress. In primary myocardium cell culture and in vivo I/R model, Klf15 deficient cardiomyocyte/myocardium has increased susceptibility to I/R injury. We also show that Klf15 deficiency affects the myocardium lipid-flux program and is essential for cardiac metabolic homeostasis during fasting (most prominent during sleep to wake transition). Additionally, we have identified and validated multiple ROS clearance enzymes involved in the I/R injury of the myocardium as direct targets of KLF15. Based on these observations, we propose that KLF15 is a hub coordinator of circadian regulation of metabolism and ROS clearance and a key determinant of the temporal susceptibility of myocardium to I/R injury in the heart. Further understanding of the precise molecular mechanism of this regulation will facilitate the discovery of novel preventative therapy against cardiac I/R injury.

Interactions among Depressive Symptoms and Genetic Influences on Cardiac Outcomes. *L. Frazier[1], J. Sanner[2], T.-Y. Yu[2], A. Morrison[3], E. Boerwinkle[3].* 1) College of Nursing, University of Arkansas for Medical Sciences, Little Rock, AR; 2) School of Nursing, University of Texas Health Science Center, Houston, TX; 3) School of Public Health, University of Texas Health Science Center, Houston, TX.

INTRODUCTION Depressive symptoms are associated with increased inflammatory protein levels but only in certain individuals. In a prospective study of patients with acute coronary syndrome (ACS), we tested a biobehavioral model in which inflammatory protein gene polymorphisms interact with depression, and we predicted greater increases in inflammatory protein levels will be observed compared to the levels caused by either gene polymorphisms or depression alone. The purpose of the proposal was to determine a well-defined, high-risk subgroup of ACS patients in which the interaction between depression and genetic polymorphisms increases the risk of subsequent major adverse coronary events (myocardial infarction, revascularization procedures, stroke, and death) more than either factor alone, in part because of their combined effect on increasing inflammatory protein levels. **HYPOTHESIS** We hypothesized that genes with a depression-by-gene interaction effect on inflammatory protein level will also have a depression-by-gene interaction effect on risk of subsequent major adverse coronary events. **METHODS** We enrolled ACS patients from two large tertiary care centers and obtained blood samples to measure inflammatory protein levels immediately after hospital admission. Inflammatory proteins and genes measured include Interleukin (IL) 6, C-reactive Protein (CRP), Tumor Necrosis Factor Alpha (TNFα), E-Selectin (SELE), and Monocyte Chemoattractant Protein-1 (MCP-1). Patients were screened for depression using Beck Depression Inventory-II scores. Demographic and clinical risk factors were collected. The hypothesis will be tested using logistic regression and survival analysis. **RESULTS** Study results are pending data analysis and are currently underway. **CONCLUSIONS** We will present study findings and discuss how the discovery of a relationship among depressive symptoms, genetics, and inflammatory protein levels in a subgroup of ACS patients provides a rationale for studying environmental triggers of depressive symptoms and the effects of depression interventions such as different medications, psychotherapies, treatment combinations, and self-management techniques like exercise on inflammatory protein levels. The results may lead to specific secondary intervention methods that consider the integrated response of the patient to inflammatory triggers and provide support for the role of genetics in modifying the relationship between depression and adverse coronary events.

2160W

A genome-wide interaction study identifies *PDE1C* genetic variants and renal function as jointly associated with coronary artery disease.
C. Ward-Caviness[1], M. Winn[1,2], C. Blach[1], C. Haynes[1], E. Dowdy[1], S. Gregory[1], S. Shah[1,2], W. Kraus[1,2], E. Hauser[1]. 1) Center for Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) Department of Medicine, Duke Univ Med Ctr, Durham, NC.

Cardiovascular disease (CVD) and chronic kidney disease (CKD) are significant causes of mortality in developed nations. CAD and CKD often co-occur, and each has a well-established a genetic basis. However potential interactions between genetic variants (SNPs) and markers of CKD that may influence cardiovascular outcomes have not been explored. We used CATHGEN, a large cardiac catheterization cohort, to perform a genome-wide interaction study that estimated associations between cardiovascular disease, indexed by the number of diseased coronary vessels, and SNP by estimated glomerular filtration rate (GFR) interactions. We used race-stratified cohorts of 2202 whites (EA) and 663 blacks (AA) followed by meta-analysis. A total of 905,956 SNPs were analyzed using a cumulative link model with a logit link. Thus we modeled the log-odds for a change in the number of diseased coronary vessels (our dependent variable/outcome), given a particular SNP-GFR interaction (our independent variable of interest). We adjusted for age, sex, BMI, hypertension, hyperlipidemia, diabetes, smoking, and race-specific principal components to adjust for potential ethnic stratification within each race-stratified cohort. We identified the 10 strongest SNP-GFR interactions for each cohort and looked for those that validated ($P<0.05$ and consistent direction of association between cohorts), or were among the strongest meta-analysis results, ranked by p-value. Using these criteria we identified rs10951304, an intronic *PDE1C* variant ($P=1.09\times10^{-04}$ AA, $P=3.51\times10^{-03}$ EA, $P=9.77\times10^{-06}$ meta-analysis). Another intronic *PDE1C* variant, rs2058411 (AA $P=1.32\times10^{-05}$), was among the 10 most significant AA associations, however this SNP did not have $P<0.05$ in the EA. *PDE1C* is a phosphodiesterase that hydrolyzes cAMP and cGMP, two important cell signaling molecules. *PDE1C* is responsible for a significant portion of cAMP hydrolytic activity in the heart, particularly in smooth muscle cells cultured from atherosclerotic lesions. These analyses take a novel approach to understanding the co-occurrence of CVD and CKD. Using our genome-wide interaction approach we have identified genetic variants in a biologically relevant gene that interact with GFR and are associated with clinically significant atherosclerosis in coronary arteries.

Meigs[1,2]. 1) Massachusetts General Hospital, General, Medicine Division, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA, USA; 3) Division of Endocrinology and Metabolic Diseases, Department of Medicine, University of Verona Medical School and Hospital Trust of Verona, Verona, Italy; 4) Section of General Internal Medicine, VA Boston Healthcare System, Boston, MA, USA; 5) Division of General Internal Medicine and Primary Care, Brigham and Women's Hospital, Boston, MA, USA; 6) Division of Endocrinology and Metabolism, Department of Medicine, Université de Sherbrooke, Sherbrooke, Québec, Canada; 7) Department of Medicine, Section of General Internal Medicine, Boston University School of Medicine, Boston, MA, USA; 8) National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA, USA; 9) Diabetes Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA; 10) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 11) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 12) Cardiology Division, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

Aim Type 2 diabetes (T2D) and subclinical atherosclerosis (SCA) are associated in adults and may share genetic risk factors. The genetic risk for T2D could act as common ground for the development of both T2D and cardiovascular disease (CVD). *Hypothesis* We tested whether T2D genetic risk is associated with higher indices of SCA. *Methods* We conducted a cross-sectional analysis in up to 2,818 participants of the Framingham Offspring Study without a history of CVD. We tested the association of a genetic risk score (GRS) of 62 confirmed T2D single nucleotide polymorphisms (SNP) with measures of SCA: coronary artery (CACS) or abdominal aortic calcium score (AACS), internal (ICA-IMT) and common carotid intima-media thickness (CCA-IMT), and ankle-brachial index (ABI). ICA-IMT, CCA-IMT, AACS, CACS, insulin and Tg/HDL ratio were log-transformed to improve normality. We used linear mixed effect models to account for family relatedness, and tested a genetic-only model (GRS adjusted for sex) and a full risk factor model (GRS adjusted for sex, Tg/HDL ratio, waist circumference, BMI, fasting insulin, fasting glucose, parental T2D). We conducted subsidiary analyses of two distinct sub-GRS comprised of 20 SNPs associated with beta-cell function (B_GRS) or 10 associated with peripheral insulin resistance (IR_GRS) to test the hypothesis that genetic risk for IR in particular would be associated with SCA. We had 80% power to detect association of the 62 SNP GRS with at least 0.42% of the variance in any SCA trait; type 1 error rate set at p-value<0.01 (p=0.05 divided by 5, the number of traits analyzed). The B_GRS and IR_GRS each had 80% power to detect at least 0.48% of the variance in any trait at p-value<0.005 (0.05 divided by 5x2 models). *Results* We found no statistically significant association of the 62 SNP T2D GRS, the B_GRS or the IR_GRS with any SCA trait in any of the models, with the smallest p-value = 0.02 *Conclusions/interpretation* Despite the strong clinical association of T2D and CVD, and known association of the GRS with T2D risk, we did not find that an increasing burden of common variant risk for T2D to be associated with any of five SCA traits. Study strengths include a comprehensive T2D GRS, detailed phenotypic characterization and an adequately powered population sample size. Limitations include the use of tag SNPs from GWAS findings; as functional variants at the 62 loci become known, a genetic basis for shared T2D-CVD risk might become apparent.

2162F

Saturated fat intake modulates the association between an obesity genetic risk score and BMI. *P. Casas-Agustench[1,2], DK. Arnett[3], CE. Smith[1], C-Q. Lai[1], LD. Parnell[1], IB. Borecki[4], Y-C. Lee[1], JM. Ordovás[1,2,5].* 1) Nutrition and Genomics Laboratory, JM-USDA-HNRCA at Tufts University, Boston, MA, USA; 2) IMDEA Alimentación, CEI UAM+CSIC, Madrid, Spain; 3) Department of Epidemiology, School of Public Health, and Clinical Nutrition Research Center, University of Alabama at Birmingham, AL, USA; 4) Division of Statistical Genomics in the Center for Genome Sciences, Washington University School of Medicine, Saint Louis, MO, USA; 5) Department of Cardiovascular Epidemiology and Population Genetics, Centro Nacional de Investigaciones Cardiovasculares (CNIC), Madrid, Spain.

Background and objectives: Combining multiple genetic variants related to obesity into a global genetic risk score (GRS) might improve identification of individuals at risk of developing obesity. Moreover, characterizing gene-diet interactions is a research challenge aimed at investigating dietary recommendations for individuals with higher predisposition to obesity. The aim was to analyze the association between obesity GRS and body mass index (BMI) in a US population, with focus on gene-diet interactions with total and saturated fat intake. **Methods:** A cross-sectional study including 783 participants from the Genetics of Lipid Lowering Drugs and Diet Network study. A weighted GRS was calculated on the basis of 62 obesity-associated variants. Anthropometrical and biochemical measurements were taken using standard procedures. Dietary intakes were estimated with a validated questionnaire. **Results:** The obesity GRS was evaluated by tertiles for BMI, participants with a higher GRS had a higher BMI (P for trend <0.001). Participants in the highest GRS tertile and with BMI $<30kg/m^2$ showed lower total fat (2.3%) and SFA (1.0%) intake compared to participants in the same tertile and with BMI $\geq 30kg/m^2$ (P=0.018 and 0.022, respectively). An interaction was observed between total fat intake and the obesity GRS for BMI (P for interaction=0.014 for continuously evaluated dietary and GRS variables). We also identified interactions between SFA and MUFA intake and GRS evaluated continuously for BMI (P for interaction=0.010 and 0.027, respectively). Finally, we obtained similar results when the SFAs were evaluated categorically according to low and high values (P for interaction=0.014 for categorical SFA intake). Interactions were also observed between total fat, SFA and MUFA intake and the obesity GRS for waist circumference (P for interaction=0.004, 0.004 and 0.015, respectively, for continuously evaluated dietary and GRS variables). **Conclusions:** Total fat and especially SFA intake interact with an obesity GRS in determining BMI in a US population. Dietary recommendations to reduce BMI in population with high obesity GRS would be to reduce total fat intake mainly by limiting SFAs.

2163W

GxE GWAS and path analysis identify a cardiovascular and metabolic risk gene EBF1. *A. Singh[1, 2, 4], M.B. Babyak[1, 4], D.K. Nolan[2], B.H. Brummett[1, 4], R. Jiang[1, 4], I.C. Siegler[1, 4], S.H. Shah[2, 3], R.B. Williams[1, 4], E.R. Hauser[2, 3, 5].* 1) Behavioral Medicine Research Center, Duke University Medical Center, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) Department of Medicine, Duke University Medical Center, Durham, NC; 4) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC; 5) Durham Epidemiologic Research and Information Center, Durham Veterans Affairs Medical Center, Durham, NC.

Understanding the relationship between genetic susceptibility, psychosocial stress and metabolic factors acting in combination to increase the risk of CVD needs diverse methodologies including gene-by-stress interaction analysis and disease pathways analysis. In this study we performed gene-environment interaction genome-wide association analysis (GxE GWAS) to identify single nucleotide polymorphisms (SNPs) whose effects on metabolic traits are modified by chronic psychosocial stress in the Multi-Ethnic Study of Atherosclerosis (MESA). The GxE GWAS for central obesity trait hip circumference identified five SNPs within the Early B-cell Factor 1 (EBF1) gene in MESA Whites. All of the five SNPs were in strong linkage disequilibrium (LD). For these SNPs the gene-by-stress interaction term p-values were genome-wide significant (Ps = 7.14E-09 - 2.33E-08), while genetic main effect p-values were not significant at the conventional genome-wide significance (Ps = 0.015 - 0.031). Further analysis identified gene-by-stress interaction effects for waist circumference, body mass index (BMI), fasting glucose, type II diabetes status, and common carotid intimal-medial thickness (CCIMT), suggesting that gene-by-stress interaction may underlie the relationship between increased central obesity and increased blood glucose, diabetes, and finally increased CVD risk and atherosclerosis. Structural equation path analysis suggested that the path from chronic psychosocial stress to CCIMT via hip circumference and fasting glucose was larger (estimate = .26, p = .033, 95%; CI = .02, .49) in the EBF1 rs4704963 CT/CC genotypes group than the same path in the TT group (estimate = .004, p = .34, 95%; CI = -.004, .012). Published analyses of the EBF1 gene interaction network connects EBF1 to PPARγ expression and SLC2A4 (GLUT4) suggesting that EBF1 plays a role in metabolic disease pathways involved in CVD pathogenesis.

Introduction: The determinants of HDL-C levels are under strong control of genes encoding HDL components like lipases, lipid transfer proteins and HDL receptors. The aim of this study was to investigate the influences of several single nucleotide polymorphisms (SNPs) and components of HDL metabolism on plasma levels of HDL-C, cholesterol and paraoxonase-1 (PON1) activity. Material and Methods: Healthy normolipidemic volunteers (Females=159, Males=153; 19 to 75 years of age) were studied. The study was approved by the local Ethics Committee on Research, following the declaration of Helsinki. Genomic DNA was extracted from peripheral blood cells and the SNPs of *LIPC* (rs1800558, rs2070895), *LIPG* (rs3813082) *APO E* (rs429358, rs7412), *PLTP* (rs6065904) and *PON1* (rs662) detected in the OpenArray® Real Time PCR Platform (Applied Biosystems). Serum Cholesterol and HDL-C were determined by enzymatic methods in an automated system (Hitachi, Roche). The size (nm) and volume (nm3) of HDL were measured in the Nanotrac Particle Size Analyzer (Microtrac, USA). Plasma activities of CETP, PLTP, hepatic lipase and lipoprotein lipase were determined by radioisotopic assays, while PON1 activity by a chromogenic method and endothelial lipase, PLTP mass and plasma insulin were determined by ELISA assays. Lecithin cholesterol acyltransferase (LCAT)-mediated cholesterol esterification rate was determined using endogenous and exogenous substrates. Multivariate stepwise regression analyses were performed in the R software to determine the main influences on plasma cholesterol, HDL-C and PON1 activity. Results: Plasma HDL-C was predicted by plasma cholesterol (R2=0.40; p≤0.0001), PLTP mass (R2=0.12; p≤0.0001), endogenous LCAT activity (R2=0.065; p≤0.0001), *LIPC* rs1800588 (TT genotype: R2=0.0025; p≤ 0.01) and *LIPC* rs2070895 (GG genotype: R=0.0017; p=0.02). Plasma cholesterol was predicted only by plasma HDL-C (R=0.40; p≤0.0001) and *APO E* rs7412 (TT genotype: R= 0.0186; p ≤0.03). On the other hand, PON1 activity was predicted by *PON1* rs662 in the TT (R=0.38; p≤0.0001) and CT (R=0.19; p≤0.0001) genotypes. Conclusions: Influences of *LIPC* rs1800588 and rs2070895 on HDL-C levels were observed in healthy normolipidemic individuals. In addition, PON1 activity was strongly predicted by *PON1* rs662 TT and CT genotypes which induced increases in its antioxidant activity. Support: FAPESP (2006/60585-9), CNPq (159980/2012-7).

Analysis of allele specific expression and transcription factor activity identifies potential gene-by-environment mechanisms of coronary heart disease risk. *O.V. Sazonova[1,2], A. Raiesdana[1], S.T. Nurnberg[1], K.S. Smith[2], V. Anaya[2], T. Quertermous[1], S.B. Montgomery[2,3].* 1) Department of Cardiovascular Medicine, Stanford University, Stanford, CA; 2) Department of Pathology, Stanford University, Stanford, CA; 3) Department of Genetics, Stanford University, Stanford, CA.

Coronary heart disease (CHD) is a complex disorder caused by a combination of environmental and genetic risk factors, the interactions of which are poorly understood. Gene-by-environment effects on the regulation of coronary artery smooth muscle cell (CASMC) phenotype are of particular interest as de-differentiation of these cells is strongly implicated in plaque development. We hypothesized that stimulating de-differentiation with fetal bovine serum would lead to changes in gene expression (GE) and allele-specific expression (ASE) in human CASMCs. To discover serum-induced genetic regulation, we applied genomic methods to quantify and statistically validate differential ASE (dASE) in CASMCs cultured in the presence and absence of serum. For gene-by-environment changes discovered through dASE, we further mined transcription factor binding data to identify potentially causal variants. In detail, CASMCs from 7 individuals were cultured using 0% or 10% serum, genotyped using the Illumina HumanExome BeadChip, and subjected to RNA-Seq. Our method identified 72 dASE genes (FDR 17%) and 10 dASE SNPs (FDR 20%) that exhibit dASE in 2 or more individuals. Only one of 72 dASE genes also showed differential gene expression (dGE) (957 dGE genes in total discovered with DESeq, FDR 5%), suggesting dASE can recover distinct mechanisms for environment-induced regulation not captured by dGE alone. Current studies are underway to identify dASE and dGE pathways related to CHD and their potential regulators. To identify potential causal mechanisms of observed gene-by-environment effects, we examined via ChIP-Seq the binding profile of TCF21 near dASE and non-dASE genes. TCF21 was selected because it regulates coronary artery development, is within a significant CHD GWAS locus, and is upregulated in CASMCs with serum exposure. We hypothesized that altered TCF21 activity may be one mechanism underlying dASE, and found statistically significant enrichment of TCF21 motif-disrupting SNPs among dASE genes compared to non-dASE genes with similar TCF21 associations ($p<0.02$). This finding indicates that dASE genes are susceptible to allele-specific TCF21 binding. Collectively, our study demonstrates that serum exposure induces significant changes in patterns of ASE via mechanisms that may involve variants within the TCF21 binding motif. This analysis provides a powerful new avenue for identifying causal gene-by-environment variants involved in CHD and other complex diseases.

A genome-wide association study reveals novel susceptibility loci for coronary artery disease in Saudi Arabs. *N. Dzimiri[1], C. Nguyen[3], S.M. Wakil[1], N.P. Muiya[1], E. Andres[1], N. Mahzar[1], B. Baz[1], S. Hagos[1], M. Alshahid[2], G. Morahan[3], B.F. Meyer[1].* 1) Dept Genetics, King Faisal Spec Hosp & Research Centre, Riyadh, Saudi Arabia; 2) King Faisal Heart Institute, King Faisal Spec Hosp & Research Centre, Riyadh, Saudi Arabia; 3) Western Australian Institute for Medical Research, University of Western Australia, Australia.

Although multiple loci have been identified for coronary artery disease (CAD) to date, using genome-wide association (GWAS) approach, no GWAS of incident CAD has been reported for Saudi Arabs. In this study, we performed a GWAS for CAD incidence in 5,418 Saudis of Arab ancestry. We discovered 57 genome-wide significant SNPs susceptible for CAD disease that reached the threshold of genome-wide significance ($P < 1 \times 10\text{-}5$). These loci mapped in or near a number of genes including CLCKA and SMYD3 on chromosome (chr) 1, LOC388946, vomeronasal 1 receptor 18 pseudogene, MTND4P28, PLCL1, and CPS1 on chr 2, RPL36AP17 and LOC131054 on chr 3, GRIK2, MAP3K5 and TRNAV37P on chr 6, ZNF804B and MKLN1 on chr 7, GINS4 on chr 8, CDKN2B-AS1 and FAM120A on chr 9, MYEOV and NARS2 on chr 11, CRADD on chr 12, MIS18BP1, PAPOLA, FMN1, LIG3, RFFL on chr 17, RAD51D, PSMB3, BC068609 on chr 19, ARHGAP40 gene on chr20s. This is the first finding of incident CAD loci identified by GWAS in Saudi Arabs. We also replicated 19 previously discovered genetic associations (including CDKN2BAS, CNNM2, PHACTR1, PPAP2B, SLC12A9), providing support for our study design. These findings provide new insights into pathways contributing to the susceptibility for CAD in the Saudi Arab population.

2167T

A genome-wide association study reveals novel susceptibility loci for obesity in Saudi Arabs. *N.P. Muiya[1], C. Nguyen[3], S.M. Wakil[1], E. Andres[1], N. Mazhar[1], B. Baz[1], D. Gueco[1], M. Najai[1], O. Alboudary[1], S. Hawari[1], S. Hagos[1], M. Alshahid[2], G. Morahan[3], B.F. Meyer[1], N. Dzimiri[1].* 1) King Faisal Spec. Hospital & Research Centre, Riyadh, Central, Saudi Arabia; 2) King Faisal Heart Institute, King Faisal Spec. Hospital & Research Centre, Riyadh, Central, Saudi Arabia; 3) Western Australian Institute for Medical Research, University of Western Australia, Australia.

To date, several genetic loci and gene networks have been detected for obesity using genome-wide association studies (GWAS) methodology. However, no GWAS study on obesity has been reported for the Saudi population yet. In this study we performed a GWAS for the prevalence of obesity in 5,418 Saudis of Arab ancestry. We discovered 94 genome-wide significant SNPs that reached the threshold of genome-wide significance ($p<1\times10\text{-}5$) and may contribute to susceptibility to acquiring obesity. These loci mapped onto or near a number of genes, including the PRE-b-Cell leukemia homeobox 1 (PBX1) and proprotein convertase subtilisin/kexin type 9 (PCSK9) on chromosome (chr) 1, NCK-associated protein 5 on chr 2, catenin (cadherin-associated protein), alpha 1 (CTNNA1) and zinc finger RNA binding protein (ZFR) on chr 5, Cub and Sushi domain-containing protein 1 (CSMD1) and zinc fingers and homeoboxes 2 (ZHX2) on chr 8. Other genes mapping on these loci were the V-Rel reticuloendotheliosis viral oncogene homolog A (avian) (RELA), the olfactory receptor, family 52, subfamily E, members 1 and 2 (OR52E1/2), signal-induced proliferation-associated 1 (SIPA1) on chr 11, bicaudal D homolog 1 (drosophila) (BICD1) on chr 12, AKAP6 on chr 14, ribosomal protein L15 pseudogene 21 (RPL15P21) on chr 17, chromosome 20 open reading frame 26 (C20orf26) and cadherin 4, type 1, R-cadherin (retinal) (CDH4) on chr 20. This is the first finding of incident obesity loci identified by GWAS in Saudi Arabs. One other previously reported genetic association, the fat mass and obesity associated (FTO) gene, was replicated, providing support for our study design. These results show a significant correlation of several genomic loci with obesity and provide new insights into pathways contributing to susceptibility for obesity.

2168F

Investigation of genome-wide DNA methylation marks associated with FV Leiden mutation in patients with venous thrombosis. *D. Aïssi[1], M. Ladouceur[2], J. Dennis[2], F. Gagnon[2], P.E. Morange[3], D.A. Trégouët[1].* 1) INSERM UMR_S 937, Paris, France; 2) Division of Epidemiology, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 3) INSERM UMR_S 1062, AP-HM, Marseille, France.

Several lines of evidence are emerging to suggest that DNA methylation marks are involved in the susceptibility of various complex human diseases including thrombosis-related disorders. As part of a general project aimed at identifying DNA methylation-sensitive regulatory mechanisms associated with biomarkers of the fibrinolysis/coagulation cascade, we measured genome-wide DNA methylation levels in peripheral blood samples of 349 patients with venous thrombosis (VT) using the dedicated Illumina Human-Methylation450 bead array. In the current study, we undertook a genome-wide analysis of 485,577 CpG sites to assess whether patients carrying the FV Leiden mutation might be associated with specific DNA methylation profiles. We identified a locus on chromosome 1 characterized by two CpG sites whose DNA methylation levels differed significantly (p = 1.32 10-11 and 3.16 10-11) between carriers (N = 98) and non-carriers (N = 251). Of note, the smallest p-value observed at the F5 gene, also on chromosome 1, was p = 0.144. The two associated CpG sites replicated (p = 8.52 10-11 and 3.57 10-7, respectively) in an independent sample of 214 individuals from 5 large French-Canadian families selected from an index case with venous thrombosis among which 53 were carriers of the FV Leiden mutation and 161 were non carriers. We further tested whether these two CpG sites were associated with biomarkers of VT risk known to be under the strong influence of FV Leiden mutation and that explores the Protein C anticoagulant pathway: the agkistrodon contortrix venom (ACV) test in the discovery population and the activated protein C resistance (APCR) in the replication sample. Strong significant associations were observed (all $p < 10\text{-}6$) which subsequently vanished ($p > 0.10$) after adjusting for FV Leiden mutation. These results may add novel insights into the epigenetic regulation of the coagulation cascade and provide evidence for the usefulness of peripheral blood methylation levels in studying biomarkers of coagulation-relevant epigenetic mechanisms.

Sudden cardiac death (SCD), a major cause of mortality among Western populations, is a clinically heterogeneous condition broadly defined as a sudden unexpected pulseless condition due to a ventricular arrhythmia. While the immediate underlying cause of SCD is considered to be electrical instability, the majority of SCD occurs in the setting of coronary artery disease (CAD). Given this link between CAD and SCD, we chose to investigate the effects of 45 single nucleotide polymorphisms (SNPs) previously associated at genome-wide significance with myocardial infarction/CAD for their potential association with SCD in a meta-analysis of 4496 cases and over 25,000 controls from 10 studies of European descent. We report a significant enrichment of genetic effects at these SNPs for SCD in the same direction as reported for CAD (32/45, P=0.005). Since both sex and age influence CAD burden and risk of SCD, we subsequently conducted analyses stratified by sex, as well as limited to samples less than or equal to 65 years of age. As seen in our overall analysis, we continue to observe the enrichment of effects in males (33/45, P=0.002) and younger samples (age<=65) (32/45, P=0.005). However, there is complete loss of the enrichment signal in the female-only subgroup (23/45, P=0.88). To investigate whether the enrichment was driven primarily by the presence of underlying CAD, we stratified the analysis on the basis of whether controls were population-based (7 studies) or had been selected to have CAD (2 studies). We confirmed the loss of the enrichment signal in the analysis using the CAD controls (20/45, P=0.54). These findings provide compelling genetic evidence for previous pathological studies that have reported a difference in etiology of disease between males and females, with a greater atherosclerotic burden seen in males than in females, and highlight the importance of assessing genetic associations with SCD stratified by sex.

2170T

An extreme phenotype approach to identify genes in Caribbean Hispanics for carotid intima-medial thickness, a preclinical marker of atherosclerosis. *S.H. Blanton[1,2], A.H. Beecham[1], L. Wang[1], C. Dong[2], D. Cabral[2], R.L. Sacco[1,2], T. Rundek[2].* 1) Dept of Human Genetics, Univ Miami, Miami, FL; 2) Dept of Neurology, Univ Miami, Miami, FL.

Carotid intima-medial thickness (cIMT) is a recognized risk factor for cardiovascular disease. The genetic underpinnings of cIMT are not known. The aim of this study was to identify risk/protective loci for cIMT using an extreme phenotype approach in the analysis of SNPs from our genome-wide association study. In individuals from the population-based Northern Manhattan Study, cIMT was measured by high-resolution B-mode ultrasound and expressed as total cIMT, a composite measure of IMT at different carotid sites. Genotyping was done with the Affymetrix 6.0 SNP array. Among the 908 Hispanics, we first calculated the cIMT residual score for each participant by regressing cIMT on known risk factors (age, sex, body mass index, fasting glucose, cigarette smoking pack-years, dyslipidemia, and hypertension). To enrich the genetic effects and increase our power to detect associations, we next identified the individuals in the extreme 10% and 20% of the residual distribution, for a total of 90 and 200 individuals on each side respectively, thus ensuring that the phenotypic extremes were largely unexplained by these known risk factors. For each of the extreme thresholds, we performed logistic regression analysis on 877K SNPs, while controlling for the top 3 PCAs. A gene based analysis was then performed based on the SNP results using VEGAS. The top gene from the 10% threshold (p=3.15E-04) was regenerating islet-derived 1 alpha (*REG1A*), which is over expressed in the early stages of Alzheimer disease and may play a role in both celiac disease and rheumatoid arthritis. Its relationship to cIMT is unclear. The top gene from the 20% threshold (p=1.5E-05) was family with sequence similarity in 120B (*FAM120B*). While this gene is not well characterized, it is a co-activator of the proliferator-activated receptor gamma family, which plays a crucial role in cholesterol and lipid metabolism. In addition to the gene based analysis, we also conducted a pathway based analysis using genes with a p<0.05 as input into WebGestalt. After adjusting for multiple testing, several pathways of interest were identified. In particular for the 20% threshold, the pathway of fat digestion and absorption was the most significant (p=1.0E-04). Novel SNPs reported here support the critical link between inflammation and cholesterol metabolism with arterial wall biology leading to subclinical atherosclerosis or to protection against atherosclerosis.

2171F

The link between hepcidin, iron and atherosclerosis: a Mendelian randomization approach. *T.E. Galesloot[1], L.L. Janss[2], D.W. Swinkels[3], S.H. Vermeulen[1].* 1) Department for Health Evidence, Radboud University Medical Centre, Nijmegen, The Netherlands; 2) Department of Molecular Biology and Genetics, Aarhus University, Aarhus, Denmark; 3) Laboratory of Genetic, Endocrine and Metabolic Diseases, Department of Laboratory Medicine, Radboud University Medical Centre, Nijmegen, The Netherlands.

Background The 'iron hypothesis' states that people with elevated serum iron levels face a greater risk of cardiovascular disease, but epidemiologic studies on associations between iron depletion and cardiovascular risk remain inconclusive. Hepcidin, central regulatory molecule of systemic iron homeostasis, might play a role in the progression of atherosclerosis. In this study, we will investigate the link between hepcidin, iron and atherosclerosis using a Mendelian randomization approach. Methods We will include participants of the Nijmegen Biomedical Study (NBS) aged 46-67 years for whom measurements of hepcidin, iron parameters and non-invasive measurements of atherosclerosis as well as GWAS data are available (N±800). We will derive heritability estimates for hepcidin, ferritin and iron and estimate the genetic correlation between these traits using GWAS data by application of Bayesian modeling techniques. Subsequently, we will apply a multivariate GWAS analysis for hepcidin, ferritin and iron using a multivariate test of association (MQFAM) implemented in PLINK. We will identify both shared (pleiotropic) and non-shared (independent) genetic regulators of hepcidin, ferritin and iron. The independent genetic variants and a combination thereof will be used as instrumental variables in a Mendelian randomization approach to study their association with atherosclerosis. Expected results Our study will apply up-to-date techniques to identify independent genetic determinants of correlated phenotypes. The identified differences in genetic etiology will be exploited to create insight in the causal roles of hepcidin, ferritin and iron in the development of atherosclerosis.

Blood pressure (BP) is a heritable determinant of risk for cardiovascular disease. To investigate genetic associations with systolic BP (SBP), diastolic BP (DBP), mean arterial pressure (MAP), and pulse pressure (PP), we genotyped ~50,000 single nucleotide polymorphisms (SNPs) that capture variation in ~2,100 candidate genes for cardiovascular phenotypes in up to 87,736 individuals of European ancestry from 36 studies. We identified 11 novel associations in independent loci containing 31 genes including PDE1A, HLA-DQB1, CDK6, PRKAG2, VCL, H19, NUCB2, RELA, HOXC@ complex, FBN1 and NFAT5, and 16 previously known associations with SBP, DBP, MAP, or PP, confirmed at the Bonferroni-corrected array-wide significance threshold ($P < 6 \times 10\text{-}7$) in a combined meta-analysis with an additional independent set of up to 68,368 individuals of European ancestry. An in depth bioinformatic analysis of the genes and variants in the 11 loci provided functional evidence to support several genes, including cis eQTL associations between SNPs and the expression of HLA-DQB1 and NUCB2. Analysis of ENCODE data identified histone modifications and motifs related to these and other novel BP signals. Druggability analysis for associated genes in this study using existing public resources, including databases of small molecules, shows that ten genes are predicted to be modified by small molecule therapeutics. In summary, we identified novel loci associated with BP and confirmed multiple previously reported associations. Our findings extend our understanding of genes involved in BP regulation, some of which may provide new targets for therapeutic intervention or drug response stratification.

2173T

Genetic and Phenotypic Architecture of Coronary Artery Disease in a Diverse Population. *I. Konidari[1], L. Wang[1], Z. Liu[1], N. Sikka[1], P. Goldschmidt[2], M.A. Pericak-Vance[1], D. Seo[1,2], G.W. Beecham[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) University of Miami, Department of Medicine, Division of Cardiology, Miami, FL, USA.

Coronary heart disease is the leading cause of death in the United States, with atherosclerosis of the coronary arteries (CAD) being one of the major underlying etiologies. Though the role of genetics on CAD has been studied in European ancestry populations, its role in Hispanic populations is unclear. To further determine the genetic etiology of CAD, we are performing a GWAS of CAD using a diverse set of cardiac catheterization patients. This study utilizes the Miami Cardiovascular Registry of the University of Miami, Miller School of Medicine. Patients were ascertained through cardiac catheterization labs; consisting of over 65% Hispanic and 15% African American. All 2,000 patients were phenotyped with a research grade read of coronary angiograms, describing the CAD in each of the 16 major coronary artery branches. Genotype data were generated using the Affymetrix 6.0 array and Illumina HumanExome beadchip platforms. Extensive QC tests were performed to ensure the integrity of the data, including sample filters and SNP filters; EIGENSTRAT methods were used to detect and subset based on race/ethnicity. Association was tested using regression-based methods, with age and sex included as covariates. Genotypes were initially analyzed within the three racial groups (White non-Hispanic, Black, Hispanic/Latino). Results indicate significantly associated variants in/near the GBA3, PMEPA1, and EPB41L2 genes. Additional analyses include tests for racial differences in the architecture of disease; that is: do different populations have different coronary branches affected at different levels? Additionally, are testing for association with disease in specific major branches; results will be presented. This study will yield important results, both about the phenotypic differences and similarities between populations, and about underlying genetic etiology of CAD.

2174F

Local ancestry inference in a genome-wide association study of a genetically diverse population with coronary artery disease. *Z. Liu[1], L. Wang[1,2], N. Vasudeva[2], P.J. Goldschmidt-Clermont[3], M.A. Pericak-Vance[1,2], D.M. Seo[3], G.W. Beecham[1,2].* 1) Dr. John T. Macdonald Foundation, Department of Human Genetics, University of Miami, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 3) Division of Cardiology, Miller School of Medicine, University of Miami, Miami, FL.

Coronary artery disease (CAD) is a leading cause of mortality in the United States with an estimated 500,000 deaths each year. Recent studies have shown the prevalence of CAD is different among different racial/ethnic populations with Native Americans being the highest (11.6%), followed by African Americans (6.5%), Hispanics (6.1%), whites (5.8%) and Asian Pacific (3.9%). Genetic risks underlying CAD are not well understood, especially those that are racially/ethnically specific. To study the genetic risk of CAD, we conducted a genome-wide association study (GWAS) of 2,000 catheterization patients from the Miami Cardiovascular Registry of the University of Miami. This dataset represents the diversity of South Florida populations, including European, African, and Hispanic/Latinos ancestry. Genotyping was performed on Affymetrix 6.0 platform, and standard QC were performed to ensure data integrity. To address population substructure, we performed local ancestry inference to identify the ancestral state of each locus. Haplotypes were estimated from publicly available reference datasets using ShapeIT. Given phasing uncertainty, we generated 100 phasing iterations for each individual and use them to infer local ancestry with the LAMP-LD/LAMP-ANC software. The 100 iterations were averaged to generate the percentage of ancestry of European, African or Native American at each locus. To validate this approach, we estimated global ancestry for each individual by averaging the results across all chromosomes and comparing it with the estimates derived from a principal component analyses (PCA). Global ancestry estimated by our approach and PCA are highly correlated (correlation coefficient between eigenvector 1 and African ancestry component $r2=0.99$; for eigenvector 2 and Native American/Asian, $r2= -0.87$), suggesting a reliable ancestry estimation by our approach. By summing across individual haplotypes, our samples composed of approximately 75% European descent, 20% African descent and 5% Native American/Asian descent. We will utilize this local ancestry information to study the contribution of ancestry specific minor alleles to the patient's anatomic atherosclerotic burden and blood pressure. The advantage of this study is that it allows us to determine common variants associated with cardiovascular disease traits that are common in all populations and unique to a specific race/ethnicity, therefore improving our understanding of CAD genetic risks.

2175W

Genetic variants affecting the expression of *DRAM2* at 1p13.3 are associated with acute myocardial infarction with different effects for STEMI and NSTEMI.
P. Salo[1], J. Sinisalo[2], J. Kettunen[3,1], A. Havulinna[4], A. Sarin[3,1], T. Hiekkalinna[1,3], S. Ripatti[3,1], P.J. Karhunen[5,6], H. Huikuri[7], M. Lokki[8], V. Salomaa[4], M. Nieminen[2], M. Perola[1,3,9]. 1) Public Health Genomics Unit, Natl Inst Health & Welfare, Helsinki, Finland; 2) Division of Cardiology, Heart and Lung Center HUCH, Helsinki University Central Hospital, Helsinki, Finland; 3) Institute for Molecular Medicine Finland (FIMM,) Helsinki, Finland; 4) Chronic Disease Epidemiology and Prevention Unit, Natl Inst Health & Welfare, Helsinki, Finland; 5) School of Medicine, University of Tampere, Tampere, Finland; 6) Fimlab Laboratories Ltd, Tampere University Hospital Region, Tampere, Finland; 7) Department of Internal Medicine, Oulu University Hospital and University of Oulu; 8) Transplantation Laboratory, Haartman Institute, University of Helsinki, Helsinki, Finland; 9) Estonian Genome Center of the University of Tartu, Tartu, Estonia.

Myocardial infarction (MI) is usually caused by coronary artery disease (CAD). The narrow-sense heritability of MI has been estimated to be 0.35 and 0.38 for males and females. Known genetic risk variants explain 11% of the additive genetic variance in susceptibility to CAD.

Despite advances in understanding the genetic basis of MI, little attention has been paid to the distinction between ST-segment elevation MI (STEMI) and non-ST-segment elevation MI (NSTEMI). The division is made based on characteristic ECG changes and the two are known to present with different characteristics. In most cases STEMI results from a complete occlusion of a coronary artery whereas NSTEMI is caused by partial or transient blockage. NSTEMI tends to present with greater minimal luminal area in the culprit artery and smaller infarct size. Curiously, recurrent infarctions are often of the same type, suggesting that some individuals may be particularly susceptible to either STEMI or NSTEMI. The possible differences in their genetic risk factors, however, remain virtually unknown.

We performed a genome-wide association study of MI (1579 cases, 1576 controls) with stratification into NSTEMI and STEMI and replicated the results in two independent study samples. We identified a novel risk locus for acute MI at 1p13.11 associated with NSTEMI (OR=1.56, P=4×10^{-10}) but not with STEMI (OR=1.14, P=0.08). We further show that the SNPs conferring risk to NSTEMI are also associated with the expression of *DRAM2* contained within the NSTEMI-associated region and provide evidence for two distinct but partially overlapping association signals at the locus.

The exact function of *DRAM2* remains unknown, but it has been shown to be required for efficient autophagy induction. Silencing *DRAM2* inhibits autophagy under starvation and attenuates p53-mediated cell death. The association of variants with both NSTEMI and *DRAM2* expression thus suggests regulation of autophagy may affect risk for NSTEMI, raising the possibility that *DRAM2* has an effect on the survival of myocardial cells during the ischemic conditions of acute MI. Furthermore, the results also show that genetic factors in part determine whether coronary artery disease results in NSTEMI rather than STEMI.

2176T

A novel MMP12 locus is associated with large artery atherosclerotic stroke using a genome-wide age-at-onset informed approach.

Genome-wide association studies (GWAS) have begun to identify the common genetic component to ischaemic stroke. However, ischaemic stroke (IS) is a syndrome with considerable heterogeneity. In analyses where clinical covariates explain a large fraction of disease risk, covariate informed designs have been shown to increase power to detect associations. As prevalence rates in IS are dramatically affected by age, and younger onset cases are likely to have higher stroke-specific genetic predisposition, we investigated whether an age-at-onset informed approach could detect novel associations. We used an age-at-onset informed design to identify novel variants associated with IS and its subtypes; cardioembolic (CE), large vessel disease (LVD) and small vessel disease (SVD) stroke in 6,784 cases of European ancestry and 12,095 ancestry-matched controls. Regression analysis to identify SNP associations was performed per centre on posterior liabilities after conditioning on age-at-onset and affection status. We sought further evidence of a novel association with LVD in an independent replication cohort of 1,526 cases, and followed up the association by examining mRNA expression levels of the nearby genes in atherosclerotic carotid artery plaques from the Tampere Vascular Study. We identified a novel association with an MMP12 locus in LVD (rs660599; p=1.6×10-7) using an age-at-onset informed approach. We found independent replication of this locus in a second population (p=0.0048), reaching genome-wide significance overall (p=1.7×10-8). The nearby gene, MMP12, was found to be significantly overexpressed in carotid plaques compared to atherosclerosis-free control arteries (p=1.2×10-15; fold change=335.6). Furthermore, all previously identified associations were found to be more significant using the age-at-onset informed approach. Our results indicate that a covariate-informed design, conditioning on age-at-onset of stroke, is likely to unearth novel variants not identified by conventional GWAS. We show this explicitly by identifying an association with a novel MMP12 locus in large artery stroke, supported by evidence of increased mRNA expression of the implicated gene in carotid plaques.

2177F

Genetic Architecture of Hypertension in a Multi-Ethnic Population.
N. Vasudeva[1], L. Wang[1], A. Beecham[1], P. Goldschmidt[2], M. Pericak-Vance[1], D. Seo[1,2], G. Beecham[1]. 1) Hussman Institute for Human Genomics, University of Miami; 2) Department of Medicine, University of Miami.

Previous genetic studies on hypertension have focused mostly on the European ancestry populations. We sought to dissect the genetic basis for hypertension in a diverse population of Hispanics, European ancestry, and African ancestry using a genome-wide association study. The 2,000 samples are ascertained through the clinic-based Miami Cardiovascular Registry, a dataset consisting of ~55% Hispanic and were genotyped using the Affymetrix SNP array 6.0. Quality control tests were performed to ensure data integrity. Linear regression was used to evaluate single variant association with Systolic Blood Pressure (SBP), Diastolic Blood Pressure (DBP), Pulse Pressure (PP=SBP-DBP), and Mean Arterial Pressure (MAP=(SBP+2DBP)/3). To account for the medication-lowered blood pressure, we added 7% and 6%; for SBP and DBP, respectively, for each antihypertensive medication taken. Age, age², gender, dyslipidemia and diabetes are significantly associated ($P<0.05$) with blood pressure in our samples and were included as covariates. Eigenstrat analysis was used to divide samples into Hispanic, White non-Hispanic, and Black subgroups. Analysis was performed within each subgroup and meta-analyzed across subgroups. Strong association ($P < 0.00001$) was found at multiple SNPs for each trait, with the strongest associations at rs9584521 near the MBNL2 gene for PP ($P=7\times10\text{-}8$) and rs7278181 in CLDN14 for SBP ($P=9\times10\text{-}8$). Interestingly, both of these loci were monomorphic in the European ancestry subgroup, and would not have shown association in a combined analysis. Additional analyses are underway, including analysis of multiple variants in aggregate and replication in an additional dataset. Our study provides essential data in a diverse population and may lead to additional insights into the genetics of hypertension.

2178W

12 Novel genome wide associations for human cardiac repolarization.
N. Verweij[1], W.G. Wieringa[1], I. Mateo Leach[1], D.J. van Veldhuisen[1], W.H. van Gilst[1], H.L. Hillege[2], R.S.N. Fehrmann[3], P.I.W. de Bakker[4], R.A. de Boer[1], L. Franke[3], P. van der Harst[1]. 1) Department of Cardiology, University of Groningen, University Medical Center Groningen, Groningen , Netherlands; 2) Trial Coordination Center, University of Groningen, University Medical Center Groningen, Groningen, Netherlands; 3) Department of Genetics, University of Groningen, University Medical Center Groningen, Groningen , Netherlands; 4) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands.

Repolarization abnormalities of the heart have been linked to ventricular arrhythmias and sudden cardiac death. Although previous studies of cardiac repolarization have focused largely on interval duration on the electrocardiogram (ECG), changes in the amplitudes may be important as well. Therefore, we performed a GWA meta-analysis on amplitudes of the ST-segment and T-wave (ST-T wave) in 15,943 Dutch individuals. Amplitudes were measured trough the lateral, inferior, anterior, septal and aVR leads of the 12 lead electrocardiogram to define the spatial location. We evaluated 2 time points resulting in 10 traits: 5 for the ST segment (at 80ms after J point) and 5 for the T wave. Across 10 traits we identified 41 genotype-phenotype associations ($p < 6.25 \times 10\text{-}9$ based on 8 independent phenotypes) clustered within 17 independent loci. Twelve of the loci are novel determinants for cardiac repolarization. We observed that SNPs with P<6.25E-09 were 3.3 fold enriched for Dnase I hypersensitivity sites in human fetal heart (Z=3.2; compared to 337 other cell types and tissues) and >10 fold enriched for p300 enhancers in the human heart (P<4E-7). This suggests that functional regulatory variants may contribute to several of the associations observed in this study. Furthermore the associations provide insights on the spatiotemporal contribution of genetic variation involved in cardiac repolarization: SNPs at KCND3, TNKS and KCNB1 showed specific associations with the ST-wave. Other loci (XPO1, KCNH2 and TBX3) were specific for the septal leads, possibly related to the function and location of structures such as the AV bundle and its branches. These analyses provide novel insights into the biology of cardiac repolarization and may help to elucidate diseases of cardiac repolarization. Supported by the Netherlands Heart Foundation (grant NHS2010B280).

2179T

A Three-stage Genome-wide Association Study Combining Multilocus Test and Gene Expression Analysis for Young-Onset Hypertension on Taiwan Han Chinese.
K. Chiang[1,2,3], H. Yang[4], J. Chen[5], W. Pan[1,2,3]. 1) Institute of Biomedical sciences, Academia Sinica, Taipei, Taiwan; 2) Graduate Institute of Life Science, National Defense Medical Center, Taipei, Taiwan; 3) Division of Preventive Medicine and Health Services Research, Institute of Population Health Sciences, National Health Research Institutes, Taiwan; 4) Institute of Biomedical Science, Academia Sinica, Taipei, Taiwan; 5) National Yang-Ming University School of Medical and Taipei Veterans General Hospital, Taipei, Taiwan.

Hypertension is a common and complex disorder. To identify genetic variants will eventually contribute to screening and management efficacy. Although many large-scale genome-wide association studies have been performed, a few studies have successfully identified replicable, large-impact hypertension loci, not to mention the scanty Chinese studies. Young-onset hypertension (YOH) is considered as a more promising target disorder to investigate than the late-onset one due to its stronger genetic component. We performed a three-stage genome-wide association study combining multilocus test and gene expression analysis to map YOH genetic variants. In the first stage, using single locus and multi-locus association tests, we analyzed Illumina HumanHap550 data from 399 YOH cases and 399 age and gender matched controls. In the second stage, differential gene expression analysis was carried out for genes flanked by 14 SNP septets identified in the first stage, using lymphoblast cell lines of the same set of case-control pairs. In the third stage, we re-examined the genetic association for four genes with both allelic and expression association signals in an independent set of 592 YOH cases and 592 controls and verified four genes (C1orf135, GSN, LARS, ACTN4) from the multi-locus test by either the independent sample or a joint analysis that combined the data from 1st and 3rd stages. All four are potential novel hypertension susceptibility genes. Among them, the same septet flanking ACTN4 was replicated by Hong Kong Hypertension Study (HKHS) and by WTCCC hypertension study (WTCCCHS), which has been associated with kidney related diseases, such as focal segmental glomerulosclerosis. LRAS was replicated in the HKHS, but not in the WTCCCHS. GSN which has been implicated in the inflammatory processes in animals may be specific to Taiwanese populations, since it was not validated by HKHS and WTCCCHS.

Background: Growth differentiation factor 15 (GDF-15), a cytokine produced in cardiovascular cells under conditions of oxidative stress and inflammation, is an independent prognostic biomarker for cardiac events. Genetic markers located close or in the *GDF15* gene have been associated with circulating GDF-15 concentrations. In this genome-wide association study (GWAS) we assess the genetic effects on GDF-15 in a large clinical study on patients with acute coronary syndrome (ACS). **Methods:** We performed a GWAS of 10 013 ACS patients enrolled in the PLATelet inhibition and patient Outcomes study (PLATO). In total 9448 patients passed genotype quality control and had measurements of GDF-15 levels at baseline. Of these, 3133 patients had additional GDF-15 measurement after one month. Clinical and genetic correlates of GDF-15 were assessed in multivariable analyses. **Results:** We identified three independent SNPs with genome-wide significance associated with baseline levels of GDF-15: rs17725099 (P-value = 1.47E-107), rs74180880 (P-value = 6.93E-46) and rs1055150 (P-value = 5.89E-10). All three SNPs were in the same region of chromosome 19, close to the *GDF15* gene, which has been reported previously to affect levels of GDF-15. The effect on levels of GDF-15 at baseline and at one month was similar for the three SNPs (adjusted beta estimates on log scale for rs17725099, rs74180880 and rs1055150 at baseline 0.16, 0.09, 0.08 and at one month 0.16, 0.10 and 0.08, respectively). The identified SNPs are located in predicted regulatory regions, such as an active promoter and strong enhancer, or overlaps with regions predicted to be occupied by transcription factors. Clinical correlates (the top five being age, diabetes, smoking, chronic renal disease and ACS type) accounted for 26.3% of the variation (R2) in log(GDF-15) and the addition of the three top SNPs increased the explained variation by 5.3% to 31.6%. **Conclusion:** We identified three independent SNPs affecting GDF-15 concentrations. The effect was similar at baseline and at one month follow-up, indicating that the genetic effects on GDF-15 are not restricted to the acute phase of ACS. The large effect on GDF-15 levels by genetic variation might influence the GDF-15 based risk-prediction in patients with ACS. Combining these three SNPs in Mendelian-randomization studies could be used to assess the causal effect of GDF-15 on clinical endpoints in longitudinal cohort studies.

2181W

An eQTL mapping strategy identifies the FN3KRP gene as a risk factor for elevated systolic blood pressure the Norfolk Island Genetic Isolate. *L.R. Griffiths[1], M. Benton[1], R.A. Lea[1], D. Mccartney-Coxson[2], M. Carless[3], H. Goring[3], C. Bellis[3], M. Hanna[1], D. Eccles[1], G. Chambers[4], J. Curran[3], J. Blangero[3].* 1) Genomics Research Centre, Griffith Health Institute, Griffith University Gold Coast, Southport, Australia; 2) Kenepuru Science Centre, Institute of Environmental Science and Research, Wellington, New Zealand; 3) Texas Biomedical Research Institute, San Antonio, Texas USA; 4) School of Biological Science, Victoria University of Wellington, New Zealand.

Hypertension affects millions of people worldwide and is influenced by a number of attributing elements, including environmental, lifestyle and genetic factors. Expression quantitative trait loci (eQTL) influence gene expression and therefore make good candidates for functional involvement in risk of hypertension. Pedigrees within founder effect populations may provide some advantage for mapping CVD genes. This study aimed to identify eQTLs associated with hypertension-related traits in the Polynesian founder-effect population of Norfolk Island (NI). We measured genome-wide transcript levels of lymphocytes from 330 individuals forming a single large pedigree from NI. Heritability analysis was used to identify significantly heritable transcripts. A pedigree-based GWAS was conducted on these transcripts to identify cis-acting eQTLs. These eQTLs and their respective transcripts were then tested for association with blood pressure traits - systolic, diastolic, arterial and pulse pressure measures. Results revealed 1712 significantly heritable transcripts within the NI pedigree. The heritability (H2) values ranged from 0.18 to 0.83 with a median of 0.32 ($P<0.05$). A pedigree-based GWAS of the heritable transcripts revealed the presence of 200 cis-acting eQTLs ($P < 1.84\times10^{-7}$). An eQTL-centric association analysis against the blood pressure traits revealed hits at HMBOX1 and FN3KRP genes for SBP, and HOXB2 gene for DBP. Integrative regression modelling of these traits incorporating both transcript level and eQTL genotype, as well as age sex and structure, verified the FN3KRP gene on chr 17q25 as a functional risk factor for elevated SBP ($R2=0.25$, $P=3.3\times10^{-15}$). This study has utilised an eQTL mapping strategy in a large pedigree from a Polynesian founder effect population to functionally implicate the FN3KRP gene in hypertension risk. The FN3KRP gene encodes the fructosamine-3-kinase, an enzyme involved in glucose metabolism. Further studies are required to assess the association of FN3KRP and its biochemical pathways with hypertension comorbidities such as diabetes and obesity.

2182T

Known SNPs in ADAMTS7, the 9p21 region, ZFAND6 and UBE2E interact with type 2 diabetes status to modify the risk of coronary artery disease in large populations. *N.R. van Zuydam[1,2], B. Voight[3], C. Ladenvall[4], R. Strawbridge[5], S. Willems[6], E. van Iperen[7], J. Hartiala[8], E. Vlachopoulou[9], E. Mihailov[10], L. Kwee[11], C. Nelson[12], M. Kleber[13], L. Qu[3], A. Goel[2], J. Kumar[15], S. Kanoni[14], N.W. Rayner[2,14], SUMMIT and CARDIoGRAMplusC4D.* 1) University of Dundee, Dundee, United Kingdom; 2) University of Oxford, Oxford, United Kingdom; 3) University of Pennsylvania, Philadelphia, United States of America; 4) University of Lund, Lund, Sweden; 5) Karolinska Institut, Stockholm, Sweden; 6) Erasmus University Medical Center, Rotterdam, The Netherlands; 7) Academic Medical Center, Amsterdam, The Netherlands; 8) Cleveland Clinic, United States of America; 9) University of Helsinki, Helsinki, Finland; 10) University of Tartu, Talin, Estonia; 11) Duke University, Durham, United States of America; 12) University of Leicester, Leicester, United Kingdom; 13) LURIC Study, Freiburg im Breisgau, Germany; 14) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 15) University of Uppsala, Uppsala, Sweden.

Patients with type 2 diabetes (T2D) are more likely to suffer from coronary artery disease (CAD) than non-diabetic individuals. In this study we aimed to identify loci that modify the risk of CAD in patients with T2D. We combined summary statistics for 2,295,146 (imputed and directly typed) SNPs from 21,623 patients with T2D (8,456 CAD cases and 13,167 CAD free controls) and 36,104 non-diabetic individuals (14,774 CAD cases and 21,330 CAD free controls) in a fixed effects meta-analysis stratified by T2D; we tested known CAD and T2D loci for an interaction with T2D status and performed a pathway analysis on the meta-analysis summary results. The meta-analysis of allelic effects from CAD case-control associations in patients with T2D identified a signal in *ADAMTS7* represented by two independent SNPs previously reported for CAD: rs11072811 (OR=1.2, frequency=0.53, p=8E-12) and rs11634042 (OR=1.1, frequency=0.57, p=4E-08). Rs11072811 had a smaller effect on CAD risk in non-diabetic individuals (OR=1.1, p=1E-02) when compared to its effect in patients with T2D, and this interaction with T2D status was significant (p=9E-03). The meta-analysis of allelic effects from CAD case-control associations in non-diabetic individuals identified the previously published signal in the 9p21 region represented by rs1333042, (OR=1.2, effect allele frequency=0.49, p=5E-20). Rs1333042 had a significant interaction with T2D status (p=3E-04), with a smaller allelic effect in patients with T2D (OR=1.1, p=4E-05). Evaluation of known T2D loci revealed that the T2D risk alleles of rs7612463 (T2D: OR=0.9, P=8E-03; ND: OR= 1.1, P=1E-02) in *UBE2E2* and rs11634397 (T2D: OR=0.9, P=3E-02; ND: OR=1.1, P=3E-03) in *ZFAND6* were associated with decreased risk of CAD in patients with T2D but with increased risk of CAD in non-diabetic individuals ($P_{interaction}$ < 5E-03), when compared to the T2D reference allele. Pathway analysis of the combined T2D and non-diabetic CAD associations identified a REACTOME pathway involved in platelet plug formation associated with CAD overall (p=9E-06), while analysis of CAD associations in patients with T2D found associations (p<1E-03) with pathways involved with cell apoptosis (BIOCARTA), fibroblast growth factor signalling (REACTOME) , nitric oxide biosynthesis and phospholipase A2 activity (GOTERM). This study suggests that known CAD SNPs in *ADAMTS7* and 9p21, and known T2D SNPs in *UBE2E* and *ZFAND6* may differentially modify CAD risk based on T2D status.

2183F

Association of Metabochip variants to systolic blood pressure in African Americans from a biorepository linked to de-identified electronic medical records. *L. Wiley[1,2], R. Goodloe[1], E. Farber-Eger[1], J. Boston[1], D. Crawford[1,3], W. Bush[1,2].* 1) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN.

Blood pressure is a heritable human trait related to a variety of clinical conditions, and hypertensive individuals have increased risk for multiple cardiovascular disorders. The Epidemiologic Architecture for Genes Linked to Environment (EAGLE) BioVU is a subset of the Vanderbilt University biorepository of ~15,000 DNA samples from non-European Americans representing African Americans (n=11,521), Hispanics (n=1,714), and Asians (n=1,122). These samples were genotyped using the Illumina Metabochip to examine influence of these variants on a variety of clinical outcomes. We examined the African American samples to identify genetic variants associated with median outpatient systolic and diastolic blood pressure measurements (excluding patients on blood pressuring lowering medications). There were 11,165 patients (63% female) with all available outcomes and covariates. The median BMI of this population was 25, average systolic and diastolic blood pressure were 74.8 (sd=65.8) and 43.9 (sd=41.6) respectively. Median blood pressure measurements were regressed on 192,270 markers from the Illumina Metabochip adjusting for gender, age, age^2, body mass index (BMI) and the three most significant principal components to adjust for population stratification. Two variants were associated with systolic blood pressure: rs4945935 and rs10857636. The intragenic variant, rs4945935 (MAF=0.02), was associated with a 4.5 point decrease in systolic blood pressure (p=3.4e-6). The other variant, rs10857636 (MAF=0.06), is intronic to *WDFY4* and is associated with a 2.4 point increase in systolic blood pressure (p=7.4e-6). Other variants in this gene have been associated with cardiovascular traits including lipid levels and quantitative subclinical atherosclerosis traits. Additionally this variant is in high linkage disequilbrium (r^2=1 in European populations) with a variant that is an eQTL for the gene *LRRC18*, which has been associated with abdominal aortic calcification. Because blood pressure changes are comorbid with multiple clinical conditions, we further adjusted these models for a global composite of all clinical diagnoses. Both associations are robust to this adjustment indicating that these SNPs directly impact systolic blood pressure and are not mediated through association with another condition.

2184W

Genome-wide association study of leukocyte telomere length identifies casein kinase 2(*CSNK2A2*) to be associated with shorter telomere length and increased cardiovascular disease risk in diabetes. *P. Natt[1], R. Saxena[2], P. Dib[1], S. Ralhan[3], G. Wander[3], D. Stowell[4], M. Payton[4], D. Sanghera[1].* 1) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Massachusetts General Hospital, Harvard Medical School, Boston, MA; 3) Hero DMC Heart Institute, Ludhiana, Punjab, India; 4) Department of Surgery, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Telomere shortening has been associated with multiple diseases including hypertension, myocardial infarction, osteoporosis, type 2 diabetes (T2D), and Alzheimer's disease. In this investigation, we have performed a genome-wide scan (GWAS) to identify the common genetic variation that may influence the relative leucocyte telomere length (LTL) and cardiometabolic risk in a diabetic cohort of Punjabi Sikhs from India and the US. Our results revealed a significant association of LTL with coronary heart disease (CHD) the mean LTL showed a gradual decline from healthy subjects to individuals with T2D and CHD showing respective mean LTL being 2.10 in healthy, 1.95 in T2D, 1.69 in CHD, and 1.59 in T2D+CHD. GWAS analysis of discovery cohort (n=1,616/842 T2D cases) identified 338 top independent signals ($p<10^{-4}$) to be significantly associated with LTL. Most promising 48 SNPs were further replicated through genotyping in an additional Punjabi Sikh sample (n=2,397/1,108 cases). On combined meta-analysis in Sikh populations (n=4,013/1,946 cases), we identified a novel locus in association with LTL at 16q21 represented by an intronic SNP rs74019837 in the *CSNK2A2* gene ($p = 4.4\times10^{-8}$). We also found significant association signals near *SPATA4*, *C5orf42*, and **FER** genes for affecting LTL with p values ranging from 2.7×10^{-5} to 3.3×10^{-6}. Our findings report an independent association of shorter telomere length with T2D and cardio metabolic risk. Interestingly, telomeric repeat binding factor 1(TRF1) serves as a substrate for *CSNK2A2*, which phosphorylates and initiates its binding to telomere. *CSNK2A2* also interacts with multiple genes and miRNAs in pathway controlling telomere length and cardiovascular disease. Future functional studies may provide clinically important insights on the interplay of genetic variation in *CSNK2A2* and environmental and lifestyle factors for affecting LTL and cardiometabolic risk in diabetes.

2185T

A Rho-GTPase pathway related gene is associated with chronic kidney disease via an interaction with coronary artery disease. *E. Hauser[1], C. Ward-Caviness[1], M. Winn[1,2], C. Blach[1], C. Haynes[1], E. Dowdy[1], S. Gregory[1], S. Shah[1,2], W. Kraus[1,2].* 1) Center for Human Genetics, Duke Univ Med Ctr, Durham, NC; 2) Department of Medicine, Duke Univ Med Ctr, Durham, NC.

Chronic kidney disease (CKD) and coronary artery disease (CAD) are intimately linked and often co-occur, implying they may share some aspects of their genetic basis. The genes related to the Rho-GTPase family been implicated in the pathogenesis of CAD in multiple studies. As regulators of the actin cytoskeleton Rho-GTPase genes have an important function in many cellular processes and potentially a function in the pathogenesis of CAD and CKD. Here we present a Rho-GTPase gene that interacts with CAD and is associated with CKD. To discover this association we conducted a genome-wide interaction study in a cardiac catheterization cohort, CATHGEN. We used an ordinal measure of atherosclerosis assessed during the catheterization, CADindex, as a measure of the extent of severity of CAD to test the hypothesis that specific genetic variants (SNPs) that interact with measures of CAD are associated with CKD prevalence CATHGEN. We used race-stratified cohorts of 2202 whites (EA) and 663 blacks (AA) to identify relevant interactions, and a subsequent meta-analysis filtered for consistent associations. We estimated 905,956 SNP-CADindex interactions via a logistic regression model, with CKD as the dependent variable (outcome). A Score test was used to calculate P-values (P), and we adjusted for age, race specific principal components, sex, BMI, hypertension, hyperlipidemia, diabetes, and smoking. We identified the 10 most significant interactions in each cohort, then filtered for those that validated, i.e. $P < 0.05$ and consistent direction of association in the other cohort. The most significant EA SNP to validate was rs11014215 located in the 5' regulatory region of the Rho-GTPase gene *ARHGAP21* (EA $P=5.6\times10^{-6}$, AA $P=0.045$, meta-analysis $P=1.3\times10^{-6}$). *ARHGAP21* is a cytoskeletal protein involved in cellular differentiation and is an activator of Cdc42, a cell cycle protein. Examining other interactions in *ARHGAP21* revealed one additional association, rs12219181 (*ARHGAP21* intron, EA $P = 0.032$). These analyses use a novel interaction analysis to identify rs11014215, located 5' of *ARGHGAP21*, as associated with CKD in a SNP-CADindex interaction model. This SNP was strongly associated with CKD in the EA cohort and validated in the AA cohort. Given the previous associations of Rho-GTPase family genes with CAD and the co-occurrence of CAD and CKD we believe this interaction brings novel information to understanding these two important chronic diseases.

2186F

Identifying interactions among social, psychosocial, and genetic factors that influence blood pressure in three multi-ethnic epidemiological cohorts: the Multi-Ethnic Study of Atherosclerosis (MESA), the Atherosclerosis Risk in Communities Study (ARIC), and the Health and Retirement Study (HRS). *J.A. Smith[1,2], W. Zhao[1,2], B. Needham[1-3], J.D. Faul[4], T.E. Seeman[5], E. Boerwinkle[6], A. Chakravarti[7], D.R. Weir[4], S.L.R. Kardia[1,2], A.V. Diez Roux[1-3].* 1) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 2) Center for Integrative Approaches to Health Disparities, University of Michigan, Ann Arbor, MI; 3) Center for Social Epidemiology and Population Health, University of Michigan, Ann Arbor, MI; 4) Survey Research Center, Institute for Social Research, University of Michigan, Ann Arbor, MI; 5) University of California Los Angeles, Division of Geriatrics, Los Angeles, CA; 6) Human Genetics and Institute of Molecular Medicine, University of Texas Health Science Center, Houston, Texas; 7) Center for Complex Disease Genomics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland.

Substantial health disparities in the prevalence, severity, and age of onset of hypertension exist across ethnic groups in the United States. Traditional approaches for examining the causes of these disparities have been fragmented into 'biological' and 'social' approaches. However, blood pressure levels are likely influenced by the interaction between multiple biological and social/psychosocial risk factors. We used data from 20,495 non-Hispanic whites and 6,307 African Americans from three large multiethnic cohorts (the Multi-Ethnic Study of Atherosclerosis (MESA), the Atherosclerosis Risk in Communities Study (ARIC), and the Health and Retirement Study (HRS)) to examine the effects of interactions between common SNP variation at 29 known blood pressure loci and social factors (education, parental education) or psychosocial factors (anger) on blood pressure levels. In gene-based analysis using the Gene-Environment Set Association Test (GESAT), we found evidence of gene-by-anger interaction for systolic blood pressure at two loci in whites (*C10orf107*, p=0.007; *PLEKHA7*, p=0.007) and two loci in African Americans (*NT5C2*, p=0.009; *ULK4*; p=0.003). For diastolic blood pressure, gene-by-anger interaction was detected at two loci in whites (*C10orf107*, p=0.0002; *PLCE1*, p=0.005). Identifying the factors that lead to the persistent differences in the blood pressures among these populations is critical for developing effective strategies to reduce disparities.

2187W

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Heritability of Serum Lipids. *T.J. Hoffmann[1], M.N. Kvale[1], Y. Banda[1], E. Jorgenson[2], S.E. Hesselson[1], L. Walter[2], S. Sciortino[2], D.K. Ranatunga[2], D. Ludwig[2], C. Iribarren[2], P. Kwok[1], C. Schaefer[2], N. Risch[1,2].* 1) University of California San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern Division of Research.

Plasma lipid concentrations are an important heritable risk factor for cardiovascular diseases that are often targets for therapeutic interventions. The Kaiser Permanente Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort contains extensive longitudinal lipid, prescription medication, and genotypes (over 675,000 markers) for nearly all of its 100,000 participants. Approximately 1 million HDL and LDL cholesterol measures from electronic health records were linked to genetic data for this analysis.

Genome-wide association studies have failed to account for a large amount of the heritability that has been estimated from family-based heritability calculations. Recently, an approach has been developed to use genome-wide association data to use the heritability of less-related individuals to estimate the heritability of a trait. This approach has not been systematically compared to heritability estimates derived from first, second, and third-degree cryptic related individuals identified in a large GWAS cohort. Preliminary results for total cholesterol show an apparent maternal effect of a higher mother-child heritability of .606 (.065 sd) than father-child (genetically determined) of .472 (.084), and a sibling heritability of .463 (.055). Overall, first degree relatives had a heritability of .486 (.038) and second degree .299 (.109), but kinship estimates from King robust were not stable enough for further degree relatives. Heritability estimates utilizing all genotyped SNPs from GCTA are .282(.018), while that of the independent significant genotyped SNPs was .12, and of independent significant imputed SNPs was .14. After regressing off the significant imputed SNPs, GCTA gave the expected reduced heritability of .141 (se .018), father-child .335 (.081), mother-child .404 (.065), full sibs .411 (.056), and first-degree .353 (.038). Using the significant SNPs, we also tested for epistasis and dominance interactions, but neither appreciably increased the variance explained. Nor did reducing the threshold for genome-wide significance to 1×10^{-6}. Similar analysis for LDL, HDL, and triglycerides will also be presented.

2188T

A family-based linkage and association studies reveal new variants near *THBS2* and *ACE* for blood pressure. *H. Kim[1], S. Im[1], S. Lee[1,2], S. Cho[3], J. Sung[3], K. Kim[1,2,4], J. Seo[1,2,5].* 1) Medical Research Center, Genomic Medicine Institute (GMI), Seoul National University; 2) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul 110-799, Korea; 3) Seoul National University School of Public Health, Seoul 151-742, Korea; 4) Psoma Therapeutics Inc., Seoul 153-781, Korea; 5) Macrogen Inc., Seoul 153-781, Korea.

High blood pressure (BP) causes global health problem as a major risk factor for cardiovascular disease and death. BP is heritable, with heritability ranging from 18% to 37%. Although recent genome-wide association studies (GWAS) have substantially contributed to understand the genetic architecture for BP, discovering new variants for explaining missing heritability still remains a major challenge. Moreover, GWAS might miss the true-positive associations within linkage regions because of too strict significance level for multiple testing. To uncover the novel candidates for BP, we performed fine mapping study under suggestive linkage regions as well as family-based GWAS using an isolated Mongolian sample of 751 individuals from 53 families. Our GWAS revealed 3 single-nucleotide polymorphisms (SNP)s for SBP and 5 SNPs for DBP reaching a significance level ($P < 1 \times10^{-5}$), which included several candidate genes such as *ACE*, *BMPER*, and *IL5*. Of these, rs4459609, an intergenic SNP near *ACE* gene (5.5 Kb away) showed a significant effect on both SBP ($P = 4.75\times10^{-6}$) and DBP ($P = 8.59\times10^{-6}$). For fine mapping association test under linkage peaks, we firstly observed two suggestive linkage regions on chromosome 6q27 (LOD for SBP = 2.4) and 5q35 (LOD for DBP = 2.0), which were consistent with previously reported linkage peaks in other populations. The subsequent association test in presence of linkage found 7 and 2 SNPs in each linkage region, respectively ($P < 5\times10^{-3}$). Top association signal under linkage peak was found for rs9393162, an intergenic SNP near THBS2 (21.3 kb away). We also confirmed that the 27 loci identified in previous GWAS were nominally replicated ($P < 0.05$), and of these loci, ADM and ZNF652 for SBP were still significant after multiple testing corrections ($P <$ (0.05/ the number of effective SNPs)). In addition, we examined associations with 10 anti-hypertensive drug target genes, and *CA1* and *SCNN1A* were statistically significant in Mongolian families. In conclusion, our strategic analysis combining linkage and association enabled the discovery of novel variants associated with BP near *THBS2* and *ACE* in Mongolian families.

2189F

Higher Degree of African Ancestry in Transfused African American Sickle Cell Patients is Associated with Red Cell Alloimmunization. *RA. Kittles, R. Machado, NA. Ellis, K. Batai, JN. Garcia, SA. Campbell-Lee.* University of Illinois Hospital and Health Sciences System, Chicago, IL.

Background: Red cell alloimmunization in transfused sickle cell disease patients occurs in approximately 30%. Because red blood cell (RBC) transfusion is an important part of therapy, the need for additional antigen matching once alloimmunization occurs is problematic, and leads to therapeutic limitations. Thus, it would be important to identify risk factors for alloimmunization in this patient population. We performed a genome wide association study (GWAS) in an attempt to identify possible genes associated with RBC alloimmunization. Methods: 157 sickle cell disease patients, including 69 who developed alloimmunization and 88 who did not were genotyped for 2,217,402 SNPs using the Affymetrix PanAFR Array. SNPs with a call rate <90%, Hardy Weinberg Equilibrium P<0.0001, or having a minor allele frequency (MAF) <1% were excluded from the analysis. In total, 2,113,177 SNPs were analyzed. Population structure was examined by principal components analysis (PCA) using the GWAS SNPs. Statistical analyses were performed using Golden Helix SVS 7. To correct for multiple testing, the genome wide significance threshold was set at $P<2.4 \times 10^{-8}$. We also selected 2,104 unlinked ancestry informative markers from the Affymetrix PanAFR array and estimated West African Ancestry (WAA) using STRUCTURE. Results: Logistic regression analyses revealed that PC 1 was significantly associated with RBC alloimmunization (P=0.04), and SCD patients in the highest ancestry quartile (>85% WAA) had significantly increased risk of RBC alloimmunization compared to patients in the lowest quartile (<75% WAA) (OR=2.7, 95% C.I.; 1.02-7.07). In the lowest WAA quartile, 18.8% of the patients were alloimmunized, while 29.5% of the patients were not. In the highest WAA quartile, 29.0% of patients were alloimmunized and 20.5% were not. No SNPs reached genome-wide significance for the association with RBC alloimmunization, although three SNPs, rs1507094 (*RALYL*), rs4345649 (*POLR1E*), and rs10941424 (*FYB*) almost reached genome-wide significance (P=1.31 × 10-6; 2.82 × 10-6; and 3.21 × 10-6, respectively). Of note, the *FYB* gene on 5p13.1 is a binding protein involved in platelet activation and expression of IL-2. Conclusions: In our study, patients with higher WAA were more likely to develop RBC alloantibodies. A larger sample size would be necessary to find SNPs which reach genome-wide significance for RBC alloimmunization.

2190W

Identifying population specific dyslipidemia variants using cross-population GWAS. *A. Ko[1], D. Weissglas-Volkov[1], R.M. Cantor[1], E. Nikkola[1], K.A. Deere[1], J.S. Sinsheimer[1], B. Pasaniuc[2], R. Brown[3], V. Salomaa[4], J. Kaprio[4,5,6], A. Loukola[5], A. Jula[4], M. Jauhiainen[4], M. Heliövaara[4], O. Raitakari[7,8], T. Lehtimäki[9], J.G. Eriksson[4,10,11], M. Perola[4,6], L. Riba[12,13], T. Tusie-Luna[12,13], C.A. Aguilar-Salinas[12], P. Pajukanta[1].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) 2Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, USA; 3) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, USA; 4) National Institute for Health and Welfare, Helsinki, Finland; 5) Department of Public Health, Hjelt Institute, University of Helsinki, Helsinki, Finland; 6) Institute for Molecular Medicine Finland FIMM, University of Helsinki,Helsinki, Finland; 7) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, Turku, Finland; 8) Department of Clinical Physiology and Nuclear Medicine, Turku University Hospital, Turku, Finland; 9) Department of Clinical chemistry, Fimlab Laboratories and University of Tampere School of Medicine, Tampere, Finland; 10) Folkhälsan Research Center, University of Helsinki, Helsinki, Finland; 11) Department of General Practice and Primary Health Care, University of Helsinki, Helsinki, Finland; 12) Instituto Nacional de Ciencias Médicas y Nutrición, Salvador Zubiran, Mexico City, Mexico; 13) Instituto de Investigaciones Biomédicas de la UNAM, Mexico City, Mexico.

The high prevalence of dyslipidemia in Mexicans is a serious health burden due to the increased risk for cardiovascular disease and medical cost. Identifying Hispanic-specific variants can accelerate our understanding of lipid disease pathogenesis in this rapidly growing U.S. minority. However, studies in admixed populations are hindered by complex population substructure that can reduce power. To address this, we conducted a genome wide cross-population study using subsamples that were selected by triglyceride (TG) levels (total n=9,065) from Mexican and Finnish cohorts. The Finnish low TG controls were frequency matched for age, BMI, and sex to eliminate known TG confounders, because the Mexican low TG controls were significantly more obese (p=2.20×10-16) despite their younger age. To increase power by reducing the candidate SNPs to those that are likely to be specific to Mexicans, we compared allele frequencies of the Mexican and Finnish low TG controls using a p-value<0.001. About 90% of the SNPs passing this threshold were ancestry informative markers (AIMs) based on the CEU and MEX HapMap data, suggesting that ~10% additional trait-related variants can be found using the cross-population GWAS approach. Using this tailored set of variants to compare Mexican high TG cases and low TG controls on a pilot study on chromosome 8 with 18,426 SNPs, we discovered two experiment-wide significant TG-associated SNPs (rs4128744, p=2.61×10-8 and rs2688358, p=3.77×10-6). To evaluate this approach, we employed local ancestry inference using LAMP-LD as an independent method to examine ancestral origins across chromosome 8. Remarkably, 7 of the top 10 TG-associated SNPs from our cross-population pilot study resided in regions with enrichment for Amerindian ancestry in the Mexican TG cases versus controls, suggesting that they represent underlying susceptibility variants in the Hispanic-specific, trait-linked regions. Given this result, our design should significantly help replication and fine mapping efforts. We also explored the top 10 SNPs for a cis effect of nearby genes on Genevar analysis of ~850 publicly available adipose RNA microarray samples. Five SNPs showed nominal to significant evidence for a regulatory cis-eQTL effect in adipose. In summary, we demonstrate that the cross-population GWAS strategy in combination with local ancestry inference is a powerful approach to identify population-specific variants that may otherwise be missed by conventional GWAS.

2191T

Genome wide association study for Arteriosclerosis Obliterans in a Japanese population. *K. Ozaki[1], T. Morizono[2], Y. Onouchi[1], A. Takahashi[3], T. Tsunoda[2], M. Kubo[4], Y. Nakamura[5,6], T. Tanaka[1,7].* 1) Laboratory for Cardiovascular Diseases, RIKEN, Ctr Integrative Medical Science, Yokohama, Kanagawa, Japan; 2) Laboratory for Medical Science Mathematics, RIKEN, Ctr Integrative Medical Science, Yokohama, Kanagawa, Japan; 3) Laboratory for Statistical Analysis, RIKEN, Ctr Integrative Medical Science,; 4) Laboratory for Genotyping Development, RIKEN, Ctr Integrative Medical Science,; 5) Human Genome Center, Institute of Medical Science, the University of Tokyo, Tokyo, Japan; 6) Section of Hematology/Oncology, The University of Chicago; 7) Department of Human Genetics and Disease Diversity, Tokyo Medical and Dental University.

Arteriosclerosis obliterans (ASO) is the most common cause of peripheral vascular disease affecting the lower limbs. ASO mainly occurs from atherosclerosis, resulting in obstruction of the blood supply to the lower or upper extremities. ASO might result from complex interactions multiple genetic and environmental factors. To reveal genetic backgrounds in the pathogenesis for ASO, we performed a genome wide association study (GWAS) in a Japanese population. Genotyping was performed by the Illumina HumanHap610-Quand BeadChip for cases and by Illumina HumanHap550v3 for controls. We applied stringent quality-control criteria and tested 789 cases and 3,383 controls for 510,687 autosomal SNPs commonly available on both BeadChip. The inflation of test statistics, $\lambda_{genomic\ control}$ (λ_{gc}) was 1.04. Through combination of this GWAS and a following staged analysis with a total of 2,647 Japanese subjects with ASO and 20,560 control subjects, we have identified two susceptible loci for this disorder on chromosome 13 and 4 (P values < 10^{-8}). To our knowledge, these are the first genetic risk factors identified for ASO.

2192F

Common autosomal variants are associated with bicuspid aortic valve in Turner Syndrome. *S.K. Prakash[1], M. Silberbach[2], S. Hooker[3], D.C. Guo[1], C. Maslen[2], C.A. Bondy[4], D.M. Milewicz[1], GenTAC Investigators.* 1) University of Texas Health Science Center at Houston, Houston, TX; 2) Oregon Health & Science University, Portland, OR; 3) Baylor College of Medicine, Houston, TX; 4) National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD.

Background: The prevalence of bicuspid aortic valves (BAV) is enriched thirty-fold in women with Turner Syndrome (TS) in comparison with the general population. We hypothesize that common autosomal variants influence the development of BAV in TS women, who may be uniquely sensitized to these variants by the loss of one X chromosome. We sought to identify autosomal BAV susceptibility genes in a cohort of TS women (average age 33 years, 38% BAV, 15% coarctation). Methods: 73 TS women of European ancestry with BAV and 120 TS women with tricuspid aortic valves were genotyped using Illumina Omni-Express arrays (668,262 SNPs). Tests of association were performed using logistic regression without adjustment for covariates. Results: TS women with 45,X karyotypes were not significantly more likely to have a BAV than those with isochromosomes, rings or Xp deletions (*P*=0.09). After removal of 11 outlier samples for the first two multidimensional scaling components, the genomic inflation factor was 1. The strongest association signals were observed on chromosomes 2, 5 and 22 and did not overlap with previously reported loci for BAV. A total of 16 SNPs in the *ITGA1* locus on 5q11.2 were positively associated with BAV (OR=4.3) with a minimum *P* value of 1.5×10-5. *ITGA1*, which encodes the alpha-1 intergrin, is a promising BAV candidate gene because it is expressed in valve tissue and is required for vascular cell adhesion and myofibroblast differentiation. Replication of these regions in independent groups of cases is ongoing. Conclusion: This is the first study to demonstrate that autosomal variants are associated with BAV in TS women, and provides evidence for gene-gene interactions in BAV formation.

Willer[1,12].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, Levanger, Norway; 3) St. Olav Hospital, Trondheim University Hospital, Trondheim, Norway; 4) Program in Bioinformatics, University of Michigan, Ann Arbor, Michigan; 5) Department of Community Medicine, Faculty of Health Sciences, University of Tromsø, Tromsø, Norway; 6) Brain and Circulation Research Group, Department of Clinical Medicine, Faculty of Health Sciences, University of Tromsø, Tromsø, Norway; 7) Department of Neurology and Neurophysiology, University Hospital of North Norway, Trosmø, Norway; 8) Department of Public Health, Norwegian University of Science and Technology, Trondheim, Norway; 9) Department of Laboratory Medicine, Children's and Women's Health Faculty of Medicine, Norwegian University of Science and Technology, Trondheim, Norway; 10) Center for Statistical Genetics, Department of Biostatistics, University of Michigan School of Public Health, Ann Arbor, Michigan; 11) Levanger Hospital, Levanger, Norway; 12) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan.

Genome-wide association studies have identified common variants that are associated with coronary artery disease or myocardial infarction (MI). While these common variants are robustly associated with CAD, they have small effect sizes and collectively explain less than 10% of the heritability in MI (currently estimated to be 40-60%). One explanation for the 'missing heritability' is the existence of low frequency (1-5%) or rare (<1%) variants with larger effect sizes. However, the majority of low frequency variants have not been included in modern GWAS arrays and cannot be well imputed from modern reference panels based on HapMap or 1000 Genome Project samples; thus their contribution to the risk of MI has not been systematically evaluated. In this project, as a first step towards addressing the potential contribution of these low frequency coding variants on the risk of MI, we addressed the question of whether some of these variants have moderate to high effect sizes as proposed. Using the Illumina HumanExome Beadchip, we genotyped 5,937 samples from the Nord-Trøndelag Health Study (HUNT): 2,969 medical-record confirmed acute myocardial infarction cases and 2,968 healthy controls. This array allowed for direct genotyping of 80,533 polymorphic coding variants as well as 44 known GWAS SNPs. We followed-up 21 coding variants in an additional 4,668 samples from the Tromsø study (Tromsø 4) including 2,350 MI cases and 2,318 controls, all from Norway. evaluated the array coverage in these Norwegian samples using whole genome sequencing combined with exome enrichment in 162 samples. The exome array provided successful genotyping for an estimated 74% of Norwegian loss-of-function or missense variants with frequency > 5%, 73% of coding variants with frequency 1-5% and 51% of rare coding variants with frequency < 1%. Despite sufficient power to detect association with low frequency variants (1-5% frequency) with moderate to high effect sizes (odds ratio 1.38-1.91) in the combined sample size of 10,333 individuals, we did not identify any novel genes or single variants that reached significance. However, we identified several strong candidate genes hovering below study-wide significance levels suggesting that low frequency and rare variants with intermediate effect sizes will likely be identified with larger samples.

Using common genetic variants to predict dyslipidemia. *C.M. van Duijn[1], S.M. Willems[1], E.J.F. Sijbrands[2], A. Dehghan[1], A. Hofman[1], B.A. Oostra[3], O.H. Franco[1], A. Isaacs[1].* 1) Dep Epidemiology, ErasmusMC, Rotterdam, Netherlands; 2) Department Internal Medicine, ErasmusMC, Rotterdam, Netherlands; 3) Department Clinical Genetics, ErasmusMC, Rotterdam, Netherlands.

Hypercholesterolemia (HC) is an important modifiable cardiovascular disease risk factor. We determined the ability of genotypic risk scores to identify individuals at increased risk of hypercholesterolemia. We calculated TC, LDL-C, HDL-C and TG risk scores in the Rotterdam Study (RS, n=10,072) and Erasmus Rucphen Family Study (ERF, n=2,715) using 157 SNPs discovered in recent meta-analyses of ≥100,000 individuals. Adding the TC score to a clinical model based on age, sex and BMI improved the prediction of HC (c-index in RS increased from 0.64 to 0.68 (P=2.1×10-31) and in ERF from 0.71 to 0.75 (P=2.9×10-9)). The LDL-C, HDL-C and TG scores combined improved prediction similarly. In RS, age specific risk showed an approximately doubled cumulative incidence of HC in the highest TC risk score quartile compared to the lowest. We compared the risk curves with carriers of Mendelian forms of dyslipidemia.In both cohorts, overall and in age strata, prevalence of HC increased with TC risk score quartile (Ptrend= 1.3×10-96 to 0.002). Odds ratios also increased with quartile, from 1.62 for the second to 3.5 for the highest quartile compared to the lowest in the total sample. Maximum OR was 3.9 for the highest quartile in the 65-74 years stratum (P=2.4×10-32). Our results show that genetic risk scores can be useful in identifying individuals at increased risk of hypercholesterolemia. Our findings also suggest that a genetic risk score can help identify individuals that would benefit from earlier and more intensive monitoring of cholesterol levels.

2195F

Genome-wide association study of laboratory markers in Kawasaki disease. *J. Kim, J. Lee, Korean Kawasaki Disease Genetics Consortium.* Asan Institute for Life Sciences, University of Ulsan College of Medicine, Seoul, South Korea.

Kawasaki disease (KD) is an acute self-limited vasculitis of infants and children, manifested by fever and signs of mucocutaneous inflammation. Children with KD show laboratory abnormalities of inflammation, such as elevated white blood cell (WBC) count, C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), and they also may have anemia, thrombocytosis, hypoalbuminemia, and elevated serum transaminases, etc. To identify genetic loci influencing important laboratory markers in KD - WBC count, neutrophil count, platelet count, CRP, ESR, hemoglobin (Hb), aspartate aminotransferase (AST), alanine aminotransferase (ALT), albumin, and total protein, we performed association studies using our previous genome-wide association study (GWAS) data of KD. Linear regression analyses after adjustment for age and sex were carried out for the 10 quantitative traits in 178 KD patients. A total of 165 loci passed our arbitrary stage 1 threshold for replication ($P < 1 * 10^{-5}$). For CRP, variants in the *CRP* gene showed the most significant associations ($P = 1.20 * 10^{-6} \sim 5.69 * 10^{-6}$) and for WBC count, a variant in the *TNFRSF13B* gene reached genome-wide significance level ($P = 2.80 * 10^{-8}$). For Hb, variants in the *SOX5* gene were the most significantly associated ($P = 9.40 * 10^{-7} \sim 4.41 * 10^{-6}$) and for albumin, the most compelling association involved a variant in the *CDKAL1* gene which was reported as being associated with albuminuria ($P < 8.73 * 10^{-6}$). Of the significant variants from the stage 1 GWA analysis, 22 were selected as candidates considering their functional importance. Further replication studies are planned to validate these results.

2196W

Novel association of endothelial function with a variant in *PEAR1*. *A.S. Fisch[1], P. Donnelly[1], M. Drolet[1], S. Newcomer[1], A. Parihar[1], K.A. Ryan[1], W. Herzog[2], A.R. Shuldiner[1], J.P. Lewis[1].* 1) Program in Personalized and Genomic Medicine, and the Division of Endocrinology, Diabetes, and Nutrition, Department of Medicine, University of Maryland School of Medicine, Baltimore, MD; 2) Department of Medicine, Johns Hopkins Medical Institute, Baltimore, MD.

The anti-platelet agent aspirin is one of the most commonly prescribed medications for prevention and treatment of coronary heart disease. However, there is great inter-individual variation in response to aspirin as measured by on-treatment residual platelet aggregation and cardiovascular outcomes. In the Pharmacogenomics of Anti-Platelet Intervention (PAPI) Study, a genome-wide association study (GWAS) in 670 healthy Old Order Amish (OOA) participants, we identified a genome-wide significant association between on-aspirin collagen-stimulated platelet aggregation and *PEAR1* genotype (rs12041331). The rs12041331 variant was also associated with cardiovascular event risk in two independent populations. *PEAR1* (platelet endothelial aggregation receptor 1) is a platelet-platelet contact receptor that modulates platelet aggregation. In addition to platelets, *PEAR1* is highly expressed in endothelial cells, which led us to hypothesize that the variant's association with cardiovascular risk may be mediated through effects on endothelial function. To investigate this hypothesis, we genotyped rs12041331 in participants of the Heredity And Phenotype Intervention (HAPI) Heart Study, a clinical intervention study with 868 healthy OOA participants in whom cardiovascular traits were assessed, including platelet aggregation and endothelial function by brachial artery flow-mediated dilation (FMD). In this cohort, we confirmed significant association between on-aspirin collagen-stimulated platelet aggregation and *PEAR1* genotype (effect size = 6.56, p = 0.037), with the minor A allele associated with decreased platelet aggregation. In addition, we found significant association between *PEAR1* genotype and FMD (effect size = 1.14, p = 0.039), with the A allele associated with increased FMD, which represents greater endothelial function. These results indicate that *PEAR1* likely plays a dual functional role in platelets and endothelium, and that *PEAR1* rs12041331 genotype is associated with both. Future studies will be required to more precisely understand the mechanisms by which *PEAR1* and its genetic variants influence aspirin response, ultimately leading to the development of more individualized and effective anti-platelet therapy.

Novel Susceptibility Loci for Resting Heart Rate: Common Genetic Variant in KREMEN1 Is a Replicable and Genome-Wide Significant in Korean and Mongolian Populations. *B. Gombojav[1, 2], D.H. Lee[3], M.K. Lee[3], M. Kho[3], Y.J. Yang[3], E. Purevdorj[7], Y.M. Song[5], K. Lee[6], J.I. Kim[2,4], J. Sung[1,3], J.S. Seo[2,4].* 1) Epidemiology, Seoul National University, Seoul, Seoul, South Korea; 2) Genomic Medicine Institute, Medical Research Center, Seoul National University, Seoul, Korea; 3) Complex Disease and Genome Epidemiology Branch, Department of Epidemiology, School of Public Health, Seoul National University, Seoul, Korea; 4) Department of Biochemistry and Molecular Biology, College of Medicine, Seoul National University, Seoul, Korea; 5) 5 Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, School of Medicine, Sung Kyun Kwan University, Seoul, Korea; 6) Department of Family Medicine, Busan Paik Hospital, College of Medicine, Inje University, Busan, Korea; 7) Department of Higher Education, Ministry of Education and Science, Ulaanbaatar, Mongolia.

Background - Previous studies have identified an increased resting heart rate as an independent risk factor of cardiovascular morbidity and mortality. Although heritable factors play a substantial role in regulating the heart rate, evidence about specific genetic determinants is limited. Objective -To identify common genetic variants associated with the resting heart rate, we did a genome-wide association study (GWAS). Methods - A total of 537,159 markers were tested for their association with the resting heart rate in a GWAS. The GWAS sample consisted of 3,029 healthy individuals from 661 families of the Healthy Twin Study, Korea (HT). The most promising markers from the GWAS were subsequently tested in a Mongolian replication samples comprised of 1,013 individuals from 73 extended families of the GENDISCAN study. Results - The SNP in the locus 22q12.1 at KREMEN1 [rs469983, minor allele frequency (MAF) = 0.130; an odds ratio = 1.74, 95% CI 1.27-2.37; combined P = 4.6×10-8] reached the genome-wide significance in combined analysis. In aggregate, this variant explains 0.6 % of resting heart rate variance. In addition, we replicated four novel susceptible loci in the replication sample: 17p12 at ADORA2B; 14q21.1 at LRFN5; 5q31.2 at SPOCK1 and 11q14.3 at NOX4. Conclusion - We have identified five novel susceptible loci for resting heart rate and kringle-containing transmembrane protein 1, KREMEN1 reached the genome-wide significance. Further studies are required to replicate these findings and to elucidate the biological mechanisms.

2198F

PMA(phorbol 12-myristate 13-acetate) regulates in vitro alternative splicing of ORL1, a gene, involved in atherogenesis and tumorigenesis.
E. Morini[1,2], J.R. Tejedor[3], B. Rizzacasa[2], M.C. Bellocchi[4], F. Ferrè[5], A. Botta[2], D. Caporossi[1], J. Valcárcel[3], G. Novelli[2,6,7], F. Amati[2]. 1) Dept. of Movement, Humanities and Health Sciences, "Foro Italico" University, Rome, RM, Italy; 2) Dept. of Biomedicine and Prevention, Tor Vergata University, Rome, RM, Italy; 3) Centre de Regulació Genòmica and Universitat Pompeu Fabra, Barcelona, Spain; 4) Dept. of Sperimental Medicine and Surgery, Tor Vergata University, Rome, RM, Italy; 5) Dept. of Biology, Tor Vergata University, Rome, RM, Italy; 6) Dept. of Internal Medicine, University of Arkansas for Medical Sciences and Central Arkansas Veterans Healthcare System, Little Rock, AR, USA; 7) St. Peter Fatebenefratelli Hospital, Rome, RM, Italy.

Lectin-like oxidized low-density lipoprotein receptor-1 (LOX-1), encoded by the OLR1 gene, is the major endothelial receptor for ox-LDL and plays a fundamental role in the pathogenesis of atherosclerosis. Furthermore recently, it has been demonstrated that an increased activity of LOX-1 is associated with cancer cell invasion. OLR1 is subjected to a physiological alternative splicing; its isoform, Loxin, lacks exon 5 and encodes for a putative truncated receptor (LOXIN) with impaired binding activity. LOXIN is considered as a natural inhibitor of LOX-1-mediated signalling and each effort to increase LOXIN expression may have a potential therapeutic effect. The expression of OLR1 and Loxin is regulated by six intronic SNPs in linkage disequilibrium and the H-risk haplotype is associated to acute myocardial infarction (AMI) and atherosclerosis. The macrophages of individuals with H-risk haplotype present a OLR1/Loxin mRNA ratio 33% higher compared to individuals with L-risk haplotype. In order to study in detail the regulation of OLR1/Loxin, we have analyzed the expression of the two isoforms in in vitro cell models (THP-1 and HeLa). We found that treatment with 100nM PMA increases OLR1 and Loxin expression levels; this increment is due to a PMA-mediated induction of OLR1 promoter. However, we observed that Loxin splicing was significantly increased after 3h ($p<0.00001$), while OLR1 splicing after 30' ($p<0.000001$). These results suggest a dual regulation of OLR1 splicing by PMA. To test this hypothesis we transfected HeLa cells with two minigenes (HIGH-risk and LOW-risk) containing the genomic sequences spanning from exon 4 to the whole 3'UTR of the OLR1 gene. These minigenes carry two different haplotypes of the six SNPs regulating OLR1 splicing. We performed a dose-curve PMA treatment at 3h and interestingly, we found that 10nM PMA up-regulates Loxin expression (FC10nM=+1.6, $p<0.05$) in HeLa transfected with H-risk (Hela-H); Loxin increase was not followed by OLR1 up-regulation and the OLR1/Loxin ratio after 10 nM of PMA was lowered to 28.1% compared to untreated HeLa-H. These results demonstrate a role of PMA in modulating OLR1 splicing in vitro, leading to an increase of the less functional Loxin isoform. At the best of our knowledge these are the first evidences of a regulation of OLR1 splicing, and provide new data addressing a future more selective and personalized therapy for diseases caused by OLR1 over-expression.

2199W

Identification of a predictive/prognostic genetic signature in Chagas Cardiomyopathy: A systems biology approach on the site of action.

Chagas disease, due to the protozoan Trypanosoma cruzi, is endemic in poor, rural areas of Latin America, but hundreds of thousands of patients now live in the USA. An estimated 300,000 new cases and 50,000 fatilities occur per year. Chronic Chagas disease cardiomyopathy (CCC) is an inflammatory cardiomyopathy that affects approximately 30% of infected individuals decades after infection. Familial aggregation of CCC suggests that there might be a genetic component to disease susceptibility. The outcome of Chagas disease is ultimately defined in the patients' hearts, a consequence of local inflammation and myocardial tissue response. We hypothesize that genetic polymorphisms control expression of several key genes in pathogenetically relevant pathways and networks in the myocardial tissue of CCC patients. The corollary is that it may be possible to establish a host genetic signature with prognostic value based on such polymorphic genes. Access to the largest Chagas disease study population assembled to date, as well as to a cryopreserved heart tissue collection allows us to set up a systems biology approach on Chagas disease, going from exhaustive analysis of molecular changes in hearts to study of genetic variants in disease groups, that couldn't be performed anywhere else. We used a multi-disciplinary approach to screen for genes whose differential expression in CCC hearts could be controlled by genetic polymorphisms. On heart tissue samples we performed a whole transcriptome analysis, microRNA profiling, and whole genome methylation analysis on the same samples. For each differentially expressed gene, we assessed whether it was associated to differential methylation or its expression pattern was under the control of concordantly altered microRNAs. Statistical analyses were conducted to merge proteomic, gene expression and methylation data in order to identify candidate genes for genetic studies. Differentially expressed genes that show no evidence of epigenetic control will have genetic variants in or around it studied using two approaches i) a case-control study based on common SNPs ii) characterization of nuclear families with multicases by exome sequencing to identify rare functional variants. We believe that this approach may allow establishing a host genetic signature with prognostic value, while revealing novel insights into pathogenesis and identifying novel therapeutic targets. This combined approach may be of use in other complex diseases.

2200T

Identification of susceptibility modules for coronary artery disease using a genome wide integrated network analysis.
C. Dong, X. Luo, S. Duan. Zhejiang Provincial Key Laboratory of Pathophysiology, School of Medicine, Ningbo University, Ningbo, Zhejiang 315211, China.

Although recent genome-wide association studies (GWAS) have identified a handful of variants with best significance for coronary artery disease (CAD), it remains a challenge to summarize the underlying biological information from the abundant genotyping data. Here, we propose an integrated network analysis that effectively combines GWAS genotyping dataset, protein-protein interaction (PPI) database, literature and pathway annotation information. This three-step approach was illustrated for a comprehensive network analysis of CAD as the followings. First, a network was constructed from PPI database and CAD seed genes mined from the available literatures. Then, susceptibility network modules were captured from the results of gene-based association tests. Finally, susceptibility modules were annotated with potential mechanisms for CAD via the KEGG pathway database. Our network analysis identified four susceptibility modules for CAD including a complex module consisted of 15 functional interconnected sub-modules, AGPAT3-AGPAT4-PPAP2B module, ITGA11-ITGB1 module and EMCN-SELL module. MAPK10 and COL4A2 among the top-scored focal adhesion pathway related module were the most significant genes (MAPK10: OR = 32.5, $P = 3.5\times10\text{-}11$; COL4A2: OR = 2.7, $P = 2.8\times10\text{-}10$). The significance of the two genes were further validated by other two gene-based association tests (MAPK10: P = 0.009 and 0.007; COL4A2: P =0.001 and 0.023). The susceptibility modules identified in our study might provide novel clues for the clarification of CAD pathogenesis in the future.

Systematic phenotype prediction in zebrafish identifies novel, disease-relevant cardiovascular gene functions.
G. Musso[1,2], M. Tasan[3,4], C. Mosimann[5,6,7], J.E. Beaver[3], E. Plovie[2], L.A. Carr[5,6,7], H.N. Chua[4], J. Dunham[4], K. Zuberi[4], Q. Morris[4], L. Zon[5,6], F.P. Roth[3,4,8], C.A. MacRae[1,2]. 1) Department of Medicine, Harvard Medical School, Boston, MA; 2) Cardiovascular Division, Brigham and Women's Hospital, Boston, MA; 3) Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA; 4) Donnelly Centre and Departments of Molecular Genetics and Computer Science, University of Toronto, Toronto, ON; 5) Howard Hughes Medical Institute, Boston, MA; 6) Stem Cell Program, Children's Hospital Boston, Boston, MA; 7) Division of Hematology/Oncology, Children's Hospital Boston, Harvard Stem Cell Institute, Harvard Medical School, Boston, MA; 8) Samuel Lunenfeld Research Institute, Mt. Sinai Hospital, Toronto, ON.

Comprehensive functional annotation of vertebrate genomes is a central step in realizing the full potential of genome-scale technologies for fundamental and translational discovery. However, the identification of novel gene functions through forward genetic screening quickly becomes overwhelming not only due to the number of surveyable genes, but also due to the increasing number of observable phenotypes. Unbiased prediction of gene-phenotype relationships offers a strategy to direct finite experimental resources towards likely phenotypes, thus maximizing de novo discovery of gene functions. Here we prioritized genes for phenotypic assay in embryonic zebrafish through genomic data integration and machine learning, predicting the effect of loss of function of each of 15,106 zebrafish genes on 338 distinct anatomical processes. Cross-validation suggested the resulting predictions to be particularly precise for certain phenotypic categories, including cardiac phenotypes. In proof-of-concept studies we validated 16 high-confidence cardiac predictions using targeted morpholino knockdown and manual blinded phenotyping in embryonic zebrafish, confirming a significant enrichment for cardiac phenotypes as compared to morpholino controls. Subsequent detailed analyses of cardiac function confirmed these results, identifying novel physiological defects for 11 tested genes, the majority of which are conserved in humans. Among these we identified tmem88a, a recently described attenuator of Wnt signaling, as a discrete regulator of the patterning of intercellular coupling in the zebrafish cardiac epithelium. These results suggest that large-scale gene prioritization in zebrafish enriches for phenotype association, thus substantially reducing survey effort in identifying novel, disease-relevant vertebrate gene functions.

2202W

Large-scale transcriptome profiling in peripheral blood mononuclear cells (PBMCs) of early-onset myocardial infarction individuals and matched controls.

Despite the substantial progress in diagnosis and therapy, myocardial infarction (MI) remains one of the major causes of mortality worldwide. MI in young adults is a rare phenomenon and the molecular mechanisms of the pathogenesis leading to MI at young age are still unclear. The aims of this study were to identify differentially expressed genes between young, non-acute MI individuals and healthy controls and to highlight underlying biological mechanisms by functional over-representation analyses. In 112 non-acute MI individuals (age at MI <= 50) and 112 age and sex matched healthy controls from the Gutenberg Health Study (GHS) gene expression levels in PBMCs were determined using Affymetrix GeneChip Exon ST1 Arrays. Differential gene expression was computed by applying linear mixed models adjusted for body mass index, hypertension, smoking status, diabetes and LDL/HDL ratio and the first four principal components. Functional analyses of significantly differentially expressed genes (FDR<=0.1) were conducted using Ingenuity Pathway Analysis. Associations between medical therapy and gene expression were identified in PBMCs of GHS controls (n=307). 183 genes were significantly associated with MI. The top four differentially expressed genes were G-protein-coupled receptor 15 (GPR15, up-regulated), ATP-binding cassette transporter A1 (ABCA1, down-regulated), selenoprotein O (SELO, down-regulated) and cardiotrophin 1 (CTF1, up-regulated). We observed a strong up-regulation of GPR15 with smoking behaviour, but the association with MI remained significant after adjustment. It had been shown that the GPR15 locus in leukocytes of smokers is hypomethylated, indicating a higher accessibility of the DNA and subsequent increased expression of GPR15, which is reflected in our data. Moreover, we observed a positive correlation between GPR15 expression and plaque formation. Pathway analysis revealed over-representations of differentially expressed genes within pathways of the renin-angiotensin system and pathways related to the pathogenesis of cardiac hypertrophy, all sharing a common mechanism, suggesting a de-regulation of intracellular Ca2+ levels. In summary, we observed over-representations of differentially expressed genes in key pathways of the cardiovascular system. The top gene GPR15 shows strong associations to smoking and plaques. Ongoing functional analysis will help to understand its role in cardiovascular disease, which could be promoted by smoking.

2203T

Investigating the role of HoxA3 during cardiac development.
V. Sanghez[1], D. Rux[2], S. Chan[2], L. Borges[3], N. Koyano[3], R. Perlingeiro[3], D. Garry[3], M. Kyba[2], M. Iacovino[1]. 1) Pediatric, Medical Genetics, LABiomed Research Institute at Harbor UCLA, Torrance, CA; 2) Department of Pediatrics, Lillehei Heart Institute, University of Minnesota, MN; 3) Department of Medicine, Lillehei Heart Institute, University of Minnesota, MN.

During embryoid body (EB) differentiation mesoderm patterns toward its major derivatives: lateral plate mesoderm to generate blood and vasculature and paraxial mesoderm to generate muscle and cardiac derivatives. Day 4 EB differentiation thus resembles the gastrulating embryos at DPC 7 (Days Post Conception). Previous studies performed by our group showed a role of HoxA3 on the generation of hematopoietic progenitor cells from haemogenic endothelium, the progenitor cell of Hematopoietic Stem Cell (HSC) in vivo. As a result of HoxA3 upregulation the genome transcriptional profile showed a repression of hematopoietic commitment and promotion of endothelial fate. Unexpectedly we found a strong repression of cardiac specific regulators both in endothelial-committed progenitors and total EBs. HoxA3 gene results to be crucial during developmental stage, indeed genetic deletion in mice results in perinatal lethality due to cardiovascular outflow tract defects as well as pulmonary defects and, as an overall phenotype, it recapitulate DiGeorge syndrome. Fate mapping has shown contribution of HoxA3 expressing cells to the outflow tract as well as right atria and ventricle. We demonstrate with functional assays and at molecular level, that upregulation of HoxA3 during mesoderm patterning strongly represses both cardiac commitment and differentiation. We are dissecting the molecular mechanism underlying this repression and we show preliminary evidence that HoxA3-dependent cardiac repression is mediated through regulation of the Notch ligand, Jagged1.

2204F

Joint Association of 31 Mitochondrial Variants with Type 2 Diabetes: The Strong Heart Family Study. *Y. Zhu[1], ET. Lee[2], SA. Cole[3], K. Haack[3], LG. Best[4], BV. Howard[4], J. Zhao[1].* 1) Dept Epidemiology, Tulane Univ Pub Health & Tropical Med, New Orleans, LA; 2) Center for American Indian Health Research, University of Oklahoma Health Sciences Center; 3) Texas Biomedical Research Institute, San Antonia, TX; 4) Missouri Breaks Industries Research Inc, Timber Lake, SD.

Background: Multiple mitochondrial variants have been associated with T2D, but a single SNP usually confers a small risk to disease. A gene-family approach taking into account the joint contribution of multiple variants may have greater power in detecting genetic associations. Objective: To evaluate the cumulative impact of 31 tagging SNPs in 13 mitochondria-related genes in American Indians participating in the Strong Heart Study (SHS). Methods: Thirty-one tagging SNPs in thirteen mitochondrial-related genes were genotyped in 1,221 American Indians residing in South/North Dakota. All subjects were recruited and examined in 1989-1991 by the SHS. We first conducted single SNP analysis by logistic regression, adjusting for age, sex, BMI, socioeconomic status, lifestyle factors, (physical activity, alcohol intake and smoking status), estimated glomerular filtration rate (eGFR) and history of cardiovascular disease or hypertension. Gene-based association was assessed by combining p-values of all SNPs within a gene based on single SNP analysis using a weighted truncated product method. The gene-family association was performed by combining p-values of all 13 genes using the same method. Sensitivity analysis was conducted to evaluate whether the observed associations were primarily driven by the most significant SNPs. Multiple testing was corrected using false discover rate (FDR). Results: Multiple SNPs showed nominal or marginal association with T2D or insulin resistance, but the association diminished after correction for multiple testing. Four genes, including CYTB (p=0.04), COX3 (p=0.04), ND1 (p=0.037) and TRNC (p=0.018), were weakly associated with T2D, but the associations disappeared after correction for multiple testing. However, a gene-family analysis comprising all 31 SNPs from the 13 genes showed significant association with T2D, suggesting that mitochondrial alleles defined by haplotypes of these SNPs contribute to T2D susceptibility. This association was not driven by the most significant SNPs. Conclusion: Although a single SNP confers only a small risk to T2D, multiple variants in the mitochondrial pathway may jointly contribute to T2D, suggesting the importance of modeling the joint impact of multiple variants on complex disease susceptibility. Our findings may provide useful information for risk classification or personalized approach to diabetes management in American Indians.

RNA sequencing of human adipose tissue identifies allele-specific expression associated with dyslipidemia. *M. Alvarez[1], R.M. Cantor[1], P.M. Reddy[1], Y. Hasin[2,3], D. Weissglas-Volkov[1], E. Nikkola[1], J. Kuusisto[4], A.J. Lusis[1,2,3], M. Laakso[4], P. Pajukanta[1].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, USA; 3) Department of Microbiology, Immunology, and Molecular Genetics, University of California, Los Angeles, California; 4) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

Cardiovascular disease (CVD) is a common cause of death world-wide. To accelerate early intervention and treatment of CVD, it is important to functionally identify mechanisms that contribute to CVD risk. A large amount of phenotype differences among individuals can be attributed to sequence variants affecting gene expression. We used adipose RNA sequencing (RNAseq) to screen for likely regulatory variants associated with high serum triglyceride (TG) levels, a CVD risk factor. Adipose tissue is highly relevant for TG metabolism, as TGs are stored there, and hydrolysis of TGs occurs predominantly in adipose tissue. We sequenced adipose RNAs of individuals with low and high serum TG levels (n=104) from the Finnish population cohort METabolic Syndrome In Men (METSIM) using 50 bp, paired-end reads and the Illumina HiSeq2000 platform at the depth of 3-4 samples/lane. We aligned and mapped the reads uniquely using STAR, and calculated read counts and called the variants using SAMtools. To investigate whether allele-specific expression (ASE) is a common functional mechanism regulating adipose gene expression in dyslipidemia, we screened variants for ASE in this preliminary sample of 104 by filtering for heterozygous variant sites with >10 mapped reads and >2 reads with the variant allele using a minor allele frequency (MAF) of >10%. We observed 17,884 potential SNPs with ASE. Among the 17,884 SNPs, 8,479 variants with significant ASE were seen in the total sample, while 4,299 variants were seen in subjects with high TG and 4,350 in subjects with low TG, respectively, using a paired t-test with a Bonferroni correction. In the high TG group, of the 4,299 variants, 1,324 were unique and in the low TG group, of the 4,350 variants, 1,273 were unique. None of the variants differed in the percent of ASE between individuals with high and low TG using the Wilcoxon rank sum test, a Bonferroni correction, and MAF>20%, suggesting that for common variants, dyslipidemia-specific differences in ASE percents are rare. The David pathway tool identified 11 significant functional categories enriched in the high TG group and 12 functional categories enriched in the low TG group that passed a Bonferroni correction, indicating that ASE variants may accumulate in molecular pathways based on the dyslipidemia status. To summarize, these novel data suggest that ASE is a common mechanism underlying differential gene expression between dyslipidemic cases and controls in adipose tissue.

2206T

Genes related to *CRKL* and mouse heart development may act as genetic modifiers to congenital heart disease in human 22q11.2 deletion syndrome. *J. Chung[1], S.E. Racedo[1], T. Guo[1], D.M. McDonald-McGinn[2,3], E. Zackai[2,3], R.J. Shprintzen[4], B.S. Emanuel[2,3], B. Funke[5,6], B.E. Morrow[1].* 1) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 3) Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 4) The Virtual Center for Velo-Cardio-Facial Syndrome, Inc., Manlius, NY; 5) Laboratory for Molecular Medicine, Partners Center for Personalized Genetic Medicine, Cambridge, MA; 6) Department of Pathology, Massachusetts General Hospital, Boston, MA.

Congenital heart disease (CHD) occurs at a rate of 7-9:1000 live births and 80% of CHD cases have no clear etiology. Approximately 70% of patients with 22q11.2 deletion syndrome (22q11DS, also known as DiGeorge/VCFS, OMIM: 192430; 188400) have a CHD, mostly of the conotruncal type, with highly variable expressivity suggesting the presence of genetic modifiers. The majority (~85%) of patients with 22q11DS have a 3 Mb deletion encompassing ~60 genes including the T-box transcription factor, *TBX1* (OMIM: 602054) and the adaptor protein, *CRKL* (OMIM: 602007), both implicated in the etiology of CHD in the disorder. There have been extensive studies regarding CHD on *TBX1*, but few have been performed on *CRKL*, which links various signaling pathways to downstream effectors. To elucidate the independent role of *CRKL* in human CHD, we analyzed echocardiograms from 15 subjects with 22q11DS encompassing *CRKL* but not *TBX1*. We found 7/15 have cardiac outflow tract alignment or septal defects, which are strikingly similar to those seen in mutant mice harboring an allelic series of *Crkl* dosage, suggesting that *CRKL* is important in its own right, and that it may serve as a genetic modifier of CHD in subjects with the typical 3 Mb deletion.

To follow up on *CRKL* as a candidate modifier gene of 22q11DS and identify additional modifiers related to *CRKL*, we performed whole exome sequencing (WES) on 176 subjects with the typical 3 Mb deletion; 74 subjects have tetralogy of Fallot and 102 have a normal heart/aortic arch. We performed a candidate gene association test, using SKAT (PMID: 23684009), on 141 genes either in *CRKL* pathways or with a known role in the development of structures related to phenotypes in *Crkl* mutant mice. Of the 141 genes, 103 have nonsynonymous single nucleotide variants (SNVs). Six genes (*NFATC4*, *HBEGF*, *CBL*, *HSPG2*, *PXN*, and *ELMOD2*) have a nominal p-value < 0.05 and empirical p-value < 0.1 after 10,000 permutations. Our top gene is *NFATC4* (p-value = 0.0073, FDR q-value = 0.2509, OMIM: 602699). Importantly, mice with mutations in *Nfatc4* have similar heart malformations as our *Crkl* mutant mice indicating that nonsynonymous variants in *NFATC4* may genetically interact with *CRKL* to modify the CHD phenotype seen in 22q11DS. We will test for genetic interactions between *Crkl* and *Nfatc4* using mouse models and perform replication studies of our findings in an independent cohort of 22q11DS subjects.

2207F

Genetic Influence of Scavenger Receptor Class B Type 1 (*SCARB1*) on Plasma Lipid Traits in non-Hispanic White Americans. *V. Niemsiri[1], X. Wang[1], M.M. Barmada[1], J.E. Hokanson[2], R.F. Hamman[2], F.Y. Demirci[1], M.I. Kamboh[1].* 1) Human Genetics, Graduate School of Public Health , University of Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, University of Colorado Denver, Aurora, CO.

Coronary heart disease (CHD) is a major public health burden worldwide. A main risk factor for CHD includes low levels of high-density lipoprotein cholesterol (HDL-C). *SCARB1* is one of the candidate genes involved in HDL-C metabolism. To identify genetic influences of both common and rare variants of *SCARB1* on plasma lipid traits, we sequenced all 13 exons, exon-intron boundaries plus 1 kb of 5' and 3' flanking regions of *SCARB1* in 95 non-Hispanic White (NHW) US individuals with the upper (n = 47) and lower (n = 48) 10th percentile of HDL-C/triglyceride (TG) distribution. Sequencing analysis revealed 44 variants (MAF ≥5%, n = 12; MAF <5%, n = 32). No statistically significant difference was observed in the distribution of rare variants between the two extreme HDL-C/TG groups (P = 0.615). We genotyped 40 relevant uncommon variants and common tag SNPs identified by our sequencing (MAF ≥5%, n = 8; MAF <5%, n = 32), plus 32 additional tag SNPs from HapMap covering the entire gene and 4 reported variants in our total NHW sample (n = 623). Of the 76 genotyped variants, 69 (MAF ≥5%, n = 39; MAF <5%, n = 30) passed QC and were further evaluated for their association with lipid traits. Based on the gene-based test, suggestive association was observed with apolipoprotein B (apoB) (P = 0.042). In single-site analysis of 39 variants with MAF ≥5%, three (rs11057844, rs701106, rs838880) and four (rs2343394, rs4765615, rs2278986, rs11057820) variants were nominally associated with HDL-C and apoB, respectively (P <0.05). Rare variant and haplotype analyses are currently underway. Our findings indicate a relatively small influence of SCARB1 genetic variation on plasma lipid and apolipoprotein levels.

2208W

Study on the association between *APOH* variants and thrombophilia. *L. Tang, X. Lu, Q. Wang, J. Yu, X. Jian, T. Guo, H. Wang, H. Liu, Y. Hu.* Institute of Hematology, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei, China.

Plasma beta 2-glycoprotein I (beta 2-GPI) is the most common autoantigen for the production of antiphospholipid antibodies. It have a variety of anticoagulant properties. Beta 2-GPI inhibits the factor XI activation in the intrinsic pathway of blood coagulation, von Willebrand factor-dependent platelet aggregation, platelet-dependent prothrombinase activity, and the procoagulant activity of thrombin. Recent studies suggest that the formation of anti-beta 2-GPI antibodies is associated with the protein structure abnormality of beta 2-GPI and that a conformational change in beta 2-GPI is sufficient to induce autoantibodies, which can confer high risk for both arterial and venous thrombosis. Therefore, we investigated *APOH* encoding beta 2-GPI as a candidate gene to identify possible variants that could contribute to thrombosis susceptibility. The putative promoter, 8 exons, and 3'-untranslated region of *APOH* were screened using a PCR-sequencing method in 60 individuals who were diagnosed with unprovoked venous thrombosis. The haploid genotypes were subsequently determined in the case-control populations (1304 versus 1334) from the MAGIC study, and the odds ratios for venous thrombosis risk were calculated by logistic regression analysis. Four common polymorphisms g.5028C>A, c.422T>C (p.Ile141Thr), c.461G>A (p.Arg154His), and c.1004G>C (p.Trp335Ser) were identified by resequencing. These variants were in complete linkage disequilibrium with one another and produced 3 haploid genotypes: wild type H1, CTGG/CTGG; heterozygous type H2, CTGG/ACAC; homozygous type H3, ACAC/ACAC. The case-control study showed that the H2 type was present in 157 venous thrombosis individuals and 135 controls; while the H3 type was identified in 12 of the thrombosis group and 2 of the control group. Thus, carriers of the H2 type and the H3 type had a 1.29-fold and 6.04-fold increased risk of venous thrombosis, respectively. The common *APOH* haploid genotypes H2 and H3 were associated with an increased risk of venous thrombosis and were common genetic risk factors for thrombophilia in the Chinese population.

2209T

APOE p.Leu167del mutation in Familial Hypercholesterolemia. *Z. Awan[1], H. Choi[1], N. Stitziel[3], I. Ruel[1], R. Husa[1], MH. Gagnon[1], RH. Wang[1], N. Seidah[2], S. Kathiresan[4], J. Genest[1].* 1) The Research Institute of the McGill University Health Centre, RI-MUHC, Montréal, QC; 2) Institut de Recherches Cliniques affiliated to Université de Montréal, IRCM, Montréal, QC; 3) Department of Medicine, Division of Cardiovascular and Statistical Genomics, Washington University School of Medicine, St. Louis, MO; 4) Broad Institute, Harvard Medical School, Cambridge, MA.

PURPOSE: Autosomal dominant hypercholesterolemia (ADH) is caused by mutations in the low density lipoprotein receptor (LDLR), its ligand apoB (APOB) or proprotein convertase subtilisin/kexin type 9 (PCSK9) genes. Yet DNA sequencing does not identify mutations in these genes in a significant number of cases with a phenotype of ADH, suggesting that ADH has multiple genetic etiologies. METHODS: Through a combination of clinical examination, biochemical analysis, candidate gene approach and next-generation exome sequencing we investigated the genetic basis of an ADH phenotype in a proband of an Italian origin. RESULTS: we identified an in-frame three base-pair deletion in apolipoprotein E (APOE, Chromosome 19:45412053-55) resulting in a Leu167del mutation. The proband presented with an acute myocardial infarction at age 43, requiring urgent coronary revascularization. He had extensive tendinous xanthomas, xanthelasmas and elevated levels of total cholesterol 11.2 mmol/L, LDL-C 9.69 mmol/L, normal HDL-C 1.62 mmol/L and triglycerides levels 1.13 mmol/L. HPLC lipoprotein profile showed selective increase in LDL-C. DNA sequencing did not identify any mutation in the LDLR, PCSK9, LDLR adapter protein-1 (LDLRAP1) and exon 26 of the APOB gene. We then performed exome sequencing on three individuals from the family. Using data derived from exome chip genotypes for association with LDL-C, the strongest evidence of association was found for the identified APOE Leu167del mutation. CONCLUSIONS: The Leu167del mutation is predicted to alter the protein structure of ApoE near the α-helix within the receptor binding domain. This report confirms that ADH can be caused by mutations within the APOE gene and represents the 4th loci causing ADH.

2210F

Role of Titin gene variants in human dilated cardiomyopathy.
R.L. Begay[1], S.L. Graw[1], G. Sinagra[2], M. Merlo[2], D. Slavov[1], G. Barbati[2], A. Di Lenarda[2], X. Zhu[1], L. Mestroni[1], M. Taylor[1]. 1) Department of Medicine, University of Colorado - CU Cardiovascular Institute, Aurora, CO; 2) Cardiovascular Department, University of Trieste, Italy.

Background: The Titin gene (TTN) is the second largest human gene and encodes the largest known human protein, titin, that plays a central role in sarcomere organization. Mutations in TTN have been difficult to study due to the large size of the gene, however recent data have shown that TTN truncation mutations lead to a dilated cardiomyopathy phenotype. The large size of TTN means that almost all individuals carry missense TTN variants, the majority of which are presumably benign yet raise challenges in the evaluation of TTN in patients with overt dilated cardiomyopathy. Methods: Our group sequenced 313 exons covering the N2B and N2BA cardiac isoforms of TTN in 135 subjects with dilated cardiomyopathy. Bioinformatic filtering for 'severe' missense variants was based on SIFT score, GERP, Polyphen2 HDVAR, low frequencies in the 1000 genome project, and Exome Sequencing Project. Results and Conclusions: Ultimately, 45 TTN 'severe' missense variants were noted in 38 probands. Segregation of 'severe' TTN missense variants was demonstrated in larger families. Seven subjects were compound TTN heterozygotes, and six subjects were double heterozygotes with a 'severe' TTN variant and a pathogenic variant in another dilated cardiomyopathy gene. Genotype-Phenotype analyses between TTN 'severe' variant carriers and non-carriers was also performed which showed a trend towards better survival in TTN 'severe' missense carriers (p=0.071). These data provide important insight for researchers and laboratory into the prevalence and phenotypic consequences of 'severe' TTN variants in dilated cardiomyopathy patients.

2211W

Desmosomal and titin gene variants in arrhythmogenic right ventricular cardiomyopathy: genotype-phenotype correlations.
F. Brun[1,2], C. Barnes[1], G. Sinagra[2], D. Slavov[1], G. Barbati[2], X. Zhu[1], R. Begay[1], S. Graw[1], B. Pinamonti[2], E. Salcedo[1], M. Taylor[1], L. Mestroni[1], Familial Cardiomyopathy Registry. 1) Cardiovascular Institute, University of Colorado, Aurora, CO; 2) Department of Cardiology, Hospital and University of Trieste, Trieste, Italy.

Background Arrhythmogenic right ventricular cardiomyopathy (ARVC) is caused by abnormalities in desmosomal proteins of the intercalated disc and desmosomal gene mutations are the principal cause of ARVC. Recently novel variants were discovered in the sarcomeric gene titin (*TTN*) that are associated with ARVC. Whether known mutation carriers differ clinically from non-carriers is not well known. To address this question, we analyzed clinical outcomes in our ARVC population based on mutation status.

Methods Thirty-eight ARVC families (66 patients) were analyzed, with a median follow-up of 77 months. Genotype-phenotype association analysis was performed, and multiple variables including symptoms, electrocardiogram/echocardiogram abnormalities, arrhythmias, pacemaker and/or ICD implantation and survival time free from death or heart transplant were compared between desmosomal mutation carriers, *TTN* carriers and non-carriers.

Results Seven patients (11%) harbored rare genetic variants in desmosomal genes (*DSP, PKP2, DSG2*, and *DSC2*), 14 (21%) carried *TTN* variants and 45 (68%) were non-carriers. Desmosomal carriers (DC) had a higher prevalence of inverted T waves in V2-3 in the absence of RBBB (100% vs. 32%, p=0.001) and epsilon waves (57% vs. 14%, p=0.007) compared to non-carriers. The *TTN* group had significantly more supraventricular arrhythmias (atrial fibrillation, atrial tachycardia) (43% vs. 0%, p=0.04) and required more pacemakers (57% vs. 0%, p=0.018). Conversely, DC required more heart transplants relative to non-carriers (57% vs. 11%, p=0.03) and exhibited a worse survival free from death or heart transplant (63% vs. 88% at 30 years and 42% vs. 88% at 50 years, p<0.001).

Conclusions This study provides valuable insights into the clinical consequences of gene mutations in individuals with ARVC. *TTN* rare variants confer greater risk for supraventricular arrhythmias and the need for pacemaker implantation relative to DC, while DC portends a greater risk for electrocardiogram abnormalities and the combined end-point of heart transplant or death compared to non-carriers.

2212T

Burden of rare variants in *PON1* is associated with ischemic stroke.
D.S. Kim[1,2], D.R. Crosslin[1,2], P.L. Auer[3,4], A.A. Burt[1], A.S. Gordon[2], C.E. Furlong[1,2], J.F. Meschia[5], M. Nalls[6], U. Peters[3], S.S. Rich[7], D.A. Nickerson[2], G.P. Jarvik[1,2], NHLBI Exome Sequencing Project (ESP). 1) Division of Medical Genetics, Department of Medicine, University of Washington School of Medicine, Seattle, WA; 2) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Zilber School of Public Health, University of Wisconsin-Milwaukee, Milwaukee, WI, USA; 5) Department of Neurology, Mayo Clinic, Jacksonville, FL; 6) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD; 7) Center for Public Health Genomics, University of Virginia, Charlottesville, VA.

Background: HDL-associated paraoxonase 1 (encoded by *PON1*) is an enzyme with broad substrate specificity and whose activity has been associated with numerous human diseases, including ischemic stroke. Common variants in *PON1* have not consistently been associated with stroke. Rare coding variation that is predicted to alter *PON1* enzyme function may be more strongly associated with ischemic stroke. **Methods and Results:** The NHLBI Exome Sequencing Project (ESP) sequenced the coding regions of the genome (exome) in 6,503 participants ascertained for heart, lung and blood phenotypes. In this sample of 4,204 participants, 496 had verified ischemic stroke. A total of 29 nonsynonymous variants were identified in *PON1*. Sequence kernel association testing (SKAT) analysis adjusting for covariates identified evidence for association ($p=1.29\times10^{-3}$; permutation $p=3.01\times10^{-3}$) with stroke. The association of *PON1* with ischemic stroke was stronger in participants with African ancestry (AA $p=5.73\times10^{-4}$; permutation $p=5.03\times10^{-3}$). Ethnic differences in the association between *PON1* with ischemic stroke could be due, in part, to the effects of $PON1_{Val109Ile}$ missense variant (overall $p=7.88\times10^{-3}$; AA $p=6.52\times10^{-4}$), found at higher frequency in AA participants (1.16%) than to European ancestry (0.04%) participants. **Conclusions:** Rare nonsynonymous exomic variation in *PON1* was associated with ischemic stroke, with stronger associations identified in those of African ancestry. Given the high morbidity and mortality of stroke and the higher prevalence of stroke in individuals with African Ancestry, further studies should replicate these findings and also functionally validate the effects of the rare nonsynonymous variants on PON1 enzyme function.

2213F

The spectrum and prevalence of genetic background noise in patients with arrhythmogenic (right ventricular) cardiomyopathy.
T.T. Koopmann[1], S. Walker[2], G. Kaur[2], S.W. Scherer[2,3], C.R. Marshall[2,3], R.M. Hamilton[4]. 1) Physiology and Experimental Medicine, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics and Genetics and Genome Biology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 3) McLaughlin Centre and Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 4) Department of Pediatrics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada.

Introduction: Arrhythmogenic (right ventricular) cardiomyopathy (ACM, previously known as ARVC) is histopathologically characterized by progressive fibrofatty replacement of myocardium, primarily of the right ventricle. Mutations associated with the disorder have been identified in genes mostly encoding proteins that form desmosomes; however, in about 50% of patients no mutation is found in the known ACM associated genes and the pathogenicity of many identified variants is unclear. To determine the spectrum and prevalence of 'genetic background noise', we sequenced the exomes of 19 ACM cases and 35 controls and performed mutation burden analysis. **Methods:** In this study, we performed whole exome sequencing of 19 unrelated ACM patients from European descent and 35 unrelated ethnicity matched control individuals and focused on the contribution of genetic variation in 52 genes previously associated with ACM, or interaction partners of these genes, to ACM susceptibility. **Results:** The mean number of variants identified in the 52 candidate genes in ACM patients was 53.8 per individual; controls had an average of 41.7 variants (*P* = NS). Mutation burden (defined as the average number of mutations per person) analysis of the identified variants revealed that non-synonymous rare variants (MAF<1%) in the 52 genes were not significantly more present in patients compared to controls (mean = 2.47 in cases versus 2.34 in controls). Non-synonymous rare variants in the previously ACM associated genes (PKP2, DSG2, DSP, DSC2, JUP, RYR2, PLN, TMEM43, TTN) also showed no significant difference in mutation burden (mean = 1.84 in cases versus 1.54 in controls). Interestingly, the overall yield of variants in the ACM genes was 73.7% in cases versus 80% in controls. Of these, 71.4% of patients and 57.1% of controls had >1 mutation. **Discussion:** This study is an evaluation of genetic variation in ACM patients versus healthy controls for the ACM susceptibility and candidate genes. Further research will be required to elucidate the role of the identified variants in ACM.

2214W

Copy number variants in patients with abdominal aortic aneurysms.
D. Majoor-Krakauer[1], K.M van de Luijtgaarden[2], H.J.M Verhagen[2], G.C.M Huijbregts[1], L. Koster[1], A.M Bertolli Avella[1], H.B Beverloo[1], L.J.C.M van Zutven[1]. 1) Dept. of Clinical Genetics, Erasmus University MC, Rotterdam, Netherlands; 2) Dept. of Vascular Surgery, Erasmus University MC, Rotterdam, The Netherlands.

Abdominal aortic aneurysms (AAA) are a major cause of morbidity and mortality in the elderly and are characterized by extracellular matrix (ECM) degeneration, dysregulation of vascular smooth muscle (SMC) cells, inflammation and atherosclerosis. In approximately 20% of cases abdominal aneurysm are familial (fAAA). No genes involved in fAAA have been identified so far. The aim of the current study was to investigate if copy number copy number variants (CNV) may add in discovering pathofysiologic pathways and genes involved in AAA formation. Methods: AAA patients referred for genetic counseling in 2011 and 2012 were included. Patients were classified as familial when at least one first-degree was reported to have an aortic aneurysm. Patients without a positive family history were classified as sporadic (spAAA). Microarray was performed in all index patients (i.e. first relative diagnosed with AAA). Microarray was performed by using the Illumina HumanCytoSNP-12v2.1 and analyzed using Nexus CopyNumber Discovery v6.1 software. Results were evaluated using the UCSC Genome Browser March 2006, the Database of Genomic Variants and an in-house database of controls. Rare CNV regions larger than 5Mb were classified as variants and CNV regions larger than 3Mb that have been observed previously in control populations at least three times were classified as polymorphisms. GeneNetworks and Ingenuity pathway (IPA) analysis was performed of the genes identified in CNV variants. Results: The study population consisted of 67 index AAA patients; 54 were classified as fAAA and 13 as spAAA. We found 12 rare CNV variants in 11 (20%) of the fAAA patients. In patients with spAAA no rare CNV were found. Tissue expression, biological process and KEGG of the genes identified in rare CNV in fAAA was performed showing frequent involvement in inflammation, glucose metabolism, smooth muscle cell or cartilage functioning. Expression of a number of genes in cicatrisation may indicate links with collagen pathways. Conclusion: These findings together with the IPA showing that a number of CNV genes are involved in the TGF-β pathway, may indicate that in familial AAA similar mechanisms may be activated as in the known genetic TGF-β, collagen, or smooth muscle cell related genetic aneurysm syndromes.

2215T

Whole-Genome Sequencing of Families with Early-Onset Myocardial Infarction.
A. Mehta[1], N. Schnetz-Boutaud2[2], D.J. Van Booven[1], L. Wang[1], Z. Liu[1], N. Vasudeva[1], M.A. Pericak-Vance1[1], J.L. Haines[2], G.W. Beecham[1]. 1) University of Miami, Institute for Human Genomics; 2) Vanderbilt University, Center for Human Genetics Research.

Coronary heart disease is the leading cause of death in the United States, with myocardial infarction (MI) being a primary clinical presentation. While genome-wide association studies of common variation have revealed a number of risk loci for MI, most of the loci have very small risk effects (odds ratios between 1.06-1.20) and they collectively explain less than 10% of the heritability of MI. To investigate the role of rarer variation in MI, we are performing whole-genome sequencing on 28 affected individuals with MI across 6 different families. Each family has at four or more individuals affected by MI, with at least one affected individual with onset under age 55. Whole-genome sequencing of these individuals will be performed using the Illumina Hiseq 2000 sequencer. Each individual will be sequenced using four lanes of the flowcell to achieve ~40x depth of coverage across the genome. The alignment will be conducted using the GATK pipeline, and variant and indel calling will be done using the Unified Genotype caller from the GATK pipeline. The variants and indels will be annotated using SeattleSeq for common annotations and Annovar for custom annotations (e.g., cardiovascular related loci, ENCODE elements, and enhancers, etc). Together, these tools provide comprehensive annotations, like functional group, conservation scores and functional prediction scores (Sift and polyphen2), frequency data from the 1,000 Genomes Project and the NHLBI Exome Sequencing Project. Additional family members that do not have WGS data will be analyzed using a genome-wide genotyping platform (i.e., exome chip) to establish phase and haplotype sharing within families, using the MERLIN software. Shared variants will be filtered based on annotation to identify those most likely to contribute to CHD. The most high-priority variants will be assessed in an independent dataset.

2216F

Exome sequencing identifies a novel candidate gene, NRG1, for serum cholesterol levels in Mexicans.
E. Nikkola[1], M. Alvarez[1], M.V.P. Linga Reddy[1], A. Ko[1], D. Weissglas-Volkov[1], C. Gutierrez-Cirlos[2], L. Riba[2,3], M.L. Ordoñez Sánchez[2], Y. Segura Kato[2], T. Tusie-Luna[2,3], C. Aguilar-Salinas[2], P. Pajukanta[1]. 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, University of California, Los Angeles; 2) Instituto Nacional de Ciencias Médicas y Nutrición, Salvador Zubiran, Mexico City, Mexico; 3) Instituto de Investigaciones Biomédicas de la UNAM, Mexico City, Mexico.

Background: It is important to identify and functionally characterize genes decreasing serum low-density lipoprotein cholesterol (LDL-C) levels to better prevent and treat hypercholesterolemia, one of the most important risk factors of coronary heart disease. The Mexican population is especially prone to hypercholesterolemia with 43% of Mexicans exhibiting total cholesterol levels >200mg/dl in a recent national survey. Familial hypobetalipoproteinemia (FHBL) is an autosomal dominant disorder characterized by low levels of plasma LDL-C, total cholesterol (TC), and apolipoprotein B (apoB). FHBL has previously been shown to be caused by mutations in the APOB, PCSK9, and ANGPTL3 genes, and loci on chromosomes 10 and 3p21 have also been linked to FHBL. However, in most FHBL cases the underlying cause is unknown. To identify genes involved in FHBL and cholesterol metabolism in Mexicans, we explored two Mexican FHBL families without known mutations in the previously identified genes. The probands of the families had a similar kinetic profile with an increased apoB-LDL and apoB-VLDL catabolic rate. **Methods and Results:** The affected and unaffected individuals from the Mexican FHBL families were exome sequenced by capturing 62Mb coding and regulatory regions. We focused on the variants shared by all affected family members and not present in the family members with normal apoB levels. We also filtered the variants based on their type, frequency, gene expression, and functional predictions using SIFT and PolyPhen. In family 1, filtering for novel missense variants and variants with minor allele frequency (MAF)<5% as well as applying the filters for gene expression and functional predictions, reduced the variant pool to 10 nonsynonymous variants. In family 2, the same filtering resulted in 2 nonsynonymous variants. To further investigate whether any of these 12 genes regulates cholesterol levels generally in Mexicans, we tested their common variants for association with TC in 3,700 Mexican individuals. Variants in one gene, neuregulin 1 (NRG1), passed the Bonferroni correction for association with TC, with rs1383966 providing the strongest signal. **Conclusions:** Exome sequencing of FHBL families and a follow up in 3,700 individuals identified the NRG1 gene for serum cholesterol levels in Mexicans. Replication in additional Mexican cohorts and functional studies are warranted to further investigate the role of NRG1 in cholesterol metabolism.

2217W

Clinical presentation and functional characterization of a c.532+1G>A splice site mutation in *CASQ2* in a patient with catecholaminergic polymorphic ventricular tachycardia.
K. Patel[1], M. Delio[1], T.V. McDonald[2], C. Montagna[1], B. Morrow[1]. 1) Department of Genetics, Albert Einstein College of Medicine, New York, NY; 2) Department of Medicine (Cardiology), Albert Einstein College of Medicine; Montefiore Medical Center, Bronx, NY.

Catecholaminergic polymorphic ventricular tachycardia (CPVT) (Ventricular tachycardia, stress-induced polymorphic; VTSIP; OMIM#604772) is an inherited disorder characterized by episodic syncope triggered through physical or emotional stress. Morphologically, the heart is normal and patients usually present with mild symptoms such as dizziness. However, if left untreated, CPVT can be highly lethal causing sudden death from ventricular tachycardia that may degenerate into ventricular fibrillation. Approximately 70% of CPVT cases are caused by dominant mutations in the Ryanodine receptor 2 (*RYR2*) gene and a further 7% are accounted for by recessive mutations in Calsequestrin-2 (*CASQ2*). Here, we report a patient who first presented with episodic palpitations and syncope related to exercise at 11 years of age. Due to intermittent QT interval prolongation, she was given the provisional diagnosis of Long QT syndrome or CPVT. None of her family members had displayed cardiovascular symptoms. We have recently identified this patient to be compound heterozygous for mutations in the *CASQ2* gene through a research based next generation sequencing initiative at our institute. We designed a custom, multi-disease target capture panel, covering 650 disease causing genes and revealed that this patient has a novel c.199C>T (p.Gln67*) mutation and a previously reported splice site mutation c.532+1G>A. No other mutations were detected in any genes linked to Long QT syndrome. Although the c.532+1G>A mutation has not yet been demonstrated to alter mRNA splicing, the mutation has been observed in a previously reported consanguineous CPVT family (PMID: 12386154) and is therefore considered most likely to be pathogenic. We are currently exploring a protein-based immuno-assay to detect aberrant *CASQ2* products, which may be formed as a result of this splice site mutation. Therefore by using our research based target panel we have been able to confirm the clinical diagnosis of CPVT in this patient. *In vitro* functional investigations will help us understand the pathogenic mechanism, which leads to the clinical presentation seen in our patient. As a result of this work, additional at-risk family members can now be offered cascade testing.

2218T

Survival is determined by mutation type and molecular mechanism in Ehlers Danlos Syndrome (EDS) type IV. *M.G. Pepin[1], U. Schwarze[1], D. Leistritz[1], M. Liu[2], P.H. Byers[1].* 1) Dept Pathology, Univ Washington, Seattle, WA; 2) Dept Biostatistics, Univ Washington, Seattle, WA.

EDS type IV, the vascular type, is caused by dominant mutations in COL3A1. Affected individuals experience life-threatening arterial dissection and rupture, bowel perforation, and uterine rupture. We present a summary of natural history and genotype-phenotype relationships for 1232 individuals (632 index cases and 600 relatives) with EDS type IV. Median survival was 51 years. Arterial rupture and dissection were the leading cause of first complications (70%) and the leading cause of death (90%). Survival differed significantly by type of mutation (haploinsufficiency, substitutions for glycine residues in the triple helix, and splice site mutations) and even the mildest genotype (null mutations) had lower survival than the US normal. Hazard ratios for donor site mutations (8.8) and any substitution for a triple helical glycine (4.6) compared to null mutations were significant. Among substitutions for glycine in the triple helical domain, substitutions that introduced serine had a 2.6 fold higher hazard than null mutations, while for substitutions by valine the hazard was 7.2 fold higher. The location of substitutions for glycine residues in the triple helical domain was not a significant factor in survival. The median survival for females was significantly greater (54 yrs) than for males (46 yrs). Pregnancy did not alter overall survival risk (Murray et al in press). Aortic rupture in young males was one factor that contributed to the poorer survival in males. Both intracranial aneurysm and coronary artery dissection presenting as "heart attack", particularly in women in the fourth decade, were more prevalent among those affected than previously appreciated. Emergency surgical repairs of arterial rupture or dissection were often unsuccessful, while planned surgery of an identified aneurysm had significantly better outcome. In instances when a death occurred during surgical repair for colon rupture (15% of recorded cases), unexpected vascular rupture was often noted. All data suggests that surveillance of the arterial tree by MRI from the time of diagnosis may be beneficial. The findings provide some guidance for surveillance and indicate that in the creation of clinical trials attention has to be paid to mutation type to balance treatment and control groups. (Supported in part by funds from the Freudmann Fund at the University of Washington).

2219F

GENOMIC ANALYSIS OF LONG QT SYNDROME IN INDIAN COHORT. *S.F. Qureshi[1], C. Narasimhan[2], A. Ali[1], A. Venkateshwari[3], K. Thangaraj[4], P. Nallari[1].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Care Hospital, Hyderabad; 3) Institute of Genetics and Hospital for Genetic Diseases, Osmania University, Hyderabad; 4) Centre for Cellular and Molecular Biology, Hyderabad.

Long QT Syndome, characterized by prolonged QTc along with congenital bilateral deafness is a result of homozygous or genetic compound variations in either of the K+ channel genes, KCNQ1 and KCNE1. Tumor Necrosis factor-alpha, a known inflammatory marker is one of the modifier genes in CVDs. Hence, genomic analysis of KCNQ1, KCNE1 and G-308A SNP of TNF-alpha gene/s was carried out in 32 LQT blood samples and 100 control samples. Molecular analyses were carried out on genomic DNA of 100 controls (50M; 50F), 32 LQTS patients and the available family members followed by In-silico analyses to establish the genotype-phenotype correlations. Genetic compounds of an intronic SNP (A2737320G) and a synonymous (S546S) SNP in KCNQ1; and a neutral substitution (G38S) SNP in KCNE1 were observed apart from genotyping of G-308A SNP of TNF-alpha gene. In KCNQ1 intronic and exonic SNPs (OR-0.36, p=0.014); and TNF-alpha G-308A SNP (OR-0.27, p=0.001), the AG genotype was found to confer protection implying the heterozygote advantage in the genetic compounds. High degree of Linkage disequilibrium was observed (D'=0.9998, 0.9278, 0.7143) indicating a strong synergistic association between the four genotypes with LQTS. In-silico analysis further confirmed mRNA secondary structure variations and altered protein binding during spliceosome processing. Codon bias and usage for KCNQ1 synonymous SNP (S546S) also revealed the higher usage of the rare variant (UCA=0.15) compared to common UCG codon (0.05) confirming the altered regulation of the protein. G38S missense substitution of KCNE1 leads to changes in stem 4 and 5 of mRNA secondary structure wherein finally a polar hydrophilic serine is being replaced by a non-polar, hydrophobic glycine disrupting the structure and function of the transmembrane protein. It is thus predicted that the variations may alter the KCNQ1 and KCNE1 transmembrane protein causing prolonged QTc. Hence, along with the potassium channel genes KCNQ1and KCNE1, TNF-alpha can be considered as a biomarker in understanding the pathophysiological features of poorly understood Long QT Syndrome. The study highlights the role of genetic compounds and their additive gene action.

Novel sarcomeric gene variations in Hypertrophic cardiomyopathy patients of Indian Cohort. *A. Rangaraju[1], M.L Satyanarayana[1], C. Narasimhan[2], P. Nallari[1].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Cardiologist, CARE Hospitals, Hyderbad, Andhra Pradesh, India.

Hypertrophic Cardiomyopathy (HCM) is a major cause of morbidity and mortality, characterized by hypertrophy of the left/right ventricle and interventricular septum with an autosomal dominant mode of inheritance. It has a prevalence of 1 in 500 and exhibits a variable clinical course ranging from being asymptomatic to severe heart failure and sudden cardiac death. Mutations in the sarcomeric genes that code for myofilaments and their supporting proteins have been identified as a cause of HCM. Despite the identification of 900 different causative mutations, the frequency of mutation rate is very low, alternatively, the effect of modifier genes could influence the degree of hypertrophy developed in response to the causal mutation. MYBPC3 and MYH7 are the two genes which have been largely implicated accounting to 50% of HCM cases. Objective: Considering the phenotypic and genotypic heterogeneity of HCM and the ethnic/geographic variation existing in the Indian population, screening for the possible genetic variations in MYBPC3 and MYH7 in HCM patients of South Indian cohort was carried out. Methodology: Blood samples of 100 controls and 100 patient samples were collected after obtaining the informed written consent along with the clinical data of the patients for genomic DNA isolation. For screening of MYBPC3 and MYH7genes, PCR based SSCP analysis was carried out. The samples with variation were further confirmed by automated DNA sequencing. Results: The present study revealed 3 novel intronic and 2 novel synonymous variations and 2 cases of compound heterozygosity, apart from 1 reported missense mutation and 1 reported synonymous variation in MYBPC3 gene. Screening of MYH7 revealed 3 novel missense variations and 1 novel synonymous variation which will be discussed. Although these variations are not highly pathogenic but might have a regulatory role in the splicing mechanism, and their effect might be influenced in the presence of modifier genes and environmental factors.

2221T

A family-based whole genome sequencing study to identify genetic determinants of platelet hyper-aggregation following aspirin in African Americans at high risk for coronary artery disease. *M.A. Taub[1], L.R. Yanek[2,3], I. Ruczinski[1], L. Huang[2], D.M. Becker[2,3], L.C. Becker[2,3], R.A. Mathias[2,3], The GeneSTAR Research Program.* 1) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Johns Hopkins School of Medicine, Baltimore, MD; 3) The GeneSTAR Program, Johns Hopkins School of Medicine, Baltimore, MD.

Background: Low dose aspirin (ASA) is given to inhibit platelet aggregation in individuals at risk for arterial thromboses and is considered standard of care for secondary prevention of coronary artery disease (CAD). We have previously identified common genetic determinants of platelet aggregation following 14-days of ASA, 81 mg/day, using a GWAS approach, and here build on a long-standing study in families with increased risk for CAD (GeneSTAR) applying a whole genome sequencing (WGS) approach. Methods: 5 African American families segregating the phenotypes of hyper-aggregators (>90th percentile of trait distribution in the full sample, N=869) and normal-aggregators (25th-75th percentile) to collagen (5 ug/ml) post ASA. 30 subjects underwent WGS by Illumina, Inc. (depth >30X). Variants were filtered (GQ>20 and segmental duplication regions masked). We determined the set of variants showing perfect co-segregation with phenotype in each family. We tabulated the number of families with perfect co-segregation at (i) each variant site; and (ii) variants collapsed over the units of CCDS transcripts focusing on variants novel to GeneSTAR, i.e. not observed in The Thousand Genomes Project. Results: We observed ~4 million (M) variants per genome, of which ~113K were private variants not shared with another family member. Of the 12.7M sites present across all the samples, 1.6M were novel to GeneSTAR. While we found no sites that showed perfect co-segregation with phenotype in all 5 families, variants in the promoters of HK1 and SLC16A11 co-segregated with phenotype in 3 families. No transcript was commonly implicated across all 5 families. However, gene ontology (GO) analysis of the 218 transcripts that co-segregated with phenotype across 4/5 families includes cell adhesion and wound healing as two of the most significant hits (hypergeometric p-value< 0.01). Restriction to only non-intronic variants within a transcript led to 141 genes in 2 or more families with a GO enrichment in epithelial cell-cell adhesion and cell adhesion genes (p-value < 0.01). Conclusions: This analysis suggests a potential role for rare sequence-identified variants in pathways of genes as determinants of platelet hyper-aggregation post ASA. Analysis is underway to asses statistical significance for these variants, extend annotation beyond coding sequence by leveraging ENCODE data, and test for replication in a sample of 100 independent WGS African American samples from GeneSTAR.

2222F

The molecular dissection of familial dilated cardiomyopathy. *J.M. Taylor[1], S.L. Reid[1], J. Hayesmoore[1], J. Woodley[1], K. McGuire[1], K. Thomson[1], E. Blair[2], H. Watkins[3], A. Seller[1].* 1) Oxford Medical Genetics Laboratories, Oxford University Hospitals NHS Trust , Oxford., Oxfordshire, United Kingdom; 2) Department of Clinical Genetics, Oxford University Hospitals NHS Trust , Oxford., Oxfordshire, United Kingdom; 3) Department of Cardiovascular Medicine, West Wing, John Radcliffe Hospital, Oxford OX3 9DU,.

Introduction: Familial dilated cardiomyopathy (DCM) exhibits considerable clinical heterogeneity both within and between families: penetrance is incomplete and age dependant. Combined clinical screening and molecular analysis is therefore essential to identify affected individuals. Currently, there are in excess of 30 genes reported to cause nonsyndromic familial DCM. This study focuses on the genetic heterogeneity of 50 familial DCM patients from a single referral centre and examines the frequency and distribution of clinically relevant variants within this discrete patient cohort.

Method: Molecular analysis of 28 DCM-related genes was undertaken within the Oxford Genetics Laboratory. Enrichment of targeted genes was undertaken using a custom built Haloplex™ kit (Agilent) and sequenced using an Illumina MiSeq. A commercial software package (NextGENe™, by Softgenetics) was used for data alignment, which was then filtered using an in-house pipeline.

Results: On average, 97.5% of target regions were consistently covered to x30 read depth and clinically relevant variants were detected in ~40% of patients. The test sensitivity is higher than expected (previously reported as 17-35% [1,2]). Pathogenic variants were found within genes responsible for the sarcomere and desmosome structure, and the sodium ion channel.

Conclusion: This study demonstrates the utility of an extensive DCM gene panel and further highlights the genetic heterogeneity of familial DCM. Clinically relevant novel genotype-phenotype associations will be discussed.

2223W

Novel homozygous missense mutations in the SLC2A10 gene in a Turkish pediatric patient with arterial tortuosity syndrome. *S.G. TEMEL[1], O. BOSTAN[2], D. PROOST[3], L. VAN LAER[3], E. CL[2], B. LOEYS[3].* 1) Histology & Embryology, University of Uludag, Faculty of Medicine, BURSA, Turkey; 2) Department of Paediatric Cardiology, University of Uludag, Faculty of Medicine, Bursa,Turkey; 3) Center for Medical Genetics, Antwerp University Hospital and University of Antwerp, Antwerp, Belgium.

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive connective tissue disorder, mainly characterized by tortuosity and elongation of the large- and medium-sized arteries with predisposition to stenoses and aneurysms. ATS is caused by mutations in the SLC2A10 gene, encoding for the facilitative glucose transporter 10 (GLUT10) and is described typically in pediatric patients. We report a 2 years old boy with ATS who initially presented with a cardiac murmur. Echocardiography at the age of one month demonstrated dilatation of the aortic root (15mm) and tortousity in the descending aorta. The main clinical findings included elongated face, saggy cheeks, micrognathia, malar hypoplasia, joint hypermobility and hyperextensible skin. Follow-up echocardiography showed an increase of the diameter of the aortic root to 32mm and 35 mm at the age of 8 months and 2 years old, respectively. Angiography and computerized tomography angiography showed fusiform aneurysmatic dilatation of ascending aorta, marked tortuosity of both pulmonary arteries and thoracic aorta, stenosis in vena cava inferior and collateral structure associated with right hepatic vein. Sequencing of the SLC2A10 gene in the proband revealed the presence of a novel pathogenic homozygous missense variant (c.727C>A). Heterozygous SLC2A10 mutations were shown in her mother and father, demonstrating true homozygosity. The pathogenic variant leads to a p.Gln243Lys change in the seventh transmembrane domain of GLUT10. The proband underwent aortic root replacement surgery. ATS resembles Loeys-Dietz and Marfan related disorders, so timely differential diagnosis is extremely important for early diagnosis and intervention of aneurysms to prevent serious vascular complications.

2224T

Mutation detection in aortopathy and other vasculopathies complicating hereditary disorders of connective tissue by next generation sequencing. *J. Vandrovcova[1], R.A. Weerakkody[1], J. Biggs[1], P.J. Norsworthy[1], C. Neuwirth[1], L. Game[1], A. Vandersteen[2], F.M. Pope[2], N.J. Cheshire[3], T.J. Aitman[1].* 1) Physiological Genomics and Medicine Group and Genomics Laboratory, MRC Clinical Sciences Centre, Imperial College London, UK; 2) National Ehlers-Danlos Syndrome Diagnostic Service & North West Thames Regional Genetics Service, North West London Hospital NHS Trust, UK; 3) Imperial Vascular Unit, St Mary's Hospital, Imperial College, London, UK.

Hereditary disorders of connective tissue are a heterogeneous group of disorders with overlapping clinical features. A proportion of these patients are at risk of early arterial rupture. Early diagnosis, screening of family members and subsequent antihypertensive therapy and vascular surveillance can therefore be life-saving. Some patients with connective tissue disorders have clinical features that suggest a specific diagnosis such as Marfan syndrome, or vascular Ehlers-Danlos syndromes (EDS), but most patients do not clearly fit such a diagnosis. Genetic testing is available but due to the cost and time associated with Sanger sequencing these tests are usually limited to familial and syndromic forms of the disease. DNA samples were obtained from 300 patients with thoracic aortic aneurysms and dissections (TAAD) and/or with a vascular EDS phenotype. To test the utility of next generation sequencing for detecting mutations in these disorders, amplicons were designed to cover exons and exon-intron boundaries of genes known to be associated with TAAD (*FBN1*, *TGFBR1*, *TGFBR2*, *MYH11*, *ACTA2*, *MYLK*) and EDS (*COL1A1*, *COL1A2*, *COL3A1*, *COL5A1*, *COL5A2*, *TNXB*). Samples were amplified using the Access Array System (Fluidigm) and sequenced by MiSeq (Illumina). In the pilot study of 126 samples 98.1% of bases were covered at 25x and 89.1% were covered at 500x. Rare likely pathogenic variants were identified in 15% of aortopathy patients (n=70) and 10% of vascular EDS patients (n=56). Analyses on a further 174 patients are ongoing. Our data indicate that pathogenic mutations in genes previously thought to be associated with only rare familial or syndromic forms of aortopathy may be implicated in a significant proportion of sporadic cases and demonstrate the potential utility of next generation sequencing for routine diagnostics of hereditary disorders of connective tissue.

2225F

New frame-shift deletion in EMD gene causes Emery-Dreifuss muscular dystrophy with severe cardiomyopathy required heart transplantation. *E. Zaklyazminskaya[1], O. Blagova[2], M. Yakovleva[1], V. Rumyantseva[1], A. Nedostup[2], D. Shumakov[3], S. Dzemeshkevich[1].* 1) Medical Genetics Laboratory, Petrovsky Russian Research Centre of Surgery RAMS, Moscow, Russian Federation; 2) Sechenov Moscow State Medical University, Moscow, Russian Federation; 3) Federal Research Centre of Transplantation and Artificial Organs, Moscow, Russian Federation.

Background. Emery-Dreifuss muscular dystrophy (EDMD) is a clinically heterogeneous disease characterized by progressive muscular atrophy, joint contractures, normal intelligence, and variable cardiac involvement. At least 6 genes are known to cause EDMD when mutated (EMD, LMNA, SYNE1, SYNE2, FHL1, and TMEM43). **Clinical case**. Male proband, 38 y.o. , has addressed to genetic counseling because of low progressive skeletal myopathy from the childhood, having walking difficulties but ambulant, moderate knees and elbows contractures, high CK level, normal intelligence, arrhythmias (HR 83-96 bpm, paroxismal atrial fibrillation, AVB I-II, RBBB, premature ventricular beats), and dilated cardiomyopathy (EF LV 33%). Proband's mother has no clinical signs of myopathy but got a pacemaker at the age of 53 y.o. Two sons, 4 y.o. and 11 y.o. are healthy. Informed consent for genetic testing was taken in accordance with Helsinki declaration. Mutations analysis was performed by PCR-based direct Sanger sequencing of coding area and adjacent intronic areas of genes of interest. Two genetic variants were detected: frame-shift deletion c.del619C in EMD gene and c.IVS4-13T>A in LMNA gene. Both variants were not found in control group of 100 healthy volunteers. Taking into account progressing of cardiac arrhythmias and high risk of sudden cardiac death in patients with EDMD, dual-chamber ICD was implanted. Patient had repeated appropriate shocks during 6 month after ICD implantation despite anti-arrhythmic therapy, and progressive impairment of cardiac pump function. Heart transplantation was proposed and successfully performed. There was no anesthetic complication during the procedure. For now, the follow-up period is 3 month with significant health improvement. **Conclusion**. We detected a novel frame-shift mutation c.del619C in EMD gene causing premature stop-codon appearance and protein shortening (p.236X). We suggest pathogenic role of this mutation in familial case of EDMD with predominance of cardiac symptoms. The role and possible modulating effect of rare novel VUCS c.IVS4-13T>A in LMNA gene is to be elucidated. Study of possible effect on LMNA mRNA processing is in progress now.

2226W

Assessment of the enrichment for rare coding variants in 16 related cases of fibromuscular dysplasia. *N. Bouatia-Naji[1,2], R. Kiando[1,2], P-F. Plouin[2,3], X. Jeunemaitre[1,2,3].* 1) Paris Cardiovascular Research Center U970 HEGP research Center, INSERM, Paris, France; 2) Paris Descartes University, Paris Cité Sorbonne, Paris France; 3) AP-HP, Centre for Rare Vascular Diseases, Hopital Européen Georges Pompidou, Paris, France.

Fibromuscular dysplasia (FMD) is an arterial disease characterized by non-atherosclerotic stenoses reported mostly in renal (70%) and extra-cranial carotid (30%) arteries. FMD predisposes to hypertension, renal ischemia and stroke, the first cause of disability worldwide. The causes of FMD are unknown and it occurs predominantly (80% of cases) in females under 50 yrs with a prevalence of ˜4/1000. The genetics of FMD is under-investigated because of the lack of large families and cohorts due to the rarity of the disease and the complexity of the diagnosis that requires artery biopsy and/or complex imaging. The aim of this study was to assess the role of rare coding and putatively functional variants in the onset of FMD in related cases. Patients are five sib-pairs and two sib-trios, all affected (N=16) with confirmed multifocal 'string-of-beads' FMD diagnosed by angiography/scanner. Mean age diagnosis is 44yrs (min=23; max=57). Exome sequencing and variant calling was performed by IntegraGen® using Agilent's capture Kit (V4) and Hiseq2000 (Illumina®) with 54X median coverage. We identified 4,311 confident (high calling-score and depth >8X) missense rare (MAF<0.02 in EVS and/or 1000G) variants predicted to be damaging (PolyPhen2) in 3,414 genes. No gene carried mutations that were specific to all patients or at least 3 out of 7 sibpairs/trios suggesting strong genetic heterogeneity in familial FMD. In order to identify genes to prioritize that might be enriched in mutations in FMD cases, we performed a genomic burden test for highly mutated genes (>= 4 variants, N=44) and used data from ˜4,300 unselected Europeans as controls (Exome Variant Server). Fischer exact test that compared variants vs non-variant alleles counts in cases and controls revealed several genes significantly (P<10e-5) enriched for putatively functional variants at the genomic level. Important fibrosis and loss of extracellular matrix (ECM) at the media of FMD arteries has been demonstrated. Using less significant threshold (P<0.01), we identified two genes involved in ECM structure, cell shape and junction, which are interesting candidates for FMD. Validation of the enrichment of statistical and candidate genes requires the extension of the current sample to larger cohorts of patients either by exome sequencing or genotyping.

2227T

Resequencing of Renin-Angiotensin-Aldosterone-System Genes Identifies Rare Variants Associated with Blood Pressure Salt-Sensitivity: The GenSalt Study. *T.N. Kelly[1], J.E. Hixson[2], L.C. Shimmin[2], Q. Zhao[1], D. Gu[3], J. He[1].* 1) Dept Epidemiology, Tulane Univ, New Orleans, LA; 2) Human Genetics Center, University of Texas, Houston, TX; 3) Cardiovascular Institute and Fuwai Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, and Chinese National Center for Cardiovascular Disease Control and Research, Beijing, China.

Genetic association studies have revealed significant associations between common variants from renin-angiotensin-aldosterone system (RAAS) genes and blood pressure (BP) responses to dietary sodium intervention. However, the role of rare RAAS variants in salt-sensitivity remains unexplored. We conducted a resequencing study to identify rare functional variants associated with BP salt-sensitivity among participants of the Genetic Epidemiology Network of Salt-Sensitivity (GenSalt) study. The GenSalt study was conducted among 1,906 participants who underwent a 7-day low-sodium (51.3 mmol sodium/day) followed by a 7-day high-sodium feeding-study (307.8 mmol sodium/day). We selected 300 GenSalt subjects with the highest and 300 GenSalt subjects with the lowest mean arterial pressure responses to the high sodium intervention to participate in the current resequencing study. Functional regions of seven RAAS genes, including ACE2, APLN, AGTR1, HSD11B1, HSD11B2, NR3C2, and RENBP were resequenced using the VariantSEQrTM system (Applied Biosystems; Foster City, CA). RAAS variants with minor allele frequencies less than 5% were collapsed according to gene and analyzed using the cohort allelic sums test (CAST). We identified significant associations between rare variants in the APLN, AGTR1, and HSD11B2 genes and BP salt-sensitivity, with p-values of 0.05, 0.03, and 0.03, respectively. Within the promoters, splice sites, exons, and 3' untranslated regions of these 3 genes, we identified 17 rare APLN variants, 20 rare AGTR1 variants, and 19 rare HSD11B2 variants. Nine percent of GenSalt participants with high salt-sensitivity were carriers of at least one of the rare APLN variants, while only 4% of salt-resistant participants were carriers. In addition, approximately 17% of participants with high salt-sensitivity were carriers of rare AGTR1 variants compared to only 11% of salt-resistant subjects. Further, 8% of those who were highly salt-sensitive compared to only 4% of those who were salt-resistant were carriers of HSD11B2 variants. In summary, we provide the first evidence for a role of rare and potentially functional RAAS variants in BP salt-sensitivity. Validation study will be needed to confirm these findings.

Whole-exome sequencing in familial calcific aortic valve stenosis. *S. LE SCOUARNEC[1,2], C. DINA[2], F. SIMONET[2], C. SCOTT[1], H. LE MAREC[2], V. PROBST[2], M. HURLES[1], N. CARTER[1], T. LE TOURNEAU[2], JJ. SCHOTT[2].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) L'institut du thorax, Inserm UMR 1087, Nantes, France.

Calcific aortic valve stenosis (CAVS) is a complex disease under the influence of risk factors (e.g. dyslipidemia) as well as genetic polymorphisms (e.g. in APOA). The identification of rare genetic variants with a strong effect would give major insights into the mechanisms leading the bone-like phenotype. Mutations in the NOTCH1 gene have been linked to aortic valve calcification but they only explain a handful of cases and also lead to congenital malformations. Our aim is to uncover the first genes involved in 'degenerative' CAVS, using families that appear to be monogenic autosomal dominant forms of CAVS, including a very large pedigree of >50 cases. First, we sequenced the exome of 20 patients affected by severe CAVS, from 9 families with ≥ 3 cases (mean depth: ~87X per patient). The hundreds of rare variants were prioritised according to their functional consequence and their segregation with the CAVS phenotype in the families. As a validation study, we sequenced a target of 499 kb (Agilent SureSelect capture, Illumina HiSeq sequencing) in 472 CAVS cases. The 499-kb target contained exonic regions of candidate genes from our exome sequencing project and linkage analysis (69 genes) or the literature (31 genes), and regulatory regions. After applying standard frequency and quality filters, we performed burden tests to identify CAVS disease genes. The identification of rare genetic variants within this project could lead to the possibility of alternative patient management for a disease that represents a major public health problem in the ageing population.

2229W

Identification and Characterisation of a Novel Gene for Cardiomyopathy. *D. Phelan[1], G. Wilson[1], K. Pope[1], G. Gillies[1], J. Sim[1], M. Bahlo[2], P. Hickey[2], C. Bromhead[2], P. James[3], D. du Sart[3], M. Delatyki[1], R. Leventer[1], D. Amor[3], P. Lockhart[1].* 1) Murdoch Childrens Research Institute, Melbourne, Australia; 2) Walter and Eliza Hall Institute, Melbourne, Australia; 3) Victorian Clinical Genetics Services, Melbourne, Australia.

Hypertrophic cardiomyopathy (HCM) is a disease characterised by hypertrophy of the left ventricle of the heart. HCM has a prevalence of ~1 in 500 individuals and is the leading cause of sudden cardiac death among young individuals. Over 20 HCM genes have been identified but at least 20% of cases remain of unknown aetiology. An extended family presented to the Victorian Clinical Genetics Service with a syndromic form of HCM in which the affected first cousins also suffered from multiple pterygia (webbing of joints). Both affected individuals were the offspring of a consanguineous relationship therefore an autosomal recessive pattern of inheritance was expected. Copy number analysis and linkage studies were performed using data from high density SNP-array analysis. A single linkage region was identified with a LOD score >1.2. This region of 15q has not previously been associated with cardiomyopathy and achieved a LOD score of 2.9. The linkage encompassed 11.4Mb and contained 169 known genes. No CNVs of interest were identified. Whole Exome Sequencing identified 100 homozygous variants within the linkage interval of which 99 were excluded by bioinformatic filtering based on minor allele frequency and predicted functional consequence. The causative mutation was a homozygous truncating variant in a poorly characterised protein that may function in cardiomyocyte differentiation. To determine the potential contribution of the gene to HCM, we sequenced the gene in a cohort of HCM patients (n=55) previously excluded for mutations in common HCM causing genes. We did not identify any predicted pathogenic variants suggesting mutations in the gene are not a common cause of HCM. To investigate the function of the gene we have characterised the expression in human and mouse tissues. The tissues showing the highest expression levels were the heart and skeletal muscle, consistent with patient phenotype. In addition, we have characterised complex patterns of tissue specific alternative splicing. Immunocytochemical studies of human and mouse heart and skeletal muscle tissue demonstrated predominant localisation to the extracellular matrix. In conclusion we have identified a novel gene for HCM. Further characterisation of this protein and it's cellular function will lead to increased understanding of the molecular basis of cardiomyopathy and result in improved clinical outcomes for affected individuals and families.

Identification of a single nucleotide polymorphism variant in TYRO3 associated with coronary artery disease risk in the ClinSeq® Study.
H. Sung[1], B. Suktitipat[1], K. Lewis[2], D. Ng[2], SG. Gonsalves[2], JC. Mullikin[3,4], LG. Biesecker[2], AF. Wilson[1], NISC Comparative Sequencing Program. 1) Genometrics Section, Inherited Disease Research Branch, National Human Genome Research Institute, NIH, Baltimore, MD; 2) Genetic Disease Research Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Comparative Genomics Unit, Genome Technology Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 4) National Institutes of Health Intramural Sequencing Center (NISC), National Human Genome Research Branch, NIH, Bethesda, MD.

ClinSeq® is a large-scale medical sequencing study designed to investigate associations of rare sequence variants with traits related to coronary artery disease (CAD). The study currently includes 1092 non-smoking participants between the ages of 45 to 65 with normal to severe coronary artery calcification scores. About 200 CAD-related traits were measured at the NIH Clinical Research Center in Bethesda, MD. Whole-exome sequencing was performed with the Agilent SureSelect 38Mb and 50Mb capture kits for 387 and 325 individuals, respectively, at NIH Intramural Sequencing Center. Single nucleotide polymorphism variants (SNVs) common to both capture regions with a call rate > 98% and minor allele frequency (MAF) > 1% were used to check for cryptic relatedness and for misspecified population stratification by multidimensional scaling analysis - 635 unrelated European Americans (EAs) were included. For each capture kit with EAs only, SNVs with at least one homozygote and a call rate ≥ 50% were included. The two capture regions with only SNVs in common were merged, yielding 439,807 SNVs. Of these SNVs, 74% and 46% had MAFs < 0.01 and < 0.001, respectively. Individuals were divided into four bins based on their 10-year Framingham risk scores for developing CAD: Bin 1 (< 5%), Bin 2 (5-10%), Bin 3 (> 10%) and Bin 4 (known CAD). The union of all SNVs in 232 individuals in Bin 1 were compared with the union of all SNVs in 89 individuals in Bin 4 using the Variant Annotation, Analysis, and Search Tool (VAAST), a probabilistic search tool in likelihood-framework based on amino acid substitution frequencies. Under the assumption of a recessive inheritance model in terms of best-scoring homozygous or heterozygous variants in the VAAST analysis, a nonsynonymous variant in TYRO3 was identified (rs62001448, MAF=0.095) with a p-value=1.01e-81. The variant allele (T) at rs62001448 was found in a heterozygous state in 16 (7%) times in 232 individuals in Bin 1 and 26 (29%) in 89 individuals in Bin 4. No variant allele (T) was found in a homozygous state. Mouse studies done by Angelillo-Scherrer at al.(2005) and Cosemans et al.(2010) indicated that a loss of function in TYRO3 would decrease thrombus formation and a gain of function would increase thrombus formation. This finding suggests the importance of TYRO3 gene in CAD and provides insight into some of the underlying genetic mechanisms of CAD in the ClinSeq® study.

2231F

Rare variants underlying a common, complex disease: exome sequencing in early-onset myocardial infarction.
H.-H. Won[1,2,3,4], N. Stitziel[5,6], R. Do[1,2,3,4] for NHLBI's Exome Sequencing Project and Myocardial Infarction Genetics Exome Sequencing Consortium. 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA; 3) Department of Medicine, Harvard Medical School, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 5) Cardiovascular Division, Department of Medicine, Washington University School of Medicine, St. Louis, MO; 6) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO.

Myocardial infarction (MI) is the leading cause of death and disability worldwide and is heritable. Studies of common genetic variation have discovered more than 45 genes and loci associated with risk for MI. Whereas rare genetic variation has long been recognized to underlie the inheritance of Mendelian diseases, the extent to which rare variation contributes to complex genetic disorders such as MI has been widely debated. The purpose of this study was to test the hypothesis that rare (frequency < 1%) DNA sequence variation contributes to risk for MI. The protein-coding regions of ~18,500 genes (the 'exome') were deeply sequenced in each of 4,000 individuals with early-onset MI (men with MI ≤ age 50; women with MI ≤ age 60) and in 3,800 individuals without MI. From this initial discovery study, we sought replication using targeted re-sequencing in larger populations (n=13,432). Rare non-synonymous mutations in two genes were more frequent in early-onset MI patients versus MI-free controls at a level of statistical significance exceeding a stringent correction for the number of genes in the genome (threshold = 2×10^{-6}). Deleterious mutations in the low-density lipoprotein receptor (*LDLR*) gene were present in 4.0% of cases compared with 1.3% of controls, representing an odds ratio for disease of 3.1 for mutation carriers ($p = 4\times10^{-10}$). In the gene apolipoprotein A-V (*APOA5*), 1.3% of cases carried a non-synonymous mutation compared with 0.6% of controls, representing an odds ratio for disease of 2.2 for mutation carriers ($p = 5\times10^{-7}$). The mutations associated with MI risk in *LDLR* and *APOA5* prominently relate to elevations in low-density lipoprotein cholesterol and triglyceride levels, respectively. We demonstrate, for the first time, that a burden of rare variants in individual genes contributes to risk for a common, complex disease and definitively establish *APOA5* as a gene responsible for MI in the population.

2232W

Rare and Common Exome Chip Variants are Associated with Fasting Glucose and Insulin Levels - The CHARGE-S Exome Chip and Sequencing Study. *J. Wessel[1], B. Cornes[2], S. Wang[3], R. Jensen[4], P. An[5], L. Lange[6], E. Lange[6], M. Nalls[7], J. Wilson[8], B. Cade[2], Y. Lu[9], R. Loos[9], V.J. Gudnason[10], J. Pankow[11], S. Willems[12], C. van Duijn[12], L. Bielak[13], X. Guo[14], L. Rasmussen-Torvik[15], M. Province[5], I. Borecki[5], J. Dupuis[3], J. Rotter[14], D. Siscovick[4], M. Goodarzi[14], J. Meigs[2], CHARGE Consortium.* 1) Dept. of Epidemiology, Indiana Univ Sch Public Health, Indianapolis, IN; 2) Department of Medicine, Harvard School of Medicine, Boston, MA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 4) Department of Medicine, University of Washington, Seattle, WA; 5) Department of Genetics, Washington University School of Medicine, St Louis, MO; 6) Department of Genetics, University of North Carolina School of Medicine, Chapel Hill, NC; 7) Laboratory of Neurogenetics, National Institute of Aging, Bethesda, MD; 8) Department of Medicine, University of Mississippi Medical Center; 9) The Charles Bronfman Institute for Personalized Medicine, The Icahn School of Medicine at Mount Sinai; 10) Icelandic Heart Association; 11) Department of Epidemiology, University of Minnesota School of Public Health; 12) Department of Epidemiology, Erasmus University Medical Center; 13) Department of Epidemiology, University of Michigan School of Public Health; 14) Department of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA; 15) Department of Preventive Medicine, Northwestern University Feinberg School of Medicine.

Genome-wide association studies (GWAS) have identified 56 loci in which common single nucleotide variants (SNVs) are associated with fasting glucose (FG) or fasting insulin (FI) levels. These SNVs explain <5% of FG or FI variation and are largely non-exonic. To identify new and rare (MAF<1%) SNVs in protein-coding regions, we tested association of FG and FI with SNVs represented on the Illumina Exome Chip. We hypothesized that some known FG- and FI-associated loci identified by GWAS harbor rare protein-coding SNVs, and that large-scale exome-wide analysis will reveal novel loci associated with FG and FI. We tested associations of 161,720 exome chip variants with FG and FI (adjusted for BMI) in up to 13,535 non-diabetic individuals of European (EA) ancestry from 3 studies in the CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology) consortium. For common SNVs (MAF ≥1%), we used single variant additive association tests. For rare SNVs we used the Sequence Kernel Association Test (SKAT) and the Weighted-Sum (W-S) tests, which aggregate variants across each gene, and combined results across cohorts using the R package, SKATMeta. Models were adjusted for age, sex, site, cohort and principal components covariates. We used SNV annotation from SNPInfo and RegulomeDB to interpret predicted functional significance of SNVs. We considered single variants with $P \leq 2\times10^{-7}$ and SKAT or W-S test results with $P \leq 2.0\times10^{-6}$ to be statistically significant. Common SNVs in known GWAS loci were associated with FG in or near MTNR1B, G6PC2 and GCK had P values$<2\times10^{-7}$; for FI, SNVs in GCKR ($P=3\times10^{-5}$) and PPARG ($P=9\times10^{-7}$) approached significance. None of the FG SNVs were in exons, but the FI SNVs were coding nonsynonymous. 76% of exome chip SNVs had MAF<1%. W-S tests identified 10 novel SNVs at the known FG locus G6PC2 that were suggestively associated with FG ($P=3\times10^{-5}$), including several predicted to be damaging and one (rs146779637), observed in all 3 studies (MAF=.003), that results in a premature stop codon (R283*). W-S testing identified 5 SNVs at a novel locus, PRKG1, that together were suggestively associated with decreased FG ($P=2\times10^{-5}$). We conclude that Exome Chip analyses confirm multiple common SNVs and identify potentially novel rare coding SNVs associated with FG and FI. These findings extend the allelic spectrum of genetic variation underlying diabetes-related quantitative traits and suggest that coding variation may influence glycemic regulation.

2233T

Novel Dilated Cardiomyopathy Mutations Identified by Whole-Exome Sequencing. *N. Chami[1,2], R. Tadros[1,2], M. Beaudoin[1], K. Sin Lo[1], L. Robb[1], F. Lemarbre[1], M. Talajic[1,2], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, Québec, Canada; 2) Faculté de Médecine, Université de Montréal, Montréal, Québec, Canada.

Introduction: Dilated cardiomyopathy (DCM) is a disorder of the heart muscle that is characterized by a dilated and impaired contraction of the left ventricle and may ultimately lead to sudden death, heart failure or transplantation. Genetic factors play a major role in DCM; however, known mutations explain less than 20% of familial cases. We hypothesized that a whole-exome approach to identify novel mutations would improve understanding of the genetic basis of DCM. Methods: We performed whole exome DNA sequencing in 26 clinically well-characterized French-Canadian families that are followed at the Montreal Heart Institute's genetic clinic. The inclusion criteria comprised four main conditions: patients had left ventricular ejection fraction, LVEF ≤ 45%, left ventricular dilatation, absence of other known causes of cardiomyopathy, as well as a family history of DCM. Next-generation DNA sequencing was done using the Illumina HiSeq2000 instrument and a paired-ends 2×101 bp protocol. Results: We identified 24,714 novel variants out of which 4,863 are coding. We show that 19% of the families in our study carry unique and novel nonsense mutations in the TTN gene, consistent with previous reports. Further, we identified a nonsense mutation in BAG3, Arg309X, which co-segregated with DCM in three families. The mutation was shared by all 14 affected members and absent in all healthy individuals. Importantly, we show that BAG3 truncating mutations are significantly correlated with early onset of DCM. Conclusion: Mutations in TTN and BAG3 account for a significant proportion of familial dilated cardiomyopathy at the Montreal Heart Institute. Our results highlight the importance of whole exome sequencing in identifying novel causal mutations in DCM which could lead to a better understanding of the disease and improve clinical testing permitting earlier diagnosis in affected families.

2234F

Whole-exome sequencing of a large cohort of patients with congenital heart disease in the Quebec founder population. *C. Preuss[1], M. Capredon[1], C. Prive[1], JC. Grenier[1], M. Samuels[2], P. Chetaille[3], P. Awadalla[1], G. Andelfinger[1].* 1) Department of Pediatrics, Centre Hospitalier Universitaire Sainte Justine, Montreal, QC, Canada; 2) Centre de Recherche de l'Hôpital Ste-Justine, Université de Montréal, Montréal, Quebec, Canada; 3) Cardiology Service, Centre Mère-Enfants, Centre Hospitalier Universitaire de Québec, Université de Laval, Québec City, Québec, Canada.

Congenital heart disease (CHD) is the most common birth defect, the most common cause of infant morbidity and the second most common cause of infant mortality in Canada. It is defined as a structural malformation of the heart and/or great vessels that is present at birth and is of functional significance. Mendelian transmission of congenital heart disease in large families is rare, even in those for which a variable expression of penetrance is observed. We have whole-exome sequenced 96 individuals with left ventricular outflow tract obstructions such as septal defects, aortic valve lesions, coarctation, and supraventricular arrhythmias which have been recruited in Quebec. Library preparation was performed using the TargetSeq enrichment kit and sequences were obtained using the SOLiD5 platform in our in house genome core facility. For several members of multiple affected families genetic linkage mapping has been performed. However, since genetic and phenotypic heterogenity is the norm even for rare Mendelian disease such as CHD, it remains a challenging tasks to make accurate and clinically useful predictions regarding the disease phenotype using classical genetic approaches. Here, we present our recent results from whole-exome sequencing highlighting that genomic, phenotypic and population context matters. The filtering for rare, potential damaging disease variants revealed a number of loci enriched for disease related pathways including histone modification, NOTCH signaling and metalloproteinases involved in heart development. Many of these rare variants identified in newly implicated candidate genes are the subject of ongoing validation and functional studies and might jointly determine the phenotype. In order to test our hypothesis whether the excess of rare, population specific variants contributed to disease risk in individuals, we will validate the identified variants and perform a population wide screening in an independent control cohort from Quebec (CARTaGENE). The heterogenous nature and often not complete penetrance of CHD suggests that composite effects and mutation clustering within families may be rather the norm than the exception for traits that have been primarily studied under the Mendelian mode of disease inheritance.

2235W

A comprehensive association study of *APOE-C1-C4-C2* gene cluster variation with plasma lipoprotein traits in U.S. Whites. *Z.H. Radwan[1], X. Wang[1], F. Waqar[1], J.E. Hokanson[2], R.F. Hamman[2], M.M. Barmada[1], F.Y. Demirci[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO.

Apolipoproteins (APO) are major determinants of plasma lipoprotein-lipid distribution and their genetic variation have significant impact on cardiovascular disease (CVD) risk, which is the leading cause of morbidity and mortality worldwide. Therefore, understanding the genetic of plasma lipid traits and determining subjects with high risk of developing CVD is of great public health importance. Although the influence of *APOE* common polymorphisms on plasma lipid traits has been extensively evaluated in diverse ethnic groups, little attention has been paid on other genes located in the same genes cluster on chromosome 19. The objective of this study was to characterize common and rare genetic variation through comprehensive sequencing of the *APOE*, *APOC1*, *APOC4*, *APOC2* genes along with their hepatic regulatory regions *HCR-1*, and *HCR-2* in 95 subjects from US non-Hispanic Whites (NHWs) with extreme HDL-C/TG levels (47 in the upper 10th percentile, and 48 in the lower 10th percentile), and then to genotype the identified tagSNPs and rare variants along with HapMap tagSNPs to cover the intergenic regions in 623 NHWs to evaluate their associations with lipid traits. A total of 115 variants (105 substitution, 10 indels) were identified in the sequencing subset of which 74% were reported, 26% were novel, 54% were common (MAF≥5%), and 46% were rare or less common (MAF<5%). The number of observed unique rare variants was higher in the high HDL-C/low TG group than in the low HDL-C/high TG group (23 vs. 15). Seventy variants (65 sequencing, and 5 HapMap SNPs) were successfully genotyped in 623 subjects followed by association analyses. Gene-based association results confirm the major contribution of this gene cluster on variation in plasma LDL-C, TC, and apoB levels. Single-locus association analysis revealed 20 significant associations with at least one lipid trait (9.65E-13≤p≤0.046). Rare variants analyses showed more significant associations with TC than with other lipid traits. Our findings confirm the significant contribution of this gene cluster in affecting plasma lipid profile and consequently the CVD risk.

2236T

Whole genome sequencing in African American families to identify genetic determinants of extreme obesity. *L. Yanek[1], M. Taub[2], I. Ruczinski[2], L. Huang[3], D. Vaidya[1], L. Becker[1], D. Becker[1], R. Mathias[1], The GeneSTAR Research Program.* 1) The GeneSTAR Research Program, Johns Hopkins School of Medicine, Baltimore, MD; 2) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Johns Hopkins School of Medicine, Baltimore, MD.

Background: African Americans (AA) have the highest rate of obesity in the US. We have noted a dramatically high prevalence of extreme obesity (BMI≥35 kg/m^2) in AAs in the GeneSTAR study of families with a history of early-onset coronary artery disease: 64 (19%) of the 339 AA GeneSTAR families had >1 relative pair with extreme obesity. We leverage whole genome sequence (WGS) data available on 3 AA families containing one or more members with extreme obesity and one or more with normal BMI (18.5-25 kg/m^2) to search for rare genetic determinants of extreme obesity. Methods: Deep (>30X) WGS was performed by Illumina, Inc, in 130 GeneSTAR subjects; analysis was restricted to 17 individuals from 3 families segregating extreme obesity. Variants were filtered (GQ>20 and segmental duplication regions were masked), and we determined the set of variants with 'perfect' co-segregation with phenotype in each family. We tabulated the number of families with 'perfect' co-segregation at (i) each variant site; and (ii) variants collapsed over the unit of each CCDS transcript. Current analysis is restricted to 'novel' sites, i.e., sites not previously noted in the Thousand Genomes Project. Results: There were ~4 million (M) sites per sample, each had ~ 2.7M heterozygous sites and as many as ~217K private variants. Cumulatively, 10.5M variant sites were noted in the 17 individuals, 1.1M of which were novel. We found 18 sites to perfectly co-segregate with the extreme obesity phenotype across all 3 families. Of these, one may affect a binding site of SPI1 to chr12:113740876..113741076. When collapsed over all non-intronic variants within transcripts, 5 transcripts mapping to three distinct genes were found to contain genetic variants perfectly co-segregating with extreme obesity in all 3 families: TJAP1, MUC6 and COL2A1. MUC6 regulates gastric mucus secretion while TJAP1 is a tight junction associated protein and COL2A1 is the alpha 1 chain of collagen Type II. Conclusions: This analysis from the WGS of 3 families suggests there are rare sequence-identified variants that may influence extreme obesity in AA families. Analysis is underway to assess (i) statistical significance of these variants; (ii) consideration of genes with known sequencing issues such as MUC6; (iii) extended analysis leveraging ENCODE data to fully assess the non-coding regions of the genome; and (iv) replication of these signals in a sample of 100 independent AA with WGS data from GeneSTAR.

2237F

***TGFBR1* mutations in a British cohort of Thoracic Aortic Aneurysm and Dissection (TAAD) patients.** *J.A. Aragon-Martin[1], A.M. Mohamed[1], A. Wan[1], A. Saggar[2], M. Jahangiri[3], A.H. Child[1].* 1) Cardiovascular Sciences Research Centre, St George's University of London, Cranmer Terrace, London SW17 0RE, UK; 2) Clinical Genetics Unit, St George's University of London, Cranmer Terrace, London SW17 0RE, UK; 3) Department of Cardiothoracic Surgery, St. George's Healthcare NHS Trust, Cranmer Terrace, London SW17 0RE, UK.

Background: TAAD is inherited as autosomal dominant with variable expression (interfamilial and intrafamilial) and reduced penetrance. Of all non-syndromic TAADs 20% have a family history for aneurysm. TAAD occurs as syndromic (MFS - FBN1, LDS - TGFBR1/2, AOS - SMAD3, EDS - COL3A1) and non-syndromic (SMAD3, TGFBR1/2, ACTA2, MYH11, MYLK) forms; with unidentified genes in 4 known loci (AAT1, AAT2, TAAD3, TAAD5). Recent studies have started to elucidate the genetic basis of non-syndromic TAAD and its genetic heterogeneity. Mutations have been found in genes encoding proteins involved in the extracellular matrix, the TGFb pathway and the contractile apparatus of aortic smooth muscle cells. Candidate genes could be those that interact with the known genes or are part of the same pathway. The aim of this study was to determine the frequency of TGFBR1 mutation in a consecutive series of TAAD patients attending a British TAAD cardiac genetics clinic. Diagnosis was based on pedigree, physical examination, echocardiogram, CT and MRI studies and operative reports.

Method: A total of 101 UK patients (80M:21F, mean age 53±13) with known TAAD who did not fulfill the revised Ghent criteria for MFS, and with no demonstrable mutations in FBN1, TGFBR2, ACTA2 or SMAD3 genes were recruited to this study. These patients were screened for mutations in all exons of TGFBR1 including intron/exon boundaries by bi-directional sequencing. Due to the unavailability of family members segregation studies were not performed. In-silico tools (GVGD, Mutation T@ster, Polyphen-2, SIFT, ESE_finder, BGDP) and human genetic variation databases (1000Genome, EVS) helped to analyse the variants.

Results: Four novel variants (p.H358Y/c.1072C>T, p.A368A/c.1104T>G, p.T375T/c.1125A>C, p.L486W/c.1457T>G) and one recurrent mutation in LDS2A (p.R487W/c.1459C>T) were identified in the serine-threonine kinase domain of the gene. In-silico analysis agrees that these 5 variants are disease causative.

Conclusion: Position 487 is a hot spot. This study suggests that mutations in TGFBR1 (4 novel mutations and 1 recurrent mutation in 5 unrelated probands) are responsible for 3-5% of TAADs and supports data from previous studies. Next-generation sequencing will help with the screening of the remaining samples to elucidate their genetic basis. Contact=jaragon@sgul.ac.uk.

RNAseq Analysis of Congenital Heart Defects. *D.M. McKean[1], D.S. Herman[1], A.G. Bick[1], D.C. Christodoulou[1], S.R. DePalma[1], J.M. Gorham[1], J. Homsy[1], J.D. Jiang[1], J.D. Overton[6], H. Wakimoto[1], S. Zaidi[6], R.E. Breitbart[2], W.K. Chung[3], R.P. Kim[4], O. Toka[5], R.P. Lifton[6], C.E. Seidman[1], J.G. Seidman[1], Pediatric Cardiac Genomic Consortium.* 1) Genetics, Harvard Medical School, Boston, MA; 2) Boston Children's Hospital, Boston, MA; 3) Pediatrics, Columbia University Medical Center, New York, NY; 4) Children's Hospital Los Angeles, Los Angeles, CA; 5) Institute of Human Genetics, Erlangen University, Erlangen, Germany; 6) Genetics, Yale University, New Haven, CT.

Congenital heart disease (CHD) is the most common type of birth defect and the leading cause of death within the first year of life. To elucidate genetic causes and transcriptional responses to CHD mutations, we performed next generation sequencing and RNAseq on cardiovascular tissues. From 119 CHD subjects, 160 cardiac tissues were obtained from 11 unique sites. For 23 subjects (46 cardiac samples), genomic sequence (whole exome or whole genome) and RNAseq data was available. High quality RNAseq reads were aligned to hg19 using Tophat1.4. Duplicate reads were removed, yielding an average of 20 million reads per subject. Gene expression levels were compared with like tissues from other subjects, from comparable neonatal mouse tissues, and from different tissue from same individuals. 76 genes expressed in neonatal mouse were not expressed in human tissues and 285 genes expressed in human tissues were not expressed in neonatal mouse. 55 genes displayed allele-specific expression (ASE) in multiple human samples (perhaps reflecting cardiac imprinting). 146 genes displayed ASE in ≥1 tissue in a single subject. Interrogation of genomic DNA is underway to consider if ASE in these subjects reflects genomic mutation. Genomic DNA was analyzed to predict RNA splice variants (Maximum Entropy, Neural Network, Splice Site Finder, Human Splice Finder, and Gene Splicer algorithms). Over 1000 unique sites were predicted to alter RNA splicing from one or more algorithms. Among >300 genes expressed in the heart, aberrant splicing was seen with 14 variants, and not seen with 9 variants. Active studies integrating allele loss with predicted splice variants are underway. Ongoing work will define the sensitivity and specificity of splice variant prediction tools.

Novel rare coding variants underlie blood lipid levels in the population: an exome array association study in 55,000 whites and blacks. *G.M. Peloso[1, 2] on behalf of the CHARGE Lipids Working Group.* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA.

Circulating low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and triglycerides (TG) are quantitative, heritable risk factors for coronary heart disease, and genome-wide association screens of common DNA sequence variants have identified many loci associated with these traits. Here, we test the hypothesis that rare coding and splice-site mutations contribute to inter-individual variation in blood lipid concentrations in the population. We characterized ~41,000 European Ancestry (EA) and ~14,000 African Ancestry (AA) samples from 13 studies using a new, rare-variant genotyping array ("the Exome Chip") that was designed based on the protein-coding sequences for ~18,500 genes ("the exome") in >12,000 individuals. Within each of the 13 contributing studies, we tested the association of plasma lipids with individual rare variants as well as sets of variants within each gene. To combine statistical evidence across studies, we performed fixed effects meta-analysis. For single variant association, we set the significance threshold to 7×10^{-8}, corresponding to a Bonferroni correction for 742,932 tests (3 phenotypes x 247,644 variants on the array). For the gene-based association, we set the significance threshold to 5×10^{-7}, corresponding to a Bonferroni correction for 105,444 tests (3 phenotypes x 17,574 genes on the array x 2 tests). The most significantly associated results for each trait replicated known associations in APOE for LDL-C, CETP for HDL-C, and APOA5 for TG. We identified two new genes with rare coding variants associated with lipid levels in EA samples: ANGPTL8 for HDL-C (Q46X, 0.1% frequency, beta=10 mg/dl, P= 9×10^{-11}); and PAFAH1B2 for triglycerides (S161L, 1.7% frequency, beta=-10%, P=4×10^{-09}). Additionally, we found two new gene associations in the AA samples: PCSK7 for HDL-C (R504H, 0.2% frequency, beta=18 mg/dl, P=3×10^{-20}); and COL18A1 for triglycerides (G111R, 1.9% frequency, beta=-16%, P=4×10^{-17}). With the Exome Chip rare variant genotyping array, we have discovered novel associations between rare variants and lipid levels.

Serum 25 (OH) D deficiency, cardiovascular disease and APOE genotypes: Increased 25 (OH) D status in APOE ε4 carriers does not protect from cardio-metabolic risk. *D. Sanghera[1], H. Finley[1], P. Natt[1], A. Subramanian[1], P. Blackett[2].* 1) Dept Pediatrics, Sect Gen, Univ Oklahoma HSC, Oklahoma City, OK; 2) Dept Pediatrics, Sect Endo, Univ Oklahoma HSC, Oklahoma City, OK.

Our earlier findings reported high prevalence of serum 25(OH) vitamin D deficiency (50<nm/L)to be associated with cardiovascular risk factors including obesity, hypertension, and type 2 diabetes (T2D) in South Asians Sikhs from India. Epidemiological and experimental evidence suggests that APOE ε4 allele protects against vitamin D deficiency, however, it appears contradictory with regard to association APOE ε4 with chronic inflammation and cardiovascular disease. The purpose of this investigation was to examine the distribution of serum 25 (OH) D in an extended sample of individuals from Punjabi ancestry residing in India and US, and to examine role of genetic variation in APOE with vitamin D levels and cardio-metabolic risk. We measured serum 25 (OH) D levels in serum sample of a total of 3,300 Punjabi participants (1,793 T2D cases and 1,560 controls and also genotyped these individuals for APOE polymorphism. A total of 78% individuals were deficient (<50nmol/L) and 56% were seriously deficient (<30nmol/L) in vitamin D levels. A highly significant, inverse relationship between vitamin D levels and T2D was observed (p<0.0001). Furthermore, (82%) diabetics were classified as vitamin D deficient compared to (74%) non-diabetic controls. Furthermore, low vitamin D levels were associated with significantly increased fasting glucose (p<0.007), systolic blood pressure (p<0.003), and body mass index (BMI) (p<0.0001), independent of T2D status. Distribution of APOE genotypes did not differ among T2D patients compared to controls. However, prevalence of APOE ε4 carriers was significantly higher in patients with coronary artery disease (CAD) (14.2%) vs. non-CAD controls (11.9%) (p=0.022). The APOE ε4 carriers had significantly higher serum levels of 25(OH) D compared to non APOE ε4 carriers and non-carriers (30.2±2.5 vs 25.8 ±2.4nm/L, p=0.021), respectively. Despite this, APOE ε4 carriers had higher fasting glucose (p=0.021), higher mean arterial pressure (p= 0.04) and lower HDL cholesterol (p=0.031). Our findings suggest that although APOE ε4 is a modulator of vitamin D status, the adverse metabolic impact associated with APOE ε4 genotype cannot be explained by better serum 25 (OH) D status.

2241W

African ancestry is associated with hypertensive cardiomyopathy in Brazilian patients with heart failure. *C. Fridman[1], M. Cardena[1], A. Ribeiro-dos-Santos[2], S. Santos[2], A. Mansur[3], A. Pereira[3].* 1) Dept of Legal Medicine, Ethics and Occupational Health, Medical School, University of São Paulo, São Paulo, Brazil; 2) Laboratory of Human Genetics and Medicine, Federal University of Pará, Belém, Pará, Brazil; 3) Department of Cardiology, Laboratory of Genetics and Molecular Cardiology, Heart Institute, Medical School, University of São Paulo, São Paulo, Brazil.

Heart failure (HF) is the final pathway for many diseases affecting the heart; it is recognized as the main risk factor for early morbidity and mortality caused by cardiovascular disease. HF is a complex trait resulting from combination of genetic, environmental, lifestyle and ethnic background, being more prevalent in black individuals. It is known that self-declared ethnicity is not a good method to ethnic classification, especially in admixed population where there is little correlation between self-declared skin color and genetic background. Herein, we investigate the association between genomic ancestry and mitochondrial haplogroups (mtDNA-hg) with different heart failure etiologies in 503 Brazilian patients. Mitochondrial haplogroups were obtained by sequencing the control region of mtDNA. Genomic ancestry was obtained using a set of 48 Ancestry Informative Markers (AIMs) INDELs type. Estimation of global ancestry proportions analyzes was done using Structure v.2.2; statistical analysis was done with SPSS 14.0. Different etiologies were observed within our sample: hypertensive(28.6%), ischemic(28.4%), valve(15.1%), chagasic(11.9%), idiopathic(9.9%) and others(6.1%). In the total sample, African mtDNA-hg was the more prevalent (46.4%), followed by Amerindian (28.2%) and European (25.4%) mtDNA-hg. Genomic ancestry showed the major contribution being European, with 57.5% (±22.1%), followed by African genomic ancestry with 28.3% (±21.7%). The analyzes of associations with different etiologies showed that individuals belonging to African mtDNA-hg and those with greater contribution of African genomic ancestry present increased risk for hypertensive cardiomyopathy development (p=0.003 OR2.05[95%I.C(1.29-3.25)]) and (p=0.002 OR6.07[95%I.C(1.96-18.9)]), respectively. Different physiologic, genetic and environmental factors are known to be related with increased propensity for sodium retention and lower bioavailability of nitric oxide in black individual, as well as increased of oxidative stress; all of them playing an important pathophysiological role in the development of hypertension. This study provided evidence of association between African ancestry (mtDNA and AIMs) and hypertensive cardiomyopathy in HF patients. Besides, this study support the importance of using AIMs and mtDNA to study the genetic of complex diseases in admixed populations, where skin color is not a good indicator of an individual's genetic ancestry. Supported: FAPESP, LIM40-HC.

Genetic Evaluation in Cardiac Neurodevelopmental Clinic: Diagnosis and Health Care Management. *P.C. Goldenberg[1], A. Parrott[1], B.J. Adler[1], J. Anixt[2], K. Mason[2], B.S. Marino[1].* 1) Cardiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Development and Behavioral Pediatrics, Cincinnati Children's Hospital Medical center.

Objective: To assess burden of clinical and laboratory-confirmed genetic disorders and utility of genetics evaluation in a cardiac neurodevelopmental clinic. **Background:** There is a known high prevalence of genetic and syndromic diagnoses in the pediatric cardiac population. These disorders may have multi-system effects, which may have an important impact on neurodevelopmental outcome. Patients and families may benefit from consultation by genetic specialists in a cardiac neurodevelopmental clinic.**Methods:** A retrospective chart review was conducted of patients evaluated in a cardiac neurodevelopmental clinic from 12/6/2011-4/16/2013. All patients were seen by a cardiovascular geneticist with genetic counseling support. **Results:** A total of 216 patients were included. 30% of patients had a previously determined clinical or laboratory confirmed syndromic diagnosis (65). Following genetics evaluation an additional 18 patients (8%) were given a new genetic or syndromic diagnosis, including rare diagnoses (Ohdo, Kabuki, and Axenfeld-Rieger syndromes), prenatal teratogenic exposures (Depakote), copy number variants, malformation associations (MURCS, VACTERL), and typical genetic diagnoses in cardiology populations (Williams, Noonan, 22q11.2 deletion, CHARGE, and Rubinstein-Taybi syndromes). There was significant increase in post-visit clinical and laboratory confirmed syndromic diagnosis in comparison to pre-visit diagnosis (p<0.001). Genetic testing was recommended for 112 (52%)patients, imaging was obtained on 17 patients (8%), 73 patients had additional recommended referrals (34%), and 14 patients had clinical lab studies (6%). Syndrome-specific guidelines were available and followed for 26 patients with known diagnosis (12%), including some that had been lost to genetics follow-up. Red Book guideline asplenia recommendations were made for 6 heterotaxy patients, and 23 families affected by LV outflow tract obstruction were advised to have echocardiograms (11%).**Conclusion:** Genetics involvement in cardiac neurodevelopmental clinic can be helpful in identifying new unifying clinical or laboratory confirmed genetic diagnoses and providing syndrome-specific care, which may impact the patient's overall health status and neurodevelopmental outcome..

Incidence of aortic root dilatation in patients with 22q11 deletion: The 3-year experience of a VCF specialty clinic. *C.B. Hills[1], S.L. Dugan[2], M.E. Pierpont[3], J.D. Sidman[4].* 1) Children's Heart Clinic, Minneapolis, MN; 2) Genetics Division, Children's Hospitals and Clinics of Minnesota, Minneapolis, MN; 3) Division of Pediatric Genetics and Metabolism, University of Minnesota, Minneapolis, MN; 4) Children's ENT and Facial Plastic Surgery, Children's Hospitals and Clinics of Minnesota, Minneapolis, MN.

Background: Congenital cardiac malformations are commonly present in patients with 22q11 deletions. Frequent malformations include cono-truncal defects such as tetralogy of Fallot, interrupted aortic arch, vascular rings/ right aortic arch, and septal defects. Aortic root dilatation has been reported in this population, but the incidence and association with specific cardiac diagnoses has not been well-defined. Method and Results: A retrospective chart review was performed for all patients seen at the Velocardiofacial Syndrome Specialty Clinic at the Children's Hospitals and Clinics of Minnesota from 2009-2012. A total of 78 individual patients were identified (age range newborn to age 29 years). Echocardiogram reports and images were reviewed for each patient. Fourteen patients were referred from outside institutions and aortic root dimensions were not available. All available echocardiograms were reviewed for each patient by a pediatric cardiologist. A total of 179 echocardiograms performed on the remaining 64 patients (range 1-20 studies per patient) were diagnostic for determining the aortic root dimension at the level of the sinuses of Valsalva. Aortic root z-scores were calculated for each diagnostic study. Thirty-two (50%) of the patients were found to have at least one study in which their aortic root dimensions z-score exceeded a valve of +2. Incidence by cardiac diagnosis varied, with the highest incidence found in patients with tetralogy of Fallot (77%); vascular ring (70%); and interrupted aortic arch (67%). Six patients out of 20 (30%) with structurally normal hearts were found to have aortic root enlargement on at least 1 echocardiogram. Several patients were found to have aortic root dimensions above normal limits with subsequent normalization of the root size for their body surface area; in others, the aortic root enlargement occurred over time. None of the patients in this cohort have required aortic root replacement or have had an aortic root dissection to date. Conclusions: Aortic root enlargement is a common finding in patients with 22q11 deletions, even in the presence of a structurally normal heart. Acute aortic root dissection has been reported only rarely in patients with 22q11 deletions, but additional research is needed to determine the incidence of progressive root enlargement with time and possible need for ongoing screening studies in this population.

Identical Adolescent Twins with Progressive Thoracic Aortic Aneurysm, Recurrent Dissection and ACTA2 Mutations. *R.B. Hinton, A. Shikany, S.M. Ware.* Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Thoracic aortic aneurysm (TAA) is a subclinical disease and some cases are associated with aortic dissection and sudden death. TAA can occur as an isolated nonsyndromic condition or in conjunction with inherited connective tissue disorders such as Marfan syndrome. The genetic basis of isolated TAA is identifiable in approximately 20% of cases with up to 14% attributable to mutations in smooth muscle actin (ACTA2). We identified 17 year-old identical twin brothers with severe fusiform TAA (aortic root Z-scores +8.0 and +7.7, respectively, and ascending aorta Z-scores +7.6 and +12.7) that progressed to multiple dissections. Twin 1 presented with dissection of an abdominal aortic aneurysm (AAA). Both brothers had marked aneurysmal dilation of the internal carotid arteries and pulmonary emboli. Eye findings were notable for mydriasis. Molecular testing identified a de novo ACTA2 p.Lys328Asn heterozygous mutation. Testing of FBN1, TGFBR1, TGFBR2, and MYH11 was normal. Histologic analysis of thoracic and abdominal aorta samples showed architectural abnormalities including subintimal hyperplasia, advential fibrosis and elastic fiber fragmentation. Smooth muscle actin, the protein encoded by ACTA2, is misexpressed in both thoracic and abdominal aorta tissue types, but the abnormalities appear more severe in TAA. Given the known inflammatory component present in AAA, we examined inflammatory markers in both TAA and AAA. Interestingly, CD-45, which is diffusely present in control tissue, is selectively increased in the adventitia layer only of TAA but increased in clusters of cells in both the media and adventitia of AAA. CD-68, a macrophage marker that is normally absent from aorta, is weakly present in TAA adventitia and strongly present in AAA media and adventitia. TGFβ signaling was also examined. Canonical (p-Smad2/3) and non-canonical (p-Erk1/2) signaling was present in controls in all three layers of the aorta. In contrast, both canonical and non-canonical signaling were strongly increased in TAA and moderately increased in AAA with disproportionate increases in the adventitia. These individuals with ACTA2 mutation demonstrate that severely progressive aneurysmal disease is characterized by smooth muscle and TGFβ signaling abnormalities in conjunction with a potential role for inflammation in the thoracic aorta.

2245T

Erythrocyte sedimentation rate (ESR) in ischemic stroke and its relation with stroke risk factors. *A. Kaur[1], A. Uppal[2], K. Kaur[1].* 1) Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Uppal Neuro Hospital, Amritsar, Punjab, India.

Elevated ESR level is considered to be reliable marker of chronic and acute inflammation. Inflammation is hallmark of ischemic stroke. Cardiovascular risk factors, chronic and acute inflammation appears to be linked closely to each other and to aggravate the occurrence of various thrombotic events involved in pathophysiology of ischemic stroke. Objective: To investigate the relationship between ESR levels and various traditional risk factors in ischemic stroke. Methodology:The study included total of 107 ischemic stroke patients hospitalized in Uppal Neuro hospital, Amritsar (Punjab), diagnosis being confirmed with MRI. Any history of hypertension, diabetes, CAD and atrial fibrillation (AF) was assessed. The patients were classified into three groups according to ESR values measured within 24 hours of admission. Results and Conclusion: A total of 107 ischemic stroke patients including 61 males and 46 females were evaluated for ESR levels, hemoglobin (Hb) content, TLC, neutrophils and lymphocyte count. Patients with ESR≤10mm/hr were included in group I (n=49) with mean age 60.1±12.2. Group II (ESR 11-25) included 72 patients with mean age 65.7±12.2 and patients (n=11) in group III with ESR levels ≥ 26mm/hr had mean age 67.6±12.4. Group I showed higher number of males (79.2%) but Group III with abnormally high values of ESR included most of females (90.9%) than group II (43.1%) and group I (20.8%). Comparison among three groups with respect to age, Hb content, TLC, neutrophils and lymphocytes was carried out with ANOVA (univariate). The difference of mean Hb levels among three groups have been found to be statistically significant (F=20.02, p<0.001). No statistical difference was observed among three groups with respect to age (F=2.29, p=0.106), TLC (F=0.78, p=0.46), neutrophils (F=2.36, p=0.09) and lymphocytes (F=2.36, p=0.09). In terms of stroke risk factors including hypertension, diabetes, CAD, no significant difference was observed. It has been concluded that higher ESR values on admission are associated with low Hb content while on other hand they are not significantly related with various traditional stroke risk factors, may be due to small sample size. Large sample size (being studied) could provide some useful information regarding the relationship between ESR and stroke risk factors.

2246F

Alpha cardiac actin mutation co-segregates with hypertrophic and dilated cardiomyopathy as well as being associated with conduction disease. *J. McGaughran[1,2], L. Hunt[1], M. Christiansen[3], J. Atherton[2,4].* 1) Gen Hlth Queensland, Royal Brisbane & Women's Hosp, Brisbane, Queensland, Australia; 2) University of Queensland, School of Medicine, Brisbane, Queensland, Australia; 3) Statens Serum Institute, Copenhagen, Denmark; 4) Department of Cardiology, Royal Brisbane and Women's Hospital, Brisbane, Queensland, Australia.

Mutations in alpha cardiac actin (ACTC1) have been rarely reported in nonsyndromic familial dilated cardiomyopathy (DCM) and hypertrophic cardiomyopathy (HCM). We report a family with both HCM and DCM associated with conduction disease requiring pacing that co-segregates with an ACTC1 missense mutation. A 40 year old woman with HCM presented for genetic testing. Her father was also said to have HCM and died whilst awaiting cardiac transplantation. She was aware that 2 of her paternal uncles were also said to have cardiomyopathy. An ACTC1 missense mutation (c.76 G>A) was identified on genetic screening. Further family studies were suggested to clarify the pathogenicity of the change. One uncle initially presented at the age of 51 years with atrial fibrillation associated with normal LV size, wall thickness and systolic function. He subsequently developed symptomatic atrioventricular (AV) conduction disease, dilated cardiomyopathy and clinical heart failure at 64 years of age and pacing was performed in view of 3rd-degree AV block (despite no negative chronotropic agents). LMNA mutation screening was negative. He also had the ACTC1 missense mutation. Another paternal uncle diagnosed with HCM also had the ACTC1 missense mutation. Conclusion: This case illustrates the phenotypic variation associated with sarcomere mutations. ACTC1 mutations have been previously reported in a small number of HCM and DCM families, however has not been previously reported in associated with conduction disease.

2247W

Cumulative Risks for Thoracic Aortic and Other Vascular Diseases Associated with ACTA2 Mutations. *E.S. Regalado[1], R.E. Lasky[2], D. Guo[1], T.A. Bensend[1], G. Arno[3], A. Child[3], T. Morisaki[4], D. Liang[5], D.M. Milewicz[1].* 1) Internal Medicine, University of Texas Health Science Center at Houston, Houston, TX; 2) Pediatrics, University of Texas Health Science Center at Houston, Houston, TX; 3) St. George's University of London, London, UK; 4) National Cerebral and Cardiovascular Center Research Institute, Suita, Japan; 5) Stanford University, Stanford, CA.

ACTA2 mutations are the most common cause of familial thoracic aortic aneurysms and dissections (TAAD) responsible for 10-14% of the disease and predispose to occlusive vascular diseases leading to stroke and coronary artery disease (CAD) with strong association of specific mutations with vascular diseases. Disease risk estimates are important for genetic counseling and surveillance of at-risk patients, but are not available for ACTA2 mutations. Using data collected from the largest cohort of individuals with a spectrum of ACTA2 mutations (n = 217), we determined Kaplan-Meier estimates of failure function for TAAD (aortic aneurysms requiring surgical repair or aortic dissections), CAD or myocardial infarct (MI), and stroke for all mutations and specific mutations occurring in at least 2 unrelated families. By age 70 years, 85% (95% CI= 74-93%) of individuals had TAAD. Percentage of individuals who had TAAD from birth to oldest age of follow-up was 100% by age 25 years for Arg179, 100% by age 45 years for Arg198, 93% (95% CI= 74-100%) by age 63 years for Arg258, 85% (95% CI= 53-99%) by age 62 years for Arg118, 75% (95% CI= 59-88%) by age 70 years for Arg149, 70% (95% CI= 37-96%) by age 76 years for Arg212, 68% (95% CI= 44-90%) by age 65 years for Arg39, 67% (95% CI= 32-95%) by age 56 years for Gly160, and 60% (95% CI= 17-99%) by age 77 years for Arg185. Using the logrank test, risk for TAAD was significantly higher for mutations altering Arg179 (p<0.001) and Arg258 (p=0.017) compared to other ACTA2 mutations. Eighteen percent (95% CI= 12-28%) of individuals had early onset CAD or MI and 13% (95% CI= 9-20%) had early onset stroke by age of 55 years. Mutation-specific risk estimates were also calculated for early onset stroke and CAD or MI. Risk for early onset stroke was significantly higher for mutations altering Arg179 (42%, 95% CI= 17-80%, p<0.001) and Arg258 (41%, 95% CI= 20-71%, p=0.001) but lower for Arg149 (4%, 95% CI= 1-26%, p=0.031). None of the specific mutations were significantly associated with early onset CAD or MI, although Arg149 showed borderline significant association (28%, 95% CI= 14-51%, p= 0.058). These findings demonstrate variable disease risk specifically for ACTA2 mutations altering Arg179 and Arg258 and provide detailed risk estimates that will aid in genetic counseling, vascular imaging and management of patients, and provide a guide for assessing aortic disease risk for other genes that predispose to this disease.

2248T

Immunohistochemical study of lysosomal Cathepsin A deficient mouse model shows accumulation of vasoactive peptides in brain. *V. Seyrantepe, S.C. Ozturk, Z. Timur, S. Akyildiz, O. Ozdemir.* Dept Molecular Biology and Genetics, Izmir Institute of Technology, Urla Izmir, Turkey.

Cathepsin A is lysosomal enzyme that makes complex with α-neuraminidase and β-galactosidase. In the complex, it activates α-neuraminidase and stabilizes β-galactosidase. Cathepsin A is an acidic serine carboxypeptidase with deamidase and esterase activities at neutral pH. It catalyzes the hydrolysis of C-terminal peptide bond which potentially affects vasoactive peptide actions in normal and pathological conditions. In order to elucidate the biological function of Cathepsin A in vivo, we previously generated knock-in mouse model with catalytically inactive Cathepsin A protein. We showed that Cathepsin A-/- mice have significantly increased arterial blood pressure and higher level of endothelin-I secreted from cultured brain cells. In this work, we present our immunohistochemical study of vasoactive peptides in brain and visceral organs from Cathepsin A -/- mice and their wild type-siblings. We showed higher level of endothelin-I and substance P accumulation in brain from 3 and 6 months old Cathepsin A-/- mice compared to wild-type mice. However, we found that Cathepsin A deficency did not result in significant accumulation in kidney, liver and lung. The detailed analysis of other vasoactive peptides including angiotension I, bradykinin and oxytocin in brain and visceral organs of Cathepsin A-/- mice will be valuable to understand better the physilogical role of this lysosomal enzyme in the modulation of vasoactive peptides and complex processes such as regulation of blood pressure.

The Yield of Clinical Genetic Testing for Isolated Left Ventricular Non-compaction (LVNC). *A.R. Shikany, A.S. Parrott, S. Ware, E.M. Miller.* The Heart Institute, Cincinnati Children's Hospital, Cincinnati, CO.

Left ventricular noncompaction (LVNC) is a distinct form of cardiomyopathy characterized by two layers of compacted and noncompacted myocardium with prominent trabeculations in the noncompacted layer. LVNC is clinically heterogeneous with subtypes including isolated LVNC (LVNC with otherwise normal left ventricular size, thickness, and function) and non-isolated LVNC (LVNC co-occurring with another form of cardiomyopathy). Mutations in 11 genes known to cause cardiomyopathy have been identified in 40% of cases of LVNC, not defined by subtype. This study sought to investigate the yield of genetic testing among patients with isolated LVNC. This retrospective chart review included patients evaluated in the multidisciplinary Cardiomyopathy Clinic at Cincinnati Children's Hospital between July 2009 and December 2012. Clinical data was collected on 169 patients from 144 families for whom LVNC was confirmed by a cardiologist. Seventy-one probands had a diagnosis of isolated LVNC and 73 probands had non-isolated LVNC. Of individuals with isolated LVNC, 46% (33/71) had genetic testing, of which 12% (4/33) had a disease-causing mutation. The yield of genetic testing in the non-isolated LVNC group was 33% (16/48). A variant of unknown significance (VUS) was identified in 21% (7/33) and 17% (8/48) of the isolated LVNC and non-isolated LVNC subtypes respectively. Of the individuals with isolated LVNC who had a disease-causing mutation, all (4/4) had a reported family history of LVNC, cardiomyopathy, or sudden cardiac death. Given the low yield of testing and risk for a VUS, results from this study suggest that testing for isolated LVNC may be of limited clinical utility in the context of a negative family history. Screening of first-degree relatives should be considered prior to genetic testing to confirm family history status. Healthcare providers should consider LVNC subtype in their provision of counseling regarding the benefits and limitations of genetic testing for LVNC.

2250W

Causative analysis of markers related to PR interval properties and atrial fibrillation after cardiac surgery. *M.I. Sigurdsson[1], J. Muehlschlegel[1], A. Fox[1], M. Heydarpour[1], P. Lichtner[2], T. Meitinger[2], C. Collard[3], S. Shernan[1], S.C. Body[1].* 1) Anesthesia, Perioperative and Pain Medicine, Brigham and Women's Hospital , Boston, MA; 2) Institut für Humangenetik, Neuherberg, Germany; 3) Division of Cardiovascular Anesthesia, Texas Heart Institute, Houston, TX, USA.

Several genetic loci linked to atrial fibrillation (AF) have also been associated with PR interval implying a mechanistic role. We determined the association between genetic variants and AF following coronary artery bypass surgery by pathways including, and independent, of the PR interval utilizing methodology that adjusts the association between a genetic marker and AF for properties of PR interval. Genetic variants associated with AF or PR interval from literature were tested for association with AF and PR interval in a cohort of 1314 patients undergoing coronary artery bypass grafting. Those associated with both were analyzed with association with poAF independent of the PR interval. Patients with AF had longer pre-operative PR interval, maximum PR interval and maximum change in PR interval and change in PR interval from pre-operative value. Two regions on 1q21 and 4q25 had several markers associated with both AF and the PR. All of those had association with AF independent of the PR interval. In contrast rs740178 on chromosome 16 (was associated with AF only via the PR interval. Our results highlight the utility of studying the molecular background of cardiac pathophysiology in a thoroughly phenotyped cohort of patient undergoing cardiac surgery.

2251T

Clinical and mutational spectrum in patients with cardiac glycogenosis related to mutations in the prkag2 gene. *J. Thevenon[1], G. Laurent[2], P. Charon[3], P. Laforêt[4], A. Millaire[5], D. Background: PRKAG2 mutations are responsible for an autosomal dominant muscular glycogenosis associating hypertrophic cardiomyopathies (HCM), ventricular pre-excitations (VPE), progressive atrio-ventricular blocks (AVB) and sometimes sudden cardiac deaths (SCD). **Objectives:** To describe the time dependent clinical occurrence of clinical manifestations of the disease. To define the indications for PRKAG2 mutation screening. **Methods and Results:** Clinical and molecular data of 34 patients from 9 families were gathered from a national French cohort of 140 patients tested for PRKAG2 gene since 2001. The pick-up rate varied from 0% when the indication was an isolated HCM to 20% when associated with a VPE (isolated short PR interval or WPW syndromes). Aside from the recurrent p.Arg302Gln (48%), we identified four new mutations. Time dependant risk of complication occurrence was estimated using a Kaplan-Meier method. At 40 years of age the chances to present with a VPE was 70% (99%-CI: 50%-87%), with a HCM was 61% (99%-CI: 41%-81%), and to die from a SCD was 20% (99%-CI: 8%-42%). At the 66 years, 32% of the patients required an implantable cardiac defibrillator and 2 required heart transplant at 55 and 60 years. No significant genotype-phenotype correlation has been found. However p.Arg302Gln mutation was less often associated with a HCM and no WPW syndrome was diagnosed in the p.Arg302Gln group. WPW radiofrequency ablation was associated with a complete AVB in 4/6 patients. **Conclusion:** Because of the risk of SCD, PRKAG2 screening may be useful in case of VPE with or without HCM.

Genetic profiling supports the causal role of type 2 diabetes, and fasting insulin and glucose in cardiovascular diseases. *E. Tikkanen[1,2], M. Pirinen[1], A.S. Havulinna[2], V. Salomaa[2], S. Ripatti[1,2,3,4].* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Hjelt Institute, University of Helsinki, Helsinki, Finland; 4) Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Epidemiological studies have identified several traits associated with cardiovascular disease (CVD), but few of these have been shown to be causal risk factors. Genetic information obtained from genome-wide association studies (GWAS) could be used to assess the causality of risk factors on disease. The aim of this study was to examine the causal biological pathways for CVD by genetic profiling of several risk factor traits. By utilizing the information from published GWAS, we generated genetic risk scores (GRSs) for blood lipids, obesity, blood pressure, inflammation and type 2 diabetes -related traits in Finnish case-cohort dataset (N=1974) with extensive clinical and follow-up data. The GRSs were calculated by summing the number of risk alleles and dividing the sum with the number of SNPs, after which each GRS were standardized (mean=0, SD=1). Associations between the GRSs and cardiovascular events were tested with Cox proportional hazards models and two-sided $P<0.05$ were considered to be statistically significant. To evaluate whether the GRS effects are governed by the proportion of heritability (h2) explained by the genetic variants, we estimated h2 from genome-wide data of Finnish cohorts (N(max)=14,073) and calculated the proportion of h2 explained by the GRS for each trait. We found that the GRSs for insulin, type 2 diabetes, triglycerides and total cholesterol increased the risk for incident coronary heart disease in an analysis adjusted for age and gender. The GRSs for type 2 diabetes and glucose were associated with incident stroke. In a multivariable analysis accounting for all risk factor traits and genetic risk scores, the GRS for insulin remained associated with coronary heart disease (HR=1.44, 95% CI 1.15-1.79). The GRSs for insulin and glucose account for 19% and 45% of the trait heritability, respectively. The proportion the GRS explains of the h2 was not correlated with the association of trait-based GRS with CVD risk (r=-0.005). We conclude that these results support the causal role of type 2 diabetes -related traits for cardiovascular disease.

Left ventricular non-compaction, Ebstein's anomaly and autosomal dominant polycystic kidney disease: A novel association and review of the vascular features of ADPKD. *L. Zahavich[1], A. Dipchand[1, 2], S. Bowdin[1, 2].* 1) The Hospital for Sick Children, Toronto, Canada; 2) University of Toronto, Toronto, Canada.

Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited renal disease and one of the most common genetic disorders with a prevalence of 1/400-1/1000. There are two known genes associated with ADKD, PKD1 and PKD2 accounting for about 90% of cases. Left ventricular non-compaction (LVNC) is characterized by persistent fetal myocardium leading to trabeculations and a thickened 2-layer myocardium. In some patients, this can result in heart failure. Familial recurrence of LVNC has been reported in about 20% of cases. Genetic causes include sarcomere gene mutations, Barth syndrome and chromosomal variants. We present a case of a 2 year old boy who was diagnosed with Ebstein's anomaly and echogenic kidneys prenatally. He presented with congestive heart failure at 3 weeks of age and was then diagnosed with LVNC. At 9 months he was found to have bilateral renal cystic disease. Family history is significant for PKD, bicuspid aortic valve and aortic aneurysm in his mother as well as PKD and valvular disease in extended maternal relatives. Testing of the MYH7 gene was organized given the association between LVNC, Ebstein's anomaly and MYH7 mutations and was normal. The patient also had a chromosome microarray which was normal. He was subsequently found to have a well described mutation in PKD1 (p.Q4042X). Vascular abnormalities are frequent in patients with ADPKD, particularly hypertension and valvular disease. Common valvular anomalies include mitral valve prolapse, mitral or tricuspid valve regurgitation and aortic root dilatation. There have been reports of left ventricular hypertrophy associated wth ADKPD, including in those who are normotensive. Previous studies have also noted an increased prevalence of dilated cardiomyopathy in patients with ADPKD. To date, there have been three reported cases of LVNC in patients with ADPKD, two adults and one pediatric case. The pathogenesis of ADPKD is currently unknown, however a 'two-hit' model of cyst formation has been hypothesized. This model proposes that PKD null cells induce apoptosis of surrounding normal cells leading to cyst formation. Cardiac defects and abnormal myocyte trabeculations have been described in PKD1 mutant mice. A potential mechanism for LVNC in patients with ADPKD could involve induced apoptosis of the myocardium leading to persistent trabeculations. Further studies of the cardiac phenotype in ADKPD are required to assess the relationship between ADPKD and LVNC.

Identification of Copy Number Variation (CNVs) in patients with Isolated Conotruncal Heart Defects: a family trio study. *J. Arteaga-Vazquez[1], A. Aguayo[1], Y. Svyryd[1], G. Vargas[2], JE. Calderon[2], C. Zamora[2], O. Mutchinick[1].* 1) Genetics, Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, México, D.F., México; 2) Instituto Nacional de Cardiología Ignacio Chávez. México, D.F.

Background: Copy number variations (CNVs) were initialy recognized as genomic non-functional rare rearrangements but currently around 180,000 CNVs are identified along the human genome and contribute approximately to 5% of genome variation among individuals. CNVs can impact phenotypes by gene dosis modifications. Besides, Tetralogy of Fallot (ToF) is present in 1/3000 live births and accounts for 60% of conotruncal malformations. Associated mutations have been described in early developmental genes including *NKX2-5*, *NOTCH1*, *TBX1*, *JAG1*, *NOTCH2*. Studying nuclear families, Greenway et al. identified seven CNVs associated with an increased risk for ToF, three of which involved genes previously associated with heart disease: *TBX1*, *NOTCH1* and *JAG1*. On the other hand, MLPA is a high performance and low cost technique that allows the analysis of over 40 target genome sequences with a single pair of primers in a single reaction. Aim: To identify the frequency and type of certain CNVs related to congenital heart disease, including those present in specific genes (*GATA4*, *NKX2-5*, *TBX5*, *BMP4*, *CRELD1*) and other 48 genomic sequences distributed throughout the chromosomal regions: 10p14, 4q35, 17p13, 22q11 and 22q13 by means of MLPA technique in a sample of Mexican patients with ToF, their parents and a control group. Material and Methods: 28 family trios in which the propositus had the diagnosis of ToF and 28 healthy controls were analyzed with the MLPA technique using the P311 and P250 kits from MRC-Holland®. Real Time-PCR and FISH with specific probes were used to validate the results. Results: One propositus showed a de novo CNV in the *TBX1* gene, involving exons 2 and 7, both parents were normal. We did not observe any CNV in the control group. Conclusions: We identified a *TBX1* gene deletion in 1/28 cases with ToF, which was not detected by conventional karyotype or FISH analysis for the 22q11 region. The proportion of cases with de novo CNVs in our sample is according to the observed by other research group. The *TBX1* variant in our patient could explain the presence of ToF due to the participation of this gene in early cardiac development. The MLPA technique allows the detection of chromosomal alterations such as microdeletion and microduplication not identified by conventional karyotype or FISH analysis, at a low cost and with a fast performance.

Identification of Global Methylation Markers for Myocardial Infarction in Males. *J.M. Devaney[1, 2], B.T. Harmon[2], E.P. Hoffman[2], S.E. Epstein[1].* 1) Head, Translational and Vascular Biology Research, MedStar Health Research Institute, Washington, DC; 2) Dept. Integrative Systems Biology Research Center for Genetic Medicine Children's National Medical Center 111 Michigan Ave, NW Washington DC 20010.

The leading cause of death in the world is coronary artery disease (CAD). There have been numerous risk factors identified for the development of CAD and it's main complication myocardial infarction (MI), including high plasma lipid concentrations, high blood pressure, smoking, diabetes, and markers of inflammation. We hypothesized that epigenetic markers may add to the growing etiology of myocardial infarction and provide additional biomarkers that can be used to predict MI in individuals with CAD. METHODS: The DNA was extracted from whole blood and analyzed for methylation changes using the Illumina HumanMethylation450 BeadChip (485,577 CpG sites). Statistical analysis was completed on 395,899 CpG sites (Partek Genomics Suite) comparing males with stable CAD (n = 7) and CAD and MI (n = 7). Any CpG sites with an average Beta value less than 0.1 was removed due to the sensitivity of the BeadChip assay. RESULTS: After the scrubbing of data, 7,131 CpG sites were significantly different between males with stable CAD and males with CAD with MI ($p < 0.05$). There were 1,710 CpG sites that showed a higher beta value in CAD group compared to CAD with MI. The top ranked CpG site by p-value ($p = 2.38 \times 10^{-06}$; cg08053846) was located in the promoter of the gene SERPINE1 and showed 81 percent higher beta value in individuals with stable CAD. CONCLUSIONS: This work provides new insight into the biological differences between individuals with stable CAD and CAD with a myocardial infarction. Additionally, we can utilize epigenetic markers to discern novel pathways involved in MI disease etiology.

Evaluation of the Familiality of Cardiovascular Diseases among Patients in a Large Healthcare System. *S. Knight[1,2], B. Horne[1,2].* 1) Intermountain Heart Institute, Intermountain Medical Center, Murray, UT; 2) Division of Genetic Epidemiology, University of Utah,Salt Lake City, UT.

Objective: To determine the familiality of cardiovascular diseases(CVD) Methods: The Intermountain Genealogy Registry, which contains genealogies for 700,000 patients(pts) in the Intermountain Healthcare System, was used. One-way and two-way genealogy index of familiality (GIF) were generated. Results: The overall pts GIF (pGIF) was 0.443. The GIF for patent foramen ovale (PFO) was >40% and myocardial infarction (MI) was >10% larger than the pGIF. No two-way GIF were >10% larger than the pGIF. Conclusions: PFO and MI had a stronger familial component than other CVD. Narrowing phenotypes may increase the GIF.

GIF	MI	HF	CAD	HTN	PFO	Valve
MI	0.488	0.462	0.470	0.453	0.474	0.466
HF		0.471	0.457	0.446	0.453	0.458

Genome-wide linkage and positional association study of blood lipid phenotypes: The GenSalt study. *C. Li[1], J.E. Hixson[2], L.C. Shimmin[2], D.C. Rao[3], D. Gu[4], J. He[1], T.N. Kelly[1].* 1) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, USA; 2) Department of Epidemiology, University of Texas School of Public Health, Houston, TX, USA; 3) Division of Biostatistics, Washington University School of Medicine, St Louis, MO, USA; 4) State Key Laboratory of Cardiovascular Disease, Fuwai Hospital, National Center of Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

The genetic mechanisms underlying lipid levels remain largely unknown. We conducted a genome-wide linkage scan and positional association analysis of blood lipid phenotypes among Han Chinese participants of the Genetic Epidemiology Network of Salt Sensitivity (GenSalt) study. Overnight fasting blood samples were drawn by venipuncture at a baseline examination among 1,881 GenSalt participants from 633 families. Total cholesterol (TC), high density lipoprotein cholesterol (HDL-C) and triglycerides (TG) were analyzed enzymatically using commercially available reagents. Low density lipoprotein cholesterol (LDL-C) levels were calculated using the Friedewald equation. Lymphocyte DNA samples were used for genotyping microsatellite markers and single nucleotide polymorphisms (SNPs). Multipoint quantitative trait linkage-analysis was performed for each of the TC, HDL-C, LDL-C, and log-transformed TG phenotypes using SOLAR software. Additive associations between each SNP in identified linkage regions (LOD>2) and the lipid phenotypes were assessed using a mixed linear regression model to account for family dependencies. The false discovery rate (FDR) method was used to adjust for multiple testing. Phenotypes were adjusted for age, gender, body mass index and field center in all analyses. Suggestive linkage signals were identified at 4p15.1-4p14 [maximum multipoint LOD score (MML)=2.45 at 4p15.1] for the LDL-C phenotype. Follow-up association analyses in this region revealed a significant association between novel marker rs2995976 and LDL-C after adjustment for multiple testing (P= 3.73×10^{-5}; FDR-Q=0.03). Mean LDL-C levels for rs2995976 genotypes G/G, A/G, and A/A were 88.36 (82.56 to 94.17), 93.06 (90.62 to 95.50), and 97.69 (95.97 to 99.41) mg/dL, respectively. SNP rs2995976 lies upstream from *PGM2*, a gene indirectly involved in pathways of fatty acid production and energy generation. Furthermore, we observed suggestive linkage at 2p11.2-2q12.3 (MML=2.22 at 2q11.2) and 11q25 (MML=2.21 at 11q25) for the log-transformed TG phenotype. Follow-up analyses did not reveal any significant association signals in this region. In summary, genomic regions on chromosomes 2, 4 and 11 may harbor important susceptibility loci for lipid phenotypes. In addition, a novel variant upstream of the *PGM2* gene was significantly associated with LDL-C. Further study is needed to confirm these findings.

2258F

Genome-wide linkage and regional association study of blood pressure response to cold pressor test in Chinese: the GenSalt study. *X. Yang[1], T.N. Kelly[2], X. Wu[1], J.E. Hixson[3], J. Chen[1], J. Cao[1], J. Li[1], L.C. Shimmin[3], J. Huang[1], D.C. Rao[4], J. He[2], D. Gu[1].* 1) State Key Laboratory of Cardiovascular Disease, Fuwai Hospital, National Center of Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; 2) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, USA; 3) Department of Epidemiology, University of Texas School of Public Health, Houston, TX, USA; 4) Division of Biostatistics, Washington University School of Medicine, St Louis, MO, USA.

The cold pressor test (CPT) has been documented to evaluate cardiovascular reactivity to stress. However, genetic mechanisms underlying blood pressure (BP) response to CPT remain unclear. We performed a genome-wide linkage scan and regional association analysis to identify genetic determinants of BP response to CPT. A total of 1,998 Han Chinese participants from the Genetic Epidemiology Network of Salt Sensitivity (GenSalt) study completed the CPT. BP measurements were obtained before and after the participants immersed their hands in ice-water for 1 minute. BP response to the CPT was defined as BP at time zero after ice-water immersion minus the pre-test BP. Multipoint quantitative trait linkage analysis was performed using SOLAR software. The additive associations between single SNPs in linkage regions (LOD>2) were assessed using a mixed linear regression model to account for familial correlations. In addition, gene-based associations under linkage peaks were also examined using the truncated product method. Age, gender, field center, and body mass index were adjusted in all analyses. The results showed that suggestive linkage signals were identified for BP responses to CPT at 20p13-20p12.3, with maximum multipoint LOD scores of 2.38 for systolic BP (SBP) response, 0.13 for diastolic BP (DBP) response and 1.30 for mean arterial pressure (MAP) response. Marker rs2326373, located in the 5' flanking region of the *SMOX* gene at 20p13, was significantly associated with DBP and MAP responses to CPT (P= 4.49×10^{-5} and 8.52×10^{-6}, respectively). DBP responses (95% CI) for genotypes G/G, G/A, and A/A were 6.84 (6.44 to 7.23), 4.11 (2.83 to 5.40), and 4.22 (3.13 to 5.31) mmHg, respectively, and MAP responses (95% CI) were 8.97 (8.56 to 9.39), 6.48 (5.27 to 7.69), and 3.91 (2.80 to 5.02) mmHg, respectively. A similar trend was also observed for SBP response. In addition, results of gene-based analyses showed that variants in genes *MCM8* and *SLC23A2* were jointly associated with SBP response to CPT (P= 4.0×10^{-5} and 2.2×10^{-4}, respectively), and variants in genes *MCM8* and *STK35* were jointly associated with MAP response to CPT (P=2.0×10^{-5} and 2.9×10^{-4}, respectively). In summary, under a suggestive linkage region on chromosome 20, we identified a novel variant near *SMOX* which showed strong and consistent associations with SBP, DBP and MAP responses to CPT. In addition, we identified gene-based associations of *MCM8*, *SLC23A2* and *STK35* in this region.

2259W

Whole-genome expression profile of calcified bicuspid and tricuspid aortic valves. *S. Guauque-Olarte[1], N. Gaudreault[1], P. Pibarot[1], P. Mathieu[1], Y. Bossé[1,2].* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

BACKGROUND: Calcific aortic valve stenosis (AS) is a fatal disease with no medical treatment other than surgery. Bicuspid aortic valve (BAV) is present in 1-2% of the population. Patients with BAV have increased risk of AS and develop symptoms 10-15 years younger than patients with a tricuspid valve (TAV). The objective of this study was to identify genes differentially expressed between BAV and TAV with and without calcification. METHODS: Twelve calcified BAV and 12 calcified TAV were explanted from white male patients who underwent aortic valve replacement surgery. All valves had the same degree of fibro-calcific remodeling. Non-stenotic TAV (controls) were taken from 12 white males who underwent heart transplantation. The gene expression profile of each valve was measured with the Illumina HumanHT-12 v4 Expression BeadChip. Normalization and quality controls were performed with the lumi package in R. Gene expression levels were compared between the three groups of valves (BAV, TAV, and controls) using the Significance Analysis of Microarrays program. A false discovery rate of 5% and a fold change cut-off of 2 were used. Pathway analysis was performed using Ingenuity Pathway Analysis. The microarray results will be compared with RNA-Sequencing data from the same valves performed on the Illumina HiSeq2000. RESULTS: Two up-regulated and 2 down-regulated genes were identified in BAV compared to calcified TAV. For the comparison BAV vs controls, 128 genes were differentially expressed including 80 genes up-regulated in BAV. Compared to controls, 42 genes were up-regulated in calcified TAV, while 21 genes were down-regulated. The genes differentially expressed between BAV and calcified TAV were significantly linked to pathways and functions related to AS development and progression including connective tissue disorders (p= 2.09E-4 - 6.07E-4), inflammatory disease (p=2.09E-4 - 2.69E-2), and cell death and survival (p=3.17E-4 - 4.53E-2). CONCLUSIONS: The gene expression profiles of calcified BAV and TAV are highly similar. In contrast, aortic stenosis induced substantial changes in aortic valves gene expression. The results of this study increased our understanding of the molecular basis of BAV and associated calcific stenosis. Expected outcomes are new therapeutic targets to prevent, slow the development or treat AS in patients with BAV and calcified TAV.

2260T

Peripheral blood microRNA profiles are associated with cardiometabolic disease. *L.C. Kwee[1], W.E. Kraus[1], U. Hidefumi[2], H. Toyoshiba[2], T. Andou[2], E.R. Hauser[1], S.G. Gregory[1], J. Bain[1], M. Muehlbauer[1], R. Urquhart[2], C.B. Newgard[1], S.H. Shah[1].* 1) Duke Institute of Molecular Physiology, Duke University Medical Center, Durham, NC; 2) Pharmaceutical Research Division, Takeda Pharmaceutical Company, Japan.

MicroRNAs (miRNAs) are short, noncoding RNA molecules that affect gene expression and have been implicated in cardiometabolic diseases. Small-molecule metabolites also are associated with these phenotypes; however, miRNA and metabolite profiles have not been integrated in cardiometabolic disease studies. We examined the relationship between circulating miRNA profiles with metabolites and cardiometabolic phenotypes to identify miRNAs that may mediate cardiometabolic outcomes. Fasting plasma samples were obtained from 712 subjects selected from the CATHGEN biorepository of patients referred for cardiac catheterization at Duke University. MiRNA levels were assayed using TaqMan RT-qPCR arrays, and the most variable quantile of mean-normalized miRNAs was used for analysis. Lipids, glucose, ketones, free fatty acids, 15 amino acids and 45 acylcarnitines were assayed using biochemical methods or targeted mass spectrometry. Outcome phenotypes were clinical cardiometabolic phenotypes (BMI, blood pressure, diabetes, and severity of coronary artery disease) and 14 orthogonal factors identified from principal components analysis of the metabolites. Regression models were used to test the association of each miRNA with each phenotype, adjusting for age, sex and race. Sixty-six miRNAs were significantly associated with at least one phenotype ($p<5\times10^{-4}$, Bonferroni adjusted for multiple testing of 101 miRNAs). Most of these were associated with a factor composed primarily of free fatty acids, serine and histidine (53 miRNAs, lowest $p=10^{-22}$) or with triglyceride levels (41 miRNAs, lowest $p=10^{-12}$); 36 miRNAs were associated with both phenotypes. The predicted gene target for the most significant miRNA, miR-21, is *YOD1*, which is involved in the biosynthesis of unsaturated fatty acids (KEGG). Additionally, multiple miRNAs were associated with long-chain acylcarnitines (10 miRNAs, lowest $p=3.1\times10^{-6}$), short-chain dicarboxylacylcarnitines (6 miRNAs, lowest $p=1.7\times10^{-6}$), a factor composed primarily of asparagine/aspartic acid and glutamine/glutamic acid (5 miRNAs, lowest $p=4.2\times10^{-5}$), and glucose (4 miRNAs, lowest $p=3.2\times10^{-5}$). In one of the largest studies of miRNAs in human cardiometabolic disease, we have identified biologically plausible and novel phenotypes associated with peripheral blood miRNA levels. These miRNAs and their predicted targets are excellent candidates for further analysis as potential regulators of cardiometabolic phenotypes.

DYNAMICS OF HSPC SUBTYPES IN NON-HUMAN PRIMATES REVEALED BY A DECADE-LONG CLONAL TRACKING STUDY. *S. Kim[1], N. Kim[6], A. Presson[2], M.E. Metzger[5], G.M. Crooks[3], D. An[4], R.E. Donahue[5], I.S.Y. Chen[1].* 1) Microbiology, Immunology, and Molecular Genetics; 2) Biostatistics; 3) Pathology and Laboratory Medicine; 4) School of Nursing, University of California Los Angeles, Los Angeles, CA 90095; 5) National Heart, Lung and Blood Institute, NIH, Bethesda, MD 20892; 6) Korean Bioinformatics Center, Daejeon, South Korea.

Hematopoietic stem cell and progenitor cell (HSPC)-based genetic therapy to treat HIV/AIDS and other previously incurable diseases is becoming increasingly realistic. To date, however, our understanding of the regenerative potentials of primate HSPCs lags far behind the level desired for current and future uses of these cells for therapeutic purposes. Here, we report detailed behavior patterns of repopulating HSPCs in four rhesus macaques transplanted for up to 12 years with autologous CD34+ HSPCs engineered with control lentivirus vectors expressing a fluorescence marker (EGFP) or therapeutic vectors expressing an shRNA against the C-C chemokine receptor type 5 (CCR5-shRNA), an essential co-receptor for R5-tropic strains of HIV-1. All animals showed normal hematopoietic recovery and maintained stable EGFP marking in all tested blood lineages. In order to study in vivo HSPC behaviors at the single cell level, vector marked clones in serially collected blood were analyzed by large-scale vector integration site (VIS) sequencing and bioinformatics analysis of genomic VIS sequences. Our long-term clonal tracking study revealed novel mechanistic insights into complex polyclonal hematopoietic reconstitution in primates, not seen in traditional population-based studies. Analysis revealed thousands of HSPC clones successfully engrafted and expanded sequentially over time in each animal, clustered into groups with different kinetics of repopulation, maintaining the total marked blood cells at a relatively stable level over the years. Consistent with recent discoveries in murine HSC studies, the long-term repopulating clones were distinctively grouped into 'myeloid-biased', 'lymphoid-biased', and 'balanced' subtypes based on their unique lineage output potentials. Interestingly, clones with more balanced lineage potentials, accounted for only 4 - 10% of the identified clones, yet predominated, contributing up to 25 - 71 % of total repopulating cells in test animals. Expression of a therapeutic gene for HIV/AIDS (CCR5-shRNA) also showed no notable effects on HSPC behaviors. This study is the first system level description of the detailed in vivo behavior patterns of primate HSPCs, providing new insights into primate repopulation. Our data also provide a potential frame of reference for future HSPC-based gene-therapies.

Long term outcome and success of liver transplantation in patients with progressive familial intrahepatic cholestasis: is there an association between genotype and outcome? *S.M. Herbst[1], J. Vermehren[2], M. Melter[2], U. Hehr[1].* 1) Center for Human Genetics, University of Regensburg, Regensburg, Germany; 2) Children's Hospital , University Hospital Regensburg, Regensburg, Germany.

Study and Objective: Infants with progressive familial intrahepatic cholestasis(PFIC) develop liver failure in the first or second decade and ultimately require liver transplantation. Three causal genes necessary for bile flow across the canalicular membrane have so far been identified: *ATP8B*1, *ABCB4* and *ABCB11*. Our aim was to further characterize the genotype phenotype relationship and to search for prognostic genetic parameters for long term outcome as well as the success of liver transplantation in order to improve individual treatment options for PFIC patients. **Method:** A total of 52 PFIC index patients were analyzed by direct sequencing between 2008 and 2012 for mutations in *ATP8B1, ABCB4* and *ABCB11*. Extensive long term follow-up data (follow-up range 2-35 years) of 8 patients with genetically confirmed PFIC was retrospectively analyzed to illustrate the specific problems in interdisciplinary medical care. **Results:** Most pathogenic mutations in PFIC patients were identified in *ABCB11* (56%), followed by *ATP8B1* (32%) and *ABCB4* (12%). Overall the most frequently detected type of mutations were missense mutations (73%), followed by truncating mutations (17%), splice mutations (7%) and small deletions (3%). 9 novel mutations were identified. Response to pharmacological therapy was insufficient in 87% of patients, thus, 62% of patients underwent biliary diversion. Subsequently, liver transplantation was performed in 5 out of 8 patients; one additional patient is currently listed for LTX at the age of 17 months. Liver transplantation was complicated by: bleeding and coagulation problems, severe rejection requiring retransplantation (1) and death (1). Interestingly, both patients with life threatening complications were carrier of a truncating *ABCB11* mutation. After successful liver transplantation the most severe long term complications were observed in *ATP8B1* mutations carriers and included: severe chronic diarrhea (>12x/d), renal failure (1 requiring renal transplant), missing catch-up growth, pancreatitis, deafness and polyneuropathy. **Conclusion:** Truncating mutations may be associated with a higher rate of complications in liver transplantation, possibly due to a stronger immune reaction towards the wild type protein. With an ongoing interdisciplinary study we address two major objectives (1) evaluating this hypothesis in a larger cohort and (2) using whole genome sequencing to search for further PFIC candidate genes in mutation negative patients.

First U.S. Orthotopic Liver Transplantation for Intractable Acute Intermittent Porphyria. *A. Ludtke[1], M. Balwani[1], L.U. Liu[2], H. Naik[1], M. Yasuda[1], A. Arvelakis[3], C. Yu[1], S.S. Florman[3], R.J. Desnick[1].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Division of Liver Diseases, Department of Internal Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Recanati/ Miller Transplantation Institute, Icahn School of Medicine at Mount Sinai, New York, NY.

Acute Intermittent Porphyria (AIP) is a rare autosomal dominant inborn error of heme biosynthesis due to the half normal activity of hydroxymethylbilane synthase. The disease is characterized by life-threatening acute neurovisceral attacks which are triggered by certain drugs, dieting, and hormonal factors that markedly increase the expression of 5-aminolevulinate synthase 1, resulting in the increased hepatic production of the neurotoxic metabolites aminolevulinic acid (ALA) and porphobilinogen (PBG). Patients may be asymptomatic, experience sporadic attacks, or may have frequent attacks, which are treated with intravenous hemin; recurrent attacks may be difficult to control even with weekly hemin infusions. Since the liver is the major source of the overproduced ALA and PBG, orthotopic liver transplantation has led to complete clinical and biochemical correction in several patients who failed medical management in Europe. Here, we report the first US liver transplantation in a 36 year old Caucasian woman with intractable AIP, who was diagnosed at age 27 (HMBS mutation R173W). She had recurrent acute attacks, which became refractory to hemin and developed complications such as generalized paresis, chronic axonal polyneuropathy, multiple port infections and had prolonged hospitalizations. She became increasingly disabled, depressed and required very high doses of opiates for pain control. After 13 months of hospitalization, orthotopic liver transplantation was undertaken. Pre-transplant urinary ALA and PBG concentrations ranged from 4.0-17.6 mmol/mol creat (norm <3.0) and 14.2-75.6 mmol/mol creat (norm <1.1), respectively; plasma ALA and PBG levels were 2.0-2.7 uM (<0.2) and 4.7-5.9 uM (<0.05). Post transplant, urinary and plasma ALA and PBG concentrations both normalized by 5 and 23 hours, respectively. The chronic AIP-related pain resolved 4 days after surgery. Histological studies of the explanted liver revealed steatosis and cirrhosis due to iron overload secondary to the chronic hemin therapy. These results demonstrate that liver transplantation can correct the metabolic defect with dramatic biochemical and clinical improvement. We conclude that liver transplantation with its inherent morbidity and mortality should be considered in severely affected patients with acute hepatic porphyrias that are refractory to current medical management.

Creation of a new mouse model for the mRNA splicing disease Familial Dysautonomia.
E. Morini[1], P. Dietrich[2], I. Dragatsis[2], M. Salani[1], F. Urbina[1], S.A. Slaugenhaupt[1]. 1) Center for Human Genetic Research, Massachusetts General Hospital/Harvard Medical School, Boston, MA; 2) Department of Physiology, The University of Tennessee, Health Science Center, Memphis, TN.

Recent studies emphasize the importance of mRNA splicing mutations in genetic disease, with some estimates suggesting that around 30% of point mutations disrupt mRNA splicing. Familial dysautonomia (FD) is an excellent disease model for studying new strategies to correct splicing defects. FD is a recessive neurodegenerative disease caused by a splice mutation in the IKBKAP gene which leads to variable skipping of exon 20. We found that the small molecule kinetin can correct the IKBKAP splicing defect and increase the amount of normal mRNA and protein in FD cell lines. We have also shown that kinetin can increase the level of functional IKAP protein in mice following oral dosing in all tissues tested, including brain. Despite these remarkable advances, including our demonstration of in vivo efficacy to increase normal IKBKAP mRNA in the blood of FD patients, we lacked animal model in which to test the effect of targeting mRNA splicing to increase IKAP protein on FD phenotype. In order to create a phenotypic model of FD in which we could also manipulate mRNA splicing we introduced an FD transgene (TgFD9), which contains the human IKBKAP gene with the major FD splice mutation, into the Ikbkap Δ20/flox mouse model by sequential mating. The introduction of the human IKBKAP transgene attenuates the severe FD phenotype that we observed in the Ikbkap Δ20/flox mouse and recreates the same tissue-specific mis-splicing defect. TgFD9/IkbkapΔ20/flox mice show a reduced growth rate but, unlike Ikbkap Δ20/flox mice which die perinatally, most FD9/Ikbkap Δ20/flox mice survive postnatally. Methylene blue staining of tongues shows that FD9/Ikbkap Δ20/flox mice have a reduction of fungiform papillae. Since several FD-like features are present at birth, we analyzed body weight, superior sympathetic ganglia (SCG), stellate ganglia (SG) and cervical DRGs in E18.5 FD9/Ikbkap Δ20/flox embryos. Already at this stage the FD9/Ikbkap Δ20/flox embryos accurately model many features of the human disease. Furthermore, we characterized the mechanism underlying the low levels of endogenous mouse Ikbkap expression in FD9/Ikbkap Δ20/flox mice. Our results demonstrate that the new TgFD9 Ikbkap Δ20/flox mouse accurately models both the disease phenotype and the tissue-specific mRNA mis-splicing defect seen in FD patients. The creation of this new model has allowed us to initiate a detailed clinical trial of kinetin and will permit testing of other strategies for targeting mRNA splicing.

2265T

Phosphatidylserine: A potential gene modifying therapy for Familial Dysautonomia?
M. Salani[1], L. Norcliffe-Kaufmann[2], J. Martinez[2], E. Morini[1], F. Axelrod[2], S. Slaugenhaupt[1]. 1) Center for Human Genetic Research,-Massachusetts General Hospital, Harvard Medical School, Boston, MA; 2) Dysautonomia Center, New York University School of Medicine, New York, NY.

Familial dysautonomia (FD) is caused by a splicing error in the IKBKAP gene that encodes human Elongator protein 1. In these patients, exon 20 is frequently skipped during mRNA splicing, but cells retain the ability to produce a low level of normal (wild-type) IKBKAP mRNA and normal IKAP protein. Phosphatidylserine (PS, Sharp-thought®), an acidic phospholipid, has been shown to raise IKAP levels in fibroblast cell lines derived from FD patients by increasing IKBKAP transcription(1).Given that PS is safe and available over the counter we conducted a preliminary study to determine if PS increases IKBKAP expression in patients with FD. We enrolled 6 patients with FD, 16 to 23 years old, in an open-label titration protocol. Patients were examined at baseline (visit 1), after 2 months of taking 300 mg/day (visit 2) and again after 2 months of taking 600 mg/day of PS (visit 3). Blood was taken at each visit and de-identified and investigators blinded to sample identity. Blood was treated with Tri-Reagent, and RNA extracted according to manufacturer's specifications. Quantitative PCR was performed to measure the level of normal IKBKAP mRNA. PS was well tolerated and there were no adverse events or unexpected clinical abnormalities. No increase in IKBKAP was observed after two months of treatment with 300 mg/day, however, we did see an increase in four of six patients after an additional two months of 600mg/day PS. Our preliminary results indicate that PS might safely raise normal IKBKAP mRNA levels in blood from patients with FD, opening an exciting potential therapeutic path for the treatment of FD. A more extensive analysis using a larger number of patients and an increased dose of PS is underway. 1 Keren et al., PLoS One. 2010 Dec 29,5 (12): e15884.

Inhibition of retinoic acid signaling rescues inner-ear defects in a mouse model of CHARGE syndrome.
J.M. Skidmore[1], E.A. Hurd[2], A. Saiakhova[3], D.L. Swiderski[4], E.D. Sperry[5], P.S. Scacheri[3], Y. Raphael[5], D.M. Martin[1,5,6]. 1) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Centre for Neuroregeneration, University of Edinburgh, Edinburgh, Scotland; 3) Department of Genetics and Genome Sciences, School of Medicine, Case Western Reserve University, Cleveland, OH; 4) Department of Otolaryngology, University of Michigan, Ann Arbor, MI; 5) Medical Scientist Training Program, University of Michigan, Ann Arbor, MI; 6) Department of of Human Genetics, University of Michigan, Ann Arbor, MI.

CHARGE syndrome, a multiple congenital anomaly disorder, and *in utero* vitamin A deficiency or toxicity share many common developmental features including craniofacial defects, vision and hearing deficits, cardiac anomalies, and growth delays. CHARGE syndrome is caused by mutations in *CHD7*, encoding an ATP-dependent chromatin remodeling protein that regulates downstream target gene expression. Here we tested, using heterozygous loss of function *Chd7* mutant mice ($Chd7^{Gt/+}$), whether *Chd7* deficiency affects retinoic acid signaling and if altered retinoic acid signaling in utero influences *Chd7* mutant phenotypes. We focused specifically on the inner ear, due to the highly penetrant semicircular canal defects observed in both humans and mice with CHD7 deficiency. RNA-seq of microdissected e10.5 inner ear tissues revealed 50% or greater upregulation of 425 genes and downregulation of 146 genes in $Chd7^{Gt/+}$ compared to wild type mice. Several genes emerged as potential targets of CHD7, including genes encoding retinoic acid synthetic enzymes (*Aldh*), degradation enzymes (*Cyp26*), and receptors (*Rar, Rxr*). To test whether retinoic acid signaling during pregnancy influences *Chd7* deficiency phenotypes, we administered retinoic acid or citral (a retinoic acid inhibitor) to pregnant mice at e7.5. $Chd7^{Gt/+}$ and wild type embryos were dissected at e14.5 and inner ear structures analyzed after paint-filling. Retinoic acid treatment worsened, or had no effect on, $Chd7^{Gt/+}$ inner ear defects, whereas citral treatment partially corrected the typically fully penetrant semicircular canal dysgenesis. Levels of retinoic acid were monitored in *Chd7* mutant vs. wild type embryos using RARE (retinoic acid response element) reporter mice, which express β-galactosidase in response to retinoic acid. $Chd7^{Gt/+}$ embryos exhibited mildly increased β-galactosidase staining in the developing cochleovestibular ganglion, consistent with enhanced RA signaling. Aberrant retinoic acid signaling and gene expression with loss of *Chd7*, together with partial rescue of *Chd7* deficient phenotypes upon retinoic acid inhibition support an essential role for vitamin A metabolism in *Chd7* deficiency states. These studies have implications for understanding the pathogenesis of phenotypes in CHARGE syndrome, including variable expressivity and reduced penetrance of organ specific defects, and for enhancing ongoing efforts to develop effective therapies for CHARGE individuals.

Myhre syndrome-causing SMAD4 mutations result in disorganization of extracellular matrix that is corrected by losartan treatment.
P. Piccolo[1], P. Mithbaokar[1], V. Sabatino[1], J. John Tolmie[2], D. Melis[3], M.C. Schiaffino[4], M. Filocamo[5], G. Andria[3], N. Brunetti-Pierri[1,3]. 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Ferguson-Smith Department of Clinical Genetics, Yorkhill Hospital, Glasgow, UK; 3) Department of Translational Medicine, Federico II University of Naples, Naples, Italy; 4) Clinica Pediatrica, Istituto G. Gaslini, Genova, Italy; 5) Centro di Diagnostica Genetica e Biochimica delle Malattie Metaboliche, Istituto G. Gaslini, Genova, Italy.

Myhre syndrome (MIM 139210) is an autosomal dominant connective tissue disorder that presents with short stature, short hands and feet, facial dysmorphic features, muscle hypertrophy, thickened skin, and deafness. Myhre syndrome is caused by recurrent missense mutations affecting codon Ile500 of SMAD4 encoding a transducer mediating transforming growth factor β (TGF-β) signaling. We investigated the functional consequences of SMAD4 mutations in Myhre syndrome fibroblasts and observed altered expression of genes encoding matrix metalloproteinases and related inhibitors and a defect of extracellular matrix deposition. Disruption of microfibril network results in increased TGF-β bioavailability. Increased TGF-β signaling and progression of aortic root dilation in Marfan syndrome, a common connective tissue disorder, can be prevented by losartan, a TGF-β antagonists and angiotensin II type 1 receptor (AT1) blocker. In this study, we investigated whether losartan is effective at improving the extracellular matrix deposition defect of Myhre syndrome cells. We showed that losartan normalizes SMAD2 phosphorylation, restores balance of metalloproteinases and related inhibitors, and improves the extracellular matrix deposition in fibroblasts from Myhre syndrome patients. The results of this study may pave the way towards therapeutic applications of losartan in Myhre syndrome.

Tumor associated macrophages in neurofibromatosis. *C. Prada[1,3], E. Jousma[2], T. Rizvi[2], J. Wu[2], S. Dunn[2], N. Ratner[2].* 1) Dept Pediatrics Genetics, Cincinnati Children's Hosp Med Ctr, Cincinnati, OH; 2) Divisions of Experimental Hematology and Cancer Biology, Cincinnati Children's Hosp Med Ctr, Cincinnati, OH; 3) Center for Genomic Medicine and Metabolism, Cardiovascular Foundation of Colombia, Floridablanca, Colombia.

Background: Plexiform neurofibromas (PNFs) are one of the most common and debilitating complications of Neurofibromatosis type 1 (NF1). In animal models, Nf1-/- Schwann cells secrete large amounts of chemoattractants (RANTES, SCF, M-CSF, and VEGF), enhancing migration of mast cells toward the peripheral nerve. Macrophages can be recruited by several cytokines including RANTES and VEGF. We previously identifed macrophages infiltrating mouse PNFs. Macrophage can have anti-tumor (M1) or pro-tumor (M2) role at different cancer stages. We hypothesized that macrophages infiltration correlates with tumor progression and macrophage depletion induces cell death in Schwann cells. Methods: We tested this hypothesis in the Dhh-Cre; Nf1flox/flox mouse model of neurofibroma and human PNFs and MPNSTs. Immunohistochemistry was performed to quantify macrophage infiltration and macrophage subtype (M1 and M2 markers) in peripheral nerves and tumors at different disease stages to evaluate if increasing numbers of Iba1+CD11b+ cells correlates with progression (n= 20). Then, we treated 7 Dhh-Cre; Nf1flox/flox mice with 50mg/kg of minocycline, a broad-spectrum antibiotic that partially depletes macrophages, by i.p. injection and 7 Dhh-Cre; Nf1flox/flox mice with vehicle control, both for 1 month, to evaluate if macrophage depletion leads to cell death in tumors. Results: Large numbers of macrophages stained with Iba1 were seen in the peripheral nerve and PNFs from Dhh-Cre; Nf1flox/flox mouse model and PNFs from human samples. Macrophage accumulation was highest in the MPNSTs of mice and humans (p<0.001). These findings show that macrophage recruitment correlates with presence of tumor and correlates with disease progression (MPNSTs>PNFs>Nf1 mutant nerve>normal nerve). Staining with anti-CD163 an M2-marker showed that MPNST have 15% of Iba1+CD163+ cells. The percentage of macrophages were similar in the cell-rich and cell-poor regions of PNFs. Flow sorting from human neurofibromas showed an average of 8% (range 1.5 to 14%) of CD11b+ cells in the PNFs. Minocycline treated tumors have decreased Iba1+ macrophages and increased Schwann cell death supporting a role for macrophages on Schwann cell survival in PNFs. Conclusion: Macrophages are a major component of NF1 peripheral nerve tumors in human and mouse with a direct effect on tumor growth and survival. Accumulation of macrophages correlates with tumor progression and depletion may become a therapeutic strategy for PNFs.

OLIGOTHERAPEUTIC STRATEGIES FOR THE TREATMENT OF FRIEDREICH'S ATAXIA. *F. Ozsolak, D. Jun Li, D. Parekh, D. Knowlton, M. Wysk, R. Subramanian, J. Barsoum.* RaNA Therapeutics, Cambridge, MA.

Friedreich's ataxia (FRDA) is a recessively inherited disorder that arises due to cellular depletion of frataxin (FXN) protein and resulting defects in mitochondrial functions. FRDA is a progressive neuromuscular disease which lacks any FDA-approved therapy. The protein coding sequence of FXN is normal in the majority of FRDA patients, and the causative basis of this disease is the under-expression of the FXN gene, suggesting that upregulation of endogenous FXN expression could be an effective therapy. The most common molecular cause of this currently incurable disease is the expansion of GAA/TTC triplet repeats in the first intron of FXN gene. Repeat expansion beyond a certain threshold causes transcriptional defects which reduce FXN mRNA and protein levels. Despite long-standing research in the pathogenesis of FRDA, the means by which GAA-repeat number elevation leads to transcriptional silencing is not clear. Unusual DNA-DNA and DNA-RNA interactions formed in the long triplet repeat stretches, defects and alterations in splicing patterns and the formation of a heterochromatin-like structure are among the hypotheses being considered. In order to gain clues into the mechanisms responsible for the FXN deficit in FRDA, we undertook genome-wide analyses to examine the global and local RNA structure and chromatin structure and composition changes in FRDA patient cells. Epigenetic screens identified two chromatin modifying complexes as being important in establishing and/or maintaining repeat expansion-induced transcriptional repression at the FXN locus. We identified a novel non-coding RNA (ncRNA) potentially responsible for directing the localized epigenetic silencing of the FXN gene. Degrading this ncRNA led to at least partial heterochromatin reversal and FXN mRNA and protein level upregulation to therapeutically significant levels. The oligonucleotide-based therapeutic approaches developed here pave the way towards the design of multiple strategies for the treatment of FRDA and may have applications for the treatment of other human diseases. You may contact the first author (during and after the meeting) at fozsolak@ranarx.com.

Positive Effects of Short Course Androgen Therapy on the Neurodevelopmental Outcome In Boys with 47, XXY Syndrome at 9 Years of Age. *C.A. Samango-Sprouse[1,3], E. Stapleton[3], C. Sprouse[1,2], T. Sadeghin[3], F.L. Mitchell[3], A.L. Gropman[2].* 1) George Washington University, Washington, DC; 2) Department of Neurology, Children's National Medical Center, Washington, DC; 3) Neurodevelopmental Diagnostic Center for Young Children, Davidsonville, MD.

Background: Positive effects of early androgen treatment on neurodevelopmental performance in prepubertal males with 47, XXY have been documented at 36 and 72 months, giving support to the link between neurobiological treatment and neurodevelopmental outcome. Two previous studies have supported improvement in specific domains of neurodevelopmental performance with early androgen treatment.

Purpose: The aim is to determine if an early course of androgen treatment (3 injections of testosterone enanthate, 25mg, each) could have a positive impact on XXY boys at 9 years of age.

Methods: 59 prenatally diagnosed males with karyotypes of 47, XXY participated with one group (n=22) receiving androgen treatment in infancy and the second group untreated (n=37).

Results: There was a significant positive treatment effect in multiple visual motor domains (VP p=0.0012, MC p=0.0129, VMI p=0.0151). A positive treatment effect was observed on the BOT (Manual Coordination p=0.0003, Bilateral Coordination p=0.0001, Body Coordination p=0.0038, Speed/Agility p=0.0328, Strength p=0.0161 Upper Limb Coordination p=0.0004, and Strength/Agility p=0.0134).

Discussion: Long-term improved function has been observed in neurodevelopmental performance in XXY males at 36 and 72 months and now at 108 months, when treated with a short course of androgen in infancy. An early course of hormonal replacement may have a permanent positive effect on the neurodevelopment outcome in XXY in brain regions with known androgen receptors. These findings suggest early hormonal replacement in XXY males alters selected and vulnerable areas of neurodevelopmental performance. This is the third study demonstrating the positive effect of androgen on developmental performance further supporting the neurobiological link androgens, brain function and neurodevelopmental performance in XXY. Our findings provide additional support for the importance of early detection and treatment of boys with XXY.

2271T

Prenatal therapy in developmental disorders: drug targeting via intra-amniotic injection to treat X-linked hypohidrotic ectodermal dysplasia. *K. Hermes[1], P. Schneider[2], P. Kreig[3], A. Dang[2], K. Huttner[4], H. Schneider[1].* 1) German Competence Centre for Children with Ectodermal Dysplasias, Department of Pediatrics, University of Erlangen-Nürnberg, Germany; 2) Department of Biochemistry, University of Lausanne, Switzerland; 3) German Cancer Research Center, Heidelberg, Germany; 4) Edimer Pharmaceuticals, Inc., Cambridge, USA.

Background: X-linked hypohidrotic ectodermal dysplasia (XLHED), the most common inherited disorder of ectoderm development, is caused by a lack of the signaling molecule EDA-A1. In the Tabby XLHED mouse model, prenatal EDA-A1 replacement via maternal injection corrected the developmental abnormalities to a far greater extent than postnatal administration to newborn pups. This approach, however, may not be optimal for achieving therapeutic levels of corrective protein in the human fetus, and additionally exposes the mother to high serum levels of the exogenous molecule. We hypothesized that direct injection of EDA-A1 replacement protein into the amniotic fluid (AF) could result in fetal uptake via lung and gut, leading to sustained drug exposure at levels sufficient for successful treatment of XLHED. **Methods**: EDI200, a human IgG1:EDA-A1 fusion protein, was tested for stability in AF using a binding ELISA. Subsequently, EDI200 was injected into amniotic sacs of pregnant wild-type mice to evaluate drug uptake and pharmacokinetics. Fetal and maternal serum levels were monitored. Based on these results, EDI200 at a dose of 100 mg/kg fetal weight was administered intra-amniotically to E15 Tabby mouse fetuses and phenotypic correction was assessed. **Results**: EDI200 was demonstrated to be stable in AF at 37° for one week without detectable loss of activity. Intra-amniotic administration to E15 wild-type mice (35 mcg EDI200/fetus) resulted in substantial fetal uptake with mean serum levels of 9.0 mcg/ml and 1.2 mcg/ml at 6 hours and 96 hours, respectively. Maternal serum levels remained <0.1mcg/ml. In Tabby mice, a single maternal injection of EDI200 at E15 proved to correct the XLHED phenotype in offspring only partially. The complete spectrum of hair, sweat gland and dentition response following E15 intra-amniotic administration of EDI200 is being evaluated through adulthood and will be presented along with statistics on fetal loss related to this therapeutic approach. **Conclusions**: Intra-amniotic protein application to mice may lead to rapid fetal uptake, sustained substantial serum levels, and efficacy comparable with intravenous injection. As amniocentesis is generally a low-risk procedure in humans, this route of delivery may be suitable for drug targeting with reduced drug exposure of the mother and longer bioavailability due to a reservoir function of AF. It may, thus, represent a novel paradigm for treatment of disorders in early human development.

2272F

A Novel, Selective and Orally-available Glucosylceramide Synthase Inhibitor for Substrate Reduction Therapy of Fabry Disease. *J. Marshall[1], K. Ashe[1], E. Budman[1], D. Bangari[1], J. Nietupski[1], R.J. Desnick[2], R.K. Scheule[1], J.P. Leonard[1], S.H. Cheng[1].* 1) Genzyme, Framingham, MA; 2) Mount Sinai School of Medicine, New York, NY.

Fabry disease, an X-linked glycosphingolipid storage disorder, is caused by a deficiency of acid α-galactosidase A (αgal). Resulting progressive accumulation of globotriaosylceramide (GL-3) and lyso-GL-3 leads to kidney, heart, and cerebrovascular disease. Presently, Fabry disease is managed by periodic infusions of recombinant αgal (enzyme-replacement therapy; ERT). However, the inability of ERT to completely address disease manifestations in the heart and kidney has encouraged the development of alternative therapies. We had previously demonstrated that substrate reduction therapy (SRT) through antagonism of glucosylceramide synthase (GCS) can delay the accumulation of GL-3 in a mouse model of Fabry disease. Here, we describe the merits of a novel GCS inhibitor (Genz-682452) with favorable pharmacological properties and safety profile in Fabry mice. Treatment of Fabry mice with Genz-682452 starting at 3 months of age resulted in greater correction of a variety of disease biomarkers than when treatment was initiated in 12 months-old mice. Mice administered Genz-682452 exhibited significantly lower tissue levels of GL-3 and lyso-GL-3 and a delayed progression of a thermal nociceptive response than their untreated counterparts. SRT with Genz-682452, perhaps because it has a different biodistribution profile, was more effective than ERT at reducing the levels of the glycosphingolipids in the kidney, heart and CNS, organs that were not well-served by ERT. Importantly, mice treated by both ERT and SRT showed the greatest response suggesting the therapies are both complementary and additive. These results affirm the potential of SRT as an alternative and potentially adjuvant therapy for Fabry disease.

2273T

Successful pregnancy and lactation in a woman with mucopolysaccharidosis type I treated with laronidase. *Y. Xue[1], M. Castorina[2], D. Antuzzi[3], C. Sung[1], S. Richards[1], G. Cox[1].* 1) Genzyme, a Sanofi company, Cambridge, MA, USA; 2) Dipartimento di Tutela della Donna e della Vita Nascente, Pediatria; Universita Cattolica del Sacro Cuore, Rome, Italy; 3) Laboratorio di Neonatologia, Dipartimento di Tutela della Donna e della Vita Nascente, Pediatria; Universita Cattolica del Sacro Cuore, Rome, Italy.

Background: Few pregnancies have been reported in women with MPS I, a lysosomal storage disorder caused by α-L-iduronidase deficiency and subsequent accumulation of glycosaminglycans (GAG) throughout the body. With the availability of laronidase enzyme replacement therapy (Aldurazyme®, Genzyme, a Sanofi company, Cambridge MA, USA) more women with MPS I may become pregnant and want to breastfeed their infants. Although in animals, laronidase has had no effect on fertility or pregnancy, the lack of human data has led to the recommendation that laronidase be used in pregnancy only if needed and to be used with caution during breastfeeding. **Methods**: We describe an ongoing, prospective, open-label trial funded by Genzyme (ALID 01803, NCT00418821) of women with MPS I who plan to receive laronidase during pregnancy and while breastfeeding. Following local ethics committee approval and signed informed consent, the first patient has completed the study and the results are presented below. The effects of laronidase on the mother during pregnancy and on her infant for 12 months after delivery were assessed periodically through physical examinations, IgG and IgM anti-laronidase antibody titers, urinary GAG, laronidase activity in breast milk, and developmental testing in the infant. Adverse events and concomitant medications were evaluated continuously. **Results**: The patient, diagnosed with MPS I Scheie, had been treated with laronidase for 3 years, enrolled in the trial during her second pregnancy and continued to receive laronidase throughout her pregnancy and while breastfeeding. A healthy 2.5 kg boy was delivered by elective cesarean section at 37 weeks gestation. The baby was breastfed for 3 months. Laronidase was not detected in breast milk. Anti-laronidase IgG antibodies were present in the mother and in the umbilical cord blood at birth. However, the infant had no detectable anti-laronidase IgM antibodies, and the IgG titer declined over time, consistent with passive maternal transmission of antibodies. Urinary GAG levels in the infant were always normal. The infant was healthy and had normal development through 12 months. No drug-related adverse events occurred. **Conclusions**: We report the first known case of a successful pregnancy outcome and normal development in an infant whose mother continued laronidase treatment during pregnancy and lactation. Further data are necessary to confirm the safety of laronidase during pregnancy and breastfeeding.

ENCORE: a randomized, controlled, open-label non-inferiority study comparing eliglustat to imiglucerase in Gaucher disease type 1 patients on enzyme replacement therapy who have reached therapeutic goals. *M. Balwani[1], T.M. Cox[2], G. Drelichman[3], R. Cravo[4], T. Burrow[5], A.M. Martins[6], E. Lukina[7], B. Rosenbloom[8], L. Ross[9], J. Angell[9], A.C. Puga[9].* 1) Dept Human Gen, Mt Sinai Med Ctr-New York, New York, NY; 2) University of Cambridge, Department of Medicine, Addenbrooke's Hospital, Cambridge, UK; 3) Hospital de Niños Ricardo Gutiérrez, Buenos Aires, Argentina; 4) HEMORIO, Rio de Janeiro, RJ, Brasil; 5) Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 6) Universidade Federal de São Paulo, São Paulo, SP, Brasil; 7) Hematology Research Center, Moscow, Russia; 8) Tower Hematology Oncology Medical Group, Beverly Hills, CA, USA; 9) Genzyme, a Sanofi company, Cambridge MA, USA.

Background: Gaucher disease type 1 is a multi-systemic lysosomal storage disorder caused by acid β-glucosidase deficiency. Intravenously administered enzyme replacement therapy has been the standard of care, however this significantly impacts quality of life. Eliglustat is a novel oral substrate-reduction therapy in development for adults with Gaucher disease type 1. This Phase 3 trial (ENCORE, NCT00943111, sponsored by Genzyme, a Sanofi company) compares eliglustat with imiglucerase in patients who had reached therapeutic goals on enzyme replacement therapy. Methods: Randomized (2:1 eliglustat: imiglucerase), controlled, open-label non-inferiority trial of 160 patients previously receiving enzyme replacement therapy for ≥ 3 years who had met therapeutic goals. The primary efficacy endpoint was percent of patients remaining stable after 52 weeks (using a pre-specified composite of spleen, liver, hemoglobin, and platelet parameters). Results: Eliglustat was statistically non-inferior to imiglucerase: 84% of eliglustat and 94% of imiglucerase patients maintained goals for all four parameters (lower bound of 95%CI of difference [-18.6%] within pre-specified non-inferiority thresholds). Individually, 94% of eliglustat patients maintained stability criteria for spleen, 95% for hemoglobin, 93% for liver, and 96% for platelets. Of the 16/99 eliglustat patients who did not meet stability criteria based on change from baseline, most patients (13/16) nevertheless had absolute values for the individual endpoints that remained within therapeutic goals. Baseline bone mineral density scores were normal in most patients and remained normal on eliglustat. Two eliglustat patients and one imiglucerase patient (2% in each arm) discontinued because of an adverse event. Over the course of 52 weeks, four adverse events were observed with ≥ 10% incidence compared with imiglucerase: fatigue (14% vs. 2%) headache (13% vs. 2%), nausea (12% vs. 0%), and upper abdominal pain (10% vs. 0%). The majority of adverse events were mild or moderate in severity for both groups. There were no treatment-related serious adverse events. Conclusions: In the Phase 3 ENCORE study, eliglustat was well tolerated and was non-inferior to imiglucerase in maintaining stability for 52 weeks in previously treated patients with Gaucher disease type 1.

2275T

The adverse event profile of eliglustat for the treatment of Gaucher disease type 1: results from a pooled analysis of four trials. *R. Mankoski, M.J. Peterschmitt, A.C. Puga, G.F. Cox, S. Marulkar, J. Angell, B. Gaemers, L. Ross.* Genzyme, a Sanofi company, Cambridge, MA.

Background: Gaucher disease type 1 is a multi-systemic lysosomal storage disorder resulting from glucocerebrosidase deficiency. Eliglustat is a novel oral substrate-reduction therapy in development for adults with Gaucher type 1. To better understand the adverse event profile of eliglustat, we evaluated pooled data from all Gaucher type 1 patients receiving eliglustat in on-going Phase 2 and Phase 3 trials. Methods: Adverse event data from four Genzyme-sponsored trials were pooled: an open-label Phase 2 trial (NCT00358150), two Phase 3 trials for which the primary analysis period is complete (ENGAGE, NCT00891202, a randomized, double-blind, placebo-controlled trial, and ENCORE, NCT00943111 , a randomized, controlled, open-label non-inferiority [to imiglucerase] trial of patients previously receiving ERT for ≥ 3 years who had met therapeutic goals), and an open-label lead-in period from the on-going phase 3 EDGE trial (NCT01074944) randomized, double-blind dosing trial). Results: A total of 393 patients received eliglustat with a mean (SD) duration of exposure of 1.4 (1.2) years and a total pooled duration of 535 patient-years. The majority of AEs had an onset within the first 6 months of treatment. Six adverse events occurred in more than 10% of patients: headache (17% overall; 12% mild, 3% moderate, 1% severe), arthralgia (14% overall; 8% mild, 5% moderate, 1% severe), nasopharyngitis (13% overall; 11% mild, 2% moderate, none severe), upper respiratory infection (11% overall; 9% mild, 2% moderate, none severe), diarrhea (10% overall; 9% mild, 1% moderate, none severe), and dizziness (10% overall; 8% mild, 2% moderate, none severe). Most AEs (81%) were considered to be unrelated to treatment by the treating physician. Across all studies, 42 serious adverse events (SAEs) were observed in 35 patients (9%). All SAEs were considered to be unrelated to eliglustat except for three that were possible related, two (in the same patient) considered to be probably related, and one considered to be definitely related. Thirteen patients (3%) had AEs that led to study withdrawal. Conclusions: The clinical development program for eliglustat is the largest for Gaucher disease type 1, and the pooled adverse event profile in this safety analysis demonstrates that eliglustat was well-tolerated and safe.

2276F

ENGAGE: A Phase 3, randomized, double-blind, placebo-controlled, multi-center study to investigate the efficacy and safety of eliglustat in adults with Gaucher disease type 1 (GD1): 9 month results. *S. Packman[1], D. Amato[2], M. Dasouki[3], G. Pastores[4], S. Assouline[5], M. Balwani[6], P.K. Mistry[7], S. Shankar[8], M.J. Peterschmitt[9].* 1) Dept Peds/Div Med Gen, Univ California Sch Med, San Francisco, CA; 2) Mount Sinai Hospital, Toronto, Canada; 3) University of Kansas Hospital, Kansas City, KS, USA; 4) New York University School of Medicine, New York, NY, USA; 5) Jewish General Hospital, Montreal, Quebec, Canada; 6) Mt. Sinai Hospital, New York, NY, USA; 7) Yale University School of Medicine, New Haven, CT, USA; 8) Emory University, Atlanta, GA, USA; 9) Genzyme, a Sanofi company Cambridge MA, USA.

Background: GD1 is one of the most common lysosomal storage disorders. Deficiency of the lysosomal enzyme glucocerebrosidase leads to accumulation of glucocerebroside in the spleen, liver, and bone marrow. Eliglustat, a novel oral substrate reduction therapy that selectively inhibits glucosylceramide synthase, is in development for the treatment of GD1. ENGAGE (NCT00891202) is a randomized, double-blind, placebo-controlled, Phase 3 trial sponsored by Genzyme, a Sanofi company investigating the efficacy and safety of eliglustat in untreated adults with GD1. Methods: Forty patients (mean age: 31.8 years; 20 males) with splenomegaly and thrombocytopenia and/or anemia were stratified by spleen volume and randomized 1:1 to receive eliglustat (50 or 100 mg BID depending on plasma levels) or placebo for 9 months. The primary efficacy endpoint was percent change in spleen volume (multiples of normal). Other efficacy measures included hemoglobin, liver volume, and platelets. Bone endpoints included bone marrow burden (BMB) scores and bone mineral density changes (DXA). Quality of life assessments included the Gaucher Disease Severity Scoring System (DS3). Safety monitoring included adverse event reporting, and lab and ECG evaluations. Results: In patients receiving eliglustat vs. placebo, mean spleen volume decreased (-28% vs. +2%, P<0.0001), mean hemoglobin increased (0.69 vs. -0.54 g/dL, P<0.0006), liver volume decreased (-5.20% vs. +1.44%, P<0.0072), and platelets increased (+32% vs. -9.06%, P<0.0001). Significant improvements (eliglustat vs. placebo) were observed for total (-1.1 vs. 0.0, p=0.002), spine (-0.6 vs. 0.1, p=0.002), and femur (-0.5 vs. 0.0, p= 0.026) BMB scores. Although patients with symptomatic bone disease were excluded, absolute change in total spine DXA Z-scores approached significance (LS mean treatment difference=0.2, p=0.06). Burden of disease, as measured by the Gaucher DS3, was significantly reduced following treatment with eliglustat vs. placebo (LS mean treatment difference=-0.3, p= 0.0452). No patient discontinued due to an AE, all of which were classified as mild to moderate; 39/40 patients transitioned into the ongoing open-label trial. Arthralgia and nasopharyngitis occurred in >10% of eliglustat vs. placebo patients. Conclusion: ENGAGE met its primary and secondary efficacy endpoints. Significant effects on bone marrow and a trend toward BMD improvement in spine were observed. Eliglustat was generally safe and well-tolerated.

2277T

Translating ManNAc into a novel therapeutic agent for patients with GNE Myopathy. *F.V. Celeste[1], L. Latham[1], J. DeDios[2], C. Ciccone[2], C. Robinson[1], J. McKew[1], M. Huizing[2], W.A. Gahl[2,3], N. Carrillo-Carrasco[1].* 1) Therapeutics for Rare and Neglected Diseases, National Center for Advancing Translational Sciences, Bethesda, MD; 2) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892; 3) Office of the Clinical Director, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892.

Background: GNE Myopathy is a rare muscular disease caused by mutations in GNE, which encodes the key enzyme in the sialic acid biosynthetic pathway. Patients have progressive muscle weakness leading to marked disability. Hyposialylation of muscle glycoproteins likely contributes to the pathophysiology. ManNAc, a pathway intermediate, prevents muscle weakness in the mouse model of GNE myopathy. Objectives: Translate ManNAc into a therapy for patients with GNE myopathy. Methods: A first-in-human Phase 1a, randomized, placebo-controlled, double-blind, single-dose study (ClinicalTrials.gov NCT01634750; IND No.78,091) was conducted to evaluate the safety, pharmacokinetics (PK), and pharmacodynamics (PD) of ManNAc. GNE myopathy subjects (n=22) were enrolled into 3 cohorts (Cohorts A: 3,000mg, B: 6,000mg, C: 10,000mg) with a 3:1 ManNAc-to-placebo ratio. Results: Grade I and II (CTCAE) adverse events were encountered, mostly unrelated to study drug. PK data are currently been evaluated. We utilized potential plasma biomarkers to evaluate the onset and duration of the PD response. Conclusions: It is critical to perform high-quality clinical trials to develop approved therapies for rare disorders. ManNAc, a promising therapy for GNE myopathy, is safe and well-tolerated. PK and PD data will guide the selection of dose and frequency for upcoming Phase Ib and IIa trials.

2278F

Evaluation of computed tomography *in vivo* to assess the therapeutic potential of cystine analogs as inhibitors of cystine stone formation in *Slc3a1* knockout mice. *A. Sahota[1], J. Parihar[2], M. Yang[1], D. Adler[3], W. Kim[4], D. Gordon[1], J.A. Tischfield[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) Dept Surgery, UMDNJ-RWJMS, New Brunswick, NJ 08901; 3) Molec Imaging Ctr, Rutgers Univ, Piscataway, NJ; 4) Dept Math and Statistics, Univ South Florida, Tampa, FL 33620.

Background: *Slc3a1* knockout mice excrete cystine in the urine and males from age 3 months have cystine stones in the bladder. Cystine crystals are present in the urine in young mice, but very little is known about stone growth *in vivo*. Imaging technologies allow detailed investigation of biological processes in live animals. Here we evaluate the utility of computed tomography (CT) for identifying the spatial and temporal patterns of cystine stone deposition in *Slc3a1* knockout male mice and for assessing the efficacy of cystine dimethyl ester (CDME), a cystine analog, in ameliorating cystine stone formation. **Methods:** Mice (2-3 months old) were screened for the presence of stones using the Albira CT scanner; approximately 60% of these mice had stones. Initial bladder volume (as an indicator of stone volume) in the stone-positive mice was calculated using InviCRO VivoQuant software. Mice were then randomly assigned to treatment (CDME, 11 mice) or control (water, 7 mice) groups. Treatment consisted of 200 µl of 10 mg/ml CDME or water alone given daily by gavage for up to 10 weeks. Volume measurements were repeated at 1-2 week intervals. Mice were then sacrificed and bladder stones weighed, counted, and measured. Data on stone size and number were analyzed using chi-square. **Results:** Initial volumes in the control and treated groups were similar (12-96 mm^3 versus 11-86 mm^3, respectively). In both cases, there was a linear increase in volume that followed the equation $y=mx+c$. The equation for the water group ranged from $y=0.39x+11.0$ to $y=1.43x+84.3$. The equation for the CDME group ranged from $y=0.99x+18.4$ to $y=2.67x+73.3$. Thus, the two groups could not be distinguished by CT analysis. There was a small difference in the percentage of stone sizes in the two groups at the 5% level. The treatment group had 9.4% more stones and the control group had 19.6% fewer stones in the 1.1-2.0 mm range. The treatment group had 26.1% fewer stones and the control group had 54.6% more stones in the 3.1-4.0 mm range. Thus, CDME administration led to cystine stones that were smaller in size but larger in number compared with untreated mice. **Conclusions:** CT is a powerful tool for differentiating cystinuria mice with stones from those without stones, but longitudinal measurement of stone volume is not suitable for evaluating CDME efficacy *in vivo*. CDME administration leads to smaller stones which, based on volume measurements, cannot be distinguished from stones in untreated mice.

2279T

Pharmacologic inhibition of cytosolic translation offers a novel therapeutic approach for mitochondrial respiratory chain disease. *M.J. Falk[1], M. Peng[2], M. Tsukikawa[1], J. Baur[3], Z. Zhang[4], D. Gasser[2].* 1) Division of Human Genetics, Department of Pediatrics, The Children's Hospital of Philadelphia and University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 3) Department of Physiology and Institute for Diabetes, Obesity, and Metabolism, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 4) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Effective therapies do not currently exist for mitochondrial disease, a heterogeneous group of genetic disorders that cause multi-organ system dysfunction across all ages and ethnicities. Pharmacologically targeting the central alterations in the nutrient-sensing signaling network that contribute to mitochondrial disease symptoms is a novel treatment approach for which we have substantial data demonstrating benefit in cell and animal models of primary respiratory chain (RC) disease. mTORC1 is a key node in the nutrient-sensing signaling network whose regulation of cytosolic protein translation is highly relevant to RC disease. Cytosolic translation is significantly upregulated in both genetic and pharmacologic models of primary RC disease. Remarkably, cellular and animal health in RC deficient models can be restored by drugs that inhibit mTORC1. In particular, B6.*Pdss2*$^{kd/kd}$ mice that have RC disease caused by a coenzyme Q biosynthetic defect show increased mTORC1 activity prior to disease onset. The otherwise lethal renal glomerular disease in these animals is prevented by feeding either probucol or rapamycin, both of which are pharmacologic agents that our data demonstrate to effectively inhibit mTORC1. Further, we have discovered that more complete inhibition of cytosolic translation by cycloheximide, a drug that blocks the elongation phase of eukaryotic translation by binding the ribosome and inhibiting eEF2-mediated translocation, effectively prevents cell death from RC inhibition with rotenone, antimycin A, or oligomycin. Cycloheximide treatment also restores total cellular respiratory capacity in the setting of rotenone-based complex I inhibition. Collectively, these data suggest that dysregulated cytosolic protein translation is a significant cause of morbidity that can be therapeutically targeted to improve health in primary RC disease.

Drug screening using the dystroglycan null zebrafish. *G. Kawahara[1, 2], J. Widrick[1], V. Gupta[1, 2], J. Myer[1], M. Gasperini[1], A. Beggs[1, 2], L. Kunkel[1, 2, 3].* 1) Division of Genetics, Program in Genomics, The Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA, USA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA, USA; 3) Department of Genetics, Harvard Medical School, Boston, MA, USA.

Zebrafish are an ideal model for biomedical research, as zebrafish genetic models mimic much of the pathology of human diseases. Dystroglycan null fish (patchytail, dag1cl500) are an excellent model of the human dystroglycanopathies as they show disturbed muscle structure and a severe reduction of birefringence at 3-7 days post fertilization (dpf). The birefringence is a result of dorsal skeletal muscle deterioration and weakness that ultimately results in lethality of most dystroglycan null mutants at 20 dpf. We have performed a preliminary drug screen of 1120-chemicals from a small, commercial molecular library, Prestwick collection using homozygous patchytail zebrafish to identify potential therapeutic chemicals for treating the dystroglycanopathies, Embryos from heterozygous dag1cl500/wt zebrafish matings were cultured in normal fish water containing pools of up to 8 compounds from the Prestwick collection, and were incubated from 1 dpf to 4 dpf. At 4 dpf the treated fish were examined by birefringence to determine if there was any reduction from the expected 25% fry showing abnormal birefringence. Fish treated with some of the pooled chemicals were genotypically confirmed as dystroglycan null zebrafish but showed no defects in birefringence compared to the untreated control. This suggests that we may have successfully identified efficacious compounds for prevention of the phenotype caused by the dystroglycan gene mutation. In this short-term screen of 1120 compounds, we found eleven candidate drugs that prevent muscle pathology by significantly reducing the proportion of fry with abnormal birefringence at 4 days. Interestingly, five of the candidate drugs are involved in gamma-aminobutyric acid regulation. Dystroglycan null embryos were treated with each of these candidate drugs for a long-term period, from 5 dpf to 20 dpf. This treatment indicated that one of the candidate compounds greatly increased survival of dystroglycan null fish. Analysis of these treated surviving dystroglycan null fish showed they had normal muscle structure and normal neuromuscular junctions, whereas these structures are observed as abnormal in the untreated mutant fish. The candidate drugs from these screens will likely be informative for development of drugs to treat human dystroglycanopathies. The discovery of a small molecule and specific therapeutic pathway that might mitigate progression of this disease is highly relevant and significant.

Genetic and pharmacological reduction of ER stress rescues glaucoma in a murine model of glucocorticoid-induced glaucoma. *G. Zode[1], A. Sharma[1], X. Lin[1], C. Searby[1,2], K. Bugge[1,2], A. Clark[3], V. Sheffield[1,2].* 1) Department of Pediatrics, University of Iowa, Iowa, IA 52242; 2) Howard Hughes Medical Institute; 3) Department of Cell Biology & Anatomy and the North Texas Eye Research Institute, University of North Texas Health Science Center at Fort Worth, TX 76107.

Topical or systemic administration of glucocorticoids is known to induce ocular hypertension in a subset of the population. If untreated, these patients can develop glaucoma with features that closely resemble primary open angle glaucoma (POAG). The mechanisms underlying glucocorticoid-induced glaucoma are not fully understood partly due to the lack of an appropriate mouse model, as well as a lack of understanding of the genetic susceptibility of this disorder. Here, we report the development of a murine model of glucocorticoid-induced glaucoma that closely resembles glaucoma features observed in patients. We demonstrate that treatment with topical ocular 0.1% dexamethasone in WT mice leads to elevation of intraocular pressure (IOP), structural and functional loss of retinal ganglion cells, and axonal degeneration similar to glucocorticoid-induced glaucoma in human patients. We further demonstrate that dexamethasone-induced ocular hypertension is associated with chronic endoplasmic reticulum (ER) stress of the trabecular meshwork (TM). Dexamethasone activates the unfolded protein response and also induces pro-apoptotic transcriptional factor Chop in the TM. Deletion of Chop in mice reduces ER stress in the TM and prevents dexamethasone-induced ocular hypertension. Furthermore, a chemical chaperone, sodium 4-phenylbutyrate (PBA) prevents dexamethasone-induced ocular hypertension by reducing ER stress in the TM. ER stress thus plays a critical role in glucocorticoid-induced ocular hypertension and the reduction of ER stress via PBA can be used as a therapeutic strategy for treatment of glucocorticoid-induced glaucoma. This study also suggests that certain genes related to the ER stress pathway such as Chop may contribute towards increased susceptibility to steroid-induced glaucoma in humans.

2282F

Sildenafil citrate results in upregulation of heme oxygenase 1 and alleviation of symptoms in the *mdx^{5cv}* mouse model of Duchenne muscular dystrophy. *M. Gasperini[1], G. Kawahara[1,2], J. Widrick[1], M. Alexander[1,2], L. Kunkel[1,2, 3].* 1) Division of Genetics, Program in Genomics, The Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA, USA; 2) Department of Pediatrics. Harvard Medical School, Boston, MA, USA; 3) Department of Genetics, Harvard Medical School, Boston, MA, USA.

Duchenne muscular dystrophy (DMD), the most common form of muscular dystrophy, is caused by lack of the dystrophin protein, with no effective treatment at present. Zebrafish are a powerful tool for high throughput drug screening in vivo. From therapeutic drug screens using dystrophin-deficient *sapje* zebrafish, we have identified four drugs that increased affected fish survival rates at 20 days post fertilization. These drugs induced upregulation of heme oxygenase 1 (Hmox1) protein expression in surviving dystrophin null fish. One of these compounds, sildenafil citrate, is reported as a known effective mammalian drug for DMD. To confirm its therapeutic effects and its upregulation of Hmox1 in a DMD mouse model, sildenafil was administered to dystrophin null *mdx^{5cv}* mice. Sildenafil was dissolved to a 400 mg/L concentration in sterile-filtered, acidified drinking water. Two male and two female 4 week-old *mdx^{5cv}* mice were given ad libitum access to treated water for 6-8 weeks. During treatment, mice were tested for exercise tolerance by monitoring activity for 6 minutes immediately before and after 15 minutes of treadmill running. After the drug treatment period, skeletal muscle was histologically and physiologically examined to check for improvement of symptoms, as well as changes in Hmox1 expression. Whereas exercise tolerance at 2 and 4 weeks of drug administration showed no significant improvement, sildenafil treated mice displayed alleviated exercise fatigue symptoms after 6 weeks of drug administration. After treadmill running, their total seconds spent resting, centimeters traveled, and number of rearing events were significantly improved over the extremely fatigued vehicle-treated dystrophic mice. The sildenafil receiving mice also had a reduced number of centralized nuclei in skeletal muscle fibers in comparison to dystrophic controls, as counted in Haematoxylin and Eosin stains of diaphragm and tibialis anterior muscle slices. Immunoblot revealed that sildenafil treatment significantly increased Hmox1 protein expression in skeletal muscle when compared to vehicle-treated wildtype and *mdx^{5cv}* mice. These results point to Hmox1 as an effective therapeutic pathway in fish and mouse models of DMD. Hmox1 and drugs that impact it will likely be informative for development of therapeutics to treat humans with DMD.

2283T

Developing Small Molecule Inhibitors of p97/VCP Disease Mutants for Neurodegenerative Diseases. *T.-F. Chou[1], C.C Weihl[2], R.J. Deshaies[3].* 1) Division of Medical Genetics, Department of Pediatrics, Harbor-UCLA Medical Center and Los Angeles Biomedical Research Institute, Torrance, CA 90502, USA; 2) Department of Neurology, Washington University School of Medicine, 660 South Euclid Avenue, Box 8111, St. Louis, MO 63110, USA; 3) Division of Biology, California Institute of Technology, Pasadena, CA 91125, USA.

p97 AAA (ATPase Associated with diverse cellular Activities; also called VCP [Valosin-Containing Protein) ATPase -- also known as p97 -- participates in key steps in ubiquitin-dependent protein quality control, autophagy, and numerous fundamentally important cellular functions. p97 targets proteins to 2 major degradation systems, the proteasome and autophagy pathways. This key role of p97 underscores its importance in protein homeostasis and strongly implicates its role in neurodegenerative diseases. Dominantly inherited missense mutations in p97 ATPase cause IBMPFD/ALS (inclusion body myopathy with Paget's disease of bone and frontotemporal dementia; amyotrophic lateral sclerosis). Some 20 single amino acid mutations in p97 have been identified. Current data suggest that all tested disease mutants form stable hexamers and have enhanced ATPase activity. We carried out a high-throughput screen to identify the first reversible p97 inhibitor, DBeQ. Following a structure-activity relationship study of the DBeQ scaffold, we constructed a library of p97 inhibitors. We have determined IC50 values of the top 3 inhibitors against 8 p97 disease mutants. Interestingly, some mutants were less sensitive to the inhibitors, with 5-fold higher IC50 values than for the wild type. We also performed enzyme kinetic analyses on wild type p97 and on the R155H and A232E disease mutants. Overall, our current data indicate that disease mutants are regulated by cofactors differently, compared to the wild type enzyme. Further study is required to develop mutant-selective inhibitors of p97 ATPase activity.

2284F

Rho Kinase Inhibition Therapy for Cerebral Cavernous Malformations.
D.A. Marchuk[1], D.A. McDonald[1], R. Shenkar[2], C. Shi[2], C.J. Gallione[1], C. Austin[2], A.G. Mikati[2], I.A. Awad[2]. 1) Molec Gen & Microbiol, Duke Univ Med Ctr, Durham, NC; 2) Neurovascular Surgery Program, University of Chicago Medicine and Biological Sciences, Chicago, IL.

Cerebral cavernous malformations (CCMs) are focal vascular malformations in the brain characterized by grossly dilated capillaries and vascular leak and hemorrhage, leading to stroke, seizure and other neurological complications. The disease occurs in sporadic or inherited (autosomal dominant) forms, the latter caused by mutation in one of three genes (CCM 1, 2 or 3). The vascular lesions in the familial cases follow a two-hit mutational mechanism of pathogenesis due to somatic mutation of the wild-type copy of the relevant CCM gene. Based on this two-hit model, we crossed heterozygous murine Ccm gene knockout alleles into mutant backgrounds with elevated rates of somatic mutation (p53 or Msh2 null alleles), and have generated robust murine models of CCM disease that fully and faithfully recapitulate the clinical phenotype. In parallel, in vitro studies have shown that the CCM proteins localize to endothelial cell-cell junctions and their loss leads to junctional instability associated with activation of RhoA and its effector, Rho kinase (ROCK). As a proof of principle, we recently demonstrated that ROCK inhibition using the drug fasudil reduces lesion burden in our murine Ccm1 model. In the current study we investigated the effect of ROCK inhibition in other Ccm murine genotypes, including a murine Ccm3 model, the most penetrant and morbid of the inherited forms in both the mouse and human. In all genotypes, fasudil treated mice exhibit decreased prevalence of CCM lesions compared to placebo controls. Lesions in treated animals exhibit fewer and smaller caverns (ie. 'immature' lesions) and are less likely associated with hemorrhage. Coming full circle, we have also now found that sporadic CCM lesions in human (the most common form of CCM) also exhibit somatic mutations in the same genes found mutated in the inherited cases. These combined data suggests mutation (somatic or inherited) of the CCM genes leads ROCK activation in all forms of CCM. Thus, ROCK inhibition may be a viable therapeutic option for all forms of CCM disease, including the most severe inherited form, CCM3, and possibly the more common, sporadic cases.

2285T

Development of a high-throughput screen for mRNA splicing modulators of IKBKAP.
F. Urbina, M. Nilbratt, E. Morini, M. Salani, S. Slaugenhaupt. Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Familial Dysautonomia (FD) is an autosomal recessive sensory and autonomic neuropathy that primarily affects the central and peripheral nervous system. All patients with FD have an intronic splice site mutation in the IKBKAP gene (IVS20+6T$\rightarrow$C) that leads to aberrant splicing, with partial skipping of exon 20. This exon skipping is tissue specific and leads to a reduction of IKAP protein that is most pronounced in the nervous system. This reduction of IKAP leads to a number of symptoms including absence of overflow tears, gastroesophageal reflux, scoliosis, and orthostatic hypotension. Previously, we showed that the plant cytokinin kinetin dramatically improves aberrant splicing in FD patient lymphoblast and fibroblast cells. Further, kinetin works to modulate splicing in vivo improving exon 20 inclusion and increasing the amount of IKAP protein in all tissues, including brain, in a mouse model. In order to work towards optimizing kinetin and identifying new compounds that might be useful as human therapeutics, we established both primary and secondary screening assays. Using a previously created FD minigene construct, a dual luciferase-based primary assay was developed and optimized for high-throughput screening of compounds. A luciferase inhibition counterscreen was also developed. A secondary qPCR assay to evaluate the level of normal IKBKAP mRNA was established to both evaluate luciferase inhibitors and 'hit' compounds in both the primary assay and in patient cell lines. This screening funnel will allow for a large number of compounds to be evaluated in both a primary and patient-based secondary screen for splicing modulation. Several kinetin-like compounds have been evaluated to date and prove that our system will permit the identification of potential new therapies for this mRNA splicing disorder.

Paradigm Shift for the treatment of cognitive deficits in Down syndrome: A novel drug treatment rescues hippocampal deficits in the Ts65Dn mouse.
J.R. Korenberg[1], P. West[2], K. Wilcox[2], G. Smith[3], R. Kesner[4]. 1) Center for Integrated Neuroscience and Human Behavior, Brain Institute, Department of Pediatrics, Univ. of Utah, Salt Lake City, UT; 2) Department of Pharmacology and Toxicology, Univ. of Utah, Salt Lake City, UT; 3) Center for Integrated Neuroscience and Human Behavior, Brain Institute, Univ. of Utah, Salt Lake City, UT; 4) Department of Psychology, Univ. of Utah, Salt Lake City, UT.

It is now time to shift the paradigm from irrevocable wiring deficits to plasticity of neural circuitry solutions for therapeutics of neurodevelopmental disorders such as Down syndrome (DS). We report the use of the Ts65Dn mouse model of DS to establish a novel approach to the neural circuit definition and rescue of hippocampal deficits involving visual-spatial learning and memory. The identification and development of treatments for cognitive limitations in people with DS has needed greater committment by the pharmaceutical industry, a broader consideration of multiple neurotransmitter systems disturbed in DS, deeper integration with multi-target candidate compounds, parallel cognitive and behavioral tests in humans and animal models, and tests that specifically query the function of a specific brain circuit of known function. We have addressed these needs with a cross-disciplinary team to implicate the serotonin 5HT6 receptor antagonists as compounds whose effects on target neurotransmitter systems is inverse and therefore corrective, to the profile of serotonergic, cholinergic and GABAergic perturbations of Down syndrome. We report a novel battery of tests that dissect hippocampal functions and are compatible in mice and humans and further, that this class of compounds improves cognitive performance without increasing the inherent risk of seizures in the Ts65Dn mouse model of DS. We report the effects of 6 compounds representing a broad spectrum of 5HT6R antagonists, each of which rescues HC deficits of object identification and spatial orientation related to the function of CA 3 and the dentate gyrus. A 7th compound did not recognize the mouse receptor and did not rescue HC deficits. The effects of acute and/or chronic administration suggests that the 5HT6R antagonists may help to both acutely increase cognitive performance and chronically, to begin to repair neural circuitry in those with Down syndrome.

2287T

Sorbent Therapy (Rx) of Erythropoietic Protoporphyria (EPP).
P. Tishler. Brigham & Women's Hosp, Channing Division of Network Medicine, Boston, MA.

Sorbent Therapy (Rx) of Erythropoietic Protoporphyria (EPP) Peter V. Tishler PURPOSE: In EPP subjects, to determine the potential of a porphyrin adsorbant colestipol to reduce or eliminate cutaneous discomfort, hepatic dysfunction/failure, and body protoporphyrin content. BACKGROUND: EPP is a cutaneous porphyria caused by enzyme deficiency (ferrochelatase) or overproduction (δ-aminolevulinic acid synthase) in the heme biosynthetic pathway. Protoporphyrin accumulates, causing cutaneous photosensitivity and rarely hepatic dysfunction/failure. Prior In vitro,studies demonstrated that sorbents, such as cholestyramine, irreversibly bind protoporphyrin, and thus may therapeutically remove protoporphyrin secreted into the GI tract. METHODS: Three adult females were studied. After a no-Rx period of baseline blood studies (48-98 days), subjects received colestipol 2 gm twice daily (optimal dosage) from July-November. The time to sun-induced onset and nature of cutaneous discomfort were determined by stopwatch and answers to a questionnaire. Erythrocyte (RBC) and plasma free protoporphyrin concentrations were determined throughout. Changes were analyzed by the Cox Proportional Hazards model for skin, and mixed effects regression methods for protoporphyrin. RESULTS: Colestipol Rx improved skin sensitivity to sun 4.5-fold to infinity; all statistically significant. No hepatic dysfunction occurred before or during Rx. Changes in mean RBC & plasma protoporphyrin concentrations (μg/dl), during vs. before Rx (RBC - 1934 + 714 [SD] vs. 1712 + 455; plasma - 9.9 + 13.4 vs. 5.8 + 8.3) were not statistically significant. CONCLUSION: Colestipol ameliorated the protoporphyrin-induced painful skin response to sun. We could not assess its effect on liver function. Since blood protoporphyrin concentrations did not change, the mechanism is unclear. Colestipol Rx should be further evaluated in a controlled trial that includes youngsters, who are more liable for hepatic failure.

Fusion with Angiopep-2 to create proteins that cross the blood-brain barrier and are taken up into cells. *J.E. Lachowicz, M. Demeule, A. Regina, D. Boivin, A. Larocque, J.-P. Castaigne.* Angiochem, Montreal, Quebec, Canada.

Enzyme replacement therapy has been used successfully to treat peripheral symptoms of lysosomal storage disorders. However, treatment of the severe CNS symptoms associated with many LSDs has been impeded by the inability of enzymes to cross the blood-brain barrier (BBB). Receptor-mediated transcytosis is one strategy for allowing large molecules to cross the BBB. The low density lipoprotein-like 1 (LRP-1) receptor binds over 40 natural ligands for BBB transcytosis. Incorporation of Angiopep-2 (An2), a peptide that binds LRP-1, into small molecules, peptides, and biologics such as mAbs has been shown to increase brain permeability. The most advanced example is a conjugate of An2 and paclitaxel (ANG1005). In contrast to paclitaxel, ANG1005 is brain-penetrant and is not recognized by the P-gp efflux pump at the BBB. In addition, reduction in tumor size has been shown with ANG1005 both in preclinical models and in patients with primary and metastatic brain tumors. A visual demonstration of the An2 conjugate technology for proteins has been achieved by creating a recombinant human An2-GFP fusion protein. In vitro, native GFP is not readily taken up by cells. In contrast to native GFP, An2-GFP incubation results in observable green fluorescence within cultured fibroblasts. Mice that are systemically treated with native GFP via carotid artery or tail vein show similar brain fluorescence to vehicle-treated mice, which is limited to the capillary basement membranes. However, An2-GFP treatment results in abundant intracellular green fluorescence in brain. Ten minutes post injection, fluorescence is largely concentrated in astocytic end feet around capillaries, while 60 minutes post injection, a widespread fluorescence distribution is observed in neurons in all brain regions examined. At the subcellular level, punctate fluorescence is localized to presumptive endosomes, indicating active cellular uptake of An2-GFP. This study demonstrates that an An2-protein conjugate crosses the BBB and is taken up by cells in the brain, both attributes being critical for enzyme replacement therapy for CNS indications. We have applied this approach to an enzyme associated with mucopolysaccharidosis to create a brain-penetrant enzyme for enzyme replacement therapy.

Novel method for oral administration of ERT for the treatment of Gaucher disease. *M. Golembo, S. Velitzki, R. Chertkoff, E. Brill-Almon, Y. Shaaltiel.* Protalix Biotherapeutics, Carmiel, Israel.

Gaucher Disease (GD) is the most prevalent lysosomal storage disorder, caused by the deficiency of the lysosomal enzyme glucocerebrosidase (GCD). The accumulation of excessive glucocerebrosides in lysosomal compartments of macrophages causes hepatosplenomegaly, anemia and thrombocytopenia as well as bone pain and fractures. Enzyme replacement therapy (ERT) with GCD has been successfully used for the clinical treatment of GD for several years. All three currently approved ERT drugs are administered by intravenous infusion every 2 weeks. Although all enzymes are safe and efficient, the intravenous administration remains a limitation which affects patients' quality of life. Thus, orally administered ERT would have the definite advantage of the well-established therapy mechanism, without the limitation of the intravenous administration and will provide continuous enzyme secretion. Oral administration of proteins is one of the challenges of the biotherapeutics industry particularly due to early degradation of the proteins in the digestive tract. One of the approved ERTs, taliglucerase alfa, is expressed in carrot cells. The use of carrot cells as natural vehicle of the expressed human recombinant GCD is intended for oral delivery of the enzyme, due to the protection from degradation provided by the composition of the plant cell wall. Enzyme expressed in the ProCellEx system, prGCD, has the optimal glycosylation profile, with exposed mannose for efficient activity. This delivery method is particularly well suited as it uses edible carrot plant cells, and provides 'ready to use' enzyme which requires no modifications to obtain optimal glycosylation suited for receptor mediated uptake in target cells. This study shows the feasibility of this approach. Non clinical studies in rats and pigs fed with carrot cells expressing human GCD at either daily or repeat administrations, showed elevated levels of active GCD in both plasma and target organs (liver and spleen). Carrot cells expressing prGCD were shown to be safe and well tolerated by the animals and caused no major adverse symptoms. Clinical trial with oral administration of carrot cells expressing prGCD is on-going in GD patients. This study will evaluate enzyme delivery which allows daily intake and slow, continuous delivery of the drug. Once the enzyme is released in the blood stream it is expected to be similar to the approved ERT for which there is established clinical safety and efficacy data.

Preliminary Findings Evaluating Safety and Efficacy of Recombinant Human N-Acetlygalactosamine-6-Sulfatase in Pediatric Patients Less Than 5 Years of Age with Mucopolysaccharidosis IVA (Morquio A Syndrome, MPS IVA). *C. Haller[1], S.A. Jones[2], P. Harmatz[3], M. Bialer[4], R. Parini[5], K. Martin[1], P. Farmer[1], P. Slasor[1].* 1) Clinical Science, BioMarin Pharmaceutical Inc. , Novato, CA; 2) St. Mary's Hospital, CMFT, University of Manchester, MAHSC, UK; 3) Children's Hospital and Research Center, Oakland, CA,; 4) North Shore LIJ Health System, Manhasset, NY; 5) Az. Ospedaliera S. Gerardo, Monza, Italy.

Preliminary results after 26 weeks of treatment from an ongoing study evaluating safety and efficacy of recombinant human N-Acetylgalactosamine-6-sulfatase (rhGALNS) in 15 MPS IVA subjects <5 years of age are reported. The mean (range) age at baseline (BL) was 3.1 (0.8-4.9) years. Based on physical examination findings at BL, the majority of subjects had abnormal musculoskeletal features (14/15, 93.3%), abnormal general appearance (10/15, 66.7%), abnormal finding for HEENT (10/15, 66.7%) and corneal clouding (7/15, 46.7%). Most subjects had normal cardiovascular (12/15, 80.0%), respiratory (15/15, 100.00%), gastrointestinal (14/15, 93.3%), genitourinary (15/15, 100.0%), and neurologic systems (14/15, 93.3%) on exam. Standing height/length (n=15) was severely affected in many subjects; 7(46.7%) at <3rd, 3(20.0%) at ≥ 3rd-<10th, 2(13.3%) at >25th-<50th, and 3(20.0%) at ≥ 50th percentiles. Normalized urine keratan sulfate (uKS) was elevated 3 fold above the mean for age matched control population with a mean (range) of 35.9 (18.8-56.5) µg/mg creatinine (n= 15). After 26 weeks of weekly infusions with 2 mg/kg/day of rhGALNS, the most commonly reported adverse events (AEs) were vomiting in 12 (80.0%), pyrexia in 11 (73.3%), and cough in 8 (53.3%) subjects. The majority of AEs were mild-moderate. Four serious AEs were reported, tonsillar hypertrophy, skin infection, sepsis and hypersensitivity. No subjects discontinued treatment, and rhGALNS had a similar safety profile as seen in older children and adults. In 8 subjects with 26 weeks of data, rhGALNS led to a substantial decrease in mean (±SD) normalized uKS by -30.5 (±15.49)% after 2 weeks that was sustained at -35.2 (±15.57)% at 26 weeks. These results demonstrate the drug's pharmacodynamic effects. Mean height/length for age z-scores did not demonstrate significant change from BL (-1.8 SD) to Week 26 (-2.2 SD) for these 8 subjects. Although there was no control group for comparison, data in the literature indicate that these children experience growth failure in early childhood. The accumulation of KS begins early in the life of MPS IVA subjects, and is progressive and life limiting. Early intervention with rhGALNS treatment is well tolerated; produces decrease in keratan sulfate storage, and may show substantial benefit in young pediatric patients.

2291T

Survival Rates and Timing of Initiation of Treatment with Enzyme Replacement Therapy (ERT) Among Patients with Classic Infantile-Onset Pompe Disease Enrolled in the Pompe Registry. *P.S. Kishnani[1], S. Jones[2], A. van der Ploeg[3], E. Mengel[4], B. Byrne[5], A. Vellodi[6], N. Leslie[7], S. Shankar[8], P. Tanpaiboon[9], D.W. Stockton[10], J.B. Hennermann[11], Z. Devecseri[12], J. Kempf[12], J. Keutzer[12], Y-H. Chien[13].* 1) Division of Medical Genetics, Department of Pediatrics, Duke University Medical Center, Durham, NC, USA; 2) Manchester Center for Genomic Medicine, CMFT, University of Manchester, UK; 3) Department of Pediatrics & Center for Lysosomal and Metabolic Diseases, Erasmus MC University Medical Center, Rotterdam, the Netherlands; 4) University of Mainz, Mainz, Germany; 5) Department of Pediatrics, University of Florida, Gainesville, FL, USA; 6) Great Ormond Street Hospital for Children NHS Foundation Trust, London, UK; 7) Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 8) Emory University School of Medicine, Atlanta, GA, USA; 9) Children's National Medical Center, Washington, DC, USA; 10) Wayne State University School of Medicine, Detroit, MI, USA; 11) Charite Universitaetsmedizin Berlin, Berlin, Germany; 12) Genzyme, a Sanofi company, Cambridge, MA, USA; 13) National Taiwan University Hospital, Taipei, Taiwan.

Background: Pompe disease presents as a clinical spectrum with variable severity, progression, and muscle involvement. Early clinical diagnosis and initiation of enzyme replacement therapy (ERT), before the development of severe, irreversible symptoms, are important, especially in very young patients with the most severe form of the disease. Aim: To report the results of a descriptive analysis of the chances of survival and ventilator-free survival and its relation to timing of initiation of ERT among patients with symptom onset ≤12 months with cardiomyopathy (classic infantile-onset Pompe disease) in the Pompe Registry, sponsored by Genzyme. Methods: All patients in the Registry with symptom onset ≤12 months with evidence of cardiomyopathy and a record of treatment with ERT were eligible for analysis. Kaplan-Meier curves were fitted, stratified by patients with a recorded first ERT infusion <3 months or ≥3 months of age. Events were defined as death and use of invasive ventilation therapy or death. The time to the event was derived as time from birth. Only patients at risk for an event were included in the analyses. Because patients from Taiwan may have been identified by newborn screening (NBS) and not clinical diagnosis, analyses were performed with and without patients with a reporting physician from Taiwan. Results: A total of 140 patients with symptom onset ≤12 months with evidence of cardiomyopathy were eligible for analysis. Patients who received their first treatment with ERT at <3 months of age (n=36) had better survival rates than patients who started ERT at ≥3 months of age (n=104) at 12 months of follow-up (94% for ERT initiation at <3 months of age vs 91% for ERT initiation at ≥3 months of age) and more noticeably at 24 months (85% vs 73%) and 36 months (81% vs 64%) of follow-up. Invasive ventilator-free survival rates also were better for patients with initiation of ERT <3 months of age (n=24) compared with patients who started ERT at ≥3 months of age (n=69) at 12 months (91% vs 90%) and more noticeably at 24 months (82% vs 66%) and 36 months (76% vs 56%) of follow-up. Results were similar at all timepoints when patients from Taiwan were excluded. Conclusions: Earlier initiation of treatment in classic-infantile onset Pompe disease patients may improve the chances of survival and lead to better clinical outcomes overall and improvement of symptoms for these young, very ill patients.

2292F

PRX-102: an efficient plant expressed ERT for Fabry disease. *A. Paz, T. Kizhner, A. Schulman, M. Golembo, E. Brill-Almon, Y. Shaaltiel.* Protalix Biotherapeutics, Carmiel, Israel.

PRX-102, is a chemically modified, plant-cell expressed recombinant human alpha-GAL-A enzyme (prh-alpha-GAL-A) developed as enzyme replacement therapy (ERT) for the treatment of Fabry disease. There are currently two ERTs of recombinant human alpha-GAL-A commercially available: agalsidase-alfa and agalsidase-beta. The plant cell expressed recombinant human alpha-GAL-A has been modified by cross-linking and the addition of PEG molecules resulting in an enzyme which exhibits higher stability and prolonged activity under physiologically relevant conditions when compared to the commercially available drugs. We demonstrated that PRX-102 is active and localizes to the intracellular target, the lysosome, in Fabry patients' cells. PRX-102 presents higher stability under physiologically relevant conditions, and extended circulation residence time as compared to available commercial ERT. Furthermore, pharmacodynamic studies using a mouse model of Fabry disease show higher uptake in target organs than available commercial ERT and significant reduction of Gb3 accumulation. The extended circulation time, together with the increased uptake of PRX-102 as compared to commercial ERT, has the potential for a more efficient ERT for the treatment of Fabry disease. Currently, the PRX 102 enzyme is under evaluation in Fabry patients as part of a clinical study.

The Influence of a Polymorphism in the Gene Encoding Angiotensin Converting Enzyme (ACE) on Treatment Outcomes in Late-Onset Pompe Patients Receiving Alglucosidase Alfa. *R.C. Baek, R.E. Palmer, R.J. Pomponio, A.J. Mcvie-Wylie.* Genzyme, a Sanofi Company, Framingham, MA.

Angiotensin Converting Enzyme (ACE) catalyzes the conversion of angiotensin I to the vasoactive peptide angiotensin II, and degrades bradykinin, a potent vasodilator. One outcome of these two actions is vasoconstriction and an increase in blood pressure. Half of the variation in human ACE activity can be accounted for by an insertion/deletion (I/D) allele in intron 16 of the ACE gene. An insertion of an Alu repeat in intron 16 results in lower ACE activity (I allele), and conversely, the deletion (D allele) results in higher ACE activity. Furthermore, the I allele has been reported to be associated with the predominance of slow-twitch muscle fibers (Type I) and the D allele with fast-twitch muscle fibers (Type II). Two publications recently suggested that the ACE I/D polymorphism modifies the clinical presentation of Pompe patients and influences treatment outcomes following alglucosidase alfa enzyme replacement therapy (ERT). Specifically, patients with the D/D genotype presented with an earlier onset of disease, higher CK levels at diagnosis, increased pain, and more severe disease progression (Fillippi et al, 2010), and had poorer treatment outcomes on ERT (Ravaglia et al, 2012). We investigated these findings in a large cohort of late-onset Pompe patients included in a randomized, placebo-controlled trial of alglucosidase alfa. Our results also suggest that patients carrying two DD alleles demonstrate an attenuated response to treatment relative to the I/D and I/I genotypes. This result was not associated with the antibody response to alglucosidase alfa. An investigation into the disease status of patients at entry into the clinical trial is ongoing.

Polymeric Nanocarriers as Vehicles for the Treatment of Lysosomal Storage Diseases. *M. Latorre-Esteves, A. Román.* Chemical Engineering, University of Puerto Rico- Mayagüez Campus, Mayagüez, PR.

Lysosomal Storage Diseases (LSDs) are a group of inheritable genetic diseases caused by mutant lysosomal enzymes, leading to the accumulation of undigested macromolecules in the lysosome, thus causing increases in lysosome size and number, cellular dysfunction, clinical abnormalities, and premature death. Some LSDs can be treated with Enzyme Replacement Therapy (ERT) through intravenous administration of a recombinant enzyme in replacement of the defective enzyme. However, this is an expensive and inefficient method with adverse side effects associated with the high enzyme amounts required for the treatment, the need of post-translational modification of the enzyme and the host immune system response. We hypothesize that nanocarriers composed of Polyethylene glycol and Polycaprolactone (PEG-PCL) block copolymers can enhance ERT by eliminating the need of enzyme modification and protecting it from host immune system until lysosomal target is reached. We have designed these nanocarriers to remain stable at physiological pH and destabilize at acidic pH, allowing them to reach the cell intact and degrade once inside the acidic lysosome, only then releasing therapeutic cargo into affected cellular organelle. In order to obtain the appropriate nanocarriers for ERT application, we synthesized a group of PEG-PCL nanocarriers, varying the production process and surfactant concentration. The most suitable combination was found by performing dynamic light scattering analysis (DLS), gel permeation chromatography (GPC), Themogravimetric Analysis (TGA) and several spectroscopic techniques. We found the nanocarriers are not cytotoxic in cell lines tested. We are currently working on the reproducibility of syntheses and protein loading capacity into nanocarriers.

Augmenting glucocerebrosidase activity in the CNS as a therapeutic strategy for Gaucher-related synucleinopathies. *P. Sardi, J. Clarke, C. Viel, M. Chan, C. Treleaven, J. Bu, L. Sweet, M. Passini, J. Dodge, L. Stanek, S. Cheng, L. Shihabuddin.* Genzyme, a Sanofi Company, Framingham, MA.

Mutations of *GBA1*, the gene encoding glucocerebrosidase, represent a common genetic risk factor for developing the synucleinopathies Parkinson's disease (PD) and dementia with Lewy bodies (DLB). PD patients with or without *GBA1* mutations also exhibit lower enzymatic levels of glucocerebrosidase in the central nervous system (CNS), suggesting a possible link between the enzyme and the development of the disease. To probe this link further, we evaluated the efficacy of augmenting glucocerebrosidase activity in the CNS of a mouse model of Gaucher-related synucleinopathy ($Gba1^{D409V/D409V}$) and a transgenic mouse overexpressing A53T α-synuclein. Adeno-associated virus-mediated expression of glucocerebrosidase in the CNS of symptomatic $Gba1^{D409V/D409V}$ mice completely corrected the aberrant accumulation of the toxic lipid glucosylsphingosine and reduced the levels of ubiquitin and proteinase-K-resistant α-synuclein aggregates. Importantly, hippocampal expression of glucocerebrosidase in $Gba1^{D409V/D409V}$ mice (starting at 4 or 12 months old) also reversed their cognitive impairment when examined using the novel object recognition test. Overexpression of glucocerebrosidase in the CNS of A53T α-synuclein mice reduced the levels of soluble α-synuclein, suggesting that this glycosidase can modulate the development of α-synucleinopathies. Hence, increasing glucocerebrosidase activity in the CNS represents a potential therapeutic strategy for GBA1-related and non-GBA1-associated synucleinopathies.

Permanent genetic modification of dividing cells using episomally maintained S/MAR DNA vectors and the correction of a cancer phenotype in renal tumour cells. *R. Harbottle[1,2], SP. Wong[2].* 1) DNA Vector Research Group, German Cancer Research Centre (DKFZ), Heidelberg, Germany; 2) Gene Therapy Research Group, Imperial College London, UK.

The simple, stable and efficient application of episomal DNA vectors to genetically modify dividing cells without the risk of integration-mediated genotoxicity provides a valuable tool in cell biology research. Here, we demonstrate the utility of Scaffold/Matrix Attachment Region (S/MAR) DNA plasmid vectors to rapidly and simply generate novel genetically modified cell lines. In this study we utilize these vectors to model the restoration of a functional wild-type copy of the gene implicated in the renal cancer Birt-Hogg-Dube (BHD) in a cell-line (UOK257) derived from a BHD patient. Inactivation of the BHD gene, encoding a protein called folliculin (FLCN) has been shown to be involved in the development of sporadic renal neoplasia in BHD. Persistent genetic correction of UOK257 cells with an S/MAR-FLCN plasmid (UOK257-FS) restores FLCN expression and normalises downstream TGFβ signalling. We demonstrate that UOK257-FS cells show a reduced growth rate in vitro and suppressed xenograft tumour development in vivo, compared to the original FLCN-null UOK257 cell line. We also show that mTOR signaling in serum-starved FLCN-restored cells is differentially regulated compared to the FLCN-deficient cells indicating the complex role of FLCN in separate signalling pathways. The novel UOK257-FS cell line will be a useful tool for studying different feedback loops in signalling pathways affected in BHD pathogenesis and provides further insight into the role of the FLCN in BHD. More significantly, this study demonstrates the suitability of episomally maintained S/MAR DNA vectors to successfully model the persistent functional expression of a therapeutic gene in a cancer cell line. It should also establish this class of vectors as effective tools for investigating signalling components differentially regulated in different cancers and to aid the identification of novel cancer markers for diagnosis and therapy. Additionally, this study illustrates the utility of this class of vectors for the genetic modification of cells without the risk of genotoxicity.

Brain-directed recombinant AAVrh10-ATP7A plus subcutaneous copper histidine extends lifespan in the *mo-br* model of Menkes disease. *E.Y. Choi, M.R. Haddad, K. Patel, S.G. Kaler.* Molecular Medicine Program, NICHD/NIH, Bethesda, MD.

Menkes disease is a debilitating X-linked recessive neurometabolic disorder caused by mutations in a copper-transporting ATPase, ATP7A. No long-term, predictably effective treatment for affected individuals has been developed in the 50 years since the initial description of Menkes disease. While subcutaneous injections of copper may bypass the defect in intestinal copper absorption and normalize blood copper levels, at least a rudimentary level of ATP7A function is needed to restore proper intraneuronal copper transport, and attain normal neurodevelopment. Notably, early copper replacement in some affected patients whose mutations permitted as little as 5-10% residual ATP7A copper transport activity led to completely normal neurodevelopmental outcomes. We found previously that intracerebroventricular (ICV) administration of rAAV (serotype 5) harboring an expression cassette with a compact version of human *ATP7A* had a salutary, synergistic effect with ICV copper admininistration in a lethal mouse model of Menkes disease, *mo-br*. This combination therapy led to higher brain copper concentrations, reduced neuropathology, and enhanced survival when administered to the lateral ventricles of newborn *mo-br* mice (Donsante et al. *Mol Ther*, 2011). A recently identified AAV serotype, rh10, shows broader neuronal tropism than AAV5, demonstrating robust transduction of multiple neuronal cell types, as well as choroid plexus epithelia. Broad neuronal transduction would be especially desirable in instances of a complete loss-of-function ATP7A mutation. Brain-directed rAAVrh.10 represents a desirable route of administration from immunological and tissue target perspectives. Therefore, we have advanced our efforts in the *mo-br* model of Menkes disease by evaluating the efficacy of ICV administration of rAAVrh.10-ATP7A in combination with subcutaneous copper histidine (CuHis). We demonstrated extended lifespan and brain neurochemical correction with this regimen. The optimal timing of these treatments to date was low dose (1.6×10^9) rAAVrh10 on day 2 with subcutaneous CuHis (10 µg) on day 5 (single administration of each). These dose-ranging preclinical studies presage application of this approach in human subjects with Menkes disease associated with severe loss-of-function ATP7A mutations.

2298F

Genotoxicity following AAV Gene Therapy for Methylmalonic Acidemia (MMA) in Mice. *R.J. Chandler, A.A. Ashok, G.K. Varshney, M.C. LaFave, W. Wu, V.J. Hofffmann, A.G. Elkahloun, S.M. Burgess, C.P. Venditti.* Nat Human Genome Res Inst, National Institutes Hlth, Bethesda, MD.

Many studies have repeatedly demonstrated the safety of adeno-associated virus (AAV) vectors. However, one report has documented an increased incidence of hepatic cellular carcinoma (HCC) in neonatal mice after AAV gene therapy and further implicated insertional mutagenesis by the vector at the *RIAN* locus as a causative factor (Donsante *et al., 2007*). We have previously demonstrated the pre-clinical efficacy of AAV gene delivery using a neonatal lethal MMA murine model. Although the evaluation of genotoxicity was not the intended focus of our studies, the long-term surveillance of both AAV-treated MMA mice and control littermates has revealed that 75% (n=48) of AAV8-CBA-Mut treated mice developed HCCs between 12 and 21 months compared to a 2% (n=41) HCC rate in untreated littermates. In addition, 50% of the mice similarly treated with a control vector, AAV8-CBA-GFP, also developed HCCs, indicating that overexpression of the Mut transgene is not responsible for the development of HCC. We next performed a dose escalation study by increasing the AAV8 dose from $7\times10^{11-12}$ GC/kg (n=16) to 1×10^{14} GC/kg (n=19) and noted a corresponding increase in the incidence of HCC from 12% to 84%, respectively. As previously observed by Donsante *et al., 2007*, our preliminary data indicates that insertional mutagenesis of the vector at the *RIAN* locus, with subsequent dysregulation of local miRNA expression, occurs in AAV-associated HCCs. Determining why AAV gene delivery is infrequently associated with tumorigenesis in mice and whether such toxicity is relevant to humans remain as unresolved questions for those using AAV in human gene therapy applications.

2299T

Developing resources to alleviate muscle atrophy in FSHD by genome engineering. *S. Das, B.P. Chadwick.* Department of Biological Science, The Florida State University, Tallahassee, FL.

Facioscapulohumeral muscular dystrophy (FSHD), a debilitating disease with currently no cure or effective therapy, is the third most common inherited form of muscular dystrophy. FSHD is primarily characterized by progressive weakness and atrophy of skeletal muscle of the face, shoulders and upper arms. Both forms of this autosomal dominant disorder (FSHD1 and FSHD2) are likely caused by the reactivation of the double homeobox gene DUX4 that is epigenetically repressed in somatic cells. The more common form, FSHD1, is caused by a contraction in the number of repeat units of the macrosatellite D4Z4 at 4q35. Each repeat unit contains the DUX4 open reading frame. FSHD2 is a result of a digenic inheritance of mutant SMCHD1 gene and a permissive 4q allele but is contraction-independent. The inappropriate expression of DUX4 in somatic muscle inhibits muscle differentiation and replenishment. Importantly, both forms of FSHD have a strict requirement for specific allelic variants of chromosome 4q and at least one unit of D4Z4, as complete loss of the repeat does not result in disease. Taking advantage of this, we are focused on development of an effective therapeutic strategy for FSHD using genome engineering in human cells through custom-built Transcription Activator Like Effector Nucleases (TALENs). Currently, we are developing TALENs to target regions immediately proximal and distal to the D4Z4 array that can be used to remove the array or disrupt the polyadenylation signal on a permissive chromosome, in order to alleviate toxic gain of function. We are currently testing candidate nucleases on model cell lines. Successful editing of the diseased allele will permit use of our custom-built nucleases, to modify patient specific induced pluripotent stem cells (iPS), with the ultimate goal of using modified cells as a possible therapeutic strategy for muscle restoration. Our approach could be used in FSHD patient-specific cell transplantation therapy, in an attempt to alleviate this debilitating condition, and improve quality of life.

Gene Therapy for Mucopolysaccharidosis VII: Evaluation of Intrathecal rAAV Vectors in the Canine Model. *B.L. Gurda[1], P. Wang[2], P. Bell[1], J. Bagel[3], T. Sikora[2], P. O'Donnell[2], Y. Zhu[1], H. Yu[1], T. Ruane[2], R. Calcedo[1], M. Casal[2], C.H. Vite[3], K.P. Ponder[4], J.M. Wilson[1], M.E. Haskins[2].* 1) Pathology and Laboratory Medicine, School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Pathology and Medical Genetics, School of Veterinary Medicine, University of Pennsylvania Philadelphia, PA; 3) Section of Neurology & Neurosurgery, Department of Clinical Studies, School of Veterinary Medicine University of Pennsylvania, Philadelphia, PA; 4) Department of Internal Medicine, Washington University School of Medicine, St. Louis, MO.

Mucopolysaccharidosis Type VII (MPS VII) is a lysosomal storage disease resulting from mutations in β-D-glucuronidase (GUSB) necessary for the catalysis of glycosaminoglycans (GAGs). The central nervous system (CNS) has been difficult to treat with systemic gene therapy due to inefficient transduction of the brain and poor diffusion of enzyme across the blood brain barrier. The goal of this study was to determine the expression of two adeno-associated viral (AAV) vectors in the CNS of MPS VII dogs, comparing intravenous (IV) injection with or without intrathecal (IT) administration. Four MPS VII dogs were treated IV at post-natal day 3 with 2E13 genome copies (GC)/kg of either an AAV9 (n=2) or AAVrh10 (n=2) vector encoding the canine GUSB cDNA under the control of a chicken beta-actin promoter. At 60 days post-IV injection one animal from each group was injected IT into the cisterna magna with the other vector (≈4E12GC/kg). Enzyme activity in the serum and CSF was monitored over 6 months, while brain and spinal cord collected at sacrifice were analyzed for GUSB activity, a secondary storage substrate (GM3 ganglioside), and vector copy number. Serum GUSB activity stabilized at ≈30% of normal in all four dogs. Activity in the CSF was near normal in the dogs that did not receive vector IT and 140- and 100-fold normal in the AAVrh10 and AAV9 IT-treated dogs, respectively. Mean biochemical GUSB activity of six brain regions was >4.5-fold normal in the IT-AAV9 dog and >2.5-fold normal for the IT-AAVrh10 dog, correlating to vector copy numbers. The activity in the cervical spinal cord was 4.7- and 2.5-fold normal for AAV9 and AAVrh10, respectively. GUSB activity in the CNS from the IV-only injected dogs was <4% of normal. Only after IT delivery were low levels of AAV-antibodies detected in the CSF. Histochemical staining for GUSB activity was widespread throughout the CNS in the IT-injected dogs: Purkinje cells of the cerebellum were particularly prominent. GUSB staining was seen in the choroid plexus of all treated dogs, likely explaining the normal GUSB activity in the CSF of the IV-only treated dogs. There was a reduction in GM3 ganglioside in the IT-treated dogs by immunohistochemistry. Somatic tissues were also analyzed. In conclusion, this study determined that IT injection of AAV vectors resulted in impressive levels of expression in the CNS of MPS VII dogs and has tremendous potential for treating the CNS manifestations of lysosomal storage disorders.

Translational Fidelity of Intrathecal Delivery of scAAV9-SMN1 for Spinal Muscular Atrophy. *M.A. Passini[1], J. Bu[1], A.M. Richards[1], C.M. Treleaven[1], C.R. O'Riordan[1], A. Scaria[1], A.P. Kells[2], L. Samaranch[2], W. San Sebastian[2], T. Federici[3], M.S. Fiandaca[4], N.M. Boulis[3], K.S. Bankiewicz[2], L.S. Shihabuddin[1], S.H. Cheng[1].* 1) Genzyme, a Sanofi Company, Framingham, MA; 2) University of California, San Francisco, CA 94103; 3) Emory University, Atlanta, GA 30322; 4) Georgetown University, Washington DC 20057.

Spinal muscular atrophy (SMA) is a pediatric neuromuscular disease caused by mutations in SMN1. Previously, we showed that delivery of an AAV vector encoding SMN1 into the CNS of a mouse model of SMA corrected several aspects of the disease and afforded a significant extension in their lifespan. Here, we determined (i) the minimal number of genetically modified motor neurons in the spinal cord of SMA mice necessary for clinically relevant efficacy, and (ii) the level of motor neuron transduction efficiency following intrathecal delivery in juvenile pigs and non-human primates. Injection of 5e10, 1e10, and 1e9 genome copies (gc) of scAAV9-hSMN1 into the CNS of SMA mice extended their median lifespans from 14 days to 153d, 70d, and 18d, respectively. Analysis of the spinal cords treated with 5e10, 1e10, or 1e9 gc showed that 30-60%, 10-30%, and <5% of the motor neurons had detectable levels of hSMN protein, respectively. Hence, achieving at least 10-30% motor neuron transduction was sufficient to significantly improve motor function and survival in SMA mice. To determine the results of gene transfer in larger animal models, a viral vector encoding GFP (scAAV9-GFP) was administered intrathecally into juvenile pigs and monkeys. Analysis showed that a motor neuron transduction rate as high as 25-75% throughout the spinal cord in these large animal studies. Thus, the number of motor neuron transduction shown necessary for clinically relevant efficacy in SMA mice could be obtained in large animal models, justifying the continual development of intrathecal gene therapy for SMA.

Treatment of MFRP (Membrane frizzled-related protein)-related degeneration in patient-specific stem cells and a preclinical mouse model. *Y. Li, Y.T. Tsai, C.W. Hsu, W.H. Wu, S.H. Tsang.* Edward Harkness Eye Institute, Columbia University, New York, NY.

In the current era of personalized medicine, a large number of genetic variants have been discovered in patients with various diseases using next-generation sequencing techniques. Traditionally, to prove that genetic variants cause diseases, we have had to rely on animal models. However, substantial differences exist between mice and humans, including but not limited to drastic differences in lifespans. For instance, dopaminergic neuron projections are shorter in relation to overall body length in mice than in humans; thus, alpha synuclein Snca knockout mice do not develop Parkinson's disease. Instead, as new reprogramming technologies have developed, it has become more feasible to generate patient-specific stem cell lines to validate sequence variants, elucidate pathophysiology, and perform targeted drug screening. We have used such reprogramming technologies to prove that a novel mutation in the *MFRP* (membrane-type frizzled-related protein) gene is pathogenic. Light microscopic images of human stem-cell-derived retinal cells taken from a patient displayed dysmorphic cells. Correction of the defect restored the patient's retinal cells' morphology and function. Similarly, correcting genetic defects in the $Mfrp^{rd6}/Mfrp^{rd6}$ mouse can restore visual function in this preclinical model of retinitis pigmentosa.

The combined use of cis-acting genetic elements to enhance non-viral plasmid stability in mammalian cells. *B. Abbas[1], M.AK Abdalla[2], M. El-Mogy[3], B. Lam[4], V. Misic[1], Y. Haj-Ahmad[1,4].* 1) Brock University, St. Catharines, Ontario, Canada; 2) Department of Biochemistry, Faculty of Science, Alexandria University, Egypt; 3) Molecular Biology Department, National Research Center, Dokki, Cairo, Egypt; 4) Norgen Biotek Corp., Thorold, Ontario, Canada.

Gene transfer and gene expression are attractive methods for the generation and the delivery of recombinant therapeutic proteins, which basically need an efficient and safe delivery tool. Viruses have been used for many years as gene transfer vehicle for the delivery and the transient expression of recombinant proteins. However, to date, there is no efficient non-viral delivery tool for expression of plasmids (pDNA) as compared to viruses. It is proposed that the unsuccessful development of non-viral vector may be due to many barriers such as the transfection efficiency and plasmid stability. It has been reported that viruses contain cis - acting RNA elements that facilitate the posttranscriptional processing and the exporting of mRNA. Furthermore, it was also reported that the DNA cis - acting matrix attachment region elements (MAR) promote homologous recombination to enhance the level of DNA stability in the cell. Moreover, BGH poly signal has been reported to facilitate mRNA stability and RNA export process. Our hypothesis is, by using the viral cis - acting elements, BGH poly signal and/or matrix attachment region (MAR) in a non-viral vector may prolong the stability and hence the expression of the delivered gene. Therefore, in this study, we constructed various plasmid vectors harboring different cis-acting elements that were evaluated for enhancing plasmid DNA as well as mRNA stability in two mammalian cell-lines, HEK293 and HeLa. Both cell lines were transfected with equal copy number and plasmid DNA and mRNA copy numbers per cell were measured during three weeks. Data showed that the combination of multiple cis-acting elements has significant, unexpected effect on both plasmid DNA and mRNA stability. In summary, these results provide valuable information to improve non-viral vectors stability and transient gene expression in mammalian cells; with implications in both, gene expression studies, as well as gene therapy.

2304F

Expression of human GNE through adeno-associated virus mediated therapy delays progression of myopathy in the GNE myopathy mouse model. *M.C. Malicdan[1,2], T. Okada[3], S. Takeda[3], F. Funato[1], M. Huizing[2], I. Nonaka[1], Y.K. Hayashi[1], Z. Argov[4], I. Nishino[1], S. Mitrani-Rosenbaum[4], S. Noguchi[1].* 1) MGB, NHGRI, National Institutes of Health, Bethesda, MD; 2) Department of Neuromuscular Research, National Institute of Neuroscience, NCNP, Tokyo, Japan; 3) Department of Molecular Therapy, National Institute of Neuroscience, NCNP, Tokyo, Japan; 4) Hadassah-Hebrew University Medical School, Jerusalem, Israel.

GNE myopathy, also known as distal myopathy with rimmed vacuoles (DMRV) or (hereditary inclusion body myopathy (hIBM) is an early adult, moderately progressive myopathy due to mutations in GNE. This gene encodes a bifunctional enzyme critical to synthesis of sialic acid. GNE myopathy so far has been shown to be a disorder due to reduced sialylation of certain glycoconjugates in tissues including the muscle, as replenishment of sialic acid in the murine model has prevented the onset of a muscle phenotype. The caveat in sialic acid supplement therapy lies in the pharmacokinetic properties of sialic acid; its relatively short half-life due to rapid excretion after oral administration implies the need to explore other modalities. This paper thus aims to demonstrate the utility of gene therapy in ameliorating the muscle phenotype of the DMRV/hIBM mouse model. In this study, we generated AAV expressing human wt-*GNE* cDNA and enhanced green fluorescent protein (eGFP) under the transcriptional control of cytomegalovirus promoter in AAV 2/8 capsids. AAV 2/8 constructs that carry either human wt GNE or luciferase (in control virus) were injected intravenously into adult and symptomatic GNE myopathy mice. Unaffected littermates were also injected as controls. At 10 weeks after injection, eGFP expression was seen in a remarkable number of cells in the skeletal muscle, liver, kidney, heart, and spleen. Measurement of mRNA with specific human versus mouse probes revealed an increase in virus-derived human GNE expression. More importantly, GNE myopathy mice injected with AAV2/8-wt h*GNE* at 47 weeks of age showed a significant improvement in survival, motor performance, muscle size and contractile properties, as compared to those mice injected with AAV2/8-luciferase. These results establish a proof of principle in using AAV-mediated gene therapy for GNE myopathy.

2305T

Antisense Therapy for Genetic Disorders. *T.R Grossman.* Antisense Drug Discoverey, ISIS PHARMACEUTICALS, Carlsbad, CA.

Advances in deciphering the complex roles RNA plays in normal health and disease have been substantial over the past decade and RNA is becoming an increasingly important target for therapeutic intervention; accordingly therapeutic strategies that modulate RNA function are becoming increasingly important. Antisense oligonucleotides (ASO) are perhaps the most direct therapeutic strategy to approach RNA and ASO technology has emerged as a powerful alternative to conventional small molecule approaches or gene replacement strategies for the treatment of genetic disorders. ASO are short, synthetic single-stranded DNA sequences designed to bind to target RNA by well-characterized Watson-Crick base pairing, and once bound to the target RNA, can modulate RNA function through a variety of post binding events. ASO-mediated gene silencing occurs either through degradative mechanisms, where the target RNA is cleaved by endogenous nucleases, or non-degradative mechanisms, where ASO binding sterically blocks or modulate translation, capping, or splicing. Genetic disorders in which a dominant mutation results in a toxic gain of function, such as liver diseases associated with aggregates in liver like Hereditary Transthyretin (TTR) Amyloidosis, are attractive to approach with ASO therapy. An ASO directed to TTR mRNA resulted in dramatic reductions in mutated TTR protein in mouse models and in normal volunteers. In addition, ASO targeting CTR1 is under evaluation as therapy for Wilson disease. ASO designed to CTR1 mRNA results in significant reduction in CTR1 levels resulting in reduction in copper levels, in the blood, brain and liver and improved liver pathology in a mouse model of Wilson disease. Furthermore, antisense oligonucleotides can be effective therapies using non-degradative mechanisms. For treatment of Spinal muscular atrophy (SMA) an ASO designed to correct SMN2 splicing, restores SMN expression and extended life span in SMN mouse model. Many additional genetic diseases are successfully being targeted with ASO technology for example; ASO inhibition of apolipoprotein B synthesis by Kynamro (mipomersen sodium) is an effective therapy to reduce LDL cholesterol concentrations in patients with homozygous familial hypercholesterolaemia. This presentation will cover antisense technology platform and will include data from preclinical research and clinical trials with ASO drugs treating multiple genomic disorders.

2306F

Acute Hepatic Porphyrias: Inhibition of Hepatic ALAS1 with an RNAi Therapeutic Provides Effective Prevention and Treatment of Induced Acute Attacks in Acute Intermittent Porphyria Mice. *M. Yasuda[1], L. Gan[1], C. Yu[1], W. Querbes[2], A. Liebow[2], K. Fitzgerald[2], R.J. Desnick[1].* 1) Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY; 2) Alnylam Pharmaceuticals, Cambridge, MA.

The acute hepatic porphyrias include four inherited disorders of heme biosynthesis that are characterized by life-threatening acute neurovisceral attacks. The episodic acute attacks are precipitated by various factors that increase the expression of hepatic 5-aminolevulinic acid synthase (ALAS1), the first and rate-limiting enzyme in the heme biosynthetic pathway, resulting in the marked accumulation of the neurotoxic porphyrin precursors, δ-aminolevulinic acid (ALA) and porphobilinogen (PBG). The acute attacks are currently treated with a series of intravenous hemin infusions, but a faster-acting and safer therapy is desirable, particularly for patients with frequent attacks. Therefore, we designed a liver-directed RNA interference (RNAi) therapeutic using small interfering RNAs (siRNAs) targeted specifically against *Alas1* (designated ALAS1-siRNAs) and evaluated its effectiveness following intravenous administration in a mouse model of acute intermittent porphyria (AIP), the most common acute hepatic porphyria. These mice have slightly elevated baseline urinary and plasma ALA and PBG levels which are markedly increased (~30- and >85-fold in plasma, respectively) by administration of the porphyrinogenic drug phenobarbital, thereby inducing a 'biochemical' acute attack. To identify a potent ALAS1-siRNA, >40 siRNAs targeting the *Alas1* gene were screened for their ability to reduce *Alas1* mRNA expression in cultured hepatic cells. The most active compounds were formulated into lipid nanoparticles for efficient hepatic delivery and evaluated for their ability to downregulate hepatic *Alas1* mRNA in wild-type mice. A single prophylactic administration of the optimal ALAS1-siRNA in the AIP mice completely prevented the phenobarbital-induced upregulation of hepatic *Alas1* mRNA/protein expression and the consequential increases of plasma and urinary ALA and PBG for approximately two weeks. When ALAS1-siRNA was infused during an induced acute attack, plasma ALA and PBG levels decreased within 8 to 12 hours, much more rapidly and effectively than a single hemin infusion. Subcutaneous injection of a hepatocyte *N*-acetylgalactosamine (GalNAc) receptor-targeted ALAS1-siRNA preparation was effective in preventing the phenobarbital-induced acute attacks, thereby facilitating convenient therapeutic delivery. These preclinical studies provide proof-of-concept for the development of siRNA-mediated therapy to prevent and treat the acute attacks in the acute hepatic porphyrias.

Silencing mutant Htt by AAV-mediated expression of RNAi ameliorates disease manifestations in the YAC128 mouse model of Huntington's disease. *L.M. Stanek, P.S. Sardi, B. Mastis, A. Richards, S.H. Cheng, L.S. Shihabuddin.* Neuroscience, Genzyme a Sanofi Company, Framingham, MA.

Huntington's disease (HD) is a fatal autosomal dominant neurodegenerative disease that results from an expansion of polyglutamine residues in the huntingtin (Htt) protein. With the identification of the underlying basis of HD, therapies are being developed that reduce the expression of the causative mutant Htt. RNA interference (RNAi) that seeks to selectively reduce the expression of such disease-causing agents is emerging as a potential therapeutic strategy for treating dominant disorders. This study examines the merits of administering a recombinant adeno-associated viral (AAV) vector designed to deliver a shRNA to target and lower Htt levels in the striatum, at correcting the biochemical and behavioral deficits associated with the YAC128 mouse model of HD. We showed that AAV-mediated shRNA expression partially reduced the levels of wild-type and mutant Htt in the striatum. Concomitant with these reductions were significant improvements in both motor and behavioral deficits in YAC128 mice. Lowering mutant Htt levels was also associated with a reduction in the number of Htt aggregates that accumulated in the striatum of YAC128 mice. These results are supportive of the development of AAV-mediated RNAi as a therapeutic strategy for the treatment of HD.

Hematopoeitic-stem-cell based therapy for HIV disease. *J. Bodor, J. Chalupnikova, K. Pavelcova, J. Jencik, R. Klubal, gp120 Consortium.* Czech Gene Bank, Prague, 4, Czech Republic.

Our aim is to develop a novel technology platform to cure HIV disease. The major innovation is to use hematopoetic stem cell (HSC) transplantation of the cells resistant to HIV (such as CCR5 delta 32 cells spontaneously occuring in 4-15% of EU population) while improving the outcome of engraftment of HIV resistant cells in HIV patients with AIDS lymphoma or leukemia by suppressing graft-versus-host disease using gp120. This is based on novel evidence for the cure of HIV infection by CCR5 delta 32 stem cell transplantation ('Berlin patient' reported in Allers et al. 2011, Blood 117: 2791) and by novel insights of the protection from graft-versus-host disease by HIV-1 envelope protein gp120-mediated in human regulatory T cells by elevated levels of cAMP (Becker et al. 2009, Blood 114: 1263; Vaeth et al. 2011, PNAS 108: 2480; Klein et al. 2012, J Immunol 188: 1091). The concept of allogeneic stem cell transplantation of the cells resistant to HIV using regimen improving function of regulatory CD4+ T cells favours suppressing graft-versus-host disease while retaining the benefits of graft-versus-leukemia effect. Therefore, the concept constitutes an outstanding example of cure rather than indefinite anti-retroviral treatment. The unprecedented power of the hematopoetic stem cell transplantation of the CCR5 delta 32 cells resistant to HIV has been proven to cure HIV infection in the case reported last year ('Berlin patient'). Successful reconstitution of CD4+ T cells at the systemic level as well as in the gut mucosal immune system was found while the patient remained without any sign of HIV infection. Furthermore, during the process of immune reconstitution, evidence for the replacement of long-lived host tissue cells with donor-derived cells indicates that the size of the viral reservoir has been reduced over the time. Next step is to create database of CCR5 delta 32 donors in Stem Cell Bank and further optimize treatment of graft-versus-host disease by gp120 in phase I clinical trials at Transplantation Unit. Clients are HIV patients with AIDS-related lymphoma or specific forms of leukemia. Side effects of HSC against HIV will be minor and restricted to graft-versus-host disease. HSC against HIV treatment costs are in the same range as the costs of HSC therapy, but considerably less expensive than lifelong anti-retroviral (ART) therapy.

2309T

Lipid storage and impaired function in iPSC and monocyte - derived Gaucher macrophages are reversed with a non-inhibitory chaperone. *E. Sidransky[1], E. Aflaki[1], N. Tayebi[1], B. Stubblefield[1], E. Maniwang[1], G. Lopez[1], E. Goldin[1], S. Patnaik[2], J. Marugan[2].* 1) Molec Neurogen, 1A213, MGB/NHGRI/NIH, Bethesda, MD; 2) NIH Chemical Genomics Center, NIH Center for Translational Therapeutics, National Center for Advancing Translational Sciences, National Institutes of Health, Rockville, MD, USA.

Gaucher disease (GD), the inherited deficiency of glucocerebrosidase, manifests with lysosomal glycolipid storage, primarily in macrophages. Chemical chaperone therapy has been developed as a means to increase glucocerebrosidase levels in patients. Since improved cell models of GD exhibiting a storage phenotype were needed to facilitate drug development, monocyte and induced pluripotent stem cell- (iPSC) derived-macrophages from patients with GD were generated and characterized. Both patient (n= 20) and iPSC-derived macrophages (n=5 lines) share the same phenotype and exhibit reduced glucocerebrosidase activity. Storage, enhanced with tagged glycolipids and erythrocyte ghosts from patients with GD, was confirmed by lipid quantification and fluorescence microscopy. The Gaucher macrophages showed efficient phagocytosis, while efferocytosis of dead cells was impaired. Intracellular reactive oxygen species production was reduced and phagosome maturation altered, indicating that Gaucher cells have defective digestion of phagocytes. Using high-throughput screening with patient spleen as the source of mutant enzyme, several non-inhibitory, small molecule chaperones for glucocerebrosidase were identified. The lead compound reversed the disease phenotype, enhanced glucocerebrosidase specific activity, reduced lipid storage and normalized the efferocytic index. Our new capability to evaluate alterations in models closely mimicking the disease phenotype should greatly enhance our understanding of disease pathogenesis and facilitate the development and characterization of new treatments for Gaucher disease.

MicroRNA-486 overexpression delays the disease pathology of dystrophin-deficient muscle. *M.S. Alexander[1], J.C. Casar[1], N. Motohashi[1], N.M. Vieira[1], M.J. Gasperini[1], J.A. Myers[1], E.A. Estrella[1], P.B. Kang[1,5], F. Shapiro[6], G. Kawahara[1], E. Gussoni[1], L.M. Kunkel[1,2,3,4].* 1) Genetics, Boston Children's Hospital/Harvard Medical School, Boston, MA; 2) The Manton Center for Orphan Disease Research at Boston Children's Hospital, Boston, MA; 3) Department of Pediatrics and Genetics at Harvard Medical School; 4) Harvard Stem Cell Institute, Cambridge, MA 02138; 5) Department of Neurology, Boston Children's Hospital and Harvard Medical School; 6) Departments of Orthopedic Surgery at Boston Children's Hospital and Harvard Medical School, Boston MA 02115.

Duchenne Muscular Dystrophy (DMD) is caused by mutations in the dystrophin gene that result in the dysregulation of many signaling pathways that interact directly or indirectly with the dystrophin protein. Previously, we identified miR-486 as being strongly reduced in its expression levels in the dystrophin-deficient mouse and muscle biopsies of human DMD patients. Here we report that transgenic overexpression of the muscle-enriched microRNA, miR-486, in mdx5cv (dystrophin-mutant) mice resulted in improved serum biochemistry, reduced apoptosis, increased myofiber size, and improved muscle regeneration following injury. Transient overexpression of miR-486 also resulted in similar improved muscle physiology in the mdx5cv mouse. Using a bioinformatic approach, we identified DOCK3, dedicator-of-cytokinesis-3, as being a direct downstream target of miR-486 in skeletal muscle. Manipulation of DOCK3 expression in myoblast cell culture had strong effects on normal and DMD myoblast proliferation, apoptosis, and differentiation capabilities. Together, these studies demonstrate that stable overexpression of miR-486 delays many of the signs of the disease pathology of dystrophin-deficient muscle.

2311T

Epigenetic upregulation of Survival of Motor Neuron 2 (SMN2) protein by oligonucleotides targeting long non-coding RNA. *K.M. Hussey[1], R. Davey[1], E. Brand[1], D. Knowlton[1], B. Schwartz[1], R. Subramanian[1], J. McSwiggen[1], A. Krieg[1], J. Keil[2], H. Cardona[2], C. DiDonato[2], J. Barsoum[1].* 1) RaNA Therapeutics, Cambridge, MA; 2) Northwestern University & Lurie Children's Hospital of Chicago Research Center, Chicago, IL.

Spinal Muscular Atrophy (SMA) is a motor neuron disease affecting 1 in 6,000 children. This inherited disease leads to muscle weakness and atrophy and is mainly caused by a deleted or defective survival of motor neuron 1 (SMN1) gene. The SMN1 (telomeric) protein is a key player in cellular splicing events as a member of the snRNP complex in spinal cord neurons. A nearly identical gene, SMN2 (centromeric), is expressed in the same cells, albeit at very low levels due to a single point mutation that results in defective splicing. SMN2 is able to functionally compensate for SMN1 and support a milder phenotype when SMN2 copy number is increased, suggesting SMN2 as a primary therapeutic target. RaNA's goal is to specifically up-regulate the transcripts derived from the SMN2 gene, ultimately increasing functional SMN2 protein and improving SMA disease conditions.

Our platform is based on a recently discovered class of long noncoding RNAs (lncRNAs) that interact with the Polycomb Repressive Complex 2 (PRC2) and act in cis to repress gene transcription. RaNA's approach is to utilize short synthetic oligonucleotides (oligos) to interfere with this lncRNA-PRC2 interaction specifically at the SMN2 locus, relieve SMN2 repression, and drive transcription of the SMN2 gene. To this end, we have identified several oligos that up-regulate full length SMN2 mRNA 3-5 fold and protein by 3-7 fold above baseline in SMA patient-derived fibroblasts. These oligos target lncRNA transcripts in the SMN2 gene locus. Our results indicate that RaNA oligos enhance transcription of full length SMN2 mRNA and functional protein as well as correct the defective splicing of the transcript. Preliminary studies in a humanized SMA mouse model suggest that RaNA oligos can positively affect preclinical outcomes.

Current in vivo studies are focused on determining the effects of RaNA oligos on various preclinical phenotypes and survival in humanized SMA mouse models. Furthermore, we are investigating global- and locus-specific epigenetic and transcriptional changes to understand the mechanisms of RaNA oligo action. Collectively, our data suggests a novel epigenetic mechanism to increase SMN2 protein production that will likely provide a significant therapeutic benefit to SMA patients.

2312F

Towards the therapy for Angelman syndrome. *L. Meng[1], A. Award[2], F. Rigo[2], A. Beaudet[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Isis Pharmaceuticals, Carlsbad, CA.

Angelman syndrome (AS) is a severe neurodevelpmental disorder caused by maternal deficiency of the imprinted gene *UBE3A*. Although the molecular mechanisms of maternal deficiency are diverse, all AS patients carry at least one copy of paternal *UBE3A*, which is silenced but intact. By correcting the expression level of *UBE3A* via activating the silenced paternal allele, the disease might be treated. *UBE3A-ATS* is the antisense transcript of *UBE3A* that negatively regulates its expression. By truncating this antisense RNA in mice, we showed that depletion of *Ube3a-ATS* is sufficient to activate expression of paternal *Ube3a* and rescue phenotypic defects in the Angelman syndrome mouse model, including motor defects, cognitive deficit, and impaired long-term potentiation. Next, to develop specific therapy for Angelman syndrome, we sought to activate paternal *Ube3a* by knocking down *Ube3a-ATS* with antisense oligonucleotides (ASOs). With screens performed in cultured mouse neurons, we successfully identified several mouse specific ASOs that can achieve full activation of paternal *Ube3a*. Different from topoisomerase inhibitors, ASOs we identified are more site-specific, with little or minimal effect on nearby paternally expressed genes of *Snrpn*, *Snord115* and *Snord116*. Compared with PBS-treated animals, mice recieved intracerebroventricular injection of ASOs show significant knock-down of *Ube3a-ATS* and activation of paternal *Ube3a* in the cortex and other brain regions four weeks post injection, indicating that the ASOs function effectively *in vivo*. Future studies aim to achieve phenotypic improvement in the Angelman syndrome mouse model following CNS administration of ASOs and identifying human-specific ASOs for treating Angelman syndrome.

Decoding the biochemistry of Snyder-Robinson Syndrome: Using yeast to model the polyamine biosynthetic defect. *J.S. Albert[1], M.K. Chattopadhyay[2], W. Bone[1], L.A. Wolfe[1], W.A. Gahl[1], C.F. Boerkoel[1].* 1) NHGRI, National Institutes of Health, Bethesda, MD; 2) NIDDK, National Institutes of Health, Bethesda, MD.

Polyamines are simple, positively charged, ubiquitous molecules that interact with anionic compounds such as DNA, RNA, and ATP. Homeostasis of the polyamines putrescine, spermidine, and spermine is essential to cell growth and survival and is maintained primarily by the biosynthetic enzymes ornithine decarboxylase (ODC), S-adenosylmethionine decarboxylase (AdometDC), spermidine synthase (SRM) and spermine synthase (SMS). The balance of spermine and spermidine is crucial for proper chromatin structure, ion channel regulation, transcription and translation. Disruptions in polyamine homeostasis are associated with Snyder-Robinson syndrome (SRS), an X-linked intellectual disability syndrome first reported in 1969. SRS results from a mutation in SMS and produces a complex multi-systemic phenotype including intellectual disability, dysmorphic facies, muscle hypotonia, kyphoscoliosis, osteoporosis, seizures, and speech and gait abnormalities. The mechanism whereby dysregulation of polyamine homeostasis results in SRS is unknown. We are using an *S. cerevisiae* knockout model of *SMS* (*SPE4*) to study the polyamine biosynthetic pathway. Using HPLC analysis, we have found that SPE4 knockout yeast strains, compared to wild-type, have only a 1.3 fold increase in spermidine under physiologic conditions and only a 1.5 fold increase in spermidine in the presence of supra-physiologic (10mM) spermidine concentrations. This attenuated increase in spermidine is similar to that observed in individuals with SRS. Spermine is undetectable in the *SPE4* knockout strain. We also found elevated levels of methylthioadenosine (MTA), a product of the biosynthetic pathway and an inhibitor of the upstream enzyme, spermidine synthase, in the cell extract of the *SPE4* knockout, but not in the media. This suggests that increase in MTA could serve to protect the cells from accumulating deleterious amounts of spermidine. These results suggest that accumulation of spermidine and deficiency of spermine are not the cause of SRS. We discuss this as well as our ongoing studies on the possible biochemical etiology for SRS.

2314F

Secondary Coenzyme Q10 deficiency in patients with BRAF mutations. *E. Trevisson[1], M.A. Desbats[1], C. Cerqua[1], M. Doimo[1], A. Casarin[1], C. Santos-Ocaa[2], P. Navas Lloret[2], L. Salviati[1].* 1) Woman and Child Health, Clincal Genetics Unit, Univ Padova, Padova, Italy; 2) Centro Andaluz de Biologia del Desarrollo, Universidad Pablo de Olavide, Sevilla, Spain.

Coenzyme Q10 (CoQ) is a small lipophilic molecule that plays fundamental cellular functions: it acts as an electron transporter between complexes I and II of the mitochondrial respiratory chain and complex III, it functions as an antioxidant and as a cofactor of several mitochondrial dehydrogenases, among which dihydroorotate dehydrogenase, an essential enzyme involved in pyrimidine biosynthesis. Coenzyme Q10 is composed of a polar quinone group derived from tyrosine and a polyisoprene tail of different length in different species . In yeast the CoQ biosynthetic pathway requires at least 12 different proteins, encoded by COQ genes, that are organized into a multienzyme complex organized around Coq4p. In humans this process is still poorly understood. Coenzyme Q deficiency is a biochemical phenotype observed in a number of different clinical conditions. A genetic classification distinguishes primary deficiencies, in which the reduction in CoQ content is caused by mutations in genes directly involved in the CoQ biosynthetic process (PDSS1, PDSS2, COQ2, COQ4, COQ6, ADCK3, COQ9), and secondary forms, which are caused by defects in genes unrelated to the CoQ biosynthetic pathway (ETF, ETFDH, BRAF,APTX). Biochemically, patients present with reduction of CoQ in skeletal muscle and in skin fibroblasts. in addition to a reduction of the enzymatic activities of respiratory chain complex I+III and II+III (two CoQ-dependent reactions). BRAF encodes for a serine/threonine kinase acting downstream to Ras and regulating the MAP kinase/ERK signaling pathway. As stated above, mutations in this gene causes cardio-facio-cutaneous (CFC) syndrome and have been associated to Coenzyme Q10 deficiency in a single patient (Aeby et al 2007). Here we described two patients affected by CFC syndrome due to BRAF mutations who display myopathic features and responded to CoQ supplementation. Measurement of CoQ from skin fibroblasts shows a reduction in ubiquinone content; also CoQ biosynthetic rate was decreased in these cells. We report the biochemical characterization of CFC patients fibroblasts. Our data indicate that CFC can be complicated by secondary CoQ deficiency and have important implications for the treatment of this condition.

2315T

Fine-mapping of the *Atp7a* promoter deletion and biochemical characterization in the *mottled-dappled* mouse model of Menkes disease. *M.R. Haddad[1], K. Patel[1], P. Sullivan[2], D.S. Goldstein[2], J.A. Centeno[3], S.G. Kaler[1].* 1) Molecular Medicine Program; NICHD, NIH, Bethesda, MD; 2) Clinical Neurosciences Program, NINDS, NIH, Bethesda, MD; 3) Division of Biophysical Toxicology, Joint Center for Pathology, Malcolm Grow Medical Clinic, Andrews Air Force Base, Camp Springs, MD.

The *mottled-dappled* (*mo-dp*) is a mouse model of X-linked recessive Menkes disease caused by a large, previously uncharacterized deletion in the 5' region of *Atp7a*, the mouse ortholog of human *ATP7A*. Affected mutants die *in utero* at E17 and show bending and thickening of the ribs, and distortion of the pectoral and pelvic girdles and limb bones (Kaler, *Nat Rev Neurol* 2011). We have embarked on a prenatal approach (Haddad et al, *Mol Ther Nucleic Acids* 2013) for rescue of *mo-dp* to provide additional proof-of-concept in support of translation to viral gene therapy for Menkes disease. To develop a reliable genotyping assay for the pre-clinical gene therapy study, we designed a custom 4x180K microarray on the mouse X chromosome and tiled 60-mer probes around the region of interest near the *Atp7a* locus. The average resolution (probe spacing) of the microarray in the vicinity of the deletion was 675 bp. We performed comparative genomic hybridization (CGH) using extracted DNA from normal and carrier *mo-dp* females. CGH revealed a deletion of ≈9.4 kb. We fine-mapped the deletion breakpoints using PCR and successfully amplified a junction fragment of 630 bp using the following primers: F-TGTCAGCCTTTCTGGGAAGT and R-CAGCACTGGGGAGGTTAAGA. Sequencing the junction fragment disclosed the exact breakpoint positions and determined that the mo-dp deletion is precisely 8,245 bp and includes 2 kb in the promoter region, exon 1 and nearly 6 kb of intron 1 of *Atp7a*. Western blot analyses of *mo-dp* heterozygote brains showed diminished amounts of full length Atp7a protein compared to normal, consistent with reduced expression due to the promoter region deletion on one allele. In addition, brain neurochemicals from heterozygous females showed statistically significant higher DA:NE and DOPAC:DHPG ratios compared to normal ($p=0.0128$ and 0.0034, respectively), consistent with partial deficiency of dopamine-beta-hydroxylase, a copper-dependent brain enzyme that converts dopamine to norepinephrine. Brain copper measurements are pending. Our results delineate the molecular details of the *mo-dp* mutation, enable a convenient genotyping assay for experimental therapeutic efforts, and disclose novel biochemical findings in heterozygous female carriers of this allele. The characterization and potential rescue of this mouse model will improve correlation of genotype with biochemical phenotype, as well as understanding of treatment response in the context of a null *Atp7a* mutation.

Defective autophagy limits IL-1 beta production by eliminating active inflammasomes in human Gaucher macrophages. *E. Aflaki, N. Moaven, B. Stubblefield, G. Lopez, E. Sidransky.* Medical Genetics Branch, NHGRI, Bethesda, MD.

Gaucher disease (GD), the most prevalent lysosomal storage disorder, is caused by mutations in GBA1, the gene encoding glucocerebrosidase (GCase). The disease is characterized by the presence of glucosylceramide (GlcCer)-laden macrophages in the liver, spleen and bone marrow. Although in GD GCase is deficient in all cell types, the phenotype manifests primarily in macrophages. There is a dynamic relationship between phagocytosis and autophagy, the evolutionarily ancient process of lysosomal self-digestion of organelles, apoptotic corpses and cytosolic pathogens. We investigated autophagy in macrophages derived from peripheral monocytes from ten patients with type 1 GD (G-Macs) and two induced pluripotent stem cell (iPSC)-derived Gaucher macrophage lines, all sharing the common GD genotype N370S/N370S. Increased P62 expression in these macrophages indicated impaired autophagy. Levels of both LC3-II and P62 were increased in G-Macs during erythrophagocytosis and inflammation, as demonstrated by inflammasome activation with LPS and ATP. Moreover, expression of VPS34 and Rab7, proteins important in the fusion of early endosomes to late endosomes, decreased significantly. Autophagosomes deliver phagocytes to lysosomes for degradation, whereas inflammasomes are activated by infection, which in turn regulates the activity of caspase-1 and the maturation of interleukin (IL)-1 beta and IL-18. Macrophage polarization, evaluated using PCR arrays, indicates that G-Macs manifest the alternatively activated phenotypes in the presence of LPS with ATP. Importantly, G-Macs show increased expression of IL-18 and IL-10, but decreased IL-1 beta expression. Our data indicates that impaired secretion of some inflammatory cytokines results from the suppression of autophagy, resulting in increased Atg16L in G-Macs. This leads to inhibition of secretion and cleavage of IL-1β in these cells in the presence of LPS and ATP. This study demonstrates that lysosome dysfunction leads to the suppression of autophagy, followed by inhibition of inflammasome activity.

2317T

Resistin increases the expression of aggrecanases in human chondrocytes. *K.O. Yaykasli[1], E. Yaykasli[2], E. Kaya[3], M. Ozsahin[4], M. Uslu[5].* 1) Department of Medical Genetics, Medical Faculty, Duzce University, Duzce, Turkey; 2) Department of Medical Biology and Genetics, Institute of Health Science, Duzce University, Duzce, Turkey; 3) Department of Medical Pharmacology, Medical Faculty, Duzce University, Duzce, Turkey; 4) Department of Physical Medicine and Rehabilitation, Medical Faculty, Duzce University, Duzce, Turkey; 5) Department of Orthopedics and Traumatology, Medical Faculty, Duzce University, Duzce, Turkey.

Objective: The adipokine, resistin, was discovered in 2001 and expressed by not only adipose tissue but also by macrophages in high levels. First, resistin has been linked to insulin resistance, but further studies have linked it to other physiological processes, such as inflammation and immunity. Rheumatoid arthritis (RA) is an inflammatory and autoimmune disease that is characterized by irreversible destruction of the extracellular matrix (ECM). Aggrecanases are the primary enzymes responsible for the degradation of ECM. Several current investigations have found that elevated resistin levels are associated with aggrecanase expression. The aim of this study was to investigate the putative roles of resistin in aggrecanases upregulation. Material and Method: Human articular chondrocytes were cultured with resistin at certain concentrations (100, 250, and 500 ng/ml). After incubation for 12h and 24h, total RNA was extracted using TriPure reagent, and 2 µg of total RNA was reverse-transcribed by random primer. The ADAMTS1, ADAMTS4, ADAMTS5, ADAMTS9, and β-actin genes expression were analyzed by quantitative real-time polymerase chain reaction. Results and Conclusion: Resistin increased the expression of ADAMTS1, ADAMTS4, ADAMTS5, and ADAMTS9 genes at 100 ng/ml and 250 ng/ml doses. The irreversible destruction of ECM by aggrecanases is a key process in RA. An elucidation of the underlying causes for elevated levels of aggrecanases may be beneficial to understanding the etiology of RA. In conclusion, resistin with inflammatory properties is involved in RA by increasing the expression level of aggrecanases. However, further studies are needed to clarify the action mechanism of resistin.

Small molecule inhibition of glucosylceramide synthase affects bone remodeling in mice. *A.J. Leger, Z. Luo, I-H. Wu, N.S. Yew, S. Ryan, K. Malley, L. Sweet, S. Schiavi, T.K. Sampath, S.H. Cheng.* Genzyme, a Sanofi Company, 49 New York Avenue, Framingham, MA 01701-9322, U.S.A.

Patients with type I Gaucher disease (GD1) present not only with hematological and visceral manifestations, but multiple bone abnormalities including osteopenia, Erlenmeyer flask deformity, bone crisis, and avascular osteonecrosis. A recent mouse model of GD1 generated via conditional knockout of glucocerebrosidase (Gba1) in hematopoietic and mesenchymal cells displayed GD1-like bone pathophysiologies including osteopenia, reductions in bone formation rate, and osteonecrosis. The skeletal phenotype present in this transgenic model was attributed to defects in both osteoblast proliferation and differentiation. Given the potential relationship between glucosylceramide (GL-1) and osteoblast activity, we sought to determine the impact of inhibiting GL-1 synthesis upon bone physiology in mice. We therefore administered the glucosylceramide synthase (GCS) inhibitor Genz-667161 (60 mg/kg/day) in chow to C57Bl/6 mice for a period of 6 weeks and subsequently examined trabecular bone in femurs and lumbar vertebrae via histomorphometric analysis. In distal femur we observed an increase in bone volume fraction with a concomitant decrease in trabecular spacing in mice treated with Genz-667161. In L4 lumbar vertebrae we also noted a decrease in trabecular spacing with an associated increase in trabecular number. These effects in lumbar vertebrae would be expected to provide an increase in bone strength. This preliminary data suggests that GL-1 and perhaps other glycosphingolipids may play a role in beneficial bone remodeling and provide the rationale for further studies that examine the effect of GL-1 upon bone formation and resorption.

2319T

Fat mass and obesity-associated (FTO) Protein interacts with CamKII and modulates the activity of CREB signaling pathway. *L. Lin, P. Jin.* Human Genetics, Emory University School of Medicine, Atlanta, GA.

Polymorphisms in the fat mass and obesity-associated (FTO) gene have been associated with obesity in humans. Alterations in FTO expression in transgenic animals affect body weight, energy expenditure and food intake. FTO is a nuclear protein and its physiological function of FTO remains largely unknown. To understand the molecular functions of FTO, we performed yeast two-hybrid screen to identify the protein(s) that could directly interact with human FTO protein. Using multiple assays, we demonstrated that FTO interacts CaMKII. FTO interacted with three isoforms of CaMKII: α, β and γ, which are protein kinases that phosphorylate a broad range of substrate. We found that the overexpression of FTO could delay the dephosphorylation of CREB in human neuroblastoma (SK-N-SH) cells. Expression levels of NPYY1 and BDNF, which are targets of CREB, were dramatically increased due to the prolongation of CREB phosphorylation in the presence of FTO. Both NPYY1 and BDNF have been shown to regulate food intake and energy homeostasis. Thus, our results suggested that FTO could potentially modulate obesity by regulating the activity of CREB signaling pathway.

An infantile case of hepatomegaly, lactic acidosis, hypoglycemia, ketosis, and hyperlipidemia of unknown etiology. *Y. Watanabe[1,2], Y. Seki[1], T. Yanagi[1], T. Mizuochi[1], T. Takeuchi[1], J. Iwamoto[1], M. Yoshino[1], S. Watanabe[3], T. Inokuchi[2], S. Yano[4], K. Yoshiura[3], T. Matsuishi[1,2].* 1) Department of Pediatrics and Child Health, Kurume University, Kurume, Japan; 2) Research Institute of Medical Mass Spectrometry, Kurume University, Kurume, Japan; 3) Department of Human Genetics, Nagasaki University, Nagasaki, Japan; 4) Genetics Division, Department of Pediatrics, LAC+USC Medical Center, University of Southern California, Los Angeles, CA, USA.

Background: Inborn errors of energy metabolism including amino acid and fatty acid metabolism defects have recently become disorders screened by tandem mass spectrometry based newborn screening. The majority of patients with these disorders show positive results with characteristic profiles suggestive of a specific diagnosis. On the contrary, patients with carbohydrate metabolism and mitochondrial respiratory chain complex (RCC) defects often do not show positive newborn screening results with characteristic profiles. Hepatomegaly, hypoglycemia, ketosis, and lactic acidosis can be seen in patients with carbohydrate metabolism and RCC defects. We had a patient with infantile onset hypotonia, chronic massive hepatomegaly, hypercholesterolemia, chronic ketosis, mild developmental delay and episodic lactic acidosis: No diagnosis could be made on the enzyme assays. Objective: To recruit and perform exome studies on patients with similar clinical findings. Case report: The patient was a 6-month-old Japanese male with hepatomegaly (fatty liver), lactic acidosis, hyperlipidemia, hypoglycemia, ketonuria, and mild developmental delay. The patient was born to a 26-year-old Japanese mother and a consanguineous Japanese father (half sibling through their mother). Pregnancy was reportedly unremarkable. The patient was delivered at 37 weeks and weighed 2940g. Apgar scores were 8^1 and 9^5. The patient was fed with breast milk. At age 5 months, generalized mild hypotonia, failure to thrive and hepatomegaly (the edge was at 14 cm below RCM) were noted by his primary pediatrician. The following laboratory studies were performed: AST 267, ALT 57, Plasma amino acids-unremarkable, urine organic acid screening-mild~ moderate elevation of xanthine, glycerol, 3-mehtylglutaconic acid, plasma acylcarnitine- C2 (40.9 uM) and C6 (0.5 uM), Ca 12mg/dl, PO4 2.9mg/dl, FFA 1791uM, total ketones 2849uM, 3OHB 2211uM/AA 638uM, blood lactate 118mg/dl, uric acid 1.14mg/dl. Enzyme assays for glycogen storage diseases including phosphorylase, debranching enzyme, and phosphorylase b kinase were unremarkable. Fructose 1,6 Biphosphatase was unremarkable. Liver biopsy at age 7 months showed severe fatty liver of unknown etiology. Mitochondrial respiratory chain assays with liver tissues were unremarkable. Discussion: The patient's presentation was suggestive of glycolytic pathway defects including fructose metabolism defects. Exome studies may identify the gene(s) responsible for the findings.

2321T

Delineation of renal-independent disease mechanism underlying Hyperphosphatemic Familial Tumoral Calcinosis caused by GALNT3 mutations. *S.G. Ziegler[1], Y. Yang[2], D. Malhotra[2], M.T. Collins[3], N. Bhattacharyya[3], R.I. Gafni[3], W.A. Gahl[4,5], H.C. Dietz[1,6].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Genetic Disease Research Branch, National Human Genome Research Institute, Bethesda, MD; 3) Craniofacial and Skeletal Diseases Branch, National Institute of Dental and Craniofacial Research, Bethesda, MD; 4) Medical Genetics Branch, National Human Genome Research Institute, Bethesda, MD; 5) Undiagnosed Diseases Program, National Institutes of Health, Bethesda, MD; 6) Howard Hughes Medical Institute, Chevy Chase, MD.

Hyperphosphatemic Familial Tumoral Calcinosis (HFTC) is characterized by progressive deposition of calcium phosphate complexes in soft connective tissues and periarticular spaces; serum phosphate levels are markedly increased. Loss-of-function mutations in three genes (*FGF23*, *GALNT3*, and *KLOTHO*) involved in renal phosphate excretion have been implicated in the pathogenesis of HFTC. FGF23, which is stabilized via O-glycosylation by GALNT3, is a circulating hormone that, with its co-factor klotho, decreases the expression of inorganic phosphate (Pi) transporter genes, *Npt2A* and *Npt2C*, in renal proximal tubule cells thus reducing Pi reabsorption. It has long been assumed that the calcification seen in HFTC is due to high levels of circulating Pi, which can then complex with calcium and precipitate. Here, we demonstrate that this calcification process can occur in an isolated, *in vitro* model system of ectopic calcification. Primary fibroblasts derived from two unrelated HFTC patients with biallelic *GALNT3* mutations can calcify *in vitro* when simulated with osteogenic media. These patients' cells also have increased tissue non-specific alkaline phosphatase (TNAP) and ENPP1 gene expression and enzyme activity; TNAP converts pyrophosphate (PPi) to inorganic phosphate (Pi), a positive regulator of calcification, while ENPP1 hydrolyzes ATP to AMP and PPi, a negative regulator of calcification. We have previously found that regulation of the PPi/Pi ratio may influence TNAP and ENPP1 levels, contributing to homeostasis. We found that HFTC cells have increased Gli-1 expression, a transcription factor that binds upstream of TNAP and increases target gene expression. To further explore the role of Gli-1 in ectopic calcification, we treated patient cells with a Gli-1 inhibitor (GANT58). GANT58 prevented calcification in our HFTC cell lines. In the literature, there is suggestive evidence that FGF23 can modulate Gli-1 expression via Gli-3. While the mechanism relating FGF23 and Gli-1 remains to be elucidated, we have demonstrated a renal-independent mechanism of ectopic calcification in HFTC and implicated the importance of Gli-1 signaling and TNAP upregulation. Further delineation of this pathway will help us better understand the basic mechanisms of ectopic calcification and potentially reveal new treatment strategies for HFTC and perhaps related disorders.

Mitochondrial diseases are amongst the most common causes of childhood neurometabolic deficiencies. They comprise a group of conditions characterized by their extensive clinical and genetic heterogeneity, making identification of the underlying disease gene difficult. Poor phenotype genotype correlations result in a wealth of candidate genes and many more have yet to be discovered. The lack of obvious candidate genes hampers gene prioritization among more than 200 known mitochondrial disease genes and provides a model situation for large scale mutation screening. In this study, whole exome sequencing and autozygosity mapping in subjects with combined OXPHOS-deficiencies revealed 9 disease-segregating mutations in *FBXL4*. This gene encodes a member of the F-box family of proteins, some of which are involved in phosphorylation-dependent ubiquitination and/or G-protein receptor coupling, thought to be localized in the nucleus and cytosol. Surprisingly, we could localize FBXL4 to mitochondria using immunoflourescence and subcellular fractionation. Muscle and fribroblast tissue of patients displayed reduced activities of all respiratory chain complexes as well as mtDNA depletion. Biochemical rescue experiments based on the lentiviral-mediated expression of wildtype *FBXL4* was used to restore reduced oxygen consumption rate of OXPHOS-defective fibroblast cell lines. All individuals manifested early-onset lactic acidemia, hypotonia and developmental delay caused by severe encephalomyopathy, whereas some presented with dysmorphism, skeletal abnormalities, poor growth, gastrointestinal dysmotility, renal tubular acidosis, seizures and episodic metabolic failure. So far, the results suggest a role of FBXL4 in organell maintenance, which is currently under investigation.

2323T

Mitochondrial dysfunction in a patient with a mutation in the *MRPP1* gene encoding a subunit of the mitochondrial RNAseP complex. *M.D. Metodiev[1], Z. Assouline[3], M. Rio[3], N. Bahi-Buisson[4], A. Munnich[1,2,3], A. Rötig[1,2,3].* 1) INSERM U781 and Foundation Imagine, Paris, France; 2) Université Paris Descartes-Sorbonne Paris Cité, Paris, France; 3) Hôpital Necker-Enfants Malades, Paris, France; 4) Departament de pediatrie, Hôpital Necker-Enfants Malades, Paris, France.

Mitochondria synthesize ATP through oxidative phosphorylation in all eukaryotic cells. Unlike other organelles, mitochondria contain their own genome, mtDNA, which in humans encodes 11 messenger-RNAs, 2 ribosomal-RNAs and 22 transfer-RNAs. The messenger RNAs are translated into 13 polypeptides, which are essential for the assembly of OXPHOS complexes (C) I, III, IV and V. Transcription of mtDNA generates long, polycistronic transcripts which are processed by mitochondrial RNAseP (mt-RNAseP) and RNAseZ at the 5'- and 3'-ends of tRNAs, respectively. RNAseP is composed of three subunits: MRPP1, MRPP2 and MRP3. Knockdown of either subunit results in inactivation of RNAseP and a decrease in the levels of mature tRNAs, mRNAs and rRNAs. Interestingly, MRPP1 and MRPP2 also function to establish N1-methylation of purines at position 9 in several tRNAs. Notably, mutations in the methyltransferase domain of MRPP1, though eliminating its methylase activity, do not affect the processing activity of RNAseP indicating that both functions are independent.

We used whole-exome sequencing in order to identify mutations in novel nuclear genes associated with mitochondrial dysfunction. We focused on a series of patients with multiple respiratory chain deficiency with no qualitative or quantitative mtDNA anomaly. This approach enabled us to identify a patient carrying a homozygous mutation in the MRPP1 gene. This patient is the only girl born to consanguineous parents of Turkish origin. She presented feeding difficulties at one month of age. She then progressively developed trunk hypotonia, nystagmus and hypertrophic cardiomyopathy. She had hyperlactatemia. She died at 5 months of age. CI and CIV deficiency was found in muscle, liver and heart. Blue-native PAGE analysis revealed a quantitative defect of CI and CIV in cultured skin fibroblasts. Northern blot analysis of RNA isolated from mutant fibroblasts shows that steady-state levels of mitochondrial transcripts are unchanged indicating that the mutation does not affect the activity of RNAseP. Analyses of the G9- and A9-methylation in tRNAs by primer extension are ongoing. In conclusion, we report here the first example of abnormal RNAseP as a cause of respiratory chain deficiency. Moreover, our results support the view that exome sequencing is a powerful tool for the identification of disease gene mutations even in sporadic cases.

2324F

Gaucher disease: Clinical, biochemical and histopathological effects of 11 years of enzyme therapy in a chronic neuronopathic variant. *Y. Sun[1,3], T.A. Burrow[1,3], W. Zhang[2], B. Quinn[1], D.P. Witte[2,3], L. Bailey[1], C.E. Prada[1,4], G.A. Grabowski[1,3].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Pathology and Laboratory Medicine, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH; 4) Centro de Medicina Genómica y Metabolismo, Fundación Cardiovascular de Colombia, Colombia.

Gaucher disease is caused by inherited mutations of *GBA1*, the resultant defective acid β-glucosidase (GCase) activity, and insufficient degradation glucosylceramide (GluCer) and glucosylsphingosine (GluS). Enzyme replacement therapy (ET) with GCase has major visceral effects, but limited efficacy in brain and lung. Here, the effects of 11 years of ET on brain and visceral tissues were examined from autopsy of a chronic neuronopathic Gaucher disease patient. The nearly complete correction of the hepatic, splenic, and bone marrow disease contrasted with the large clusters of CD68 positive Gaucher cells in the interstitia/alveolae of lungs, and, ubiquitously, within the periadventitial spaces of brain blood vessels, i.e., macrophages. In the brain, a few such macrophages were within the cerebellar, basal ganglial and hippocampus parenchyma. Only few perivascular macrophages were positive for the macrophage mannose receptor (MMR). In addition to large losses of neurons and absence of Purkinje cells, the above brain regions were positive for GFAP (astrogliosis), phosphorylated Tau, and synuclein, indicating proinflammation and neurodegeneration. GluCer and GluS accumulations were in massive mesenteric lymph nodes and lungs, but not in the liver. In lung and lymph nodes, major GluCer species were GC16:0, GC24:0 and GC24:1. In brain, cortical gray matter, basal ganglia, and hippocampus had large GluCer and GluS accumulations. In the white matter enriched regions, brainstem and spinal cord, GluCer and GluS levels were very low. This may reflect cell type (neuron and microglia vs. oligodendrocyte) specific GluCer metabolism. In basal ganglia and hippocampus, GluCer species contained the long acyl chain GC24:0 and GC24:1, indicative of their visceral origin and presence in the predominant perivascular Gaucher cells that were unaffected by ET. These unique data show that long-term ET with mannose-terminated GCase was corrective for liver, spleen, and bone marrow. In comparison, ET had limited access to lung, lymph nodes, and brain. Surprisingly, the perivascular storage cells, which are on the vascular side of the blood brain barrier, were negative for the MMR, thereby blunting the effects of MMR-targeted ET, which has significant impact for therapies on either side of the blood brain barrier. In particular, the extra- and intra-parenchymal CNS Gaucher cells indicates the need for non-ET based therapies for global correction in the brain.

Intracellular itinerary of normal and mutant ATP7A in polarized motor neurons. *L. Yi, S.G. Kaler.* Molecular Medicine Program, NICHD/NIH, Bethesda, MD.

The P-type ATPase ATP7A regulates cellular copper homeostasis by its activity at the trans-Golgi network and plasma membrane, with location normally governed by intracellular copper concentration. In addition to causing Menkes disease, defects in ATP7A may lead to the disease variants occipital horn syndrome, and ATP7A-related distal motor neuropathy, a newly discovered adult-onset condition that resembles Charcot-Marie-Tooth type 2 disease and for which the precise pathophysiology remains obscure. We previously characterized the two ATP7A motor neuropathy mutations (T994I, P1386S) and identified molecular mechanisms for abnormal intracellular trafficking of ATP7A in affected patients' cells (Yi et al., *Hum Mol Genet* 2012). Our subsequent experiments have demonstrated that knockdown of the adaptor protein complex 1 (AP-1) leads to preferential plasma membrane localization of ATP7A under normal copper conditions. Both an ATP7A truncation mutant with deletion of the carboxyl-terminal 14 amino acid residues (including the di-leucine motif), and a di-leucine ATP7A mutant (LL to AA at residues 1487/1488) recapitulated the PM localization seen with AP-1 knockdown. In contrast, adaptor protein complex-2 (AP-2) knockdown resulted in failure to retrieve ATP7A from the plasma membrane after cellular copper depletion. Immunoprecipitation experiments confirmed the physical interaction of AP-1 and AP-2 with wild-type ATP7A. These interactions were each abrogated by the P1386S mutation, consistent with our prior finding of destabilized 8th transmembrane helix insertion associated with this allele. Taken together, our data implicate AP-1 and AP-2 in normal ATP7A trafficking by binding the carboxyl-terminus dileucine motif. Motor neurons are polarized cells with somatodendritic and axonal segments. We found that wild type ATP7A localizes in the somatodendrite region of differentiated NSC-34 motor neurons whereas the P1386S allele mainly localizes in axons. Taken together, our results suggest that AP-1 normally retains ATP7A at the trans-Golgi network in the somatodendritic segment of motor neurons, that disruption of this interaction results in release of ATP7A to the axons or axonal membranes, and that the latter effect is intensified by the loss of interaction with AP-2, thus disturbing normal directional polarity and leading to motor neuron disease.

Characterization of an ACAD10 Deficient Mouse Model: Pathological and Biochemical Analyses. *K. Kormanik[1], D. El Demellawy[2], A-W. Mohsen[2], A. Karunanidhi[2], M. Reyes-Mugica[2], J. Vockley[1,2].* 1) University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA 15224; 2) University of Pittsburgh School of Medicine, Pittsburgh, PA 15224.

Acyl-CoA dehydrogenase 10 transcript (ACAD10) codes for 1059-aa peptide with a ~400-aa C-terminus domain homologous to members of the ACAD flavoenzymes family involved in oxidation of fatty acids and intermediates of aa metabolism. A polymorphism in the ACAD10 gene has been linked to obesity in Pima Indians, but its physiological role remains unknown. The objective is to identify the role of ACAD10 in physiology and its link to diabetes. We have generated an ACAD10 deficient mouse and an anti-ACAD10 antibody to conduct pathological, biochemical, and molecular studies. Deficient animals are viable and fertile, but accumulate excess abdominal adipose tissue. Pathological studies reveal that ACAD10 deficient mice manifest an early inflammatory liver process and secondary splenic extramedullary hematopoiesis. Although skeletal muscle is histologically normal, deficient mice have elevated creatine kinase when fasted indicative of rhabdomyolysis. Metabolomics analysis identifies elevated levels of malonylcarnitine, succinylcarnitine, methylmalonylcarnitine, glutaroylcarnitine, adipoylcarnitine in deficient mouse urine samples. Immunological studies reveals antigen detected in pancreas, lung and brain and localized to peroxisomes. RNAseq analysis reveals a broad spectrum of changes in gene expression including genes involved in the response to oxidative stress. We've made significant progress towards identifying the role of ACAD10 in physiology.

2327T

Mutations in *HADHB*, which encodes the β-subunit of mitochondrial trifunctional protein, cause infantile onset hypoparathyroidism and peripheral polyneuropathy. *K. Yamada[1], M. Naiki[1,2], N. Ochi[3], Y. Kato[4], J. Purevsuren[5], R. Kimura[1], D. Fukushi[1], S. Hara[6], Y. Yamada[1], T. Kumagai[7], S. Yamaguchi[5], N. Wakamatsu[1].* 1) Dept Gen, Inst Dev Res, Aichi Human Serv Ctr, Kasugai, Aichi, Japan; 2) Dept Pediatr, Nagoya Univ Grad Sch Med, Aichi, Japan; 3) Dept Pediatr, Daini-Aoitori Gakuen, Aichi Pref Hosp Habilit Ctr, Aichi, Japan; 4) Inst Health Sci, Tokushima Bunri Univ, Tokushima, Japan; 5) Dept Pediatr, Med, Shimane Univ, Shimane, Japan; 6) Dept Pediatr, Toyota Memor Hosp, Aichi, Japan; 7) Dept Pediatr Neurol, Kobato Gakuen, Aichi Human Serv Ctr, Aichi, Japan.

The mitochondrial trifunctional protein (MTP) is a hetero-octamer composed of the four α- and four β-subunits, which catalyzes the final three steps of mitochondrial β-oxidation of long chain fatty acids. To date, only two cases with MTP deficiency have been reported to be associated with hypoparathyroidism and peripheral polyneuropathy. We report that sibling cases born to consanguineous parents have MTP deficiency associated with infantile onset hypoparathyroidism and peripheral polyneuropathy. Genome-wide linkage analysis and array CGH analysis eliminated known diseases associated with autosomal recessive forms of isolated hypoparathyroidism or hereditary sensorimotor neuropathy (Charcot-Marie-Tooth disease). Yet, we identified a homozygous mutation (c.1175C>T, [p.A392V]) in exon 14 of *HADHB* located at the determined disease locus in the subjects. Biochemical analysis revealed that the presented subjects had MTP deficiency. Structural analysis indicated that the identified A392V and the reported N389D mutations associated with hypoparathyroidism are both specifically located near the active site and affected the conformation of the β-subunit. The present study demonstrated that missense *HADHB* mutations could cause infantile onset hypoparathyroidism. Since MTP deficiency is a treatable disease, MTP deficiency should be considered when subjects have hypoparathyroidism as the initial presenting feature at infancy.

Thiamine pyrophosphate deficiency secondary to TPK-1 mutation presenting as Leigh's disease: diagnosis and management within a sibling pair. *J.I. Fraser[1,2], S. Yang[3], A. Vanderver[4], T. Chang[4], L. Cramp[4], K. Chapman[3], G. Vezina[5], P. Smpokou[3], U. Lichter-Konecki[3], D.J. Zand[3].* 1) Medical Genetics Branch/NHGRI/NIH, Bethesda, MD; 2) Department of Pediatrics, CNMC, Washington, D.C; 3) Division of Genetics and Metabolism, CNMC, Washington, D.C; 4) .Department of Neurology, CNMC, Washington, D.C; 5) Department of Radiology, CNMC, Washington, D.C.

Background: Thiamine pyrophosphate (TPP) is essential for pyruvate dehydrogenase complex, α-ketoglutarate dehydrogenase, and branched-chain ketoacid dehydrogenase function. Five patients have been reported with thiamine pyrophosphokinase-1 (TPK1) deficiency, with encephalopathy, extrapyramidal, bulbar, and cerebellar signs, and metabolic decompensation leading to death. Some patients received high dose thiamine therapy. Patients: We present a sibling pair with Leigh's disease, progressive hypotonia, regression, and chronic encephalopathy. Whole exome sequencing in the younger sibling demonstrated homozygous TPK1 mutations. The older sibling had died from progressive neurologic disease with metabolic strokes, and the younger sibling had progressive neurologic decline. MRI demonstrated putamen and thalamic abnormalities in the younger, with similar and progressive evolution in the older sibling. The patient was started on high dose thiamine, niacin, biotin, and α-lipoic acid; ketogenic diet was initiated to reduce metabolic burden. He subsequently demonstrated improvement in neurologic function, with reattainment of lost milestones. Conclusions: TPK1 deficiency should be considered in children with Leigh's disease without identifiable mutations, and this gene should be evaluated as a candidate for testing in commercially available sequencing panels. Reducing metabolic burden in these children by addition of supplements and transition to ketogenic diet may reverse some of the neurologic progression and improve outcome.

2329T

Deficiency of the mitochondrial phosphate carrier presenting with myopathy or cardiomyopathy: two new cases. *L.C. Pyle, E.J. Bhoj, M. Li, R.C. Ahrens-Nicklas, C. Ficicioglu, N. Sondheimer, M. Yudkoff.* Section of Metabolic Disease, Children's Hospital of Philadelphia, Philadelphia, PA.

The SLC25A3 mitochondrial phosphate transporter is required to facilitate transport of inorganic phosphate across the inner mitochondrial membrane, for production of ATP via oxidative phosphorylation. Isoform A is expressed in heart and muscle, while B is the predominant isoform expressed in other tissues. Deficiencies in this transporter have been reported in five individuals to-date, across two sibships. Here we report two new cases of pathologic SLC25A3 mutations, in two different families, both presenting in the neonatal period. Case 1 presented as neonatal primary lactic acidosis, with subsequent improvement when intubated, but recurrent failure to extubate. Mitochondrial next generation sequencing revealed a homozygous IVS-9 mutation in SLC25A3, which has been previously shown in previous family 1 to cause a novel splice site, affecting an isoform specific to heart and skeletal muscle. This patient also has hypertrophic cardiomyopathy. Case 2 presented as neonatal severe hypertrophic cardiomyopathy. Mitochondrial next generation sequencing revealed two novel predicted pathogenic variants in SLC25A3. These cases expand our understanding of the SLC25A3 presentation. They also highlight the relevance of mitochondrial studies in the setting of neonatal cardiomyopathy and neonatal primary lactic acidosis.

2330F

Use of next generation sequencing (NGS) in mitochondrial (mt) disorders: whole mitochondrial genome analysis. *S. Seneca[1,2], K. Vancampenhout[2], G. Van Dyck[2], J. Smets[3], A. Van Lander[3], R. Van Coster[3], D. Daneels[2], W. Lissens[1,2], L. De Meirleir[4].* 1) Center for medical genetics, UZ Brussel, Brussels, Belgium; 2) Vrije Universiteit Brussel (VUB, REGE), Brussels, Belgium; 3) University Hospital Ghent, Division of Paediatric Neurology and Metabolism, Ghent, Belgium; 4) UZ Brussel, Division of Paediatric Neurology, Brussels, Belgium.

Mitochondrial (mt) diseases are a heterogeneous group of disorders, caused by both nuclear and mt genome mutations. A correct diagnosis is challenging, mainly because of the absence of clear phenotype-genotype correlations, the existence of heteroplasmy (presence of at least two different mt genotypes in the same cell) and the very large number of genes involved. Current traditional molecular diagnoses for disorders caused by a mt DNA defect, relies on the identification of (common) point mutations and large deletions with sequencing and Southern blot procedures. Complete mt genome sequencing, using Sanger nucleotide sequencing techniques, is reserved only for few well selected patients. The method is laborious, and not very sensitive to detect nucleotide variations below 15-20% heteroplasmy. Next Generation Sequencing (NGS) is a booming technology, promising to be an accurate and cost effective method to investigate considerable amounts of DNA, including the complete mt genome of patients. DNA samples of thirty patients with a (suspected) mt disorder were sequenced using the Ion PGM™ sequencer. Their mt genome has previously been characterized. A 100% coverage of the whole mt genome was obtained, 99.6% of the variants were concordant with Sanger sequencing. In depth sequencing allowed a sensitive detection of (pathogenic) heteroplasmic variations in a range of 4 to 79%, both in patients and controls. A sensitivity down to 4% is a major advantage in comparison with dideoxy nucleotide analysis. In addition, large multiple and single deletions, with visualization of their breakpoints, were identified. This study shows that NGS will be playing a major role in the molecular diagnostics of mt DNA disorders.

2331T

Variability in the level of erythrocyte glucose uptake in two patients of Glut1 deficiency syndrome with the same SLC2A1 mutation. *N. Ishihara[1], J. Natsume[1], K. Yanagihara[2], Y. Fukuhara[3], K. Yamada[3], Y. Yamada[3], Y. Azuma[1], T. Negoro[1], N. Wakamatsu[3], K. Watanabe[1,4].* 1) Dept Pediatrics, Nagoya Univ Grad Sch Medicine, Nagoya, Japan; 2) Dept Dev Med, Osaka Med Ctr and Res Inst for Maternal and Child Health, Osaka, Japan; 3) Dept Genet, Inst Dev Res, Aichi Human Service Ctr, Aichi, Japan; 4) Dept Med Sci, Faculty Health and Med Sci, Aichi Shukutoku Univ, Aichi, Japan.

Purpose: Glucose transporter 1 deficiency syndrome (Glut1-DS) is a congenital metabolic disorder characterized by intractable seizures with early infantile onset, developmental delay, movement disorders and acquired microcephaly. The diagnosis is based on hypoglycorrhachia, impaired in vitro glucose uptake into erythrocytes, and heterozygous mutations in *SLC2A1* gene. Here we report two patients with the same *SLC2A1* mutation and different results in the erythrocyte glucose uptake to reveal clinical heterogeneity in Glut1-DS. Subjects and Methods: Subject 1 is a 15-year-old girl, born to healthy non-consanguineous parents. Atypical absence seizures and dystonic posturing were seen since 2 years of age, and astatic episodes after a long walk has seen since 10 years of age. Hypoglycorrhachia and decreased erythrocyte glucose uptake were observed. She was diagnosed with Glut1-DS and started on the ketogenic diet. Subject 2 is a 17-year-old girl, born to healthy non-consanguineous parents. Since 4 years of age, she showed myoclonus, ataxia, and loss of consciousness with drooling. Such events were mostly seen in the late afternoon, and recovered with eating. Hypoglycorrhachia was observed while erythrocyte glucose uptake was normal. We did not start ketogenic diet, because of undetermined Glut1-DS diagnosis. Results: We performed direct sequencing of DNA extracted from white blood cells of the two subjects, and identified the same mutation in *SLC2A1* (R330X). To ensure the function of R330X, we constructed wild type and R330X FLAG tagged *SLC2A1* expression vectors and transfected to HEK293 cells. Wild type *SLC2A1* expressed at plasma membrane while R330X stayed in cytoplasm. Thus *SLC2A1* harbouring R330X is non-functional. Discussion: This is a first report of a Glut1-DS patient with normal erythrocyte glucose uptake caused by R330X mutation. There is variability in the level of erythrocyte glucose uptake even in patients with the same *SLC2A1* mutation, and it might be misleading. As Glut1-DS is a treatable epileptic encephalopathy, early diagnosis and treatment should be necessary. Conclusion: Glut1-DS caused by heterozygous mutations may show various level of erythrocyte glucose uptake, thus mutation analysis of *SLC2A1* should be performed for correct diagnosis.

2332F

Suspected mitochondrial myopathies in the era of genomic medicine. *A.M. Atherton[1,2], S.F. Kingsmore[2], B.A. Heese[1,3], S.E. Soden[2,4], C.J. Saunders[2,3], E.G. Farrow[2], L. Willig[2,5], N.A. Miller[2], L.D. Smith[1,2,3].* 1) Division of Genetics, Children's Mercy Hospitals and Clinics, Kansas City, MO; 2) The Center for Pediatric Genomic Medicine, Children's Mercy Hospitals and Clinics, Kansas City, MO; 3) Pathology and Laboratory Medicine, Children's Mercy Hospitals and Clinics, Kansas City, MO; 4) Division of Developmental and Behavioral Sciences, Children's Mercy Hospitals and Clinics, Kansas City, MO; 5) Division of Pediatric Nephrology, Children's Mercy Hospitals and Clinics, Kansas City, MO.

Mitochondrial myopathies (MM), a heterogeneous group of inherited disorders with multisystem involvement, can be caused by genetic alterations in the nuclear or mitochondrial genome. Historically, individuals with a suspected MM were diagnosed based on blood and/or cerebral spinal fluid biochemical testing, neuroimaging or invasive muscle biopsy results. Nonspecific results often lead to the diagnosis of a "suspected mitochondrial myopathy". Extensive, generally expensive, molecular testing panels for genes causing MM are available but may also be uninformative. We explored the utility of exome sequencing for molecular diagnosis by analyzing whole exome sequences of 19 patients from 15 families with clinical symptoms suggestive of a mitochondrial disorder without a definitive diagnosis. Five of the patients (26%) were confirmed to have a primary MM, five patients (26%) were identified as having an unrelated disorder with secondary mitochondrial dysfunction, one patient (5%) has likely pathogenic variants in novel MM candidate genes and eight patients (42%) had negative testing results. Overall, 58% of patients received a molecular diagnosis utilizing whole exome sequencing. These results support the initial use of whole exome sequencing in patients suspected of having a MM as this testing modality is more practical, efficient, specific and cost effective.

2333T

Mucopolysaccharidosis IVA (Morquio A) Molecular Analysis: A Review of the Advantages and Limitations of Molecular Testing of GALNS in the Diagnosis of Morquio A. *M. Hegde[1], M. Al Sayed[2], A. Mucopolysaccharidosis IVA (MPS IVA, Morquio A) is an autosomal recessive lysosomal storage disease. Mutations in the gene lead to deficient N-acetylgalactosamine-6-sulfatase (GALNS) activity. Laboratory diagnosis is commonly based on urinary excretion of keratan sulfate, decreased GALNS enzyme activity in vitro, which is the gold standard for diagnosis, and molecular analysis of the GALNS gene. Accurate and efficient diagnosis of Morquio A can be challenging. We focus our review here specifically on the use of molecular testing/mutational analysis, as performed by authors' institutions, to elucidate the challenges of molecular testing for GALNS and we recommend potential solutions. Situations in which mutations were or can be missed are explored. Recommendations for reducing the rate of missed mutations include: parental testing to confirm biallelic inheritance, analysis to identify cases of partial/whole GALNS gene deletions or uniparental disomy, and use of advanced methods other than DNA sequencing to find otherwise undetectable mutations. To support accurate diagnoses we recommend providing clear, interpretable molecular testing reports and suggest caution when using mutation prediction programs. A global, open-access, locus-specific database of GALNS mutations is also proposed to facilitate improved dissemination of information and to help reduce the number of mutations with unknown significance identified by GALNS sequencing.

2334F

Practical strategies for the identification of common mutations in Mucopolysaccharidosis IVA patients. *F. Kubaski[1], A.C. Brusius-Facchin[1-2], P.F.V Medeiros[3], R. Giugliani[1-2], S. Leistner-Segal[1-2].* 1) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil; 2) 2-Universidade Federal do Rio Grande do Sul/ Post Graduation Program in Medicine: Medical Sciences; 3) 3-Universidade Federal de Campina Grande/ Hospital Universitário Alcides Carneiro, Campina Grande, Brazil.

Mucopolysaccharidosis IVA or Morquio A syndrome, is an autosomal recessive disorder caused by deficiency of lysosomal enzyme N-acetylgalactosamine-6-sulfatase (GALNS), which results in lysosomal storage of the glycosaminoglicans keratan sulfate and chondroitin-6-sulfate in tissues, causing clinical manifestations. The phenotypes vary from the classical form with severe bone dysplasia, corneal opacity, short trunk dwarfism, heart involvement with a life span of 20 to 30 years, to an attenuated form with mild bone involvement and normal life span. Both forms of Morquio A patients have normal intelligence. The prevalence of MPS IVA ranges from 1/76.000 to 1/640.000 live births. Objectives: To analyze and characterize the genotype of Brazilian patients with MPS IVA, through molecular study of recurrent mutations in GALNS gene, enabling the estimative of frequency and the establishment of a protocol for routine screening for these mutations. Methods: Molecular analysis of GALNS gene was performed in 48 Brazilian patients by ARMS-PCR to detect six recurrent mutations (p.G116S/ p.G139S/ p.N164T/ p.L307P/ p.S341R/ p.R386C) followed by amplification of coding regions by PCR of all exons and sequencing. Results: These mutations were found in 47.9% of our sample, which were present in 40.6% of the alleles. The most frequent mutation was p.S341R (16.7%), followed by p.R386C (11.5%), p.G116S (7.3%) and p.N164T (3.1%). The mutations p.G139S and p.L307P were found only once in two different patients. After screening for recurrent mutations, we started sequencing all exons of GALNS. Until the present moment we found 2 described mutations in homozygosis (p.V239F and p.R386H). Furthermore, three new mutations were identified: p.V16E, p.E51K and p.C165Y (all homozygous and born from consanguineous parents). Conclusions: In Brazil, mutation p.S341R was found only in patients from the Northeast region. The identification of heterozygous individuals within these families will be important for genetic counseling and for estimating the disease prevalence in this region. Further studies to identify the origin of this mutation, including haplotype and segregation analyses are in progress, and will be evaluated in conjunction with epidemiological data. Sequencing of the whole coding region of GALNS will be important to define the genotype in the remaining patients and to allow correlations regarding the patients' phenotype.

2335T

Oligosaccharides As Biomarkers For Mucopolysaccharidosis IVA. *G. Asif, L. Arthur, E. Woolley, X. Li, M. He.* Human Genetics, Emory University, Atlanta, GA.

The mucopolysaccharidoses (MPS) are a group of lysosomal storage disorders with deficiencies in lysosomal hydrolases that are needed for degradation of glycosylaminoglycans (GAGs). In this study, we describe a characteristic group of urinary oligosaccharides found in patients with various types of MPS, such as mono antennary monosialo oligosaccharide and bi-antennary disialo oligosaccharide as well as certain galactosylated oligosaccharides. We found that these groups of oligosaccharides could be used as first tier diagnostic screening in urine for majority of the known MPS subtypes, including MPS I, II, III, IVA, VI. It was reported previously that lysosomal hydrolases involved in GAG degradation, such as N-Acetylgalactosamine-6-sulfate sulfatase (GALNS), forms a lysosomal multi-enzyme complex with neuraminidiase, galactosidase and cathepsin A. Thus the elevation of these sialylated and galactosylated oligosaccharides in MPS patients could reflect the disruption of supramolecular organization of the lysosomal multi-enzyme complex. To explore whether these biomarkers have significantly different profile from normal profile, 125 control urine samples were analyzed and 13 known MPS IVA patients' free oligosaccharide profiles were compared. Our analysis reveals that the mono-antennary monosialo oligosaccharide and bi-antennary disialo oligosaccharide at m/z 1532.76 and 2547.6, respectively, were significantly higher in MPS IVA patients than their levels in controls. The concentration of these two oligosaccharide biomarkers in urine, once normalized with urine creatinine level, does not significantly differ between urine collected at different time points of the same day or at different time points through 6 month of the study in MPS IVA patients. Therefore, these urinary oligosaccharides may serve as reliable biomarkers for the screening and potentially disease monitoring in patients with MPS IVA.

2336F

Biochemical, Molecular, and Clinical Presentations of 3 Patients with X-linked Epsilon-Trimethyllysine Hydroxylase (TMLHE) Deficiency, A Disorder of Carnitine Biosynthesis Associated with Autism Spectrum Disorder. *M. Comeaux, C. Schaaf, A. Petel, Y. Yang, F. Scaglia, A. Beaudet, S. Elsea, Q. Sun.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Previous research showed that deletion of exon 2 in the gene encoding epsilon-trimethyllysine hydroxylase (TMLHE) may be a risk factor for non-dysmorphic autism. Biochemical determination of trymethyllysine (TML) and γ-butyrobetaine (GBB) in plasma and urine of affected individuals can be used as biochemical markers for diagnosis of this disorder. We present the biochemical, molecular, and clinical phenotypes of three new patients with TMLHE deficiency. Patient 1 is a 4 year-old boy with a diagnosis of autism spectrum disorder who presented to genetics due to a recent episode of regression. Chromosome microarray (CMA) analysis was normal in this patient; however, whole exome sequencing found a hemizygous c.961_962del (p.I321fs) mutation in the *TMLHE* gene. Furthermore, biochemical analysis showed a low level of plasma carnitine, and analyte testing showed normal plasma and grossly abnormal urinary TML levels. The patient was subsequently placed on L-carnitine supplementation (200 mg/kg/day, divided in BID dosing), and his symtomatology has shown marked improvement in joint attention, eye contact, and social interaction. Patients 2 and 3 are twins born at 37 weeks of gestation who presented at birth with congenital heart defects. CMA analysis found a 4.5 Mb deletion of 8p23.1, a region that contains over 20 genes and has previously been associated with congenital heart defects. Additionally, the CMA found a hemizygous deletion of Xq28 that encompassed exon 2 of the *TMLHE* gene with a minimum deletion size of 3 kb in both sibs. Subsequent biochemical testing of plasma and urine revealed extremely high TML, low GBB, and normal carnitine values. These findings were discussed with the family and close monitoring of the twins' development was recommended in light of the Xq28 finding. These cases highlight the benefits of biochemical testing in combination with CMA and whole exome studies toward early diagnoses and prevention of symptoms associated with autism. Furthermore, they emphasize the importance of including disorders of carnitine biosynthesis in the differential diagnosis of patients with autism spectrum disorder especially given that some of the associated phenotypes may be amenable to carnitine supplementation.

Detection of 4-hydroxy-2-oxoglutarate aldolase metabolites in urine for the diagnosis and monitoring of primary hyperoxaluria type III. *L. Hasadsri, P. Loken, D. Gavrilov, D. Matern, K. Raymond, P. Rinaldo, S. Tortorelli, D. Oglesbee.* Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Rochester, MN.

Background: Mutations in the HOGA1 gene, encoding the mitochondrial enzyme 4-hydroxy-2-oxoglutarate aldolase (HOGA), were recently discovered to cause what is now known as primary hyperoxaluria type III (PH3). PH3 is a rare, autosomal recessive disorder characterized by the onset of recurrent kidney stone formation and progressive nephrocalcinosis during childhood. Molecular analysis of HOGA1 is currently available on a research basis, but the functional consequences of many variants found in this gene are still poorly understood. Timely diagnosis of patients with PH3 thus remains a significant challenge. HOGA catalyzes the conversion of 4-hydroxy-2-oxoglutarate (HOG) into glyoxylate and pyruvate, the final step in the metabolism of hydroxyproline. Patients with PH3 have been reported to have increased excretion of HOG and other HOG-related metabolites in their urine. Here, we describe the development of a novel method for the detection of urinary metabolites in PH3 via gas chromatography-mass spectrometry (GC-MS). **Methods:** Urine samples were treated with hydroxylamine hydrochloride at pH 9 and extracted with 5:1 (v/v) ethyl acetate/ propan-2-ol, then evaporated to dryness under nitrogen. Residues were derivatized with BSTFA+TMCS and pyridine and analyzed on an Agilent 6890/5975 operating in scanning mode, with either helium or hydrogen as the carrier gas. **Results:** HOG was undetectable in urine by routine organic acid analysis, even when present at high concentrations and after oximation. When oximated in an alkaline solution and extracted under more polar conditions, however, trimethylsilyl derivatives of HOG were easily identified, as were oxalic, glycolic, glyceric, glyoxylic, and pyruvic acid. Utilizing hydrogen for the mobile phase reduced sample run time by approximately 50%, and resulted in significantly improved resolution of the oxalate and glyoxylate peaks. Sample preparation time was <5 hours, and analytical run time was 8 minutes. **Conclusions:** GC-MS analysis of urine can provide a rapid, sensitive, and non-invasive means for the diagnosis and biochemical characterization of primary hyperoxaluria type III. Next steps include optimizing the assay's extraction efficiency, and characterizing urine samples from individuals with a molecular diagnosis of PH3, asymptomatic heterozygous carriers, and patients with a strongly suspected diagnosis of PH3.

Mitochondrial disorders are a genetically and clinically highly heterogeneous group of diseases characterized by faulty oxidative phosphorylation. Despite good progress in the field, most disease causing mutations still have to be identified. We applied whole exome sequencing in 250 unrelated individuals with juvenile-onset mitochondrial disorder. In a quarter of patients, we detected mutations in known disease genes. In another quarter of patients, we identified mutations in genes previously not associated with mitochondrial disorders. While mutations in some genes are rare like MGME1, the first exonuclease involved in mitochondrial replication (Kornblum et al., Nat. Genet. 2013), mutations in other genes are more frequent, with ACAD9 being the most common finding with 13 cases. New examples are ELAC2, a tRNA modifying enzyme involved in the translation of mitochondrial proteins, and FBXL4, a protein with yet unknown function associated with reduced mitochondrial protein content. Exome sequencing allows for comprehensive detection of disease causing mutations, most notably, it allows for the detection of mutations in genes not predicted to encode mitochondrial proteins. It therefore represents the method of choice for the molecular diagnosis of the heterogeneous group of mitochondriopathies for which it has permitted rapid identification of new genes. Further improvement of the sequencing technology holds promise for a further increase in yield by increasing coverage and detecting indels and copy number variants. However, several issues remain to be considered including how to tackle diseases caused by di- or oligogenic mutations with synergistic effect, how to annotate variants in non-coding regions and how to identify mutations with dominant effect. Nevertheless, in addition to shedding light on mitochondrial physiology, each newly identified gene augurs the possibility for new treatment options, as for example riboflavin supplementation in the case of mutations in the riboflavin transporter SLC52A2 or the flavoprotein ACAD9.

2339T

Diagnosis of adrenoleukodystrophy using liquid chromatography-mass spectrometry. *M. Kosuga[1], H. Nakajima[2], K. Kida[1], J. Fujimoto[2], T. Okuyama[1].* 1) Department of Clinical Laboratory Medicine, National Center for Child Health and Development, Tokyo, Japan; 2) Clinical Research Center,National Center for Child Health and Development, Tokyo, Japan.

Adrenoleukodystrophy (ALD) is caused by a mutation in the ABCD1 gene and results in the apparent defect in peroxisomal beta oxidation and the accumulation of the saturated very long chain fatty acids (VLCFA). Hematopoietic stem cell(HSCT) transplantation is the only treatment that can stop the demyelination that is the hallmark of the cerebral forms of the disease. In order to be effective, HSCT should be done at an early stage of the disease. Thus, development of a simple screening method is important to enable the identification of pre-symptomatic ALD patients before showing symptoms of brain involvement. ALD is associated with an accumulation of VLCFA, particularly cerotic acid (26:0) and its metabolite lysophosphatidylcholine (Lyso PC26:0), which means that these molecules could be biomarker targets in the detection of ALD. We have developed a mass screening method for ALD through the quantification of Lyso PC or saturated fatty acid with different lengths of acyl chain using a liquid chromatography-mass spectrometry (LC-MS) selective reaction monitoring system. Those lipids could be extracted from dried blood spots. The analysis of each of the lipids with LC-MS was completed within 5 minutes per sample, thus it would be an ideal method for screening of ALD.

Creatine Deficiency Due To Targeted Disruption Of Alanine:Glycine Amidinotransferase Leads To Learning And Memory Deficits. *W. Craigen[1, 2], Y. Lai[2], M. Costa-Mattioli[3], L. Stoica[3], P.J. Zhu[3], L. Mbye[1].* 1) Molecular & Human Genetics; 2) Pediatrics; 3) Neuroscience, Baylor College of Medicine, Houston, TX.

Phosphocreatine serves as an important reservoir of high-energy phosphate for ATP synthesis in tissues that have fluctuating demands for energy. Human disorders of creatine biosynthesis and transport exist, leading to intellectual disabilities, epilepsy, and poor growth. Creatine biosynthesis requires two enzymes, the first, L-arginine:glycine amidinotransferase, the product of the Gatm gene, catalyzes the rate-limiting transfer of the amidino group from arginine to glycine, yielding guanidinoacetate and ornithine. We generated a mouse strain lacking Gatm. Homozygous Gatm deficient mice have an almost complete absence of creatine and guanidinoacetate, and exhibit poor growth and muscle weakness. A consequence of creatine deficiency is the global reduction in skeletal muscle and brain mitochondrial respiratory chain activities, and a compensatory increase in mtDNA content and citrate synthase activity. Gene expression profiling reveals the activation of the integrated stress response. When challenged with the seizure-inducing drug kainate, creatine deficient mice are resistant to the induction of status epilepticus and epilepsy-associated mortality. When tested for associative learning by fear conditioning paradigms, creatine deficient mice have a marked deficit in learning, and are similarly compromised in the Morris water maze test. This animal model of creatine deficiency demonstrates the central role creatine metabolism plays in normal neurologic functions.

Somatic Mosaicism with Reversion to Wild Type in Congenital Disorder of Glycosylation, Type IIb. *H. Vega[1], L. Wolfe[1], DR. Adams[1], M. He[2], S. Rosenzweig[3], WA. Gahl[1], C. Boerkoel[1].* 1) National Human Genome Research Institute, National Institute of Health, Bethesda, MD; 2) Department of Human Genetics, Emory University, Atlanta, GA; 3) National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD.

Somatic mosaicism with reversion to wild type resulting in correction of inherited mutations is a rare phenomenon that results in the proliferative advantage of cells containing the wild type allele. We report on a family with two affected sibs with Congenital Disorder of Glycosylation (CDG-IIb) caused by mutations of mannosyl oligosaccharide glucosidase (MOGS). CDG-IIb, which is characterized by severe developmental delay, generalized hypotonia, dysmorphic features, hygammaglobulinemia and accumulation of tetrasaccharide (Glu3Man1) in urine, is reported as a single case of lethality in the neonatal period. Our patients survived the neonatal period and were 11 and 6 years old when evaluated. These two CDGIIb patients bear three different mutations: a c.370C>T nonsense mutation of exon 2 inherited from the mother and two missense mutations in exon 1, c.65C>A and c.329G>A, inherited from the father. We hypothesized that mutation reversion might account for the survival of these children. To test this, we cloned and sequenced PCR products from blood-derived genomic DNA and found six different alleles in addition to the maternal and paternal inherited alleles. These new alleles,which are absent in both parents, range from alleles free of mutations to alleles with the all three mutations in cis. We propose that this wide range of alleles was generated as a result of somatic recombination, and that somatic mosaicism for reversion to wild type allele explains the survival of these CDG-IIb patients.

The clinical and mutation spectrum of Korean patients with urea cycle disorders. *H.W. Yoo[1,2], B.H. Lee[1,2], G.H. Kim[2], J.M. Kim[2], Y.M. Kim[1], J.H. Kim[1].* 1) Department of Pediatrics, Asan Medical Ctr, University of Ulsan College of Medicine, Seoul, Korea; 2) Medical Genetics Center, Asan Medical Ctr, Korea.

Urea cycle disorder (UCD) is caused by the deficiencies of the six enzymes, carbamoyl phosphate synthetase (CPS), N-acetylglutamate synthetase (NAGS), ornithine transcarbamoylase (OTC), argininosuccinate synthetase (ASS), argininosuccinate lyase (ASL) and arginase (ARG) or mitochondrial ornithine transporter (ORNT1). This study was undertaken to review the clinical and molecular genetic characteristics of Korean UCD patients diagnosed in one institution. A total of 68 patients, 30 males and 38 females, from 66 unrelated families were diagnosed based on genetic and biochemical profiles during past 15 yrs. UCD manifested in neonatal period in 38 patients (64.4%), whereas 27 patients (45.8%) were late onset UCD. The remaining two patients (3.4%) were identified in presymptomatic periods. Thirty patients (44.1%) were diagnosed as OTC deficiency, 22 (32.4%) as ASS deficiency, 10 (14.7%) as CPS deficiency, 3 (4.4%) as ASL deficiency, 1 as argininemia, 1 as Hyperonithinemia-Hyperammonemia-Homocitrullinuria (HHH) syndrome, and 1 as NAGS deficiency. Mutation detection rate was 97.7 % (43/44 alleles) in the ASS1 gene, 90.0 % (24/27 alleles) in the OTC gene, and 100 % (6/6 alleles) in the ASL gene, whereas it was 55.6 % (10/18 alleles) in the CPS1 gene. Total 25 novel mutations were identified. Most patients presented as symptomatic hyperammonemia, whereas an argininemia patient as spastic diplegia without pronounced hyperammonemia, and 2 patients were identified in asymptomatic period by familial screening or tandem mass screening. Among 42 patients with hyperammonemia over 300 umol/L, 25 were managed by peritoneal dialysis or continuous renal replacement therapy, whereas 17 managed conservatively. The clinical outcomes were normal neurological development (19 patients, 32.2%), neurological deficit (26 patients, 44.1%), and death from hyperammonic encephalopathy (13 patients, 22.0%). Liver transplantations were performed in 3 patients. This study portrayed the full-spectrum of clinical and molecular genetic characteristics of UCDs in Korea. More efforts are needed for early identification and urgent management of each patient with UCD to improve the long-term neurological outcome.

2343T

Leigh syndrome and myoclonic epilepsy caused by novel mutation in AIMF1 gene. *T. Honzik[1], A. Vondrackova[1], V. Stranecky[2], M. Rodinova[1], H. Kratochvilova[1], H. Hansikova[1], P. Klement[1], M. Magner[1], S. Mazurova[1], J. Zeman[1], M. Tesarova[1].* 1) Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University and General University Hospital in Prague, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University and General University Hospital in Prague, Czech Republic.

Mutations in X-linked AIMF1 gene, encoding the Apoptosis-Inducing Factor Mitochondrion-associated 1, cause disruption of the respiratory chain complexes, decrease stability of mtDNA and increase apoptogenic stimuli. Only 11 patients from 3 families were reported, so far. Severe encephalomyopathy and Leigh syndrome was present in four children and progressive axonal neuropathy, deafness and cognitive impairment were present in 7 patients (Cowchock syndrome; CMTX4). Here we describe another patient with neonatal onset of the disease with hypotonia, myoclonic epilepsy, hearing loss, visual impairment, severe encephalopathy, Leigh syndrome and lactic acidosis. In addition, the boy had hyporeflexia compatible with axonal neuropathy and died at the age of 18 months. Muscle biopsy demonstrated mild myopathic pattern with accumulation of SDH product. In tissues obtained at autopsy, the activity and amount of complex I and IV was decreased in muscle, brain and heart and the activity of complex II was upregulated. Targeted sequencing of mitochondrial exome revealed novel hemizygous mutation c.1391T>G (p.Leu464Trp) in AIMF1 gene on chromosome X. Conclusions: X-linked AIMF1 encephalomyopathy due to apoptosis-inducing factor defect should be considered in the differential diagnostics in patients with Leigh syndrome, axonal neuropathy and myoclonic epilepsy. Supported by IGA NT 14156/3 and IGA NT 13114/4.

2344F

Reduced levels of ATP7A protein in a male child with subtle features of Menkes disease in the absence of *ATP7A* mutation suggest a novel defect in transcriptional regulation associated with a unique disorder of copper metabolism. *K. Patel[1], G. Golas[2], D. Adams[2], C. Tifft[2], C.S. Holmes[3], D.S. Goldstein[3], L. Yi[1], W.A Gahl[2], S.G. Kaler[1].* 1) Molecular Medicine Program; NICHD/NIH, Bethesda, MD; 2) Undiagnosed Disease Program; NHGRI, NIH, Bethesda, MD; 3) Clinical Neuroscience Program; NINDS, NIH, Bethesda, MD.

We evaluated a 6 year old white male from the NIH Undiagnosed Disease Program for a possible Menkes disease variant. His term birth was normal with Apgar scores recorded as 8 at both 1 and 5 minutes. Early neurodevelopment was markedly delayed. Since infancy, he has remained a diagnostic conundrum despite extensive testing. Based on normal plasma neurochemicals at age two years, Menkes disease was excluded. Physical examination findings at age 6 years included dysmorphic facies, coarse hair texture, alternating esotropia, generalized hypotonia, mild joint laxity, and moderate intellectual disability. Hair analysis showed *pili torti* in 4/25 (16%) of hair shafts obtained at age 9 months, and 7/35 (20%) hair shafts at age 6 years. A positive control hair specimen, obtained from a 3 year old classic Menkes patient receiving copper injection treatments, showed 6/25 (24%) *pili torti*. A brain MRI/MRA at age 6 years showed vascular dilation and tortuosity of the major arteries within the Circle of Willis. The patient had low-normal levels of serum copper (64 µg/dl) and ceruloplasmin (172 mg/L). Plasma catechol ratios were normal when tested at age 2 years and again at age 6 years, indicating normal peripheral activity of dopamine-beta-hydroxylase (DBH), a copper-dependent enzyme. However the catechol ratios in his cerebrospinal fluid at age 6 years were just within the range from a cohort of classic Menkes disease patients. DNA sequence analysis failed to reveal any abnormality in the *ATP7A* coding regions, splice junctions, and known regulatory elements. However, Western blot assay of the patient's fibroblasts revealed approximately 90% reduction in ATP7A protein quantity compared to wild-type cells. The residual ATP7A protein was normal-sized and exhibited proper intracellular trafficking itineraries in response to varying concentrations of copper. The patient's phenotype does not fit well with any of three recently identified autosomal recessive copper metabolism phenotypes caused by mutations in: 1) a copper chaperone (CCS), 2) an acetyl CoA transporter (AT-1), or 3) the sigma 1 alpha subunit of adaptor protein complex 1 (AP1S1). We therefore hypothesize a defect in an unrecognized transcriptional regulator of *ATP7A* and predict that delineation of the precise molecular basis of this syndrome (underway via whole exome sequencing) will reveal yet another novel cause of abnormal human copper metabolism, and one which may be amenable to therapeutic intervention.

2345T

Mutational analysis of ATP7B gene in 19 Vietnamese patients with Wilson Disease. *H. Cam Tu, Tr. Thinh Huy, T. Tue Nguyen, Ph. Le Anh Tuan, T. Van Thanh, Tr. Van Khanh.* Center For Gene Protein research, Hanoi Medical University, Hanoi, Hanoi, Viet Nam.

Wilson disease (WD) is an autosomal recessive inherited disease caused by abnormalities of the copper-transporting protein encoding gene ATP7B with over 600 mutations described. Identification of mutations has made genetic diagnosis of WD feasible in many countries. In this study, we examined ATP7B for mutations in 19 unrelated Vietnamese WD patients who were diagnosed as WD base on typical clinical symptoms. Their clinical characters are Kayer-Flesicher rings presence, Neurological symptom, Serum ceruloplasmin (around 10mg/dl), Hepatic dysfunction. All 21 exons and exon-intron boundaries of the ATP7B gene were amplified by polymerase chain reaction from the genomic DNA of the patients and then analyzed by direct sequencing. Totally, we identified 15 mutations, of which 4 mutations were novel: p.S105Stop (c.417T>A), g.81007T>A, c.47/48-CGGCG, p.D1027H (c.3079G>C) and 11 mutations were reported previously: p.K832R (c.2650A>G), p.V456L (c.1523G>C), p.V1140A (c.3419T>C), c.-118/117+GCCGC, p.T850I (c.2549C>T), p.L1371P (c.4112T>C), p.A604P(c.1967G>C), p.Y715D (c.2143T>G), p.Y765G (c.2295C>G), p.G943D (c.2827G>A), p.C985T (c.2945G>A). Among these, p.V456L (c.1523G>C) (25%), c.47/48+CGGCG (19 %) and 118/117+GCCGC (8%) were the most frequent mutations. Five patients were homozygous, fourteen patients were compound heterozygote. Our study will broaden our knowledge about ATP7B mutations in WD patients in Vietnam, and be helpful for clinical genetic testing. Keywords: ATP7B gene, mutational analysis, Wilson disease.

2346F

Intellectual disability and movement disorder caused by a homozygous mutation in N-glycanase (NGLY1) gene: A novel disorder of glycoprotein metabolism. *M.A. Jones, C. da Silva, A. Bibb, S. Warren, M. He, M.R. Hegde, M.J. Gambello.* Dept of Human Genetics, Emory University, Atlanta, GA.

NGLY1 encodes N-glycanase, a deglycosylating enzyme, which is proposed to be a component of the ER-associated degradation (ERAD) pathway. This pathway is responsible for the degradation of misfolded glycoproteins. Defects in NGLY1 are predicted to result in the accumulation of misfolded glycoproteins due to impaired degradation. We performed clinical whole exome sequencing on a 2 year-old girl and identified a homozygous nonsense mutation c.1201A>T (p.R401X) in exon eight of the NGLY1 gene. Both parents are carriers of this mutation. An older sister with a similar phenotype also has the homozygous nonsense mutation. Two unaffected siblings do not carry this mutation. The clinical features of the 2 yr old girl and her sister include severe intellectual disability, abnormal movements, absent speech, hypotonia and mild dysmorphic features. She had an extensive negative evaluation including: a chromosomal microarray, plasma amino acid, urine organic acid and acyl carnitine analysis, transferrin and N-glycan analysis, brain MRI, muscle biopsy, mitochondrial genome sequencing, lysosomal enzyme panel, and MECP2 analysis. The p.R401X mutation has been recently reported in another individual in trans with a c.1891delC mutation. Similar phenotypic features shared among all three individuals include developmental delay and involuntary movements. The movement disorder in our patient and her sister were notable for occasional hand-wringing reminiscent of classic Rett syndrome. We are currently screening MECP2 negative patients as well as children with similar phenotypes for mutations in NGLY1 to determine the prevalence of this novel neurogenetic disease. We propose that NGLY1 should be considered in the differential diagnosis for patients with severe intellectual disability and abnormal movements. Identification of additional patients with this rare disorder will allow further characterization of the phenotypic spectrum and natural progression of the disease.

2347T

Comprehensive molecular investigation of the pathologial effects of Menkes disease missense mutations. *L.B. Møller, T. Skjørringe, S.S. Thorborg.* Kennedy Center, Rigshospitalet, Glostrup, Denmark.

As an attempt to predict the functional consequence of substituted nucleotides in the ATP7A gene we have investigated the effect of 36 selected missense mutations in the ATP7A gene according to the resulting ATP7A transcript and protein including the intracellular localization. ATP7A encodes a copper-translocating ATPase belonging to the family of P-type ATPases. Mutations of ATP7A lead to Menkes disease, which is an X-linked, lethal disorder of copper metabolism. The ATP7A protein has a dual function: In basal copper levels ATP7A is located in the trans-Golgi network where it is responsible for delivery of copper across the membrane for cuproenzyme biogenesis. In excess intracellular copper levels, the steady state distribution of ATP7A shifts to the plasma membrane where the protein is responsible for pumping copper from the cell. Fibroblasts obtained from Menkes patients with missense mutations in the ATP7A gene was used as source for ATP7A mRNA and protein investigation. Investigation of ATP7A transcript was performed by RT-PCR and real-time PCR. ATP7A Protein quantitation and localization revealed was performed by Western blotting and immunofluoresecence. Notably, the pathogenic effect of almost one third of the missense mutations is not due to functional importance of the affected residue, as the mutations affect splice sites, splicing silencers, mRNA stability or protein stability, leading to absence or reduction of the resulting ATP7A protein. More than two third of the mutations abrogates copper dependent trafficking, probably by affecting phosphorylation, dephosphorylation, copper binding or copper transport. Only two out of 36 missense mutations show normal copper dependent trafficking. These results emphasized the importance of using a comprehensive spectrum of analyses to reveal the deleterious effect of missense mutations.

2348F

The effect of homozygous deletion of BBOX1 gene on carnitine level and fatty acid beta-oxidation. *A. Rashidi-Nezhad[1,2], S. Talebi[3], S.M. Akrami[3], A. Reymond[2].* 1) Maternal, Fetal & Neonatal Research Center, Tehran University of Medical sciences, Tehran, Iran; 2) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 3) Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran.

Carnitine is a key molecule in energy metabolism and functions in the transport of activated fatty acids into the mitochondria. Carnitine hemostasis achieved and remained through oral intake, renal reabsorption and de novo biosynthesis. Unlike the dietary intake and renal reabsorption, the importance of de novo biosynthesis pathway in carnitine hemostasis remains unclear, due to lack of animal models or patients with the defect of this pathway. Here we evaluate metabolic and molecular study on carnitine level in a patient deficient in carnitine de novo biosynthesis. The proband was a 42 months old girl with microcephaly, speech delay, growth retardation and minor facial anomalies. ArrayCGH was used to detect small genomic imbalances. Quantitative PCR (qPCR) was used to confirm array results. Carnitine profile and metabolic investigation were performed according to routine laboratory protocols. The proband showed 221 Kb interstitial homozygous deletions at 11p14.2. Since BBOX1 gene is located in this region, the proband has no de novo biosynthesis of carnitine. Although free carnitine level in the proband was in normal range, acylcarnitine to free carnitine ratio (AC/FC ratio) was high but near the upper limit of reference range. Almost all the other evaluated metabolites were normal. In conclusion,we present the first report of a patient with the complete defect of carnitine de novo biosynthesis. Although this condition can result in a slight increase in AC/FC ratio but, it may not give rise to clinical manifestations of carnitine deficiency disorders.

2349T

Glycerol Kinase Transgenic Mice Have Increased Risk For Obesity. *C. Ho[1], A. Badjatiya[1], K.M. Dipple[1,2].* 1) Dept of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Dept of Pediatrics, Division of Genetics, University of California. Los Angeles, CA.

Glycerol kinase deficiency (GKD) is an X-linked inborn error of metabolism with a lack of genotype-phenotype correlation. Glycerol kinase (GK in humans, Gyk in mice) not only phosphorylates glycerol, but also performs other protein functions that may explain the pathogenesis of GKD. We recently developed a liver-specific *Gyk* transgenic mouse strains to understand the alternative functions of GK, including its role in adipogenesis and obesity. Male wildtype (WT/WT), heterozygous (WT/T) and homozygous (T/T) transgenic mice were placed on either regular chow or high fat (HF) diet for 12 weeks and monitored for weight gain and percentage body fat. Fasting glucose and cholesterol levels were measured from blood plasma to assess their risk for obesity and type II diabetes mellitus (T2DM). WT/T and T/T mice on HF diet gained more weight, 2.8% and 11.3% respectively, than WT/WT mice ($p<0.05$). Nuclear magnetic resonance analysis revealed both wildtype and transgenic mice had at least two-fold increase in percentage body fat as a result of consuming the HF diet. The elevated body weight in transgenic mice was also validated based on weighing of various tissues, including the mass of liver, visceral fat, perirenal fat and subcutaneous fat pads. T/T mice on chow diet had significantly greater mass in the liver tissue (25.8%), visceral fat pads (53.3%), and perirenal fat pads (40.2%) compared to the WT/WT mice ($p<0.05$), suggesting that *Gyk* overexpression is associated with abdominal obesity. Blood glucose and cholesterol tests showed that T/T mice on HF diet had higher triglycerides levels (16.4%), total cholesterol levels (41.3%), and fasting glucose levels (45.4%) relative to WT/WT, also implying high risk for obesity and T2DM ($p<0.05$). This study demonstrates that GK is involved in fat deposition and adipogenesis, and its overexpression increases risk of obesity and T2DM in mice. In addition, we propose that our *Gyk* transgenic mouse strains may serve as a useful model for obesity and T2DM research.

Novel heterozygous and homozygous mutations in the gap junction protein gamma-2 (*GJC2*) gene. *G. Hobson, D. Stubbolo, N. Manolakos, V. Funanage.* Nemours Biomedical Res, A I duPont Hosp Children, Wilmington, DE.

Recessive mutations in the gap junction protein gamma-2 (*GJC2*) gene cause Pelizaeus-Merzbacher like disease (PMLD), a rare hypomyelinating leukodystrophy. The clinical phenotype of PMLD is similar to that of the X-linked Pelizaeus-Merzbacher disease (PMD) and includes features such as spasticity, ataxia, dystonia, nystagmus, and developmental delay. A distinguishing feature of PMLD is the presence of brainstem auditory evoked potentials, which are typically absent in PMD. There have been reports that dominant point mutations in *GJC2* are associated with hereditary lymphedema type IC. Associated features include mild to severe swelling of the limbs and recurrent cellulitis. For the first time in our Molecular Diagnostics Lab, we report a cohort of patients and family members who have mutations in *GJC2* . For each patient, the entire coding region, surrounding intron, and promotor region of *GJC2* were sequenced. Family members, when available, were screened for the mutation(s) seen in the proband. Any changes from the reference sequence were analyzed via SIFT, PolyPhen, and Mutation Taster. These mutations include novel and previously reported single heterozygous, homozygous, and compound heterozygous mutations. The mutations are scattered throughout the entire coding region, as well as two different mutations in the promoter region. Three patients from different families had the c.-167A>G promotor mutation, which supports the previously reported hypothesis that this is a common pathogenic mutation in *GJC2*. The mutations p.Pro90Ser, p.Arg104Vfs*106, p.His252Arg, and p.Thr398Ile were each seen in two different families. Both the p.Pro90Ser and p.Thr398Ile have been reported previously, which suggests that these two mutations are also relatively common. For those patients with only one heterozygous mutation in the *GJC2* gene having PMLD symptoms, we suggest the possibility of an additional mutation being present in a region not sequenced, variable expressivity, or autosomal dominant inheritance. Further parental and familial genetic testing and phenotypic review should be completed to help make this distinction.

2351T

Arylsulfatase A Deficiency in Thai MLD Patients. *S. Nujarean[1], L. Thampratankul[2], L. Choubtum[3], D. Wattanasirichaigoon[1].* 1) Division of Medical Genetics, Department of Pediatrics, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, 10400 Thailand; 2) Division of Neurology, Department of Pediatrics, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, 10400 Thailand; 3) Research Center, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, 10400 Thailand.

Metachromatic Leukodystrophy (MLD) disorder is the lack of Arulsulfatase A (ARSA) enzyme which missing of ARSA enzyme lead to damage nervous system, kidney and other organs. MLD is an autosomal recessive disease caused by mutations in ARSA gene which ARSA gene is located on chromosome 22q13.33.It contains 8 coding exons and encodes 539 amino acid (NM_000487.5).This study; we identify mutations in ARSA gene in Thai MLD patients. The following in 8 exons of ARSA gene.

2352F

Unexpected findings of hexosaminidase B deficiency in a 39 yr old asymptomatic female identified during routine carrier screening for Tay-Sachs disease. *A. Schneider[1], R.B. Keep[2], M. Sobel[4], J. Liao[3], C. Yu[3], R. Kornreich[3].* 1) Dept Gen, Albert Einstein Med Ctr, Philadelphia, PA; 2) Quest Diagnostics, Horsham, PA; 3) Mount Sinai School of Medicine, New York, NY; 4) Abington Reproductive Medicine, Abington, PA.

Sandhoff disease is a rare autosomal recessive lysosomal storage disorder caused by mutations in the HEXB gene which results in the deficiencies of both Hexosaminidase A and B. Tay-Sachs disease (TSD), a related GM2 gangliosidosis, results from mutations in the HEXA gene causing the deficiency of Hexosaminidase A only. While similar disorders, Sandhoff disease is much less common than TSD and has no known ethnic predilection. Sandhoff disease presents with a wide range of phenotypes, from infantile to adult-onset, all of which are progressive to varying degrees. Detection of TSD and Sandhoff carriers is routinely performed via a standard heat inactivation Hex A% and total hexosaminidase activity assay using an artificial 4-MUG substrate. This assay can also diagnose TSD and Sandhoff diseases. Individuals affected with Sandhoff disease have a very low total hexosaminidase activity (<100 nmol/hr/mg) with a disproportionately high percentage Hex A (high 80s to 100%). This patient is a 39-year-old asymptomatic female of Sephardic Jewish ancestry. Her parents are from Syria and Yemen and are non-consanguineous. She was referred for a clinical genetics evaluation by an infertility practice due to abnormal enzyme results suggestive of Sandhoff disease. Blood was received for confirmational purposes. The leukocyte percent Hex A activity was 89.3%, which is higher than our Sandhoff carrier range (76.4 - 85.2%, 80.2 % ± 2.8, n=16). The total hexosaminidase activity was 456 nmol/hr/mg, which is reduced to 27% of the normal mean (1659 nmol/hr/mg, n=3939) or 57% of the Sandhoff carrier mean (798 nmol/hr/mg, n=16). Sequencing of the HEXB gene revealed four variants: c.214C>T, c.619A>G, c.1627G>A, and c.*81_*82delTG (homozygous). The variant c.1627G>A is a known heat labile allele in Oriental Jews. Both c.619A>G and c.*81_*82delTG are common polymorphisms which have been reported to reduce Hex B activity. In addition, a variant of unknown significance, c.214C>T causing a Leu->Phe substitution at position 72, is predicted to be a deleterious mutation by Polyphen and SIFT. Although, the effects of these variants in vivo are difficult to predict, her in vitro hexosaminidase B activity was indeed reduced; therefore, the late-onset clinical manifestation of GM2 accumulation cannot be excluded in this patient.

2353T

Comprehensive mutation screening of the AGXT gene in patients with primary hyperoxaluria type-1. *S. Khaliq[1,2], A. Abid[1], S. Shahid[1], S. Hashmi[3], S. Sultan[4], T. Aziz[5], S.A.H. Rizvi[5], S.Q. Mehdi[1].* 1) Centre for Human Genetics and Molecular Medicine, Sindh Institute of Urology and Transplantation , Karachi, Pakistan; 2) Department of Human Genetics, University of Health Sciences (UHS), Lahore, Pakistan; 3) Department of Pediatric Nephrology, (SIUT), Karachi, Pakistan; 4) Department of Pediatric Urology, (SIUT), Karachi, Pakistan; 5) Department of Urology, (SIUT), Karachi, Pakistan.

AAbstract: Primary Hperoxaluria type 1 (PH1) is a rare autosomal recessive disorder caused by the deficiency of alanine glyoxylate aminotransferase (AGT) enzyme encoded by the AGXT gene. It is characterized by recurrent nephrolithiasis, nephrocalcinosis and end stage renal disease. The three most common mutations in the exons 1, 4 and 7 have been found in more than 50% of the cases. Hence, mutation screening of these three exons has suggested being the 1st-line test to avoid liver biopsy. Since the facilities for liver biopsy are not commonly available in this region, mutation screening is the only reliable procedure for the diagnosis of PH1. Mutation analysis was carried out by direct sequencing of the AGXT gene in 150 patients. The age of onset of PH1 was 1-16yrs. They rapidly progressed to renal failure at adolescence. The study was approved by the IRB and conformed to the Tenets of the Declaration of Helsinki. We have found 17 mutations in 44 patients in which three mutations were novel. They included one splice-site, four indel and twelve missense mutations. The most common p.G350D mutation was found in 12 patients (8%). The age at onset of PH1 in these patients was 5-16 yrs. Of these, three children developed renal failure. One patient had encountered transplant rejection due to the recurrence of oxalosis. Another common mutation p.G190R was found in 7 cases (4.6%). The mutation p.G82E was present in three patients on the background of the AGT-Ma allele. Interestingly, the most commonly reported mutation c.508G-A (p.G170R; 20-40% allele frequency) was not found in our patients. Another common c.33dupC (12% allele frequency in Caucasians) that leads to protein truncation was found in only five patients (3.3%). AGT-Mi allele was found in 12 patients (8%) that mostly occurred in combination with the p.G350D mutation which is not reported elsewhere. Linkage disequilibrium among the AGT-Mi was not found in this study. Mutations in the AGXT gene have been identified in more than 90% of the cases worldwide. However, they were found in only 30% of the cases in this cohort. It is noteworthy that the most commonly reported mutations are not prevailing in our patients, therefore, mutation screening of the whole AGXT gene needed to be carried out in these patients.

2354F

Mutation of the iron-sulfur cluster assembly IBA57 gene causes lethal myopathy and encephalopathy. *N. Ajit Bolar[1,8], A. V. Vanlander[2,8], C. Wilbrecht[3,8], N. Van der Aa[1], J. Smet[2], B. De Paepe[2], G. Vandeweyer[1], F. Kooy[1], F. Eyskens[4], E. De Latter[2], G. Delanghe[5], P. Govaert[5], J.G. Leroy[2], R. Lill[3,6,7], R. Van Coster[2], L. Van Laer[1], B. Loeys[1].* 1) Department of Medical Genetics, University of Antwerp, Antwerp, Edegem, Antwerp, Belgium, Belgium; 2) Department of Pediatrics, Division of Pediatric Neurology and Metabolism, University Hospital Ghent, 9000 Ghent, Belgium; 3) Institut für Zytobiologie, Philipps-Universität Marburg, Robert-Koch Str. 6, 35032 Marburg, Germany; 4) Provinciaal Centrum voor de Opsporing van Metabole Aandoeningen (PCMA), Department of Pediatrics/Metabolic Diseases, Faculty of Medicine and Health Sciences, Antwerp University Hospital and University of Antwerp, 2000 Antwerp, Belgium; 5) Department of Neonatology, Paola Children's Hospital ZNA Middelheim, 2000 Antwerp, Belgium; 6) Max-Planck-Institut für terrestrische Mikrobiologie, Karl-von-Frisch-Str. 10, 35043 Marburg, Germany; 7) LOEWE Zentrum für Synthetische Mikrobiologie SynMikro, Hans-Meerwein-Str., 35043 Marburg, Germany; 8) The authors wish it to be known that, in their opinion, the first 3 authors should be regarded as joint First Authors.

The iron sulphur [Fe-S] proteins play an important role in redox reactions of the mitochondrial electron transport chain. The de novo synthesis and maturation of these proteins is highly complex and involves more than 25 biogenesis factors. In this study, we have identified two siblings from consanguineous parents who died perinatally from a condition characterised by generalised hypotonia, respiratory insufficiency, anthrogryposis, microcephaly, congenital brain malformations and hyperglycinemia. Analysis of the catalytic activities of the mitochondrial respiratory complexes I and II indicated deficiency in skeletal muscle, suggestive of an inborn error in the mitochondrial iron-sulfur cluster (ISC) biosynthesis pathway. Homozygosity mapping revealed the IBA57 gene, which is known to be involved in the biosynthesis of mitochondrial [4Fe-4S] proteins and present in the largest homozygous region on chromosome 1, as a candidate gene. Mutation analysis of IBA57 identified a c.941 A>C transversion causing the amino acid change p.Gln314Pro. Biochemical analysis of skeletal muscle and skin fibroblasts of affected individuals indicated severely decreased amounts of IBA57 and a decrease in various 4Fe-4S proteins and in proteins covalently linked to lipoic acid. IBA57 depleted HeLa cells reflected biochemical defects consistent with observations in patient derived cells. Defects could be rescued by the introduction of wildtype IBA57 and partially by mutant IBA57. Further functional analysis revealed an increased sensitivity of mutant IBA57 to degradation via proteolysis. Our findings suggest that the mutation leads to functional impairment and degradation below physiologically critical levels, resulting in the condition observed in the patients. In conclusion, we have identified a novel metabolic disorder presenting with a lethal complex biochemical phenotype caused by defective assembly of the ISC protein, IBA57.

2355T

Genetic variation in a gene involved in glycosphingolipid biosynthesis. *O.M. Amaral, A.J. Duarte, E. Pinto, I. Ribeiro, L. Lopes, D. Ribeiro.* Department of Human Genetics, INSA, IP , 4000-Porto, Portugal.

The main objective of this work was to investigate the possible existence of genetic variation in the UGCG gene. The UGCG gene encodes an enzyme essential in the first step of the glycosphingolipid biosynthesis process. Its genetic variation could lead to differences in biosynthesis and be related to phenotypic divergence in various genetic diseases of the glycosphingolipidoses group. In order to test this hypothesis we attempted to identify the extent of variation in the UGCG gene in order to relate it to phenotypic variation. Methods and samples: DNA was extracted from blood samples and/or fibroblast cell lines using an automated apparatus. Biological samples were obtained from healthy donors, with informed consent. In addition, all traceable identification was removed, so as to guarantee their anonymous nature. Skin fibroblast cell lines were obtained from the Corriel Institute (USA). The UGCG gene (exons and flanking intronic regions) of six control individuals was sequenced using standard methods. Results: In this work we present the identification and distribution of genetic variations among the control samples studied. The results obtained with the different samples showed the existence of several polymorphic changes. Discussion: Polymorphisms in the UGCG gene may interfere with the amount of substrate available for degradation in specific diseases along the same pathway. Thus, the degree of genetic variability might influence the phenotypic expression as well as the lysosomal burden. Conclusion: Assessment of variation in the UGCG gene should be considered, particularly in patients who do not comply with the expected genotype/phenotype correlations. Additional information: This work was carried out with financial support obtained from FCT-Portugal: project PIC/IC/82822/2007(2009); AJD and DR were beneficiaries of BI grants from Fundação da Ciência e Tecnologia (FCT/MCTES) - Portugal. Corresponding author: Olga Amaral, olga.amaral@insa.min-saude.pt.

A zebrafish model of cblC disease displays growth retardation that improves with vitamin B12 therapy. *N.P. Achilly[1], J.L. Sloan[1], K.S. Bishop[1], M.S. Jones[1], V.J. Hoffman[2], R.B. Sood[1], C.P. Venditti[1].* 1) Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Office of the Director, National Institutes of Health, Bethesda, MD.

Cobalamin C disease (*cblC*) is the most common inborn error of intracellular cobalamin metabolism. It is caused by mutations in *MMACHC*, a gene responsible for processing and trafficking intracellular cobalamin. Defects in this pathway impair the function of two cobalamin-dependent enzymes: methylmalonyl-CoA mutase and methionine synthase. Disease manifestations can include growth failure, anemia, congenital microcephaly, heart defects, and progressive blindness. At present, the pathological basis of these symptoms remains unknown, and no animal model exists. To replicate clinical manifestations experienced by patients with *cblC* disease, we created a series of loss of function alleles in the zebrafish orthologue of *MMACHC* using zinc-finger nucleases. Of these, we chose p.L44PfsX21 (hg12) and p.G32VfsX48 (hg13), transmitted by two independent founders, for phenotype analysis. F2 $mmachc^{hg12/hg12}$ and $mmachc^{hg13/hg13}$ fish survived the embryonic period but displayed growth impairment after 14 days post-fertilization (dpf). By 21 dpf, the standard length (SL) and height at the anterior of the anal fin (HAA) were significantly reduced; $mmachc^{hg12/hg12}$ fish (SL 6.94 ± 0.07, HAA 0.77 ± 0.03 mm) and $mmachc^{hg13/hg13}$ (SL 7.40 ± 0.07, HAA 0.86 ± 0.01 mm) fish were smaller than the wild-type and heterozygous fish (SL 10.39 ± 0.18, HAA 1.48 ± 0.03 mm) ($p<0.0001$). Histological examination of $mmachc^{hg12/hg12}$ fish revealed a complete absence of the secondary lamellae in the gills, which contain specialized cells for gas and ion exchange. Thinner retinal layers and a possible defect in the morphology of the photoreceptor outer segments were also observed. The concentration of methylmalonic acid (MMA), a classic biomarker of *cblC* disease, was elevated by 289-fold in $mmachc^{hg12/hg12}$ fish. OH-cobalamin (OH-cbl) injections are the main treatment administered to the patients and ameliorate some of the disease-related complications. When $mmachc^{hg12/hg12}$ fish were maintained in water supplemented with OH-cbl (100 µg/ml) for 21 days, SL increased by 25% ($p<0.05$) and HAA increased by 30% ($p<0.01$) compared to the untreated group. The zebrafish model of *cblC* disease we generated recapitulates several of the phenotypic and biochemical features of *MMACHC* deficiency, demonstrates a response to conventional therapy, and should be useful to delineate the pathophysiological mechanisms in this common disorder of cobalamin metabolism.

Identification of a novel mutation in the human ARSB gene on chromosome 5q14.1 for Muchopolysacharidosis type VI patients in southwest Colombia. *M.A. Acosta Aragón[1], J.R Lago[2], F. Barros[2], A.M. Carracedo Alvarez[2-3].* 1) Pediatrics Department, College of Medicine, University of Cauca, Popayán, Cauca, Colombia, Ph.D; 2) Clinical Hospital of Santiago de Compostela, Galicia, Spain M.D; 3) Institute of Legal Medicine, College of Medicine, University of Santiago de Compostela, Galicia, Ph.D.

Introduction: The MPS VI or Maroteaux-Lamy Syndrome is a recessive multisystemic progressive lysosomic storage disease caused by a deficiency of N-acetylgalactosamine 4-sulfatase enzyme or Arylsulfatase B. A total of 32 patients MPS VI patients are identified in Colombia, sixteen in Cauca Department (southwest Colombia) corresponding to 50% of the total cases with Maroteaux-Lamy syndrome registered in the country. All sixteen patients were identified clinically and by enzyme assay. Two of these individuals with severe form of disease belong to an Amerindian reservation(Guambiano ethnicity). Objetive: to analyze the genomic variations in the Arysulfatase B gene in two patients with severe phenotype of disease and identify ethnic and family backgrounds of the MPS VI Patients in Cauca Department. Subjects: We studied two native patients and their relatives.Data was obtained from charts and families of patients including ethnic and family backgrounds. Methods:It was PCR/sequencing of the 8 exons and their flanking regions in Arysulfatase B gene.We accomplished the validation of exonic changes by computational methods (Alamut 2,HGVS 2). We used 20 single nucleotide polymorphisms (SNPs) for haplotype characterization with a Sequenom Mass Array analyzer. Results: We characterized both alleles in the patients and their relatives identifying a novel mutation p.Ser403X no reported before, both in homozygous or heterozygous form.In addition we identified the same haplotype in the two homozygous patients and their heterozygous relatives when analized this gene with intragenic SNPs.These results together with the genealogy analysis, strongly suggest an inbreeding effect in this population. Conclusions: A novel mutation in the human ARSB gene was reported. It produces a premature stop codon. These results emphasize the broad molecular heterogeneity of Maroteaux-Lamy syndrome and contribute to the establishment of a genotype/phenotype correlation in this disease. The high frequency of MPS VI patients in the Cauca Department and the ethnic characteristics are suggestive that a population genetic factor can be responsible,such as in this study an isolated population with strong inbreeding and consanguinity.Studies with another families of this region with molecular characterization of the mutation by sequencing and the phylogeographic identification of the origin and dispersion of the gene will be performed to clarify this ethnic prevalence.

2358F

Two novel mutations in acid α-glucosidase gene in two patients with Pompe disease. *A. Aykut[1], H. Onay[1], M. Kose[2], E. Erbas Canda[2], E. Karaca[1], M. Coker[2], F. Ozkinay[1].* 1) Department of Medical Genetics, Ege University Faculty of Medicine, IZMIR, bornova izmir, Turkey; 2) Department of Pediatric Metabolic Disease, University Medical Faculty, Izmir, Turkey.

Glycogen storage disease type II (GSD-II), also known as Pompe disease (OMIM #232300), is a rare progressive autosomal recessive disorder characterized by deficiency of acid α-glucosidase (GAA) that results in abnormal glycogen deposition in the muscles. Mutations in the GAA gene cause Pompe disease. The infantile-onset form is the most severe form. Most of the infantile-onset form patients present with hypotonia and cardiomyopathy in early infancy. The first case presented is a second child of consanguineous parents, born at term after an uneventful pregnancy. At the age of 9 months infantile type Pompe disease was suspected based on hypertrophic cardiomyopathy. Unfortunately her previous sister died from hypertrohic cardiomyopathy suggesting Pompe disease at 7 months old. The diagnosis was confirmed by measuring acid alpha-glucosidase activity in serum (0.4 µkat/kg protein). Although enzyme replacement therapy was started at 9 months, patient died from sudden cardiac arrest at 1 year old. Genetic analysis of the parents revealed a novel missense mutation p.Q682R in GAA gene which was not previously reported. Second case, is a child of nonconsanguineous parents, born at term after an uneventful pregnancy. Infantile type Pompe disease was suspected based on hypotonia/generalized muscle weakness at 6 months. Sensorineural hearing loss and optic atrophy were detected. Echocardiography was normal. Levels of creatine kinase, or creatine kinase-myocardial band isoenzyme were typically elevated. She had GAA enzyme activity that was less than 1 percent of normal. She died from respiratory weakness at 2 years old. Genetic analysis of the mother revealed a novel nonsense mutation p.Q255X in GAA gene which was not previously reported and father had p.R224W which was previously described. We report two families wherein molecular diagnosis for Pompe disease was performed and we have identified two novel mutations in the GAA gene which were not previously described.

New dominant *ALDH18A1* mutation in two unrelated children with neurodevelopmental delay, cataracts, cutis laxa, and intracranial arterial tortuosity. *J. Ganesh[1], A.E. Lin[2], I. Sahai[2], E.H. Zackai[1], S. Chadwick[1], T.L. Toler[2], P.H. Byers[3,4], U. Schwarze[3].* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) Mass General Hospital for Children, Boston, MA; 3) Department of Pathology, University of Washington, Seattle, WA; 4) Department of Medicine, University of Washington, Seattle, WA.

Cutis laxa syndromes are genetically heterogeneous. To date, mutations in *ALDH18A1*, encoding Δ^1-pyrroline-5-carboxylate synthase (P5CS), have been reported in five families. In four families biallelic mutations were present, and in the fifth there was a causative heterozygous mutation. We identified an apparently dominant *ALDH18A1* mutation (c.413G>A, p.Arg138Gln) in two unrelated infants with a complex phenotype that overlapped with the findings in reported patients and included failure to thrive, neurodevelopmental delay, bilateral cataract, intracranial arterial tortuosity, skin laxity, and a metabolic profile of low serum ornithine, citrulline, arginine, proline, and mildly elevated ammonia. P5CS is a bifunctional mitochondrial enzyme with both gamma-glutamyl kinase (γ-GK) and gamma-glutamyl phosphate reductase activity. It catalyzes a critical step in the biosynthesis of proline and ornithine, a substrate of the urea cycle and precursor in arginine biosynthesis. The heterozygous mutation that we identified in both infants results in substitution of an evolutionarily conserved arginine by glutamine at position 138 within the γ-GK domain. In the first child (P1) the mutation occurred *de novo* on the paternally derived allele. In addition there was a maternally derived polymorphic variant (c.896C>T, p.Thr299Ile) that has a heterozygote frequency of about 20% among European-Americans. In the second child (P2) the mutation arose *de novo* and there was no background polymorphic minor allele. We identified no other alteration in the gene sequence or relative mRNA abundance of the products of the two alleles in fibroblasts. These findings are consistent with the concept that the substitution of arginine by glutamine at this site represents a new dominant mutation and is sufficient to cause the phenotype. P1 was treated with L-arginine, leading to resolution of irritability, feeding difficulties, and tremors within a few weeks, and sustained improvement in growth and development after sixteen months. In P2 treatment with citrulline, ornithine, proline, and ascorbic acid was initiated with some improvement. Although mutations in *ALDH18A1* appear to be a rare, both dominant and biallelic mutations should be considered in young children with skin laxity, neurodevelopmental delay, cataracts, and arterial tortuosity and in whom sequence analysis of the growing number of other "cutis laxa genes" has not led to a diagnosis.

Molecular Characterisation of known mutations in Congenital Adrenal Hyperplasia patients (CYP21A2 gene) : Genetic & Diagnostic implications. *R. KHAJURIA[1], A. KUMAR[1], D. PAL[1], U. SHARMA[1], A. BHANSALI[2], R. WALIA[2], R. PRASAD[1].* 1) biochemistry, PGIMER, CHANDIGARH, India; 2) ENDOCRINOLOGY,PGIMER,CHANDIGARH,INDIA.

Abbreviations : SW-Salt Wasting, SV-Simple virilising, NC- Non classical, ACRS-Amplification created restriction site. Background : Congenital Adrenal Hyperplasia (CAH) is frequent autosomal recessive disease, with a wide range of clinical manifestations from severe classical form to late onset form. Most cases of CAH, the inherited inability to synthesize cortisol, aldosterone with subsequent overproduction of androgens, are caused by mutations in steroid 21 Hydroxylase gene. As a complement to hormonal measurements, mutation analysis of CYP21A2 gene is potentially important tool in diagnosis of steroid 21 Hydroxylase defiency and genetic counselling. Objective & methods : Our aim was to determine the frequency of common CYP21A2 gene mutations. Clinical and hormonal evaluations were used to categorize the patients in Salt Wasting (SW), Simple Virilizing (SV) and Non Classical (NC) forms. About 95 % of mutant alleles have apparently been transferred from linked pseudogene (CYP21P) to active gene (CYP21A2).-Molecular analysis of CYP21A2 was performed for detection of common mutations viz large gene deletions by PCR, ACRS, restriction method and product sequencing in 38 patients. Results : Disease causing mutations were identified in total 38 patients comprising SW(n=12), SV(n=18) and NC(n=8). Single gene deletion was found with frequency of 18.4 % in SW, SV patients whereas homozygosity was found with 7.9% in these cases. Heterozygous R356W mutation was found in SW (n=4), SV(n=3) and NC (n= 1). Heterozygous i2g mutation was found in SW (n=1) case. Heterozygous Q318X mutation was also present in SV(n=2) patients. Compound heterozygous patients were present in the cohort. Conclusions : This is a comprehensive study showing deleterious mutations in functional,CYP21A2 gene in our CAH population.

Spectrum of hyperhomocysteinemia in the pediatric and adolescent age group with MTHFR genotype in a north Indian cohort. *A. Lomash, S. Kumar, S. Kumar Pandey, A. Singh, S. Kumar Polipalli, S. Kapoor.* Division of Genetics, Department of Pediatrics, Maulana Azad Medical College, New-Delhi 110002, India.

Objective:Spectrum of hyperhomocysteinemia in the pediatric and adolescent age group is rarely reported from Indian ethnicity.We evaluated the clinical spectrum & association of MTHFR C677T & A1298Cgene polymorphisms with plasma homocysteine conc.in North Indian Cohort Materials & Methods:We analysed a cohort of 40patients referred to us for estimation of Plasma Homocysteine.Fasting plasma total homocysteine conc.were measured using RP-HPLC & genotype frequencies of the MTHFR gene at positions C677T & A1298C were ascertained using PCR-RFLP method.The age groups at presentation were divided into 0-12years(pediatric),12-18years(adolescent)&>18years(adult).Statistical calculation for genotype frequencies was carried out with Kruskal Wallis test using STATA software & p value less than <0.05 were considered significant Results:20subjects demonstrated hyperhomocysteinemia in the pediatric age.The mean age at presentation was 6.22years(6.22±SD2.83)The commonest presentation was stroke(60%),diminution of vision(20%),developmental delay(20%),neuroimaging finding was an infarct(30%)& lens dislocation(20%).Six cases presented in the adolescent age group with mean age of 13.6years(13.6±SD 1.57).The commonest reason for referral was stroke75% and 25%with lens dislocation.Seizures were seen in 33%cases.In the adult age group,14 cases with mean age at presentation was 25.43years(25.43 ±SD.5.97),presented with Deep Venous Thrombosis(29%),Diminution of vision(29%),Stroke(14%)Recurrent abortions(14%),Osteoporosis(14%),young MI with family history(14%).The frequencies of the AA,AC,CC genotype in cases&controls were 15%,72.5%& 10% and 87.5% & 12.5%.The frequencies of the CC,CT,TT genotype in cases&controls were 50%,50% and 75% & 25% respectively Conclusion:Stroke was the commonest reason for referral across all age groups.The commonest reason for suspicion of abnormality in Homocysteine metabolism remained suggestion of classic disease due to lens subluxation.Adult onset suspicion was clinically heterogeneous.The odds ratios of the A1298C genotypes were significantly different(17.0RR)between Patients and normal controls.The frequencies of C677T haplotype were significantly higher(3RR)in the patients than in the control group.A very Low frequency of T allele was demonstrated.Hyperhomocysteinemia is a significant contributor to pediatric and adolescent stroke.Genotypes A1298C &C677T appear to confer significant susceptibility to the development of Hyperhomocysteinemia.

2362F

A homozygous *UQCRC2* mutation cause a neonatal onset metabolic decompensation due to complex III deficiency. *N. Miyake[1], S. Shoji[2], Y. Goto[3], N. Matsumoto[1].* 1) Yokohama City University, Yokohama, Kanagawa, Japan; 2) Genetics Division, Department of Pediatrics, LAC+USC Medical Center, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 3) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, NCNP, Kodaira, Tokyo, Japan.

The mitochondrial respiratory chain generates energy as adenosine triphosphate (ATP) by means of the electron-transport chain and the oxidative-phosphorylation system. The mitochondrial respiratory chain is composed of five complexes: I, II, III, IV, and V. Mitochondrial complex III (CIII) deficiency is a relatively rare disease presenting high clinical and genetically heterogeneous. Until now, mutations in four genes have been known to cause autosomal recessive CIII deficiencies: *UQCRB, UQCRQ, BCS1L and TTC19*. *UQCRB* and *UQCRQ* encode components of CIII itself, while *BCS1L* and *TTC19* produce mitochondrial assembly factors. Here, we report three patients from a consanguineous Mexican family presenting with neonatal onset of hypoglycemia, lactic acidosis, ketosis, and hyperammonemia. According to the evidence of consanguinity, we hypothesized that this disease inherited in autosomal recessive fashion. By linkage analysis using SNP mapping array, we narrowed down the linked region to 36 Mb. At the same time, we utilized whole exome sequencing for one affected individual and picked up the homozygous variants. Then, we successfully found a homozygous missense mutation in *UQCRC2* (NM_003366), which encodes mitochondrial ubiquinol-cytochrome c reductase core protein II, in all three affected individuals. In its native state, the CIII monomer is quickly converted into a catalytically active homodimer that is incorporated into a supercomplex, and this supercomplex functions as a single enzyme. Based on structural modeling, the mutation (p.Arg183Trp) was predicted to destabilize the hydrophobic core at the subunit interface of the core protein II homodimer. Furthermore, *in vitro* studies using fibroblasts from the patient clearly indicated CIII deficiency, as well as impaired assembly of the supercomplex consisting of complexes I, III, and IV. This is the first described human disease caused by *UQCRC2* abnormality.

2363T

Assaying interallelic complementation in vivo at the Mut locus with adeno-associated (AAV) viral gene delivery. *J.S. Sénac, C.P. Venditti.* National Human Genome Research Institute, National Institute of Health, Bethesda, MD.

Methylmalonic acidemia (MMA) is caused by mutations of the mitochondrial gene methylmalonyl-CoA mutase (MUT). Among the wide spectrum of partial activity or *mut*⁻ mutations, the mechanism of enzymatic impairment has been defined only for selected mutations, such as p.G717V, which has been documented to be an adenosylcobalamin K_m mutant. We generated transgenic mice that ubiquitously express the murine p.G717V homologue (p.G715V) as a stable transgene (*Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$) and have established that this new model mimics the physiologic and phenotypic manifestations observed in *mut*⁻ MMA patients, such as dietary induction of severe methylmalonic acidemia and the inducible formation of megamitochondria in the liver. Previous publications have demonstrated that cell lines harboring some MUT mutations, such as p.G717V mutation, could be 'rescued' by alleles with distinct mutations, such as p.R93H. Using a yeast expression approach, we first established that the co-expression of the murine homologues of these mutations, Mut p.R91H and p.G715V, produced a recombinant Mut enzyme with improved kinetic parameters compared to either allele, supporting previous cell culture observations. We next hypothesized that we could recapitulate interallelic complementation in vivo using an rAAV vector to deliver the p.R91H *mut* transgene to *Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$ mice. A single retro-orbital injection of ($5e^{10}$ GC) of AAV2/9-CBA-Mut-pR91H was performed in adult mice. Following delivery, weight and metabolites were monitored. As early as one week post injection, *Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$ mice demonstrated a significant weight increase (p=0.04) compared to treated heterozygote littermates, an effect similar in magnitude to that observed in MMA mice treated with a gene therapy vector configured to express wild type Mut. Our results suggest that the phenotypic improvement is secondary to increased Mut activity mediated by interallelic complementation of mutant alleles in vivo. We are conducting detailed physiologic and phenotypic characterization of the treated *Mut*$^{-/-}$;Tg$^{INS\text{-}CBA\text{-}G715V}$ mice to further define the mechanism(s) and consequences of interallelic rescue. Using a *mut*⁻ mouse model and rAAV mediated gene delivery, we establish a new platform to study the trans-effects of mutant MUT alleles and the foundation to examine small molecule activators of the MUT activity.

2364F

A molecular genetic study of Japanese families of Creatine Transporter Deficiency. *T. Wada[1], M. Tachikawa[2], S. Ohtsuki[3], S. Itoh[3], H. Shimbo[4], H. Osaka[4].* 1) Medical Ethics and Medical Genetics, Kyoto University School of Public Health, Kyoto, Kyoto, Japan; 2) Division of Membrane Transport and Drug Targeting, Graduate School of Pharmaceutical Sciences, Tohoku University, Sendai, Japan; 3) Department of Pharmaceutical Microbiology, Graduate School of Pharmaceutical Sciences, Kumamoto University, Kumamoto, Japan; 4) Division of Neurology, Kanagawa Children's Medical Center, Yokohama, Japan.

Cerebral creatine deficiency syndrome (CCDS) is considered to be a potentially treatable intellectual disability syndrome. The common clinical feature of CCDS is intellectual disability, expressive speech and language delay, autistic behavior and epilepsy, and is composed of three genetic syndromes, Creatine transporter deficiency (CTD; MIM 300036), L-arginine:glycine amidinotransferase deficiency (MIM 602360), and guanidinoacetate methyltransferase deficiency (MIM 601240). CTD is an example of X-linked Intellectual Disability (ID), caused by mutations in SLC6A8 on Xq28. Although this is the second most frequent genetic cause of ID in Europe or America after Fragile X syndrome, there are few reports of Japanese cases and many patients should remain to be diagnosed in Japan. We have established a new simple high performance liquid chromatography screening method to determine the concentrations of guanidinoacetic acid, creatine, and creatinine in urine, which are diagnostic for differentiating these three types of CCDs. We have examined the urine samples of 106 patients (74 males and 32 females) with developmental disabilities at our medical center using this HPLC method as diagnostic screening test, and found three cases of CTD, one de novo case, and two familial cases, showing the characteristic pattern of the urine analysis, elevated creatine/creatinine ratio, and normal level of guanidinoacetic acid. And the other two familial cases whose 1H-MRS study indicated CTD as their diagnosis, and the urine analysis showed the specific pattern for CTD. All five cases have mutations in the SLC6A8 gene, including exon 5-13 deletion (de novo); c.1681 G>C, p.Gly561Arg in exon 12; c.321_323del CTT, p.Phe107del in exon 2; c.1661 C>T, p.Pro554Leu in exon 12; c.514 T>C, p.Cys172Arg in exon 3. All mutations are novel, and all mothers except one are carriers of the mutations. Our result indicates that our HPLC method is useful for diagnosis of CDDS, and a systematic diagnostic system of this syndrome should be established in Japan to enable us to estimate its frequency and develop the treatment.

2365T

Epidemiological studies of *POLG* mutations in Polish patients with mitochondrial disease of unknown etiology - preliminary data. *D. Piekutowska-Abramczuk, J. Trubicka, S. Łuczak, P. Kowalski, D. Jurkiewicz, E. Ciara, M. Borucka-Mankiewicz, M. Pelc, M. Krajewska-Walasek, E. Pronicka.* Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland.

Studies on molecular background of mitochondrial diseases (MD) indicate *POLG* mutations as one of the most common defects (up to 25%) in this group. The spectrum of *POLG*-related disease inherited in autosomal recessive or dominant manner is broad and still not fully defined. Currently, it includes the main phenotypes of AHS, MCHC, MEMSA, MIRAS, SCAE, SANDO, PEO, and less frequently LS, MNGIE, MERRF, MELAS, and SMA-like. Worldwide epidemiological studies point the widespread occurrence of the common c.1399G>A (p.A467T), c.2542G>A (p.G848S), and c.2243G>C (p.W748S) mutations up to 2%, in different European populations but also stress significant differences in the frequency of carriers depending on its' ethnicity. Retrospective group of 150 Polish patients with clinical suspicion of mitochondrial disease and negative results of standard molecular analysis (including identification of common point mtDNA mutations: m.3243A>G in *MTTL1*, m.8344A>G in *MTTK*, m.8993T>G/C in *MTATP6*; large-scale mtDNA rearrangements; and nuclear encoded *SURF1* and *SCO2* mutations (in selected cases) were enrolled to the study. DNA samples were isolated from the blood, saliva, urine, muscle, and liver biopsy specimens with phenol-chloroform extraction. Genotyping of the samples for the presence of recurrent *POLG* mutations was performed by Real-time PCR technique with specific TaqMan allele discrimination assays on Light Cycler 480 II instrument (Roche). Identified mutations were sequenced using ABI PRISM dye terminator cycle sequencing kits and automatic sequencing system Applied Biosystems 3130. Only W748S variant was found in the studied MD group; in one case in homozygous and in six cases in heterozygous form, all in patients with Alpers-Huttenlocher syndrome. Significant predominance of p.W748S mutation indicates similarity of the genotype identified in Polish and Nordic patients, that is not common in another part of the world. Evaluation of the carrier frequency of the common *POLG* mutations in a large cohort of MD is under way. There is a possibility of the presence of new data. The study was financed by National Science Centre, projects no. 2012/05/B/NZ2/01627 and 2857/B/P01/2010/39, CMHI S126/12 and EU Structural Funds, project POIG.02.01.00-14-059/09.

2366F

A synonymous polymorphic variation in ACADM exon 11 affects splicing efficiency and may affect fatty acid oxidation. *G.H. Bruun, T.K. Doktor, B.S. Andresen.* Biochemistry and Molecular Biology (BMB), University of Southern Denmark, Odense, Denmark.

Medium-Chain acyl-CoA dehydrogenase (MCAD) is an important gene in the mitochondrial fatty-acid beta-oxidation of medium-chain fatty acids and its deficiency results in the most frequent fatty acid oxidation defect in humans. In recent studies combining genome-wide association and metabolomics, a single-nucleotide polymorphism (SNP), rs211718C>T, located far upstream of the MCAD gene (ACADM) was found to be associated with improved beta-oxidation of medium-chain fatty acids. We examined the functional basis for this association and identified linkage between rs211718 and the intragenic synonymous SNP c.1161A>G in ACADM exon 11 (rs1061337). Employing ACADM minigenes we show that c.1161A is associated with aberrant splicing of exon 11, which is corrected by c.1161G. This may result in more full length MCAD from c.1161G alleles. RNA-oligonucleotide affinity purification analysis suggests that the improved splicing of the c.1161G allele is due to changes in the relative binding of the splicing regulatory proteins SRSF1 and hnRNP A1, indicating that this sequence variation either abolish an exon splicing enhancer (ESE) or create an exon splicing silencer (ESS) or both. Analysis of publicly available RNA-seq data from several hundred cell lines, show significantly more reads with c.1161G than with c.1161A in heterozygous individuals, supporting that c.1161A>G is a functional SNP, which leads to higher MCAD expression, perhaps due to improved splicing. We used the same minigene based approach for functional testing of other sequence variations in ACADM exon 11, among them the prevalent disease-causing c.985A>G mutation. These results further supported the notion that nucleotide changes in ACADM exon 11 are not neutral and may have effects by affecting splicing efficiency. This study is a proof of principle that synonymous SNPs are not neutral and that all single nucleotide changes may potentially affect splicing. By changing the binding sites for splicing regulatory proteins they can have significant effects on pre-mRNA splicing and thus protein function.

2367T

Patients affected with Fabry disease have an increased prevalence of Raynaud's phenomenon: an investigation of 222 patients. *D.P. Germain[1, 2], O.I. Atanasiu[2], A. Cordier[2], K. Benistan[2].* 1) Division of Medical Genetics, University of Versailles, Garches, France; 2) Referral Center for Fabry disease, Hôpital Raymond Poincaré, Garches, France.

Background: Fabry disease (FD, OMIM 301500) is an X-linked inborn error of glycosphingolipid metabolism due to the deficient activity of alpha-galactosidase A, a lysosomal enzyme. FD is the paradigm of a multi-systemic disease with a variety of signs and symptoms and a large phenotypic variability. While the progressive systemic deposition of globotriaosylceramide (Gb3) and secondary metabolites (lysoGb3) is known to have protean clinical manifestations with, in particular, vascular and autonomic nervous system involvement, the prevalence of Raynaud's phenomenon was not previously studied. **Patients and methods**: the presence of Raynaud's phenomenon was non-invasively investigated in 222 consecutive patients affected with classic (n = 207) or late onset (n = 15) FD, through medical history assessment, questionnaire, photographs and physical examination. All clinical cases of FD were confirmed by alpha-galactosidase A enzymatic assay and/or genotyping of the GLA gene as part of an exhaustive baseline evaluation prior to enzyme replacement therapy. **Results**: a total of 34 patients (15.3%) affected with classic FD were found to have Raynaud's phenomenon. **Discussion**: this is the first evidence of an increased prevalence of Raynaud's phenomenon in patients affected with Fabry disease. This further expands the clinical phenotype of the disease and may constitute an additional endpoint to monitor the outcome of enzyme replacement therapy or emerging therapies (active site specific chaperones). Studies are ongoing to characterize the pathophysiologic mechanism(s) of Raynaud's phenomenon in Fabry disease.

Natural History of Gangliosidosis, and Therapeutic Interventions. *J. Utz[1], R. Zeigler[2], J. Raymond[3], P. Karachinski[3], C.B. Whiltey[1].* 1) Adv Therapies, Pediatrics, Univ Minnesota, Minneapolis, MN; 2) Neuropsychology, Pediatrics, Univ Minnesota, Minneapolis, mn; 3) Neurology, University of Minnesota, Minneapolis, MN.

Background: The ganglioside accumulation has been implicated in the mechanisms of central nervous system (CNS) neurodegeneration in several lysosomal diseases including Tay-Sachs disease, Sandhoff disease, GM1-gangliosidosis and even the mucopolysaccharidoses. The ongoing natural history study has improved understanding of MRI findings and neurocognitive decline, as well as identifying new findings of clinical presentation in gangliosidoses that may be useful as clinical outcome measurements, and include increased intracranial hypertension,cardiac anomolies, gum tissue and dental disease, rapidly progressing megencephaly, and neurogenic bladder. Monotherapies such as miglust, an inhibitor of glucosylceramide synthase in the glycosphingolipid pathway, and chaperone theray with pyrimethamine have yielded disappointing results with no benefit observed in most cases. Microglial activation with release of inflammatory mediators is increasingly recognized as an important aspect of ganglioside-associated CNS damage and may provide an additional therapy target. Hypothesis: The DANSER regimen, an oral combination therapy for the gangliosidoses that targets glycosphingolipid precursor accumulation while simultaneously targeting microglial activation and downstream inflammatory processes, may provide a more comprehensive treatment strategy intended to slow and/or stabilize disease progression of the gangliosidoses. Methods: The DANSER regimen includes miglustat with ketogenic diet to enhance bioavailability of miglustat and minimize its side effects, pyrimethamine to reduce ganglioside accumulation for GM2 diseases, ibuprofen and anti-oxidant therapy to reduce damaging CNS inflammatory processes. Outcome monitoring at baseline, 4 to 6 months, 12 months, and then annually thereafter, includes volumetric MRI, neurocognitive testing, neurological exam, serum and CSF inflammatory markers, leukocyte enzyme activity, and ophthalmology exams. Natural history data and DANSER regimen data provide a retrospective and prospective assessment of natural disease pathology and the safety and efficacy of of a combined therapy approach. Results: To date, 10 patients have provided natural history data and started DANSER regimen. Overall, the DANSER regimen has been well tolerated. Neuropsychiatric evaluations have shown improvement in some domains for patients using the goal miglustat dose. These preliminary results warrant continued study.Supported by NIH U54NS065768.

Biochemical and hematologic laboratory studies in a cohort of patients with Barth Syndrome. *H. Vernon[1, 2], R. McClellan[2], A. Cordova[1], R. Kelley[2], Y. Sandlers[2].* 1) Inst Gen Med, Johns Hopkins Hosp, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

Barth Syndrome is a rare X-linked disorder characterized by dilated cardiomyopathy, skeletal myopathy and neuropenia. It is caused by defects in Tafazzin, an enzyme responsible for modifying the acyl chain component of cardiolipin. In order to gain a better understanding of clinical laboratory values in this rare disease, we measured hematologic and biochemical values in a cohort of patients. We analyzed urine organic acids, red blood cell fatty acids, and plasma 3-methylglutaconic acid (3-MGC) in 28 individuals with Barth Syndrome from ages 10 months to 30 years. The average plasma 3-MGC level in patients was 1087.5 nmol/L +/- 435 (nl. 162+/- 68 nmol/L). Our previous principal component analysis of urine organic acids in Barth Syndrome patients revealed elevations in beta hydroxyisobutyrate, aconitate, 3-MGC, and 2-ethylhydracryate compared to controls. In this current cohort, the average urine values were: aconitate 34.9 µg/mg Creatinine (+/- 16 µg/mg Cr), beta hydroxyisobutryate 21.7 µg/mg Creatinine (+/- 27 µg/mg Cr), 3-MGC 44.6 µg/mg Creatinine (+/- 25 µg/mg Cr), and 2-ethylhydracryate 6.7 µg/mg Creatinine (+/- 25 µg/mg Cr). We measured 55 fatty acids in red blood cells, and found only that C16:1 trans fatty acid was significantly different than control values, with Barth Syndrome patients having an average level of 0.312 ug/mL +/-0.08 vs. normal controls with an average level of 0.820 ug/mL +/-0.2. Complete blood counts were measured in 17 affected individuals, from age 3y11m to 30y2m. Average white blood cell count was 5664 cells/mL +/- 1798, average hemoglobin was 13.5 mg/dL +/- 1.4, average absolute neutrophil count (ANC) was 1935 cells/mL +/- 1225, and average absolute monocyte count (AMC) was 894 cells/mL +/- 449. The range for ANC was 300-4900 cells/mL, with 4 of 17 patients having neutrophil counts <1000 cells/mL. The range for AMC was 500-2400 cells/mL, with 5 of 17 patients having monocyte counts at or above 1000 cells/mL. Prealbumin levels were measured in 18 affected individuals, from ages 3y11m-30y2m months. Values ranged from 8 to 22 mg/dL (nl. 20-40), with an average of 16.9 +/- 4.02. 13 of 18 measurements were below the lower limit of normal. R-squared analysis revealed no correlation between age and these laboratory parameters. Our studies augment the knowledge of the laboratory values to be expected in individuals with Barth Syndrome, and expand upon the expected biochemical laboratory profiles.

2370F

The emerging natural history of cross-reactive immunologic material (CRIM)-negative Infantile Pompe disease patients treated with recombinant human GAA. *K.B. Sheets, S.G. Banugaria, S.M. DeArmey, D.S. Bali, C.W. Rehder, P.S. Kishnani.* Duke University Medical Center, Durham, NC.

Deficient lysosomal acid alpha-glucosidase (GAA) leads to glycogen accumulation resulting in progressive, debilitating muscle weakness. Enzyme replacement therapy (ERT) with recombinant human GAA (rhGAA) prolongs survival in patients with Infantile Pompe disease (IPD); however cross reactive immunologic material (CRIM)-negative (CN) status is a well-appreciated prognostic factor influencing poor clinical outcome. CN patients lack residual GAA expression and typically mount an immune response with high sustained antibody titers (HSAT) resulting in significant clinical decline and ultimately death at median age of 27.1 months despite continued ERT. Immune tolerance induction (ITI) with ERT initiation is now standard care for CN IPD. Nonetheless, sporadic CN cases lacking significant immune responses have emerged in recent literature. We aimed to assess natural history and treatment outcomes in CN IPD to determine how often patients mount immune responses against rhGAA. As part of an Institutional Review Board approved study we completed retrospective analysis of outcome measures for 20 CN IPD patients receiving ERT monotherapy. Median age at diagnosis was 2.5 months and 3.5 months at ERT initiation. Of the 20, 45% patients required ventilation by median age 11.3 months [8.2-25.3 months]. Most developed anti-rhGAA antibodies (17/20), with 82.4% (14/17) mounting HSAT [median peak 204800; range:51200-1638400]. Three maintained intermediate antibody titers [peak values 25600 and 51200], while three had low antibody titers peaking at 200 and 800. Median age of death for 15/20 patients was 29.6 months [14.7-51.4 months]. Of the remaining five, the single patient with HSAT at 76 months of age is the only case to receive ITI in the entrenched setting, as previously published. One patient at 69 months has intermediate titers and antibodies values continue to fall without ITI. Three patient outliers at 73, 62 and 39.5 months old maintain low titers without ITI. Variable immune responsives in this small subset of CN IPD warrants further investigation into the influence of genotype, age at start of ERT, potential HLA involvement and other genomic factors. Our data provide further evidence that CN IPD patients receiving ERT alone develop HSAT with reduced survival and poorer clinical outcomes, which necessitates prophylactic ITI to prevent HSAT as opposed to prolonged ITI treatment in the entrenched setting with greater safety risks and less likelihood of success.

2371T

Hepatic adaptations during infection: implications for inborn errors of metabolism. *P. McGuire[1], L.N. Singh[1], S. Matsumoto[2], K. Saito[2], T.N. Tarasenko[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) National Cancer Institute, National Institutes of Health, Bethesda, MD.

Although individually rare, the inborn errors of metabolism (IEM) constitute a medically important class of disorders, the untreated clinical course of which can feature severe neurologic disease and even death. Viral infections play a significant role in precipitating life-threatening acute decompensations in IEM. Acute decompensations are defined as a functional deterioration in metabolic status and may result in a range of hepatic metabolic perturbations including hypoglycemia, acidosis and hyperammonemia, depending on the disorder. We hypothesized that hepatic metabolic adaptations or perturbations that normally occur during infection will not be tolerated in IEM. To help define the hepatic metabolic response to infection, we employed mouse models of respiratory infection (influenza A/PR/8) and simulated viremia in C57Bl/6 (B6). After 5 days of infection with influenza, B6 mice displayed hepatic sensitivity characterized by increased AST and ALT and liver mtDNA depletion. mRNA microarray studies revealed antiviral and immune response signatures suggestive of hepatic sensing of influenza. Global biochemical profiling using a multi-tiered (i.e. GC-MS and LC-MS/MS) metabolomic platform showed significant reductions of long chain fatty acids and components of coenzyme A synthetic pathway consistent with increased beta- oxidation. To simulate immune activation due to viremia, mice were injected with the viral dsRNA mimic, poly I:C. During this sterile immune activation, hepatic metabolomic profiling showed significant depletion of several cofactors and their precursors including nicotinamide, NAD+, FAD, riboflavin and FMN. Since these co-factors are involved in various aspects of energy metabolism, we profiled in vivo mitochondrial function by MR spectroscopy using hyperpolarized ^{13}C-pyruvate. Following intraperitoneal poly I:C treatment for 3 days, B6 mice displayed significant increases in ^{13}C-lactate and 13C-alanine, consistent with mitochondrial perturbations and decreased entry of ^{13}C-pyruvate into the TCA cycle. Overall, our findings suggest that infection may result in increased utilization of long chain fatty acids, which may be functionally impaired if the carnitine cycle or fatty acid oxidation is affected by the underlying IEM. In addition, immune activation may also have more direct effects on hepatic energy metabolism, which has implications for patients with mitochondrial disease and other IEM with significant mitochondrial dysfunction.

2372F

Distinctive neurocognitive and neuropsychiatric phenotype for mucopolysaccharidosis type I (Hurler-Scheie syndrome) associated with mutation L238Q of the alpha-L-iduronidase gene. *A. Ahmed, C. Whitley, R. Cooksley, E. Shapiro.* Department of Pediatrics, University of Minnesota, Minneapolis, Minnesota.

The lysosomal enzyme alpha-L-iduronidase hydrolyzes terminal iduronic acid from heparan sulfate and dermatan sulfate, and is an essential step in GAG degradation. Mutations of its gene, IDUA, yield a spectrum of mucopolysaccharidosis (MPS) type I clinical disorders. The IDUA mutation, c.712T>A (p.L238Q) was previously noted as a mild mutation. In a longitudinal study of MPS brain structure and function (Lysosomal Disease Network), we found this mutation in 6 of 23 Hurler-Scheie syndrome patients. We hypothesized that L238Q, when paired with a nonsense mutation, is significantly more severe than other missense-nonsense combinations. Methods: Of 6 patients with a L238Q mutation, the L238Q allele was paired with a nonsense mutation in 4 patients, paired with a deletion in 1, and with a splice site mutation in another. This group was compared to 6 Hurler Scheie patients closely matched in age with 3 with missense-nonsense, 2 missense-missense, and 1 splice site-nonsense genotypes. Medical history was compiled into a Physical Symptom Score (PSS). Assessment of IQ, attention, memory, spatial ability, adaptive function and psychological status were measured. Results: No group differences were found in age at evaluation (17.8 and 19.3 years), duration of ERT, or PSS. By history, all were reported to be average in IQ (4/6 with documentation) in early childhood. All (100%) of the L238Q group had a psychiatric history and sleep problems compared to none (0%) of the comparison group. Significant differences were found in depression and withdrawal on parent report measures. IQ was lower in the L238Q group (mean IQ 74) than the comparison group (mean IQ 95; $p < 0.008$). Attention, memory, and visual-spatial ability scores were also significantly lower. Three occurrences of shunted hydrocephalus, and 4 of cervical cord compression were found in the L238Q group; the comparison group had1 occurrence of unshunted hydrocephalus and 2 of cord compression . Discussion: The missense mutation L238Q, when paired with a nonsense mutation, is associated with significant, late-onset brain disease: psychiatric disorder, cognitive deficit, and general decline starting at a later age than in Hurler syndrome with a mutation-related rate of GAG accumulation and its pathologic sequelae. This particular genotype-phenotype may provide insight into the genesis of psychiatric illnesses more broadly. Consideration of methods for early, brain-targeted treatment in these children is necessary.

2373T

Oral manifestations in a patient with infantile onset Pompe disease: newly recognized findings.
L.S. Kehoe[1], T. Anupama[2], P. Kantaputra[3]. 1) 1.Division of Genetics and Metabolism, Children's National Medical Center, Washington, DC; 2) 2.Department of Dentistry, Children's National Medical Center, Washington DC, USA; 3) 3.Craniofacial Genetics Laboratory, Division of Pediatric Dentistry, Department of Orthodontics and Pediatric Dentistry, Faculty of Dentistry, Chiang Mai University, Chiang Mai 50200, THAILAND.

Pompe disease is a lysosomal storage disease caused by mutations in the acid alpha glucosidase (GAA) gene. Mutations in GAA impair glycogen degradation, leading to excessive glycogen storage in lysosomes. The clinical spectrum of the disease ranges from a rapidly progressive infantile form to a slowly progressive late-onset form. The hallmarks of the classic infantile form are progressive, generalized muscle weakness and hypertrophic cardiomyopathy. A 9-year-old female first presented with weakness and hypertrophic cardiomyopathy at 3 months old. The diagnosis of infantile onset Pompe was confirmed by enzyme and molecular analyses. Enzyme replacement therapy (ERT) was started at age 5 months. Over time she has experienced generalized muscle weakness and has been G-tube dependent. A recent echocardiogram was normal. Physical examination showed myopathic facies, bilateral ptosis, hypernasality and generalized muscle weakness with no ectodermal dysplasia features. Oral examination revealed malocclusion related to mid-face hypoplasia and prognathic mandible. Panoramic radiographs at age 8 years demonstrated very large pulp chambers with poorly formed dentin of the maxillary permanent central and lateral incisors. The tooth roots were extremely short. Taurodontism of the maxillary permanent first molars and hypodontia were noted. There is no family history of hypodontia or other dental anomalies. Dental and craniofacial abnormalities in infantile onset Pompe disease have been understudied. Malocclusion has been described in at least one patient with the infantile form. Our patient presented with hypodontia, dental anomalies and anterior crossbite secondary to mandibular prognathism and hypoplastic maxilla which have never been reported in infantile onset Pompe survivors. Tooth agenesis or hypodontia is one of the most common congenital anomalies in humans and can be an isolated finding or be part of a genetic syndrome. Mutations in several genes involved in early craniofacial development and transcription factors cause isolated hypodontia. The correlation between GAA gene function and tooth agenesis is unknown. Further studies are strongly suggested. ERT has modified the natural history of the disease. Patients live longer leading to the discovery of new findings. Dental anomalies in Pompe disease might be an overlooked part of this syndrome. Since early dental care may improve orodental health, a thorough oral examination is encouraged.

Assessment of Bone Mineral Density by Dual Energy X-ray Absorptiometry in Patients with Mucopolysaccharidoses.
H. Lin[1,2,3,4], S. Lin[1,2,3], C. Chuang[1], M. Chen[1,2,3], D. Niu[4,5]. 1) Departments of Pediatrics and Medical Research, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Medicine, Mackay Medical College, New Taipei City, Taiwan; 3) Department of Early Infant Care and Education, Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 4) Institute of Clinical Medicine, National Yang-Ming University, Taipei, Taiwan; 5) Department of Pediatrics, Taipei Veterans General Hospital, Taipei, Taiwan.

Patients with mucopolysaccharidoses (MPS) have a skeletal dysplasia that is associated with poor bone growth and mineralization. However, only limited information exists regarding the assessment of bone mineral density (BMD) in relation to age and treatment in these disorders. Therefore, we performed dual energy x-ray absorptiometry (DXA) to characterize lumbar spine BMD in 30 MPS patients. Our study population was all Asian, mostly male (70%), and predominantly pediatric (87% <19 years of age). The median age was 10.8 years (range 5.0 years to 23.7 years). MPS types included I (n=2), II (n=12), IIIB (n=2), IVA (n=9), and VI (n=5). For the 26 patients <19 years of age, standard deviation scores (Z-scores) for height, weight, body mass index (BMI), and BMD were -4.53 ± 2.66, -1.15 ± 1.55, 0.74 ± 1.23, and -3.03 ± 1.62, respectively, and all were negatively correlated with age ($p < 0.05$). There were 21 (81%), 8 (31%), 0 and 18 patients (69%) below -2 Z-score for these four parameters, respectively. However, after correction for height-for-age Z-score (HAZ), HAZ adjusted BMD Z-score was -0.7 ± 1.24. Eight patients (31%) met our center's criteria for osteopenia (HAZ adjusted BMD Z-score <-1), and 4 patients (15%) had osteoporosis (HAZ adjusted BMD Z-score <-2). Of 8 patients with MPS I, II or VI who underwent follow-up DXA after receiving ERT for 1.0 to 7.4 years, all showed an increase in absolute BMD values, and 3 out of 5 patients who started ERT at the pre-pubertal age revealed an improvement in HAZ-adjusted BMD Z-score. These findings and the follow-up data can be used to develop quality of care strategies for patients with MPS.

Mucopolysaccharidosis VII (MPS VII; Sly syndrome) is a lysosomal storage disorder caused by the deficiency of β-glucuronidase (GUS). To understand the natural history of MPS VII, extensive knowledge of the spectrum of disease severity, the rate of progression and distribution of specific symptoms in untreated patients with MPS VII is needed. In this study, we investigated the onset, severity, management and natural progression of the disease via a retrospective review of MPS VII cases. Anonymous information of signs and symptoms of MPS VII patients was collected by conducting interviews to physicians and by reviewing published literature. To date, 112 patients from 23 countries were analyzed. Of these, 64 patients had an infantile or adolescent form of the disease and 48 patients were classified with non-immune infantile hydrops fetalis (NIHF). About 70 percent of patients with the infantile or adolescent forms of the disease had symptoms one year before diagnosis. In contrast, most patients with NIHF were diagnosed during pregnancy, as early as 20 weeks of gestation. Some patients survived only a few months and died from respiratory, renal or cardiac insufficiencies. A few improved thereafter resembling later onset forms. The presentation of the disease is heterogeneous with phenotypes ranging from severe to mild exhibiting normal intelligence. Our study shows that over 50% of individuals with late onset forms are characterized mostly with macrocephaly, coarse facies, pulmonary and cardiac disease, hepatosplenomegaly, cognitive impairment, short stature, and dysostosis multiplex. The data collected in this study will help to establish the natural history of MPS VII disease and to determine potential clinical endpoints.

2376F

Cobalamin C disease with fulminant hyperammonemic presentation in the neonatal period. *N.S. Abul-Husn, A.C. Yang, C. Yu, H. Chen, G.A. Diaz, J.D. Weisfeld-Adams.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Combined methylmalonic acidemia (MMA) and homocystinuria, cobalamin C type (cblC disease) is the most common inherited disorder of cobalamin (vitamin B12) metabolism. CblC disease is caused by mutations in the *MMACHC* gene, which lead to failed synthesis of adenosylcobalamin and methylcobalamin, essential cofactors for the mitochondrial enzyme methylmalonyl-CoA mutase (encoded by the *MUT* gene) and the cytosolic enzyme methionine synthase, respectively. CblC disease typically presents with progressive neurological deterioration in the newborn period, with later progression to multi-systemic disease. Although the clinical manifestations can vary, cblC disease is phenotypically quite distinct from either isolated MMA or isolated homocystinuria. Here, we describe the unusual case of a neonate from consanguineous parents who presented with severe hyperammonemic encephalopathy and metabolic acidosis, a presentation not typically seen in cblC disease. Newborn screen showed elevation of C3 acylcarnitine (12.56 µmol/L; normal range < 7.00 µmol/L) with low plasma methionine (0.18 µmol/L; normal range > 0.25 µmol/L). Initial plasma ammonia level was 1150 µg/dL (normal range 15 - 50 µg/dL). Plasma homocysteine was measured at 146 µmol/L (normal range 5 - 15 µmol/L), suggesting a defect in both adenosylcobalamin and methylcobalamin (i.e. cblC, cblD, or cblF disease). Urine methylmalonic acid was massively elevated at 20,482 mmol/mol creatinine (normal range < 5 mmol/mol creatinine), similar to levels observed in cases of isolated MMA caused by *MUT* deficiency prior to initiation of treatment at our center. Post-mortem studies showed homozygosity for the common c.271dupA allele in *MMACHC* in DNA recovered from patient fibroblast cultures, confirming the diagnosis of cblC disease. Further studies using next-generation sequencing revealed a heterozygous missense mutation (c.1991C>T) in the *MUT* gene that is predicted to be pathogenic using standard *in silico* analyses. This suggests that variants in other genes associated with cobalamin metabolism may play a role in modifying the clinical presentation of cblC disease, resulting in catastrophic presentations early in the neonatal period.

2377T

Molecular analysis of patients diagnosed as *cblC*. *A. Brebner, D. Watkins, D.S. Rosenblatt.* Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

Patients with combined homocystinuria and methylmalonic aciduria and mutations in the *MMACHC* gene constitute the *cblC* complementation group, the most common inborn error of vitamin B_{12} (cobalamin) metabolism. Approximately 550 patients are known to exist worldwide. Sanger sequencing of *MMACHC* in 39 *cblC* patients diagnosed by somatic cell complementation identified at least one mutation in 36. Four of these mutations were novel: two missense mutations [c.158T>C (p.L53P) and c.566G>A (p.R189H)]; one nonsense mutation [c.292C>T (p.Q98X)]; and a mutation that results in a deletion of exon 2. The missense mutation c.158T>C was seen in four patients that were asymptomatic at the time of ascertainment. Three were found by newborn screening for methylmalonic aciduria, and one from a metabolic screen in an adult with a presumably unrelated cancer. One patient developed symptoms only when she was 14 weeks pregnant, at age 24. In three cases the c.158T>C mutation was found in combination with a previously known *MMACHC* mutation. In the fourth, no second mutation was identified within the coding sequence, in the 5' and 3' UTRs, or in the *MMACHC* promoter. Sequencing of cDNA identified c.158T>C in apparent hemizygosity, suggesting an unidentified mutation in a non-coding region that eliminated expression of the second allele. The c.566G>A mutation was identified in one asymptomatic patient that was picked up on newborn screen. Both missense mutations affect conserved residues and were predicted to be probably damaging by Polyphen-2 with scores of 1.000. The nonsense mutation c.292C>T was seen in one severely affected early onset patient who presented with seizures, hypotonia and poor feeding. In another patient that died in infancy, sequencing of gDNA seemed to show the patient was homozygous for the common c.271dupA mutation. However amplification of the cDNA showed a heterozygous deletion of exon 2; there were two products, one normal size and the other 200bp shorter. Sequencing demonstrated the shorter product was lacking exon 2. This brings the total number of mutations seen in *cblC* patients to 80. In one of the three patients with no identified *MMACHC* mutation, re-examination of results of cellular studies showed an ambiguous complementation assay and a biochemical picture consistent with the *cblF* or *cblJ* disorder. Sequencing of the *LMBRD1* gene revealed that this patient was homozygous for the common c.1056delG mutation, demonstrating the diagnosis of *cblF*.

2378F

Glycemic deregulation in Congenital Central Hypoventilation Syndrome. *F. Moreau[1], K. Braun[2], J. Amiel[3], T. Dery[4], G. Jedraszak[4], S. Goudjil[1], G. Kongolo[1], H. Trang[5], P. De Lonlay[6], M. Mathieu[4], A. Leke[1], G. Morin[4].* 1) Pediatric Reanimation, Amiens University Hospital, Amiens, France; 2) Pediatric Endocrinology, Amiens University Hospital, Amiens, France; 3) Genetic department, Necker-Enfants Malades Hospital, Paris, France; 4) Genetic department, Amiens University Hospital, Amiens, France; 5) Ondine curse rare disease reference center, Robert Debré Hospital, Paris, France; 6) Inherited metabolic diseases rare disease reference center, Necker-Enfants Malades Hospital, Paris, France.

Background Congenital Central Hypoventilation Syndrome (CCHS; OMIM 209880) is a life-threatening disorder with an impaired ventilatory response to hypercarbia and hypoxemia. This core phenotype is associated with lower-penetrance anomalies of the autonomic nervous system including Hirschsprung disease and tumors of neural-crest derivatives. CCHS is due to heterozygous mutations of PHOX2B gene, mainly polyalanine repeat expansions. In the past 12 years, recurrent hypoglycemia has been reported in 6 CCHS patients and was always related to high plasmatic insulin level. Interestingly, a recent study in CCHS patients observed a chronic tendency to hyperglycemia. Case report The delivery of this female baby occurred by caesarian section at 40 WG for fetal bradycardia. Apgar score was 9/9/9. Apneas led to tracheal intubation. Abdominal distension required a discharge colostomy and Hirschsprung disease was diagnosed. After recurrent sleeping apneas, the diagnosis of CCHS was confirmed (PHOX2B: c.590dup, p.Gly199ArgfsX161 - J. Amiel). First hypoglycemia was observed at 6 weeks of life, consecutively to seizure. The hypoglycemias were profound, recurrent, occurred after 1.5-2.5 hours fast, without ketone bodies, sensitive to Glucagon. Insulinemia was 21.1 µUI/ml (glycemia 1.9mmol/L). Enrichment of alimentation with carbohydrates and diazoxide (10-15 mg/kg/d) allowed a good control. During continuous glucose monitoring, recurrent hyperglycemia was observed. Discussion Hyperinsulinism in CCHS patients is probably not coincidental, but the characteristics of the hypoglycemias are different of those observed in hyperinsulinism by channelopathies, suggesting a different mechanism. Insulin hypersecretion in CCHS could be secondary to pancreatic hypertrophy, PHOX2B-/-mice presenting an increased number of β cells. An abnormal function of carotid body glomus cells could also be suspected. Functions of glomus cells combine O2 and glucose sensor to prevent neuronal damage by acute hypoxia and/or hypoglycemia. Carotid glomus cells derive from neural crest and CCHS is a disease of neural crest derivatives. In two CCHS patients, the corpus bodies were found smaller than controls with a marked decrease in the number of glomus cells. But carotid bodies are histologically normal in mice harboring a heterozygote +7 alanines expansion. However, the role of fast in hypoglycemias, and the coexistence of hyperglycemias suggest carotid glomus insensitivity to glucose.

2379T

Fabry Disease in Northern Ireland.
F.J. Stewart[1], A. Muir[2], J. McOsker[2], T. Jardine[2], A. Wilson[1], P. McKeown[2]. 1) Dept Genetic Medicine, Belfast City Hosp, Belfast, United Kingdom; 2) Belfast Heart Centre, Royal Victoria Hospital, Belfast, United Kingdom.

Fabry disease is a multi-system lysosomal storage disease due to a deficiency of alpha galactosidase. It is caused by mutations in the GLA gene which is on the X chromosome. It differs from many X-linked disorders in that females frequently show clinical features. Affected individuals may show the classical form or a more attenuated form. Treatment for this condition is available in the form of enzyme replacement therapy with agalsidase beta (Fabrazyme) and agalsidase alpha (replagal). The incidence has been estimated at approximately 1:50 000 males (Desnick 2001). However a newborn screening study suggested an incidence of 1:3000 with an 11:1 ratio of individuals with the more attenuated phenotype (Spada 2006). Northern Ireland has a population of 1.7 million. To date we have found 11 families who have Fabry disease within which are 46 individuals with a GLA mutation. All individuals with a mutation are followed up on an annual basis at our multidisciplinary Fabry clinic. Three families have the p.A13P mutation. All other mutations are seen in only one family and they are Exon 1 deletion, p.R392SfsX2, p.R220X, c.144delG, p.W209X, p.A13T, p.D313G and c.802_804delCA. 10 patients are aged under 18. The eldest female is aged 79. The eldest male is 75. The typical skin angiokeratoma are seen in 6 individuals - all male. 16 show signs of cardiac involvement. Two patients have had small strokes but most over the age of 30 show some bright changes on MRI. No patients have renal failure though some show evidence of mild proteinuria. 11 patients are on treatment with agalsidase alpha and 7 with agalsidase beta. The remaining patients are monitored on an annual basis with cardiac and renal investigations. They have either declined ERT treatment or have no clinical features to warrant treatment at this stage. The majority of our patients have come from family follow up of the index cases and the offer of genetic testing to at risk relatives. This may explain why we have a significant number of individuals not currently on treatment. These figures suggest an incidence of at least 1:37000 in our population. We feel that we do not have 100% ascertainment of cases and therefore we believe this may be an underestimate of the true incidence. We feel that family follow up of newly diagnosed cases and genetic testing of at risk relatives is essential as clinically asymptomatic individuals may miss out on the opportunity for monitoring and possible treatment.

Hepatocerebral mitochondrial DNA depletion syndrome with atypical brain MRI findings due to heterozygote mutations in the MPV17 gene including a novel mutation: clinical, biochemical and molecular analysis.
A. Iglesias. Dept Pediatrics, Div Med Gen, Columbia Univ Med Ctr, New York, NY.

Hepatocerebral mitochondrial DNA depletion syndrome is a known clinical entity. Mutations in the MPV17 gene are causative, but rare and the natural history of the phenotype is incomplete. Moreover, liver transplant is ethically controversial due to brain involvement. A case of a 13 month-old boy with the diagnosis is discussed. He was born full term after uneventful pregnancy. Parents are from Pakistan and are first cousins. Jaundice was diagnosed at 3 months improving by 5 months; but recurred at 9 months. At 1 year he was found to have elevated direct bilirubin, alkaline phosphatase, AST/ALT and AFP and negative metabolic evaluation except for high lactate and negative PFIC testing. Normal chromosomes and SNP-array with areas of homozygosity were done. Needle liver biopsy was done: giant cell hepatitis, cirrhosis with micro/macro vesicular steatosis; abnormal mitochondria were seen on EM. mtDNA testing on liver was inconclusive. Brain MRI: mild delay in myelinization in the internal capsule and white matter changes sparing cerebellum and basal ganglia. Liver transplantation was discussed, but not performed due to clinical severity and uncertain diagnosis. A muscle biopsy was performed: positive mtDNA depletion (>95%). Molecular testing for mtDNA depletion syndrome was done. Heterozygosity for 2 mutations in the MPV17 gene: c.284dupG [p.Phe96LeufsX17] and c.293 C>T [p.Pro98Leu (P98L) was found confirming the diagnosis. Both mutations are predicted to be pathogenic. The latter, P98L has been previously reported in Pakistan. The former, although predicted to be pathogenic, has not been previously reported. Due to clinical complications the patient passed away few days after the muscle biopsy without being transplanted. Therefore, although the diagnosis did not affect the patient's outcome, it helped to console the parents and plan for future pregnancies. In conclusion, this case well exemplifies the value of how a strong clinical suspicion, despite inconclusive liver biopsy results, can help to achieve a definitive diagnosis. Moreover, the brain MRI changes, although non-typical, raised concerns about the ethical decision about liver transplant. In hindsight, the diagnostic decisions taken seemed appropriate; but future characterization of additional cases with mutations in the MPV17 gene (especially this particular genotype) will be needed to address this clinical dilemma while teaching us about this fascinating condition.

Genetic Associations with Neonatal Acylcarnitine Levels.
C.J. Smith[1], A.M. Momany[2], S.L. Berberich[3], J.L. Murray[2], K.K. Ryckman[1]. 1) Department of Epidemiology, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) State Hygienic Laboratory, University of Iowa, Iowa City, IA.

Background: Short-chain acylcarnitines are critical for normal cellular metabolism. Variation in acylcarnitine levels may be indicative of a variety of adult metabolic deficiencies such as Type 2 Diabetes Mellitus and may be associated with specific genotypes. Recent genome-wide association studies of the adult human metabolome have identified genetic variants associated with multiple acylcarnitine levels; however, to our knowledge, no studies have examined this at birth. We have previously shown that acylcarnitine levels are highly heritable at birth. **Objective:** We examined single nucleotide polymorphisms (SNPs) in candidate genes implicated in adult metabolism with the normal variation in short-chain acyclarnine levels in newborns. **Methods:** Our analysis included genetic data and analyte measurements for 425 term born (40 weeks gestation) singleton neonates. We examined 10 short-chain acylcarnitines including C0, C2, C3, C3-DC, C4, C4-DC, C5, C5:1, C5-OH and C5-DC as measured by tandem mass spectrometry as part of routine newborn screening performed by the State of Iowa Hygienic Laboratory. We excluded from analysis any neonate that had an abnormal newborn screen, was on total parenteral nutrition or those for whom the sample was not obtained between 24 and 72 hours after birth. DNA was extracted from the residual dried blood spot card and 22 SNPs in 7 candidate genes were genotyped using the Fluidigm® SNP Genotyping platform. We analyzed each SNP-analyte level for association using Kruskal-Wallis tests. **Results:** Of the 220 SNP-analyte associations 8 were significant by Bonferroni correction (p-value <2×10-4). Three SNPs (rs3794215, rs3916, rs555404) in the short chain acyl-CoA dehydrogenase gene (ACADS) were associated with neonatal C4 levels. The GG genotype of rs3794215 (P=9.9×10-20), the CC genotype of rs3916 (P=2.0×10-27) and the CC genotype of rs555404 (P=1.6×10-17) were all associated with higher neonatal C4 levels. There were also significant (P<0.01) associations with 2 SNPs (rs11746555 and rs17622208) in the solute carrier family 22 (SLC22A5) gene with C0, C4-DC, C5 and C5-OH. **Conclusions:** We have replicated SNP associations observed between adult metabolic traits and the ACADS and SLC22A5 genes in newborns. This research has important implications for not only detection of rare inborn errors of metabolism but also life course epidemiology.

2382F

Presenting optional newborn screening in the context of mandatory newborn screening: The case of Duchenne muscular dystrophy.
S.E. Lillie[1], B.A. Tarini[2], B.J. Zikmund-Fisher[1]. 1) Department of Health Behavior and Health Education, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI.

Purpose: Many mandatory newborn screening (NBS) programs have expanded to include optional tests that require parents to make explicit decisions. Parents' decisions may depend not only on NBS information, but also the context in which it is presented. We examined whether presenting optional NBS for Duchenne Muscular Dystrophy (DMD) with or without the context of mandatory NBS would influence intended utilization of and attitudes towards DMD NBS. Methods: U.S. adults recruited from Amazon Mechanical Turk (N=2,991) read a hypothetical vignette and learned about DMD and DMD NBS for their (hypothetical) newborn boy. Participants were randomized to one of three vignettes that presented information about DMD NBS by itself (no context), with a description of mandatory tests that just listed the total number of tests ('bundled' mandatory context), or with a listing of each mandatory test ('unbundled' mandatory context). We assessed intended utilization and attitudes towards the optional test. Results: Most participants reported they would utilize DMD NBS (68.6%). Participants were more likely to choose DMD NBS if they also read about DMD NBS in the context of mandatory NBS (either bundled or unbundled) versus when the test was presented by itself with no larger context (Bundled: OR=1.54, p<0.01; Unbundled: OR=1.35, p<0.05). Participants who read about DMD NBS with no context of mandatory NBS reported such testing to be less important and reported that they would worry more about DMD NBS results than those provided with the context of mandatory NBS (F=3.40, p<0.05; F=3.48, p<0.05). Conclusions: Future optional NBS programs should describe how optional tests fit into overall mandatory NBS programs. Increasing attention to how the framing of communications about testing influences parental behavior will become more and more important as optional NBS programs continue to expand.

2383T

Lysosomal Disease Newborn Screening in Mexican Population. *J. Navarrete[1], A. Rivera[2], A. Limon[1], E. Covian[1].* 1) Dept Gen, Hosp Sur PEMEX, Mexico City, Distrito Federal, Mexico; 2) School of Medicine, Universidad Anahuac, Mexico Norte, Mexico City, Distrito Federal, Mexico.

The goal of newborn screening is almost always to make a specific diagnosis for the purpose of providing medical intervention to avoid or ameliorate symptoms. In Mexico we began with newborn screening since 1977 but with very few inborn errors of metabolism, phenylketonuria, galactosemia, congenital hypothyroidism, sickle cell anemia and cystic fibrosis, after 10 years other disorders including some aminoacidopathies have been included. Petroleos Mexicanos is a big institution with aproximately 10 thousand workers and their families. Since 2005 a larger newborn screening has been done to all newborns in this insitution through all the country. We test for most aminoacidopathies including organic acidurias, hemoglobinopathies, G6PD deficiency, adrenal hyperplasia, cystic fibrosis, biotindase deficiency and since August 2012 we included immunodeficiency syndrome, Gaucher disease, Niemann Pick(A/B) disease, Pompe disease, Krabbe disease, Fabry disease, MPS I. We present are results of 2500 newborns screened since last year, their follow up and early treatment.

2384F

Enhancing case detection of selected inherited disorders through expanded newborn screening in the Philippines. *C. Padilla[1,2].* 1) Newborn Screening Reference Center, National Institutes of Health, University of the Philippines Manila; 2) Department of Pediatrics, College of Medicine, University of the Philippines Manila.

Background. Newborn screening in the Philippines currently includes screening for 6 disorders - congenital hypothyroidism (CH), congenital adrenal hyperplasia (CAH), phenylketonuria (PKU), glucose-6-phosphate dehydrogenase (G6PD) deficiency, Galactosemia (GAL) and maple syrup urine disease (MSUD). With improved newborn screening technologies, the potential of screening more than 70 disorders is possible. Worldwide, there has been a move towards increasing the number of disorders included in newborn screening panels. The California Newborn Screening Program (CNSP) screens for over 70 disorders and its database includes a large number of Filipino newborns. Objectives. To ascertain the profile of Filipino newborns screened through the CNSP and to extrapolate these data to the Philippine newborn population in order to assess the potential value of expanding the Philippine newborn screening program. Methods. The newborn screening database of the CNSP was reviewed. Projections based on the California data were made relative to expanded newborn screening and related outcomes in the Philippines. Results: From 2005 to 2011, a total of 3,460,839 newborns were screened in the CNSP which included 111,127 Filipinos. Among the Filipinos, 199 were confirmed as having one of the screened disorders categorized as follows: endocrinology disorders (51); hemoglobinopathies (109); amino acid disorders (6); organic acid disorders (7); fatty acid disorders (10); and other disorders (16). Extrapolating these findings to the Philippine newborn population predicts the detection of significant additional cases of screened disorders including: 2180 hemoglobinopathies, 140 organic acid disorders, 200 fatty acid disorders, and 240 other disorders. Conclusion: Data from the CNSP show significant cases of serious disorders detected by newborn screening in Filipino babies that are not currently detectable in the limited newborn screening program in the Philippines. Expanding the panel of screened disorders to approximate that in the CNSP will result in significant numbers of additional case detections in the Philippines that will save lives and reduce unnecessary negative health outcomes as a result of early detection and treatment.

Hyposialylation in glomerulopathies is mitigated by N-acetylmannosamine therapy. *M. Huizing[1], M.C. Malicdan[1], P. Leoyklang[1], O. Okafor[1], T. Yardeni[1,2], M.F. Starost[3], P.M. Zerfas[3], Y. Anikster[2], A. Volkov[4], B. Dekel[5], J.B. Kopp[6], W.A. Gahl[1].* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD, USA; 2) Metabolic Disease Unit, Sheba Medical Center, Tel Hashomer, Tel Aviv, Israel; 3) Division of Veterinary Resources, ORS, NIH Bethesda, MD, USA; 4) Department of Pathology, Sheba Medical Center, Tel Hashomer, Israel; 5) Pediatric Nephrology Unit, Sheba Medical Center, Tel Hashomer, Israel; 6) Kidney Disease Section, NIDDK, NIH, Bethesda, MD, USA.

Biallelic mutations in murine *Gne*, coding for UDP-GlcNAc 2-epimerase/ManNAc kinase, the key enzyme in sialic acid biosynthesis, result in glomerular disease with podocyte effacement due to hyposialylation. We showed that oral supplementation with the sialic acid precursor N-acetylmannosamine (ManNAc) ameliorated the proteinuria and improved the podocyte foot process architecture and glomerular sialylation status of mutant mice. A panel of fluorescent-labeled lectins (including WGA, SNA, HPA, and PNA) applied to kidney sections, indicated aberrant sialylation of predominantly O-linked glomerular glycans in mutant mice kidneys; this normalized after ManNAc treatment. Since hyposialylation has sporadically been suggested in human glomerulopathies, we applied the lectin panel to renal tissue sections from 40 patients with unexplained glomerulopathies. An unexpectedly high number of biopsies (8) had glomerular hyposialylation similar to that seen in our mouse model, indicating that this condition may occur relatively frequently, and also that ManNAc may be a therapy. To gather more preclinical data, we induced podocyte hyposialylation in mice by intraperitoneal injection of (*Vibrio cholera*) sialidase, removing sialic acids from glycans. Sialidase-injected mice developed proteinuria and renal failure in a dose-dependent manner. Their glomerular glycoproteins were hyposialylated and their podocytes were effaced, similar to our *Gne* knock-in mouse model. Importantly, oral prophylaxis and treatment with ManNAc significantly reduced their proteinuria and podocyte injury. Although the exact mechanisms and consequences of glomerular hyposialylation requires further study, oral ManNAc therapy could benefit patients with glomerular hyposialylation; ManNAc has minimal toxicity, is easily (orally) administered and could replace or supplement existing therapies. Moreover, ManNAc is currently being tested in a Phase 1 clinical trial for the treatment of the rare hyposialylation disorder GNE myopathy; it could be repurposed for trials in patients with glomerular hyposialylation.

THERAPEUTIC HYPOTHERMIA FOR HYPERAMMONEMIC METABOLIC CRISES: A PILOT STUDY. *U. Lichter-Konecki[1], J. Poeschl[2], D. Dimmock[3], S. Baumgart[4].* 1) Div Gen & Metabolism, Children's National Med Ctr, Washington, DC; 2) Neonatal Intensive Care, Dept. Pediatrics, Children's Hospital, University of Heidelberg, Heidelberg, Germany; 3) Division of Genetics, Dept. of Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 4) Div Neonatology, Children's National Med Ctr, Washington, DC.

Background: Neonates with urea cycle disorders (UCDs) or organic acidemias (OAs) and acute hyperammonemia (HA) and encephalopathy are at great risk for brain injury, intellectual disability, and death. Nutritional support and renal replacement therapy are used to treat the severe hyperammonemia of neonatal onset disease. Neuroprotection during rescue treatment may improve neuropsycholigical outcome. Animal experiments and small clinical trials in acute liver failure indicate that therapeutic hypothermia (TH) is neuroprotective in HA. We report results of a feasibility and safety pilot study of whole body cooling for neonates with acute HA and encephalopathy. Methods: Encephalopathic, hyperammonemic neonates with symptoms of UCDs or OAs requiring dialysis were enrolled. The whole body of the patients was cooled to 33.5 °C +/- 1°C. After 72h they were slowly rewarmed. Data of age-matched historic controls were also collected for comparison. Results: Seven patients were cooled using the pilot study protocol and their data were compared to data of seven historic controls. All patients survived dialysis and TH, 6 patients were discharged home, five feeding orally. The main complication was hypotension. Conclusion: TH treatment for hyperammonemic neonates was feasible and safe when administered in intensive care units experienced in cooling and dialyzing neonates and managing metabolic crises. TH however adds to the complexity of the treatment of these critically ill children and should not be done unless proven efficacious in a randomized clinical trial.

Polymyositis: A Common Misdiagnosis For Late Onset Pompe Disease. *V. Kasturi[1], S. Jain[1], V. Juel[2], P. Kishnani[1].* 1) Medical Genetics, Duke University Medical Center, Durham, NC; 2) Department of Neurology, Duke University Medical Center, Durham, NC.

Background: Pompe disease (PD) is a progressive neuromuscular disorder caused by acid alfa glucosidase (GAA) deficiency leading to accumulation of glycogen in lysosomes. PD is broadly categorized into 2 subtypes. Infantile PD is rapidly progressive and fatal within the first year of life, secondary to cardiorespiratory failure without treatment. Late onset Pompe disease (LOPD) is primarily recognized as a proximal limb girdle muscle dystrophy with pulmonary involvement that leads to respiratory failure. There are many other presentations for LOPD including ptosis, WPW syndrome, basilar artery aneurysm, lingual weakness, rigid spine syndrome, polymyalgia rheumatic, and polymyositis amongst others. LOPD is often misdiagnosed with significant diagnostic delays. With the advent of ERT, and the knowledge that early treatment impacts a better clinical outcome, early recognition of the disease is critical. Case Presentation: We present a case of a 44-year-old male admitted to the ICU in acute respiratory failure leading to cardiac arrest. His past medical history included a diagnosis of 'idiopathic scoliosis syndrome' and low back pain from the age of 29. He reported difficulty keeping up with his lifestyle due to his muscle weakness, tiredness and hyper somnolence. There was a history of weight loss and muscle wasting in the past 18 months. His CPK, thyroid function testing, ANA, anti Ro, La, RNA polymerase, Troponin, Rheumatoid Factor, and myositis antibodies were negative. EMG showed findings consistent with an inflammatory myopathy. A muscle biopsy showed nonspecific myopathic findings and no glycogen accumulation. A diagnosis of polymyositis was made and the patient was started on steroids. During the recent hospitalization, given findings of slowly progressive adult onset myopathy with prominent involvement of axial, limb girdle, and respiratory muscles, a diagnosis of Pompe disease was suspected. This diagnosis was confirmed by low enzyme activity and two mutations in GAA gene, c. -32-13T>G and c.1827delC: (p. Tyr609X). Diagnostic delay was 16 years from the initial onset of symptoms and 2 years from onset of severe symptoms, similar to what has been reported in the literature. A review of the literature showed polymyositis as a common misdiagnosis for PD. We present this case to demonstrate the diagnostic odyssey often encountered in clinical practice, and to raise awareness about polymyositis as a common misdiagnosis of Pompe disease.

2388F

Emerging Next-generation Therapies for Pompe Disease. *R.J. Moreland, K.M. Taylor, A. McVie-Wylie, N.P. Clayton, B.M. Wentworth, R.K. Scheule, S.H. Cheng.* Rare Disease Science, Genzyme, Framingham, MA 01701.

Recombinant human acid α-glucosidase (rhGAA) is approved globally for the treatment of Pompe disease based on its ability to prolong invasive ventilator-free survival in infants, and improve or stabilize muscle and respiratory function in adults with the disease. The natural history, presentation, and progression of Pompe disease are extremely heterogeneous. Accordingly, the response to treatment is also variable and a minority of patients treated with rhGAA has shown marginal or no improvement. To address this, we are working on alternative therapeutic strategies that might be brought to bear in the management of this disease. These include the development of a second-generation enzyme (neoGAA) with improved potency and ability to target skeletal muscle. Preclinical studies with neoGAA in Pompe mice showed an approximately 5-fold enhancement in potency at clearing glycogen stores from a variety of tissues relative to unmodified GAA. Associated with this greater clearance in lysosomal glycogen are measurable improvements in motor function and coordination. Yet another approach that we are exploring is substrate reduction therapy that seeks to lower the rate of synthesis of tissue glycogen. As a first step, we have begun to validate potential drug targets that might support substrate reduction for Pompe disease.

2389T

Efficacy of long-term velaglucerase alfa on hematological and visceral parameters in treatment-naïve patients with type 1 Gaucher disease. *A. Zimran[1], I. Kisinovsky[2], E.A. Lukina[3], D. Elstein[1], D. Zahrieh[4], E. Crombez[4], P. Giraldo[5].* 1) Shaare Zedek Medical Center and Hebrew University-Hadassah Medical School, Jerusalem, Israel; 2) Your Health SA, Buenos Aires, Argentina; 3) Hematology Research Center, Moscow, Russia; 4) Shire, Lexington, MA, USA; 5) CIBERER and Hospital Universitario Miguel Servet, Zaragoza, Spain.

Purpose: We assessed the long-term efficacy of velaglucerase alfa in patients with type 1 Gaucher disease (GD1). Methods: Treatment-naïve GD1 patients aged ≥2 years received velaglucerase alfa (45 or 60 U/kg every other week [EOW]) in two Phase III trials and an extension study. Results: 39 GD1 patients were randomized to 45 or 60 U/kg EOW and enrolled in the extension study. Mean treatment duration was 54.5 (SD 9.9) months. At baseline: median age, 29 years (range 6, 62); n=8 <18 years; n=21 male; n=9 splenectomized; median hemoglobin concentration, 10.9 g/dL (range 7.1, 14.4); median platelet count, 77×10^9/L (range 13, 310); and median volumes of the spleen and liver, normalized to body weight (BW), 2.80% BW (range 0.96, 13.03) and 3.77% BW (range 1.90, 7.96) respectively. Longitudinal analysis showed mean (95% CI) changes from baseline to months 24, 36, and 60, respectively, for: hemoglobin (g/dL), (n=38) 2.68 (2.25, 3.10), (n=37) 2.68 (2.26, 3.11), and (n=10) 3.32 (2.72, 3.92); and platelets (10^9/L), (n=37) +100.3 (76.1, 124.6), (n=34) +102.5 (77.9, 127.1), and (n=8) +88.3 (54.3, 122.4). Longitudinal analysis showed mean (95% CI) changes from baseline to months 24, 39, and 63, respectively, for: normalized splenic volume, (n=30) -66% (-71%, -59%), (n=27) -71% (-76%, -66%), and (n=9) -78% (-83%, -73%); and normalized hepatic volume, (n=39) -27% (-31%, -22%), (n=36) -33% (-37%, -28%), and (n=9) -39% (-44%, -33%). No new safety concerns were identified. Conclusions: Improvements from baseline in hematological and visceral parameters were maintained during the extension study in GD1 patients receiving long-term velaglucerase alfa treatment.

2390F

Delivery of α-*N*-acetyl-glucosaminidase via choroid plexus-directed viral gene therapy as an enzyme replacement in cerebrospinal fluid for Sanfilippo B syndrome. *S-H. Kan[1], S.Q. Le[1], M.R. Haddad[2], E-Y. Choi[2], A. Donsante[2], S.G. Kaler[2], P.I. Dickson[1].* 1) Department of Pediatrics, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, USA; 2) Molecular Medicine Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA.

Sanfilippo syndrome type B (Mucopolysaccharidosis IIIB, MPS IIIB) is a rare autosomal recessive lysosomal disorder caused by the deficiency of α-*N*-acetylglucosaminidase (NAGLU) which leads to accumulation of heparan sulfate glycosaminoglycans (GAG). The development of effective systemic ERT for MPS IIIB is hampered by inadequate mannose 6-phosphorylation and resultant diminished cellular uptake of recombinantly-produced human NAGLU. In addition, NAGLU must traverse the blood-brain barriers to reach the brain and affect the neurological phenotype.

We created a modified NAGLU fused with the receptor-binding motif of insulin-like growth factor-II (NAGLU-IGF-II). NAGLU-IGF-II shows enhanced ability to enter cells compared to untagged NAGLU, due to its ability to utilize the cation-independent M6P receptor, which is also a receptor for IGF-II. Recombinant adeno-associated virus serotype 5 (rAAV5) is selectively tropic for choroid plexus epithelia when administered into the cerebral ventricles. The choroid plexus epithelia are specialized cells that project into the brain ventricles, produce cerebrospinal fluid (CSF), and exhibit a slow rate of turnover. Transduction of these cells with rAAV5 would be expected to enable a protein encoded by the vector transgene to be secreted into CSF. To deliver NAGLU-IGF-II to the CSF, a rAAV5 construct containing the NAGLU-IGF-II cDNA was produced. Under stereotaxic guidance, a pilot *in vivo* study in MPS IIIB mice was performed using intracerebroventricular injection of 5×10^{10} rAAV5 viral particles. At 16 days post-AAV5 injection, robust NAGLU activity was detected (1.47-4.35 units/mg protein) in brain sections of affected mice, versus 0.00 in untreated affected mice, and 0.22 in heterozygotes ($p<0.05$ for each comparison). Immunohistochemistry showed expression of NAGLU-IGF-II in choroid plexus epithelia, as well as detectable enzyme in hippocampal and amygdala neurons from brain hemispheres both ipsilateral and contralateral to AAV5 injection. Evaluation of the effects of treatment on GAG storage is underway.

This therapeutic approach combines the advantages of choroid plexus-directed gene therapy with NAGLU-IGF-II might provide a permanent and effective treatment that delivers enzyme to CSF for the treatment of Sanfilippo B syndrome.

2391T

Humoral immune response against enzyme replacement therapy (ERT) alters enzyme distribution in Mucopolysaccharidosis I mice. *S.Q. Le, S-H. Kan, M. Vera, Y. Herskovitz, M. Srour, P.I. Dickson.* Dept Pediatrics, LA Biomed Harbor-UCLA, Torrance, CA.

Mucopolysaccharidosis type I (MPS I) is an inherited and progressive lysosomal storage disease which is caused by lack or low level of α-L-iduronidase (IDU), an important enzyme participating in glucosaminoglycan (GAG) metabolism. Enzyme replacement therapy with recombinant human IDU (rhIDU) is available, but a humoral immune response to rhIDU may limit its effectiveness.

We studied the tissue and cellular distribution of rhIDU in naïve and sensitized *Idua*$^{-/-}$ mice to determine the effects of the humoral immune response on rhIDU distribution. Weekly exposure to rhIDU was given to sensitize *Idua*$^{-/-}$ mice (n=13) via tail-vein injection from 4 to 16 weeks of age. Of the ten surviving sensitized mice (three died prior the completion of the injections), five showed anti-rhIDU IgG antibody titers ranging from 3 to 30 OD units/ml and were designated 'high-titer,' while five had titers <1 OD units/ml and were designated 'low-titer'. Incubation of MPS I fibroblasts with serum from high-titer mice led to ~40% reduction in rhIDU uptake compared with antibody-free serum. Sensitized, high-titer mice had an average ~33-45% lower enzyme activities in high reticuloendothelial (RE) content organs (liver, spleen, thymus) and ~33-70% lower enzyme distribution in low RE organs (lung, kidney, heart, brain) compared to naïve mice by the fluorescence labeled enzyme. Cellular rhIDU distribution in these organs was examined using immunostaining with antibodies against IDU. In high-titer mice, rhIDU was mainly localized in Kupffer cells in liver, while low-titer mice showed rhIDU in both Kupffer cells and hepatocytes. The humoral immune response against rhIDU may alter the distribution of the enzyme on a tissue and cellular level. This finding may have implications for human MPS I patients undergoing enzyme replacement therapy with rhIDU.

Lysosomal Disease Network. *C.B. Whitley[1], B. Diethelm-Okita[1], J.R. Utz[2], J.C. Cloyd[2], D.C.C. Erickson[1], E. Shapiro[3], Investigators of the Lysosomal Disease Network.* 1) Gene Therapy Ctr, Univ Minnesota, MMC 446, Minneapolis, MN; 2) Experimental and Clinical Pharmacology, University of Minnesota, Minneapolis, MN; 3) Neuropsychology, University of Minnesota, Minneapolis, MN.

The lysosomal diseases have become a test bed for some of the most innovative and advanced experimental treatments. Collaborative clinical research on these rare disorders and their treatment is absolutely crucial to make substantial progress. The Lysosomal Disease Network (LDN) brings together more than 500 researchers and clinicians across the country, Patient Advocacy Groups (PAG), and other interested partners, and has generated a synergistic research and educational consortium to advance treatment of these diseases. In NIH-funded multi-center program, longitudinal studies of the natural history of 11 lysosomal disease categories and 11 pilot studies of measurement of outcome and phase I/II clinical trials are focused on several themes. Central nervous system (CNS) disease has been the most difficult to treat as well as to measure. A significant focus will be on quantitative methods of CNS structure and function providing a standard toolbox across the network in the Mucopolysaccharidoses (MPS), Batten disease, Niemann-Pick type C, Mucolipidosis type IV, Late Infantile Neuronal Ceroid Lipofuscinosis, Glycoproteinoses, GM2-gangliosidoses, Sandhoff disease, and Wolman disease. A study on Pompe disease focuses primarily on the immune modulatory factors affecting treatment response. Additionally, we include a study on bone disease in the MPS and a set of innovative studies on Fabry disease in which collaborators will carry out the natural history of kidney structure and function, pulmonary function as a marker of disease progression in children, and identification of Fabry disease among high-risk populations. The LDN provides support for all of these projects, leveraging additional resources from PAG and industry, in the hope of fostering research on other lysosomal diseases and providing the impetus for more in-depth studies of pathophysiology and treatment. The LDN provides substantial support for at least two post-doctoral trainees each year for career development in lysosomal diseases as well as an international research meeting (The 10th annual **WORLD Symposium**, Feb 10-15, 2014, San Diego, CA, USA) for sharing of research findings, education, and network synergy. The website **www.LysosomalDiseaseNetwork.org** provides an educational, research, and clinical resource for the Network, patients, physicians, and the public. (Support by NINDS, NIDDK, ORDR-NCATS, U54NS065768).

The effect of citrulline and arginine supplementation on lactic acidemia in MELAS syndrome. *A. El-Hattab[1], L. Emrick[2], W. Williamson[2], W. Craigen[2], F. Scaglia[2].* 1) King Fahad Medical City, Riyadh, Saudi Arabia; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA.

Introduction Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome is a common mitochondrial disorders in which energy depletion due to mitochondrial dysfunction can explain many of its the multi-organ manifestations. There has been growing evidence that nitric oxide (NO) deficiency occurs in MELAS and can play a major role in the pathogenesis of several complications including stroke-like episodes, myopathy, and lactic acidosis. Arginine and citrulline act as NO precursors and their administration can restore NO production in MELAS. Therefore, arginine and citrulline can be of therapeutic utility in treating NO deficiency-related manifestations in MELAS. Lactic acidemia is a cardinal manifestation of MELAS and results from an inability of dysfunctional mitochondria to generate sufficient ATP, leading to shunting of pyruvate to lactate. Moreover, hypoperfusion can result in lactic acidosis due to decreased oxygen delivery to peripheral tissues and shifting to anaerobic glycolysis. NO deficiency in MELAS can result in decreased blood perfusion and therefore aggravates lactic acidosis. In this study we hypothesized that arginine and citrulline supplementation will lower plasma lactate in patients with MELAS via increasing NO availability and improving perfusion. **Methods** We measured plasma lactate in 10 adults with MELAS before and after 48 hours of oral L-arginine supplementation. The study was subsequently repeated before and after L-citrulline. **Results** Average plasma lactate was lower after arginine (3.16→2.99 mmol/L) and citrulline supplementations (3.17→2.94 mmol/L). This reduction was statistically significant ($p<0.05$) and more consistent after citrulline supplementation. **Conclusions** The reduction in lactate after arginine and citrulline supplementation add more evidence to their potential therapeutic utility to restore the NO deficiency in MELAS. A previous study showed that both arginine and citrulline supplementations increase NO production in MELAS with citrulline resulting in a higher increment. In this study the lactate reduction was more significant and consistent after citrulline which can be due to the superiority of citrulline in increasing NO production leading to a better perfusion. These results also suggest that citrulline can have a better therapeutic effect. Additional assessments of the clinical effects of arginine or citrulline supplementation on different aspects of MELAS are needed.

Phenylbutyrate for therapy of pyruvate dehydrogenase complex deficiency. *R. Ferriero[1], A. Bourton[2], L. Bonafé[3], M. Baumgartner[4], D. Kerr[5], E. Morava[6], R. Rodenburg[6], M. Brivet[2], N. Brunetti-Pierri[1,7].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Laboratoire de Biochimie, AP-HP Hôpital de Bicêtre, Le Kremlin Bicêtre, 94270 France; 3) University of Lausanne, Lausanne, 1011 Switzerland; 4) Division for Metabolic Diseases, University Children's Hospital, Zürich 8032 Switzerland; 5) Center for Inherited Disorders of Energy Metabolism, Case Western Reserve University, Cleveland, OH 44106, USA; 6) Department of Pediatrics and the Institute of Genetic and Metabolic Disease (IGMD), Nijmegen Centre for Mitochondrial Disorders (NCMD), Radboud University Medical Centre, Nijmegen, The Netherlands; 7) Department of Translational Medicine, Federico II University of Naples, 80131 Italy.

Deficiency of nuclear-encoded pyruvate dehydrogenase complex (PDHC) is one of the most common inborn errors of mitochondrial energy metabolism. Most patients show progressive neurological degeneration and lactic acidosis. Affected patients present with a graded spectrum of severity ranging from the most severe Leigh syndrome with overwhelming lactic acidosis and death in the neonatal period to a milder form with carbohydrate induced ataxia. Most cases result from mutations in the X-linked gene for the E1α subunit (PDHA1) of the complex while fewer patients carry mutations in genes for E1β (PDHB), E2 (DLAT), E3 (DLD) and E3BP (PDHX) subunits or PDHC phosphatase (PDP1). PDHC activity is tightly regulated by phosphorylation and four isoforms of PDK (PDK1 to 4) phosphorylate the E1α subunit thereby reducing the activity of the complex. Conversely, dephosphorylation by phosphatases (PDP1 and PDP2) restores enzyme activity. We have previously shown that phenylbutyrate increases residual activity of PDHC by increasing the unphosphorylated enzyme and reduces lactic acidosis. Phenylbutyrate, and not its bio-product phenylacetate, increases PDHC activity through inhibition of E1α phosphorylation mediated by PDK1, PDK2, and PDK3 whereas PDK4 is not affected. We investigated phenylbutyrate on multiple cell lines harboring mutations in PDHA1 and genes encoding other components of the complex. Large deletions affecting PDHA1 and PDHX that result in lack of detectable protein were unresponsive to phenylbutyrate. PDHA1 mutations localized in the proximity of the catalytic site were responsive whereas mutations affecting the Arg349-α residue, involved in interaction with E1β subunit, were consistently unresponsive to the drug. PDHC activity was enhanced by phenylbutyrate in cells harboring PDHB, PDHX, and DLD missense mutations. Because phenylbutyrate is already approved for human use in other diseases, the findings of our studies have the potential to be rapidly translated for treatment of patients with PDHC deficiency and other forms of primary and secondary lactic acidosis. The results of the present study may help predicting whether a patient with PDHC deficiency is responsive to phenylbutyrate treatment based on the affected gene, type and location of the mutation.

2395T

A novel mutation in GLUD1 causing Hyperinsulinism Hyperammonemia in a patient with high density of homozygosity on microarray. *J.D. Odom[1], M. Gieron-Korthals[2], D. Shulman[2], P. Newkirk[2], E.J. Prijoles[3], A. Sanchez-Valle[2].* 1) Morsani College of Medicine, University of South Florida, Tampa, FL USA; 2) Department of Pediatrics, University of South Florida Morsani College of Medicine, Tampa, FL USA; 3) Clinical Division, Greenwood Genetic Center, Greenwood, South Carolina USA.

We describe a 28-month girl with congenital hyperinsulinism/hyperammonemia (HH) syndrome due to a de novo mutation (His507Tyr) in the glutamate dehydrogenase gene (GLUD1) not previously reported in the literature. She initially presented with intrauterine growth restriction, patent foramen ovale, peripheral pulmonic stenosis, and dysmorphic features. Her initial exam revealed wide anterior fontanel, bilateral posterior hair whorls, blue sclera, flat nasal bridge and posteriorly rotated low set ears. Chromosomal microarray analysis utilizing Affymetrix 6.0 platform revealed arr. (1-22, X) x2, with a high density of noncontiguous regions of homozygosity indicating possible consanguinity. Family history was unremarkable except that consanguinity was suspected as both parents were from a small village in Mexico. She had multiple short runs (1-10Mb) of allele homozygosity throughout the genome, consistent with limited outbreeding. She was suspected to have a recessive syndrome that had not yet been identified. At 8 months old, she presented to the emergency room with new onset seizures and hypoglycemia (39 mg/dL). Seizures were described as episodes of unresponsiveness and staring; body stiffness occurred with some episodes and cyanosis with most. She had frequent seizures until 18 months of age, most of which were triggered by hypoglycemia. Electroencephalogram showed encephalopathy with epileptic activity in the left centro-parietal region. Her hypoglycemic workup revealed excessive insulin level (6 µIU/mL at blood glucose of 44 mg/dL), negative urine ketones, low beta-hydroxybutyrate, and hyperammonemia (150-200 umol/L). DNA analysis revealed a novel mutation in GLUD1 that has not been previously described, predicted to be deleterious by SIFT and PolyPhen-2.1.0 programs. Parental DNA testing confirmed the mutation to be de novo, supporting the diagnosis of this autosomal dominant metabolic disorder. Her hypoglycemia initially responded well to 10 mg/kg/d diazoxide, however, she was subsequently admitted with recurrent seizures and gastroenteritis. Glycemic control was achieved with 15 mg/kg/d diazoxide and a leucine-restricted diet. At present, seizures are controlled with levetiracetam. She is thriving, but has global mild developmental delay that is attributed to her chronic hyperammonemia or an underlying unidentified genetic disorder whose locus is in one of the areas of homozygosity.

2396F

Pathogenic study of mitochondrial complex I deficiency and Leigh syndrome in Drosophila model. *Z. Li[1], K. Zhang[1], J. Guan[1, 4], C. Haueter[1, 2], H. Sandoval[1], H. Bellen[1, 3], B. Graham[1].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX 77030; 2) Methodist Hospital, Houston, TX 77030; 3) Howard Hughes Medical Institute, Houston TX 77030; 4) Medical Student, Baylor College of Medicine, One Baylor Plaza, Houston, Texas 77030.

Mitochondrial disorders, including oxidative phosphorylation (OXPHOS) disorders, affect at least 1 in 5,000 individuals. Isolated complex I deficiency is the most frequently observed OXPHOS defect (64%) and is a common cause of Leigh Syndrome with no effective treatments available. NDUFS3 is a Fe-S cluster-containing subunit of Complex I in electron transport chain. Oxidative stress is an important pathogenic factor in OXPHOS deficiencies as well as in diseases with secondary defects of mitochondrial metabolism. We have generated mutant NDUSF3 alleles in Drosophila through P-element excision of CG12079, the Drosophila ortholog of NDUFS3. Phenotypic characterizations include molecular, biochemical,immunohistochemical, electrophysiological and behavioral analyses as well as treatment with antioxidants. Recessive mutations of NDUFS3 cause severe deficiency of Complex I activity with abnormal assembly. Most animals without NDUFS3 fail to pupate and die during larvogenesis, however, rare adult escapers survive and experience a shortened lifespan. NDUFS3-deficient flies exhibit increased levels of oxidative stress demonstrated by fluorescence markers and decreased mitochondrial aconitase activity. Evidence for mitochondrial proliferation includes dramatically increased citrate synthase activity and increased Spargel gene expression (Drosophila ortholog of PGC-1 α). Mutant flies also exhibit neurological dysfunction manifested as increased sensitivity to mechanical stress, abnormal morphology of larval neuromuscular junction, defective climbing ability and perturbed retinal function. The adult mutant NDUFS3 phenotypes are fully rescued by ectopic genomic rescue of NDUFS3 and partially rescued by vitamin E analogs supplemented in food. These results demonstrate that the loss of NDUFS3 in Drosophila causes Complex I deficiency and increased oxidative stress. These studies also demonstrate that Drosophila is a useful model system for investigating the pathogenesis of mitochondrial disease as well as for exploring therapeutic strategies.

Long term follow up of 15 patients with methylmalonic acidemia following solid organ transplantation. *J.L. Sloan, I. Manoli, C.P. Venditti.* NIH/NHGRI/GMBB, Bethesda, MD.

Methylmalonic acidemia (MMA) is a devastating disorder, recalcitrant to medical management in many cases. Solid organ transplantation, including liver (LT), combined liver-kidney (LKT) or kidney transplants (KT), has been reported in >40 patients with isolated MMA. However, there is little systematic information on long-term outcomes and there are currently no guidelines regarding indications for transplant in MMA. We describe the natural history up to 15.4y post-transplant in 15 individuals with MMA (13 mut, 1 cblA, 1 cblB). There were 3 LT, 8 LKT and 4 KT recipients in our cohort . The mean age at transplant was 14.3 yrs (range 1.3-31.4 yrs) and mean follow up 5.1 yrs (range 0.8-15.4 yrs). All 11 patients status post LT or LKT remained metabolically stable (65.1 yrs combined follow-up), with the exception of one LKT patient, who had numerous hospitalizations due to gastrointestinal dysmotility. A previously reported mut0 patient who developed renal failure requiring KT 1-year post-LT and a worsening movement disorder after liberalizing her diet. Another mut0 patient with KT suffered repeated hospitalizations for metabolic decompensations and developed optic nerve atrophy 3 yrs after transplant. Transplantation improved metabolic parameters (72-93% decrease), primarily due to correcting renal function in those who received KT, but all had persistently elevated methylmalonic acid in plasma (71-1383 μM, nl <0.4), urine (166-4446 mmol/mol cr, nl<3) and total whole body MMA output (23-382 μmol/kg/day). Despite the massive MMA elevations, two LKT patients >12 yrs post transplant had eGFR >80 ml/min/1.73m2. Studies in this patient group, the largest assembled to date, afford the following conclusions: 1. LT and LKT, but not isolated KT, completely prevent ketoacidotic crises. 2. After LT, patients can develop renal failure and therefore require careful monitoring and this is also a theoretical risk for LKT and KT patients. 3. Although solid organ transplantation improves biochemical parameters, adequate metabolic control is required following the procedure due to the risk for late complications of the disease. Further studies are needed on the association of genotype and metabolic correlations pre- and post-procedure and the outcomes achieved, to develop guidelines about the optimal timing and procedure indicated for each patient.

Neuroimaging and neuropathology reveal dysmyelination in canine mucopolysaccharidosis I. *P. Dickson[1], J. Provenzale[2,3], S. Chen[2], I. Nestrasil[4], S-h. Kan[1], S.Q. Le[1], E. Lotshaw[1], J. Jens[5], J. Yee[1], N.M. Ellinwood[5], M.A. Guzman[6], C. Vite[7], V. Kovac[4], E.G. Shapiro[4].* 1) Dept Pediatrics, LA BioMed Harbor-UCLA Med Ctr, Torrance, CA; 2) Duke University Department of Radiology, Durham, NC; 3) Emory University Department of Radiology, Oncology and Biomedical Engineering, Atlanta, GA; 4) University of Minnesota Department of Pediatrics, Minneapolis, MN; 5) Iowa State University Department of Animal Science, Ames, IA; 6) St. Louis University Department of Pathology, St. Louis, MO; 7) University of Pennsylvania, School of Veterinary Medicine, Philadelphia, PA.

The cause of neurological deterioration due to mucopolysaccharidosis (MPS) is poorly understood. While many investigations focus on neurodegeneration, evidence suggests that white matter involvement may also be important. Hyperintense white matter lesions on brain imaging studies correlate with cognitive impairment in patients (1), and MPS patients show reduced fractional anisotropy (FA, a measure of white matter integrity) on diffusion tensor imaging of the corpus callosum that correlates with specific measures of attention (2). We performed neuroimaging and neuropathological evaluation of the corpus callosum (a major white matter structure) in canine MPS I. We studied nine MPS I dogs, four unaffected carriers, and four MPS I dogs treated with intrathecal recombinant alpha-L-iduronidase (IT rhIDU) 0.05 mg/kg every 3m from 4m to 21m. Dogs were imaged at end-study (mean age 24m for carrier, 21m for IT-treated, and 20m for untreated MPS I). Mean whole corpus callosum volumes were lower in MPS I dogs vs. carriers (p=0.02). Corpus callosum volume was preserved with IT rhIDU (p=0.006 vs. untreated MPS I). Diffusion tensor imaging demonstrated that fractional anisotropy was reduced in MPS I dogs vs. carriers (p=0.004 for genu and 0.008 for splenium of the corpus callosum), and the component of fractional anisotropy that was most abnormal was an increase in radial diffusivity (consistent with demyelination). The IT rhIDU-treated dogs showed fractional anisotropy values intermediate between carriers and MPS I dogs. Ultrastructural evaluation of the corpus callosum revealed thinning and disruption of the myelin sheath in MPS I dogs. Myelin-related genes showed small but consistent reduction in the expression by RT-PCR showed a small but consistent reduction in the expression of myelin-related genes in MPS I dogs vs. controls. Western blots showed reduced myelin basic protein and phosphorylated myelin basic protein in the corpus callosum of MPS I dogs. We quantified LC/MS showed abnormalities of myelin lipids by LC/MS, including a 37% reduction in sphingomyelin in MPS I dogs (p<0.001). Abnormal diffusion tensor imaging of the corpus callosum, which correlates with attention loss in MPS I patients, appears to be due to dysmyelination in MPS I dogs. Further studies, including determining the mechanism of these abnormalities, are underway. (1)Vedolin L, et al. Am J Neurorad 28 (2007) 1029-33. (2)Shapiro E, et al. Neuropsychiatric Outcomes in PKU Patients Treated With Sapropterin: Results from the Randomized, Controlled PKU ASCEND (PKU 016) Trial. *S. Prasad[1], B. Burton[2], A. Feigenbaum[3], M. Grant[4], R. Hendren[5], R. Singh[6], S. Stahl[3], C. Zhang[1].* 1) BioMarin, Novato, CA; 2) Children's Memorial Hospital of Chicago, Chicago, USA; 3) University California San Diego, San Diego, USA; 4) St. Christopher's Hospital for Children, Philadelphia, USA; 5) University California San Francisco, San Francisco, USA; 6) Emory University, Decatur, USA.

Background: Phenylketonuria (PKU) patients often exhibit attention deficits similar to attention deficit hyperactivity disorder (ADHD). Methods: PKU 016 is the largest health outcomes study in PKU. This randomized, placebo-controlled trial evaluated baseline neuropsychiatric impairment, specifically ADHD behaviors, symptoms of anxiety (HAM-A rating scale), depression (HAM-D rating scale) and executive dysfunction (BRIEF rating scale), and the effects of sapropterin dihydrochloride (Kuvan) on these impairments after 13 weeks of treatment in 206 children and adults with PKU. The primary endpoint was the total score on the ADHD Rating Scale (ADHD-RS) commonly used to evaluate symptoms of inattentiveness and hyperactivity. Results: Mean patient age was 22.5±11.6 years, with 42% aged <18 years. Baseline blood Phe was 841.4±473.1 μmol/L. 35% of the sample had symptoms of ADHD at baseline. 118/206 were sapropterin responders (defined as blood Phe level reduction ≥20%). Among sapropterin responders, ADHD-RS total score was improved in the sapropterin group compared with placebo (mean change from baseline -9.1±2.2 vs -4.9±2.0, P=0.085), driven by a statistically significant and clinically relevant change in the inattention subscale (-5.9±1.4 vs -2.5±1.3, P=0.036). Conclusions: Sapropterin was associated with improvement in inattention among children and adults with PKU who had a Phe response to sapropterin therapy.

2400F

Effect of Globotriaosylceramide (Gb3) on cytokine profile in dendritic cells and monocytes. Consequences for Fabry disease. *P. Rozenfeld, P. De Francesco, J. Mucci, R. Ceci.* Dept Immunolgia, Univ Natl de La Plata, Buenos Aires, Argentina.

Fabry disease (FD) is an X-linked genetic disorder characterized by the deficiency in the activity of the lysosomal enzyme α-galactosidase A (αGal). This defect leads to the accumulation of neutral glycolipids, mainly globotriaosylceramide (Gb3). Clinical manifestations in males include angiokeratoma, hypohidrosis, cornea verticillata, proteinuria, acroparesthesia. Death usually occurs at 4th decade of life because of kidney, cardiac or cerebrovascular problems. Previous results of our group showed increased expression and production of proinflammatory cytokines in peripheral blood mononuclear cells (PBMC) from patients with EF, in particular dendritic cells (DC) and monocytes (M).The aim of this study is to investigate the effects of Gb3 on the production of cytokines in DC and macrophages (MΦ) derived from normal PBMC monocytes treated with DGJ, an inhibitor of αGal.PBMC were isolated from normal buffy coats, and M were purified and cultured in the presence of GM-CSF and IL-4, or M-CSF, to induce their differentiation into DC and MΦ, respectively. Obtained cells were then cultured in the presence or absence of 20μM Gb3 and/or 200μM DGJ and the levels of IL-β, IL-6 and TNFα were analyzed in the supernatants. Both cultures showed a significant increase in production of IL-1β and TNFα, relative to the control, only in the case of combined Gb3 and DGJ treatment (DC p=0.0018 and p=0.0041, MΦ p=0.0002 and p=0.0054, respectively). A similar trend was observed for IL-6. Moreover, addition of a TLR4-blocking antibody completely abolished the observed effect in MΦ treated with Gb3 and DGJ.These results show that Gb3, possibly by interacting with TLR4, can induce a proinflammatory state, similar to that observed in PBMC from patients with FD, and could be directly involved in the pathogenesis of this disease.

Is common mutation in SCO2 associated with reproductive failure in the Polish population? Preliminary study. *S. Łuczak[1], D. Piekutowska-Abramczuk[1], A. Jezela-Stanek[1], K. Chrzanowska[1], M. Kugaudo[1, 2], A. Cieślikowska[1], A. Kochański[1], P. Kowalski[1], E. Ciara[1], J. Trubicka[1], D. Jurkiewicz[1], M. Pelc[1], M. Borucka-Mankiewicz[1], M. Krajewska-Walasek[1], E. Pronicka[1].* 1) Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland; 2) Department of Child and Adolescent Psychiatry, Medical University of Warsaw, Warsaw, Poland.

Mutations in the SCO2 gene (22q13) lead to severe COX deficiency observed mainly in muscles, heart and brain. A common, g.1541G>A (p.E140K), substitution is identified at least on one allele (in heterozygous or homozygous form) in all reported patients. Analysis of genotype-phenotype correlation revealed the presence of two distinct clinical patterns of disease: phenotype of early beginning (at birth or in fetus) with hypertrophic cardiomyopathy as a leading symptom, and neurological phenotype of delayed begining with encephalomyopathy. There are a few data of the possible association between mutation in SCO2 and fetal wastage, especially in fetuses with a heterozygous form of common mutation. The aim of this preliminary study was to attempt to verify the existence of probable association SCO2 mutations with early spontaneous abortions. We examined 64 DNA samples from couples with at least 3 miscarriages in family history (44 samples of whole blood on EDTA and 20 dry blood spots on Guthrie cards). Genomic DNA was eluted from dried blood spots using 5% Chelex-100 resin and extracted from peripheral blood leukocytes by phenol/chloroform procedure or by automatic isolation (MagNa Pure equipment). Genotyping for the presence of the specific mutation was performed by Real Time PCR analysis with Taqman probes (DNA concentration about 30 ng/µl). The probes were designed to 150 nt fragment of the SCO2 gene (position in the reference sequence in the NCBI database: gi|281182726:495-644). The study did not reveal the presence of common mutation in the examined group. Every patient was homozygous for the wild form. Since this is a preliminary study and the study group has less than 100 persons, the existence of correlation between reproductive failure and SCO2 mutations can not be excluded. Carriership of common mutations in the Polish population is relatively high (1:147), so the planned extension of the study group with early abortions seems to be fully justified. Based on reported data in all cases with positive family history (recurrent abortions, fetal wastage, neonatal deaths characterized by cardiomyopathy, myopathy or encephalopathy), screening for the g.1541G>A mutation should be performed. The study was financed by National Science Centre, project no. 1154/B/P01/2011/40, EU Structural Funds, project POIG.02.01.00-14-059/09 and CMHI project no. S126/12.

Frequency of inherited metabolic diseases (IMDs) in high-risk children in a North Indian tertiary care hospital. *S. Attri[1], A. Patial[1], P. Kumar[1], P. Singhi[1], S. Singhi[1], S. Sharda[1], C. Kumari[2], I. Dwivedi[1], S. Kapoor[2], L. Kratz[3].* 1) Pediatrics, Postgraduate Inst Medl Education & Research, Chandigarh, India; 2) Division of Genetics, Lok Nayak Hospital & Maulana Azad Medical College, New Delhi, India; 3) Biochemical Genetics Laboratory, KKI, Baltimore, USA.

Introduction: Newborn screening, not commonplace in our country necessitates the shift to high risk screening. We present our data from a cohort in North India. Aims and objectives: To study the frequency of various IMDs in high-risk children. Methods: A total of 220 suspected cases with red flag signs suggestive of a metabolic disorder were enrolled from March 2012 till January, 2013 from various wards of the Advanced Pediatric Centre like pediatric intensive care unit, neonatal intensive care unit, emergency department and out-patient neurodevelopment clinic. Children from age group 0-15 years were included. These patients were subjected to initial blood and urine screening tests followed by thin-layer chromatography, tandem mass spectrometry for dried blood spots, gas chromatography mass spectrometry of urine samples and high performance liquid chromatography on plasma and urine samples. Enzyme estimations were done for biotinidase and prolidase deficiencies. Results: Majority of the children (112/220) were in the age group of 1-15 years. Male to female ratio was 1.5:1. We were able to diagnose 13% children with IMDs. Eighteen children had hyperhomocysteinemia and/or homocystinuria, out of which seven had combined homocystinuria and methylmalonic aciduria. Other disorders detected were glutaric aciduria (2), fumaric aciduria (2), biotinidase deficiency (2), congenital lactic acidosis (1), primary hyperoxaluria (1), maple syrup urine disease (1), prolidase deficiency (1) and urea cycle defect (1). Conclusions: Amongst the investigated children, 13% were diagnosed with IMDs. The most common IMDs were homocystinuria and cobalamin defect. Implementation of a national newborn screening is of paramount importance.

2403T

Different Combinations of *ACADS* Mutations Cause SCAD Deficiency in an Infant and His Mother. *A.N. Dang Do[1], J. Cox[1], M. Johnson[1], L. Kratz[2], T. Wang[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Biochemical Genetics Laboratory, Kennedy Krieger Institute, Baltimore, MD.

Short-chain acyl-coenzyme A dehydrogenase (SCAD) deficiency is an autosomal recessive disorder of fatty acid oxidation caused by short-chain acyl-CoA dehydrogenase (*ACADS*) deficiency. More than 35 disease-causing mutations and two common variants (R171W and G209S) have been identified in *ACADS*, which encodes an enzyme responsible for the dehydrogenation of butyryl-CoA during the first steps of short-chain fatty acid beta-oxidation. Clinical presentations of patients with confirmed SCAD deficiency vary considerably from asymptomatic individuals to patients with poor feeding, hypoglycemia, hypotonia, developmental delays, and epilepsy. Since SCADD is an autosomal recessive disorder, parents of affected infants identified through newborn screening are rarely investigated. We report a case of metabolically and molecularly confirmed SCAD deficiency in an asymptomatic newborn male infant and his mother who had subtle symptoms of this disorder during periods of metabolic stress. The 6-1/2 week old infant was found to have elevated C4 and C4/C2 ratio by state newborn screening, and the suspected diagnosis of SCADD was confirmed by finding increased plasma butyrylcarnitine (C4: 0.82 nmol/ml; nl <0.62) and urinary ethylmalonate (EMA: 60 mg/g creatinine; normal < 30). Sequence analysis of *ACADS* in this infant identified three coding variants: one reported mutation, R107C; one apparent truncated variant, c.660-699del40; and one common variant, G209S. Careful review of the family history revealed that his mother had a history of fasting-related fainting episodes, which were relieved by taking snacks or sugar-containing drinks. Metabolic studies of the mother revealed an increased plasma butyrylcarnitine level (C4: 1.92 nmol/ml; normal <0.62) and increased urinary excretion of ethylmalonate (EMA: 122 mg/g creatinine; normal <15 for adult). Sequence analysis of *ACADS* in the parents showed that the mother carried two apparent deleterious mutations (R107C and c.660-699del40) in *cis* and a presumed functional variant, G281S, in *trans*; while the father was a carrier for a common variant, G209S. This case exemplifies the need for careful evaluation of parents of confirmed SCADD infants to identify subtle clinical symptoms suggestive of this recessive metabolic disorder.

2404F

A formal approach to evaluating the neuropsychiatric manifestations of PKU: Assessing the content validity of ADHD rating scales in phenylketonuria. *K. Mooney[1], S. Prasad[1], S. Kummer Shaffer[2], K.S. Gries[2], P. Auguste[2], D. Bilder[3], K.W. Wyrwich[2].* 1) BioMarin, Novato, CA; 2) United BioSource Corporation, Bethesda, MD; 3) University of Utah, School of Medicine, Salt Lake City, UT.

Background: Adults and children with phenylketonuria (PKU) demonstrate symptoms of Attention-Deficit/Hyperactivity Disorder (ADHD). Both the self-reported Adult ADHD Self-Rating Scale (ASRS) and parent-completed ADHD Rating Scale (ADHD RS-IV), based on DSM IV criteria, have been validated and successfully measure changes over time in features of inattentiveness and hyperactivity/impulsivity in ADHD. However, these instruments have not been validated for their appropriateness to measure these concepts in the PKU population. The objectives of this study were to: 1) elicit descriptions of participant-perceived PKU symptoms, and 2) assess the content validity of the ASRS and ADHD RS-IV in measuring inattentive and hyperactive/impulsive symptoms in adults and children with PKU. Methods: Following IRB approval, adults with PKU (n=13) and parents of children with PKU ages 8-17 (n=15) were recruited for one-on-one interviews exploring their or their children's PKU symptom experiences. At the end of each interview, adults completed the ASRS, parents completed the ADHD RS-IV (reporting their children's behaviors), and all participants provided their insights on the clarity, comprehensiveness, and relevance of the respective instrument in measuring PKU-related symptoms. Results: Participants reported inattention-related symptoms much more frequently than hyperactive/impulsive symptoms. The emergent participant-reported inattentiveness symptoms matched well with respective questions in the ASRS and ADHD RS-IV. Most participants reported that the ASRS and ADHD RS-IV questions were clear, meaningful, and relevant to their own, or their children's experience with inattentiveness, but they were less supportive of the hyperactive/impulsive subscale. Conclusions: The qualitative interviews demonstrated concept elicitation support for concepts related to inattentiveness. The ASRS and ADHD-RS IV demonstrated the clinical relevance of these instruments for assessing relevant inattentive symptoms associated with PKU in persons ≥8 years old. Additional research is ongoing to understand the psychometric properties of these ADHD instruments in the PKU population. Furthermore, exploration of psychiatric aspects of PKU and other metabolic diseases using valid measurement instruments yields important insights into the clinical manifestations of such disease.

2405T

The role of innate immune system activation and signaling in vascular disease in the MPS I canine model. *M. Vera[1], S.Q. Le[1], S. Kan[1], P. Dickson[1], R. Wang[2].* 1) Dept of Pediatrics, Division of Medical Genetics, Harbor-UCLA Medical Center, Torrance, CA; 2) CHOC Children's, Orange, CA.

Vascular disease in mucopolysaccharidosis I consists of regions of arterial intimal-medial thickening characterized by glycosaminoglycan storage, vascular smooth muscle proliferation, and elastin fiber disruption. The latter features are suggestive of innate immune system signaling pathways including those mediated by the Toll-like receptor family. These intraluminal lesions do not completely respond to enzyme replacement therapy or bone marrow transplantation, therefore understanding the initiating events leading to this phenotype is likely to be important in designing effective treatment. Our goal in this project is to identify and quantify the relationship between glycosaminoglycan storage and innate immune system mediated inflammatory signaling in MPS I vascular disease. Our hypothesis is that innate immune system stimulation leads to macrophage activation and production of cytokines, including TGFβ, that stimulate extracellular matrix remodeling and vascular smooth muscle cell proliferation. Our preliminary data indicate an increased expression of TGFβ and increased activation of downstream signaling mediators within these arterial lesions in MPS I canine arterial disease. We are continuing to study the causal relation between glycosaminoglycan storage and Toll-like receptor signaling in the development of this vascular phenotype.

Defective T-cell function in a mouse model of Citrullinemia Type I. *T.N. Tarasenko, J. Gomez-Rodriguez, P.J. McGuire.* National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Although inborn errors of metabolism (IEM) are often exacerbated by infection, whether having an IEM impacts immune function is less well characterized. Lymphocyte activation is accompanied by dramatic changes in metabolism suggesting that certain IEM may also affect immune cell function. Argininosuccinate synthetase (ASS) is present in multiple tissues and is known to play a role in the conversion of citrulline to arginine, and nitric oxide generation. ASS deficiency in humans results in the urea cycle disorder known as known as citrullinemia type I, and is characterized by grossly elevated plasma citrulline levels and hyperammonemia. In human tissues, we demonstrated ASS protein in components of the immune system including naïve T-cells, thymus and spleen, however, the role of ASS in these normal tissues remains to be defined. Based on the expression of ASS, we hypothesized that ASS deficiency will result in T-cell defects. To evaluate this question, we are characterizing immune function in hypomorphic $ASS1^{fold/fold}$ (*fold/fold*) mice. As previously published, the lifespan of *fold/fold* mice is reduced at 3 weeks. Interestingly, studies of immune organs revealed significantly smaller thymi and spleens, absent mesenteric lymph nodes, and a marked reduction in T-cell numbers despite normal expression of lineage and activation surface markers. Adeno-associated virus 8-mediated correction of liver ASS to enhance *fold/fold* survival resulted in a greater recovery of splenic T-cell numbers despite the persistence of the ASS enzyme defect in splenic T-cells. However, in vitro studies in *fold/fold* T-cells demonstrated abnormal differentiation into various T-cell subsets critical for immune responses including Th1, Th2, Th17 and Treg cells. In vivo characterization of *fold/fold* immune cells is currently underway using bone marrow chimeras with immunization and influenza infection protocols. In addition, a trans vivo approach using humanized mouse models is being utilized to explore the role of human ASS in immune organs and other immunologic niches. Finally, to further understand potential immune consequences of this IEM, clinical characterization of immune status in patients with ASS deficiency and related disorders is currently underway in the NIH Clinical Center. Overall, our work suggests that ASS deficiency may translate into specific immune defects and may have implications for patients with citrullinemia Type I.

2407W

Local and International Medical Geneticists and Genetic Counselors Collaboration: The First Vietnamese-North American Genetics Conference in Hanoi, Viet Nam. *K. Leppig[1], M. Laurino[2], D. Sternen[3], J. Thompson[4].* 1) Genetic Services, Group Health Cooperative, Seattle, WA; 2) Institute for Public Health Genetics, University of Washington, Seattle, WA; 3) Laboratory Medicine, Seattle Children's Hospital, Seattle, WA; 4) Molecular Genetics Laboratory, BC Children's and Women's Hospital, Vancouver, BC.

The commitment of local Vietnamese medical geneticists Dr. Dung Chi Vu at the National Hospital of Pediatrics and Dr. Nguyen Viet Nhan at Hue College of Medicine and Pharmacy served as the strong foundation for collaboration with international genetic professionals. The shared goals of the local and international partnership were to bring together genetic providers from across Viet Nam to discuss the scope of current genetics care provided in the country; facilitate collaboration and mentorship with international colleagues; discuss examples of new technologies that may allow more cost effective genetic testing; and highlight the field of genetic counseling as part of health care delivery. A longer term goal was to develop a sustainable genetic counseling training program within Viet Nam to anticipate the need for specialized professionals who can work with the increasing number of geneticists as newborn screening and medical genetics services are rapidly growing. To achieve these goals, the first Vietnamese-North American Genetics Conference was held in Hanoi, Viet Nam on March 25-26, 2013. Targeted attendees of the meeting were health care providers in Viet Nam who are involved in the care of children with genetic conditions and birth defects. Over 300 physicians, laboratory specialists, nurses, researchers, medical students, international non-governmental organization workers, and government officials attended. There were over 20 presentations by Vietnamese experts and internationally recognized North American geneticists. A genetic counseling workshop discussed the history of genetic counseling, roles of genetic counselors, establishment of the Philippines genetic counseling program as a model for strategic curriculum development, and the ethical, legal and sociocultural issues of genomic medicine. Conference attendees confirmed joint interest in the creation of a genetic counseling program within Viet Nam. As such, the 2nd Vietnamese-North American Genetics Conference is being planned in conjunction with the 2014 Asia Pacific Conference on Human Genetics in order to foster the ongoing local and international partnership of genetic professionals. Certainly, this year's conference offered transparency and recognition of the current needs and invaluable opportunities on how to best integrate the field of medical genetics and genetic counseling in Viet Nam's existing health care and educational system.

2408W

Making sense of a primary care role in genetics: Views of genetics professionals. *J.C. Carroll[1], S. Morrison[2], F.A. Miller[3], B.J. Wilson[4], J.A. Permaul[5], J. Allanson[2,6].* 1) Dept of Family & Community Medicine, Mount Sinai Hospital, University of Toronto, Canada; 2) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 3) Institute of Health Policy, Management and Evaluation, University of Toronto, Canada; 4) Department of Epidemiology and Community Medicine, University of Ottawa, Canada; 5) Department of Family Medicine, Mount Sinai Hospital, Toronto, ON, Canada; 6) Department of Pediatrics, University of Ottawa, Canada.

Background: Developments in genetics are widely expected to implicate primary care providers (PCPs), who, as first contact professionals with a foundational role in most health care systems, may need to be better equipped. Yet public policy efforts to enhance the relationship between primary care (PC) and genetics vary widely. Initiatives in some jurisdictions such as the UK seek to `mainstream' genetics knowledge and services, while in others such as Canada, top-down initiatives have not been pursued. Objectives: To explore the role of genetics health professionals (GHPs) in building relationships with the PC community. Method: Qualitative methodology. GHPs working at genetics centres in Ontario, Canada were invited to participate in semi-structured focus groups or telephone interviews. Purposeful sampling was used to ensure diversity by type of GHP, and type of centre (academic, community, northern). Transcripts were analyzed using a qualitative interpretive approach. Findings: 5 focus groups and 2 interviews were conducted with GHPs (6 clinical geneticists, 24 genetic counselors, 4 nurses, 4 lab staff, 3 administrators) from 5 of 10 regional genetics centres and 2 of 3 northern outreach clinics across Ontario. Through interactions with their patients, very limited direct interactions with PCPs, and occasional educational events that involved PCPs, GHPs sought to make sense of the nature of PCP practice, and to imagine a PCP role in genetic medicine. GHPs acknowledged their limited understanding of the PCP role (and the role of different PCPs) in health care, and had little awareness of how genetics might fit into PCPs' practice. GHPs saw a role for PCPs in genetics, but expressed concern at a perceived lack of knowledge of genetics, as reflected in both under and over referring, and PCPs' ability to incorporate new genomic discoveries into practice. GHPs also reflected on whether existing communication methods with PCPs were effective, and recognized a need to understand what PCPs might want from the genetics community. Conclusions: Widespread expectations of a PCP role in genetic medicine are shared by GHPs in Ontario, Canada. But in the absence of policy direction or organizational support, GHPs struggle to make sense of how this might work. In this context, in addition to identifying knowledge and capacity deficits, parameters of a productive collaboration between PCPs and GHPs need to be developed.

2409W

A Brief Curriculum for Physician Orientation to Clinical Whole Genome Sequencing. *M.A. Giovanni[1,2], J. Krier[2], J.L. Vassy[2,3], D. Lautenbach[3], R.C. Green[2,3], M.F. Murray[1] for The MedSeq Project.* 1) Geisinger Health System, Danville, PA; 2) Harvard Medical School, Boston, MA; 3) Division of Genetics, Brigham and Women's Hospital, Boston, MA.

The MedSeq Project is a randomized clinical trial examining the impact of whole genome sequencing (WGS) in clinical care. In this study, 200 patients will receive WGS or usual care in the context of either primary or specialty care. Physicians are engaged by the study as research subjects and asked to recruit patients from their practice. This report describes a brief educational curriculum developed and administered to physicians participating in the research in order to prepare them to receive clinical reports from WGS. All of the physicians engaged in the educational program have appointments at Brigham and Women's Hospital in Boston. So far, we have enrolled 10 primary care providers trained in internal medicine (4 men and 6 women) and 7 specialists trained in both internal medicine and cardiology (5 men and 2 women). A 6.5 hour continuing medical education (CME) course was designed and offered to participating physicians prior to patient engagement. The curriculum included two 75-minute in-person didactic sessions, and 12 self-study case-based educational modules, allowing multiple modalities to facilitate engagement of busy physicians. The case studies were designed to highlight key concepts in genomic medicine. In addition, a library of resources was created and made available online to supplement the course lectures and self study cases. Pre- and post -education surveys were conducted to measure the impact of the educational program. Additional data on the confidence and performance of physicians following the patient disclosures are being tracked. As genomic sequencing is integrated into the practice of medicine, motivated clinicians will seek opportunities to improve their knowledge and understanding of applied genomics prior to delivering results to their patients. A short curriculum of didactic sessions and self-study, coupled with relevant learning resources, has been created to enhance physician preparedness for delivering genomic results to their patients and data will be presented evaluating its effectiveness.

2410W

Teaching Physicians about Genomic Medicine. *I. Maya[1], I. Basel-Vanagaite[1,2,3,4], E. Basel-Vanagaite[1], A. Koifman[5,6], DM. Behar[7], R. Tomashov-Matar[1], R. Sukenik-Halevi[8], A. Reches[9], M. Shohat[1,2].* 1) medical genetics, Recanati Genetic Institute, Petah Tikva, Israel; 2) The Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Pediatric Genetics, Schneider Children s Medical Center of Israel, Petah Tikva, Israel; 4) Felsenstein Medical Research Center, Rabin Medical Center, Petah Tikva, Israel; 5) Institute of Human Genetics, Soroka University Medical Center, Beersheba, Israel; 6) Ben-Gurion University of the Negev, Beersheba, Israel; 7) Rambam Medical Center, Haifa, Israel; 8) Meir Medical Center, Kfar Saba, Israel; 9) Souraski Medical Center, Tel Aviv, Israel.

Background: Due to new discoveries in genomic medicine, clinical guidelines are increasingly recommending the incorporation of genomic tests or therapeutics into routine care, especially as the transition of genetic knowledge from research laboratories into clinical practice is becoming more and more a part of health care systems. Primary care practitioners suffer from inadequate knowledge and skills in medical genetics and many are unaware of the technical, ethical, legal and psychosocial implications of genetic testing. Methods: We initiated a “genomic education” program for the purpose of teaching primary care practitioners new advanced knowledge on genomic medicine. We emphasized the main take-home messages for physicians, which were: risk calculation for various genetic diseases, recognition of the mode of inheritance from the pedigree, guidelines for decision-making on which molecular tests to use, and the interpretation of test results and their clinical implications. Results: To date, 48 physicians have participated in 3 “genomic education” program, which included lectures, workshops and guided tours in genetic laboratories. In the “pre-course” examination the average score was 57% (range 20%-80%), whereas in the “post-course” examination it was 77% (range 74%-100%). The average improvement in score as a result of the course was 21% (range 0%-80%). The physicians who participated in our program reported a very high level of satisfaction from the content as well as the concept of a “one-week update”. Conclusion: A one-week “genomic education” program is an effective strategy to update primary care physicians in order to improve their care of patients.

Hello Genetics (Alô Genética): A Brazilian strategy to provide guidance and education in genetics to primary health care providers. *T. Vieira[1,2], D. Nadler[1], L. Silva[1], N. Murcia[1], C. Giugliani[3], C. Rafaelli[1], R. Giugliani[1,4,5].* 1) Medical Genetics Service, Hosp Clinicas Porto Alegre, Porto Alegre RS, RS, Brazil; 2) Bioethics Service, Research and Post-graduation Group, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 3) Department of Social Medicine, Universidade Federal do Rio Grande do Sul School of Medicine, Porto Alegre, Brazil; 4) INaGeMP - Instituto Nacional de Genética Médica Populacional, Porto Alegre, Brazil; 5) Department of Genetics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil.

Introduction: the integration of Medical Genetics (MG) into Primary Health Care (PHC) seems to be an alternative to develop actions of improve diagnosis, prevention and management of genetic conditions, and to facilitate access of patients to specialized health care. Therefore, it is desirable that PHC providers obtain basic knowledge about MG, including the immediate measures to be taken when dealing with the most important conditions. Aims: to provide remote support to PHC providers to support their actions when facing a patient/family with a genetic condition, and to provide a long range continuing education program in medical genetics to PHC providers. Methods: a remote support facility was set up in 2013 at Medical Genetics Service, Hospital de Clinicas de Porto Alegre, in the Southern part of Brazil, accessible by the toll-free telephone number 0800 642 6761(in addition to email and internet).This new service was advertised at public health services of the Porto Alegre area by displays, and to a broader area also by emails. In addition, a continuing free education program in Portuguese was built, which could be accessed over the internet by PHC providers. Results: in the first months of activity, `Hello Genetics' was accessed by phone, email and internet by a growing number of PHC providers, mainly from the geographic area where advertisement was performed with displays; registration for the internet courses is also being increasingly requested(courses to be started in Q3 2013), mostly from PHC providers from the same region. Conclusions: the proposed strategy seems to fill a gap, helping PHC providers to access specialized medical genetics centers, obtaining the information needed to better manage and refer patients, and improving knowledge in the subject. However, advertisement should be increased to enable the program to expand nationally.

Experimental and Computational Biologists: Lessons learned from a transdisciplinary training program. *M.A. Fernandez-Altuna[1], I. Imaz-Rosshandler[2], A.L. Escobedo-Ramos[1], M. Mata-Sotres[1], C. Rangel-Escareño[2].* 1) National Institute of Genomic Medicine, Education and Outreach Office, Mexico City, México; 2) National Institute of Genomic Medicine, Computational Genomics, Mexico City, México.

The National Institute of Genomic Medicine is the reference center of research on genomic medicine in México. It hosts scientists, technicians and students from many disciplines within the biological sciences. There is also the counterpart group of scientists in the fields of mathematics, statistics, physics and computational sciences. A collaborative effort between the director of the Education and Outreach office and scientists of the Computational Genomics consortium implemented a 4-week transdisciplinary training program. Idea adapted from the original cross-training program at the Broad Institute. The program was a real success the first time in 2012 and even more for the 2013 run. We would like to share the experiences from both years and present a full panorama of lessons learned from the initiative. We will provide educational perspectives on creating graduate programs that efficiently combine a quantitative and qualitative training in Biology.

2413W

Human Genetic Variation: A Flipped Classroom Exercise in Cultural Competency. *K. Tuttle[1], S. Dasgupta[2].* 1) Pediatrics, Massachusetts General Hospital, Boston, MA; 2) Medicine, Biomedical Genetics, Boston University School of Medicine, Boston, MA.

PURPOSE

Our understanding of human genetic variation has deepened through the Human Genome and International Hap Map Projects, which gave us a high-resolution view of human genetic variation and ancestry. Applying this knowledge to evaluation of ancestry-based genetic testing strategies is a key component of the practice of culturally competent medicine.

METHODS

To emphasize the clinical relevance of population genetics, we designed a required flipped classroom module for the first year Medical Genetics course at Boston University. The concepts of population genetics and Hardy-Weinberg equilibrium are introduced through an interactive on-line exercise. In class, the students then explore application of these concepts to clinical cases, specifically considering how geographic ancestry and genetic variation influence the appearance of false positive and negative results, the ramifications of resulting variants of unknown significance or incidental findings, and the psychosocial aspects of direct-to-consumer genetic testing.

RESULTS

The introductory exercise's pre-test and post-test as well as the course final exam allowed us to assess knowledge gains over time in understanding the interplay between historical human migration patterns and genetic variation in modern populations. 179 medical students were involved in the study. The percentage of students getting the correct answer on the conceptual population genetics questions on the pre-test, post-test, and final exam were 60.2%, 76.8%, and 95.4% respectively. Student performance on the quantitative Hardy-Weinberg questions on the pre-test, post-test, and final exam, demonstrated that 50.2%, 92.1%, and 62.4% answered correctly. We were also able to directly measure the positive impact of the flipped classroom module through the use of audience response technology and course survey results, which demonstrated strong student engagement with the content.

CONCLUSIONS

The curricular design of this session allows us to introduce complex, critical concepts relating to cultural competency in a scientifically rigorous way. In order to help our future physicians gain the scientific expertise to practice culturally competent medicine, we will need to promote integration of similar exercises into the pre-clerkship phase of medical school curricula.

2414W

How is high school students' genomic literacy correlated with their attitudes toward promotion of genomic studies? A comparison with a result of general public survey in Japan. *I. Ishiyama[1], T. Tanzawa[2].* 1) Department of Child Care and Education, Teikyo-Gakuen Junior College, Yamanashi, Japan; 2) Faculty of Education, Shizuoka University, Shizuoka, Japan.

This study aimed to 1) assess high school students' genomic literacy level, 2) reveal their attitudes toward genomic studies promotion related to medicine, and 3) identify associated factors to the approval of promotion. High school students were sampled from 2 high schools to be sure to contain a variety of academic level students. The number of respondents was 354. Attitude survey was conducted in the `Basic Biology' class at each school on January 2013. Students have already studied the unit of genetics. The date was analyzed using logistic regression models and compared with the results of nationwide opinion survey which was targeted general public and conducted in the same period. These surveys included the following same queries; 1) subjective and objective understanding of genome science, 2) pros and cons of medicine-related genomic studies promotion, and 3) attitudes toward science in general. Responses of subjective and objective understanding were calculated into scores of genomic literacy. Concerning high school students, the average score of subjective understanding was 8.6 (range 0-10), objective understanding was 5.3 (0-10), genomic literacy was total 13.5 (0-20). The average score of genomic literacy in general public was 10.5 (0-20). The term of `Genome' was recognized by 99.7% students, while 31.9% of general public responded that they never heard of the term. Result also showed that approximately 3/4 students favored genomic studies related to medicine. Pros and cons were divided into agree (74.8%) and cannot decide (24.4%), while only 0.8% expressed disagree. The similar result was shown in general public survey (agree: 71.6%, cannot decide: 27.6%, disagree: 0.9%). No correlation was found between literacy level and approval of promotion in students, whereas strong correlation was found in general public. Interest in science and technology in general, and willingness to use new products developed by technological innovation were correlated with the approval. In conclusion, even if high school students are knowledgeable about genomics, they don't necessarily support the genomic studies in medicine. If anything, it's important for them to develop their interest and trust in science through biology class.

2415W

Geneticists Teaching Genetics to New Orleans K-12 Schools and Universities. *F. Tsien, J. Loupe, A. Iyengar.* Department of Genetics, LSU Health Sciences Center, New Orleans, LA.

While the latest breakthroughs within the field of genetics continue to increase in complexity, they are more frequently mentioned in the media and are becoming increasingly relevant to our health, highlighting the growing need for the public to become more “genetics literate”. One way to better inform the public is to incorporate genetics concepts into K-12 school and college curricula in effective, novel ways. The LSU Health Sciences Center (LSUHSC) has created two programs: the LSUHSC/New Orleans Schools Science Partnership Program for 4th graders and the LSUHSC Hands-on Genetics and Career Workshop Program for middle, high school, and undergraduate students (established in 2006 and 2009 respectively). Geneticists have partnered with teachers to make genetic concepts and other science topics easier to understand and less intimidating, to improve academic achievements in science, to introduce K-12 and undergraduate students to diverse role models in the sciences (including females and underrepresented minorities), to increase students' awareness of potential career paths in science and genetics, and to train geneticists to present to the lay public and interact directly with the community. Instructors include faculty, graduate students, and postdoctoral fellows from the LSUHSC Genetics Department. Activities involve hands-on experiments and videos pertaining to genetic concepts found in the media (cancer, forensics), and topics from the students' curriculum (cells, DNA). We have established a science and genetics education “pipeline” that includes the elementary school, middle school, high school, and college levels, leading to genetic internships in our institution. Anonymous pre- and post- workshop evaluations and demographic questionnaires reveal that students understand and retain lesson information regardless of socioeconomic or academic background. Students' quantitative standardized test and classroom exam scores demonstrate gains following implementation of the programs. Qualitative evaluations of student gains in knowledge include a Science Jeopardy competition, science fair projects, internships, and anecdotal information from teachers and students. These programs have introduced genetic concepts to approximately 750 elementary school students, 220 middle school students, 1055 high school students, and 250 undergraduates. The hope is that these programs will ultimately inspire some students to pursue lifelong careers in the genetics field.

2416W

Accelerating public awareness of personal genetics. *M.E. Gelbart, L. Tomaselli, D. Waring, T. Wu.* Personal Genetics Education Project, Department of Genetics, Harvard Medical School, Boston, MA.

The Personal Genetics Education Project (pgEd; www.pged.org) is using a unique platform of strategies to address the widening gap between what researchers are learning at the frontiers of genetics and what the public understands. First, pgEd is working to advance awareness through television with Hollywood, Health & Society at the USC Annenberg Norman Lear Center. Second, pgEd is continuing to develop the on-line game, Map-Ed (www.map-ed.org), which we launched in March to spread awareness of core concepts in genetics. Third, pgEd organizes the annual GETed conference, which brings together experts in education, research, health, entertainment, and policy to develop strategies for accelerating public awareness. Fourth, pgEd is building a freely available on-line curriculum that addresses the benefits as well as the ethical, legal, and social implications of personal genetics. Finally, pgEd is training high school teachers in biology, health, social studies, and beyond to engage an entire generation of young people on the topic of personal genetics.

2417W

Parents and newborn screening decisions: empirical assessment of specific educational messages. *B.J. Wilson[1], B.K. Potter[1], J.C. Carroll[2], J. Little[1,3], D. Castle[4], D. Avard[5], P. Chakraborty[6,7], S. Craigie[1], H. Etchegary[8], L. Lemyre[9], F.A. Miller[10], G.A. Wells[1], J. Millburn[6], R. Rennicks White[11, 12], G. Tawagi[11], M. Walker[11, 12, 13], CIHR Emerging Team in Genomics in Screening.* 1) Department of Epidemiology & Community Medicine, University of Ottawa, ON, Canada; 2) Family Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 3) Canada Research Chair in Human Genome Epidemiology); 4) ESRC Innogen Centre, University of Edinburgh, Edinburgh, UK; 5) Centre of Genomics and Policy, McGill University, Montreal, QC, Canada; 6) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 7) Department of Pediatrics, University of Ottawa, ON, Canada; 8) Clinical Epidemiology, Memorial University Newfoundland, St John's, NL, Canada; 9) School of Psychology & Institute of Population Health, University of Ottawa, ON, Canada; 10) Institute of Health Policy, Management and Evaluation, University of Toronto, ON, Canada; 11) Department of Obstetrics, Gynecology and Newborn Care, The Ottawa Hospital, ON, Canada; 12) Clinical Epidemiology Program, Ottawa Hospital Research Institute, ON, Canada; 13) Department of Obstetrics and Gynecology, University of Ottawa, ON, Canada.

Background: In many jurisdictions, systematic parental education about newborn screening (NBS) seems to be limited, perhaps because screening may be seen as routine care and not a separate intervention requiring conscious decision-making by a parent. However, even where screening is mandated, parental education provides benefits such as promoting trust in health services and preparing for the process and potential outcomes of NBS. However, NBS programs may be concerned that more comprehensive education may lead to higher parental anxiety and lower acceptance rates. Debates on secondary bloodspot use are also relevant to this issue. `Education' is a broad concept, and there appears to be no empirical evidence on the most important content of education for parents. This study is designed to formally test the impact of specific components of potential NBS educational content on parents' decision making. **Objectives**: To measure and compare expecting mothers' responses to specific NBS educational messages in a jurisdiction where screening is encouraged but not mandated. **Methods**: The study sample is women with low-risk pregnancies attending routine second trimester ultrasound clinics in Ottawa, Ontario. Using a factorial survey, participants are randomized to receive different combinations of messages about NBS: the possibility of false positive/negative results; pain from the heel-prick; potential for over-diagnosis; storage/secondary use of bloodspots; and nature of parental consent (25=32 discrete message combinations being assessed). The primary outcome is the mean score (max 100) on the Decisional Conflict Scale (DCS). **Results**: From a target sample size of 500, we report data on the first 129 respondents. The mean DCS score is 27 (range 0-89). Over 90 percent intend to accept NBS; actual uptake will be tracked prospectively, with consent. In univariate analyses, no statistically significant differences are observed in DCS scores in those receiving/not receiving specific messages, with the exception of the storage/secondary use of bloodspots message (p=0.02), a lower mean DCS score associated with receiving specific information. Further analyses will examine interactions between specific messages, the effect of the absolute number of messages (cognitive burden), and associations with other respondent characteristics including their apparent understanding of key messages. Implications for design of NBS parental education will be discussed.

2418W

On 30th anniversary of Orphan Drug Act: a review of resources to inform and connect rare disease patients. *M.H. Dunkle[1], J. O'Leary[2], H. Hyatt-Knorr[3], M. Snyder[3], J. Lewis[3].* 1) Communications, National Organization for Rare Disorders (NORD), Danbury, CT; 2) Genetic Alliance, Bethesda, MD; 3) National Institutes of Health Genetic and Rare Diseases Information Center, Bethesda, MD.

The Orphan Drug Act (ODA) of 1983 brought major new incentives to encourage the development of therapies for patients with rare diseases. It also launched a coordinated effort, involving patient organizations, government agencies and others to address the unique and previously unaddressed needs of patients and families affected by rare diseases. During this 30th anniversary year, three of the primary sources of information and connection for rare disease patients provide a brief review of the history of rare disease information since 1983 and highlight a few of the major resources available to patients and families today. The three collaborating entities are the National Organization for Rare Disorders (NORD), which was established by patient organizations in 1983 after the ODA was enacted; Genetic Alliance, established in 1986 by NORD, the March of Dimes, and the Maternal and Child Health Bureau of the Health Resources and Services Administration; and the NIH Genetic and Rare Diseases Information Center (GARD), established in 2002 by the NIH National Center for Advancing Translational Sciences/ Office of Rare Diseases Research and the NIH National Human Genome Research Institute. Current initiatives include NORD's Rare Disease Database, regional patient organization meetings, and RareConnect, global online patient communities established by NORD and its European counterpart, EURORDIS; Disease InfoSearch, an online database of advocacy organizations and resources for genetic conditions and Genes in Life, to provide easy access to Genetic Alliance's many resources and tools related to health and genetics information; and the GARD Information Center for patients and their families, as well as researchers and medical professionals, in which trained Information Specialists staff a toll-free phone line, provide customized responses in English and Spanish, and create web content based on questions received from the public so that it is responsive to public `here and now' issues. Together, these three entities, NORD, Genetic Alliance, and GARD, are providing valuable and complementary information services to the rare disease community.

`Will he be bald?' Introducing the general public to the genomic era. *M. Kriek[1], K. Kraaijeveld[1,3], H. Sminia[2], B. Gravendeel[4], M. Schilthuizen[4], J.T. den Dunnen[1].* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, Leiden, Netherlands; 2) Netherlands Bioinformatics center (NIBC), Nijmegen, The Netherlands; 3) Hogeschool Leiden, The Netherlands; 4) Naturalis Biodiversity Center, Leiden, The Netherlands.

We stand today on the threshold of a new era. Within the foreseeable future analysis of complete genomes will play a prominent role in society in the broadest sense. It will have immediate implications for healthcare, agriculture, biodiversity research and many other aspects of the world around us. LeveDNA!* is a Dutch initiative that aims to create public awareness of DNA-sequencing and its applications. The focus is on high school students, as they already possess some background knowledge and their generation is thought to be exposed to DNA sequencing most frequently in the near future. Our approach is to invite the public to contrive interesting questions that can be addressed by DNA sequencing. LeveDNA! attempts to realize such ideas by finding support for sampling, sequencing and analysis. Secondly, we actively initiate projects that bring our target audience in contact with DNA sequencing, often in collaboration with scientific partners. Projects conducted so far include: (I) Sequencing the genome of a DJ from a popular Dutch radio station, followed by a dedicated evening of his daily radio show. During the three-hour broadcast, listeners were given the opportunity to ask questions about the DJ's genome. 'Is he a carrier of a genetic disorder? Will he be bald? Is he a night owl?' are some of the many questions asked. (II) LeveDNA!, in collaboration with an initiative to teach the public about evolution (Evolution MegaLab), made an attempt to identify genes that contribute to the colour patterning of garden snail shells. (III) Organisation of a DNA-day, where participants are taught about DNA and where they can isolate and analyse small parts of their genome. (IV) Shaking Science, a biodiversity project where students sampled fresh water around the Natural History museum; the sequence determined can be analysed by everybody using a simplified Blast tool. Finally, (V) high school students sequencing organisms in fresh water of a major river in the Netherlands, the Rhine. LeveDNA! creates a platform where the general public and experts directly interact, exchange knowledge and discuss social consequence of the new technologies. *LeveDNA!: “Leve” (Dutch) stands for both “life” and “hurray”.

Personalized medicine - what do people think? *L. Leitsalu[1,2], A. Allik[1], A. Metspalu[1,2,3].* 1) Estonian Genome Center of the University of Tartu, Tartu, Estonia; 2) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 3) Estonian Biocentre, Tartu, Estonia.

Estonia has several factors favorable for large-scale, innovative projects in the healthcare sector, such as implementing personalized healthcare due to several reasons. The factors that the genomic information originates from a single center, the health care sector is regulated on a national level, having one major healthcare funding office, and a single university educates all healthcare professionals, all contribute to a unified system. Additionally, the relatively small population size of 1.34 million makes it logistically more feasible to implement projects on a nationwide scale. The success of such a project depends largely on the support of the public. Public's perspectives were investigated through a phone survey by TNS Emor polling agency in spring of 2011. The sample included 1000 individuals between the ages of 15-74 and was composed to be proportional to the Estonian population structure with respect to age, gender, and nationality. The topics investigated included - role of genetics in common complex diseases, attitude towards the use of genetic information, motivators and barriers for genetic testing, and reported hypothetical effect on health behavior. The results of the first wave of the survey suggested that the majority is interested in genetic testing and that genetic information would reportedly increase the likelihood that doctor's recommendations for changes in health behavior will be followed. The most common motivator for testing was the opportunity for doctors to provide better care, while the most common barrier was fear for receiving unwanted information. The open-ended comments demonstrated several misconceptions about genetic testing and more information on the topic of genetic testing was frequently asked for. This spring the Government of Estonia has officially expressed its support for introducing personalized healthcare in Estonia. There has been an increasing amount of media coverage on topics of genetic testing and personalized medicine over the past few years. Now we are conducting a second wave of the survey to see whether any changes can be detected over the past two years. The results are used for the development of educational resources in order to improve genetic literacy among the general public to avoid unsound effects, unrealistic expectations and misconceptions, and facilitate effective use of genomic information in personalized healthcare.

2421W

Vignettes as an aid to deciding about genetic testing. *D. Zallen.* Dept Sci & Tech in Society, Virginia Tech, Blacksburg, VA.

Genetic tests are currently offered in doctors' offices and by commercial laboratories widely advertised on the Internet. Though genetic information can be very useful for some people, for others it can produce severe personal and family problems without any significant corresponding medical benefit. Within the confines of a standard medical office visit, it is difficult to provide consumers with the information that will enable them to make informed decisions about whether a particular form of genetic testing is right for them. Also, there are too few genetic counsellors. New educational approaches are needed. Consumers deciding whether or not to test need guidance not only in understanding the technical aspects of genetic testing but also in assessing its suitability with regard to their personal values, psychological makeup, and family dynamics.

As part of an investigation of new educational tools, we have developed a set of short dramatized vignettes based on more than 150 interviews (D.T. Zallen, “To Test or Not to Test”, Rutgers 2008) with consumers who were considering genetic testing for susceptibility to common disorders. Testing for predisposition to the late-onset form of Alzheimer's disease was selected as the central focus. The vignettes, presented by male and female actors of various ages and heritage backgrounds, draw on the actual experiences of consumers and the reasons they have given both for and against having testing.

These vignettes were reviewed in two stages by three different focus groups whose participants were recruited through ads placed in the major regional newspaper. All the focus groups found the dramatized vignettes compelling and balanced. The first group judged that the visual background needed to be softened and the actors placed in a more natural setting. The vignettes were then re-shot with such a setting. The prevailing view of the subsequent two groups was that the vignettes were more informative than relying solely on written text and were an effective way to help them identify their own value preferences and reach appropriate decisions.

The use of dramatized vignettes is a novel and effective approach to providing consumers with a means of clarifying the various value dimensions associated with genetic testing prior to deciding whether or not to undergo a genetic test.

Incorporating Bioinformatics into the Undergraduate Genetics Curriculum through an Authentic Research Project. *B.V. Bowling, E.D. Strome.* Biological Sciences, Northern Kentucky University, Highland Heights, KY.

Genomics and bioinformatics are advancing fields that have become an integral part of a broad spectrum of biological research. As a result, it is increasingly important for undergraduate genetics courses to include basic bioinformatic tools and genomic concepts to prepare students for the modern biology workforce. At Northern Kentucky University, we've introduced these through an authentic research project in which students investigate the role of *Saccharomyces cerevisiae* open reading frames designated as coding for `putative proteins' within the Saccharomyces Genome Database. Students perform wet-lab experiments using classic genetic techniques in order to create knockout strains for their gene of interest and then assess phenotypes; as well as bioinformatics analyses conducted on individually assigned ORFs and then data are synthesized in order to develop a hypothesis of the function of the gene product within the cell. The bioinformatics and comparative genomics analyses include multiple sequence alignment, conserved domain identification, cellular localization prediction, reviewing interaction and expression data, and gene deletion phenotypes. The *in silico* approaches allow students to apply genetic (and additional biological) concepts to an authentic research question, provide experience with bioinformatics tools, and challenge students to analyze and synthesize data from various sources. The project culminates in a brief presentation by each student in which they summarize the most important evidence collected for the role of their gene product in the cell. These activities have been shown to be effective in our sophomore-level, multi-section laboratory course involving several instructors. Instructors report increased engagement relative to previous labs and a substantial portion of the students (74%) felt that they learned even more from this project than other lab projects. The vast majority of the students indicate the research was challenging (93%) and that they are better prepared to take on investigating a problem without a known solution (82%). The lack of established answers contributed to student anxiety about the assignment. Many students have the urge to check to see if they are `right,' and instructors have to balance encouraging independence while also reassuring students of their analyses. Incorporating formal mechanisms for peer feedback throughout the process has helped with students' confidence in their work.

Integrating authentic research in human genetics into an undergraduate liberal arts curriculum to enhance the pace of rare disease gene discovery for underserved populations. *R. Jinks[1,2], B. Davis[1], D. Roberts[1], E. Rice[1], K. Brigatti[1], E. Puffenberger[3], K. Strauss[3,4].* 1) Biology, Franklin & Marshall College, Lancaster, PA; 2) Biological Foundations of Behavior Program, Franklin & Marshall College, Lancaster, PA; 3) Clinic for Special Children, Strasburg, PA; 4) Lancaster General Hospital, Lancaster, PA.

Next-generation sequencing accelerates disease gene discovery, especially for orphan diseases, though at present it outpaces functional studies needed to provide 'proof of causation.' This problem was underscored by a recent funding opportunity from the NHGRI requesting assistance with functional studies for 75 rare, potentially pathogenic alleles discovered through the NIH Undiagnosed Diseases Program. Working from a small, community-based, clinical laboratory, the Clinic for Special Children has identified more than 130 allelic variants associated with disability, disease, or untimely death among the Amish and Mennonite (Plain) populations of North America. In collaboration with the Clinic, we developed an HHMI-funded program that integrates rare disease gene discovery research into our undergraduate curriculum. Roughly 150 students per year in our introductory cell biology and neuroscience courses clone disease genes and study the functional impacts of gene variants through expression in mammalian cell culture. We use these authentic research experiences to teach key concepts in cell biology, genetics, and neuroscience. Students later build upon this experience in upper-level courses in neuroscience, genetics, cancer biology, and immunology in which they engage in semester-long research projects in small teams, each conducting functional studies of a single novel gene variant. These experiences engender talented undergraduates to assume greater research responsibility through independent study and summer research projects that transition them into the role of co-PI for the gene and disease they have chosen to study. Data published through this project (PLoS ONE 7:e28936) were recently used by another institution to diagnose a critically-ill, non-Plain newborn with lethal neonatal seizure-rigidity syndrome (Sci Tran Med 4:154ra135). This provides important proof-of-concept for integrating novel disease gene functional studies into a carefully structured undergraduate research curriculum. Students in our Public Health program are collaborating with the Clinic to develop handbooks to help parents care for children with special medical needs with the goal of producing one to two high-quality disease handbooks annually. Our program represents a model for engaging undergraduates in meaningful research at the front lines of biomedical science and public health in ways that directly impact the diagnosis and care of children with rare inherited disorders.

2424W

Inverted Curriculum: An Online Activity Replaces In Class Lecture to Teach Regulation of the Lactose Operon in a General Genetics Undergraduate Classroom. *T. Kelson[1], M. DeWall[1], S. Minnich[2], G. Arrizabalaga[2], J. Anderson[2], D. Knox[2].* 1) Biol Dept, Brigham Young Univ, Idaho, Rexburg, ID; 2) Imaging and Science Engineering Education Group, Univ of Idaho, Moscow, ID.

A revolution currently underway to change the traditional college classroom is being referred to as the "flipped" classroom. Instructors provide resources and require students to learn content on their own outside of lecture and then, class time is used to review, answer questions, practice problems, and apply concepts. In short, lecture is moved out of the class and `homework' is moved in. We are investigating a novel approach to undergraduate teaching in Genetics - a 3 credit undergraduate General Genetics class where students spend 2 hours in lecture each week and 1 hour outside of class in meaningful, supervised activities. In order to accomplish this we are investigating the use of online activities that will teach the material in much the same way that a faculty member would in a face-to-face lecture environment. The University of Idaho has developed an online tool to teach gene regulation in bacteria, specifically the lactose operon. We tested the efficacy of this online tool over a 2 semester time period, as follows - we taught the same material to students from 2 undergraduate General Genetics classes: one in a formal lecture setting (n=36) and the other through the use of this online tool (n=52). After instruction, both groups were administered the same homework assignment. Our results showed that both groups performed equally well on the same homework assignment (average score = 94%). As a follow-up to assess retention, the students were tested on this same material one month later, with results supporting that they did remember much of what they learned the first time (average score = 71%). Each participating student also completed a questionnaire. When asked about the online tool, most students responded that they found the online activity useful and that it helped their comprehension of the lactose operon. Based on our positive results over several semesters, we no longer lecture on the lactose operon in our classroom; instead, the students complete an online assignment prior to coming to lecture, and we now spend classroom time developing critical thinking skills in gene regulation. We use problem-based and teamwork activities in the classroom to enhance deeper learning of gene regulation. We have demonstrated that the use of technology can enhance, not replace, instruction of genetics topics that, in the past, have been difficult for some students to learn in lecture settings.

The Research Connection: Development of an integrated institutional pediatric research infrastructure as a model framework for multi-institution implementation and collaboration. *S.K. Savage[1], C.M. Clinton[1], W.A. Wolf[1,2], D.M. Margulies[1,2,3,4].* 1) Program in Genomics, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA; 3) Division of Developmental Medicine, Boston Children's Hospital, Boston, MA; 4) Center for Biomedical Informatics, Harvard Medical School, Boston, MA.

Our objective is the development and implementation of a fully-integrated research infrastructure to power and enhance discovery within Boston Children's Hospital (BCH) and across collaborating institutions. To achieve this goal, we reviewed and assessed existing research resources and identified gaps and areas of need. We then designed a set of core research and clinical services, called the Research Connection, to supplement existing operations and handle the varied needs of BCH investigators, clinicians, and collaborators. The BCH Biobank is patient-centric repository of leftover clinical samples linked with electronic medical record data to facilitate biospecimen-based research. By offering Biobank enrollment across the entire institution, we attain broad reach over a diverse population of children and adults, creating a large and rich research cohort. Claritas Genomics, BCH's new genetics and genomics diagnostic laboratory, provides cutting-edge measurements, analyses, and revisable reporting for both research and clinical samples. BCH's Interpretive Genomic services allow for refined interpretation, clinical correlation, and specialty care management, drawing on clinical and scientific expertise within the institution. Finally, our novel approach to integrated clinical and research genetic result return leverages existing and expanding BCH clinical services to provide appropriate result disclosure and genetic counseling. This design allows our research infrastructure to be optimized to accommodate multi-institutional collaboration via a new collaborative agreement structure called the Pediatric Research Network. To support the concept of a Pediatric Research Network, we have initiated collaborative relationships with other pediatric hospitals, where components or the entire Research Connection model may be adopted and tailored to meet their unique institutional needs. By implementing a common research infrastructure like the Research Connection across multiple sites, coupled with a collaborative agreement across institutions, we create an opportunity for an extensive 'virtual' research repository to support large-scale research, foster collaborations, and enhance discovery that would otherwise not be possible. This structure may be the future of genomic research design for large and small institutions.

2426T

Revisiting the role of gamete and embryo donor registries on the transmission of genetic information between donation relatives, in light of the principle of beneficence. *V. Couture[1], M.-A. Dubois[1,2], R. Drouin[1], J.-M. Moutquin[3], C. Bouffard[1].* 1) Division of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Quebec, Canada; 2) Me Hélène Guay Office, Montreal, Quebec, Canada; 3) Department of Obstetrics and Gynecology, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Quebec, Canada.

Introduction: In the context of assisted reproductive technology, the transmission of genetic information between relatives may have implications for prevention, diagnosis, treatment, and reproductive decision-making. In the case of gamete and embryo donor-conceived people, where there is no previous contact between donors and their sibling, this issue acquires greater complexity. The creation of gamete and embryo donor registries is one of the strategies that has been developed to make information available between donation parties. However, the nature, flow, preservation, and accessibility of genetic and medical information depend on the type of registry. Whether national, institutional or independent, each type may have different repercussions on the health protection of donor-conceived people, donor, siblings, and offspring. Under these conditions, our objective was to identify the ethical implications of the transmission of genetic and medical information through donor registries, in light of the principle of beneficence. Methods: Bioethical analytical approach: (1) typology of donor registries (2), analysis of their strengths and weaknesses, and (3) introduction of the principle of beneficence in the analysis of their impact. Results: A donor registry has as its main benefits the opportunity to track hereditary disease and prevents future gamete donation by an affected donor. It can also help in the diagnosis of genetic disease as well as in the prevention of late-onset conditions. According to the principle of beneficence, the needs and values of all donation parties have to be considered. A registry must address the issues surrounding the uncertain liability of donors associated with the transmission of genetic and medical information, as well as the protection of their anonymity. An effective counseling service has to be provided to avoid unnecessary distress for all the parties. To maximize the benefits of gamete and embryo donor registry, the national type with proper counseling and clear guidelines appears to be the most respectful solution to promote the health of all donation parties. Conclusion: Despite the complexity of genetic and genomic issues for the development of a national donor registry, the principle of beneficence offers us the opportunity to pursue the present and future needs of all donation parties.

Participant views of re-consent and broad consent in cancer genetics research. *K. Edwards[1, 2], D. Korngiebel[3], L. Pfeifer[2], J. Scott[4], N. Shridhar[1], D. Kaufman[5], D. Bowen[6], C. Condit[7].* 1) Institute for Public Health Genetics, School of Public Health, University of Washington, Seattle, WA; 2) Epidemiology, School of Public Health, University of Washington, Seattle, WA; 3) Biomedical Informatics and Medical Education, School of Medicine, University of Washington, Seattle, WA; 4) National Coalition for Health Professional Education in Genetics, Lutherville, MD; 5) Genetics & Public Policy Center, Johns Hopkins University, Washington, DC; 6) Community Health Sciences, School of Public Health, Boston University, Boston, MA; 7) Communication Studies, University of Georgia, Athens, GA.

Background: Institutional Review Boards and researchers protect participants in genetic research, but the preferences of participants do not sufficiently inform policy currently. With the proliferation of biobanks intended to support future studies that go beyond the scope of their original consent, fully understanding participant preferences for re-consent is a pressing concern. The Participant Issues Project (PIP) addresses this gap. Methods: PIP study participants were drawn from the Northwest Cancer Genetics Registry and included cancer patients, controls, and relatives. Thirty telephone interviews were conducted and analyzed using content and thematic analysis. Questions asked participants to consider diverse scenarios: the research focus had changed from the original study; re-consent of a minor achieving majority; for-profit studies; and the use of broad consent forms. Results: The majority of participants agreed that re-consent was necessary when the study direction changed significantly (e.g., a different disease) or a child participant became an adult. Participants favored re-consent in order to provide study information and control of the use of their data, However, participants felt re-consent was not needed if the study shifted to examine a different gene's effect on the same cancer. Several participants indicated that genetics was a broad umbrella that covered the gamut of gene-related research, and some expressed a strong preference that research make best possible use of study data for the greater good. Most participants' willingness to participate in research would not be affected if the researcher or institution profited or if a broad consent form were used. Conclusions: There were specific scenarios where the majority of participants felt re-consent was needed and other scenarios where it was not needed. For many participants, the perceived value of re-consent appears to lie largely in keeping participants informed of future studies and updated on the research progress, while for others, it is to control the use of their data. It is not known whether satisfying the need for information will change participant perspectives on the desire for re-consent.

2428T

Balancing Patient Privacy While Supporting Rich and Convenient Access to Clinical Genomic Data. *E.R. Riggs[1], J. Berg[2], C. Bustamante[3], D.M. Church[4], W.A. Faucett[1], M. Feolo[4], D.H. Ledbetter[1], D. Maglott[4], C.L. Martin[1], D. Metterville[5], J. Mitchell[6], R. Nussbaum[7], J. Ostell[4], S. Plon[8], H. Rehm[5,9], L. Rodriguez[10], W. Rubinstein[4], M. Watson[11], International Collaboration for Clinical Genomics.* 1) Geisinger Health System, Danville, PA; 2) University of North Carolina, Chapel Hill, Chapel Hill, NC; 3) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 4) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD; 5) Laboratory for Molecular Medicine, Partners Healthcare Center for Personalized Genetic Medicine, Cambridge, MA; 6) Department of Biomedical Informatics, University of Utah, Salt Lake City, UT; 7) Division of Genomic Medicine, Department of Medicine, University of California, San Francisco, San Francisco, CA; 8) Departments of Pediatrics and Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 9) Department of Pathology, Harvard Medical School, Boston, MA; 10) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 11) American College of Medical Genetics and Genomics, Bethesda, MD.

It is becoming clear that access to large datasets of genomic variants and observed phenotypic consequences is critical to our understanding of human genomic variation and its applications to basic science, public health, and improved patient care. However, these datasets must be maintained in ways that both respect patient privacy and support active use by the scientific community. The International Collaboration for Clinical Genomics (ICCG) is a group of laboratories, clinicians, and researchers working closely with the National Center for Biotechnology Information (NCBI) to develop ClinVar, a publicly available repository of genomic variants, associated phenotypic information, and clinical classifications with supporting evidence. Laboratories are beginning to submit their data, which include a mixture of both de-identified and potentially identifiable information regarding variants and individual cases observed during the course of clinical testing and research studies. Given that a large amount of ClinVar's data will be derived from patient testing results and may warrant different levels of protection, it is critical that ICCG develops clear policies regarding patient privacy, and appropriate data access. Current data access policies and requirements of similar databases were initially developed to accommodate traditional research applications of the data, and remain appropriate for these types of applications; however, many of the requirements, such as IRB-approved protocols, annual usage reports, and the requirement to fully download entire datasets in order to search for variants may represent barriers to potential clinical users. Possible solutions may include a clear statement of appropriate use, alternative methods of user authentication, accurate data use accounting, and interactive, dynamic methods of data access. Representatives from ICCG, NCBI, NIH, and other stakeholder groups are collaborating to discuss what types of initiatives may be necessary. Our goal is to create an environment of 'adaptive governance' to support the unique needs of our multi-faceted user community while maintaining the confidentiality of our patient participants.

2429W

Utility of the X chromosome pattern of inheritance: the identification of close relatives through direct-to-consumer (DTC) genetic testing. *K. Johnston.* Retired from HealthCare Partners Medical Group, 3565 Del Amo Blvd. Torrance California 90503.

Members of the public who are looking for their birth parents can now order autosomal tests directly from ancestry companies to aid in their search for cousins who carry identical by descent (IBD) DNA segments. Females who are looking for their birth fathers, and both males and females who are looking for their birth mothers can utilize the matching X chromosome IBD segments they receive simultaneously from these companies. Extensive pedigrees compiled by close cousins who are related by way of the X chromosome provide useful links. The inheritance pattern of the X chromosome is unique. When studying pedigrees, all lineages that show two males in a row (father to son) can be eliminated from the family tree. X chromosome tracking aids in the identification of the most recent common ancestor(s) between two closely related DNA cousins. In addition, extensive online genealogical records submitted by the public, especially those that include living relatives, facilitate in the identification of collateral lines. In some cases, paternity testing is no longer needed to confirm a lineage when close relatives (e.g. half-siblings) are contacted, then are willing to be tested and matched through one of the DTC ancestry companies or online third party tools. Unsuspecting birth fathers, sperm donors and parents who have put up a child for adoption can now be traced through online pedigrees provided by closely related genealogists with the help of public records and familial DNA testing. An example involving two recently matched second cousins will demonstrate the steps involved.

NIH's approach and expectations for genomic data sharing: The draft NIH Genomic Data Sharing Policy. *D. Paltoo[1], A. Bailey[2], C. Fomous[1], K. Langlais[1], E. Lueketmeier[1], T. Paine[1], R. Wise[2], L. Lyman Rodriguez[2].* 1) Genetics, Health, and Society Program, Office of Science Policy, Office of the Director, NIH, Bethesda, MD; 2) Division of Policy, Communications and Education, National Human Genome Research Institute, NIH, Bethesda, MD.

Since 2007, the Policy for Sharing of Data Obtained in NIH Supported or Conducted Genome-Wide Association Studies (GWAS) has governed the sharing of GWAS data from human participants in research supported by NIH funding. The GWAS Policy established the expectation that all such data be made available, with exceptions as warranted, for secondary research uses that are consistent with research participants' informed consent. Rapid advances in DNA sequencing and other high-throughput technologies have increased the volume, complexity, and types of data generated in genomic studies. To ensure the full value of genomic data in light of this growth, NIH has drafted the Policy for Genomic Data Sharing in NIH-Supported or NIH-Conducted Studies (GDS Policy), which updates and expands on the 2007 NIH GWAS Policy. The draft GDS Policy encompasses a broader range of data types (e.g., GWAS data and genomic, transcriptomic, or epigenomic data produced by array-based technologies, or data obtained from high-throughput sequencing technologies) from research in both human and nonhuman or model organisms, and updates expectations for data submission, data release, and human participant protections. As with the NIH GWAS Policy, the draft NIH GDS Policy is founded on the principle of maximizing public benefit by facilitating broad data sharing to advance the understanding of public health needs, while ensuring the responsible oversight of genomic data sharing. Through notices in the Federal Register and NIH Guide as well as two public webinars in the summer of 2013, NIH obtained public perspectives on all aspects of the draft GDS Policy, as well as on related data management topics such as the potential benefits and harms of broadly sharing genomic research data; scientific, technological, policy, or legal strategies or factors, that would minimize risks and should be considered when genomic data is shared through open access repositories; and models that NIH should consider to facilitate access to large-scale controlled-access data, enhance data utility, and protect participant interests. The comments were publicly posted on the NIH GDS website [http://gds.nih.gov] after the close of the public comment period. NIH expects this policy to be implemented in 2014. This presentation provides an overview of the draft NIH GDS Policy, the public consultation process and key public comments, and expectations for NIH GDS Policy implementation.

The Potential Power of Personal Genomics in Reducing Social Stereotypes: Attitudinal Study and Computer Animation of Results for 4,000 Japanese Respondents. *T. Kido[1], M. Swan[2].* 1) Rikengenesis, Tokyo, Japan; 2) DIYgenomics, Palo Alto, U.S.

This paper provides a flagship study of ethics and discrimination as individuals react to information about individual genetic differences. The study reports on the results of the analysis of social physiological statistics related to the impacts of the emergence of personal genome services. We were interested in determining how we might choose to respect others, not discriminate against others, and want to know differences among people. We would also like to understand the basic mechanisms underlying the reason for why discrimination emerges in our society. We conducted focus group discussions in a small lecture group in Tokyo University. Next, based on these discussions, we developed web-based survey systems with computer animations. We conducted 30 web-based interviews with 30 questions to more than 4000 Japanese individuals. A.Focus Group Discussions Focus group discussions on personal genome services revealed that a variety of opinions exist on both positive and negative sides. We classified these opinions, and asked more than 4000 Japanese people to vote on their favorite opinions. B.Web-based surveys and statistical investigations We created animation stories for symbolizing discrimination against people with a handicap and analyzed the responses. Our preliminary results that involved survey with more than 4000 volunteers revealed the following: 56.9% of people believed that society discriminates against people, with handicaps. 61.7% of people wished to have information about their genomes, even if it revealed a handicap. These preliminary results pose interesting questions about why a majority of people might believe in the existence of discrimination in our society, while they believe that they themselves are not discriminating. Social psychological research is expected to shed further light on these questions. This work demonstrates the importance of constructing frameworks for philosophical social psychological research with respect to new emerging information technologies. One of the biggest things we have seen emerge as people have their genetic data is that everyone realizes they have one 'handicap' or another - every person is at higher genetic risk than the average for one of the top 20 health conditions. This means the frame shifts from: A. Me (non-handicapped) vs. them (handicapped) to: B. We are all 'handicapped' (genetically predisposed) for some condition This has been one of the great destigmatizing influences of genomics.

2432T

Investigating the interplay of patients' hopes and expectations of Next Generation Sequencing. *K. Clift, A. Fiksdal, R. Topazian, A. Kumbamu, J. McCormick.* Mayo Clinic, Rochester, MN.

PURPOSE: The aim of this study is to describe the hopes and expectations of individuals engaged in the process of utilizing next generation sequencing (NGS) as a clinical tool. Participants include patients presenting to the Mayo Clinic Individualized Medicine Clinic (IM Clinic) who have a cancer that has failed standard treatments or have a diagnostic odyssey, their family members, and the clinicians involved in the care of the patient. METHODS: We conducted semi-structured interviews with 16 patients and their family members who were referred to the IM clinic throughout multiple points of the process of NGS. Audio recordings of the interviews were transcribed and analyzed using inductive narrative analysis. Future research activities will include more interviews and surveys of patients and their families entering the IM Clinic and throughout their journey as well as clinicians. RESULTS: The patients verbalized their understanding that the probabilities of finding something from NGS that will benefit them directly are low. However, patients maintained optimism despite having been advised by clinicians and genetic counselors that NGS is a relatively new process in the clinical realm and as such the possibility of it resulting in a beneficial outcome cannot be guaranteed. A prominent theme that emerged from the interview data was that the patients' hopes were nuanced by more 'realistic' expectations. To illustrate, one patient said that her hopes were to find out anything possible and her mother added: 'Our hopes are that...next week you will call and say we found a gene and we can fix it' to which the patient inserted a sarcastic aside that demonstrated her awareness of the likelihood of their hopes coming to fruition: 'And we're buying you Cinderella's castle and you get to live in it!' But despite their tempered understanding, many patients upheld what they knew to be unrealistic hopes and chose to move forward with NGS anyway. DISCUSSION: Patients' hopes and expectations can influence their decision-making in deciding whether to proceed with novel clinical testing. Understanding the interplay of patients' hopes and expectations may prove valuable to health care providers and genetic counselors as they guide individuals through the process of NGS. As NGS becomes increasingly integrated into clinical care, clinicians and researchers must continue to investigate the implications of using these technologies from a patient perspective.

2433W

Genetic privacy in the European Union - exploring the impact of the proposed Data Protection Regulations. *A. de Paor.* Centre Disability Law & Policy, Natl Univ Ireland, Galway, Galway, Galway, Ireland.

With advances in genetic science and technology, genetic information is becoming increasingly available and accessible. However, the deluge of genetic information raises many ethical and legal issues that may threaten advancing science, in the absence of appropriate regulation. One such issue is the violation of genetic privacy. Genetic information is a sensitive and inherently personal type of information that can reveal intimate details about an individual and an individual's family. In light of the sensitive nature of genetic information, the potential abuse is clear, as is the desire to protect such information from access and disclosure. Therefore, there are compelling reasons to maintain the privacy and confidentiality of genetic information. In the European Union (EU), the Data Protection Directive (introduced in 1995) provides a strong data protection framework that protects the privacy of personal information. However, there is currently no substantive provision for genetic data and no specific reference to this category of information, indicating a gap in the privacy protection for genetic data in the EU. Recent developments indicate an intention to include genetic data within the scope of EU data protection laws, with the European Commission proposing a new Regulation. With these new Regulations, the Commission aims to develop an updated data protection framework. It is committed to reform and modernise data protection legislation, in line with the realities of today's society, and changing norms. The draft Regulations identify 'genetic data' as a category of personal data designated for special protection. 'Genetic data' is defined broadly to include 'all data, of whatever type, concerning the characteristics of an individual that are inherited or acquired during early prenatal development', thus presumably incorporating all genetic data as well as family medical history and other genetic related health information. As regards protection of genetic privacy in third party contexts, these draft Regulations are welcomed as explicitly recognising genetic information as a category that deserves protection. This paper will explore the issue of genetic privacy in the EU. It will examine the current data protection framework, as well as the proposed reform of the EU data protection framework and the impact that these reforms will have on the protection of genetic data.

2434T

An evidence-based framework for incidental findings from exome sequencing in the pediatric setting. *E.T. DeChene[1,2], S. Mulchandani[2], M.C. Dulik[1,2], L.K. Conlin[2], J.L. Abrudan[1,2], B.A. Bernhardt[3], K. Izumi[1], S.E. Noon[1], R.E. Pyeritz[3], A. Santani[2], I.F. Slack[1], C.A. Stolle[2], A.B. Wilkens[1], I.D. Krantz[1], N.B. Spinner[2].* 1) Dept of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Dept of Pathology & Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Dept of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Clinicians and laboratories are considering how much secondary information to return to patients undergoing genome-wide tests. The use of exome and genome sequencing has led to an increase in discovery of secondary or incidental findings (IFs), which are clinically relevant genetic variants unrelated to the reason the test was ordered. The issues surrounding genetic IFs in pediatrics are particularly complex, because most children and adolescents cannot fully comprehend implications of potential IFs or independently consent to testing. However, ACMG recommends that laboratories search out and report certain medically actionable IFs, due to the potential impact on the child's or family's health. Funded by the NHGRI's Clinical Sequencing Exploratory Research Program, the Pediatric Genetic Sequencing (PediSeq) Project at The Children's Hospital of Philadelphia (CHOP) and University of Pennsylvania is exploring best methods for performing exome and genome sequencing and returning IFs in the pediatric setting. PediSeq's Oversight Committee (OC) carefully considered the result options offered to families, creating a balance in the principles of beneficence, non-maleficence and patient autonomy. Our current framework allows families to opt to receive results related to medically actionable (MA) childhood-onset disease, MA adult-onset disease, and carrier status for recessive disorders. The OC agreed that certain conditions are immediately MA (IMA) requiring immediate change in treatment or care based purely on genetic diagnosis (in the absence of symptoms). We believe that we are obligated to release IMA results regardless of a family's preferences, due to the likely impact on a child's long-term health. Initially categorization of IFs was established by OC consensus. Due to the subjectivity of this approach, we developed an evidence-based categorization method centered on gene/disease evidence; affected gender and age of onset; availability of treatment or management; and disease severity. Here we present our current IF framework and verify its utility by categorizing over 40 IFs identified in the CHOP CytoGenomics Laboratory. For example, Brugada and several childhood cancer syndromes were categorized as IMA. We propose that carefully categorizing IFs and offering families options for most IFs they receive, along with detailed pre-test counseling, is the best way to balance patient autonomy with our ethical and legal responsibilities to patient care.

ELSI as applied to non-invasive prenatal testing. *M.W. Leach.* University of Louisville, Louisville, KY.

This year is the 10th anniversary of the completion of the Human Genome Project. ELSI, or Ethical, Legal, and Social Implications Research Program, received a portion of the total project's funding. With the advances and uptake in non-invasive prenatal testing (NIPT), the same justifications for ELSI support funding of research and counseling resources to balance the ethical, legal, and social implications of NIPT. The development of prenatal testing for aneuploidy has received public funding through research grants. Since the introduction of NIPT in 2011, private and public health insurers are now including NIPT in its coverage of prenatal care. Under the Patient Protection and Affordable Care Act (PPACA), prenatal care and maternity care services will be required to be provided as no-cost preventive services and as essential health benefits by private insurers. The investment and coverage of NIPT, however, has been limited to the testing itself. Coverage and inclusion of NIPT as part of prenatal care are premised on professional medical organization guidelines and statements recognizing NIPT as another accepted prenatal testing option to be offered patients. These same guidelines and statements, though, emphasize the need for pre-test and post-test counseling, and the testing manufacturers themselves have stated the need to develop educational materials for patients and providers. The ELSI Research Program was established out of recognition that the Human Genome Project necessarily involved significant ethical, legal, and social implications. So, too, does NIPT. With the lack of risk to the mother coupled with the most accurate screening results yet, testing companies and clinicians are reporting increased uptake in NIPT and a corresponding decrease in uptake of invasive diagnostic testing. Prenatal testing for aneuploidy is premised on informed consent and patient autonomy. But, since its inception, studies have found challenges in achieving informed consent and respect for autonomy based on lack of understanding of prenatal test results and the tested-for conditions. To ensure prenatal testing for genetic conditions and its latest development, NIPT, are administered ethically, legally, and with respect to its social implications, corresponding public research funding and private insurance coverage is justified for research and counseling resources.

Research Policy of the Genome Science Project in Japan. *J. Minari*[1], *K. Kato*[1,2]. 1) Biomedical Ethics and Public Policy, Osaka University, Osaka, Japan; 2) Institute for Integrated Cell-Material Science (iCeMS), Kyoto University, Kyoto, Japan.

A new large-scale project, the Genome Science Project, started in Japan in 2010. It is a five year project funded by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The project aims to support various genome researchers in Japan who are funded by MEXT and selected through an annual open call; it does so by providing services of high-throughput DNA sequencing and high-grade information technology. A program in the project, Medical Genome Science Program (MGSP) handles human specimens and sequences the whole genome/exome to support the selected researchers, and thus naturally has to take into account various ethical, legal and social implications. For this, a special group, Research Unit for the ELSI of Genomics, has been established within the project. In starting the MGSP, we had to create a model informed consent form (ICF) template. The process necessarily involved the consideration of major ethical issues of personal genome research, such as returning research results and incidental findings. First, we surveyed existing informed consent documents, and then came up with a draft of the ICF template based on a consideration of the Japanese context. To further refine the draft of the ICF template, we held repeated discussions with executive genome researchers of the MGSP. Through the discussion, we achieved some consensus regarding the research policy of the ICF template. However, for a key issue~returning research results and incidental findings~clear consensus could not be achieved. On this issue, we confirmed that many genome researchers hold the following views: in Japan most personal genome studies aim toward an understanding of the causes and mechanisms of diseases; and the disclosure of research results for clinical purposes was usually beyond the scope of the original aims of research. As a general policy, we decided to leave the decision to each MGSP applicant. In this research activity, we crafted a research policy of personal genome analysis in Japan, in which the cooperation with genome researchers in the MGSP was invaluable for incorporating pragmatic aspects of research. The lessons learned and experiences gained in establishing our research policy can be expected to share a number of similarities with those in other personal genome research and in clinical practice in Japan, and they may serve as a starting point for their policy-making activities.

Effect of Using a Family History Tool on Communication with Family and Health Care Providers. *C. Wang*[1], *A. Sen*[2], *M. Plegue*[2], *M. Ruffin*[2], *S. O'Neill*[3], *W. Rubinstein*[4], *L. Acheson*[5] *for the Family Healthware Impact Trial group.* 1) Boston University School of Public Health, Boston, MA; 2) University of Michigan, Ann Arbor, MI; 3) Northwestern University, Chicago, IL; 4) National Institutes of Health, Bethesda, MD; 5) Case Western Reserve University, Cleveland, OH.

The family health history offers an ideal proxy to assess genomic risk and is the simplest applied genomic tool available. The Family Healthware™ Impact Trial set out to evaluate the clinical utility of a family history tool developed by the CDC. Primary care patients were randomized to receive usual care with generic prevention messages, or personalized familial risk and prevention messages based on self-recorded family history of common cancers, diabetes, heart disease, and stroke (O'Neill et al., 2009). This study examines the impact of Family Healthware™ on communication behaviors; specifically, communication with family members and health care providers about family health history. Analyses focused on those who had not talked with a family member (2254/3866, 58%) or health care provider (1894/3866, 72%) about their family history during the 6 months preceding study entry. GEE models were run, adjusting for practice clustering and controlling for age, gender and study site. At baseline, communication about family history with either family members or health care providers did not differ between intervention and control groups. At 6 month follow-up, participants randomized to the intervention were more likely to report having talked about their family history to family members compared to those randomized to usual care (42% vs. 37%, p=.052). Not surprising, women were more likely to talk with their family members about family history than men, OR: 1.18, CI (1.01, 1.38). Talking with health care providers about family health history at follow-up was more likely at sites that enrolled patients with upcoming medical appointments, but did not differ between intervention and control groups (44% vs. 41%, n.s.). Additional analyses among Family Healthware™ users showed that women at increased familial risk for heart disease were more likely to discuss their familial risk with family members, as were men at increased familial risk for heart disease or diabetes. There was also evidence of a dose effect among men such that those at elevated familial risk for a greater number of diseases were more likely to communicate with family members. In sum, Family Healthware™ prompted more communication about family history with family members but not health care providers. Future research should explore reasons for not communicating and identify approaches to encourage greater sharing of family history information, particularly with health care providers.

2438T

Mapping the next generation sequencing industry. *M.A. Curnutte*[1], *K.L. Frumovitz*[1], *J. Bollinger*[2], *G.H. Javitt*[3,4], *K.S. Carner*[3], *D. Kaufman*[2], *A.L. McGuire*[1]. 1) Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX; 2) Genetics & Public Policy Center, Washington, DC; 3) Sidley Austin, LLP, Washington, DC; 4) Berman Institute of Bioethics at Johns Hopkins, Baltimore, MD.

The next generation sequencing industry is rapidly evolving, as companies quickly transition from research services to clinical care. New business models are emerging, with companies offering a variety of services that have policy and regulatory implications. It is important to understand the development of the industry, and to anticipate policy issues that might impede clinical translation. We conducted a comprehensive web-based analysis with the aim of identifying the key business models within the next generation sequencing industry. This includes private companies offering a range of services from sequencing platforms to data analysis and storage. We confirmed our findings with company representatives and experts in the fields of genetics and biotechnology to deepen our understanding of the industry. To date, we have focused on accurately capturing the companies' customer base and practices and services. We present the main business models and discuss the regulatory implications of each. Our preliminary findings show that there is little competition amongst technology providers and increased market expansion in the areas of data analysis, storage, and informatics. As these technologies are incorporated into clinical diagnosis, we question how regulators will respond, and whether the modification of existing legal frameworks will be applicable or adequate. For example, will CLIA regulation apply to the complex analytics necessary to interpret sequence data, and if so are existing regulations appropriately tailored to these new methodologies? Will FDA assert jurisdiction over NGS-based laboratory testing, as it has over 'laboratory developed tests'? We anticipate that NGS may enable the separation of the core phases of clinical laboratory testing~preanalytic, analytic, and postanalytic~ into separate domains performed by different entities, which in turn may necessitate new models of regulation.

2439W

The commercialization of non-invasive prenatal testing: will a private market drive effective clinical translation? *A. Agarwal*[1], *L. Sayres*[1], *M. Cho*[2], *R. Cook-Deegan*[3], *S. Chandrasekharan*[3]. 1) Duke University School of Medicine, Durham, NC; 2) Stanford University Center for Biomedical Ethics, Stanford, CA; 3) Duke University Institute for Genome Sciences and Policy, Durham, NC.

Since its 2001 US market introduction, non-invasive prenatal testing (NIPT) using cell-free fetal DNA found in maternal blood has provided the ability to analyze fetal genomes for genetic conditions without relying on commonly used invasive procedures. Unlike other prenatal tests, NIPT is being primarily driven by private industry, setting precedent for a new market landscape. The prenatal testing field, estimated to be worth up to 1.3 billion US dollars per year, provides strong commercialization incentive as a rapidly growing sector of molecular diagnostics. Already, four US-based companies are offering NIPT for chromosomal aneuploidies as early as ten weeks into pregnancy and plan to expand offerings in the future. Intellectual property rights are playing a key role in the commercialization of NIPT, and raise questions about positive and negative effects on implementation. To address this issue, we assembled a NIPT patent and business landscape, and identified over 100 US patents and applications containing at least one claim to the use of cell-free fetal DNA for prenatal testing. We found that the four major US companies offering NIPT have applied for or received patents, and many of these have been exclusively licensed. All four are currently involved in patent infringement lawsuits, and interference proceedings are ongoing. The effect on availability and future NIPT development will depend heavily on the outcome of this litigation, validity and scope of claims, and licensing strategies. It is possible that litigation related costs could increase prices, decreasing the cost-effectiveness of using NIPT and limit patient access. Also, companies may withhold collected data to secure a market advantage, potentially undermining quality assurance initiatives and decision-making, especially if information about test utility in specific clinical contexts is not freely available. On the other hand, patents may help secure investment to drive future innovation in NIPT technology. While long-term effects are challenging to predict with ongoing litigation, it is necessary for physicians, patients, and other stakeholders to consider the risks and benefits associated with the private sector driving clinical NIPT adoption. As NIPT begins to cover more genetic conditions and becomes a standard of care, it is critical to understand the legal, regulatory, and commercialization aspects of this technology to ensure effective implementation and clinical use.

2440T

Continuity of care of patients with inherited Genetic disorders. *H. Azimi[1,3], S. Ghavimi[2].* 1) Psychogenome, Nepean, Ontario, Canada; 2) Shahid Beheshti Medical University, Tehran, Iran; 3) All Saints Univeristy School of Medicine, Dominica.

Objective: Continuity of care of patients with inherited Genetic disorders. Methods: Survey of patients and physicians was completed by phone, email and in the hospital. Patients answered a series of questions based on the continuity of care they received from their physicians. Physicians in the survey answered a questioner based on how they felt they contributed to the patients overall health by knowing the knowledge of genetics necessary in order to have the best continuity of care for the patients. Results: Of 100 patients surveyed , 34 (34%) with MENIIB syndrome, 11 (11%) diagnosed with Diabetes Mellitus type 2 and 25 (25%) diagnosed with Hemochromatosis. 40 patients (40%) had mixed disorders and their opinion was coupled to make one group. Out of the physicians surveyed, 34 Endocrinologist agreed that having the knowledge of Genetic, and studying their patients diseases allowed them to have a better a relationship with the patients in order to deliver the best continuity of care for them. Primary care physicians surveyed all agreed that cross multi-care for patients in the continuity of care practicum allowed them to better treat and deal with their patient's diseases. All the physicians agreed that being up-to-date with the current genetics advancement they can have the best continuity of care for their patients. 100 Physicians participated in this survey. Conclusions: Knowing more about genetic disorders of our patients, will help to better build a relationship with them. This relationship can help the patient's better cope and live a more productive healthier life. Physicians working as primary care physicians need to be up to date with current genetics advancement, and they need to make sure that the patients they care and treat are aware of genetics basis of their diseases as per this survey indicated.

2441W

Communicating with biobank participants: preferences for receiving aggregate results and providing updates to researchers. *J. Mester[1,4], M. Mercer[2], A. Goldenberg[2], R. Moore[3], C. Eng[1,3,4], R. Sharp[1,2,5].* 1) Genomic Med Inst, Cleveland Clinic, Cleveland, OH; 2) Dept of Bioethics, Cleveland Clinic, Cleveland, OH; 3) Dept of Genetic and Genomic Sciences, Case Western Reserve Univ, Cleveland, OH; 4) Taussig Cancer Inst, Cleveland Clinic, Cleveland, OH; 5) Center for Genetic Research Ethics & Law, Case Western Reserve Univ, Cleveland, OH.

Biobanks collect biological materials and/or health information for ongoing and future biomedical research. Guidelines recommend return of individual research results under certain criteria but do not discuss aggregate results or study updates. Previous work has found that biobank participants desire updates, but preferences as to the extent or manner have yet to be explored. Thus, we surveyed participants in a long-standing protocol-driven research biobank. Eligible participants were drawn from an IRB-approved study of patients with personal/family history suggestive of Cowden syndrome, a poorly-recognized hereditary condition predisposing to breast, thyroid, and other cancers. Participants gave blood samples and access to medical records and had no other interactions with researchers. The biobank had 3,618 participants at time of sampling. Survey eligibility included enrollment ≥18 years and within the biobank's first 5 years, normal *PTEN* analysis, and contiguous United States address. Multivariate logistic regression analyses were performed to identify predictors of participant interest in internet vs. non-internet-based communication modes and communication modes allowing for participant/researcher interaction vs. one-way communication. Independent variables for the regressions included demographic characteristics and attitudinal variables logically or theoretically associated with desired modes of receiving general research updates. Variables were narrowed by independent Pearson correlations by cutoff $p<.2$. Variables with $p<.02$ were considered predictors of preferences. Surveys were returned from 840/1267 (66%) eligible subjects. Most (97%) wanted to receive general updates about the study with 92% wanting updates at least yearly. Participants wished to receive updates via paper (66%) or emailed (62%) newsletter with 95% selecting one of these options. 31% were not comfortable with any e-communication mode, with older, less educated, and lower-income persons strongly preferring offline approaches ($p<0.001$). Most (93%) had no concerns about receiving updates. 97% were willing to provide updates to researchers by post (71%) or email (50%). Plans to communicate results and updates should be made during study development and participants should be able to select if and how to receive them during informed consent. Study demographics may optimize communication modes. Funders should monetarily support the infrastructure needed for these efforts.

2442T

The European Network for Human Congenital Imprinting Disorders - a new COST Action (BM1208). *T. Eggermann[1], E.U. BM1208 members[2].* 1) RWTH Aachen, Aachen, Germany; 2) COST Action.

Imprinting disorders (IDs) are a group of rare congenital diseases affecting growth, development and metabolism with a lifelong impact on patients' quality of life. Despite their common underlying (epi)genetic aetiologies, IDs are usually studied separately by small research groups working in isolation, and the basic pathogenesis and long term clinical consequences of IDs remain largely unknown. Efforts to elucidate the aetiology of IDs are currently fragmented across Europe and standardisation of diagnostic and clinical management is lacking. This COST Action will, for the first time, draw together researchers of all eight known human IDs in an interdisciplinary pan-European and worldwide Network for Human Congenital IDs, working to advance understanding of the pathophysiology with the major aim of translating this knowledge to improvement of diagnostic and clinical management for the benefit of the patients and their families. The Action will harmonise a common ID classification system, develop guidelines for treatment through consensus, create standard operation procedures (SOPs) for diagnosis based on best current practice, coordinate databases held in different countries to make them compatible and useful as a springboard for collective research initiatives, identify new imprinting disorders and causative mechanisms through collaborative effort, educate researchers and stimulate translational exchange. The ID network consists of >30 groups from >15 countries. It will join forces and complement studies to reduce health care costs and increase the life quality of patients suffering from IDs. The Action has started in June 2013, but is still open for further partners.

2443W

The `eugenics' program and public health genomics in China and their implications towards East Asia. *K. Muto[1,2], B. Zhao[2], H. Hong[1,2].* 1) Dept Pub Policy, IMS, Univ Tokyo, Tokyo, Japan; 2) Graduate School of Frontier Sciences, Univ Tokyo, Tokyo, Japan.

Background: China has a high population growth rate, and thus faces great challenges in terms of population growth, health care and economic development. The State launched a family-planning policy in 1980, to control the size and raise 'the general quality of the population'. As part of this family-planning policy, a new 'eugenics' program was developed to ensure the health of mothers and infants, and to improve the quality of the newborn population. As a result of economic development and improvements in medical treatment, the Chinese infant mortality rate dropped from 32 to 12 out of every 1,000 births in one decade. The National Medium- and Long-term Program for Science and Technology Development (2006-2020) set as a priority the acquisition of key technologies to ensure that the country's population remains below 1.5 billion, and its birth defect rate below 3%. Purposes: To facilitate further discussions how both the new bioethics concept and the old disability concept have changed in China, we have looked back and analyzed the first criticisms of the Western science community with regard to the Chinese eugenics program of the 1990s and examine the future impact in East Asia. Methods: Using literature review methods in this study, we collected topical statements from academic societies, government documents, law, and guidelines. We also reviewed articles identified in PubMed and CNKI databases. Results: Western geneticists have fiercely criticized the program as an 'abuse of genetics' and a 'violation of human rights' (Morton, 1998). In contrast, some argue the law would help reduce births of physically or mentally abnormal babies. To look back at the history of the eugenics movement and its ensuing legislation, the term 'eugenics' is defined differently in China than it is in other nations. Discussions: Japan and Korea import non-invasive prenatal testing (NIPT) from the US, even though the two countries have different views and attitudes toward it. At this time, Chinese companies are developing cheaper NIPT through their own original methods. Ideally, NIPT developed in China should be in harmony with other Asian and Western countries, as a basis of a Chinese 'eugenics' program that is balanced ethically and scientifically.

2444T

The attitudes of patients with cystic fibrosis and their parents towards direct-to-consumer genetic testing. *S. Janssens[1], C. Binst[2], I. Mahieu[2], A. De Paepe[1], P. Borry[3].* 1) Center for Medical Genetics , University Hospital Ghent, Ghent, Oost-Vlaanderen, Belgium; 2) Master Life Sciences and Medicine, University of Ghent, Belgium; 3) Center for Biomedical Ethics and Law, University of Leuven, Belgium.

BACKGROUND: Knowledge of carrier status enables prospective parents to make informed reproductive decisions. Recent technological advances in molecular genetics facilitate large-scale population carrier screening. In this prospect reflection is necessary about the desirability to offer community-based (preconception) carrier screening in the healthcare system. At this moment, commercial companies have started to offer preconceptional carrier tests directly to consumers. METHODS: As part of a survey developed to evaluate attitudes towards preconceptional carrier screening for cystic fibrosis (CF), attitudes towards Direct to Consumer testing (DTC) were assessed. The study population was recruited from a register of 157 patients with CF who consult at least once in 3 months at the pneumology department at the University Hospital of Ghent, where one of the eight Belgian reference centers for CF is located. All the parents of CF patients under 18 years and all CF patients aged 16 years and older who attended the clinic in the period between August 13 and December 11 2012 were asked to fill in a questionnaire. An approval from the local research ethics committee was obtained. RESULTS: In total 134 questionnaires were distributed of which 112 were returned. Response rate was 86.7% for the parents and 79.7% for the CF patients aged 16 years and older. 78.3% of the patients with CF and 87.1% of the parents had never heard about testing for carrier status of genetic diseases through the internet. Only 21.7% of the patients and 12.9% of the parents were aware of this possibility. Of the total survey population 57.7% finds that people have the right to order such a test directly at a commercial company. However, 57.1% of respondents disagrees that someone should be able to obtain the results without medical supervision. Only 4.3% of the patients with CF and 9.4% of their parents would buy a carrier test for other conditions then CF through a DTC genetic testing company. DISCUSSION AND CONCLUSION: Awareness about DTC genetic testing for carrier status is low. Although a majority supports the right of individuals to access a carrier test directly, less than half of the respondents supports that individuals would receive test results without a physician. Only a minority would consider buying a carrier test from a DTC genetic testing company.

2445W

Genetic causal beliefs of morbidity: associations with health behaviors and outcome beliefs of behavior changes during two decades in the general population. *A.H. Haukkala[1], N. Hankonen[1], H. Konttinen[1], M. Perola[2], H. Kääriäinen[2], V. Salomaa[2].* 1) Social Reseeach, University of Helsinki, Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland.

Background: The role and meaning of genetic information has increased considerably during the last decades . We examined changes in causal beliefs for morbidity and their associations with health behaviors and control beliefs from 1982 to 2002. Methods: Five population-based risk factor surveys from 1982 to 2002, participants aged 25 to 64 years (n=37,503). Subjects were asked to choose the most important cause for morbidity from the list of ten alternatives. Outcome expectancies of health behaviour changes were assessed with 2 items. Health behaviors included self-reported physical inactivity, current smoking and obesity based on measured height and weight. Findings: Prevalence of genetic causal belief increased from 4% (1982) to 10%(1992) and remained at that level until 2002. Older age groups were more likely to choose genetic causes while there were no associations with gender or education. Lack of exercise and overweight increased while inappropriate diet and stress diminished as causal beliefs for morbidity during the study period. Smokers, physically inactive and obese respondents chose less often physical inactivity, smoking or diet as causes for morbidity and more likely genetic causes for morbidity. Genetic causal belief group had more pessimistic outcome expectations of health behavior changes. These associations remained similar during two decades. Discussion: The proportion of those who choose physical inactivity and overweight as the most important cause for morbidity has increased from 1982 to 2002. Despite increased public discussion about genomics the relative proportion of people with a genetic causal belief has remained low and associations with pessimistic expectancies on health behavior changes have remained the same during two decades.

2446T

A systematic approach to the development of evidence-based family history screening in pediatric primary care. *E. Edelman[1], B.K. Lin[2], N. Mikat-Stevens[3], L. Vasquez[4], K. Hughes[5], J. Scott[1].* 1) NCHPEG, Lutherville, MD; 2) March of Dimes, White Plains, NY; 3) American Academy of Pediatrics, Elk Grove Village, Il; 4) HRSA, Rockville, MD; 5) Harvard Partners, Boston, MA.

Background: While family health history (FHH) is recognized as an important risk assessment and management tool for primary care pediatric providers (PCPs), numerous barriers to its integration have been documented, including limited time, provider knowledge and confidence, and lack of guidelines and tools to support collection and management. Objective: To determine conditions for inclusion on a novel electronic FHH and clinical decision support (CDS) tool for PCPs. Methods: A multi-method approach was used to determine inclusion of conditions for a pediatric FHH tool. Semi-structured interviews focusing on FHH practices were conducted with diverse PCPs (4 pediatricians, 1 family medicine physician, 1 family medicine and 1 pediatric nurse practitioner) recruited from the AAP Genetics in Primary Care Institute. Interviews were analyzed using qualitative thematic analysis. The published literature regarding PCPs' use of FHH and the validity and utility for pediatric and adult conditions was reviewed. Practice guidelines and pediatric FHH forms (13 from pediatric practices and internet searches) were analyzed to determine FHH screening practices. Data on conditions were recorded in a database and analyzed using descriptive statistics. Practice findings and interview themes were summarized to inform condition selection. Criteria adapted from Yoon et al. (2003) were used to determine inclusion and focused on the clinical utility of screening in the general pediatric population. Results: Seventy-six conditions for possible inclusion on the panel were identified. Fifty conditions met criteria, most of which were common conditions such as asthma, intellectual disability, and mental illness. Conclusion: This is the first report to propose an evidence-based approach to determine conditions for pediatric FHH screening. This study presents a model for tool development that can be applied to other institutional or national efforts to develop FHH or genetic CDS tools for diverse clinics. These efforts are increasingly relevant to geneticists as they are called to provide guidance on FHH and genomic data standards in electronic health records and health information technology systems. Next steps include development of risk assessment algorithms and clinical decision support and identification of solutions for interoperability with electronic health records.

2447W

An Assessment of Perceived Medical and Psychosocial Needs of Families that have Children Affected by Duchenne Muscular Dystrophy in Madurai, India. *S. Kejriwal[1], K. Ormond[1], V.S. Arun[2], L. Stanislas[2], C. Siskind[1].* 1) Stanford University, 450 Serra Mall, Stanford, CA 94305; 2) Muscular Dystrophy Foundation India, 26-B, 1st Street, State Bank Colony-II, Bypass Road, Madurai - 625 010, Tamil Nadu, India.

Duchenne muscular dystrophy (DMD) is a hereditary progressive neuromuscular condition that affects approximately 1 in 3500 male children worldwide, and which leads to various medical, psychological and social needs for children and their families. Medical, social and cultural barriers in developing countries are likely to pose additional, unique needs for families. In order to determine these needs, we recorded, transcribed and analyzed 20 interviews with a total of 29 family members of children affected with DMD in Madurai, India. Participants were recruited based on variation in socioeconomic status, literacy, age and number of affected children, and number of deceased children. The main themes that evolved from the interviews centered on issues related to medical care, access and mobility, emotional difficulties and social support. Some aspects of these issues were specific to affected individuals and their families in India, whereas others were also experienced - albeit to a lesser degree - by their counterparts in developed countries. The former consisted of major inadequacies in healthcare, medical communication, psychosocial management and financial support. The latter consisted of underdeveloped solutions to mobility-related difficulties, a lengthy diagnostic process, and a lack of awareness amongst the medical community and society at large. In summary, our study revealed numerous unmet needs of families that have children affected by DMD in Madurai, India. Long-term solutions to unmet needs may include: 1) policy change to improve healthcare funding and mobility infrastructure, 2) development of ancillary services such as genetic counseling and social work, 3) spreading awareness amongst government authorities, the medical community and society at large, and 4) cross-talk between advocacy groups and health professionals. Relatively immediate solutions may include 1) guidance of families towards appropriate medical resources by advocacy groups, 2) increased investment in fundraising activities by advocacy groups to provide relief from financial strain, and 3) collaborations between muscular dystrophy advocacy groups and organizations that are invested in finding solutions to mobility needs of the disability community at large.

2448T

Reporting of incidental copy number variation (CNV) detected by chromosomal microarray analysis in `normal' parents/family members - A review of 3500 cases. *A. Patel, S.W. Cheung, P. Stankiewicz, A. Breman, S.R. Lalani, J. Smith, C. Shaw, S. Peacock, A. Braxton, L. Ellis, P. Ward, J.R. Lupski, A. Beaudet, W. Bi.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

When interrogating the human genome, it is sometimes the case that the most significant finding is unrelated to the referring diagnosis. Such incidental findings can pose challenges with regard to which results should be revealed, to whom and by whom. Such issues have begun to be addressed with the recent ACMG recommendations for reporting incidental findings in Clinical whole Exome and Genome sequencing. While some incidental findings are currently of uncertain clinical significance, others are medically actionable and reporting of these incidental copy number variations (CNVs) can have a significant impact on risk counseling for future pregnancies and other family members at risk, as well as enabling interventions to improve health outcomes. In the course of performing chromosomal microarray analysis (CMA) on 3500 apparently 'normal' parents/family members for interpretation of variants of unknown clinical significance in the proband, we incidentally found 28 (0.8%) clinically relevant CNVs including [1] mosaic or full chromosome aneuploides, [2] genomic disorders with incomplete penetrance, [3] carriers of X-linked Mendelian traits, [4] carriers of autosomal recessive disorders, [5] cancer susceptibility and [6] dominant adult onset disorders. Reporting of incidental findings is not new to medicine, so should reporting incidental findings in whole genome analysis be any different? Should the current ACMG recommendations for reporting incidental findings incorporate incidental CNVs?

Brudno[1,8], C. Shuman[1,3,4], P. Ray[1,2,4,7].* 1) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Clinical and Metabolic Genetics, Dept of Paediatrics, Hospital for Sick Children, Toronto, ON, Canada; 4) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 5) Department of Paediatrics, University of Toronto, Toronto, ON, Canada; 6) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 7) Department of Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada; 8) Department of Computer Science, University of Toronto, Toronto, ON, Canada; 9) Department of Laboratory Medicine and Pathology, University of Toronto, Toronto, ON, Canada; 10) Joint Centre for Bioethics, University of Toronto, Toronto, ON, Canada; 11) McLaughlin Centre, University of Toronto, Toronto, ON, Canada; 12) Centre for Clinical Ethics; Providence Healthcare, St. Joseph's Health Centre and St. Michael's Hospital; Toronto, ON, Canada; 13) The Donnelly Centre, University of Toronto, Toronto, ON, Canada; 14) Department of Bioethics, The Hospital for Sick Children, Toronto, ON, Canada.

The transformative potential of whole genome sequencing (WGS) lies in its use in individualized genomic medicine, where knowledge of an individual's genomic variants guides health care decisions throughout life. However, there are multiple challenges: Many disease genes have yet to be discovered; bioinformatic tools are still under development, the diagnostic advantages of WGS are largely unproven; the clinical utility and socioeconomic impact of identifying incidental medically actionable genomic variants (MAVs) in children are unknown; and existing counselling models are inadequate for clinical genomics.

To address these and other knowledge gaps we have created a paediatric 'Genome Clinic.' This multi-disciplinary research platform has several distinctive features, including: a) The project treats an individual's genome as a source of genetic information to be repeatedly queried over time in order to manage overall health, rather than a one time test performed to diagnose a pre-existing disorder. As a result, MAVs are a major focus of study rather than an inconvenient burden. b) Focusing on children offers the greatest potential for increased quality of life years. c) Project scope is broad - from development of new bioinformatics tools and discovery of new genes to health policy inquiries, assessment of models of clinical care and the ethics of consent. d) Project design emphasizes an interactive partnership between patients, parents and health care researchers in discovering the medical and psychological risks and benefits of genomic medicine. e) The Genome Clinic offers WES/WGS-based clinical research projects a 'safe harbor' for managing incidental findings.

Piloting our bioinformatics pipeline using a curated list of 2000+ disease genes found 5-13 MAVs and 5-18 carrier variants/individual requiring manual evaluation. We are enrolling 50+ children/year who are under investigation for a genetic disorder, along with their parents. Participants are counselled regarding WGS and given options of learning about specific classes of adult-onset MAVs and carrier variants. Variants relevant to the primary disorder are returned by the referring physician, while pharmocogenomic variants, MAVs, and carrier variants are disclosed to participants by Genome Clinic geneticists and genetic counsellors. Our systematic approach mitigates potential risks and maximizes benefits of this new clinical care model.

Frequency of ACMG recommended 57 gene incidental findings from whole exome sequencing in a cohort of 47 adult individuals. *J. Wynn[1], M.L. Cremona[1], J. Martinez[1], Y.H. Cheung[1], W.K. Chung[1,2].* 1) Department of Pediatrics, Columbia University Medical Center; 2) Department of Medicine, Columbia University Medical Center.

The American College of Medical Genetics (ACMG) recently recommended mandatory return of secondary findings for 57 genes in patients receiving clinical whole exome and whole genome sequencing (WES/WGS). Before implementation, the frequency of mutations in these genes in an unselected cohort should be determined to appreciate the impact of this policy on clinical practice. We completed WES on 47 adult individuals and analyzed results for secondary findings in the 57 ACMG genes. Variants in Human Gene Mutation Database were identified, and any variants with a minor allele frequency > 2% in the 1000 Genomes and Exome Variant Server were removed. The literature for all remaining variants was reviewed and only Class I variants using ACMG criteria were classified as mutations. Five participants had previously had negative genetic testing of the BRCA1 and BRCA2 genes. For the other 42 subjects, the indication for WES was unrelated to the conditions on the ACMG list. A published pathogenic mutation in one of the 57 genes was identified in 13% (6/47) of participants. We identified 3 (6.4%) participants with SCN5A mutations; 2 of the 3 participants had no personal or family history suggestive of Long QT or Brugada syndrome. One participant had a history of two relatives who passed away suddenly <50 years. We identified 2 participants (4.3%) with mutations in cardiomyopathy genes (MYBPC3 and MYH7). One participant had recently had an echocardiogram showing mild concentric left ventricular hypertrophy with an intraventricular septal wall thickness of 1.3cm (normal 0.6-1.1). The other participant was asymptomatic and had never had an echocardiogram. One subject had a mutation in the MSH6 gene. She had never been diagnosed with cancer but her mother had a history of colon and uterine cancer .We found a frequency of secondary findings in 13% of adult participants for conditions that are believed to be rare. Few participants had a personal or family history of the condition identified by the secondary finding. These findings suggest problems with the accuracy of mutation classifications in the literature and/or inflated estimates of the penetrance for these conditions in an unselected population. Our results indicate there will be a significant burden to the clinical community to return secondary findings for these 57 genes, and perhaps implementation of any policy to return secondary findings should await curation of the mutation databases and genetic literature.

2451W

Incidental Findings and the ACMG Guidelines: What is the Real Burden? *J.J. Johnston[1], D. Ng[1], S.G. Gonsalves[1], K.L. Lewis[1], D.N. Cooper[2], J. Berg[3], H.L. Rehm[4], L.G. Biesecker[1].* 1) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, USA; 2) Institute of Medical Genetics, School of Medicine, Cardiff University, Heath Park, Cardiff, UK; 3) Department of Genetics, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, North Carolina, USA; 4) Partners Healthcare Center for Personalized Genetic Medicine, Boston, Massachusetts, USA.

With the ever-increasing use of exome sequence analysis in both research and the clinic, the issue of how to handle incidental findings has become controversial. The American College of Medical Genetics and Genomics (ACMG) has published guidelines detailing a list of genes/diseases that should be analyzed in all clinical exomes, with clinically relevant results being returned to the patient. We set out to assess the feasibility of these guidelines using the ClinSeq® dataset. In all, 951 exomes were analyzed for missense, nonsense, splice site, and insertion/deletion variants in the ACMG-suggested list of 57 genes. A total of 1,340 unique variants were identified. Filtering on a minor allele frequency of <0.01 reduced the list to 1,214 variants. Clinical labs will need to rely on published literature in order to annotate relevant findings. The ACMG guidelines recommend the use of curated databases to identify previously annotated variants followed by thorough re-evaluation of evidence for causation. Current variation databases include the Human Gene Mutation Database (HGMD), individual Locus-Specific Databases (LSDBs) and ClinVar. A total of 372 identified variants were annotated in the subscription version of HGMD (HGMD Professional) and an additional 164 variants were annotated in available LSDBs. Of these 536 variants, 211 were predicted to be causative for a disease on the ACMG disease list in at least one database. Further manual curation reduced the list of returnable causative variants to 27. Four variants were identified in multiple individuals bringing the total number of variants to return to 33. Eleven individuals had variants in *LDLR* or *APOB*, probably representing a bias of the ClinSeq® cohort selected for cardiovascular disease. Identifying 33 variants in our cohort of 951 individuals suggests a burden of approximately 3.5%; removing the *LDLR* and *APOB* variants reduces that burden to 2.3%. However, as current databases vary quite widely in terms of both quality and completeness, the real burden lies in the annotation of these variants. Although the identification of variants in certain genes can contribute important health information to patients, the current state of the field is such that making sense of these variants is both challenging and time consuming. It is clear that improvements in the annotation of mutation database are urgently required to address this problem.

2452T

An assessment of the prevalence of rare nonsynonymous variants within the genes listed in the ACMG Recommendations for Reporting of Incidental Findings in Clinical Exome and Genome Sequencing. *S.P. Strom[1], H. Lee[1], J.L. Deignan[1], K. Das[1], E. Vilain[2,3], W.W. Grody[1,2,3], S.F. Nelson[1,2,3].* 1) Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 2) Human Genetics, UCLA, Los Angeles, CA; 3) Pediatrics, UCLA, Los Angeles, CA.

BACKGROUND: The American College of Medical Genetics recently released guidelines which recommend the reporting of incidental findings (IF) when performing clinical exome or genome sequencing. Specifically, the ACMG has stated that laboratories performing this type of testing should report ‘known pathogenic’ and ‘expected pathogenic’ variants within a list of 57 genes, all but three of which act in an autosomal dominant fashion. In these guidelines, the ACMG has estimated that 1% of individuals will carry a known or expected pathogenic variant in any one of these 57 genes. However, as no clinical grade database currently exists to assess which variants in each of these genes are known to be pathogenic, variant interpretation falls to each individual laboratory. Although guidelines state ‘these recommendations should not be construed as an expectation that the laboratory comprehensively assess these genes for all variants,’ compliance without such analysis requires currently unavailable variant annotation. METHODS: We analyzed prior clinical exome sequencing results at UCLA from 226 de-identified individuals (either index or parental cases) to identify all high quality ($Q \geq 500$) potentially pathogenic variants in any of the 57 IF genes. We define potentially pathogenic as: nonsynonymous variants with a population allele frequency <1%. RESULTS AND CONCLUSIONS: Contrary to the a priori estimate in the ACMG guidelines, we identified at least one potentially pathogenic variant within an IF gene in 184 out of 226 individuals (81%). 36% of variants identified are located at an HGMD annotated locus. A total of 294 unique variant loci, or approximately 1.3 per individual on average, were identified. As the combined disease prevalence of all IF gene disorders is far less than 81%, the majority of these variants are likely not clinically significant. However, identifying the subset of variants that are potentially significant represents an additional interpretive burden for the laboratory. Until clinical grade variant databases exist for all of these 57 genes, laboratories may need to report all potentially pathogenic variants in the IF genes rather than only reporting a select few, if the ‘fiduciary duty to prevent harm’ aspired in the guidelines is to be met. For now, laboratories attempting to implement these guidelines should work with ordering physicians to coordinate an appropriate approach for discussing incidental findings with each patient or family.

Do preferences matter? Creating and assessing a novel preference-setting tool for the return of genomic research results. *P.L. Bacon[1], S.K. Savage[1], S.I. Ziniel[2,8,9], K.D. Christensen[5], N.L. Huntington[2,7], E.R. Weitzman[2,4,8], P.L. Taylor[2,4], R.C. Green[2,5,6], I.A. Holm[1,2,3].* 1) Program in Genomics, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA; 3) The Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA; 4) Children's Hospital Informatics Program, Boston Children's Hospital, Boston, MA; 5) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA, United States; 6) Partners Center for Personalized Genetic Medicine, Boston, MA; 7) Division of Developmental Medicine, Boston Children's Hospital, Boston, MA; 8) Division of Adolescent Medicine, Boston Children's Hospital, Boston, MA; 9) Program for Patient Safety and Quality, Boston Children's Hospital, Boston, MA.

Whether and how research participants receive individual research results (IRRs) from genomic studies has generated great concern, and many argue that participants should be allowed to designate their preferences for IRR return. The goal of this study was to develop an online preference-setting tool for the return of IRR and to determine if parents anticipate greater benefit and satisfaction from enrolling their child in biobanks where they could set preferences for IRR versus biobanks where they could not. The preference setting tool was informed by a large survey conducted at Boston Children’s Hospital (BCH) assessing parents’ interest in enrolling themselves and their children in a hypothetical genetic research repository and preferences for return of IRR. The tool was further refined through cognitive interviews with parents of BCH patients to understand what dimensions of a condition mattered most with parents as they decided if they were interested in receiving a genetic result. The resulting preference setting model is based on a) the preventability of the condition and b) the severity of the condition. Parents may also opt-out of any of four categories of results: mental illness/psychological conditions; developmental disorders/learning disabilities; childhood-onset degenerative conditions; and adult-onset conditions for which there are no interventions during childhood. We then developed an online survey in which participants were randomized to be enrolled into one of four hypothetical biobanks with different results return policies: 1) participant receives no IRRs; 2) participant receives all IRRs; 3) participant chooses to receive all or no IRRs (‘binary choice’); and 4) participant sets preferences for return of IRR using the online tool (‘granular choice’). We pilot tested the survey with parents of children seen at BCH. Preliminary data suggests that, when given a choice, the majority of parents elect to receive all possible IRRs about their children. Those parents who chose to receive all IRRs using the preference-setting tool rated the highest satisfaction of the 4 groups. In addition, the ‘granular choice’ group had the greatest proportion of parents stating that they would participate in a biobank that resembled the one they were randomized to. Preliminary findings will be confirmed in a forthcoming survey of 20,000 parents of patients at BCH.

Biobank Participants' Perspectives on Aggregate Result Return. *E. Bane[1], E. Ludman[2], J. Richards[2], G. Jarvik[3], S.M. Fullerton[4].* 1) Institute for Public Health Genetics, University of Washington, seattle, WA; 2) Group Health Research Institute, Seattle, WA; 3) Medical Genetics, University of Washington, Seattle, WA; 4) Bioethics and Humanities, University of Washington, Seattle, WA.

Introduction: Researchers and policy makers have recommended returning, where feasible, aggregate (or summary) results of research conducted using biospecimens to biobank participants (Beskow et al. 2012). There is, however, lack of consensus on best practices for aggregate return, particularly about how and when to communicate results; participants' perspectives on such issues would be valuable to incorporate into policy and practice. To date there have been few explorations of participant preferences with respect to the receipt of aggregate results and even fewer in the context of biobank participation that may involve genetic investigation. Here, we report a preliminary exploration of participant preferences and perspectives on the necessity for, and mode of, returning aggregate results of genomic biorepository research. **Methods**: Fifteen semi-structured interviews were conducted with participants in the Northwest Institute of Genetic Medicine (NWIGM) biorepository at the Group Health Cooperative and University of Washington in Seattle, Washington. NWIGM participants were interviewed by telephone about their perspectives on, and preferences for, return of results from research using human tissues. Interviews were recorded and de-identified transcripts subjected to a directed content analysis. **Results**: The participants interviewed reported a desire for individual results, and expressed a clear preference for allocating funds designated for return of summary results to additional research. In the event that aggregate results were to be returned, these participants preferred to receive them in the form of emails, letters, or websites rather than in-person interviews or phone calls. **Conclusions**: The results of this preliminary research indicate that while participants of genomic biorepository research are interested in research results, participants view individual results as more relevant than aggregate results, and are more invested in the objectives and fruition of the research itself than in receiving results per se. These results suggest individuals should be consulted regarding preferences prior to formation of overarching policy regarding aggregate return, and indicate that further research with larger and more representative cohorts is warranted.

2455W

Scripps Idiopathic Diseases of Man Study: The First 2 Years. *C.S. Bloss[1], S. Topol[1], B.F. Darst[1], A. Torkamani[1,2], N.J. Schork[1,2], E.J. Topol[1,2,3].* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 2) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 3) Scripps Clinic Medical Group, La Jolla, CA.

Introduction: The Scripps Idiopathic Diseases of Man (IDIOM) study aims to facilitate diagnosis and treatment of individuals with rare or idiopathic diseases through the use of whole genome sequencing (WGS) integrated with clinical assessment and multidisciplinary case review. We will describe the IDIOM study, including the operational protocol and descriptive statistics for the first, nearly 100, patient referrals. We will also present data on return of results for cases enrolled to date, including patient and provider preferences for the types of results returned from WGS, as well as perceptions of the return-of-results communication itself. Methods: IDIOM patient inquiries that pass initial screening are forwarded for review by a 12-person scientist-clinician panel that includes physicians, bioinformaticians, sequencing experts, ethicists, and nurses. Criteria include the presence of a grave condition that has remained undiagnosed despite extensive medical follow-up. For selected cases, WGS results are delivered back to the proband's referring physician, who is then responsible for returning the results to the patient. Patient and physician attitudes, preferences, and perceptions of the physician-patient return-of-results communication are assessed via semi-structured interviews and standardized questionnaires. Results: To date, 85 patient referrals for IDIOM have been received and screened, 30 have undergone 2nd tier review by our clinician-scientist panel, and 9 patients and their families have been enrolled. With respect to return of results, baseline data indicate that the majority of patients would prefer to receive sequencing results for the presenting condition along with secondary findings in multiple disease categories. Data from the completed return-of-results sessions suggest notable variation in patient satisfaction with communication of results by the referring physician. Case-by-case findings will be discussed in detail. Conclusion: The Scripps IDIOM study is a fully functioning program at the interface of clinical care and research, focused on the recruitment, screening, clinical evaluation, and WGS of individuals with undiagnosed diseases. We hope that results from this study will inform the effective, sustainable, and cost-effective use of WGS for rare/unknown disease diagnosis in community hospital settings by practicing physicians.

2456T

Should Secondary Findings From Whole Exome And Whole Genome Sequencing Be Released To Research Subjects? Our Ethical Responsibility. *C.A. Campbell[1,2], T. Bair[1], D. Kolbe[1], R.J.H. Smith[1,2].* 1) Iowa Institute of Human Genetics, Iowa City, IA, USA; 2) Department of Otolaryngology - Head and Neck Surgery, University of Iowa, Iowa City, IA, USA.

Whole exome (WES) and whole genome sequencing (WGS) are powerful tools that have facilitated the identification of multiple genetic causes of human disease. Genetic variants identified incidental to this primary discovery process are referred to as secondary findings. The American College of Medical Genetics (ACMG) has recently recommended that when WES and/or WGS are requested for clinical diagnostic purposes, the final variant report should include secondary findings in a defined set of 57 disease genes. These 'Recommendations for Reporting of Incidental Findings in Clinical Exome and Genome Sequencing' target genes primarily associated with hereditary cancer and cardiovascular disease since therapeutic intervention and/or screening make disease treatment and/or prevention possible. Analysis of data from the NHLBI Exome Sequencing Project on the Exome Variant Server (EVS) shows that there are 8,483 variants in European-American exomes in these genes. We will present the likelihood of identifying an ACMG-reportable variant in a research exome. As researchers, we must address this risk and the ACMG guidelines if we are to enroll patients with appropriate informed consent in genetic studies in which WES and/or WGS is planned. As the detection of variants depends on data quality, a summary of data quality for these genes using the SureSelectXT Human All Exon V4 (Agilent) capture and sequencing performed using paired-end chemistry on the HiSeq 2000 platform (Illumina, San Diego, CA) will be presented.

In the rapidly changing landscape of human genetics researchers are confronted with the dilemmas of; if, how, and when to give back research results to study participants. We will discuss the unique issues surrounding implementation of these guidelines in a research setting. In addition, the role of the genetic counselor in a research laboratory performing WES and/or WGS will be described. We propose select language in the informed consent document to deal with various reporting options.

2457W

`We don't know her history, her background': Adoptive parents' perspectives about sequencing results. *J. Crouch[1], J. Yu[2], A.G. Shankar[2], H.K. Tabor[1,2].* 1) Seattle Children's Research Institute, Seattle, WA; 2) University of Washington, Department of Pediatrics, Seattle, WA.

Pediatric exome and whole genome sequencing (ES/WGS) can provide parents with a wide range of genetic information about their children. Adoptive parents may especially benefit from ES/WGS results because they often lack information about their children's family health history. There are no data on adoptive parent perspectives about pediatric ES/WGS information, including what kinds of results they want, potential benefits and risks to their families, and how to respect the developing and future autonomy of their adoptive children. We conducted four focus groups with parents of adopted children (n=26) about WGS. Participants were predominantly female (73%) and European-American (77%), with a mean age of 49 years old (range 35-66). The majority of parents (65%) adopted at least one of their children internationally and 42% had two or more adopted children. Adoptive parents viewed WGS results as potentially beneficial for providing unknown medical information about their children; specifically, information that parents often know about their biological children such as family history of disease. Parents hoped that genetic information could help guide prevention, treatment and management of existing health concerns and diagnoses for their children. Genetic information about ancestry was important to many adoptive parents, particularly those whose children were adopted internationally, to provide a greater sense of identity in the absence of information about family and cultural origins. In fact, several parents described using and receiving targeted marketing from direct-to-consumer companies for genetic ancestry testing of their adopted children. Many parents cited concerns about their children's privacy, including potentially increased privacy risks for adopted children. Most parents wanted to defer disclosure of genetic information about late onset disease and reproductive risks in order to respect their children's future autonomy. These results suggest that adoptive parents want to receive WGS results in order to learn ancestry and medical information that biological parents already have, and that tailored policies and tools may be needed for offering and returning ES/WGS results in this population.

2458T

Human genetic researchers and biobank leaders support the return of high-risk, actionable research findings but face numerous impediments to responsible return of results. *R. Dvoskin[1], J. Bollinger[1], K. Kreger[1], A.A. Padon[1], K.L. Edwards[2], D. Kaufman[1].* 1) Genetics and Public Policy Center, Berman Institute of Bioethics, Johns Hopkins University, Washington, DC; 2) University of Washington, School of Public Health, Department of Epidemiology, Seattle, WA.

Background: Biobanks and genetic cohort studies are important tools in the search for genetic and environmental factors underlying a broad range of diseases. The data generated by these resources may include genetic information of potential significance to study participants. Whether, and which, individual research results should be returned are under heated debate. As policies and recommendations evolve, it is useful to consider the opinions and practices of the research and biobank communities. **Methods**: 59 U.S.-based genetic researchers and biobank leaders were interviewed about human subjects issues including the return of research results. Semi-structured interviews were transcribed, coded, and analyzed for themes. Reasons for and against returning results were summarized. **Results**: A majority of interviewees were not opposed in principle to the idea of returning some medically useful research results. Interviewees raised a number of arguments against their return, however, most of which fell into five categories: practical and logistical reasons; the uncertain quality and meaning of the data; excessive cost and personnel burdens; the risk of doing more harm than good; and the lack of guidance regarding researcher and biobank obligations. Two common reasons for returning results were a perceived duty to disclose information that could benefit someone's health, and participants' right to their own information. Additional reasons included participants' desire for results, improving trust in the research community, and rewarding participation. Many believed that any results returned should be actionable, validated, and indicate a high risk for disease. Researchers' opinions and decisions about returning results are also dependent on the relationship between an investigator and the research participants and whether participants are clinical patients or healthy volunteers. **Conclusions**: Concerns about uncertain or unconfirmed results and ambiguity about researchers' obligations may influence decisions to return results. In addition to providing guidance on what results to return and when, recommendations should consider the importance of contextual factors and address the practical, financial, and ethical challenges to disclosing research results. Researchers' support for the return only of well-understood genetic findings and for transparency about the quality and meaning of research data agree with public preferences observed in some previous studies.

2459W

Focus group exploration of return of research results. *W.A. Faucett[1], S.N. Fetterolf[2], L.H. Rogers[1], S.A. Martin[1], M.S. Williams[1], D.J. Carey[2].* 1) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 2) Geisinger Health System, Danville, PA.

A goal of the eMerge project was to develop methods to return to biobank participants clinically confirmed (CLIA) research results. Geisinger Health System currently has three active biobanks with 43,000+ participants including MyCode, a general population biobank; AAA, a biobank for abdominal aortic aneurysm families; and NASH, a biobank for bariatric surgery patients. Biobank consents allow for re-contact but none of the biobank consents currently allow research results to be placed in the electronic medical record. Geisinger is considering a model in which the expectation would be to return research results. The project goal was to determine the best approaches to return results. Biobank participants were contacted via opt-in letters to participate in focus groups held in their local clinic offices. Six patient focus groups in rural Pennsylvania towns have been held since November 2012 with a total of 93 participants (57% female, 43% male). Of these participants, most were 61-70 years old (~42%; >71: ~22%; 51-60: ~23%; 41-50: ~8%; 18-40: ~5%). Educational backgrounds varied(college degrees: ~33%; beyond high school: 28%; high school diploma/GED: ~34%; less than high school: 4%). Nearly half of all focus group participants have been Geisinger patients for at least 20 years (49.5%), and ~85% received all or most care from Geisinger. The group discussions included five areas related to results: pharmacogenomics; recessive carriers; increased risks for preventable or treatable diseases (e.g. colon cancer); increased risk for diseases that cannot be prevented or treated (e.g. Alzheimer's disease); and variants of uncertain significance (VUS). The overall consensus of focus group participants is that they would want to have all of their research results returned no matter the severity of the disease or clinical impact. Most felt they would want to know about a VUS. The vast majority of participants wanted the results returned to them and to their healthcare provider at the same time. They stated that educational materials should be developed for participants and healthcare providers as results are returned. Most participants approved of the results being documented in their Electronic Medical Records. Results of the participant focus groups will be used to develop surveys for all biobank participants on the return of research results and focus groups consisting of Geisinger healthcare providers who may potentially be returning these research results.

2460T

Pleiotropy and the potential return of (additional) incidental information with incidental result return. *S.M. Fullerton[1], J.M. Kocarnik[2].* 1) Bioethics and Humanities, University of Washington, Seattle, WA; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA.

Introduction: Recent discussion regarding the return of incidental findings generated in the course of whole genome sequencing has focused on returning only information that meets stringent thresholds of clinical validity and utility. Most recently, an American College of Medical Genetics and Genomics (ACMG) statement recommended that variants in 57 genes associated with 24 phenotypes are sufficiently important that they should be sought out and reported when any clinical sequencing is performed (Green et al. 2013). A potential problem with such recommendations, however, is that they do not address the issue of pleiotropy, where a single gene is associated with multiple phenotypes that may differ in their appropriateness for return. For example, one genotype-phenotype relationship may be clinically actionable while another might be of unproven validity. Since the genetic information is the same, returning information on the former also returns information on the latter. To estimate the potential extent of this issue, we sought to evaluate how many of the genes in the ACMG recommendation list might be associated with additional phenotypes. **Methods:** We searched the Online Mendelian Inheritance in Man catalog, a publicly accessible database of human genes and genetic disorders (OMIM.org). We performed a search on each of the 57 MIM genes listed by the 2013 ACMG recommendations, and recorded how many and what kind of MIM phenotypes were noted as associated with variants in each gene. **Results:** As of 5/31/2013, the majority (>75%) of these genes were linked to more than one MIM phenotype, with a few genes associated with greater than 10 phenotypes. However, the ACMG recommendations typically only identified one of these phenotypes as the rationale to search out and report variants in these genes as incidental findings. **Conclusion:** Most of the genes in the ACMG list of recommendations have known pleiotropic relationships with phenotypes beyond those listed, suggesting that additional information about genetic associations may be conveyed regardless of clinical utility. No guidance is provided for how to deal with this extraneous yet readily-obtainable information. Pleiotropy appears to be a pervasive issue that has been under-considered in current incidental findings guidelines. Future guidelines will need to consider the potential impact of such pleiotropic relationships on whether, and if so how best, to return individual genetic results.

2461W

Reasons associated with different levels of interest in receiving individual genetic research results: a public survey. *L. Jamal[1,2], J. Bollinger[1], R. Dvoskin[1], D. Kaufman[1].* 1) Genetics and Public Policy Center, Johns Hopkins University, Washington D.C; 2) Kennedy Krieger Institute, Baltimore, MD.

Objectives: To a) differentiate between the individual research results (IRRs) that participants would like to receive back from genomic research study and those they would be merely satisfied with, and b) determine the relative importance of clinical and personal utility (reasons why) for different demographic groups. **Background:** Despite guidelines for reporting IRRs to participants in genomic studies, whether and how to return them remains a matter of researcher and institutional review board (IRB) discretion. Few researchers have practical experience selecting results to return and deciding how to do so with limited time and resources. **Methods:** An online survey of a random national sample of 1,474 U.S. adults, fielded in both English and Spanish, measured public attitudes about receiving and using individual research results collected or discovered as part of a proposed national cohort study. **Results:** Given a choice, 55% of respondents wanted all of their individual research results, while 33% preferred only results pertaining to preventable or treatable ('actionable') conditions and 12% expressed no desire to receive IRRs. The same fraction wanting IRRs was observed across all demographic and racial groups. The most important reason participants wanted to receive their IRRs was clinical utility, but majorities of those wanting some and all results saw value in sharing the information with family members and gathering information on implicated diseases. Half of respondents who wanted all their results said so 'because they belong to' them, compared to 25% of those preferring only actionable information ($p = 0.05$). The most common reasons people would not want any results were lack of interest and a perception that returning results was not the purpose of research. Few significant demographic differences in attitudes were noted. **Conclusions:** Nearly half (45%) of the public does not want to receive all research results, given a choice. Participants who desire IRRs are primarily motivated by an interest in information with clinical utility. Personal utility was also an important factor, and an acute sense of fairness seems to be a key reason why some individuals want all results instead of just actionable ones.

User satisfaction with a web-based tool for self-guided management of results from ES/WGS. *S.M. Jamal[1], J. Yu[1], J. Crouch[2], A.A. Lemke[2], M.J. McMillin[1], A.G. Shankar[1], K.M. Dent[3], M.J. Bamshad[1,4,5], H.K. Tabor[1,2].* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Seattle Children's Research Institute, Seattle, WA; 3) Department of Pediatrics, University of Utah, Salt Lake City, UT; 4) Seattle Children's Hospital; 5) Department of Genome Sciences, University of Washington, Seattle, WA.

A major obstacle to taking full advantage of exome and genome sequencing (ES/WGS) data in a clinical setting is how to effectively manage incidental or secondary results. Use of traditional approaches (e.g., face-to-face interview with a provider) for each result that could be offered for return is simply untenable. Over the past several years, we have developed a return of result strategy based self-guided management of results using a web-based tool called My46 (http://www.my46.org). My46 enables users to set preferences for which results they want to receive, to change their preferences over time, to review standardized information about each trait for which a result is available, and to receive each result privately and conveniently. The usability of such a tool partly depends on whether individuals can successfully complete each task needed to manage results return and whether they are comfortable doing so. We tested the usability and satisfaction of setting ES/WGS result preferences with My46 in adults (n=47) with Mendelian or complex diseases enrolled in ES projects. Participants were primarily European American (94%), female (83%), and 26 to 81 years old (mean=44). The mean composite scores for a modified Computer System Usability Questionnaire were highly positive, on a scale of 1 to 5 with 5 being most favorable: usefulness=4.68 (3.68-5.00), information quality=4.58 (3.14-5.00) and interface quality=4.46 (3.00-5.00), with an overall score of 4.61 (3.68-5.00). The majority of participants (96%) indicated it was simple to use My46, 91% found the information provided in My46 easy to understand, and 81% indicated My46 had all the functions and capabilities they expected it to have. Most participants (75%) indicated they were satisfied with the use of My46 as a way to select preferences, thought My46 had the right kind of information to aid in decision making, and would recommend My46 to someone else for managing genetic results. A subset of individuals (n=21) were interviewed after setting their preferences, and all reported that the site was easy to use, simple, thorough and user-friendly. These individuals valued that setting their preferences using My46 was fast and efficient, though some expressed concern that use of confirmation 'pop-ups' was unnecessary. These results suggest that usability and satisfaction with My46 are high, and underscore the need for further development and testing of web-based approaches for ES/WGS results management.

The Industry Pharmacogenomics Working Group (I-PWG) Perspective on Providing Individual Research Results and Incidental Findings to Clinical Trial Research Participants. *S.K. Prucka[1], L.J. Arnold[2], J.E. Brandt[1], S. Gilardi[3], L.C. Harty[2], F. Hong[4], J.S. Malia[5], D.J. Pulford[6].* 1) Tailored Therapeutics Genetics, Eli Lilly and Company, Indianapolis, IN; 2) Pfizer Worldwide Inc., 445 Eastern Point Road, Mail Stop 8260-2143, Groton, CT; 3) Bristol Myers Squibb - Hopewell, Attn: Terrye DelMonte, Clinical Genetics Operations, Biomarker Technologies, Blg 3A-209A, 311 Pennington-Rocky Hill Rd, Pennington, NJ; 4) Amgen Inc., One Amgen Center Drive, M/S 38-3-B, Thousand Oaks, CA; 5) Purdue Pharma LP, One Stamford Forum, Stamford, CT; 6) GlaxoSmithKline R&D, Medicines Research Centre, Gunnels Wood Road, Stevenage, Hertfordshire, SG1 2NY, United Kingdom.

The pharmaceutical industry has not been a prominent figure in recent discussions regarding the return of individual genetic research results and incidental findings. The Industry Pharmacogenomics Working Group (I-PWG) however, is well-positioned to comment on issues related to providing genetic research results that are generated from clinical trials. The I-PWG consists of representatives from 20 pharmaceutical companies engaged in pharmacogenomics research as part of product development. Industry-sponsored genetic research is typically directed at understanding the safety and efficacy of the therapeutic compound under development and researching the genetics of disease to better define subgroups that are the most likely to receive a benefit. This research progresses alongside the development of a therapeutic compound from pre-clinical work through clinical trials and often continues with post-marketing studies after product is launched on the market. The majority of this research is exploratory in nature and many years may pass before the clinical implications can be confirmed and validated. Without clear clinical relevance, the benefit of providing genetic research results to participants is unclear. Further, given the exploratory nature of this research, many of the assays employed may not yet have been fully validated or meet the local requirements for sharing with research participants. When results are provided, the Investigator at each clinical trial site is responsible for delivering this information. Investigators' varying levels of genetic literacy can make it challenging to communicate the information required for a thorough understanding of both the research opportunity and associated results, especially given that the focus of the Investigator/patient relationship is typically on the overall trial and not pharmacogenomic research opportunities. In cases where the research is conducted many years after the clinical trial is closed, communicating results may be difficult given the challenges of maintaining contact with Investigators and research participants (particularly for global trials). Here we plan to discuss the challenges and opportunities with the goal of contributing to the development of criteria to assess which genetic results are best suited to provide research participants, adding to this discussion the need to consider the feasibility of implementing these criteria when working in a global clinical trial environment.

2464T

Interest in different types of individual genome sequencing results among younger breast cancer patients. *M.R. Ray[1], J. Ivanovich[1], B.B. Biesecker[2], L.G. Dressler[3], R. Dresser[4], M.S. Goodman[1], P.J. Goodfellow[5], K.A. Kaphingst[1].* 1) Division of Public Health Sciences, Washington University School of Medicine, Saint Louis, MO; 2) Social and Behavioral Research Branch, National Human Genome Research Institute, Bethesda, MD; 3) Mission HealthCare, Asheville, NC; 4) Washington University School of Law, Saint Louis, MO; 5) College of Medicine, Ohio State University, Columbus, OH.

Background: Critical communication challenges arise if individual results from genome sequencing are returned. Patients diagnosed with breast cancer at a young age are a key population for early application of genome sequencing to identify susceptibility alleles and variants affecting treatment response. Empirical data are needed regarding what genome sequencing results are of interest to these patients to inform ongoing policy discussions for return of results. Methods: We conducted 48 semi-structured individual interviews with women diagnosed with breast cancer at age 40 or younger to investigate their interest in different types of genome sequencing results. We stratified recruitment by family history of breast cancer and BRCA1/2 mutation status to examine differences across subgroups. Interviews focused on interest in return of individual results for six types of gene variants: affect risk for a preventable disease; affect treatment response; uncertain clinical significance; affect risk for a disease that cannot be prevented or treated; carrier status; and ancestry or physical traits. Descriptive statistics were used to examine types of variants of greatest and least interest. Qualitative thematic analysis of interview transcripts was conducted using NVivo. Results: Participants identified variants that affect risk for a preventable disease (81%) or affect treatment response (17%) as those of greatest interest, often due to clinical actionability: '... you can delay the onset of any real symptoms or issues...it's always gonna come back to quality of life.' Participants had the least interest in variants without a health meaning (56%) or that affect risk for an unpreventable or untreatable disease (27%). Lack of interest in the latter type often related to quality of life: 'If there's nothing I can do about it, I'd rather live as happy a life as possible.' Participants differed in their interest in variants of uncertain clinical significance, with some suggesting the information might have meaning in the future, while others thought it could cause unnecessary worry. Conclusions: Participants had the greatest interest in clinically actionable results; results that might negatively impact quality of life were of less interest. However, interest in different types of results, and perceptions of clinical and personal utility, varied. Policies for return of individual genome sequencing results should take into account differences in patient preferences.

Ethically Optimized Consents for Pediatric Whole Genome Sequencing. *R. Zlotnik Shaul[1, 2, 3], M.S. Meyn[2, 4, 8, 9, 10], M. Szego[3, 5, 6, 7], R. Hayeems[8], C. Shuman[8, 9, 10], N. Monfared[4], S. Bowdin[4, 5, 8, 10].* 1) Bioethics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Dept of Paediatrics, University of Toronto, Toronto, ON, Canada; 3) Joint Centre for Bioethics, University of Toronto, Toronto, ON, Canada; 4) Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 5) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 6) McLaughlin Centre, University of Toronto, Toronto, ON, Canada; 7) Centre for Clinical Ethics: Providence Healthcare, St. Joseph's Health Centre and St. Michael's Hospital: Toronto, ON, Canada; 8) Division of Clinical and Metabolic Genetics, Dept of Paediatrics, The Hospital for Sick Children; 9) Program in Genetics & Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 10) Dept of Molecular Genetics, University of Toronto, ON, Canada.

Whole genome sequencing (WGS) is a transformative technology for gene discovery and clinical care, but the clinical use of WGS presents major challenges to existing ethical frameworks. Most agree that medically actionable genomic variants (MAVs) should be disclosed to research participants/parents, but there is no consensus on what constitutes a MAV or what obligation researchers and clinicians have to look for and report MAVs that are incidental to the research or diagnosis at hand. For WGS of children decision-making is especially complex, since clinically relevant variants identified in a child's genome may have health implications for relatives. There is a paucity of published data examining the perceived benefits and risks of WGS from the perspectives of patients/parents and health care providers. An examination of 43 pediatric research consent forms from across Canada highlighted the variability and lack of national/international guidelines on how incidental findings should be treated. Developing a consistent, ethically defensible, innovative and inquiry-based approach to informed consent and return of WGS results in the pediatric context is essential. The Hospital for Sick Children's Genome Clinic is a multidisciplinary research project for which we have designed a novel consent process for pediatric WGS. A morally innovative feature of the consent is the choice given to parents and/or capable patients about the disclosure of MAVs associated with adult-onset disorders and carrier status. Past genetic testing paradigms have generally not favored disclosing this information to parents since testing/disclosure was not considered to be in the best interest of the child. Aligned with emerging guidelines we have interpreted best interests more broadly: the presence of an incidental MAV (e.g. BRCA 1 or 2) in the patient has potential health implications for the parent and knowledge about parental disease-risks, has implications for the best interests of the child. Additional features of our consent process will be described as part of this presentation. To help evaluate our consent, we are using structured interviews and qualitative analysis to examine participant/parent perceptions/expectations regarding WGS and the consent process and clinician expectations/challenges regarding WGS. Our inquiry is the first to examine these issues in a Canadian pediatric population and will be used to develop evidence-based standards for informed consent for WGS.

Evaluation of ACMG Recommended Incidental Findings in Clinical Whole Exome Sequencing. *E. Haverfield[1], A. Daly[1], A. Fuller[1], N. Smaoui[1], K. Retterer[1], P. Vitazka[1], G. Richard[1], W. Chung[2], S. Bale[1].* 1) GeneDx, Inc., Gaithersburg, MD; 2) Columbia University Medical Center, New York, NY.

Whole exome sequencing (WES) has the potential to identify incidental findings, or genetic variants that can result in medical implications unrelated to the primary indication for testing. The American College of Medical Genetics and Genomics (ACMG) recently recommended reporting incidental findings in 57 genes for individuals undergoing WES. These 57 genes are primarily associated with an increased risk for cancer or cardiac disease. The ACMG estimated that ~ 1% of patients undergoing WES will have reportable incidental findings. To evaluate this, the frequency of incidental findings in these 57 genes was examined in 50 de-identified probands who had WES and did not have cardiac disease or cancer as a test indication. The 57 genes were assessed for sequence changes present at ≤2% frequency in the 1000 Genomes database, and further reviewed for variant frequency in sub-populations, evidence for pathogenicity in the literature, and consistency with the expected mutation spectrum of the gene. The initial screen yielded 345 variants, of which 318 variants were eliminated based on high frequency in at least one ethnic sub-population, leaving 27 variants requiring further assessment. Of those, ten mutations (one in each of 10 individuals) met the criteria outlined by the ACMG to be reportable as known pathogenic (KP) or expected pathogenic (EP), demonstrating that 20% of WES cases have a reportable incidental finding. Of the 10 mutations, two were in cancer-related genes, six in cardiac-related genes and one mutation each was identified in a gene associated with hypercholesterolemia and malignant hyperthermia. Identification of incidental findings in 20% of patients undergoing WES has significant implications for ordering clinicians, genetic counselors and the clinical laboratories providing testing. Clinicians who return incidental findings to probands and families have an increased responsibility for pre and post-test counseling as well as medical follow-up, while clinical laboratories must integrate additional bioinformatic and analytic resources into these evaluations. The costs associated with the additional efforts could be substantial. Going forward, it will be important to continue to evaluate the impact of reporting incidental findings on patients and providers.

Giving and receiving: comparing parents', paediatricians' and genetic health professionals' opinions about uncertain chromosomal microarray results. *E. Turbitt[1,2], D. Amor[1,2], J. Halliday[1,2], S. Metcalfe[1,2].* 1) Murdoch Childrens Research Institute, Melbourne, Australia; 2) The University of Melbourne, Melbourne, Australia.

Chromosomal microarray (CMA) testing for childhood investigations has been on the Australian Medical Benefits Schedule (the federal healthcare funding scheme) since 2010. This has enabled a range of clinicians to order the test, including non-specialists. Although CMAs improve diagnostic yields, they also increase the detection of variants of uncertain clinical significance. The opinions of parents, paediatricians and genetic health professionals regarding CMA result disclosure in a clinical setting have not been documented. Our aim was to investigate and compare the perspectives of these three groups.

Following 15 qualitative interviews with key informants, a questionnaire was designed and piloted with 11 parents. Recruitment of parents was then undertaken at community-based immunisation sessions, and recruitment of paediatricians and genetic health professionals was undertaken using email invitation via listservs.

Responses were received from 147 parents, 154 paediatricians and 52 genetic health professionals. Interim analysis indicates all health professionals preferred to disclose all CMA results, regardless of level of certainty relating to clinical significance. At most, 75% of parents reported definitely wanting to receive all result types, with the remainder being unsure (Kruskal-Wallis:p<0.001). Despite this widespread preference to disclose uncertain results, health professionals reported experiencing difficulty explaining them to parents. Parents perceived uncertain results as having less practical value (e.g. access to services/treatment) and predicted these results would cause more anxiety than a certain result.

This study offers novel insight into the opinions of parents and health professionals about the disclosure of uncertain CMA results in Australia. Results demonstrate a degree of discordance between health professionals and consumers, which should be considered in development of optimal national guidelines for reporting genomic information.

2468T

Development of a decision aid for the selection of incidental genome sequencing results. *Y. Bombard[1,2,3], K. Schrader[1], E. Glogowski[1], M. Salerno[1], S. Patil[2], M. Massie[4], R. Rau-Murthy[1], M. Corines[1], C. Manschreck[1], J. Vijai[6], Z. Stadler[1], S. Lipkin[5], K. Offit[1,5,6], M. Robson[1], (first and second authors have equal contributions).* 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) University of Toronto, Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, Ontario, Canada; 4) Department of Psychiatry and Behavioral Sciences, Memorial Sloan-Kettering Cancer Center, New York, NY; 5) Weill Cornell Medical College, New York NY; 6) Cancer Biology and Genetics Program, Memorial Sloan-Kettering Cancer Center, New York, NY.

Background: Conceptual frameworks have been developed to guide the disclosure of incidental results from whole genome or exome sequencing (WG/ES), however limited tools exist to support patient decision-making about the receipt of large volumes of incidental data. We aimed to: (1) develop and evaluate a decision-aid categorizing incidental WG/ES results and (2) explore perceived utility and decision-making regarding the categories of results. Methods: We developed a decision-aid based on Berg et al's 'binning' scheme. Variants are categorized by their level of actionability and potential for distress. Bin 1 includes variants with established disease prevention or treatment guidelines (as the ACMG recent guidelines); Bin 2 includes clinically valid variants without established interventions and is further divided into 2a,b,c (refer to companion abstract by Schrader for binning methodology); Bin 3 includes carrier results; Bin 4 contains variants of unknown significance. We are pre-testing the decision-aid through interviews and focus groups with a convenience sample (n≈40) recruited from hospital waiting rooms. The decisional conflict scale assesses satisfaction and effective decision-making. Data analysis includes qualitative content analysis and descriptive statistics. Results: Preliminary results demonstrate wide variation in selection and perceived utility of the bins. Participants favored Bin 1 because results were actionable. They perceived Bin 2a unlikely to have major health/lifestyle impact. Bin 2b was difficult to understand because it consists of a heterogeneous group of variants (carrier, diagnostic and progressive results). Progressive diseases were perceived as more distressing, precluding selection of Bin 2b. Selection of Bin 2a and 2c was driven by motivations to employ risk-reducing behaviors and inform life plans. Selection of Bin 3 varied by attitudes towards reproductive intervention. Participants had mixed views about sharing results with relatives, doctors and among researchers. Conclusion: Preliminary results suggest that this decision-aid can foster informed decision-making, which involved trade-offs between potential distress with perceived clinical or lifestyle benefits, or informing life-plans. However perceptions of utility and 'distressing results' may diverge from clinical definitions and expectations. Future work will evaluate decisional-conflict and potential re-conceptualization of Bin 2.

2469W

Actionable incidental findings in the 1000 Genomes dataset.
E. Olfson[1], C.E. Cottrell[2], N.O. Davidson[3], N.O. Stitziel[4,5], L. Chen[1], S. Hartz[1], S. Koul[2], R. Nagarajan[2,6], N.L. Saccone[6], L.J. Bierut[1]. 1) Department of Psychiatry, Washington University School of Medicine, St Louis, MO; 2) Department of Pathology and Immunology, Washington University School of Medicine, St Louis, MO; 3) Division of Gastroenterology, Department of Medicine, Washington University School of Medicine, St Louis, MO; 4) Cardiovascular Division, Department of Medicine, Washington University School of Medicine, St Louis, MO; 5) Division of Statistical Genomics, Washington University School of Medicine, St Louis, MO; 6) Department of Genetics, Washington University School of Medicine, St Louis, MO.

Purpose: Advances in genomic sequencing have increased the likelihood of uncovering incidental findings. The goal of this study was to provide a conservative estimate of the frequency of actionable incidental findings using the 1000 Genomes dataset and to present a multi-stage systematic approach for identifying these findings. Our approach not only focused on diseases that several specialists agree should be returned as incidental findings in clinical sequencing studies, but also incorporated literature review and expert opinion to provide a lower bound estimate of the prevalence of incidental findings. **Methods:** Candidate single nucleotide variants in 17 genes associated with 11 dominant actionable conditions were extracted from the 1000 Genomes Browser. These variants were filtered using the Human Gene Mutation Database and defined parameters, appraised through literature review, and examined by a clinical laboratory specialist and expert physician. Only variants that the clinical specialists agreed were pathogenic were identified as incidental findings. **Results:** From the 1000 Genomes Browser, 22 162 single nucleotide variants were extracted from the 17 genes, and filtering led to 119 candidate variants. Literature review refined this number to 11 variants, and clinical specialists agreed that 2 were likely pathogenic: *LDLR* p.Trp4* associated with familial hypercholesterolemia and *KCNH2* p.Leu552Ser associated with Long QT syndrome. For 3 variants, 2 in *APC* and 1 in *MLH1*, there was discordance between the pathogenicity predictions of the specialists: while the clinical laboratory specialist determined that they were variants of unknown significance or rare polymorphic variants, the expert physician identified these variants as probably pathogenic. **Conclusion:** Among individuals from diverse populations, at least 0.2% carry an actionable pathogenic variant, demonstrating that a non-trivial number of individuals will benefit from incidental finding return. As our knowledge about the medical actionability of diseases, genes, and specific variants evolves, the likelihood of uncovering these findings will increase. The time-consuming process of manual review, coupled with differences in the pathogenicity thresholds of specialists, indicate a need for streamlined classification allowing rapid identification of actionable incidental findings as well as reliable guidelines for variant evaluation to ease the translation of genomics into clinical care.

2470T

Binning framework for a decision aid for the selection of incidental genome sequencing results.
K. Schrader[1], Y. Bombard[1,3,4], E. Glogowski[1], M. Salerno[1], S. Patil[3], M. Massie[5], R. Rau-Murthy[1], M. Corines[1], C. Manschreck[1], J. Vijai[2], Z. Stadler[1], S. Lipkin[6], K. Offit[1,2,6], M. Robson[1], (first and second authors have equal contributions). 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Cancer Biology and Genetics Program, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 4) University of Toronto, Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, ON; 5) Department of Psychiatry and Behavioral Sciences, Memorial Sloan-Kettering Cancer Center, New York, NY; 6) Weill Cornell Medical College, New York, NY.

Trepidation of disclosure of incidental genomic results stems from a perceived difficulty in adequately counseling patients about the broad scope of available findings and implications. To simplify this process, Berg [2011,2013] pioneered the concept of 'binning' incidental results based on medical actionability (Bin1) or, in it's absence, the potential for psychological harm with disclosure (Bin2a-c). We have adapted these bins and propose further modifications to attempt to improve patient understanding and decision-making. Berg's bins acted as a guiding framework for our decision aid, and were adapted by consensus of our working group of medical and cancer geneticists, genetic counselors, and a public health genomics researcher. Adaptations include: adding Bin3, which allows patients to learn healthy carrier status (for diseases on New York State's newborn screening panel) without the rest of Bin2b; moving genes identified as medically actionable by the ACMG [2013] to Bin1, recommending but not mandating Bin1 disclosure; limiting Bin2a SNPs to those used by Coriell Personalized Medicine Collaborative, limiting the number of pharmacogenomic SNPs, and limiting Bin2c to few progressive diseases with which the lay population is generally familiar. Compared to Berg's bins, Bin2b still contains disease genes ineligible for the other bins, and Bin2c contains selected genes with the highest subjective risk for psychological harm. Bin4 still contains uninterpretable data not available for disclosure. Determination of medically actionable genes is an iterative process and concerted efforts have developed frameworks for doing this in a reproducible manner. Determining which genes may cause psychological harm and comprise divisions of Bin2 is decidedly more subjective. Adapted bins are pretested in the decision aid (refer to companion abstract Bombard et al). Preliminary findings suggest patients have difficulty accepting the broad implications of Bin2b, thus we propose remodelling using an alternate framework to separate genes into three inherent divisions 1) Diagnostic: suggesting static, congenital conditions that are potentially diagnosable with further clinical investigation 2) Carrier: with no anticipated phenotype and 3) Predictive: suggesting risk for future disease eg. progressive degenerative disorders. Patient data will guide whether additional parsing (or merging with other bins) may enable patients to make more informed decisions.

2471W

How Interested are Parents in Genome Screening for Their Newborns?

R.C. Green[1,2], S.S. Kalia[1], H.L. Levy[3], I.A. Holm[4], S.E. Waisbren[3,5]. 1) Department of Medicine, Division of Genetics, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Partners Center for Personalized Genetic Medicine, Boston, MA; 3) Division of Genetics, Boston Children's Hospital, Boston, MA; 4) Division of Genetics, Program in Genomics, and the Manton Center for Orphan Diseases Research, Boston Children's Hospital, Boston, MA; 5) Department of Psychiatry, Boston Children's Hospital, Boston, MA.

Background: Parents of newborns are highly stressed while in the hospital after delivery, yet this would be the most efficient time to enroll such parents into empirical studies of newborn genome screening (NGS). Concerns about enrollment at this time include whether discussing this topic would cause parents to question or refuse state-mandated newborn screening (NBS), and whether parental interest in NGS research would be the same if queried several months later, after the post-partum period. Methods: We surveyed parents of healthy neonates on the post-partum unit at Brigham and Women's Hospital about their interest in participating in research where their infant would receive NGS. Parents rated their interest on a 5-point Likert scale from 'not at all interested' to 'extremely interested'. We are currently re-contacting these parents and have so far surveyed 66 parents at 3-6 months after delivery with the same questions. Results: Parents were systematically approached while on the post-partum unit and 87.3% agreed to participate. Among 216 parents queried about their interest in NGS, none questioned or declined state-mandated NBS. Responses were dichotomized to 'not at all' or 'a little' interested in NGS, versus 'somewhat,' 'very,' or 'extremely' interested. In the hospital, 182 (84.3%) parents were at least 'somewhat' interested in NGS, and 101 (46.8%) were 'very' or 'extremely' interested. Level of interest was not significantly associated with parents' age, sex, race, education, income, or number of biological children. Among the 66 parents surveyed again after 3-6 months, 53 (80.3%) were at least 'somewhat interested' in NGS in the hospital vs. 55 (83.3%) at follow-up. However, the intensity of interest declined slightly over time; 32 (48.5%) were 'very' or 'extremely' interested in the hospital vs. 27 (40.9%) at follow-up. At 3-6 months, 58 parents (87.9%) remained equally interested in NGS, while 3 (4.5%) became less interested, and 5 (7.6%) became more interested. Conclusions: These preliminary data suggest that parents of healthy neonates can be surveyed about NGS in the hospital without threatening compliance on conventional NBS. Interest in research that would involve NGS is high among parents of newborns in the hospital, with nearly half reporting that they would be 'very' or 'extremely' interested in such research. Interest in NGS appears to remain high 6 months later, though the intensity of the interest may decline slightly over time.

Psychological responses to genetic risk disclosure among individuals at imminent risk for Alzheimer's disease and their study partners: findings from the REVEAL Study.

K.D. Christensen[1], J.S. Roberts[2], J.H. Karlawish[3], T.O. Obisesan[4], L.B. Waterston[1], L.A. Cupples[5], W.R. Uhlmann[6], E. McCarty Wood[7], R.C. Green[1,8] on behalf of the REVEAL Study Group. 1) Dept Medicine, Div Genetics, Brigham & Women's Hosp/Harvard Med, Boston, MA; 2) Department of Health Behavior & Health Education, University of Michigan School of Public Health, Ann Arbor, MI; 3) Department of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Department of Medicine, Howard University, Washington, DC; 5) Departments of Biostatistics & Epidemiology, Boston University School of Public Health, Boston, MA; 6) Departments of Internal Medicine & Human Genetics, University of Michigan, Ann Arbor, MI; 7) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 8) Partners HealthCare Center for Personalized Genetic Medicine, Boston, MA.

Background: Studies of genetic risk assessments for common disease consistently show that individuals are not adversely affected by results. However, few studies have enrolled populations at imminent risk for disease onset or examined the impact on care partners. **Methods**: The REVEAL Study enrolled patients with mild cognitive impairment (MCI) and their cognitively normal study partners, typically a spouse or adult child. Depending on randomization, genetic counselors disclosed 3-year Alzheimer's disease risk estimates (range: 8-57%) based on age and MCI diagnoses alone or in conjunction with *APOE* genotypes. Primary outcomes included general anxiety, per the State-Trait Anxiety Inventory (STAI) short form; and general depression, per the Geriatric Depression Rating Scale (GDRS). Test-related distress was assessed secondarily using the Impact of Events Scale (IES). Individuals with baseline scores suggesting moderate anxiety or depression were excluded from participation. **Results**: Among 61 patients assessed to date (mean age 72; 46% male; 18% Black), mood scores 6 weeks post-disclosure were well below cutoffs for concern (cutoffs: STAI=17, GDRS=8, IES=26) for both the genotyped group (STAI=11.7, GDRS=1.9, IES=11.4) and control group (STAI=11.9, GDRS=2.7, IES=15.7). Changes from baseline did not differ by randomization arm or genotype. However, IES scores 3-days post-disclosure were greater among ε4-positive patients than control (Δ=5.9, p=.03) and ε4-negative patients (Δ=7.3, p=.01), although differences were not observed at the 6-week follow-up. Among study partners, post-disclosure STAI and GDRS scores were also well below cutoffs for the genotyped group (STAI=12.3, GDRS=1.3, IES=11.4) and control group (STAI=11.6, GDRS=1.6, IES=11.4). Changes from baseline in study partners were not observed by randomization arm, but IES scores of partners of ε4-positive patients were greater than partners of ε4-negative patients 3-days post-disclosure (Δ=8.4, p=.01). Differences in IES scores among study partners were not observed at the 6-week follow-up. **Conclusions**: Genetic risk information about imminent onset of a common disease did not pose significant short-term psychological risks. Test-related distress immediately following disclosure was greater among participants with increased genetic risk and their study partners, but effects were transient. Results correspond with prior work on healthy adults, and extend those findings to potential caregivers.

2473W

The impact of genetic risk disclosure for Alzheimer's disease: Findings from the REVEAL Study APOE ε4 homozygotes. *L.B. Waterston[1], J.H. Karlawish[2], J.S. Roberts[3], C.A. Chen[4], K.D. Christensen[1], R.C. Green[1, 5] for the REVEAL Study Group.* 1) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Department of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Health Behavior & Health Education, University of Michigan School of Public Health, Ann Arbor, MI; 4) Boston University School of Public Health, Boston, MA; 5) Partners Healthcare Center for Personalized Genetic Medicine, Boston, MA.

Background: Prior work has shown that individuals at increased risk for Alzheimer's disease (AD) because they carry at least one copy of the APOE ε4 allele experience greater test-related distress, perceive greater AD susceptibility, and make more changes to health behaviors than ε4 negative (ε4Neg) individuals. Analyses to date have not differentiated between ε4 homozygotes (ε4HM) and ε4 heterozygotes (ε4HT), however. Methods: Cognitively normal adults (mean age 57; 64% female; 84% White, 15% African American; 88% with family history of AD) across three randomized trials learned their APOE genotypes and AD risk estimates (range: 6-77%) based on their genotype, gender, ethnicity, and family history. Primary outcomes measured at 6 weeks, 6 months and one year post-disclosure were symptoms of anxiety, depression, and test-specific distress. Also assessed at one year were perceived AD risk (proportions endorsing 'high' or 'very high'), self-reported behavior changes (diet, exercise, taking medications or vitamins) and overall impact of risk disclosure. Results: Of 648 genotyped participants, 399 were ε4Neg (62%), 221 were ε4HT (34%), and 28 were ε4HM (4%). ε4Neg, ε4HT and ε4HM's did not differ in serial depression or anxiety measures (all $p>0.05$). Test-specific distress was higher among ε4HT and HM's at all time points (all $p<0.0001$), but ε4HT and ε4HM's did not differ on this measure (all $p>0.05$). Differences in percentage of ε4HT and ε4HM's perceiving their AD risk as high were not evident (64% versus 72%; $p>0.05$), but both groups perceived their AD risk as higher than ε4Neg's ($p<0.001$). ε4HM's were more likely than ε4HT's and ε4Neg's to report 12-month changes in diet (61% versus 34% and 27%), exercise (58% versus 30% and 28%) and taking medications or vitamins (58% versus 38% and 27%) (all $p<0.001$). ε4Neg's were more likely than other groups to rate the overall impact as positive (74%, $p<0.001$), but ε4HT's and ε4HM's did not differ in their percentages rating the overall impact as positive (50% vs. 50%). Conclusions: Disclosure of ε4 homozygote genotype was not associated with increased perceived risk of AD, depression, anxiety, test-specific distress, or overall impact ratings compared to being a heterozygote; but it was correlated with greater likelihood of engaging in putative AD risk reducing behaviors. Such findings can inform future efforts to disclose APOE genotype to ε4 homozygotes in research trials, consumer settings or clinical practice.

2474T

A historical overview and a reflection on bioethical and ELSI activities for basic researches in human genetics and genomics in Japan. *N. Yamamoto, K. Kato.* Biomedical Ethics and Public Policy, Graduate School of Medicine, Osaka University, Suita, Osaka, Japan.

Over 20 years have passed since the human genome project started. Including genetic-recombination era, it is more than half a century. Though it may come across as being a short period compared to the history of many scientific disciplines, the world of biology significantly changed with these new genetics and genomics. Furthermore, this new science gave the great impacts to bioethical and ELSI activities that appeared in that almost same period in Japan. We first overview a history of bioethical and ELSI activities, focusing on the following four kinds of activities; the bioethics committees of ministries, the ethics review boards in the institutes, the specialist groups or committees for ELSI in the large-scale research projects, and the bioethicists in the academic sector. From these viewpoints, it was shown that the people or groups have created new ways or changed old ones to respond the requirements conducting the research appropriately. For example, the fundamental rights of the research participants, such as the donor autonomy and privacy protection, became guaranteed in the written research guidelines since around 2000 by the efforts of the ministries bioethics committees. However, comparing these activities and present science and social situations, it was also revealed that there are a few remaining issues that have been considered less, therefore have not been fully introduced in the formal systems, such as the right of the populations, the right of the people other than a direct relationship to the donors of DNA, the long-term storage and reuse of the data, and the ethical status of human genome itself. In addition, we looked back the activities of another category of actors, that is, the scientists engaging basic research in molecular genetics and genomics. Some of the scientists' concerns are different from the ones described above, because their research are not directly associated with newly born issues in bioethics nor ELSI. What they are concerned was more about the governance or the national/societal policy of the science. What we would like to show in this study is that in Japan there are many bioethical and ELSI related activities and they have different beginning and process of development. We believe that we can learn many lessons from these historical analyses for the better design of future ELSI activities in the field of genetic and genomics.

2475W

Result of the bioethics questionnaire survey of Nepali university students on genetic testings. *H. NUMABE[1,2], R. POKHAREL[3].* 1) Department of Genetic Counselling, Graduate School of Humanities and Sciences, Ochanomizu University, Bunkyo-ku, Tokyo, Japan; 2) Department of Paediatrics, Kyoto University Hospital, Kyoto, Japan; 3) Department of Orthopaedics, Institute of Medicine, Tribhuvan University Teaching Hospital, Kathmandu, Nepal.

In Asian countries such as Japan, Korea, and China, genetic testing has been carried out using similar methods with accuracy comparable to western countries. However, the implementation of testing is influenced by various factors such as population policy, economic situation, and the medical system of each government, as well as the bioethical view of each individual. Especially, culture plays a substantial role in genetic medicine and reproductive medicine. It is thus imperative to take cultural influence into consideration when giving genetic counseling and genetic testing to patients and clients in Japan and in the other Asian countries. We made the questionnaire survey of Japanese university students on genetic diagnoses, and reported the result at the ASHG Meeting in 2008. The questionnaire was consist of properties of the student, considerations to spiritual matters, acceptability of an artificial abortion, the time of the beginning of human life, and considerations to various genetic testing. We made the similar questionnaire survey in Nepal in 2012. We make an interim report. In Nepal, 70 medical students (65 Hindu, 2 atheists, 1 Buddhist, 1 Muslim, 1 Jewish person) answered our questionnaires. Fifty students recognized that the human life begins from the fertilization. Acceptances of genetic testing were as follows: Clinical genetic testing 91%, [Postnatal] Predictive Genetic Diagnosis 74%, Genetic Carrier detection 84%, Prenatal diagnosis 82%, Preimplantation genetic diagnosis (PGD) 81%. We also compare the results of Japanese and Nepali.

2476T

Attitudes and concerns of educated scientists undergoing whole exome sequencing. *A. Fiksdal, N. Lindor, K. Johnson, K. Hunt, K. Mensink, J. McCormick.* Mayo Clinic, Rochester, MN.

Background: Next-generation sequencing technologies have advanced rapidly over the past decade, resulting in a dramatic decrease in the cost of whole genome and whole exome sequencing. Although these technologies are quickly being incorporated in the practice of individualized medicine, very little research has been conducted evaluating the process of sequencing from a patient perspective. Methods: Mayo Clinic is currently conducting a study in which 10 educated scientists with no history of a specific disease or medical condition are receiving whole exome sequencing (WES) at no cost. We initially invited 40 individuals to participate in a lottery to offer genetic counseling and testing to 10 participants. Those who declined or did not respond to the invitation were not included in the lottery. Participants attended two genetic counseling sessions prior to sequencing. They also completed three surveys assessing attitudes and experiences related to the WES process before, between, and after the genetic counseling sessions. We analyzed the surveys using standard qualitative methodology. After participants receive their WES results, they will participate in an additional genetic counseling session and focus group. We will also complete interviews with those who were not chosen by the lottery. Results: Participants were generally comfortable with the WES process. Only one participant reported concerns regarding confidentiality of data. The same participant also reported concerns about colleagues learning their genomic information. Additionally, no participants reported being concerned about how they might react to particular genetic information. Participants reported more concerns in the context of how WES may affect their families. In survey 3, 3/10 participants agreed with the statement 'I am concerned about how a family member might react about a particular finding if I were to share it with them.' These participants cited the 'impact on their [family members'] health and psychological state', actionability of results, and specific concerns voiced by family members as factors that influenced their views. Conclusion: Although the majority of our sample did not report significant concerns regarding the WES process, issues surrounding the returning and sharing of results emerged as an area that required careful consideration. Such issues will be examined in greater depth in future surveys and focus groups after participants receive their results.

Parental decisions following prenatal diagnosis of chromosomal abnormalities around Nagoya, Japan. *N. Suzumori[1], K. Kumagai[1], S. Goto[1], A. Nakamura[2], S. Saitoh[1], M. Sugiura-Ogasawara[1].* 1) Nagoya City University, Nagoya, Japan; 2) Chiba University of Commerce, Chiba, Japan.

Indications for amniocentesis at 15-18 weeks of gestation include advanced maternal age, maternal serum screening results, ultrasonographic findings for congenital malformations or markers of aneuploidy, and chromosomal abnormality in a previous pregnancy. Cytogenetic karyotype analysis by amniocentesis is highly accurate as compared to cell free fetal DNA testing, which has become clinically available in a few countries for women at increased risk of fetal aneuploidy. When an abnormal karyotype is identified by prenatal diagnosis, parents are faced with decision options that include termination versus continuation of the pregnancy. Decisions concerning prenatal testing and termination of pregnancy in case of affected fetuses are complex and may be influenced by a variety of factors, such as the country's health system, its abortion laws, as well as social and cultural backgrounds Parental decision-making to terminate or continue a pregnancy was studied after prenatal diagnosis of a chromosome aneuploidy among a sample of patients around Nagoya, Japan. The 1051 amniocentesis cases at 15-18 weeks of gestation were analyzed. The 60 cases of chromosomal anomalies with aneuploidies were diagnosed by conventional cytogenetic analysis. Of the 45 diagnoses of autosomal chromosome aneuploidies, pregnancy was terminated in 93.3%. Of the 15 cases diagnosed with sex chromosome aneuploidy, pregnancy was terminated in 46.7%. The differences of parental decisions with respect to maternal age, gestational week at diagnosis, number of pregnancies per individual and existing number of children were not significant in patients diagnosed with autosomal or sex chromosome aneuploidy. The present study indicates that when diagnosed with a chromosome aneuploidy in which a severe prognosis was expected, most of the couples decided to terminate the pregnancy in Japan.

Parental causal attributions of OCD and implications for genetic counseling: An exploratory study. *H.J. Andrighetti[1], A. Semaka[2], S.E. Stewart[2], C. Shuman[1], D. Chitayat[1], R. Hayeems[1], J.C. Austin[2].* 1) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada.

Introduction: Studies assessing etiological understanding and interest in genetic counseling have been conducted among patients with complex psychiatric illnesses including schizophrenia and bipolar disorder. Obsessive compulsive disorder (OCD) is an anxiety disorder with primarily pediatric onset and well-documented unique impacts on family functioning. Limited research has been done on etiological understanding and the potential role of psychiatric genetic counseling among families affected by OCD. The purpose of this study is to explore parents' etiological understanding of OCD, and the potential value of psychiatric genetic counseling in this population.

Methods: Parents of children diagnosed with OCD were recruited through the BC Children's Hospital OCD Clinic and Translational Research Program. We administered qualitative semi-structured telephone interviews consisting of open-ended questions exploring participants' experiences with their child's OCD, causal attributions of OCD, and perceptions of two genetic counseling scenarios. Interviews were audio-recorded, transcribed, and analyzed thematically using qualitative content analysis and elements of grounded theory.

Results: Interviews with 13 parents of 13 different children with OCD revealed that their experiences with OCD are complicated by the evolution of the condition and treatments over time, stigmatization of child and parents, and significant impacts on the child's life and family functioning. Parental causal attributions for OCD were diverse, but often involved elements of self-blame. Psychiatric genetic counseling was perceived as useful for decreasing parental blame and guilt and empowering parents to make well-informed decisions.

Conclusions: These data provide insight into the education and counseling needs of this population, marking the first step towards provision of effective and comprehensive genetic counseling services for families affected by OCD. These results are similar to findings from research on other complex psychiatric illnesses and can be used to inform future studies and practice guidelines for other anxiety-related and/or pediatric-onset psychiatric disorders.

An exploration of families' experiences regarding a comorbid diagnosis of neurofibromatosis type 1 (NF1) and autism spectrum disorder (ASD) in their child: guiding screening and disclosure practices. *L. Baret[1,2], R. Hayeems[1,2], P. Parkin[1,2], C. Shuman[1,2], M. Carter[1,2], P. Kannu[1,2], D. Chitayat[1,2], A. Shugar[1,2].* 1) The Hospital for Sick Children, Toronto, Ontario, Canada; 2) University of Toronto, Toronto, Ontario, Canada.

Introduction: Recent studies have identified an increased prevalence of autistic symptomatology in the NF1 population. Given these findings, it has been suggested that screening and diagnostic practices for young children with NF1 be expanded to encompass screening for ASD. Little is known about the attitudes of key stakeholders (parents of children with NF1 and ASD) regarding screening implementation.

Objective: We aim to explore the experiences of parents of children diagnosed with both NF1 and ASD and to probe their attitudes towards the potential implementation of early universal ASD screening for children with NF1.

Methods: We conducted a comprehensive retrospective chart review ascertained via the NF1 pediatric database at the Hospital for Sick Children. The chart review identified 22 children from 21 families with clinically confirmed diagnoses of both NF1 and ASD. With informed consent, we conducted 16 open-ended, semi-structured interviews with parents (73% response rate). Transcripts were analyzed for thematic patterns using qualitative content analysis.

Results: Most parents expressed relief after receiving an ASD diagnosis. Different meanings were conferred to the two diagnoses. The ASD diagnosis was perceived to be more closely tied the childs identity, thereby conferring a greater impact on the parental psychosocial construct. The ASD diagnosis had both intrinsic and instrumental value for families as it also allowed them to access appropriate resources. In comparison, the meaning attributed to the NF1 diagnosis was reported as less consequential. Interestingly, perceptions shifted if severe NF1 complications were experienced. Parents acknowledge the challenges associated with potential universal ASD screening; they fear a double label could provoke anxiety and present an additional barrier to adapting to NF1. Yet they almost unanimously support early ASD screening.

Conclusion: Implementing ASD screening for children with NF1 is likely to be beneficial for families if screening guidelines also address the psychosocial and medical impacts of an early comorbid diagnosis.

2480F

Perspectives of Adolescents Regarding their Genetic Counseling Experience: A Qualitative Study. *A. Pichini[1], K. Sappleton[1], M. Kaufman[1], C. Shuman[1], D. Chitayat[1,2], R. Babul-Hirji[1].* 1) Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Prenatal Diagnosis and Medical Genetics, Mount Sinai Hospital, Toronto, Ontario, Canada.

Adolescence is a period of development that involves creating a sense of individuality, self-concept, sexual identity, independence, relationships, personal values and goals. This stage of adjustment can be complicated by having a genetic condition, and genetic counseling can play a crucial role in providing information and support to this adolescent patient population. We sought to investigate the experiences and perspectives of adolescents with a genetic condition regarding their genetic counseling interaction. Information gleaned from this study will contribute to the development of an adolescent-focused framework to enhance the provision of genetic counseling. This study utilized a qualitative exploratory approach, specifically the Interpretive Description methodology. Eleven semi-structured interviews were conducted in person and by telephone, with adolescents diagnosed with a genetic condition who received genetic counseling between the ages of 12 and 18 years at The Hospital for Sick Children. Transcripts were analyzed thematically using qualitative content analysis. Preliminary analysis indicates the following themes: (i) adolescents view genetic counseling as distinctly important for understanding the underlying cause of their condition; (ii) genetic counseling plays a crucial role in helping adolescents appreciate the significance of their clinical management or surveillance; (iii) visual aids, particularly the pedigree, are helpful to conceptualize how the genetic condition segregates in the family; (iv) adolescents are interested in learning about recurrence risks for future children even if family planning is not of immediate relevance; (v) adolescents prefer having parents present during the session, except during discussions about prognosis and life expectancy. To our knowledge, this study is the first to explore the perspectives of adolescents with respect to their genetic counseling experience. These findings can inform emerging genetic counseling approaches unique to this patient population, and facilitate in the transition process from pediatric to adult care within patient and family-centered contexts.

Reproductive genetic counseling - The most suitable timing? -.
N. Takeshita, A. Takashima, Y. Yasuda, T. Adachi, I. Sasaki, K. Yokokawa, M. Manrai, T. Ichinose, A. Ishida, M. Urita, A. Yokoyama, T. Kinoshita. Department Obstetrics & Gynecology, Toho University, Medical Center Sakura Hospital 564-1 Shizu, Sakura, Chiba, Japan 285-8741.

[Introduction] Thorough genetic counseling is essential for preimplantation genetic diagnosis and prenatal diagnosis. However, there are more than a few cases in which the time available for the diagnosis is limited. Here, we discuss and report the importance of timely counseling based on our experiences in two prenatally diagnosed cases. [Case] (1) A 38-year-old unipara. An urgent hysterotomy was performed due to polyhydramnios and non-reassuring fetal status at the previous delivery. The newborn child died at one-day old due to respiratory failure and was diagnosed clinically having congenital myotonic dystrophy. This result made us to suspect the same disease in the mother and the mother was followed up at our department of internal medicine. Two years later, she visited our hospital with a history of secondary amenorrhea and was diagnosed as being pregnant. On learning about her unexpected pregnancy, she was confused, as she had been told that a natural pregnancy would be difficult and she did not wish to have the baby. She was already 15-weeks pregnant. (2) A 31-years old unipara. Her father was diagnosed as having adrenoleukodystrophy and being treated for it. She delivered a girl one and a half years previously. Because she was suspected to be a carrier based on the biochemical findings, she visited our hospital to seek counseling for her next pregnancy. While she and her husband were receiving counseling, her pregnancy was detected. [Results] Because in both cases, both the husband and wife sought a prenatal diagnosis, we set up an appointment for villi collection urgently at another institution and the gene analysis was performed. Prenatal diagnosis could be obtained in both cases. [Conclusion] In reproductive genetic counseling, some explanations about the next pregnancy is provided, however, the understanding usually becomes vague with time. In addition, we should keep in mind that a pregnancy is not always planned. It goes without saying that the independence of the client must be respected in genetic counseling, however, it is also important to establish a continuous communication and support system in reproductive genetic counseling in cases with time limitation.

2482F

Whole exome sequencing: Assessing what patients want to know.
K. Hitch[1], G. Joseph[2], J. Guiltinan[1], J. Kianmahd[3], J. Youngblom[1], A. Blanco[2]. 1) California State University, Stanislaus, Turlock, CA; 2) University of California, San Francisco, San Francisco, CA; 3) University of California, Los Angeles, Los Angeles, CA.

Whole exome sequencing (WES) uses next generation sequencing to provide information on nearly all functional, protein-coding regions in an individual's genome. Given the vast amount of information and incidental findings that can be generated from this technology with potentially significant health implications for patients and their family members, it is imperative to understand the patients' perspectives on genomic sequencing. To explore this topic, semi-structured interviews were conducted with 19 adult patients who consented to WES in the research setting. All participants were previously diagnosed with Lynch syndrome based on high microsatellite instability in their tumors and absence of one or more mismatch repair proteins based on immunohistochemistry results, but received uninformative negative results through traditional molecular testing methods. Nearly all participants believed that the benefits of receiving all possible WES results outweighed the potential risks. The majority of participants conveyed the sentiment that relative to coping with a cancer diagnosis, information generated from WES would be manageable. Participants' experience with Lynch syndrome influenced their notions of genetic determinism, their tolerance for uncertain results, and their family communication plans. Participants preferred to receive WES results in person from a genetic counselor or medical geneticist so that an expert could explain the meaning and implications of the potentially large quantity and range of results. Participants were keen on individual choice and empowerment, as demonstrated by their desire for direct access to WES results and transparency between clinicians and patients. These results underscore the need to study the needs and preferences for return of genomic sequencing results with various populations in order to effectively communicate the possible implications of this new technology and appropriately return results. The opinions of these patients revealed several pretest implications when consenting patients to genomic sequencing. Clinicians should provide direct and clear information about the results patients do or do not have control over choosing to receive. To ensure adequate anticipatory guidance and informed consent, laboratory consent forms should include the differing types of possible WES results and clinicians should divulge to patients the possible implications that could result from receiving WES data in detail.

2483F

Parents' understanding of uncertain chromosomal microarray results: a search for meaning.
L.A. Kiedrowski[1, 2], K.M. Owens[3], B.M. Yashar[2], J.L. Schuette[3]. 1) Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI.

Chromosomal microarray analysis (CMA) is utilized as first-tier testing for unexplained anomalies and developmental delay. This technology has improved diagnosis rates, but results classified as variants of uncertain significance (VUS) challenge both clinicians and parents. We developed a semi-structured telephone interview guide to explore parents' knowledge and interpretation of genetic test results and the impact of results and genetic counseling for CMA VUS. We interviewed parents (n=14) who received genetic counseling for their children's CMA VUS. Interview transcripts were analyzed for cross-cutting themes. Several thematic areas were identified, including comprehension of testing, scientific uncertainty, impact of results, expectations, and patient satisfaction. Participants demonstrated a wide range of recall and personal interpretation regarding whether test results provided a causal explanation for their children's health issues. Participants also maintained contradictory interpretations, i.e. describing the result as an answer but not an explanation for illness, or vice versa. Despite varied interpretation, parents consistently applied meaning by incorporating results into a personal context. Many expressed benefits to having a result, including obtaining further services and personal validation. A wide variety of emotional impacts (e.g. relief, loss, and guilt) were also noted; parents described an adaptation/coping process similar to that which occurs after a positive genetic test result. Recall of terminology, including `VUS' and precise CMA abnormality, was poor. However, the majority demonstrated an understanding of the concept of scientific uncertainty. Evidence of retention of relevant concepts without specific terminology warrants further consideration of the language and content that is truly necessary in genetic counseling for this type of finding. Reassuringly, all participants recalled and were interested in recommended follow-up with the genetics clinic, but had misconceptions as to the specific reasons for such a return visit and what this process entails. These results provide insight into the patient-and-family experience of genetic counseling for uncertain genomic findings. They emphasize the importance of exploring uncertainty in CMA VUS results with parents and highlight a number of areas for potential attention or improvement in the clinical encounter.

2484F

Comparing uptake of testing and psychosocial impact in pregnant and non-pregnant women offered carrier screening for fragile X syndrome.

S. Metcalfe[1,2], M. Martyn[1], J. Emery[3], J. Halliday[1,2], S. Donath[1,2], J. Cohen[4], the FaXeS study team. 1) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Australia; 2) Dept Paediatrics, The University of Melbourne, Melbourne, Australia; 3) Dept General Practice, The University of Western Australia, Perth, Australia; 4) Fragile X Alliance and Centre for Developmental Disability Health Victoria, Monash University, Melbourne, Australia.

Offering population carrier screening to women for FXS identifies those at increased risk of having an affected child, and provides women with information about their own health risk. Concerns have been expressed around educational and counselling difficulties associated with the complex genetic and health information inherent in FXS carrier screening. Hence we examined decision-making, knowledge and attitudes in non-pregnant and pregnant women in the general population offered carrier screening for FXS. Women were approached through general practice, obstetric or ultrasound clinics, and received written information and telephone pre-test counselling with consent. At home, women decided about testing and completed a questionnaire (Q1), which they returned in the mail with their buccal sample as appropriate. A premutation (PM) or grey zone (GZ) result was discussed by telephone and women offered genetic counselling; test-negative results were mailed. All women received a second questionnaire (Q2). A sub-group of women were interviewed either at the time of making the decision or after completing Q2; program evaluation interviews were conducted with clinic staff. 1237 women initially consented: 702 non-pregnant and 535 pregnant women. Excluding 80 women who subsequently withdrew from the study, 85% and 81% returned Q1 while 76% and 70% returned Q2 respectively. 71% non-pregnant and 59% pregnant women chose testing; 0.4% (n=3) received a PM and 2.0% (n=15) a GZ result. Overall, 85% had good knowledge (≥7/10 correct) at Q1. 77% non-pregnant and 68% pregnant women had positive attitudes towards the test. Pregnant women were less depressed and less stressed than non-pregnant women on the Depression Anxiety Stress Scale, with no differences between tested and non-tested. Scores on this scale were in the normal range for all but a few women. Women who chose not to be tested had significantly higher decisional conflict than those who were tested, but scores were in the normal range. The majority of women offered FXS carrier screening had good understanding despite the complex nature of the information, with minimal psychosocial impact. These may be related to the extensive prior field-testing of the written information and the pre-test counselling embedded within this study, important elements for consideration in screening programs. Overall, women supported the availability of being offered screening, although testing before pregnancy was preferred.

2485F

A study in contrasts: The effect of personal genomic testing on perceived risk of melanoma and lung cancer in the PGen Study.

D.A. Carere[1], P. Kraft[1], C.A. Chen[2], L.A. Cupples[3], T. Moreno[4], J. Mountain[5], J.S. Roberts[6], R.C. Green[7], the PGen Study Group. 1) Department of Epidemiology, Harvard School of Public Health, 677 Huntington Avenue, Boston, MA 02115; 2) Data Coordinating Center, Boston University School of Public Health, 801 Massachusetts Avenue, Crosstown 3rd floor, Boston, MA 02118; 3) Department of Biostatistics, Boston University School of Public Health, 801 Massachusetts Avenue, Boston MA 02118; 4) Pathway Genomics Corporation, 4045 Sorrento Valley Blvd., San Diego CA, 92121; 5) 23andMe, Inc. 1390 Shorebird Way, Mountain View, CA 94043; 6) Department of Health Behavior and Health Education, University of Michigan School of Public Health, 1415 Washington Heights, Ann Arbor, MI 48109; 7) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, 41 Avenue Louis Pasteur, Suite 301, Boston, MA 02115.

Background: In the Impact of Personal Genomics (PGen) study, we collaborated with Pathway Genomics and 23andMe to follow new customers for 6 months, linking individual genetic results with longitudinal survey data. Here we evaluate the impact of genetic results on perceived risk (PR) of two cancers with primarily non-genetic risk factors: lung cancer (PR_L) and melanoma (PR_M). We predicted that an elevated risk genetic result would be associated with an increase in PR and that the effect would be modified by baseline PR. Methods: PR was measured on a 5-point scale from *much lower than average* (1) to *much higher than average* (5) at baseline (pre-results) and 6 months post-results. Genetic results were based on common variants from genome-wide association studies and dichotomized as *elevated risk* or *average/low risk.* Linear regression for change in PR (6 months minus baseline) was performed, adjusting for baseline PR, age, sex, education, income, race, and company. Analyses stratified by baseline PR, and interaction terms between baseline PR and genetic result, were evaluated. **Results:** Among 890 participants for whom data on lung cancer risk was available, the proportion rating themselves at above average risk was constant (12.9% at baseline; 11.4% at 6 months). Genetic result was significantly associated with change in PR_L (p<.0001). In those who received an *elevated risk* result, PR_L increased by an average 0.40 points on the 5-point scale; PR_L was unchanged in those with an *average/low risk* result. The effect of genetic result was greater in those who reported an above average risk at baseline than those who did not, but the difference was not significant. Data on melanoma risk was available for 509 participants, and the proportion rating themselves at above average risk for melanoma fell significantly from 48.5% at baseline to 35.2% at 6 months (p<.0001). Genetic result was significantly associated with change in PR_M (p<.0001), with no effect modification by baseline PR_M. PR_M was unchanged in those with an *elevated risk* result, but decreased by an average 0.61 points in those with an *average/low risk* result. **Conclusions:** The effect of genetic result on PR_L and PR_M is significant but modest. For lung cancer, an *elevated risk* result has a greater influence on PR than an *average/low risk* result, while the opposite is true for melanoma. This finding could be explained by consumers' non-genetic risk factor exposure status, and further analysis is warranted.

2486F

Genetic testing for cardiovascular risk can promote better control over controlled risk factors during one year follow up in women. *O.A. Makeeva, V.V. Markova.* Inst of Medical Genetics, Tomsk, Russian Federation.

Aim of the study was to test a hypothesis that genetic testing for disease predisposition can have bigger impact on controlling existing controlled risk factors for future disease than regular medical recommendation on improving life style. **Methods and samples**: To test the hypothesis two samples of relatively healthy overweight young adults were recruited during routine annual medical examination. First sample (N=95), 70% males, mean age 31±6 years, mean body mass index (BMI) 28.3 ±2.9, undergo medical consultation in respect to reduce their body mass as the obesity is a risk factor for a number of diseases, including cardiovascular disease (CVD). Second sample (N=103), 71% males, mean age 31±6, mean body mass index 29.3±3.5 undergo similar recommendation on body mass lowering and were offered to undergo genetic testing in respect to cardiovascular risk assessment. After informed consent obtained, blood samples were withdrawn and genotyping for several well know risk alleles completed. In a month period subjects were invited for genetic consultation and their risk for CVD communicated. In one-year period subjects from both samples were contacted to invite for the follow up visit. The information about their weight and BMI was collected. **Results**: Weight difference (difference between weight measures at the first and follow-up visits) was analyzed for two samples. Both samples reduced their weight to some extent. Mean weight difference for the group without genotyping was (-1.51±0.35) kg and for the group which undergo genetic risk assessment it was (-2.29±0.45) kg which was not significantly different. When men and women were analyzed separately, it was revealed that in women weight reduction was significantly higher in the subgroup underwent genetic testing (-4.22±0.80 vs -0.82±0.55) kg, p=0.0006, while in men it did not differ (-1.50±0.53 vs -1.81±0.43) kg. In subjects who were genetically tested this association did not depend on a risk estimate (high, low, average risk of CVD). Risk estimates distribution did not differ between men and women. **Conclusion**: Women tend to pay more attention for doctor's recommendation in respect to body mass control when this was followed by genetic risk assessment, but risk estimate itself was not the factor, which had influence. Men generally tend to respond to doctor's recommendation for BMI reduction and genetic testing for the future health problems had no impact.

Disease Status and Genetic Testing Among Consumers of Two Personal Genomics Companies: Findings from the PGen Study. *S.F. Meisel[1], J. Wardle[1], J. Mountain[2], T. Moreno[3], S.S. Kalia[4], J.S. Roberts[5], R.C. Green[4] for the PGen Study group.* 1) Health Behaviour Research Centre, University College London, London, United Kingdom; 2) 23andMe, Inc; 3) Pathway Genomics; 4) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School; 5) Department of Health Behavior & Health Education, University of Michigan School of Public Health.

Background: There is a widespread assumption that risk prediction is a major driver of consumer interest in genetic testing. However, an alternative motivation might be to find out whether existing diseases have a genetic etiology; a phenomenon that has not yet been studied. **Methods:**This analysis examined interest in genetic testing in relation to disease status using data from the PGen (Impact of Personal Genomics) Study, a prospective study in collaboration with two genetic testing companies, 23andMe and Pathway Genomics.Baseline data on current diagnoses, demographics, and family history (FH) was used to examine whether having a particular diagnosis predicted interest in receiving a genetic test result for that condition.Analyses were carried out for 12 conditions included in the genetic profile (Arthritis, Asthma, Heart Disease (HD), High Cholesterol, Diabetes, Obesity, Breast Cancer, Skin Cancer, Multiple Sclerosis, Ulcerative Colitis (UC), Macular Degeneration and Bipolar Disorder). For each condition, we tested whether having a diagnosis was associated with being more likely to express `high' interest in receiving genetic test feedback for the same condition. **Results:** 1801 consumers responded to the baseline survey.Their mean age was 48 years (SD 15.6 years), they were predominantly white (89.4%), just over half were women (60.5%), and nearly half were at least college educated (47.1%). About 80% of them had a diagnosis of at least one of the 12 conditions.The proportion of consumers who expressed high interest in the test results ranged from 28% (UC) to 68% (HD). For each condition, logistic regression analysis revealed that after adjusting for demographic and personal variables and the company offering the test, having a diagnosis of that condition was a strongly significant predictor of interest, with odds ratios (OR) ranging from 1.7 (HD) to 17.9 (Bipolar disorder). FH for each condition had ORs from 1.6 (Arthritis) to 2.4 (Breast Cancer), and effects were considerably smaller for age, sex, ethnicity and education, ranging from 0.6 (Arthritis) to 1.7 (Diabetes). **Conclusions:**These findings suggest that some consumers might seek genetic testing not only for its predictive value, but also to explore the etiology of a condition they already had.This motivation has so far not been described in the debate about clinical utility of consumer based genetic testing, but should be considered as an important factor influencing decisions to seek testing.

Pathways to and through genetic testing and cancer aged 18-25. *L.M. Hoskins[1], A. Werner-Lin[2].* 1) Clinical Genetics Branch, National Cancer Institute, National Institutes of Health; 2) School of Social Work, New York University.

Background: Much of the extant literature on the psychosocial aspects of BRCA1/2 mutation testing aggregates mutation carriers of all ages in recruitment, analysis, and interpretation. This strategy does not adequately address the needs of the youngest genetic testing consumers, i.e., women aged 18-25. Despite low absolute cancer risk estimates before age 30, BRCA1/2 mutation-positive women aged 18-25 feel vulnerable to a cancer diagnosis but find themselves in a management quandary because the clinical utility of screening and prevention options are not yet well defined for such young carriers. This presentation aims to demonstrate the unique developmental, relational and policy influences, as well as the challenges, experienced by very young BRCA mutation-positive women as they complete genetic testing and initiate cancer risk management. Methods: This study integrated qualitative data from three independent investigations of BRCA1/2-positive women recruited through cancer risk clinics, hospital-based research centers, and online organizations. We present three representative cases, selected from this larger study of 32 BRCA1/2 mutation-positive women aged 21-25 who tested positive for a BRCA1/2 gene mutation between 2 and 60 months prior to data collection. Findings: The first case describes the maturation of a young woman whose family participated in a national cancer registry. The second addresses a young woman who completed genetic testing after learning that her unaffected father was a mutation carrier. The third case highlights a young woman parentally bereaved in childhood who presented for genetic testing due to intense family pressure. Together, these cases suggest that BRCA1/2-positive women aged 18-25 are challenged to reconcile their burgeoning independence from their families with risk-related support needs. Conclusions: Young women who carry deleterious mutations in BRCA1 and BRCA2 face not only increased short-term and lifetime risk of developing cancer, but also a unique set of challenges related to managing cancer risk during an already demanding phase of life. Loved ones acting in ways meant to care for these young women may inadvertently apply pressure, convoluting family support dynamics and autonomous decision-making. Ongoing support from competent healthcare professionals will enable these young women to remain informed and receive objective counsel about their risk- management decisions.

Moving Up Mastectomies: Emerging Adulthood, Surveillance Fatigue and the Affordable Care Act of 2010. *A. Werner-Lin[1], L. Hoskins[2].* 1) Silver School of Social Work, New York University, New York, NY; 2) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health.

Significance: Increasingly, women aged 18-25 pursue genetic testing to identify a BRCA gene mutation, despite low absolute cancer risk and the lack of evidence-based risk management options during these years. Complicating risk management decisions are a family context that clouds autonomous election of risk management strategies with prolonged grief and uncertainty. Further, the Affordable Care Act created a public policy context that provides insurance coverage to dependents until they turn 26, enabling them to have genetic services covered. Methods: This study integrated qualitative data from three independent investigations of BRCA1/2-positive women recruited through cancer risk clinics, hospital research centers, and online organizations. Data were originally subsumed as a part of each study cohort. 26 participants aged 18-25 at data collection were re-analyzed. In 2011, 6 BRCA1/2 mutation-positive women aged 21-25 were recruited at the meeting of a web-based advocacy group. All 32 women tested positive for a BRCA1/2 gene mutation between 2 and 60 months prior to data collection. Investigators used grounded theory and interpretive description to conduct both within and cross-study analysis. Findings: Women from all three cohorts expressed the need for clarity in recommendations for screening and prevention before age 25, especially with consideration of early and regular exposure to mammography-based radiation and hormones used in birth control. Parents strongly influenced testing decisions; participants frequently used family providers, which complicated issues of privacy and disclosure. Five participants completed risk-reducing bilateral mastectomy or had one scheduled, four of these reported the timing of the procedures was due to their ability to have care covered by a parent's robust insurance policy, and to the desire to minimize the repeated anxiety surrounding regular breast screening, characterized as `surveillance fatigue.' All reported lifestyle change to support healthy living. Implications: While renegotiating independence from their families, BRCA1/2 mutation positive emerging adult women may be in need of expert guidance from, and prolonged engagement with, health and mental health providers who can address their medical needs and unique psychosocial challenges. The Affordable Care Act may inadvertently endorse rapid risk reducing surgery, earlier than anticipated, before adult dependents `age out' of a parent's insurance plan.

High satisfaction and low distress after diagnostic whole-exome sequencing in adults. *N. Hoogerbrugge[1], A.S. Sie[1], W.A.G. Zelst-Stams[1], M.R. Nelen[1], H.G. Yntema[1], L. Spruijt[1], J.A. Veltman[1], I. Feenstra[1], J.B. Prins[2].* 1) Human Genetics, Radboud University Medical Center, Nijmegen, Netherlands; 2) Medical Psychology, Radboud University Medical Center Nijmegen, Netherlands.

Background: Our Human Genetics department is one of the first offering diagnostic two-step whole-exome sequencing (WES). This study aimed to evaluate acceptance, risk perception and distress of WES in adults. **Patients/Methods**: Between August 15th 2011 and June 20th 2012, 213 patients were offered diagnostic WES for colorectal/kidney cancer <40 years (n=51), deafness (n=60), blindness (n=41) or movement disorders (n=61), 177 (83%) accepted. Baseline questionnaires including risk perception and heredity-specific distress (IES) were sent to 141 adults with normal intellectual ability, 111 (79%) were returned. Follow-up after initial WES-results from disease-related gene sets, including satisfaction, is ongoing (currently n=89). **Results**: Baseline responders were diagnosed with: 26% cancer, 27% deafness, 12% blindness, 35% movement disorders. Median age was 49 [22-79], 50% women, 83% with a positive family history. At follow-up, diagnostic suggestive mutations were found in 30%. Nearly all responders (92%) were satisfied with WES. Heredity risk perceptions were similar in baseline and follow-up: believing heredity caused their disease (76% and 69%) and expecting WES to find a genetic cause (49% and 43%). However, significantly fewer patients expected incidental findings (29% versus 18%, p=0.01) and more believed chance likely caused their disease (47% versus 59%, p=0.052). Heredity-specific distress was reported in only 18% versus 17%. **Conclusion**: Acceptance was high in the group offered diagnostic WES after genetic counseling. Adults with normal intellectual ability reported low distress. After initial WES-results, they were highly satisfied. At follow-up heredity risk perceptions were unchanged and fewer patients expected incidental findings, while perceptions of random causality increased.

A Study of Perception of Health Problems in Patients with Prader-Willi Syndrome by Their Caregivers and the Caregivers' Health Care Behaviors. *W. Khunin, P. Tanpowpong, D. Wattanasirichaigoon.* Department of Pediatrics, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Background: Prader-Willi syndrome (PWS) is a rare genetic disorder characterized by infantile hypotonia, lethargy, feeding difficulty, poor weight gain, followed by excessive eating, morbid obesity, obstructive sleep apnea, endocrinopathies, cognitive impairment, and multiple behavioral problems later in life. Treatments include multidisciplinary medical approach as well as behavioral and environmental modification by caregivers at home, which require excessive understanding and patience. The present study is aimed to explore perception of health problems in patients with PWS by their caregivers and the caregivers' health care behaviors. Methods: This is a descriptive study. Eligible subjects were primary caregivers of patients with confirmed PWS. The caregivers answered questionnaire by mail, or by phone or face-to-face interview. The questionnaire questions comprise demographic data of the caregivers and the children, health problems of the patients, and the caregiver's health care behavior which include regularity of medical follow-up and the major reason of loss follow-up; promotion of the children to take part in social activities; registration for disability benefit card; urgent needs for help; impact to the family members by having a child with PWS. We also asked the effect of having patients with PWS onto their family planning, acceptance for prenatal diagnosis, and choosing option for termination of pregnancy if the fetus was found affected prenatally. Results and Conclusion: Thirty-one caregivers participated the study, including 29 mothers and 2 fathers. The age ranges from 2 to 25 years (mean age 9 years). In regards to health problems, the frequency of health problems that caregivers perceived are as followed: obesity 24/31, sleep problem 13/14, short stature 11/14, undescended testes 8/9, obcessive-compulsive 13/29, developmental delay 21/31, regular follow-up 25/31, register for disability benefit card 19/31, having patient with PWS effect their physical health 15/31 and psychosocial/emotional health 29/31. In term of acceptance for prenatal diagnosis (PND) for the next pregnancy, 28/31 accepted PND and 15/28 would op termination of pregnancy. In conclusion, the study add the value of caregivers' perception which will be essential for tailoring patient care and for helping the caregiver to cope with stress and get support for themselves as well.

Is it `just like any other test?': Parents experiences with array cGH in pediatrics. *R. Babul-Hirji, N. Hoang, R. Hayeems, R. Weksberg, C. Shuman.* Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada.

Background: Understanding families' perceptions of the value and complexity of array cGH testing will enhance its delivery in the clinical setting. This information will also serve to inform the implementation of next-generation sequencing in pediatrics. **Methods:** Sixty-nine families who pursued array cGH testing for children with congenital anomalies +/- delay were invited to participate in semi-structured interviews. Fourteen families accepted, 19 declined, and 44 have not responded. Of the 13 interviews conducted to date, parents represented diverse ethnic backgrounds and the majority were well educated. The age of the child at time of array cGH ranged from 3 days to 21 years with an average age of 6.8 years. Six had an uncertain result, 4 had a pathogenic result, and 3 had a benign result. Qualitative analytic techniques were consistent with interpretive description. **Results:** Preliminary analysis indicates the following themes: (i) microarray test is not readily distinguished from other genetic tests; (ii) uncertainty is experienced regardless of result type and responses to this uncertainty include both hope and frustration; (iii) families articulate a personal utility of array results even if they do not perceive specific utility for medical management, access to support services, and family planning. **Conclusion:** Our finding that families do not distinguish among types of genetic tests should be considered in the context of pre-test genetic counseling. While emerging frameworks for genome-based testing emphasize extensive counseling about the nature and possible outcomes of testing, parents appear to focus on the rationale for testing and the potential for additional diagnostic information. Finally, emerging genetic counseling approaches should be informed by our finding that receiving uncertain information does not appear to compound the intrinsic uncertainties associated with caring for a child with a rare or undiagnosed genetic condition, but this merits further research.

2493F

Impact of a brief theory-driven intervention on family communication about cancer family history in a diverse urban clinic. *J. Bodurtha[1], D. Bowen[3], J. Borzelleca[2], R. Corona[2], M. Gyure[2], A. Krist[2], A. Maibauer[2], D. McClish[2], V. Rodriguez[2], J. Quillin[2].* 1) Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD; 2) Virginia Commonwealth University, Richmond, VA; 3) School of Public Health, Boston University, Boston, MA.

It is recognized that the public generally understands the importance of family health history (FH), but its translation from a topic of family discussion to a driver of preventive care is suboptimal. Women, as the family `kinkeepers' are positioned to gather FH and share cancer (CA) prevention information. Family discussion of FH can open doors to genetic understanding and impact patient-centered care that incorporates differing risks based on FH. The KinFact (R01 CA140959) intervention was based in the Coordinated Management of Meaning (communication is a process of coordinating actions with others and making/managing meanings) and Daly's 6-step communication process (Prepare, Ask relatives - How much they know? How much do they want to know? Share information, Respond to feelings, Plan and follow-through). We tested in a randomized trial whether a 20-minute individual CaGene pedigree-informed educational intervention in an urban academic women's health clinic could impact women's subsequent gathering and sharing of CA FH information. Control participants received an informational CA brochure. 490 adult women not selected for CA risk were randomized and followed at 1, 6, and 14 mos. Mean age was 33.4 yrs, 59% were African-American, ~1/3 were uninsured, and 1/3 were pregnant. 74% of women had at least one 1st or 2ndo relative with a CA FH. There were no baseline differences in demographics or + CA FH. In a preliminary analysis more intervention than control women gathered FH information by 14 mos (47% vs. 36%, p=0.036). Controlling for race, the REAL-G genetic literacy measure, and CA FH, the intervention effect remained (p=0.0176). Also more intervention than control women shared CA information with relatives by 14 mos (44% vs. 33%, p=0.0162). Controlling for race, genetic literacy and cancer FH, the intervention effect remained (p= 0.0168). In addition the intervention was equally effective for women who were African-Americans or of other races, as well as of varying genetic literacy or CA FH. The KinFact intervention undertaken in a population at risk for disparities in genetic services may be useful in enhancing family discussions of CA risk information as an important step in promoting patient- and family-centered outcomes and adaptable and scalable in other settings. Educating women to enhance their `kinkeeping' skills may allow them to partner more effectively with their families and providers in discussing CA risk and prevention.

Cancer Genetics Referral Patterns of Physicians and Patient Socio-Demographics. *J. Cohn, W. Blazey, S. Koehler, B. Laurent, V. Chan, M. Jung, D. Tegay, B. Krishnamachari.* NYIT College of Osteopathic Medicine, Old Westbury, NY.

BACKGROUND: Genetic testing can aid with the selection of cancer screening and preventive health services in high-risk patients. Studies demonstrate that physicians are more likely to order genetic testing based on patient inquiry rather than on recommended guidelines. Literature also shows that there are racial disparities in patient use of genetic services that do not appear to be explained by differences in socioeconomic factors. The association between patient use of genetic services and physician behaviors is not well studied. METHODS: The goal of this study was to investigate racial and socio-economic disparities in cancer genetic risk assessment and referral patterns in clinical practice. A survey was administered to physicians (predominantly primary care physicians) evaluating physicians' awareness of the racial and socioeconomic details of their patients, their genetic risk assessment and referral patterns. RESULTS: 139 physicians completed the survey. 26.6% (n=37) of the physicians reported conducting frequent genetic risk assessment and 44.6% (n=62) reported frequently referring patients for genetic services. 13.8% (n=19) reported that at least 25% of their patients were African American, and 26.8% (n= 37) did not know what percentage of their patients were African American. Additionally, 35.8% (n=59) did not know what percentage of their patients were Latino/Hispanic and 34.9% (n=58) did not know what percentage of their patients were classified as living at poverty levels. Those who conducted frequent risk assessment were more likely to state that they would refer a non-English speaker for genetic testing regardless of language barriers (OR=8.34, 95% CI: 1.08,64.69, p<0.05). Those who frequently referred patients for genetic services were more likely to state they would refer a Medicaid patient for genetic testing even when they thought the testing costs would not be covered (OR=2.44 , 95% CI: 1.20, 4.99, p<0.05). CONCLUSIONS: Most research has focused on disparities in genetic services from the perspective of patient preferences and behaviors. In this study, about a third of physicians surveyed reported not knowing the socio-demographic breakdown of their patient populations and may not be conscious that some of their patients come from socio-demographic groups less likely to pursue genetic services on their own. Further research must focus on clinical practice and physician behaviors.

Prenatal chromosome SNP microarray analysis: Genetic counseling issues and dilemmas. *H. Cabral[1], S. Schwartz[1], J. Tepperberg[1], I. Gadi[1], V. Jaswaney[1], R. Burnside[1], K. Phillips[1], E. Keitges[2], H. Risheg[2], V. Potluri[3], R. Pasion[1], B. Rush[1], H. Taylor[1], L. Kline[1], J. Shafer[1], P. Papenhausen[1].* 1) Laboratory Corporation of America, Reseach Triangle Park, NC, United States; 2) LabCorp/Dynacare, Seattle, WA, United States; 3) LabCorp/Dyna-Gene, Houston, TX, United States.

Prenatal microarray analysis has been employed for a number of years, but its popularity has grown exponentially over the past two years, especially with the publication of the NICHD study. For ~2 ½ years we have utilized an Affymetrix SNP microarray platform to study over 8,000 prenatal patients. This work has highlighted some of the counseling issues that have become important with this analysis that is not part of traditional counseling for cytogenetic analysis. This includes the possible detection of uniparental disomy (UPD), suggestion of consanguinity and the detection of small copy number gains and losses and determination as variants of unknown significance (VOUS), pathogenic changes or recessive disorders. Most problematic are the small copy number changes detected and the lack of follow-up by families to better delineate whether these changes are normal variants or pathogenic changes. When abnormalities were detected as VOUS, there was family follow-up in ~ 79.7% of cases, but when the change was thought to be pathogenic, only 57.1% had follow-up. For patients referred because of AMA, anxiety or a positive maternal serum screen, there was 66.7% family follow-up after the detection of an abnormality, but only 59.1% family follow-up in patients ascertained due to ultrasound abnormalities. Patients with suspected UPD had family follow-up 50% of the time while pregnancies with structural chromosomal abnormalities subsequently studied by the array had parental studies in 45% of the cases. This work has highlighted a number of counseling issues including: (1) Need for pre-test counseling delineating the ramifications of the potential findings; (2) Importance for families to indicate the potential relationships among the parents prior to the information being detected in the analysis; (3) Lack of follow-up when potential UPD is identified, especially as >1/3 of suspected cases are not confirmed; (4) Importance of parental follow-up to differentiate VOUS from pathogenic abnormalities when a copy-number change is identified (5) Difficulty involved when normal carrier parents are identified in cases of new microdeletion syndromes associated with autism and other abnormalities; (6) Realization for the need to include microarray technology into Genetic Counseling programs to help prepare new graduates for the complexities involved; and (7) Critical need for trained laboratory genetic counselors to assist in the dissemination of the results to providers.

2496F

Offspring Risk Perceptions: Adolescents and Young Adults with Congenital Heart Disease Agree with their Parents (and both are wrong!). *S.M. Fitzgerald-Butt[1, 4], K.M. Fry[1], A.N. Zaidi[2,4], C.A. Gerhardt[3,4], V. Garg[1,2,4], K.L. McBride[1,4].* 1) Center for Cardiovascular and Pulmonary Research, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) The Heart Center, Nationwide Children's Hospital, Columbus, OH; 3) Center for BioBehavioral Health, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 4) Department of Pediatrics, College of Medicine, The Ohio State University, Columbus, OH.

As individuals with congenital heart disease (CHD) now typically survive into adulthood, the risk of CHD in their offspring is a pertinent concern. Parents are the typical source of medical information through childhood but adolescents and young adults (AYA) must have sufficient knowledge to assume responsibility for their medical care. Therefore, we examined offspring risk perceptions using both categorical (below average, average, above average) and continuous (0-100%) measures, as well as their associations with demographic characteristics, knowledge of heart defect name, CHD diagnosis complexity, CHD perceived severity and general genetic knowledge in AYA and their parents. Participants included 196 AYA, 15-25 years old with structural CHD (mean age=19.0 years, 54% male, 85% Caucasian) and 179 parents (mean age=47 years, 34% male 94% Caucasian) who were recruited from an outpatient cardiology clinic (85% AYA consent rate). All participants were asked the name of their/their child's CHD and completed measures of demographics, genetic knowledge, perceived CHD severity, and perceived risk for an offspring with CHD. CHD complexity was rated as simple, moderate, or great. Categorical perceptions of risk were similar in AYA and parents with only approximately a third of participants endorsing higher risk (34% AYA, 35% parents) while two-thirds endorsed average or lower risk. The perception of being in the high risk category was associated with higher genetic knowledge (p<.001, p=.018) and higher perceived CHD severity in a hypothetical baby (p=.039, p=.001) in both AYA and parents, while Caucasian race (p=.008) and higher median household income (p=.001) were associated in just the AYA and perceived future heart defect severity (p=.016) was associated in just the parents. The ratings of risk on a continuous scale were extremely variable and remarkably high among both the AYA and parents, ranging from 0-100% with a mean of 36.8% (*SD*=24.3%) and 34.1% (*SD*=23.5%), respectively, with a mode of 50% and increased selection of 25% and 75% in both groups. The majority of AYA and parents have an inaccurate categorical risk perception and their continuous risk perception may represent poor numeracy skills and either lack of or inaccurate knowledge of risk. These results highlight the need to provide accurate offspring risk information to both AYA and parents, possibly while also providing additional genetic and numeracy education.

2497F

Emerging changes in genetic counseling and reproductive decision making based on AGG mapping of fragile X carriers. *A.G. Hadd[1], A. Glicksman[2], J. Coppinger[1], N. Ersalesi[2], J. McCarver[1], E. Blatt[1], W.T. Brown[2], J. Skeen[1], G.J. Latham[1], S.L. Nolin[2].* 1) Research and Technology Development, Asuragen, Inc, Austin, TX; 2) NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Fragile X carriers of intermediate and premutation alleles are increasingly identified as the result of broader guidelines for fragile X testing, increased participation in genetic screening and improvements in PCR technology. Consequently, more women are identified who have ambiguous risks for expansion to a full mutation in their offspring. Recent studies have demonstrated that the presence of AGG interruptions correlates with substantially reduced risk for transmitting a full fragile X mutation. We report the risks for full mutation expansions based on AGG analysis from over 2500 samples and 1000 FMR1 transmissions and highlight case studies of how these individualized risks changed genetic counseling and reproductive planning. Logistic regression was used to determine the predictors of allele instability (any change in repeat length) and risk for expansion to a full mutation (>200 CGG repeats). Consistent with prior data, the risk of expansion was associated with the total maternal repeat length and number of interspersed AGGs. A regression curve was used to establish risks and 95% confidence intervals for each repeat length and number of AGGs. In a parallel study, demographic and ordering information, prior fragile X testing results, and post-AGG analysis outcomes were obtained from a subset of 87 consecutive clinical samples received for AGG testing. The majority of providers ordering testing were from Infertility/Reproductive clinics, and indicated that patients use AGG testing to make decisions about IVF.In these 87 samples, the majority of carriers had reduced post-test risks for transmitting full fragile X mutations. Five premutation carriers, however, had increased post-test risk, such as a woman with 68 CGG but no AGG whose a priori risk of expansion to a full mutation increased from approximately 5% based on repeat length alone to approximately 27%. These findings demonstrate the ability to individualize the risk for transmitting a full mutation expansion. The refined risk estimates have implications for genetic counseling and provide important information to patients regarding reproductive decisions. These findings suggest ascertainment of AGG status should be considered as part of the work-up of women of reproductive age who have FMR1 alleles in the 45-90 CGG range.

2498F

A Two-Stage Approach to Genetic Risk Prediction of Breast and Ovarian Cancer. *P.M. Atienza[1,2], J. Chipman[3], K. Hughes[4], C.I. Amos[5], B. Arun[6], G. Parmigiani[3,7], S. Biswas[8].* 1) School of Public Health - Biostatistics Department, University of North Texas Health Science Center, Fort Worth, TX; 2) Alcon Research, Ltd., Fort Worth, TX; 3) Department of Biostatistics and Computational Biology, Dana Farber Cancer Institute, Boston, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Department of Community and Family Medicine, Geisel College of Medicine, Dartmouth College, Hanover, NH; 6) Department of Breast Medical Oncology and Clinical Cancer Genetics, University of Texas M.D. Anderson Cancer Center, Houston, TX; 7) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 8) Department of Mathematical Sciences, University of Texas at Dallas, Richardson, TX.

BRCAPRO is widely used in genetic counseling to identify patients at high risk for hereditary breast or ovarian cancer. However, it requires extensive information on the patient's family history, which is a hindrance for its use in many health care settings. Recently, we proposed simplified versions of BRCAPRO for settings that do not require exhaustive genetic counseling (Breast Cancer Research and Treatment, 139:571-579, 2013). As simpler versions lead to loss in accuracy as compared to BRCAPRO, here we propose a two-stage approach to balance the tradeoff between the amount of information used and the accuracy achieved in assessing the risks. In the first stage, only a limited amount of family history will be analyzed using simpler versions of BRCAPRO. If the risk at this stage is sufficiently high, BRCAPRO, with exhaustive family information, will be used in the second stage to potentially achieve more accurate predictions. We consider four first stage tools: (1) BRCAPROLYTE uses information on relatives up to the second degree but for those affected with breast and/or ovarian cancer only; (2) BRCAPROLYTE-Plus additionally imputes the ages of unaffected relatives based on an external data source; (3) BRCAPROLYTE-Simple imputes the family structure and the ages of unaffected relatives up to the second degree; (4) BRCAPRO-1Degree uses information on only the first-degree affected relatives. The second stage is BRCAPRO for all these tools. We develop a methodology to evaluate the overall performance of a two-stage approach. In particular, we compute sensitivity, specificity, and predictive values, and area under the ROC curve (AUC) of a two-stage approach by considering different combinations of the first and second stage cutoffs. We also evaluate the clinical implications of using a two-stage approach. We use 2,713 probands from seven sites of the Cancer Genetics Network and MD Anderson Cancer Center to evaluate our approach. The proposed two-stage approach has comparable discrimination and calibration as BRCAPRO if the latter is applied to all probands. The overall AUCs are 0.782 (BRCAPROLYTE), 0.783 (BRCAPROLYTE-Plus), 0.782 (BRCAPROLYTE-Simple), and 0.775 (BRCAPRO-1Degree) while the AUC for BRCAPRO is 0.783. Also, the two-stage approach substantially reduces the genetic counseling and testing burden. Thus, we conclude that this approach can be adapted for genetic risk prediction of breast or ovarian cancer on a large scale.

Clinical implications of Variants of Unknown Significance in Chromosomal Microarrays in pregnancies in Israel. *H. Yonath[1, 2], S. Rienstein[1], J. Shamash[1], M. Berkenstadt([1], M. Dicastro[1], S. Eisenberg- Brazilai[1], N. Goldstein[1], M. Frydman[1,2], E. Pras[1,2].* 1) Inst Human Gen, Sheba Med Ctr, Ramat Gan, Israel; 2) Sackler Medical School, Tel-Aviv University, Tel-Avivi, Israel.

Background: One of the main concerns in finding a Variant of Unknown Significance (VOUS) in Chromosomal Microarray (CMA) during pregnancy is the implication it would have on the decision to continue or terminate it. Many couples in Israel have a low tolerance for abnormalities detected during pregnancy and prefer to terminate a pregnancy if an abnormality is found. The goal of this study was to evaluate the decision made by the parents regarding pregnancies in which a VOUS was found, in a large genetic institute in Israel. Methods: 305 prenatal CMA cases were evaluated. The arrays were oligonucleotide specially targeted prenatal arrays (Agilent arrays designed by Medical Genetics Laboratory at Baylor College of Medicine). The significance of the variants was determined based on local guidelines that are very similar to the ones described by Wapner et al (1). Parental CMA were performed in order to determine whether the finding is inherited or de novo. Genetic counseling was provided to the couples. Results: VOUS were found in 36 cases (12%), About half of them were inherited. And the indications were mainly abnormal US and parental concern. None of these pregnancies were terminated. Conclusions: Though there is a high concern that VOUS in CMA would lead to the termination of pregnancy, our results show that if there is no clinical data that suggests that the abnormality is pathogenic, and with the proper genetic counseling, the results do not lead to termination of the pregnancy. A gift to the children - genetic testing at the end of life. *M. Mikhaelian[1], K. Stears[2].* 1) InVitae Corporation, San Francisco, CA; 2) St. Vincent's Hospital, Billings, MT.

INTRODUCTION: Recent publications discuss targeted testing for patients dying of ovarian cancer. Less is known about end of life testing for a patient with a complex history that does not directly point to a specific genetic disorder. Here we present the case of a patient who was seen for genetic counseling in order to learn what genetic mutations she may pass onto her descendants. The patient was consented for and tested for 262 genetic conditions by InVitae Corporation. CASE REPORT: The patient is a 81-year-old terminally ill woman with a history of peripheral vascular disease, pulmonary emboli, stroke, melanoma, breast cancer, calcium deposits, spinal stenosis, hyperlipidemia, hypertension and peripheral artery disease. She has three children. She has a family history of vascular disease, liver disease and cancer in first degree relatives and sudden cardiac death in a second degree relative. She did not have any previous genetic testing. The patient was interested in testing to provide carrier information for her descendants. Using the InVitae Assay, the patient tested for 262 conditions, including cardiac arrhythmias, a 50 gene cancer panel, clotting disorders and multiple other inherited conditions. A homozygous mutation for HFE related hereditary Hemochromatosis was found. The results prompted an additional Hemochromatosis evaluation, which was negative. DISCUSSION: The testing provided relevant information to the patient's children about the risk of Hemochromatosis and the reduced relative risk of inherited arrhythmias, clotting disorders and cancer predisposition. Broad genetic testing can be used as a supplement to DNA banking in a patient with a complex personal and family history. Issues around obtaining informed consent and genetic counseling about results are discussed. A description of the genetic counselor's personal experience with this case is also detailed.

Using the Cleveland Clinic Score to predict for germline *PTEN* mutations in the analytical algorithm of Cowden syndrome: a cost effectiveness study. *J. NGEOW[1], J. Mester[1], C. Eng[1, 2, 3].* 1) Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic, Cleveland, Oh; 2) Taussig Cancer Institute, Cleveland Clinic, Cleveland, Oh; 3) Department Of Genetics And Genome Sciences, And Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, Oh.

Background: Cowden syndrome (CS) patients with germline *PTEN* mutations are at increased risk of benign and malignant features. Our group has developed an online risk calculator, the Cleveland Clinic Score (CC Score) to determine the patient's likelihood of harboring a germline *PTEN* mutation. The higher the CC score, the higher the probability of an underlying germline *PTEN* mutation. CC Score of 10 corresponds to an estimated 3% pathogenic *PTEN* germline mutation risk. Issues that affect clinical testing include sensitivity and specificity of the test, the benefit to the patients and the possible negative ramifications of the results, and the cost. The aim of this study was to assess the cost-effectiveness of using different CC Score thresholds to improve the yield of the diagnostic algorithm of CS. **Methods**: Data from an existing multicenter prospective study in which 3541 probands satisfying relaxed CS clinical criteria were used. *PTEN* mutation scanning, including promoter and large deletion analysis, was performed for all subjects. A decision model was developed to estimate the number of mutation carriers and the incremental costs of alternative case-finding methods for detecting *PTEN* mutation carriers. Strategy 1 involved *PTEN* testing of all individuals meeting relaxed CS clinical criteria. Strategy 2 involved *PTEN* mutation testing only in individuals with CC Scores ≥ 10. Incremental costs of using different CC Score thresholds (15, ≥20) for detecting *PTEN* mutation carriers were additionally evaluated. For each strategy, the number of individuals tested, mutations detected, missed, false positive results were computed. One-way sensitivity analysis was performed to assess robustness of estimations. *Results*: Pathogenic *PTEN* mutations were identified in 250 individuals (7.1%). Sensitivity for detecting *PTEN* mutation carriers using CC Score cutoff of 10 (strategy 2) was 83% and specificity was 71%, missing 49 patients with germline *PTEN* mutations. Average cost per *PTEN* mutation detected using Strategy 1 was $21246 compared with $8455 for Strategy 2. The incremental cost per additional mutation detected using Strategy 1 (all patients tested) was $73714 **Conclusions**: Use of clinical risk calculators such as the CC Score is a cost-effective pre-screening method in the selection of patients for *PTEN* germline analysis when CS is suspected.

2502W

Genetic tests evolution in the Genomic era. Is cost evaluation a relevant factor in health care planning? *D. Coviello[1], C. Lanza[1], A. Seri[1], M. Parodi[1], P. Casale[2], A. Fabbri[2], S. Casati[3], M. Esposto[2].* 1) Laboratory of Human Genetics, E.O. Ospedali Galliera, Genoa, Italy; 2) Management Control Unit, E.O. Ospedali Galliera, Genoa, Italy; 3) UNIAMO, Italian Patient Federation on Rare Diseases, Venice, Italy.

In the last thirty years, medical genetics has improved molecular diagnosis according to the evolution of gene technology, but it is really in the last five years that the new revolution of next generation sequencing (NGS) has open a new window not only on research but also on diagnostic testing. Laboratories performing routine genetic testing started their activity using mainly home made protocols derived from research studies. Now the scientific framework and the laboratory activities are completely changed: the number of known disease genes has increased, automation is applied also to genetic laboratories, certification and accreditation procedures of genetic services are in place, information and awareness among public and all stakeholders are crucial. Purpose of the study: both public National Health systems (NHS) and private laboratories or companies need to deal with costs of genetic testing performed with traditional methodologies or with the new strategies derived by the introduction of NGS. Since it has not been clearly defined how many genomic tests have enough clinical utility, the investigation of their costs could be a way to establish a correct public health policy. Methods used: Activity-based costing (ABC) is a methodology that identifies activities and assigns the cost of each activity taking into account resources to all products and services according to the actual consumption by each. This methodology has been applied to the steps of diagnostic processes of our genetic laboratory. Summary of results: The analysis of the activities has identified a number of indicators to assess the workload for every professional who participates in the process of diagnosis. A second part of the analysis has evaluated the proportion of material used for each activity (test or portion of the process). All these parameters have been incorporated into a software able to split all the lab costs (personnel, material and general costs) for each test provided. This tool can be used in several ways: it can be useful in comparing the costs among different laboratories, in comparing the performance of the same laboratory in subsequent years or to make a priority list of genetic/genomic tests to provide, taking into account costs/benefits data.

2503W

Innovation in genomic medicine to realize the bioeconomy in Mexico. *S. March[1,2], F. Valdez-Ortega[1,2], G. Soberon[2,3], J. Frenk[2,4], G. Jimenez-Sanchez[1,2,4].* 1) Global Biotech Consulting Group (GBC Group), Mexico; 2) Genómica y Bioeconomía AC, Mexico; 3) Mexican Health Foundation, Mexico; 4) Harvard School of Public Health, Boston, MA.

A bioeconomy is one based on the use of research and innovation in the biological sciences to create economic activity and public benefit. It is a large and rapidly growing segment of the world economy that provides substantial public benefit. The growth of the bioeconomy is due in large part to the development of genomics. In Mexico, genomic sciences are vigorously developing with a robust infrastructure and training programs (Jimenez-Sanchez G, el al. Design and implementation of a platform for genomic medicine in Mexico. In: Genomics and health in the developing world.(D Kumar Ed, Oxford University Press, 2012). To stimulate strategic synergies for innovation in genomics, we established Genomica y Bioeconomia, a non-for-profit organization led by experienced leaders in genomics, health policy, economy, business development, legal and social sciences (www.genomicaybioeconomia.org). Our initial results include a comparative analysis of knowledge-based economic initiatives in emerging economies including China, India, and Brazil. This led to specific recommendations as to how an emerging economy like Mexico can orient major genomic programs into innovation and economic development (Jimenez-Sanchez G, et al. Genomics and Bioeconomy: A window of opportunity for economic growth in Mexico. COLMEX-COLNAL, 2012). Genomic medicine is one of the key areas where previous work and novel developments in science and industry make it necessary to establish the grounds for implementation of genomic applications into medical practice. This is the case for pharmacogenomics, where scientific evidence and recommendations by regulatory agencies make it important to develop cost-benefit analyses for some of the most commonly used tests. We initiated an economic evaluation of the Warfarin sensitive test in the context of net present values for Mexico. Initial evidence indicates that this test could be used in the public health arena. Based on current technologies and the knowledge of genetic variation in the Mexican populations, we established a join effort with the Mexican Government to develop a regulatory framework for pharmacogenomics and the infrastructure required at the COFEPRIS (FDA equivalent) laboratory facilities. Results from this initiative include a nation-wide network to establish synergies between academy, industry and government to develop innovation in genomics oriented to public health challenges of the Mexican population.*Supported in part by CONACYT.

Awareness of genetic breast cancer epidemic in Iceland. *V. Stefansdottir[1], J.J. Jonsson[1,2,3], O.Th. Johannsson[4].* 1) Medical Genetics, The National Univ. Hosp. of Iceland, Reykjavik, Reykjavik, Iceland; 2) Dept. of Biochemistry and Molecular Biology, University of Iceland; 3) The Genetical Committee of the University of Iceland; 4) Dept. of Medical Oncology, The National Univ. Hosp. of Iceland.

Following Angelina's Jolie statement on her BRCA1 status, awareness of possible BRCA mutation in families was considerably raised. Less than a day after the statement, the CEO of deCode Genetics announced that from its research, the company had data on all BRCA2 mutation carriers in Iceland. Identifying them in their coded databases would be an easy task if permission to do so from the authorities would be granted. Also that it was a duty to the population to inform all at risk about their genetic status. A `genetic storm' broke out. Over the next few days over 200 people called or emailed our cancer genetic counseling clinic (CGC) for information about the BRCA genes and genetic counseling. And the media caught on. In Iceland, a country with 320.000 inhabitants, two founder BRCA mutations are known; the BRCA1 c.5074G>A, and the BRCA2 c.771_775del5. The prevalence of the BRCA1 mutation is unknown. The prevalence of the BRCA2 mutation is thought to be 0.6%. Cancer genetic counseling is done by the aid of an electronic genealogy database for all Icelanders back to 1850 at least and The Icelandic Cancer Registry, a population based nationwide cancer registry going back to 1911 for breast cancers and 1952 for other cancers. Use of the database and registry, based on presumed consent, enables for very fast and accurate workup and risk assessment. The CGC unit at the National Landspitali University Hospital has been in operation since December 2006. One genetic counselor and one part-time oncologist work at the unit. From December 2006-January 2013, 700 individuals have come for counseling. the majority of BRCA2 families are thought to have been identified and all BRCA1 families. As families can be traced very far back and the initial BRCA2 carrier has been identified from the 16th century, one question is always: `What part of Iceland is your family from? When a BRCA mutation is found, the carrier gets an information letter about the mutation and the genetic counseling service to distribute to his family. We describe how a very small CGC unit coped with a very big workload and complex counseling issues in a very short time.

My46: a genetic counseling extender. *K.M. Dent[1], S.M. Jamal[2], J.H. Yu[2], H.K. Tabor[2,3], M.J. Bamshad[2,4].* 1) Department of Pediatrics, University of Utah, Salt Lake City, UT; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Treuman Katz Center for Pediatric Bioethics, Seattle Children's Research Institute, Seattle, WA; 4) Genome Sciences, University of Washington, Seattle, WA.

My46 (http://www.my46.org) is an innovative web-based tool designed to enable self-guided management of genetic testing results. This online tool empowers individuals and families to make decisions about what genetic test results might be of utility to them and their children, and why they might want or not want such results. A primary focus of My46 is to educate individuals about genetics, risk of transmission, and medical conditions thereby providing genetic counselors more time to focus counseling sessions on interpreting genetic results and exploring their impact. To facilitate this aim, My46 has developed an open-access `Learning Center' that includes standardized summaries of a wide range of medical conditions written in patient-friendly language (`Trait Profiles'); key considerations to think about before receiving genetic testing results (`What you should know about genetic testing'); an introduction to human genetics with an extensive glossary of terms; and links to external resources for families and healthcare professionals (`More Resources'). The Trait Profiles can be searched by trait name (e.g., sickle cell disease) and are organized into seven categories (disease risk, carrier status, medication response, genetic syndromes, metabolic disorders, newborn screening conditions, and ancestry). The Trait Profiles include information on characteristics of the condition, diagnosis/testing, management/surveillance, genetic counseling, special consideration, resources with direct links to GeneReviewsTM, and key references. All Trait Profiles can be printed as pdf documents. Each Trait Profile is written by a genetic counselor, edited by the My46 team for readability, and reviewed by a clinical geneticist. The goal is to write a Trait Profile for each condition for which genetic testing is available. To date, the My46 team has received over 120 draft Trait Profiles, written by genetic counselors from around the world. As a result, the Trait Profiles broadly capture the expertise of genetic counselors in a single repository, greatly benefiting vast numbers of patients. Collectively, the My46 Learning Center is a valuable resource to the genetic counseling community and will enhance the delivery of genetic counseling services.

Engaging health professionals in evaluations of emerging genomic technologies. *C. Catley[1], J. Little[1, 2], S. Nicholl[1], H. Etchegary[3], J.C. Carroll[4], D. Castle[5], L. Lemyre[6], B.K. Potter[1], B.J. Wilson[1], CIHR Emerging Team in Genomics in Screening.* 1) Department of Epidemiology and Community Medicine, University of Ottawa, ON, Canada; 2) Canada Research Chair in Human Genome Epidemiology; 3) Clinical Epidemiology, Memorial University Newfoundland, St John's, NL, Canada; 4) Family Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 5) ESRC Innogen Centre, University of Edinburgh, Edinburgh, UK; 6) School of Psychology & Institute of Public Health, University of Ottawa, ON, Canada.

Background: The successful integration of emerging genomics technologies into mainstream health care requires their acceptance and adoption by professionals across many disciplines and specialties. It is well established that interventions of known effectiveness are not used as intended, and that ineffective or harmful interventions continue to be used inappropriately. We need insight into factors which influence professionals' own evaluations of genomic technologies, to guide effective and responsible implementation strategies. A major threshold in the adoption of new knowledge (and practices) is that of salience - perceived relevance to individual practice. We are conducting a pilot study of a method for engaging health professional audiences in evaluations of emerging genomic technologies which takes this into account. **Objectives:** To (a) understand how health professionals frame their understanding of emerging genomic technologies and (b) identify specific factors that may facilitate and challenge the appropriate adoption of these technologies in professional medical and nursing practice. **Methods:** A structured interactive workshop combines a largely didactic component (describing the range of genomic approaches in health care) and an interactive component which presents hypothetical case studies of different potential applications of genomics in routine practice. Participants engage in moderated discussion, and are encouraged to capture personal reactions to the content through ongoing written narrative. Non-participant observers capture discussion points in real time. Survey data are captured before, during, and post-workshop. A mixed methods approach is taken for data analysis. **Results:** We have conducted workshops with physicians and nursing professionals in primary care and a range of specialties. Results summarizing participants' evaluations of the utility of genomic approaches, and shifts in key attitudes compared with pre-workshop baseline, will be presented. The necessity of prompting participants' evaluation of the salience of genomic approaches generally, as a prerequisite for meaningful reflection on specific applications, will be discussed. We will also discuss the challenge of developing a workshop format that is efficient in its use of participants' time, and the relationship between professional engagement and continuing professional education exercises.

2507W

Uptake of a web-based patient-entered cancer family history collection tool. *M. Doerr[1], S. Griffith[2], C. Eng[1].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Department of Quantitative Health Sciences, Cleveland Clinic, Cleveland, OH.

Background: MyFamilyHealthHistory (MyFHH) is a family history collection tool developed by Cleveland Clinic (CC) for use in oncology settings. MyFHH is a CC quality improvement initiative to increase the efficiency of cancer family history collection without introducing care disparity. We have previously shown patients who complete MyFHH are more likely to attend cancer genetics clinic appointments (93% vs. 63% attendance in those not completing). We thus investigate determinants of MyFHH uptake. Methods: Between Aug 2009 and Sept 2012, 1161 patients scheduled appointments triggering MyFHH invitation. Cancer-specific family history is obtained for first and second degree relatives. Univariable/multivariable analysis of the association between completion status and personal history of neoplasm, sex, age and socioeconomic status (SES) was performed. Demographic data was extracted from the electronic medical record; median household income by ZIP Census Tabulation Area was used as a proxy for SES. Results: 359 (31%) completed MyFHH. Of 1161 invited, 877 (76%) had a personal diagnosis of neoplasm, 1002 (84%) were female, and 994 (87%) were age <65 yrs. In univariable analysis, we did not find evidence of a difference in the odds of completing MyFHH based on personal diagnosis of neoplasm (p= 0.353). Men showed a reduction in the odds of completing MyFHH as compared to women (OR 0.69; 95%CI 0.46, 1.04), although the difference between the groups was not statistically significant (p=0.097). Notably, individuals age ≥65yrs were significantly less likely to complete MyFHH as compared with those age <65yrs (OR 0.47; 95%CI 0.31, 0.71; p<0.001). There was no difference in the odds of completing MyFHH based on SES (p=0.513). On multivariable analysis, after adjusting for personal diagnosis of neoplasm, sex, and SES, individuals age ≥65yrs remained significantly less likely to complete MyFHH as compared to those age <65yrs (OR: 0.48; 95%CI: 0.32, 0.72; p<0.001). Conclusions: MyFHH uptake does not vary by personal diagnosis of cancer, sex, or SES. Our study identified patients age ≥65yrs as less likely to use MyFHH than those <65yrs. Future efforts to facilitate patients ≥65yrs use of MyFHH could lead to improved cancer genetics clinic attendance.

2508W

Perspectives on Universal Screening for Lynch Syndrome in a Managed Care Setting. *J.V. Davis, T. Kauffman, J. Reiss, C. McGinley, K. Arnold, M. Gilmore, K.AB. Goddard.* Science Programs, The Center for Health Research, Kaiser Permanente, Portland, OR.

Background: The Hereditary Non-polyposis Colorectal Cancer (HNPCC) study is a clinical trial conducted in an integrated health-care system~Kaiser Permanente Northwest (KPNW). Our goal is to determine whether universal screening for Lynch Syndrome among all newly diagnosed colorectal cancer cases increases the use of genetic counseling, compared with the current practice of physician-based referrals or self-referrals to medical genetics. In this phase of the trial, we interviewed health plan leaders and providers to better understand requirements for successful implementation of universal screening. Methods: We investigated factors that might hinder or facilitate implementation of universal screening for Lynch Syndrome in all newly diagnosed colorectal cancer patients. We conducted fifteen semi-structured interviews with KPNW leaders and key staff in pathology, oncology, medical genetics, gynecology, surgery, and laboratory services. Using NVivo software, we applied thematic analysis to the interview audio transcripts. Results: Informants identified 10 departments that should be represented in planning and implementation decisions. Key decisions to be made include: patient selection criteria, consent protocols, choice of Microsatellite Instability (MSI) or Immunohistochemistry (IHC) testing~or both~for initial testing, laboratory selection, and whether to include patients with endometrial cancer in the screened population. These decisions will influence several potential barriers and issues. Justification of screening decisions based on quantitative benefit analysis will be necessary, as will tracking mechanisms for orders, results, and surveillance follow-up. Training and workload burden are perceived as potential concerns in some departments. Clinicians consistently supported systematic testing, suggesting a broader belief within the organization that it is `the right thing to do.' Conclusion: Successful implementation of effective systematic screening for Lynch Syndrome is contingent on favorable benefit analysis and buy-in and coordination of many departments. Program development should include assessment of alternate screening strategies. Barriers must be addressed to achieve a process that is both well integrated and cost effective.

The awareness and need of genetic counseling service in Korea. *H. Kim*[1,2]. 1) Medical Genetics, Ajou Univ Med Sch, Seoul, South Korea; 2) Chairman, Korean Foundation for Rare Disease(KFRD), Seoul, South Korea.

Genetic counseling service which is well recognized as an integral part of clinical genetics service deals with diagnosis and management of genetic condition as well as genetic information presentation and family support in the developed countries of world. Korean Health care system is known for providing one of the most cost-effective services in the world. It is covered by the uniform national health insurance policy for which most people in Korea are mandatory policy holders. The necessity of genetic counseling service has been recently recognized by Korean medical communities, however, genetic counseling as an integral part of medical service is yet to be delivered to patients and their families in need. KFRD has held educational workshops and seminars on Genetic Counseling in eight university hospitals during 10 months period from Sep. 2011 to June 2012 to in order to educate and inform pts. and their families of rare disease, what is "genetic counseling service", and with full understanding of accurate "medical and genetic" information on the dis. involved, how can genetic counseling help pts. and their families to cope appropriately with consequence of the disease. Survey questionnaire were administered to 1663 attendees to evaluate the awareness and need of genetic counseling service. Among 1000 respondents, 79% reported that "previously never heard about genetic counseling service", 83% found that participation in workshop &/or seminar was helpful to comprehend the meaning of "genetic counseling" for them, and 98% indicated that "genetic counseling service" would be helpful to overcome with the condition for pts. and their families of rare disease. Based upon the result of the study, it is necessary to provide further educational workshops and seminars to increase public awareness on genetic counseling. And it is clear that the need of genetic counseling service for pts. and their families of rare disease should be met as an integral part of medical services earliest possible for better management of dis. and quality of life. Furthermore recognition and understanding of the fact that the scope and role of genetic counseling is expanding in post genomic era of personalized medicine for delivery of quality health care, will lead to the efforts to overcome obstacles in providing genetic counseling service in korean health care system.

2510W

Modelling of downstream counselling impact of ACMG Recommendations for Reporting of Incidental Findings in Clinical Exome and Genome Sequencing. *L. Burnett*[1,2,3], *L.C. Ding*[1], *D. Chesher*[1,2], *R. Lew*[2,3], *A. Proos*[1,2]. 1) PaLMS Pathology North, NSW Health, Royal North Shore Hospital, St Leonards, Sydney, NSW, 2065, Australia; 2) Sydney Medical School - Northern, Royal North Shore Hospital E25, University of Sydney, Sydney, NSW, 2065, Australia; 3) Department of Obstetrics and Gynaecology, QEII Research Institute for Mothers and Infants, The University of Sydney, NSW, 2006 Australia.

Purpose To predict the clinical impact of expanded testing with Massively Parallel DNA Sequencing using the ACMG Recommendations for Clinical Reporting of Incidental Findings.

Design Mathematical modelling of gene and variant frequencies.

Methods A diagnostic panel of clinically significant genetic conditions was simulated, based on the American College of Medical Genetics and Genomics (ACMG) Recommendations. The number of patients with significant variants in one or more conditions that would be detected using the screening panel was calculated from known (or best estimate) prevalence. Where a range of variant prevalence data was available, we selected the lowest and highest values, and calculated the most-likely value as the geometric mean, while where only a single datum was available, we selected half and twice this prevalence as the lower and higher limits. Assuming all tested disorders were inherited independently, the probability calculation used was $1- [(1-p1)*(1-p2)*...(1-p24)]$, with p1 to p24 as the carrier frequencies of the 24 proposed ACMG conditions. Calculations were repeated separately for the lower and higher limits. The proportion of individuals screened who would require supplementary consultation and genetic counselling was calculated.

Results The proposed ACMG recommended screening panel would require supplementary consultation and genetic counselling for 2.7% (range 1.6%-6.9%) of screened individuals.

Conclusion Reporting of incidental findings arising from massively parallel sequencing will require increased clinical follow-up and genetic counselling referrals. The number of such individuals will vary with the particular population being screened as well as the choice of genes included in the screening panel. This will have implications for health care workforce and infrastructure planning. New models of genetic education and counselling may be required to cope with these projected demands.

Factors that drive pediatric medical management following chromosome microarray analysis. *R. Hayeems*[1,2], *N. Hoang*[1], *S. Chenier*[4], *J. Stavropoulos*[1], *S. Pu*[1], *S. Wodak*[1], *R. Babul-Hirji*[1], *J. Davies*[3], *L. Velsher*[3], *J. Aw*[3], *R. Weksberg*[1], *C. Shuman*[1]. 1) Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Institute of Health Policy Management and Evaluation, Univ Toronto, Toronto, ON, Canada; 3) Genetics, Medcan Clinic, Toronto, Ontario, Canada; 4) Département de pédiatrie, Centre Hospitalier Universitaire de Sherbrooke, Sherbrooke, Quebec, Canada.

Background: Understanding management practices triggered by microarray analysis will inform clinical utility and resource planning. We explored the association between patient clinical characteristics and medical recommendations that follow pediatric microarray. **Method:** Of 1664 microarrays ordered in a pediatric tertiary care hospital in 2009/2010, 945 (56.8%) met inclusion criteria for this historical cohort study. Of these, 281/945 had a reportable microarray result (29.7%) and 664/945 had a benign result (70.3%). All cases with a reportable result and a random sample of benign cases were reviewed. The primary outcome sought was new medical recommendations following microarray result reporting. **Results:** Medical recommendations were provided for 328/451 cases (72.7%). Binomial log link regression analyses of relative risk (RR) indicate that pathogenic microarray results are associated with increased management recommendations compared to benign results [RR=1.36, 95% CI (1.17, 1.59)] but only a slight increase among those with uncertain results compared to benign results [RR=1.22, 95% CI (1.07,1.40)]. In addition, age <12 months is associated with increased management recommendations compared to children >5 years [RR=1.44, 95% CI (1.27, 1.64)]. The presence of multiple congenital anomalies (MCA) alone is associated with slightly more management recommendations than developmental delay (DD) alone [RR=1.37, 95% CI (1.02, 1.84)]. In a two-factor model assessing the effects of result type and phenotype, the effect of pathogenic results is retained [RR=1.34, 95% CI (1.15,1.55)] but the effect of MCA is marginal [RR=1.36, 95% CI (1.02,1.82)]. In a two-factor model assessing the effects of result type and age, the effects of result type and age are retained [RRpath=1.27, 95% CI (1.14,1.43); RRage=1.42, 95% CI (1.25,1.60)]. **Conclusions:** Of the variables considered, pathogenic results and age are the strongest drivers of new medical recommendations in a pediatric cohort. Uncertain microarray results only drive medical management marginally. These finding warrants further study with respect to establishing clinical utility.

The NINDS Repository Biomarkers Discovery Collection: A Public Resource of Biomaterials for Neurodegenerative Disease Research. *C. Tarn*[1], *M. Self*[1], *K. Gwinn*[2], *M. Sutherland*[2], *C. Pérez*[1], *W. Muhammad*[1], *G. Balaburski*[1], *M. Frasier*[3], *L. Vincent*[3], *R. Corriveau*[2]. 1) The NINDS Repository, Coriell Institute for Medical Research, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD; 3) Michael J Fox Foundation, New York, NY.

Neurological disorders present a massive challenge to healthcare systems globally. Identification of novel and reliable biomarkers that would allow for more efficient diagnosis, monitoring of disease onset and progression, and assessment of response to therapeutics, holds immense promise for improving clinical outcomes in individuals affected with disorders such as Parkinson's Disease and Huntington's Disease. The National Institute of Neurological Disorders and Stroke (NINDS) Repository at the Coriell Institute, also known as the NINDS Human Genetics Resource Center, has an overall mission of accelerating discovery of causes and risks for neurological disease by sharing biomaterials and de-identified clinical data. As a centralized facility for storage, processing, and distribution of biofluids (cerebrospinal fluid, plasma, serum, whole-blood, urine) and nucleic acid (DNA and RNA), the NINDS Repository serves as an integral component in the effort to identify and validate biomarkers of neurological disease. The establishment of large collections of biological samples obtained longitudinally from both affected and neurologically healthy individuals should prove invaluable for furthering investigation of biochemical markers via transcriptomic, proteomic, or metabolomic approaches. Currently the NINDS Repository collects samples under multiple NINDS sponsored biomarker initiatives including the Parkinson's Disease Biomarkers Program (PDBP) and the Neurobiological Predictors of Huntington's Disease (PREDICT-HD), as well as a jointly sponsored study (BioFIND) on Parkinson's Disease in collaboration with the Michael J. Fox Foundation. The NINDS Repository aims to: (i) ensure that samples collected for biomarker discovery are of premier quality by collaboratively establishing unified standards of sample collection; (ii) provide rapid feedback to clinical sites regarding sample appearance and quality; (iii) maintain secure, high quality sample storage conditions with real-time monitoring and recording systems; (iv) perform standardized laboratory processing and quality assurance using validated operating procedures. The NINDS Repository thus provides a vital resource for research designed to discover and validate biomarkers of neurological disorders. Biomarker discovery samples are available upon request either directly from the NINDS Repository web catalog (http://ccr.coriell.org/NINDS), or via NIH-sponsored resources with links to the online catalog.

Measuring treatment preferences of parents of children with Duchenne muscular dystrophy using best-worst scaling. *H.L. Peay[1], I. Hollin[2], H. Sheffer[1], J.F.P. Bridges[2].* 1) Parent Project Muscular Dystrophy, Richmond, VA; 2) Department of Health Policy and Management, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Purpose: Duchenne muscular dystrophy (DMD) is a progressive disorder with no approved treatment. Individuals lose ambulation at ~8-12 yrs and die in the 3rd decade. There are no data on priorities for DMD treatments. We quantified the preferences of parents/guardians for potential DMD treatments' benefits and risks. Methods: Engagement with clinicians, industry, and parents yielded 6 treatment attributes (muscle function, lifespan, amount of post-approval data, nausea, risk of bleeds, arrhythmia risk) with 3 levels each. Attributes/levels were reasonable based on treatments under trial. Best-worst scaling (BWS) case 2 was used in a survey of U.S. parents of children with DMD. Participants were presented 18 benefit/risk combinations based on an orthogonal main-effects design. In each profile, respondents chose the best and worst aspect. Under assumptions of sequential best-worst and homogeneity across respondents, a choice model was estimated using McFadden's conditional logistic regression. Parameters were effects-coded (ensuring levels were anchored around zero) and relative attribute importance calculated based on overall utility differences across the attribute's levels. Results: Of 119 parents/guardians, the average age was 43.7 (SD 7.7) and predominately Caucasian (92%), married (90%), biological mothers (67%). Relatively, the most important attribute was preservation of muscle function~accounting for 27% of the variation across model attributes, and comprising the most and least preferred levels (stopping the progression of weakness and no effect on weakness, respectively). This was followed by: risks of arrhythmia and bleeds, each accounting for ~21% of the variation; changes in life span (17%); nausea (10%); and additional years of post-approval data (4%). Conclusion: This study presents a unique and robust approach to prioritizing treatment benefits/risks. Though presented with hypothetical treatments, participants exhibited preferences and non-random choices. Stopping or slowing weakness progression accounted for the largest proportion of variation in attributes. Muscle function was prioritized over lifespan and risks. Our data suggest side effects/risks could be compensated for by stopping weakness progression. However, the experiment revealed no cumulative benefit profile that offset the most severe risk profile, suggesting a limit to risk tolerance. Future research will focus on preferences heterogeneity and latent-classes.

2514W

A review of the Welsh breast cancer screening programme for women with a family history of breast cancer at a moderately increased risk. *S.L.M. Nisbet[1], L. Murray[2], K. Pegington[2], M.T. Rogers[1], K. Gower-Thomas[2,3], A.J. Murray[1].* 1) Institute of Medical Genetics, University Hospital of Wales, Heath Park, Cardiff, South Glamorgan, United Kingdom; 2) Breast Test Wales, 18 Cathedral Road, Cardiff, CF11 9LJ, UK; 3) Royal Glamorgan Hospital, Ynysmaerdy, Llantrisant, Pontyclun, CF72 8XR, UK.

In Wales, women with a family history of breast cancer are referred to the All Wales Medical Genetics Service (AWMGS) for risk assessment, genetic counselling and discussion of screening options. Those women who are assessed to be at an increased for breast cancer are offered regular mammographic screening through a centrally-coordinated, national screening programme, which is run by Breast Test Wales (BTW). BTW is the organisation in Wales that delivers the NHS Breast Screening Programme (NHSBSP), offering 3-yearly mammography to all women in the general population aged 50 to 70 years. BTW took over the provision of all family history screening in Wales in 2001, in order to provide a more equitable service and to facilitate better data collection and quality assurance. Unlike the NHSBSP which provides screening on mobile mammography units, the family history screening is delivered in the three regional BTW centres in South East Wales (Cardiff), Mid & West Wales (Swansea) and North Wales (Llandudno). Since AWMGS established a cancer genetics service in 1999 our understanding of familial breast cancer risk assessment has improved significantly, and several different risk assessment algorithms and software packages have been developed. Following the recent publication of the updated guidance on Familial Breast Cancer by the National Institute of Health and Clinical Excellence (NICE), we commenced a review of all women previously assessed as being at a moderately increased risk, who are currently enrolled in the BTW Family History Screening Programme to ensure women have been given an accurate risk assessment and are not being screened inappropriately Women were informed about the review when attending for their annual mammogram and advised that they would be contacted if we felt their risk or screening requirements had changed. Every woman's family history has been reviewed and their risk recalculated using the Boadicea web application developed by the Centre for Cancer Genetic Epidemiology at the University of Cambridge. This model has been well validated and is one of the risk assessment models endorsed by NICE. We will present the results of the pilot study conducted in the South East Wales region, which is now being extended across Wales. We will discuss the implications for the future assessment of women at an increased risk for breast cancer in Wales, which resulted from this review and some of the difficulties associated with a large scale review.

2515W

Documenting family history of cancer and referral for genetic counseling and testing in screening families at risk of hereditary breast or colorectal cancer. *I. Shapira, K. Cheng, V. John, K. Sultan, R. Sharma, D. Gokalp Yasar, N. Nyatanga, N. Eisler, J. Cho, E. Taioli.* Hofstra North Shore LIJ School of Medicine, Lake Success, NY.

Background Over 30% of colorectal cancer (CRC) is diagnosed at stage 3 due to low screening. Family history is the most important tool to identify hereditary cancer syndromes. Screening in families at hereditary risk reduces cancer morbidity and death. Prior studies demonstrate a low rate of family history documentation and low referral rates for genetic counseling and genetic testing. Aims 1) Assess the documentation of family history in different settings: hospital CRC versus office (breast cancer-BrCa-) in syndromes with similar penetrance such as Lynch and hereditary breast ovarian cancer syndrome (HBOC). 2) Define barriers to family history documentation. Methods: We evaluated the documentation of family histories in in charts of 630 consecutive colorectal cancer patients admitted for initial surgery in hospital and 295 Br Ca patients seen in office breast their initial oncology consultations between 2009-2011. Statistical analysis was performed for each group of patients using Normal method with standard error of proportion of 0.261 for 95% confidence interval (normal value 1.96) Of the 630 CRC patients, 237/630 (37%) had cancer family history recorded for the 1st degree relatives and 41/ 630 (7%) had cancer family history recorded for their 2nd degree relatives. The Amsterdam II criteria for referral to genetic cancer counseling and testing requires documentation of family history of 3 generations (first and second degree relatives and the proband): only 7%[95%CI 6.7%-7.7%] of the entire cohort of CRC patients, and only 6% of the colorectal cancer patients diagnosed under the age of 50 years old satisfied the Amsterdam II criteria. Of BrCa patients seen in office: 213/ 295 (71% [95%CI 47%-87%]) had 3-generations pedigrees documented in their family history had documentation of family history and 82/295, (29%) did not have three generation pedigrees documented; Conclusions: Appropriate referral for genetic counseling and genetic testing requires a complete and accurate documentation of family history. Significant differences were seen between the breast cancer charts and colorectal cancer charts, with greater accuracy of family history documentation and higher referral rates among breast cancer patients. To obtain improvement in the identification and management of patients at high risk and their family members, significant improvements in family history documentation are needed. Education is part of the answer.

2516W

Needs assessment of individuals with 22q11.2 Deletion Syndrome transitioning from pediatric to adult health care settings. *W.L.A. Fung*[1,2,3,4], *E. Leung*[5], *A.S. Bassett*[1,2,3]. 1) Department of Psychiatry, University of Toronto Faculty of Medicine, Toronto, Ontario, Canada; 2) The Dalglish Family Hearts and Minds Clinic for 22q11.2 Deletion Syndrome, Toronto General Hospital, University Health Network, Toronto, Ontario, Canada; 3) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 4) Departments of Psychiatry and Clinical Genetics, North York General Hospital, Toronto, Ontario, Canada; 5) Office of Continuing Education and Professional Development, University of Toronto Faculty of Medicine, Toronto, Ontario, Canada.

Background: The multi-systemic clinical manifestations of 22q11.2 deletion syndrome (22q11.2DS) make the provision of comprehensive care for patients challenging. A coordinated, multidisciplinary team approach in the provision of care is recommended in Practice Guidelines. While several comprehensive 22q11.2DS centers have been established for children - and the world's first such center for adults recently established in Toronto, Canada - the provision of such coordinated care had been identified as a particular challenge for 22q11.2DS patients transitioning from pediatric to adult health care setting. We sought to assess the needs of 22q11.2DS patients transitioning from pediatric to adult health care setting. Methods: A multi-pronged approach was utilized in assessing the needs of these patients. This included paper surveys of 22q11.2DS patients and families, phone interviews of 22q11.2DS patients and families, as well as electronic surveys of professionals involved in the care of these patients and families. Questions of both quantitative and qualitative nature were used. Results: Considerable differences were identified between 22q11.2DS patients and families in terms of their perspectives on the patients' 1) knowledge of 22q11.2DS; 2) ability to transition to adult health care setting and adult life overall; 3) social and emotional well-being. In general, patients rated themselves as having more knowledge regarding 22q11.2DS and greater social and emotional well-being, compared to their families' ratings. Patients also expressed a higher level of confidence in their ability to transition to adulthood than their families' rating. The key challenges identified by these families included psychological, emotional and behavioral issues associated with 22q11.2DS, the availability of social supports to patients, and the negative effects of these symptoms on the patients' support systems. Findings from the professional stakeholder surveys will be presented at the annual meeting. Conclusion: To our knowledge, this is the first needs assessment conducted on 22q11.2DS patients transitioning from pediatric to adult health care setting utilizing a multi-pronged approach. These findings will help inform the development of an evidence-based transition program to enhance the care of these patients and their families.

2517W

The DSD-Translational Research Network, a national research and clinical network to improve health for people with Disorders of Sex Development. *E. Delot*[1], *D.E. Sandberg*[2], *E. Vilain*[1]. 1) Human Genetics, UCLA, David Geffen Sch Med, Los Angeles, CA; 2) Mott Children's Center, University of Michigan, Ann Arbor.

Disorders of Sex Development (DSD) are congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical. For families, the birth of a child with a DSD, with the uncertainty it brings regarding the child's gender and future psychosexual development, is believed to be extraordinarily stressful. Clinical care in DSD has been severely hampered by a fragmented research agenda, leaving fundamental gaps in knowledge of DSD pathology or treatment outcomes. Our long-term goal is to establish an environment in which clinical care of persons affected by DSD is evidence-based and guided by research that identifies factors impeding or enhancing opportunities for a positive quality of life across the lifespan. With the support of the NICHD, we created the DSD-TRN, to establish best practices by: 1) Building a sustainable infrastructure for translational research, including: - an interactive registry that will maintain standardized data from clinical sites, provide actionable information to clinical care teams and patients/families to support diagnosis and treatment management, and foster rapid translation of new evidence into clinical practice; - a collaborative network of researchers, clinicians, and patient/family advocates that will drive the research agenda and objectively monitor the impact of translational research at the bedside. 2) Standardizing radiological, biochemical, histological evaluations, descriptions of genital phenotype and post-surgical appearance and function. 3) Identifying biological and social factors associated with variability in psychosocial, psychosexual, and quality of life outcomes in patients with DSD. 4) Identifying novel pathophysiological mechanisms & improving the molecular diagnosis of DSD. The DSD-TRN network currently includes 5 academic centers (UCLA, U. Michigan, UCSF, Seattle Children's Hospital, Cincinnati Children's Hospital) with multidisciplinary teams (urology, genetics, endocrinology, psychosocial, etc.), multiple consultants (ethics, cancer, cost-effectiveness,...) and an Advisory Board with representatives of the major DSD patient advocacy groups. Deliverables already in place include a new exome-based genetic testing platform that allowed identification of novel variants in DSD patients, clinical use data collection forms integrated with electronic medical records, information brochures for patients and a registry of patient data to support future evidence-based clinical practice.

2518W

Whole genome sequencing vs. family history: physician perceptions of clinical utility. *J.L. Vassy[1,2,3], R.C. Green[1,6], J. Krier[5], D. Lautenbach[6], K.D. Christensen[6], M.A. Giovanni[7], M.F. Murray[7], A.L. McGuire[4] for The MedSeq Project.* 1) Department of Medicine, Harvard Medical School, Boston, MA, USA; 2) Division of General Medicine and Primary Care, Brigham and Women's Hospital, Boston, MA, USA; 3) Section of General Internal Medicine, VA Boston Healthcare System, Boston, MA, USA; 4) Baylor College of Medicine Center for Ethics and Health Policy, Houston, TX, USA; 5) Medical Genetics Training Program, Harvard Medical School, Boston, MA, USA; 6) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA, USA; 7) Geisinger Health System, Danville, PA, USA.

Background The uptake of whole genome sequencing (WGS) into patient care will depend in large part on whether physicians perceive it to have clinical utility. It is informative to compare the perceived utility of WGS to the current benchmark of genetic risk assessment in clinical care: family history (FmHx). Standard medical practice includes at least a cursory FmHx assessment, while for most physicians WGS remains an experimental technology. We hypothesized that physicians would find FmHx more clinically useful than WGS now but that they expect the utility of WGS to increase in the future. **Methods** We have enrolled primary care physicians and cardiologists to participate with their patients in the MedSeq Project: a randomized trial of WGS in clinical care. Before enrolling patients, we surveyed physicians about their perceived clinical utility for FmHx and WGS. We asked them to rate on a scale of 1-10 (`Not at all Useful' to Extremely Useful') how useful they thought the study's FmHx and WGS reports would be for `managing [their] patients' health' at two times: now and in the future. We categorized responses as not useful (1-5) or useful (6-10) for descriptive analyses. We used paired t-tests to compare the reported utility ratings of FmHx vs. WGS. **Results** Of 17 physicians (mean age 52 years), 9 (53%) were women, and 5 (29%) were of non-white race. Nine (53%) were primary care physicians, and 11 (65%) reported no genetics training beyond the usual medical school curriculum. The majority of physicians said FmHx would have clinical utility both now and in the future (n=15, 88%, for both responses). In contrast, only 4 (24%) said that WGS would have utility now. However, 15 (88%) predicted that WGS would have future utility for their patients' care. Physicians rated FmHx to have higher utility than WGS now (mean responses 7.6 vs. 4.2, $p<0.001$), but they rated FmHx and WGS to have similar utility for the future (mean responses 7.9 vs. 7.5, $p=0.49$). **Conclusions** Physician participants of the MedSeq Project rated FmHx to have greater utility than WGS for the present-day management of their patients' health, but they expected this utility gap to close in the future. Whether and how quickly this gap closes will likely depend on how the clinical genomics community addresses barriers to integrating WGS into patient care.

Conceptualizing family history taking in clinical pediatric practice. *L. Tessier[1], B.K. Potter[1], J. Brehaut[2], P. Chakraborty[3,4], J.C. Caroll[5], J. Allanson[4], J. Little[1,6], D. Castle[7], B.J. Wilson[1], CIHR Emerging Team in Genomics in Screening.* 1) Department of Epidemiology & Community Medicine, University of Ottawa, ON, Canada; 2) Clinical Epidemiology Program, Ottawa Hospital Research Institute, ON, Canada; 3) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 4) Department of Pediatrics, University of Ottawa, ON, Canada; 5) Family Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 6) Canada Research Chair in Human Genome Epidemiology; 7) ESRC Innogen Centre, University of Edinburgh, Edinburgh, UK.

Introduction: Family history (FH) is regarded as offering useful information in many clinical settings, for identifying potential genetic disease but also for risk assessment for many complex disorders. However, very little is known about how it is applied in pediatrics. Understanding how and why pediatricians collect FH data, and how they use it, would be helpful in evaluating its potential clinical utility. Recognizing that patterns of clinical practice reflect attitudes, knowledge, and many contextual factors, we wanted to develop a conceptual model of FH taking in pediatrics to guide further research. With a view to developing evidence-based tools for pediatricians, this model will be used to inform qualitative interviews with practitioners, and subsequently in developing a survey for pediatricians working in different health care settings. **Objectives**: To develop a conceptual framework of FH taking in pediatric practice as the basis for implementation research. **Methods**: We used as a starting point the Theoretical Domains Framework (TDF), which is being used in health services and implementation research. The TDF groups 33 psychological theories of behavior, with 14 identified domains (behavior change mediators) which can be applied to understanding specific professional behaviors. Using the TDF promotes a broad, comprehensive view of a topic, and its linkage to known psychological theories facilitates the informed development of interventions such as FH tools. We conducted literature reviews and consulted with experts in pediatrics, family medicine, cognitive psychology, and health services research to map each of the 14 TDF domains to specific aspects of FH taking as a `behavior'. **Results**: The following TDF domains appear relevant to exploring FH taking by pediatricians (terminology reflects original description of the framework): `knowledge'; `skills'; `social/professional role and identity'; `beliefs about capabilities'; `optimism'; `beliefs about consequences'; `reinforcement'; `intentions'; `goals'; `memory, attention and decision processes'; `environmental context and resources'; `social influences'; `emotions'; `behavioral regulation'. Each domain maps to ≥1 published theory. We will present detailed explanations of each domain, and clinical examples to illustrate how the framework can be applied to understanding how pediatricians take FH, and their attitudes towards this as a component of practice.

Genetic counsellors' preferences for Preimplantation Genetic Diagnosis: Designing a Discrete Choice Experiment. *E. Goh[1, 2], W. Ungar[2], D. Marshall[3], F. Miller[1]*. 1) Institute of Health Policy, Management and Evaluation, University of Toronto, Toronto, ON, Canada; 2) Child Health Evaluative Sciences, The Hospital for Sick Children Research Institute, Toronto, ON, Canada; 3) Department of Community Health Sciences, University of Calgary, Calgary, AB, Canada.

Preimplantation genetic diagnosis (PGD) permits couples at high risk of a genetic condition to test an embryo for it prior to pregnancy. In the absence of explicit Canadian public policy regarding conditions of use, the decisions of front line clinicians (genetic counsellors, GC) guide clinical practice.

Discrete choice experiments (DCE) are a valid method for quantifying preferences and for measuring trade-offs between the characteristics of alternatives. Our qualitative research included 2 focus groups of practicing GC in Toronto, using a semi-structured focus group guide to identify factors that are important to GC in recommending public PGD coverage to inform our DCE. The first focus group explored what GC deemed relevant using open probes. These criteria were combined with a literature review as probes in the second focus group to generate a list of common coverage criteria. GC ranked the criteria individually, drawing on their perception of importance. Field notes and rankings were descriptively analyzed to identify insights surrounding coverage criteria. Pre-testing of the draft DCE survey was completed using a cognitive interview protocol with 7 GC.

The following attributes were identified as relevant for inclusion: i) PGD indication (childhood-onset condition, adult-onset condition, and adult-onset cancer predisposition), ii) risk of the genetic condition (50%, 25% and 1%), iii) fertility status of couple (infertile or fertile), iv) family history (have children at least one of who is affected, have children none of whom are affected, or have no children) and v) number of *in vitro* fertilization cycles to be funded (1 cycle, 3 cycles or 6 cycles). Based on pre-testing, PGD indication appeared to be the most important factor in deciding between the alternatives.

This qualitative study identified factors deemed important to GC in informing public PGD coverage. Most, but not all of the factors were highlighted in the literature. A DCE was designed based on these attributes. A pilot study of the quantitative phase is currently being undertaken (results expected July 2013, N=20). The results of the DCE can be used to quantify trade-offs amongst these factors and quantify national GC preferences for PGD, which can help inform public policy.

Identification and Characterization of Genetic Services in Peru. *M.R. Cornejo-Olivas[1,2], M.R. Velit-Salazar[1,3], T. Avalos-Cruz, MD[4], M.M. Duenas-Roque, MD[5], M. Inca-Martinez[1,6], A.P. Mora-Alferez, MD[7,8], S.M. Siccha-Arancibia[3], M. Brunner-Sciarra, MS, PhD[3], P. Mazzetti, MD, MBA[1,6], M.I. De Michelena, MD, PhD[3,8], C. Matos-Miranda, MD, MsC[3,9]*. 1) Neurogenetics Research Center, Instituto Nacional de Ciencias Neurologicas, Lima, Peru; 2) Northern Pacific Global Health Research Fellows Training Consortium, Bethesda, US; 3) Universidad Peruana Cayetano Heredia, Lima, Peru; 4) Ministerio Publico, Lima, Peru; 5) Hospital Nacional Edgardo Rebagliati Martins, Lima, Peru; 6) Universidad Nacional Mayor de San Marcos, Lima, Peru; 7) Instituto Nacional de Enfermedades Neoplasicas, Lima, Peru; 8) Instituto de Medicina Genetica, Lima, Peru; 9) Montreal Children's Hospital Research Institute - McGill University. Montreal, Canada.

Statement of purpose. By 2004, genetic consultations, molecular diagnosis and research in human genetics in Peru were performed in a few centers in Lima, the country's capital city. In the last decade, genetic services have significantly grown but are still unregulated. Our study aims to identify and characterize the institutions offering human genetic services in Peru. **Methods**. A cross-sectional study was carried out using web search and interviews that were conducted with geneticists and other field-related professionals from institutions offering clinical, molecular and/or research services in human genetics in Peru. The survey was realized using a standard collecting data form. The study obtained IRB approval. **Results**. From the sixty-two identified institutions, forty of them completed the survey. The majority (92.5%) are located in Lima. Public health institutions represent 25%; five percent are public forensic institutions; 10% belong to both private and public universities, from which only two offer postgraduate training in human genetics; 5% are non-profit organizations; 55% are private genetic centers dedicated to specific laboratory activities including karyotyping (52.5%), FISH (32.5%), paternity testing (17.5%) and other molecular diagnostic techniques, such as PCR (50%), qPCR (27.5%), gene sequencing (27.5%) and others (25%). More than half of the participating institutions (55%) claim to perform basic and clinical research; only ten institutions have published a total of thirty-eight MEDLINE indexed papers. Twenty-one institutions offer genetic counselling and four some kind of genetic treatment. **Conclusions**. Public genetic institutions in Peru generally combine clinical, laboratory genetic services and research; while private centers offer specific procedures. Molecular diagnosis for genetic diseases is still very limited. Karyotyping, FISH, PCR and qPCR are the most available techniques in the country. Despite scarce training opportunities, human genetic services are growing in Peru but are still mainly located in Lima. We envision this information to be helpful in generating human genetic networks and defining public health policies in Peru.

Diagnostic application of targeted resequencing for familial nonsyndromic hearing loss. *B. Choi[1], G. Park[2], J. Kim[2], A.R Kim[2], B.J Kim[2], T. Park[2], S. Oh[2], K. Han[2], W. Park[3, 4].* 1) Seoul National University, Bundang, Gyeong Giido, South Korea; 2) Seoul National University, Seoul, South Korea; 3) Sungkyunkwan University, Suwon, South Korea; 4) Samsung Genome Institute, Samsung Medical Center, Seoul, South Korea.

Identification of causative genes for hereditary nonsyndromic hearing loss (NSHL) is important to decide treatment modalities and to counsel the patients. Due to the genetic heterogeneity in sensorineural genetic disorders, the high-throughput method can be adapted for the efficient diagnosis. To this end, we designed a new diagnostic pipeline to screen all the reported candidate genes for NSHL. For validation of the diagnostic pipeline, we focused upon familial NSHL cases that are most likely to be genetic, rather than to be infectious or environmental. Among the 32 familial NSHL cases, we were able to make a molecular genetic diagnosis from 12 probands (37.5%) in the first stage by their clinical features, characteristic inheritance pattern and further candidate gene sequencing of GJB2, SLC26A4, POU3F4 or mitochondrial DNA. Next we applied targeted resequencing on 80 NSHL genes in the remaining 20 probands. Each proband carried 4.8 variants that were not synonymous and had the occurring frequency of less than three among the 20 probands. These variants were then filtered out with the inheritance pattern of the family, allele frequency in normal hearing 80 control subjects, clinical features. Finally NSHL-causing candidate mutations were identified in 13(65%) of the 20 probands of multiplex families, bringing the total solve rate (or detection rate) in our familial cases to be 78.1% (25/32) Damaging mutations discovered by the targeted resequencing were distributed in nine genes such as WFS1, COCH, EYA4, MYO6, GJB3, COL11A2, OTOF, STRC and MYO3A, most of which were private. Despite the advent of whole genome and whole exome sequencing, we propose targeted resequencing and filtering strategy as a screening and diagnostic tool at least for familial NSHL to find mutations based upon its efficacy and cost-effectiveness.

2523T

Automating Clinical Exome Analysis. *M.N. Bainbridge[1,2,3], E.B. Venner[3], C. Eng[2], Y. Yang[2], R.A. Gibbs[1,2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Whole Genome Sequencing Lab, Baylor College of Medicine, Houston, TX; 3) Codified Genomics, LLC, Houston, TX.

The clinical use of genome wide sequencing is now commonly available and is poised to be ubiquitous in the next year, however, several challenges remain in the timely and cost effect analysis of these data. Initial review and prioritization of the hundreds of potentially disease causing variants is critical for making accurate diagnoses. Unfortunately, this first step is expensive, laborious, time consuming and prone to error. We have developed an information pipeline and set of algorithms to fully automate this initial review process. Initially, we capture clinician expertise regarding the patient phenotype and use this information to prioritize genes based on phenotypic overlap with diseases. This enable those with less medical training to identify variants which likely contribute to the patients phenotype and promote these variants for further review. Additionally, using this data as well as a rich set of annotation information about each variant and gene, we can automate the categorization of the variants according to ACMG guidelines. We tested our algorithms on a series of clinical exome cases that were previously solved by standard methods and found that the causative variant was almost always within the top 15 of all rare, protein changing variants. Further, we were able to identify other, strong candidate variants that were not highly prioritized using manual methods including in cases where multiple genes were suspected of contributing to the phenotype. Further, these improvements reduce the time spent on the initial variant review to approximately half. These analysis methods are critical in a clinical setting. They aid in reducing costs, time, and errors in the initial review greatly improving the quality of the test.

Design and validation of Next Generation Sequencing reference standards for oncology. *J. Goodall, C. Lowe, C. Thorne, A. Mulligan, J. Frampton, B. Burke, K. Schmitt, P. Morrill.* Horizon Diagnostics, Cambridge, Cambridgeshire, United Kingdom.

Horizon Discovery has established a range of best in class, genetically defined, genomic reference standards, including FFPE blocks and purified gDNA. These standards offer a sustainable and highly defined source of reference material to laboratories, proficiency schemes, and manufacturers. Here we present the design and validation of our Next Generation Sequencing (NGS) quantitative multiplex reference standards. NGS offers significant advantages for mutation detection, enabling the simultaneous detection of multiple mutations in multiple genes, and provides a digital readout of the mutation frequency. Challenges remain however, not least the number of different platforms, each presenting different systematic bias, and the need for extensive validation of the analytical pipeline to ensure variant calling is correctly and consistently achieved. A method for standardisation and verification is therefore required that goes beyond the current widespread use of HapMap controls. In response to the need for a better NGS reference standard, Horizon has leveraged its proprietary genome editing technology to create a multiplex reference standard covering many commonly assayed cancer mutations. The power of this approach is that virtually every characteristic of our reference standard can be defined, from the molecular constitution of the genome, to the DNA output associated with each product batch. Each sample contains key oncogenic mutations including KRAS G13D and G12D, PIK3CA H1047R, BRAF V600E, EGFR T790M, NRAS Q61K and KIT D816V represented at defined allelic frequencies ranging from 1 to 25%. Furthermore, >20 defined mutations in other disease relevant genes including PTEN, CTNNB1, ALK, FGFR2, MET, IDH1, NOTCH and BRCA1 are present. Digital PCR is used to quantify each mutation, enabling the precise quantification of mutational frequency. We show that the data obtained by NGS on our multiplex standard closely matches our digital PCR data, thereby validating the use of the standard as a tool that can be used as routine reference material by any lab intending to use NGS for clinical diagnostics. The multiplex reference standard described here establishes the integrity of the NGS workflow from enrichment and sequencing through to bioinformatics and data interpretation.

Simultaneous detection of point mutations and exonic deletions by target gene capture and deep sequencing. *Y. Feng, G-L. Wang, H. Cui, J. Wang, V.W. Zhang, L-J. Wong.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background: Next generation sequencing (NGS) has demonstrated its clinical utility in the identification of point mutations but not the detection of large intragenic deletions, which is extremely important in elucidating its presence as a compound heterozygous mutation to a point mutation or accounting for an apparently homozygous mutation in autosomal recessive cases. **Method:** An analytical algorithm to detect exonic deletions was developed by comparing the normalized coverage depth (CD) of each coding exon of the testing sample to CD of that particular exon from a group of controls. **Results:** This algorithm allows detection and confirmation of homozygous and heterozygous deletions of various captured genes. This includes homozygous deletions of *MPV17* exons 3-7 deletion of a patient with mtDNA depletion syndrome, *LPIN1* exon 18 of a patient with rhybdomyolysis, and a hemizygous *PHKA2* exons 27-30 deletion of a male patient with GSD. In addition, there are compound heterozygous exonic deletions with point mutations, including *CPS1* E9-11, *citrin* E3, *TK2* E1-2, partial *OTC* exon 2 deletions, and a *CACT* E5-9 deletion originally identified as an apparently homozygous point mutation. **Conclusion:** It is extremely valuable to be able to detect point mutations and large exonic deletions simultaneously using target gene capture/NGS approach.

Next Generation Sequencing Coupled with a Novel Multiplex PCR Protocol for Comprehensive Genetic Screening of Maturity Onset Diabetes of the Young in India. *A. Chapla[1], D.M. Mahesh[1], D. Varghese[1], S.V. Nadig[1], H.S. Asha[1], R.T. Varghese[1], M. Inbakumari[1], F. Christina[1], S. Mathai[2], T.V. Paul[1], N. Thomas[1].* 1) Department of Endocrinology, Diabetes and Metabolism, Christian Medical College, Vellore, Tamil Nadu, India; 2) Department of Pediatric Endocrinology, Christian Medical College, Vellore, Tamil Nadu, India.

Maturity Onset Diabetes of the Young (MODY) is a monogenic disorder with an autosomal dominant pattern of inheritance characterized by β-Cell dysfunction. It accounts for around 1-2% of patients with diabetes and typically presents before the age of 25 years. Till date mutations in at least 13 different genes have been reported to cause MODY. Due to an overlap of clinical features with polygenic Type 1 Diabetes (T1D) and Type 2 Diabetes (T2D), identification of patients with MODY is a diagnostic challenge. MODY genetic screening is of immense clinical importance and a confirmed genetic diagnosis would help streamline therapy. However, due to limitations in the scalability of the current diagnostic platform, performing genetic screening of a comprehensive panel of the identified MODY genes has been hindered in the past. As a result, majority of MODY patients are stereotypically classified as T1D or T2D and may potentially receive inappropriate therapy. This study aimed to establish genetic screening of a comprehensive panel of 10 MODY genes consisting of HNF1A, HNF4A, GCK, HNF1β, IPF1, NEUROD1, KLF11, CEL, PAX4, and INS. A novel multiplex PCR was established to enrich the target genes and further sequencing was performed on Ion Torrent Personal Genome Machine. Using this approach 95% of the targeted DNA was covered at a depth of 50 or more reads per nucleotide and at a minimum average base coverage depth of 300X. MODY genetic testing was carried out in 50 subjects with young onset diabetes of which 35 met the clinical criteria of MODY. We Identified mutations in seven patients, which include four with NEUROD1 mutation (novel c.175 G>C p.E59Q, novel c.-162G>A 5'UTR, and c.723C>G p.H241Q), one with HNF4A mutation (c.505G>A p.V169I coseggregating with c.493-4G>A and c.493-20C>T), one with GCK mutation (c.1318G>T p.E440X) and one with HNF1B mutation (novel c.274 C>T p.L92F). These mutations and the other identified rare variants were confirmed by Sanger sequencing. Further, to validate this protocol we compared the Ion torrent sequencing data of HNF1A with conventional Sanger sequencing in 10 subjects. Novel Multiplex PCR coupled with Ion Torrent Next Generation sequencing has allowed us for the first time to perform comprehensive genetic screening in Asian Indians in a rapid and cost-effective way. With this parallelized sequencing approach we have identified a higher frequency of NeuroD1 mutations, a pattern of MODY different from the Western population.

Many types of DNA damage can be detected with Two-Dimensional Strandness-Dependent Electrophoresis (2D-SDE). *J.J. Jonsson[1, 2], B. Gudmundsson[1, 2], H.G. Thormar[2, 3], A.G. Sigurdsson[2], S. Thongthip[4], M. Steinarsdottir[1], A. Smogorzewska[4].* 1) Dept. of Genetics and Molecular Medicine, Landspitali, Reykjavik, Iceland; 2) Dept. of Biochemistry and Molecular Biology, University of Iceland, Reykjavik, Iceland; 3) Lifeind/BioCule Inc., Reykjavik, Iceland; 4) Laboratory of Genome Maintenance, Rockefeller University, New York, NY.

Two-Dimensional Strandness-Dependent Electrophoresis (2D-SDE) in manual minigels or premade microgels is a novel technique for nucleic acid analysis. In the first dimension nucleic acid fragments are separated based on length and strandness i.e. double-stranded DNA, single-stranded DNA and RNA•DNA hybrids. The nucleic acids are heat denatured before the second dimension electrophoresis and in the second dimension all fragments are single-stranded and separate only based on length. We tested if 2D-SDE could detect various types of DNA damage in vitro and in vivo. Each sample was run in duplicate both uncut and cut with Mbo I, an enzyme which cuts both single- and double-stranded DNA. Single-stranded breaks, either nicks or gaps, were detected as horizontal streaks on 2D-SDE extending from uncut DNA molecules too large to efficiently enter the gel. Double-stranded breaks generated an arc in the gel. DNA molecules with interstrand crosslinks (ICL) migrated as an arc behind normal dsDNA molecules. In contrast, DNA with intrastrand crosslinks and bulky adducts were bent and migrated in front of that arc. Single-stranded DNA molecules, too damaged for complementary strand binding, formed a diagonal line. 2D-SDE detected DNA damage at comparable level of sensitivity to the well known comet assay. However, 2D-SDE allowed direct detection of damaged molecules and subfractions could be isolated form the gel. 2D-SDE could also be used to analyze cfDNA. 2D-SDE can detect many common types of DNA damage and the effects of DNA repair. Applications include testing quality of biosamples and efficiency of various molecular procedures were damage to DNA is common. Examples include extensive damage detected in CHIP-Seq experiments and FFPE samples. Applications also include genotoxicity testing, chemosensitivity testing and diagnosis of genome instablity and DNA repair disorders.

Next generation molecular diagnosis of patients with retinal degeneration. *L. Lan, N. Li, J. Chiang.* Casey Molecular Diagnostics Laboratory, Portland, Oregon.

Molecular diagnosis of inherited retinal degeneration has been difficult due to the following reasons: (1) locus heterogeneity (more than 200 genes involved); (2) allele heterogeneity (many private mutations); (3) overlapping clinical presentations; and (4) progressive nature of some conditions. The arrival of mass parallel sequencing: Next Generation Sequencing (NGS) provides an opportunity to revolutionize the task. At the Casey Molecular Diagnostic Laboratory, we have developed a method combining the specificity and low cost of PCR enrichment with Illumina MiSeq NGS platform. Several hundred clinical samples have been sequenced using this combination of methods thus far. Based on our experience, false positive and false negative callings are concerns. The presence of low coverage regions (gaps) is another concern. Mutations can be missed below cutoff (false negative), while sequencing artifacts above cutoff generate false positive results. Homozygous deletions can be missed if gaps are not filled. Therefore, after data analysis, gaps are also filled in by PCR and Sanger sequencing, and mutations and novel variations are confirmed by Sanger sequencing regardless of the quality score. The biggest drawback of this individual disease panel approach is for patients with uncertain clinical diagnoses, as multiple panel testing may be required in order to find mutations. At this time, we are developing a PCR based approach of testing the entire non-syndromic retinal degeneration genes plus some common syndromic genes. With the buildup of our database by testing more genes and confirming mutations and novel variations by Sanger sequencing, we aim to improve molecular diagnoses of patients with retinal degeneration. Our unique approach and experience will be presented.

Using Targeted Next Generation Sequencing for Diagnosis and Screening in Newborns. *T.D. Sokolsky, E.W. Naylor, A. Bhattacharjee.* Parabase Genomics, Inc., 100 Morrissey Blvd, Boston, MA 02125.

Newborns are disproportionately affected by rare monogenic diseases including hearing loss, inborn errors of metabolism, and lysosomal storage disorders. A diagnosis is critical in order to begin treatment early and prevent mortality or lifelong debilitation. Unfortunately, the current tests for newborns are limited in scope and scalability. Diagnostic confirmation often includes time-consuming and expensive serial single gene testing, which can result in reducing the available treatment window and increasing the risk of long term effects. We believe that next generation sequencing technology has the power to help infants in a way that conventional diagnostic approaches cannot. Targeted next-generation sequencing (TNGS) has allowed expansion of genetic testing across a large number of diseases. Here, we report on a new multi-gene panel that targets hundreds of genetic diseases predominantly affecting newborns and which neonatologists have recommend for inclusion in population based screening. Our panel encompasses diseases and symptoms such as hearing loss, hypotonia, hepatomegaly and failure to thrive. Through our TNGS pipeline, sequencing capacity can be maximized for high coverage of targeted regions along with decreased turnaround time and increased throughput. This optimized pipeline with lower per sample cost and better accuracy in variant calling can translate in the clinic to an accelerated patient diagnosis. Our TGNS approach focuses on the exonic regions of approximately 300 genes and uniquely also includes the entirety of specific genes, such as those for hearing loss and cystic fibrosis, where variants of clinical relevance are often found in non-coding regions. This design expands detection beyond exclusively exonic panels while maintaining the advantages of a smaller targeted panel. In our lab we additionally demonstrate improvements to extraction methods for small sized samples from newborns (e.g. DBS, saliva) in order to yield DNA in quantities sufficient for target enrichment by hybrid-capture and sequencing. Thus mitigating the need for whole genome amplification and associated biases. Our pipeline provides a sample to answer solution by incorporating our advances in sample prep, reduced sequencing run times with the latest instruments, and implementing commercial grade bioinformatic analysis with automated variant calling tools and interfaces.

Targeted Sequencing of Genes Causing atypical Hemolytic Uremic Syndrome and Coagulation Disorders. *S. Theru Arumugam[1], K. Meganathan[2], D. Kissell[1], S. Jodele[3], R. Gruppo[2], K. Zhang[1].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Division of Hematology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Division of Bone Marrow Transplantation and Immune Deficiency, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Sanger sequencing of multigenic disorders can be technically challenging, time consuming and very expensive. Recent advancements in Next-generation sequencing (NGS) not only facilitated the discovery of new disease genes, but also transformed the routine clinical diagnosis of genetic diseases. In this study, we evaluated the performance of NGS in detecting the DNA sequence variations in 52 genes causing atypical hemolytic uremic syndrome and coagulation disorders. Targets covering the exons, flanking intronic and regulatory regions of these genes were enriched using RainDance microdroplet PCR and sequenced, as single end 50 bp reads, on the Illumina HiSeq 2500 instrument. The raw sequence reads from each sample were subjected to molecular genetics laboratory's (MGL) NGS data analyses procedure, which include: (1) quality filtering of raw reads (2) mapping high quality reads to reference sequence and simultaneously detecting sequence variants using NEXTGene software (3) identifying potential true sequence variants using MGL criteria and (4) confirmation of variants with Sanger sequencing. A total of eight samples with known mutation were included in the pilot study and an average of about 20 million raw sequence reads were generated from each sample. About 97% of reads in each sample met the quality criteria and of which, approximately 67.5% aligned to the reference sequences of these 52 genes. We observed that about 98.6% of 145 kb target regions, covering exon and 20 bp flanking intronic regions, had at least 40 sequence reads. The data is currently being analyzed and results of this study will be presented.

Application of targeted next-generation sequencing in clinical diagnostics. *B. Sikkema-Raddatz, L.F. Johansson, E.N. de Boer, K. van Dijk-Bos, P. van Norel, J. Dijkhuis, M. Viels, M. Meems, A. Schipper, Y. Vos, H. Westers, B. Leegte, J.G. ter Beest, L. van der Heijden, A.H. van der Hout, L.G. Boven, J.P. van Tintelen, R. Almomani, R.H. Sijmons, J.D.H. Jongbloed, R.J. Sinke.* Department of Genetics, University of Groningen, University Medical Centre Groningen, Groningen, Netherlands.

Purpose: The challenge in genetic diagnostics is to apply one comprehensive test for heterogeneous diseases. The number of genes to examine in a particular clinical case can be relatively large because phenotypes of many hereditary syndromes are known to overlap and different genes may underlie a single syndrome. Our aim was to design and implement various targeted next generation sequencing (NGS) gene-panels, starting with those disorders that account for the majority of current diagnostic requests. Methods: As proof of principle we developed a gene-panel based on Agilent Sure Select Target Enrichment® for simultaneous mutation detection for 48 genes associated with hereditary cardiomyopathies. To assess test-sensitivity and specificity we performed a validation on 84 patients. For 24 of these Sanger Sequencing (SS) data for up to six genes were available. Pools of 12 samples were sequenced using 151 bp paired-end reads on an Illumina MiSeq® sequencer and analyzed using NextGene® and Cartagenia-NGS® software. Subsequently, an extended gene-panel targeting 55 cardiomyopathy-associated genes was implemented in routine diagnostics. To date, more than 200 patients have been analyzed. In parallel, a targeted NGS gene-panel for 70 cancer predisposition genes was designed and validated in a similar manner. Results: For the cardiomyopathy gene-panel, 99 percent of all bases had a coverage of ≥30 reads per nucleotide. Because of poor coverage a total of 11 regions were analyzed in parallel using SS. We identified ~21000 variants (~250 per patient). SS was performed for 168 variants (155 substitutions, 13 indels). Al were confirmed, including a deletion of 18 bps and an insertion of 6 bps. Compared to previous routine diagnostics based on SS, application of our NGS-method resulted in increase of diagnostic yield from 15 percent to about 50 percent. Results for validation of the cancer gene-panel were comparable; 99 percent of all bases with ≥30 reads per nucleotide, for 22 regions SS is performed in parallel, no false positive or negative results upon confirmation with SS of 180 variants. The first patients are now being tested in diagnostics. Conclusion: Targeted NGS of a disease-specific subset of genes can be reliably implemented in diagnostics to analyze large numbers of genes in parallel with significantly improved diagnostic yield. Additional gene-panels i.e. for epilepsy and neurodegenerative disorders are currently being designed and implemented.

Improved Accuracy and Precision in Clinical Next Generation Sequencing with the SmartChip TE™ Target Enrichment System. *J. Dunne, W. Dong, G. Hein, S. Silveria, S. Derveaux, A. Chang, S. Anandakrishnan, M. Leong, M. Sanchez, D. Batey, S. Husain.* WaferGen Biosystems, Fremont, CA.

The main challenge for clinical targeted next-generation sequencing methods is obtaining complete and uniform coverage of all target regions. Some popular methods for target enrichment rely on lengthy and inefficient hybrid capture or multiplexed PCR techniques, resulting in lower coverage and more off target reads. To address these challenges, WaferGen has developed the high-density SmartChip TE System. One SmartChip TE panel supports conducting hundreds to thousands of parallel, singleplex PCR reactions to efficiently enrich desired target regions in less than 3 hours. Results of a recent study used a SmartChip TE Panel (140 kb target region) targeting exonic regions in a 17 gene set in 16 cancer cell lines (NCI 60). High design rates and percent bases on target ensured specific amplification necessary for efficient enrichment. The sequencing results from SmartChip TE enriched targets showed coverage at 20x and 100x of 98.8%; and 98.2%; respectively with a uniformity of coverage of 98% at > 10% of mean coverage. Comparison of performance between AmpliSeq and HaloPlex designs and the SmartChip TE custom designs will be presented. The unprecedented enrichment quality is achieved with flexibility of running up to 2500 unique singleplex reactions on a single SmartChip TE chip. The results indicate that CLIA-certified or clinical research laboratories can utilize the SmartChip TE system to obtain the most complete and uniform coverage among target enrichment technologies.

2533F

Improved genetic testing for monogenic diabetes using targeted next generation sequencing. *H. Lango Allen, R. Caswell, E. De Franco, S. Flanagan, G. Hysenaj, K. Colclough, J. Houghton, M. Shepherd, A.T. Hattersley, M.N. Weedon, S. Ellard.* University of Exeter Medical School, Exeter, United Kingdom.

Current genetic tests for diagnosing monogenic diabetes rely on selection of the appropriate gene for analysis according to the patient's phenotype. Next generation sequencing enables the simultaneous analysis of multiple genes in a single test. Our aim was to develop a targeted next generation sequencing assay to detect mutations in all known MODY and neonatal diabetes genes.

We selected 29 genes in which mutations have been reported to cause neonatal diabetes, maturity-onset diabetes of the young (MODY), maternally inherited diabetes and deafness (MIDD) or partial lipodystrophy (FPLD). We designed an exon-capture assay to include the coding regions and conserved splice sites. A total of 114 patient DNA samples were tested: 32 with known mutations and 82 previously tested for MODY (n=33) or neonatal diabetes (n=49) but in whom a mutation had not been found. Sequence data were analysed for the presence of base substitutions, small indels and exonic deletions or duplications.

All known mutations and polymorphisms (n=70 different variants) were detected including 55 base substitutions, 10 small insertions or deletions and 5 partial/whole gene deletions/duplications. Previously unidentified mutations were found in 5 patients with MODY (15%) and 9 with neonatal diabetes (18%). Most of these patients (12/14) had mutations in genes that had not previously been tested. These included mitochondrial m.3243A>G mutation; previously missed intronic *HNF4A* (c.358+5G>A) mutation; mutations in *EIF2AK3* and *SLC19A2* not originally tested because patients were referred before the onset of syndromic features; *ABCC8* mutation that was missed because of allelic dropout caused by a polymorphism within a primer binding site; and novel mutations in *GCK*, *PDX1* and *GATA6*.

In conclusion, our novel targeted next generation sequencing assay provides a sensitive method for simultaneous testing of all monogenic diabetes genes. The increased number of genes tested led to an improved mutation detection rate.

2534W

NGS Data Analysis for a Primary Immunodeficiency Gene Panel using Haloplex Enrichment Method.
J. Durtschi[1], E.M. Coonrod[1], R.L. Margraf[1], H.R. Hill[1,2,3,4], K.V. Voelkerding[1,2], A. Kumáovics[1,2]. 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 3) Department of Medicine, University of Utah School of Medicine, Salt Lake City, UT; 4) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Haloplex (Agilent) gene target enrichment offers a cost effective and efficient work flow for library preparation followed by Illumina MiSeq sequencing and was used to develop a panel targeting 94 primary immunodeficiency associated genes. Haloplex capture uses restriction enzymes to digest genomic DNA and then probes selectively capture and amplify DNA in 100 to 500 base DNA segments tiled across target regions. Haloplex sequence data is characterized by non-randomly distributed sequence inserts defined by the limited set of restriction enzymes used and unwanted Illumina adapter sequence at read 3' ends when sequencing goes beyond the end of shorter Haloplex insert sizes. In this study we evaluate Haloplex data processing and analysis issues encountered in our 94 gene panel. A custom Haloplex panel was designed for 94 genes associated with primary immune deficiency disorders and used to prepare NGS libraries for 40 samples. Four samples were indexed and multiplexed per Illumina MiSeq, 2x150, paired end run. Read data were trimmed of MiSeq adaptor sequence present at some 3' read ends, aligned, and analyzed using Cutadapt, BWA, and GATK softwares, respectively. During Haloplex data processing, Illumina adapter sequence was identified and trimmed from an average 40% of reads amounting to 13% of bases trimmed per data set. After this trimming, over 10% of reads were shorter than 100bp suggesting that these reads came from unintentional Haloplex inserts below the 100bp minimum. Inferred insert size analysis of alignments also indicated insert sizes less than 100bp for over 10% of read pairs. Median coverage in coding regions of panel genes was much higher in Haloplex samples versus three typical Nimblegen v3 exomes (on average, 1062 versus 123) but the fraction of the same coding regions with coverage below 30 was higher in Haloplex versus exomes (11% versus 4%) indicating less uniform coverage of Haloplex data. Of the collection of 702 different coding region variants that passed basic variant filters in at least one of 40 samples, 23% were not seen in the 5,400 exome data set, indicative of a high false positive rate. However, many likely false positives appear at systematic, trackable locations. Our ongoing study indicates that, when properly managed, these Haloplex data characteristics lead to an effective enrichment method for our multi-gene panel assay for the clinical testing of primary immunodeficiencies.

2535T

Detection of copy number variants in whole exome sequencing data in routine genome diagnostics.
N. de Leeuw, J.Y. Hehir-Kwa, D. Lugtenberg, M. del Rosario, J. de Ligt, R. Pfundt. Dept Human Genetics, Radboud University Medical Centre, Nijmegen, Netherlands.

Genome wide high resolution SNP array analysis has been used in our laboratory for the detection of copy number variations (CNVs) as a first tier diagnostic tool since 2009. In the past two years, we have increasingly used whole exome sequencing (WES) for the detection of clinically relevant single nucleotide variations (SNVs) and small insertion-deletions in our diagnostic setting for a variety of genetic diseases. In addition to this SNV detection, we recently demonstrated the clinical utility of WES to detect CNVs in a representative dataset from patients with intellectual disability (ID) in whom diagnostic SNP array analysis previously detected de novo, pathogenic CNVs. Based on these results, we implemented CNV detection in WES data parallel to the existing SNV detection, thereby increasing the range of genetic variation and the diagnostic yield that can be obtained from WES data. We started with the retrospective analysis of a total of 205 patients with ID and their parents who had previously been sent in for WES diagnostic trio analysis. Parental data were used to determine the inheritance or de novo occurrence of the CNVs, and also served as an estimation for the likelihood of detecting an incidental finding. We will compare the results of CNV detection in exon-targeted WES data for a total of 615 samples with high resolution genome wide SNP array (Affymetrix CytoScan HD array) data from 3,500 patients and parents. Our discussion will focus on the differences in resolution, the detection rate of clinically relevant CNVs and their copy number state, as well as on the frequency of incidental findings. We show that WES can be successfully used to efficiently reach a diagnosis in a patient by analysing both SNVs as well as CNVs, making WES a suitable approach as a first tier diagnostic test for patients with ID and/or congenital anomalies.

Clinical interpretation and reporting of secondary findings from genome sequencing: lessons learned from the first 15 cases of The MedSeq Project.
H.M. McLaughlin[1,2], J. Krier[3,4], W.J. Lane[1,5], D. Metterville[2], I. Leshchiner[2,4,6], B.H. Funke[1,2,7], J.L. Vassy[4,6,8], M. Murray[9], I.S. Kohane[3,4,6,10], S.W. Kong[3,11], C. MacRae[4,6], M.S. Lebo[1,2,5], R.C. Green[4,6], H.L. Rehm[1,2,5] for The MedSeq Project. 1) Department of Pathology, Harvard Medical School, Boston, Massachusetts, USA; 2) Laboratory for Molecular Medicine, Partners Center for Personalized Genetic Medicine, Cambridge, Massachusetts, USA; 3) Department of Pediatrics, Harvard Medical School, Boston, Massachusetts, USA; 4) Department of Medicine, Brigham and Women's Hospital, Boston, MA, USA; 5) Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA; 6) Department of Medicine, Harvard Medical School, Boston, Massachusetts, USA; 7) Department of Pathology, Massachusetts General Hospital, Boston, Massachusetts, USA; 8) VA Boston Healthcare System, Boston, Massachusetts, MA; 9) Geisinger Health System, Danville, Pennsylvania, USA; 10) Department of Pediatrics, Boston Children's Hospital, Boston, Massachusetts, USA; 11) Department of Medicine, Boston Children's Hospital, Boston, Massachusetts, USA.

The MedSeq Project is a randomized clinical trial that aims to develop tested approaches for the evaluation and reporting of genome sequencing data and seeks to assess the impact of integrating genome sequencing into clinical care. MedSeq participants in the sequencing arm of the study receive a summary of secondary findings returned in a General Genome Report (GGR). The GGR features a concise summary of genome-wide secondary findings with clearly delineated sections for (1) highly-penetrant monogenic disease risk; (2) carrier status for phenotypes associated with recessive inheritance; (3) pharmacogenomic associations; and (4) blood groups. Here, we describe bioinformatics, interpretation, and reporting approaches for The MedSeq Project. Population frequencies from 1000 Genomes and the Exome Variant Server, loss-of-function predictions, and variant databases such as the Human Gene Mutation Database are used to filter potential disease-causing variants from the 3-5 million variants produced from each genome sequence, resulting in 100-130 variants requiring manual assessment per case. Comprehensive evidence-based variant and gene assessments are performed for each variant to identify those with evidence for causing highly penetrant disease, typically 1-5 per case, which require Sanger confirmation. Finally, a team-based approach is utilized to determine variant inclusion and a concise, information-rich GGR is drafted using the GeneInsight® software system. All results are summarized on a single page with ~3 additional pages of supporting material providing the evidence for disease association, disease and phenotypic descriptions, details on pharmacogenomic associations, and serologically confirmed blood antigen results. Our experience from The MedSeq Project highlights important considerations in the reporting of secondary findings and provides a framework for interpretation and reporting practices in clinical genome sequencing.

Analytical Performance of a Next-Generation DNA Sequencing-based Clinical Workflow for Genetic Carrier Screening. *G.J. Porreca, M. Umbarger, C. Kennedy, P. Saunders, B. Breton, N. Chennagiri, D. Maganzini.* Good Start Genetics, Cambridge, MA.

Next-generation DNA sequencing (NGS) is poised to displace genotyping technology for clinical applications because it promises richer information at low cost. However, to date a number of considerations including sequence accuracy and completeness, as well as workflow scalability, have limited its adoption in the clinical laboratory. Here we describe a NGS-based platform designed for genetic carrier screening in a clinical setting. A set of 15 genes are isolated from genomic DNA by automated multiplex target capture, tagged with molecular barcodes, and pooled and sequenced on the Illumina Hiseq system. Reads from each sample are de-multiplexed, aligned to a reference, and integrated into accurate genotype calls which are then interrogated for pathogenic mutations. A total of 42,858 bp were targeted for capture by a set of molecular inversion probes designed to tile across the target such that each base was captured by at least three different probes. Across a set of 182 DNA samples derived from cell lines or blood, a median of 99.71% of bases were sequenced to sufficient depth and quality for inclusion in genotype calling. Replicate runs exhibited a high level of concordance, with 17 discordant single nucleotide variant (SNV) calls out of 5,177,206 across 126 samples. Concordance of genotype calls with bi-directional Sanger sequence of PCR amplicons derived from a set of 194 samples was 99.97% at SNV positions (1 out of 4,001 Sanger SNV calls discordant), and 99.9999% at non-variant positions (8 out of 6,992,754 Sanger non-variant calls discordant). We identified, in a set of 55 samples, a total of 92 mutations (out of 92) that have been previously reported to be causative of recessive Mendelian disease. We also determined that 9 previously uncharacterized samples contained mutations that were either known or expected to be pathogenic. Clinical carrier screening has traditionally been performed using genotyping technology, and demands high analytical accuracy. Our NGS platform achieves exceedingly high concordance with Sanger sequencing, long considered an accuracy gold standard. Furthermore, we made high-confidence genotype calls across the vast majority of basepairs within our target regions. Taken together, these results indicate that NGS, when paired with the appropriate sample preparation methodology, automation, and data analysis, can deliver the performance required for use in clinical carrier screening.

2538T

Targeted exome sequencing identifies two pathogenic *DYNC2H1* variants in a fetus with short-rib-polydactyly syndrome. *K.I. Varvagiannis[1,2], P. Makrythanasis[2], F. Santoni[2], J.-M. Pellegrinelli[3], P. Extermann[4], C. Brockmann[1], C. Gehrig[1], M. Guipponi[1,2], J.-L. Blouin[1,2], S.E. Antonarakis[1,2], S. Fokstuen[1].* 1) University Hospitals of Geneva, Service of Genetic Medicine, Genome Clinic, Geneva, Switzerland; 2) University of Geneva, Department of Genetic Medicine and Development, Geneva, Switzerland; 3) University Hospitals of Geneva, Department of Gynecology and Obstetrics, Geneva, Switzerland; 4) Dianecho, Geneva, Switzerland.

The short-rib-polydactyly syndromes (SRPS) represent a heterogeneous group of ciliary skeletal dysplasias characterized by a narrow thorax, short ribs and limbs and polydactyly. To date, more than 10 genes have been associated with this mainly autosomal recessively inherited phenotype.

We applied targeted exome sequencing on an affected fetus presenting with micromelia, postaxial polydactyly of both hands and feet, short ribs and a severe cardio-thoracic disproportion. The pregnancy was terminated at 18+3 gestational weeks based on the ultrasound findings.

Exome sequencing was performed on the fetus' DNA using an Illumina HiSeq2000. Bioinformatic analysis was carried out using BWA, samtools, pindel and ANNOVAR. Analysis was targeted to the 10 genes previously implicated in SRPS: *NEK1, DYNC2H1, IFT80, WDR35, EVC2, EVC, TTC21B, WDR19, IFT122, IFT43,* while masking the rest of the detected variants. An 8x and 30x coverage of 99.57% and 98.29% respectively, was achieved for the 10 genes. Variant calls were annotated and filtered for their presence in known genome databases (1000Genomes, dbSNP, Exome Variant Server) as well as in our in-house variant database. Two candidate variants were identified in *DYNC2H1* - a splicing variant (NM_001377.2:c.1953G>A) previously reported in the literature and a novel missense (NM_001377.2:p.(Ala1542Val)) - as well as a 16 bp insertion in *TTC21B* leading to a frameshift and a premature termination codon (NM_024753.4:p.(Thr8Valfs*4)). Sanger sequencing was performed for confirmation of the variants and verification of their phase. Both parents were found to carry one *DYNC2H1* variant, while the mother was carrier of the *TTC21B* insertion, establishing the genetic diagnosis of SRPS in the fetus.

While the analysis was ongoing the couple went through a second termination of pregnancy due to recurrence of an affected fetus. Sanger sequencing, revealed the presence of the two *DYNC2H1* variants but absence of the *TTC21B* variant.

Our results demonstrate that targeted exome sequencing is an efficient and cost-effective approach for the identification of pathogenic variants in genetically heterogeneous disorders.

Validation of an Accurate, High-Throughput Multiplex qPCR Assay to Confirm CMA Clinical Findings. *L.E. Northrop, V. Aggarwal, V. Jobanputra, M. Mansukhani, B. Levy.* Columbia University, Department of Pathology & Cell Biology, Division of Personalized Genomic Medicine, New York, NY.

Chromosomal microarray analysis (CMA) is the standard cytogenetic screening method in clinical constitutional laboratories, especially in patients with developmental delay and intellectual disability. The demand for CMA in prenatal patients is likely to increase following the findings of the recent NICHD multicenter prenatal study, recognizing the need for a more comprehensive screening technology. Confirmation of abnormal CMA results is easily achieved by Fluorescence *in situ* hybridization with BAC probes (BAC-FISH), especially when dealing with imbalances >500kb in size. However confirmation of duplications <500kb is often difficult due to interpretive challenges and confirmation of deletions <200kb there is often no available BAC probe. Furthermore, the cost of BAC probes can be high with a long turn-around-time (TAT) of several weeks. Given these limitations, we investigated an alternative molecular-based method for confirmation of abnormal CMA results. Several clinical labs use qPCR copy number (CN) testing for confirmation of their abnormal CMA results. However, there are no universal published guidelines on the design and validity of qPCR as a confirmation testing method in a clinical setting. A validated qPCR method for CN confirmation is merited in abnormal CMA cases with smaller imbalances. Especially in clinical labs that need to be in compliance with New York State Standards of Clinical Laboratory Practice. We have designed a cost-effective, high-throughput RT-qPCR method with a quick TAT for the confirmation of CMA aberrations that are reported in our clinical laboratory. A brief description of our design consists of taking direct genomic DNA to a 96 well plate with 28 references run in triplicate, the proband, parents &/or sibships (if available). We developed a multiplex assay which includes the 'test' gene and 'endogenous' gene in a combined SensiFast lo-rox master mix (Bioline) detected by fluorescence probe capture (IDT). This method is highly accurate & specific in confirming CN for CMA with a TAT of approximately one week from design to result. By this approach, we have accurately confirmed CMA abnormalities that could not be confirmed by BAC-FISH (either because of probe availability or due to BAC size limitations). Our validation cohort consists of imbalances as small as 5kb and as large as 483kb. We propose qPCR as the standard method when confirming CMA duplications <500kb and deletions <200kb in a clinical setting.

Detection and quantification of somatic mutations in Klippel-Trenaunay Syndrome using digitally counted nanodroplets. *N.M.K. Kamitaki[1], V. Luks[2], R. Murillo[2], S.A. McCarroll[1], M. Warman[1,2,3].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Orthopaedic Research Laboratories, Department of Orthopaedic Surgery, Boston Children's Hospital, Boston, MA; 3) Howard Hughes Medical Institute, Boston Children's Hospital, Boston, MA.

All human tissues contain cells with somatically acquired mutations. Those mutations that cause disease may be difficult to identify. When the fraction of cells having a somatic mutation is high in an available tissue, the disease causing mutation can be identified using commonly applied sequencing methods, such as massively parallel sequencing of exomes or genomes, or PCR-based amplifications and sequencing of candidate genes. When the frequency of mutant cells is low, mutation detection becomes much more challenging with these methods. Our molecular approach is based on using allele-specific digital PCR in nanodroplets. We designed primers and allele-specific probes, where each reference and mutation-specific probe for a given site have different fluorophores, to target five of the most common *PIK3CA* mutations found in overgrowth syndromes and cancer. We start off with a standard PCR mix and after adding the sample, emulsify the solution into tens of thousands of nanodroplets, each of which contains the materials requisite for PCR, but only some of which contain a template DNA molecule from the patient's genome. We count the number of droplets positive for each fluorophore using a Bio-Rad QX1000 Droplet Reader. This allows digital counting of the abundance of each allele, allowing us to not only detect if mutant alleles are present, but also to quantify their frequency. We previously identified somatic mosaic missense mutations in *PIK3CA* in three patients with Klippel-Trenaunay Syndrome (KTS). Using this molecular approach to screen affected tissue samples from 28 individuals with KTS we identified mutant allele frequencies ranging from 2.7% to 16% in 21 of these patients. This suggests that the majority of patients with KTS have recurring mutations in *PIK3CA*. Our results do not preclude all KTS being caused by somatic mutations in *PIK3CA*, since our assay was designed to query only five common mutations. Advantages of digital PCR using nanodroplets include low reagent costs, rapid turnaround, and ease in adding new mutations to the assay. Additionally, we have been able to consistently detect 0.1% mutation frequencies within dilution series, demonstrating the high sensitivity of this assay. Using this technique to initially screen affected tissue for *PIK3CA* mutations will reduce the number of samples that will need to be tested using more expensive and time consuming mutation detection methods.

2541T

Prenatal Testing of novel mutations of Maple syrup urine disease by next-generation sequencing. *S. Chen, X. Li, H. Ge, X. Pan, F. Chen, H. Jiang.* BGI-Shenzhen, Shenzhen, Guangdong, China.

Objectives: The applications of massively parallel sequencing technology to fetal cell-free DNA (cff-DNA) have brought new insight to noninvasive prenatal diagnosis. However, most previous studies based on maternal plasma sequencing have been restricted to fetal aneuploidies. Our study aim to report the first case to combine the target capture next-generation sequencing (NGS) for identifying new mutations in unexplained Mendelian disorders cases and NIPT of single-gene disorders by maternal plasma DNA sequencing together, to prove the feasibility and potential of clinical integration. **Methods:** We recruited a pregnant couple with a maple syrup urine disease (MSUD) proband child to develop our method. Target capture next-generation sequencing was performed to identify new mutations in the related gene. The maternal plasma was isolated for DNA extraction and target sequencing with a semi custom array. Then, a haplotype-assisted strategy was developed to detect whether the fetus is inherited the pathogenic mutations in target gene. **Results:** We identify a heterozygosis duplication in exons 2-4 of gene BCKDHA in proband and father, a potential variant, c.392A>G in BCKDHA, in proband and mother. The parental haplotype was constructed successfully in this trio family by target region sequencing. Then, a sensitive Hidden Markov Model (HMM) was used to identify the parental transmitted allele and recombination breakpoints in the maternal plasma. In the pathogenic gene, BCKDHA, the fetal inherited the same alleles with the proband, which indicated it was also a MSUD patient. Real-time PCR and Sanger sequencing performed on DNA samples of amniotic fluid and umbilical cord blood were consistent with our diagnostic results. **Conclusions:** Target capture and NGS have significant efficacy and scalability for identifying new genes or new mutations in unexplained Mendelian disorders cases and NIPT by maternal plasma DNA sequencing has been proved to be feasible for noninvasive detection of single-gene disorders. This is the first report to use the complicated pipeline in real clinical setting, to combine the target capture next-generation sequencing for identifying new mutation and noninvasive prenatal testing by maternal plasma DNA sequencing for prenatal testing together, which indicate the potential use in routine clinical practice.

New allele-specific real-time PCR system with automatic interpretative program for genotyping of SNPs related to pharmacogenetics. *D. Kim, S. Byun, J. Seo, C. Lee.* Molecular Diagnostics Division, Bioneer Corporation, Daejeon, Korea.

Various human SNP (single nucleotide polymorphism) markers have been found to be involved in drug metabolism. The accurate analysis of genetic variations of particular genes encoding drug metabolic enzymes is critical for pharmacogenetics. Direct sequencing is used as a gold standard for genotyping of candidate genes, however, a faster and higher-throughput method is often required for the tests in clinical laboratories. Recently, we developed a new real-time PCR system, ExiGenotyper, with the automatic interpretation program for SNP genotyping, and genotyping kits of VKORC1 and CYP2C9, CYP2C19, and TPMT (thiopurine S-methyltransferase). SNP genotyping of VKORC1 and CYP2C9 genes is useful for determining the optimal warfarin dose. The CYP2C19 gene is a subtype of cytochrome p450 which is related with clopidogrel dosing. The TPMT gene encodes a protein that catalyses S-methylation of aromatic and heterocyclic sulfhydryl compounds, and TPMT activity can be estimated through the SNP genotyping of the TPMT gene. The allele-specific primer method was used for real-time PCR in this system for the determination of SNP genotype. For the evaluation of the system and the genotyping kits, SNP verified clinical samples by direct-sequencing were used. ExiGenotyper warfarin genotyping results of 82 human genomic DNA samples agreed with direct sequencing results. ExiGenotyper CYP2C19 genotyping results of 59 human genomic DNA samples were in concordance with direct-sequencing and ExiGenotyper CYP2C19 genotyping results of 26 samples agreed with results from a commercially available POC device. ExiGenotyper TPMT genotyping results of 246 human genomic DNA samples were in agreement with direct sequencing. The results suggested that the new system we developed allows accurate and rapid genotyping of SNP and is applicable in clinical laboratories.

Discrepant Tay-Sachs disease enzyme and DNA carrier screening results in the African American population. *D. Neitzel, H. Travassos, N. Faulkner, S. Hallam, V. Greger.* Good Start Genetics, Cambridge, MA.

Tay-Sachs disease (TSD) is a common autosomal recessive condition in the Ashkenazi Jewish population. It has also been observed at higher frequencies in other populations. TSD carrier screening is currently recommended by ACOG and other societies for high-risk populations, as well as for couples where at least one member is high-risk. Screening consists of both DNA analysis of the HEXA gene as well as HexA enzyme analysis. Screening has led to a significant reduction in the incidence of TSD in the high-risk populations. Today, most new cases of TSD are born to couples where at least one member of the couple does not belong to a high-risk population. According to ACOG's position statement, 'biochemical analysis should be used for individuals in low-risk populations'. At the time of result reporting, we noted a high percentage of indeterminate and positive TSD enzyme results without mutations present in the African American population (AA), leading us to retrospectively evaluate the data on all samples tested. Good Start Genetics' TSD DNA sequencing test detects 67 known disease-causing mutations (including the 7.6kb deletion) plus novel truncating mutations. HexA enzyme activity was assessed on leukocytes. Out of 2656 individuals tested, 144 self-reported as AA. 16/144 (11%) were enzyme positive and 46/144 (32%) were indeterminate. In comparison, 15/1038 (1.5%) were enzyme positive and 82/1038 (7.9%) were indeterminate in self-reported Caucasians. No mutations or pseudodeficiency alleles were identified in any of the TSD enzyme positive or indeterminate AA individuals. Based on enzyme data alone, the observed carrier frequency in our AA population is 1/9 versus an expected frequency of 1/300. Given the low incidence of TSD in the AA population and the fact that no mutations could be identified in these samples, this result raises questions about the reliability of enzyme analysis in the AA population. Another commercial laboratory has also reported a higher than expected percentage of TSD enzyme indeterminate and positive results in the AA population without identifying any DNA mutations. However, only the most common mutations were tested. Our data is based on more extensive DNA analysis, and we corroborate their findings. The reference ranges for HexA enzyme activity need to be re-evaluated. Despite guidelines, enzyme analysis is NOT currently an accurate method to assess TSD carrier status in the AA and possibly other populations.

Diagnostic Sequencing - implemention into routine processes. *K. Stangier, T. Paprotka.* GATC Biotech, Konstanz, Germany.

Next generation sequencing is on its way to play a more and more important role for analyzing genetic and genomic diseases and finding its way into clinical diagnostics. We will present the workflow of the implementation of next generation sequencing into routine processes for diagnostic and clinical purpose. Starting from the approach to design and set up pilot projects through validation studies the whole cycle till the product launch will be illuminated. Data on sensitivity and sensibility from a clinical study as well as from the final product will be shown. The data sets include analysis of genetic disorders, cancer and prenatal diagnostic of more than 7,500 patients. Also, the implementation of the final test in a ISO accreditation will be described. Utilizing Next Generation Sequencing in clinical and genetic diagnosis and personalized disease risk profiling is very important in the future. Further optimization of samples isolation and preparation as well as sensitivity and data analysis pipelines will help to integrate Next Generation Sequencing into a common clinical setup.

Molecular Genetic Diagnosis of Fanconi Anemia in Chinese patients.
X. Chen[1], H. Liu[2], W. Teng[2], F. Wang[2], Y. Wang[2], Q. Yin[2], M. Wang[2], L. Guo[2], P. Zhu[1]. 1) Department of Hematology, Peking University First Hospital, Beijing, China; 2) Molecular Medicine Lab, Hebei Yanda Hospital, Hebei, China.

Background: Fanconi anemia (FA) is a group of hereditary diseases, the typical clinical manifestations including anemia and multiple congenital malformations. However, FA patients didn't always with malformation, thus gene mutation inspection is useful in diagnosis and differential diagnosis of FA and autoimmune aplastic anemia (AA), aplastic anemia - paroxysmal hemoglobinuria syndrome (AA-PNH). Method and Cases: FANCA, FANCC, FANCG gene mutation analysis by PCR and Sanger sequencing, PNH phenotype detection by flow cytometry and chromosome breakage test was performed in 28 cases which clinically suspected FA. Results: 1) 12 cases were identified carrying FA gene mutation, 4 males and 8 females. Bone marrow failure symptoms began at 0.5 to 15 years old, with a median age of 5 years old. 2) 10 cases carrying FANCA mutations, 1 with FANCC mutations, 1 with FANCG mutations. Biallelic mutations were identified in 3 cases, respectively were FANCG W184X homozygous, FANCA L1249RfsX16 and 3067-2A>C, FANCA H330LfsX2 and P1324L. Only one heterozygous mutation were identified in each other 8 cases, including FANCA Q123X, R413C, Q563R, A840P, L871V, S858R, E878RfsX8, A958V and FANCC R334W. Pedigree analyses were performed in 5 families and all confirmed being hereditary. 3) 6 out of the 12 gene mutation-positive cases clinically with café au lait spots and/or organ malformations. Chromosome breakage test were positive in 4 out of 6 gene mutation-positive cases. 4) A significant proportion of PNH cells were detected by flow cytometry in one FANCA mutated patient, with CD55 (-) 66.68% and CD59 (-) 68.81% in granulocyte. However, the patients showed multiple sporadic mutations rather than clonal mutations in PIGA gene. Conclusions: Gene mutation inspection is useful in diagnosis and differential diagnosis of FA, AA and AA-PNH.

Estimating the contribution of unidentified mutations in autosomal recessive disorders.
L.P. ten Kate[1], M.E. Teeuw[1], A. Sefiani[2,3], F-Z. Laarabi[2,3], I. Hama[3], L. Henneman[1], M.C. Cornel[1]. 1) Dept Clinical Genetics, VU Univ Med Ctr, Amsterdam, The Netherlands, Netherlands; 2) Dept Medical Genetics, Nat. Inst. of Health, Rabat, Morocco; 3) Center of Human Genomics, Fac. of Medicine and Pharmacy, Univ. Mohammed V Souissi, Rabat, Morocco.

It has been shown before that the total pathogenic gene frequency (q) of an autosomal recessive disorder can be estimated from existing mutational data, provided that (a) the overall inbreeding coefficient (F) of patients in the sample is known and above zero; and (b) for all patients in the sample bi-allelic mutations are found (1,2). Not infrequently however, some patients reveal only one mutation or none at all even though they meet the clinical criteria. For instance, in a sample of 175 Moroccan Familial Mediterranean Fever (FMF) patients 43 were found with bi-allelic MEFV mutations (27 homozygotes and 16 compound heterozygotes), 23 with only one identified mutation, and 109 without any identified mutation. Average F in this sample was 0.0122. Suppose we may assume that all 23 patients with only one identified mutation are in fact compound heterozygotes, with the second mutation unidentified, how many of the 109 patients without an identified mutation would then be homozygotes of the same unidentified mutation? This question can be solved because there is a fixed ratio between homozygotes (HO) and compound heterozygotes(CH) for any given allele ai, depending on F and q only, as shown in the following equation: HO/CH = $[F + (1\text{-}F)\, a_i.q]/[2q(1\text{-}F)(1\text{-}\, a_i)]$, in which a_i represents the relative frequency of allele a_i. Taking now the observed HO/CH ratios of identified alleles as a reference, one will be able to make a proximal estimate of the number of homozygotes with the unidentified allel (in this case 17), and subsequently the total pathogenic gene frequency including the unidentified mutation. As the HO/CH ratio will be smaller when there are two or more different unidentified alleles, and as some of the heterozygotes may in fact be real heterozygotes, the above estimate is a maximum one. So, at least 92 of the FMF cases in this sample were not caused by recessive MEFV mutations. Other explanations for their existence are needed. (1) Ten Kate et al. J Community Genet 2010; 1: 37-40 (2) Giallusi et al. Eur J Hum Genet 2013; Mar 13, doi: 10.1038/ejhg.2013.43 [Epub ahead of print].

The effect of Long-Term Frozen Storage of Urine Samples on the detection of Chlamydia trachomatis in comparison to Preserved - Room temperature Urine Samples.
M.AK Abdalla[1], M. El-Mogy[2], C. Moreira[3], R. DiPietro[4], T.A Haj-Ahmad[5], Y. Haj-Ahmad[3,5]. 1) Department of Biochemistry, Faculty of Science, Alexandria University, Egypt; 2) Molecular Biology Department, National Research Center, Dokki, Cairo, Egypt; 3) Brock University, 500 Glenridge Avenue, St. Catharines, ON, L2S 3A1; 4) Department of Biochemistry, Faculty of Science, McMaster University, ON, Canada; 5) Norgen Biotek Corp., 3430 Schmon Parkway, Thorold, Ontario, Canada, L2V 4Y6.

Chlamydia trachomatis is a widespread sexually transmitted disease that can be avoided by the early detection of the pathogen. Urine is a biological sample that can be considered for the detection of the pathogen. However, some studies have shown that long terms frozen urine is not suitable for molecular based assays, likely due to degradations. The main goal of this work was to compare the effect of urine chemical preservation and storage at room temperature and urine stored at 4ºC and -70ºC on the quality of the isolated DNA and hence the detection of pathogens in urine. Briefly, urine sample was spiked with known amount of Chlamydia trachomatis, and then subdivided into three sets of samples: One set of samples were stored at 4ºC, the second set at -70ºC and to the third set was chemically preservative and stored at room temperature. Total genomic DNA was isolated both at time zero and after three months. Total Urinary DNA as well as Chlamydia DNA were purified and were analyzed qualitatively using conventional and Real-time PCR. The data shows the effect of storing urine samples at different storage conditions, with or without preservative, on the quality of the isolated DNA and hence on the detection of Chlamydia from urine.

2548F

De-novo occurrence of SMN1 deletions: parental origin and frequencies.
K. Eggermann, T. Eggermann, K. Zerres, S. Rudnik-Schöneborn. RWTH Aachen, Aachen, Germany.

Spinal muscular atrophy (SMA) is a severe neuromuscular disorder characterized by degeneration of anterior motor neurons, resulting in a progressive muscle weakness and paralysis. SMA is caused by mutations in the survival motor neuron 1 (SMN1) gene in 5q13. The homozygous deletion of the SMN1 gene accounts for nearly 95 %; of SMA patients and the vast majority of parents are heterozygous carriers, as de-novo mutations occur in only 1-2 % of patients. However, in a number of parents two SMN1 copies can be detected. This can either be explained by two SMN1 copies on the same chromosome 5q13 and the deletion on the other (genotype 2 +0), or by a de-novo deletion and a regular SMN1 distribution in the parent (genotype 1+1). Several tests for SMN copy number analysis (e.g. MLPA, qPCR) have been developed, aiming at the identification of heterozygous carriers of the SMN1 deletion. However, they do not allow the differentiation between carriers of the 2+0 and the 1+1 genotype. Interestingly, in the patients with a de-novo deletion a significant preponderance of paternal chromosomes affected by the mutation has been observed (12 paternal de-novo deletions versus 2 maternal ones). Here we report on our molecular findings of more than 200 parents of SMA patients with a homozygous deletion. All probands were investigated by MLPA; in parents with two SMN1 copies microsatellite typing was performed. In 7 parents two SMN1 copies were identified, among them four with a 2+0 genotype. Three parents had a regular 1+1 genotype (non-carriers). The de-novo deletion twice affected the maternal chromosome and once the paternal SMN1 copy. Our results and those from the literature (n>830) show that (a) about 5 % of SMA parents carry two SMN1 copies, (b) about one third of those can be explained by de-novo deletions in the patients. We also conclude that the previously observed imbalance between paternal and maternal chromosomes affected by the de-novo deletion may be biased by the small number of cases. Finally we want to emphasize that the differentiation between the different genotypes in SMA parents (2 +0 versus 1+1) does not only provide information that will assist the SMA families in further family planning but it also contributes to a more accurate risk assessment for further relatives.

2549W

A Connective Tissue Disorders NGS Panel: Development, Validation, and Novel Findings. *J. Lee, M. Basehore, S. McGee, K. Kubiak, K. King, K. Champion, J. Jones, M. Friez.* Greenwood Genetic Center, Greenwood, SC.

Connective tissue disorders represent a heterogeneous group of more than 200 recognized conditions for which the connective tissues are the primary pathologic target. Connective tissues are the structurally supportive components of the body that form a framework or structural matrix, connect body tissues, and provide protection of organs and storage of energy. While certain connective tissue disorders are associated with definitive phenotypes, some patients may have non-specific or atypical presentations. Many patients might also present with similar features due to the clinical variability and variable expressivity observed among these disorders. For these cases, we have developed and validated a targeted sequencing panel for routine clinical diagnostic testing, using RainDance™ microdroplet enrichment and SOLiD™ Next Generation Sequencing (NGS), to analyze the coding and flanking intronic regions of 31 genes associated with various connective tissue disorders simultaneously. This method enables the detection of single nucleotide changes and small duplications and deletions in genes that, collectively, are associated with at least 80 distinct connective tissue disorder phenotypes. Molecular testing was performed using our diagnostic NGS panel on an initial cohort of 22 patients with suspected connective tissue disorders. We identified novel likely-pathogenic changes in four (18%) of these patients, including a heterozygous frameshift alteration in *COL5A1* in a patient with a phenotype consistent with Ehlers-Danlos syndrome, an apparently homozygous frameshift alteration in *ZNF469* in a patient with features of Brittle Cornea syndrome, a heterozygous nonsense alteration in *TNXB* in a patient with joint hypermobility, and a heterozygous frameshift alteration in *COL1A1* in a patient with features of Osteogenesis Imperfecta. Of the remaining patients, only two (9%) were found to have normal results, with no molecular alterations, and 16 (73%) had at least one variant of uncertain clinical significance. These preliminary findings suggest that our targeted NGS panel may have a potentially high diagnostic value for patients with suspected connective tissue disorders. Furthermore, the simultaneous analysis of a panel of 31 connective tissue disorder genes enables a more efficient diagnostic strategy compared to a single-gene approach using traditional Sanger sequencing.

2550T

Validation of clinical NGS vs. sanger sequencing: Measuring the value of orthogonal testing. *S. Lincoln, S. Kash, Y. Kobayashi, G. Nilsen, J. Sorenson, M. Cargill, R. Scott.* InVitae, San Francisco, CA.

Next Generation Sequencing (NGS) technology can help expand clinical use of constitutional genetic testing by allowing large numbers of genes to be rapidly tested in patients at low cost. However, broad adoption of NGS requires demonstration of clinical-grade accuracy, in part to address concerns about false positive findings in increasingly large gene panels. Because of these concerns many clinical NGS labs confirm pathogenic variants in patients using Sanger sequencing, adding to cost and slowing turn-around times.

We have embarked on a set of studies to measure the performance of clinical NGS by comparison with Sanger, and these studies may help determine the need for orthogonal confirmation. We apply NGS to individuals who have undergone traditional genetic tests, including both patients with various indications as well as reference DNAs from the Get-RM Program. We enrich for individuals with pathogenic variants (~50%) to measure sensitivity as well as specificity, and among those individuals we enrich for certain variation classes known to be challenging for NGS. At the same time, one study cohort is being selected prospectively to include unbiased representation of all patients indicated for genetic testing under current clinical guidelines.

To date over 200 individuals have been tested by Illumina NGS and also by Sanger, with our NGS lab blinded to the other results. In these we see 100%; concordance for both variant and reference bases called. We plan to expand these studies to include about 1000 samples by the time of the ASHG 2013 meeting and to 2000 thereafter.

We are also augmenting the study with 9 HapMap samples, for which we have collected multiple data sets into a 'gold standard' for over 200 clinically relevant genes. These samples allow many variant and invariant positions to be studied per sample, with the caveat that known pathogenic variants are found less frequently than they are in clinical samples.

NGS data quality depends on careful choice of platform, assay, algorithms, parameters and QC criteria. We will describe our methods in addition to the validation study details. We intend to quickly make as much of the above data public as possible.

2551F

Success and flaws when using NGS for molecular diagnosis. *K. Rocha, M. Lazar, G. Yamamoto, M. Aguena, V. Takahashi, R. Pavanello, M. Passos-Bueno.* Gen e Biol Evolutiva, Inst Biocien Univ Sao Paulo, São Paulo, SP, Brazil.

The Human Genome Research Center (HGRC) offers molecular diagnosis to several diseases, mainly neuromuscular disorders and some cases of skeletal dysplasias using traditional molecular biology techniques such as MLPA, for detecting targeted deletions or duplications, or Sanger sequencing, in cases caused by small nucleotide changes. Unfortunately, a considerable number of cases of these disorders remain unconcluded, mostly because several of them are characterized by clinical and genetic heterogeneity, while in some others, as Duchenne muscular dystrophy, where around 30% are caused by point mutations, the high cost of Sanger sequencing method is unaffordable for most of the Brazilian families. In order to expand the number of conclusive molecular diagnosis, we designed a custom next-generation sequencing panel containing approximately 200 genes for MiSeq (Illumina) sequencing. These genes are associated with two main disease groups: neuromuscular disorders and skeletal dysplasias. We analyzed 26 patients: in six of them, the disease-causing mutation was known (control group), 15 had clinical symptoms compatible with neuromuscular disorders and 5 with skeletal disorders. We were able to detect the pathogenic mutations in five out of six control patients (83.3%). Among the neuromuscular patients, we identified disease causing mutations in 11(73.3%), but we were only able to confirm the clinical hypothesis for 2 skeletal dysplasia patients (40%). The low detection rate in the later group could be explained by two main reasons: the absence of the gene associated with their clinical features in our panel and lack or insufficient coverage at the targeted region due to the high CG content of some genes (e.g. *TWIST1* and *COL18A1*). The low coverage of some exons of *COL18A1* also explains why we could not detect, in the control group, all the previously known mutations. In spite of that, our experience has been positive: we identified mutations in at least 8 different genes or regions that we currently do not offer testing by Sanger sequencing, including *DMD*. In conclusion the results have shown that NGS is a powerful tool to improve the detection of mutations for clinical diagnosis. FAPESP/CEPID, CEGH.

2552W

Clinical utility of next generation sequencing for the molecular diagnosis of genetically heterogeneous retinitis pigmentosa. *J. Wang[1], V.W. Zhang[1], FY. Li[1], C. Truong[1], G. Wang[1], P.W. Chiang[2], R.A. Lewis[1,3], L.J. Wong[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Casey Eye Institute, Oregon Health and Science University, Portland, OR; 3) Department of Ophthalmology, Baylor College of Medicine, Houston, TX.

Background: Retinitis pigmentosa (RP) is one of the most genetically heterogeneous disorders. Mutations in over 100 genes have been associated with both non-syndromic and syndromic RP. Identification of disease-causing mutations is essential for genetic counseling, carrier testing, and future gene-specific therapies. Simultaneous sequencing of multiple genes for RP by a high throughput next generation sequencing (NGS) is a cost-effective approach to that goal. . Methods: We developed a target gene capture sequencing (TCS) approach with the NimbleGen solution-based capture design of 66 genes currently known to cause RP, followed by NGS analysis on Illumina HiSeq2000. Results: A total of 202,800 bp of target sequences including 939 coding exons and 20 bp of flanking intron regions were sequenced to an average depth of 700X per base. Six consistently poorly covered exons were completed by PCR/Sanger sequencing to ensure 100% coverage for the entire coding regions. The phase I validation sample has a total 135 variants being identified, which are 100% concordant with Sanger sequencing results. Phase II validation was performed on 12 samples with known mutations in 4 different genes: ABCA4, RP1, RPE65, and USH2A. All previously detected disease-causing mutations were identified correctly. We also have analyzed 25 samples from unrelated individuals with pigmentary retinal dystrophies, LCA, or RP-related disorders. Deleterious mutations were detected and confirmed in 19 patients with autosomal recessive, dominant and X-linked inheritance. Our positive detection rate is 76%. In addition to single nucleotide substitution and small indels, homozygous insertion of a 355 bp Alu sequence in exon 10 of the MAK gene in two unrelated patients, and a homozygous exonic deletion in the EYS gene in one patient were detected in this cohort. Conclusion: Our data underscore the important clinical utility of NGS-based analysis in the molecular diagnosis of RP. A strategic data analysis has proven accurate for mutation- and variant-identification and annotation. The deep exonic base-to-base coverage of all coding regions plus Sanger confirmation allow the accurate identification of all point mutations, small indels, and even large Alu insertions, which is difficult to detect from NGS data. The TCS approach greatly improves the diagnosis of RP in a cost and time efficient manner.

2553T

Evaluation of fragile X screening methods for early detection of affected infants. *P. Mueller, J. Lyons, G. Kerr.* Newborn Screening and Molecular Biology Branch, CDC, Atlanta, GA.

Purpose: Expanded CGG repeats (≥ 200 repeats) in the FMR1 promoter are known to cause Fragile X in males; premutations (55 to 199 repeats) cause fragile X-associated primary ovarian insufficiency in females and tremor/ataxia syndrome in both males and females. Since the GC content in these expanded repeats is near 100%, the larger CGG repeats are very difficult to PCR amplify while normal repeats amplify preferentially. Therefore, it is difficult to distinguish between normal homozygous females (20% to 40% of females), and those with one normal allele and a CGG expansion. The goal of this study was to evaluate and modify, as needed, published methods for detecting CGG repeat expansions in the FMR1 gene promoter region for potential use as a Fragile X screening assay. Methods Used: We have evaluated and tested modifications of PCR-based screening methods including those using CGG targeted primers, melting point curves, and heat pulses during PCR extension to facilitate the detection of large CGG repeats. Results: Our analysis of 80 normal, 3 gray-zone, and 38 pre- and full mutation samples using the protocol by Tassone that includes a CGG targeted primer (J Mol Diagn, 10:43-49, 2008) called all correctly except one female heterozygous normal and expanded sample. The Orpana (Anal Chem, 84:2081-2087, 2012) heat pulse method using agarose gel electrophoresis detects pre- and full mutation males since there is no visible product for the normal allele even if the amplicon from an expansion is not evident. Female full expansions with a normal allele are less evident. The Teo method (Clin Chem 58:568-579, 2012) using a melting curve analysis of triplet-primed PCRs in both the 5' and 3' directions resulted in optimal temperature cutoffs that were different from the published method necessitating optimization in each laboratory. The 3' assay gave the more robust optimal combination of sensitivity and specificity for pre- and full mutations. Conclusions: The Tassone method gave the best performance for both males and females, while the Orpana method worked well for males. The 3' Teo assay was more robust than the 5' assay. A cost analysis based on reagent and supply cost with amortization of major equipment over 5 years, assuming 55,602 samples/year (median of annual state births, 2010), indicated that the Orpana method was the least expensive at $2.25/sample, followed by the Tassone method at $4.25/sample and the Teo method at $5.71/sample.

Development and implementation of AJPNxt, a 51 mutation Ashkenazi carrier screening panel built on the Illumina BeadXPress™ platform. *J.M. Buis, S. Birkeland, J. Sugalski, C. Holland, J. Stoerker.* Research & Development, aMDx Laboratory Sciences, Ann Arbor, MI.

Members of the Ashkenazim are at elevated risk for a number of inherited genetic syndromes. Widespread and successful adoption of carrier screening amongst the Ashkenazi Jewish community has greatly reduced the incidence of these inherited diseases. We have developed an expanded screening panel for 51 mutations across 18 diseases prevalent in this community using the Illumina, Inc. BeadXpress Platform. This panel comprises 8 multiplex PCR amplification reactions and subsequent allele specific primer extensions pooled for the detection of 103 independent wild type or mutant signals at once via VeraCode™ technology. Due to widespread adoption of carrier screening in the Ashkenazi community and population dispersion, a significant percentage of recently born disease affected individuals have either uncommon or de novo mutations. As such, we have included the addition of several less common variants across multiple diseases and will track incidence of these for justification of additional rare variants of pathological importance in future panels. This laboratory developed test was validated using a mutation enriched third party blinded set of 479 samples containing 232 known positive samples, from mixture of controls or samples split with an authority laboratory. The validation proved the test is 100% sensitive for mutations tested and greater than 99% specific. Here, we report on the first cohort of patients screened across a geographically diverse section of the US over the first 8 months of testing. This includes our initial individual mutation disease rates, overall detection rates across our panel and the serendipitous finding of homozygotes.

Development of a Target-Capture Gene Panel for Clinical Genomic Sequencing in Bronx, NY. *M. Delio, K. Patel, A. Maslov, J. Cai, J. Shan, S. Maqbool, B. Calder, A. Golden, J. Greally, B. Morrow, J. Vijg, C. Montagna.* Albert Einstein College of Medicine, Bronx, NY.

Next-generation sequencing (NGS) has the great potential to improve clinical care for children to diagnose rare Mendelian diseases as well as for adults to provide specific treatments such as for various cancers. Based upon medical need of individuals receiving clinical care at Montefiore Medical Center, we designed a custom gene panel, spanning 5 Mb and consisting of 650 genes targeting known Mendelian loci, some pediatric diseases and several hotspot genes in various cancer types. To determine the sensitivity and specificity of our custom panel we also used several predesigned panels (Ion Torrent) and Whole Exome Sequencing (WES) on cancer samples. The gene panel was created using the Roche-NimbleGen SeqCap V3 capture system and samples were sequenced using the Illumina HiSeq 2500 Rapid Run technology. A total of 24 DNA samples were analyzed, including 7 control DNA samples with known variants. Sequence data was annotated and variants were identified through the Wiki-based Automated Sequence Processor (WASP) analytical pipeline (PMID: 22942009) and customized analysis using the Broad Institute Genome Analysis Tool Kit. Of the 17 subjects (15 unrelated, 2 related), eight had known Mendelian disorders, eight had pediatric diseases and one had breast cancer (tumor/normal). We identified likely causative variant(s) in two unrelated subjects that included mutations in CASQ2, p.Gln67*, c.532+1G>A (Ventricular Tachycardia, Catecholaminergic Polymorphic, 2; OMIM#611938) and TP53, p. Arg213* (Breast Cancer; OMIM#114480), two related subjects (siblings) that included mutations in LDB3, p.V118M (Cardiomyopathy, Dilated, 1C; OMIM#601493) and possible causative variants in eight additional subjects. To further evaluate two breast cancer samples, two additional targeted cancer panels were used (AmpliSeq Cancer Hotspot and the Comprehensive Cancer Panel using the Ion Torrent Technology). In addition, we performed (WES) on the breast cancer sample and matched control tissue. We identified a pathogenic nonsense variant in the TP53 tumor suppressor gene. This variant was detected on all platforms. We found targeted capture high-throughput sequencing to be a cost effective, time sensitive and an efficient approach in detecting pathogenic variants to aid the diagnosis of individuals in our Bronx patient population.

2556T

Clinical whole exome sequencing (WES) coupled with whole mitochondrial genome sequencing at Baylor Whole Genome Laboratory (WGL). *Y. Ding[1], D.M. Muzny[1], J.G. Reid[1], A.C. Hawes[1], M. Wang[1], M.N. Bainbridge[1], N. Veeraraghavan[1], Y. Han[1], H. Dinh[1], D.P.C. Ng[2], C.J. Buhay[1], J.V. Korchina[1], M.L. Landsverk[2], V. Zhang[2], M. Scheel[1], W. Liu[1], N. Saada[1], J. Ma[1], J. Chandarana[2], L.K. Dolores-Freiberg[2], S. Matakis[1], R. Najjar[1], R.A. Gibbs[1], A.L. Beaudet[2], C.M. Eng[2], Y. Yang[2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX77030; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030.

Baylor WGL is a CLIA and CAP certified clinical laboratory which has provided clinical WES since October 2011. To date, we have received approximately 1700 cases including about 1600 germline WES cases and 100 cancer WES cases. Clinical reports have been issued from over 1000 cases, with a positive rate of 26%. Our data indicate the efficiency and cost effectiveness of WES for patients with complicated and unspecific clinical presentations suggestive of genetic etiology. However, while WES can replace nuclear gene sequencing as the first tier test, mitochondrial genome cannot be accurately sequenced from standard WES assays and has to be ordered separately if mitochondrial related disorders are indicated. In order to streamline test ordering process for referral physicians, we have been offering clinical WES coupled with mitochondrial genome sequencing (MGS) for every WES sample at no additional charge. Our clinical WES utilizes solution whole exome capture probe set VCRome 2.1, which covers approximately 200K coding exons while the entire mitochondrial genome is captured by one long range PCR amplification. Currently, manual Illumina Barcoded Paired-End (BC PE) capture library and mitochondrial whole genome shotgun library are sequenced on Illumina HiSeq2000 or 2500 platforms. Samples are multiplexed in loading (3 samples per HiSeq lane) and the corresponding mitochondrial barcoded libraries are spiked into the same lane at a ratio of 1:20 without additional sequencing cost. Quality control (QC) check points are set up for each major processing step, success rates of 99% and 96% for WES capture library and mitochondrial shotgun library respectively, and success rate of 99% for sequencing on HiSeq2000 or 2500 have been achieved. The median coverage for whole exome is 160X with approximately 13 Gb per WES sample, while median coverage for mitochondrial genome is 28,000X with 0.9 Gb per MGS sample. Greater than 95% of the targeted exome sequences and 100% mitochondrial sequences are covered at 20X or more. Currently, about 200 samples are processed at WGL for whole exome and whole mitochondrial genome analyses every month. Validation of Beckman Biomek NXp/Span-8 robots platforms has been initiated to accommodate the increasing sample volume with preliminary results demonstrating high quality data comparable to those from the manual processing.

BRCA1/2 Genomic Rearrangements and Characterization of Familial Breast Cancer.
Y.J. Hyun[1], S.H. Seo[1], M.W. Seong[1], S.I. Cho[1], S.S. Park[1], S.W. Kim[2]. 1) Seoul National University Hospital, Seoul, South Korea; 2) Department of Surgery, Seoul National University Bundang Hospital, Seongnam, Korea.

Introduction: Germline mutations in BRCA1 and BRCA2 are known to increase the risk for developing familial breast and ovarian cancer. The large genomic rearrangements (LGRs) involving the BRCA genes have been reported to account for variable proportion of familial breast cancer patients according to ethnic populations. Here, we studied the contribution of LGRs in BRCA1 and BRCA2 to high-risk breast cancer patients in Korea. Methods: A total of 243 patients with two or more familial history of breast cancer (BC) or one or more familial history of ovarian cancer (OC) were enrolled in the study. All patients were screened by direct sequencing (n= 177), or mutation scanning like fluorescence-based conformation-sensitive gel electrophoresis (F-CSGE) or denaturing high performance liquid chromatography (DHPLC) and/or direct sequencing (n=66). Multiplex ligation-dependent probe amplification (MLPA) was done in 144 patients who were mutation negative for the BRCA genes. Results: BRCA1 mutations were detected in 48 patients and BRCA2 mutations in 53 patients. One patient was harboring both BRCA1 and BRCA2 mutations. Among 144 BRCA mutation negative patients, BRCA1 LGRs were identified in three one and no BRCA2 LGR was identified. In addition, the BRCA1 LGRs account for 6.25% (3/48) of all BRCA1 mutations in this population. Conclusion: This study suggests that MLPA might be considered in BRCA1/2 mutation negative familial BC or OC patients in Korea, although contribution of LGRs is low in this population.

2558W

Utility and Limitations of Exome Sequencing for the Molecular Diagnosis of Bilateral Sensorineural Hearing Loss.
V. Jayaraman[1], J.S. Brunton[1], A. Sasson[3], M. Sarmady[3], J.L. Abrudan[1,2], M.C. Dulik[2], E.T. DeChene[1,2], S.E. Noon[1], A. Wilkens[1], A. Dickinson[1], M. Kaur[1], L.K. Conlin[2], N.B. Spinner[2], P.S. White[3], I.D. Krantz[1]. 1) Dept of Pediatrics, Children's Hospital of Philadelphia, PA; 2) Dept of Pathology & Laboratory Medicine, Children's Hospital of Philadelphia, PA; 3) Center for Biomedical Informatics, Children's Hospital of Philadelphia, PA.

Bilateral sensorineural hearing loss (BLSNHL) has significant genetic heterogeneity with more than 200 associated genes. Current testing for BLSNHL is either done by Sanger sequencing or next generation sequencing (NGS) of gene panels. These tests can be cumbersome and are not comprehensive. We report the results of applying exome sequencing for the diagnosis of BLSNHL. This work was carried out through the CHOP/UPenn Pediatric Genetic Sequencing (PediSeq) project, an NHGRI funded grant, to study the application of exome and genome sequencing to clinical care. Samples from 30 affected individuals with BLSNHL (10 positive controls and 20 unknown samples) were analyzed following exome capture (Agilent SureSelect v4), and sequencing (Illumina HiSeq 2000) at an average coverage depth of 100X. Reads were mapped to human genome GRCh37 using Novoalign; post processing and analysis was performed using a combination of Picard and GATK. A list of 267 BLSNHL genes was used as a filter for analysis. Our goals were to determine 1) the coverage for all 4,208 exons in the 267 target genes; 2) the number of BLSNHL variants not captured and 3) the number of known variants in our 10 controls that were correctly identified and the ability to identify causative mutations in the unknown cohort. The percentage of exons completely covered at 20X varied across individuals from 72.3% to 78.7% with the average being 75.3%. The average percentages of partially covered and not covered exons were 20.5% and 4.3% respectively. Overall, 65.3% of exons had consistent complete coverage in at least 90% of our sample population. Based on the number of uncovered exons, we calculate that 192 out of a total of 3,119 known variants (6.2%) reported in HGMD would be missed. Of the 10 positive controls, all 16 pathogenic mutations were covered. However, 3 of those mutations were partial exon deletions and therefore not identified through the variant calling pipeline. When assessing a targeted gene panel, such as the 267 BLSNHL panel studied here, dropping read depth criteria to 5X did not significantly alter the number of variants needing to be evaluated and increased the ability to identify causative mutations. Although WES may be effective for diagnosis of heterogenous disorders, there are significant limitations to the current platforms which greatly impact the significance of a ‘negative’ result and appropriate single gene or NGS panels should be considered for targeted diagnostic testing.

2559T

The Mayo Clinic experience with short stature and search for genetic causes of idiopathic cases.
A. Kochhar[1], J. Rustin[2], M. Goodenberger[2], Q. Stein[3], A. Mroch[3], L. Borovik[3], L. Davis-Keppen[3], E. Thorland[2], G. Velagaleti[4], S. Kirmani[1], A. Lteif[5], P.L. Crotwell[3], J.C. Hodge[2]. 1) Department of Medical Genetics, Mayo Clinic, Rochester, MN; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Sanford Clinic USD Genetics Laboratory, Sanford Children's Hospital, Sioux Falls, SD; 4) Pathology Department, University of Texas Health Sciences Center, San Antonio, TX; 5) Pediatric Endocrinology, Mayo Clinic, Rochester MN.

Short stature is a multifactorial trait that is influenced by numerous genes and environmental factors. The subcategory of idiopathic short stature (ISS) is defined as height two standard deviations below the mean for age and sex in the corresponding population, without evidence of an endocrine, nutritional or genetic syndrome cause. While the etiology of most ISS cases is unknown, ~2-5% of such patients have defects in the transcription factor-encoding gene *SHOX* or its enhancers, which is located in the Xp/Yp pseudo-autosomal region 1 (PAR1). Our study aims to describe the diagnostic spectrum of short stature observed at Mayo Clinic and to identify copy number changes in *SHOX* and its regulatory elements to further define the mutation heterogeneity at this locus as well as in 121 other genes potentially associated with stature in ISS patients. A custom high-density Agilent oligonucleotide 8x60k chromosomal microarray was developed that targets genes associated with idiopathic and syndromic short stature, genes suggestive of a potential role in stature, and the PAR1 area including *SHOX*. An IRB-approved retrospective effort to identify ISS cases involved chart review of demographics, clinical presentation, lab data and imaging results from patients referred to Mayo Clinic Rochester for short stature between 2009 and 2012. We classified 200 patients with short stature: 43 (21%) ISS, 45 (22%) constitutional delay of growth and puberty, 23 (11%) nutritional, 27 (13%) identified genetic syndrome, 19 (9%) syndromic short stature with no identifiable cause, 12 (6%) endocrinopathy, 12 (6%) chronic systemic disease, 5 (2%) intrauterine growth retardation and 14 (7%) short stature due to miscellaneous causes. The ISS patients were approached for consent to perform custom chromosomal microarray testing. A prospective effort also ascertained ISS patients from pediatric endocrinology and medical genetics at Mayo Clinic and Sanford Children's Hospital. Finally, cases referred for short stature that were normal by clinical testing using a chromosomal microarray not specifically targeting stature genes were also included. To date, these combined recruitment methods have resulted in analysis of 66 samples and the identification of two PAR1 deletions (1.3 Mb and 1.9 Mb) encompassing *SHOX* and two duplications (448 kb) that overlay an evolutionarily conserved region near *SHOX* of possible significance. This study is ongoing with a recruitment target of 200 patients with ISS.

2560F

Two *HEXB* genotypes affect Tay-Sachs disease carrier identification by enzymatic activity assay. *J. Liao, M. Luo, L. Shi, J. Goldman, L. Edelmann, C. Yu, R. Kornreich.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Tay-Sachs disease (TSD) is an autosomal recessive, neurodegenerative disorder caused by mutations in the *HEXA* gene, which lead to deficient activity of the Hex A enzyme and the accumulation of its substrate GM2 ganglioside in neural cells. Hex A is comprised of two subunits, α and β encoded by *HEXA* and *HEXB* respectively. A related isozyme, Hex B consists of two β subunits. To prevent TSD in high-risk populations, measurement of Hex A enzymatic activity has been routinely used as the primary method of carrier screening. This assay utilizes a synthetic substrate, 4-MUG, which can be hydrolyzed by both Hex A and Hex B, in combination with a heat-inactivation step, to differentiate the activities of the heat-labile Hex A from heat-stable Hex B in fluids or blood cells. TSD carriers, noncarriers, and affected individuals can be identified by their different ranges of Hex A%. Here we describe four TSD carriers identified by mutation analysis whose Hex A% results from enzymatic activity assay in leukocytes showed that one was a noncarrier (Hex A%: 68.4) and the other three were within the inconclusive range (avg. Hex A%: 53.0±2.7). *HEXB* gene sequencing revealed a c.[1627G>A; *81_*82delTG] genotype in the first case (noncarrier by Hex A%) and a c.[619A>G(+)*81_*82delTG] genotype in the other three (inconclusive by Hex A%). An additional 41 TSD carriers confirmed by both mutation analysis and Hex A% (avg. Hex A%: 43.1±4.7) were screened for these two genotypes. None of them had c.[1627G>A; *81_*82delTG] genotype and the allele frequency of c.[619A>G(+)*81_*82delTG] genotype in these carriers was 9.8% (8/82), no different than the general population. These results, therefore, suggest that these two genotypes are strongly associated with atypical Hex A% findings as all four mutation positive individuals who also had these polymorphisms did not have enzyme results in the carrier range. The 1627G>A and the *81_*82delTG polymorphisms have been reported to reduce the thermostability and enzymatic activity of Hex B, respectively. The c.[619A>G(+)*81_*82delTG] genotype has also been previously found in five TSD carriers with normal serum Hex A%. Therefore, these two genotypes may cause ambiguous TSD carrier identity by raising Hex A% as a result of decreasing Hex B thermostability and/or activity. They have potential to mask the true TSD carrier status in population screening and should be considered when performing TSD carrier screening by enzymatic activity assay.

2561W

Classification and interpretation of *PRSS1*, *SPINK1* and *CFTR* sequence variants found in idiopathic and hereditary pancreatitis. *A. Millson[1], C. Miller[2], E. Lyon[1,2,3].* 1) ARUP Inst Clin & Exp Path, ARUP Labs, Salt Lake City, UT; 2) ARUP Laboratories, Salt Lake City, UT; 3) Pathology Department, University of Utah, Salt Lake City, UT.

Hereditary pancreatitis is an autosomal dominant disease with variable expression caused by mutations in the *PRSS1* gene. Pathogenic mutations in two other genes, *SPINK1* and *CFTR*, may also contribute to idiopathic pancreatitis and are usually inherited in an autosomal recessive or multifactorial fashion. Thus, sequencing of the *CFTR*, *PRSS1* and *SPINK1* genes helps determine if there are genetic factors contributing to hereditary and idiopathic pancreatitis. Progeny, a clinical data management software program, is used at ARUP Laboratories to track patient symptoms and molecular sequencing results. This enables us to determine if there is a genotype/phenotype correlation, allows for consistent classification of identified variants and provides for quality assurance in laboratory reporting. Data entered in Progeny includes patient demographics, symptoms, risk factors, family history, and *CFTR*, *SPINK1* and *PRSS1* sequencing results (nucleotide and amino acid changes, mutation type, mutation effect and classification). The ARUP Progeny database was queried to find the pathogenic mutation detection rates in 913 individuals undergoing full gene sequencing of *PRSS1*, *SPINK1* and *CFTR*. Twenty-two percent of patients carried one *CFTR* mutation, 12.9% carried one *CFTR* and one *SPINK1* mutation, 4.9% carried one *SPINK1* mutation, 2.4% carried one *PRSS1* mutation and 2.5% carried two *CFTR* mutations. One case out of the 913 had two *CFTR* and one *SPINK1* mutation, and two cases had one *SPINK1* and one *PRSS1* mutation. Three cases carried two *SPINK1* mutations. No mutations were found in 64.2% of the cases.

2562T

Challenges of reporting incidental findings: follow-up on a FBN1 mutation identified by clinical WES testing. *Z. Niu[1], M.R. Bekheirnia[1], P. Ward[1], A. Braxton[1], F.J. Probst[1], G.S. Patel[2], L. Immken[2], Y. Yang[1], C.M. Eng[1].* 1) Molecular Human Genetics, Baylor College of Medicine, Houston, TX; 2) Specially for Children, Austin, Texas.

The recent advances in next generation sequencing and the success of whole exome sequencing have brought many changes to laboratory diagnosis. Beyond identifying causative mutations, the comprehensive nature of the genomic approach necessitates proper reporting of incidental findings, recommended by the '13 ACMG guideline. Here, we discuss our experience and follow-up on an *FBN1* mutation, as an example of the challenges associated with reporting incidental findings from clinical WES testing.

Marfan syndrome (MFS, MIM#154700) is a connective tissue disorder with variable clinical manifestations in the skeletal, ocular and cardiovascular systems. Aortic dilation, dissection and mitral valve prolapse are common in MFS patients. However, aortic root dilation may not be noted without aortic insufficiency or rupture, as one of leading causes of premature death in MFS patients. Clinical WES performed in the Medical Genetics Laboratories at Baylor College of Medicine identified a heterozygous c.3509G>A (p.R1170H) mutation in the *FBN1* gene in a 2 year old patient without known cardiovascular issues, who was diagnosed with mental retardation AD 5 (MIM:612621) based on clinical presentation and a *de novo* mutation in *SYNGAP1* (PMID:23161826). Considerable literature discussed segregation of the p.R1170H mutation with Marfanoid habitus, myopia and mitral valve prolapse, but aortic dilation was not present in most cases (PMID:7870075,9837823, '11ICHG-1132W). We report it as a medically actionable finding based on potential benefit, noting variable phenotypic expression. Further evaluation of the child revealed an enlarged aortic root (22 mm, z=3.99), hindfoot deformity and retrognathia. The parent of this patient, who also carries the p.R1170H mutation, is asymptomatic for MFS with the exception of malar hypoplasia. To our knowledge, this is the 1st patient with the p.R1170H mutation in *FBN1* exhibiting aortic root dilation at a young age. Based on above results, close monitoring is needed for cardiovascular complications and intervention.

In summary, the case reported here demonstrates the benefit and challenges of returning incidental findings with proper consent, thorough communication and deliberate follow-up evaluation. Collective information and additional studies could broaden the phenotypic spectrum of the p.R1170H mutation in the *FBN1* gene.

2563F

Clinical experience with "TaGSCAN," a targeted next-generation based sequencing test for 514 genes using symptom-driven analysis. *C.J. Saunders[1,2], E. Farrow[1], S.E. Soden[1,3], N.A. Miller[1], D. Dinwiddie[4], L. Willig[1,3], L. Zellmer[1,2], L. Smith[1,3], S.F. Kingsmore[1,2,3].* 1) Center for Pediatric Genomic Medicine; 2) Department of Pathology; 3) Department of Pediatrics, Children's Mercy Hosp, Kansas City, MO; 4) Department of Pediatrics, University Of New Mexico, Albuquerque, NM.

We designed and clinically validated a targeted next generation sequencing-based test for 514 genes, representing 795 childhood genetic diseases. "TaGSCAN" (for Targeted Gene Sequencing and Custom Analysis) uses Illumina hybrid enrichment with a custom probe set, 2 × 100 cycle sequencing (500X coverage), and a trio of novel software applications, developed in-house. The latter include Sign and Symptom Assisted Genome Analysis (SSAGA), Rapid Understanding of Nucleotide variant Effect Software (RUNES) and Variant Integration and Knowledge in Genomes (VIKING). These tools tailor variant results by customizing the list of genes analyzed for each patient based on phenotype. This limits incidental findings, carrier status, and the number of variants requiring interpretation. This low-cost assay may be used as a broad screen for unknown genetic conditions as well as a more specific test to sequence discrete genes or small panels of genes with high clinical suspicion. TaGSCAN includes a diverse range of genes for which no clinical testing is available in the United States, including IL12RB1, LRP2, IFNGR1, IFNGR2, PLEKHG5, and SNAP29, ANTXR2. Since clinical validation of this test, we have run a total of 121 samples, including both research and clinical patients with 34 (28%) of these returning a positive or likely positive result. Positive genes in this sample set include common genes like CFTR, ACADM, PAH, F8 and G6PD, as well as genes associated with very rare conditions, such as IGHMBP2, SLC16A2, IL12RB1, NR5A1, ERCC6, and PLA2G6. Of the 56 tests run clinically, 43 were ordered as single gene or small (<5 genes) panels, for which the diagnostic yield was 35%. 13 clinical tests were run as symptom-driven screens, for which 3 (23%) were positive. A prospective cost analysis performed on the first 51 patients comparing charges for sending the test out versus billing for TaGSCAN indicates an estimated savings of over $185,000.

2564W

Establishment of Molecular Diagnostic Platform for Leber Congenital Amaurosis using Extensive Multi-Gene Panel Sequencing. *S.H. Seo[1], Y.S. Yu[2], JM. Hwang[3], H. Park[1], S.I. Cho[1], S.S. Park[1], MW. Seong[1].* 1) Departments of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Departments of Ophthalmology, Seoul National University Hospital, Seoul, Korea; 3) Department of Ophthalmology, Seoul National University Bundang Hospital, Seongnam, Korea.

Introduction: Leber congenital amaurosis (LCA) leading to blindness is genetically heterogeneous, and thus confirming the molecular diagnosis can be challenging. So far, more than 10 genes have been discovered to be associated with this disease, but these genes account for a small proportion of LCA in this country. Herein, we developed an extensive diagnostic multi-gene panel including more than 200 retinal dystrophy-associated genes. **Methods:** Twenty LCA patients were participated in the study, including 2 patients with previously defined pathogenic mutations, in order to verify the performance of our diagnostic platform. A total of 203 genes were analyzed by enrichment of all coding regions and flanking intronic regions with a customized NimbleGen SeqCap EZ Choice library (Roche) and sequencing with a HiSeq (Illumina). All pathogenic variants discovered and low-coverage regions under 10X of coverage depth were resequenced by Sanger method. **Results:** On average, the coveage depth was 800X per base pair (bp), and only less than 1% of the regions showed coverage under 10X. Two patients for assay validation were successfully confirmed using multi-gene panel sequencing. Among remaining 18 patients, two pathogenic mutations were detected in 5 patients including two novel LCA genes as well as known LCA genes like CEP290 and RPGRIP1. In additional 8 patients, only single possibly pathogenic mutations were found. **Conclusion:** Our extensive diagnostic platform has identified novel genetic causes in LCA patients. We demonstrated the successful use of massive parallel sequencing in confirming the molecular diagnosis of LCA patients, and that multi-gene panels can be used with more advantages over exome sequencing in the clinical fields.

2565T

Detection of low-level mosaic microdeletion in Neurofibromatosis type 1. *J. Xie, A. Poplawski, C. Fu, T. Callens, J. Williams, H. Zhan, L. Messiaen.* Dept of Genetics, Medical Genomics Laboratory, University of Alabama at Birmingham, Birmingham, AL.

Neurofibromatosis type 1 (NF1; MIM#162200), an autosomal dominant neurocutaneous disorder affecting ~1 in 3000 individuals worldwide, is caused by mutations in *NF1* gene. The *NF1* gene has a high mutational rate compared to other disease-related genomic loci. As many as 30-50% of NF1 patients present as sporadic cases, i.e. do not have a parent affected by the disorder. A fraction of these 'founder' cases presents with mosaicism for a *NF1* mutation, as a consequence of *de novo* mutations arising postzygotically during embryonic development. Mosaicism is an important consideration in NF1, given its impact on the clinical phenotype and transmission risks. Estimation of the frequency of mosaicism in sporadic NF1 is however challenging due to the notorious variability of the phenotype, the complexity of the *NF1* mutational spectrum and the limitations of the current techniques to accurately detect low-level mosaicism for all of the potential mutational targets in the *NF1* gene. A first estimation on the frequency of *NF1* mosaicism was provided through the study of patients carrying an *NF1* microdeletion as identified using Multiplex Ligation-dependent Probe Amplification (MLPA) and confirmed using FISH (Messiaen et al. Hum Mutat. 32, 213, 2011). The frequency of 10% in this cohort necessarily is an underestimate, as low-level mosaic microdeletions would have been missed in the initial assessment. We recently identified a mosaic NF1 patient carrying an *NF1* microdeletion in only 8% blood cells (4% of the alleles). Such low-level mosaicism will escape detection using MLPA or aCGH. Therefore, in order to facilitate more sensitive and accurate molecular diagnosis for *NF1* microdeletions, we developed a fast, sensitive and cost-effective method utilizing droplet digital PCR (ddPCR). ddPCR allows measurements of smaller fold changes compared to MLPA or aCGH. TaqMan® copy number assay probes were used for the target *NF1* and reference *RNase P* genes and absolute measurements were obtained using the droplet reader. Our data showed that ddPCR can reliably detect mosaic *NF1* microdeletion in as low as 5-10% blood cells ($p<0.05$). As upon transmission, the *NF1* microdeletion tends to result in a more severe phenotype with earlier age of onset in the constitutionally affected patient. Sensitive detection of this specific type of mutation in 'founder' patients is warranted as a part of a comprehensive assessment.

Incorporating new disease genes into clinical whole exome sequencing (WES): annotation update, interpretation challenges and customized familial studies. *Y. Yang[1], F. Xia[1], J. Beuten[1], Z. Niu[1], M.S. Leduc[1], R.E. Person[1], M.T. Hardison[1], J. Zhang[1], M. Bainbridge[2], J.G. Reid[2], A.C. Hawes[2], Y. Ding[2], A.A. Braxton[1], P.A. Ward[1], M.L. Landsverk[1], A. Willis[1], D.M. Muzny[2], S.E. Plon[1,3], J.R. Lupski[1,2], A.L. Beaudet[1], R.A. Gibbs[2], C.M. Eng[1], Baylor Whole Genome Laboratory (WGL).* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX.

The pace of disease gene discovery is accelerating through utilization of NGS technologies, availability of large-scale biology data and accumulated knowledge of gene function. Hundreds of new disease genes are identified each year. Translating new research discoveries into clinical laboratory practice in an accurate and timely manner can lead to improved diagnostic sensitivity and better understanding of genotype-phenotype correlations. For example, of the 265 positive cases diagnosed by clinical WES at Baylor WGL during the period of January 2012 through May 2013, 13% harbor causative mutations in disease genes discovered since January 2012. WES testing is an ideal platform for timely incorporation of new disease genes since it interrogates the entire coding regions of the genome, making it possible for updating disease gene annotation at any time during or even after the analysis process. However, extensive literature review to verify new Mendelian disorders and disease-causing mechanisms must be performed. The clinical laboratory should also make every effort to facilitate familial mutation studies for new disease genes, which usually do not yet have single-gene clinical tests available.

Clinical WES offered by Baylor WGL has a turnaround time of 15 weeks. During this period the disease gene list is updated twice, one time prior to the initial data review and the second time during laboratory director review, to ensure the most inclusive consideration possible for candidate disease genes. We also re-analyze cases after completing WES reports as new disease genes are published. In addition, we re-investigate the strength of evidence for new genes by reviewing published data on inheritance, functional studies and disease causing mechanism. This close follow-up of clinical cases leads to additional definitive and possible diagnoses. For example, we reported a patient with mutations in *MEGF8* (gene published November 2012, WES diagnosis reported the same month), another patient with a mutation in *HDAC8* (case signed out July 2012 as negative, gene published September 2012, diagnosis updated the same month), and recurrent diagnoses from disease genes (*MAGEL2,ASXL3*) discovered by our laboratory. Follow up communications with referring physicians are conducted and customized targeted mutation analyses, including prenatal testing when applicable, are made available on a clinical basis for assessment of family members.

2567W

Implementation of a Quality Assurance Program for Next Generation Sequencing Based Tests. *Z. Yu[1], M. Sarmady[2], T. Tischler[1], B.A. Brown-Kipphut[1], M. Shafiq[1], N.N. Fernandes[1], Z. Fan[1], M.S. Boltz[1], J.B. McKnight[1], B.N. McLarney[1], L.C. Davidson[2], M.J. Italia[2], J.W. Pennington[2], P.S. White[2], P.V. Warren[1], C.A. Stolle[1], A. Santani[1].* 1) Department of Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Center for Biomedical Informatics, Children's Hospital of Philadelphia, Philadelphia, PA.

Clinical laboratories are governed by regulations from Clinical Laboratory Improvement Amendments (CLIA) and select laboratories also follow guidelines from the College of American Pathologists (CAP). These regulations are in place to ensure high standards and reliable test results in the clinical environment. Next generation sequencing (NGS) has revolutionized genomic medicine and is now being increasingly applied to clinical molecular diagnosis. Despite this increasing popularity, implementation of NGS in a clinical environment is challenging due to the inherent complexities of the rapidly evolving NGS technologies and the accompanying requirements for sophisticated data analysis. Moreover until recently, few guidelines or resources were available for institutions interested in implementing a clinical NGS program. Using the NGS accreditation criteria from the CAP checklist as a guideline, we developed a framework to address four major areas of a NGS based quality management program: i) validation testing, ii) quality assurance, iii) proficiency testing, iv) bioinformatics. We share our experience in this regard with the development and implementation of four targeted NGS based panels that were created to identify germline mutations in four common disorders. Validation testing was performed on 33 specimens to establish the analytical performance characteristics of these four laboratory developed tests. Quality control procedures were established to monitor all components of these tests including reagents, instrumentation and bioinformatics. Proficiency testing was performed to assess laboratory performance. A workflow management quality control system (Pegasus) was used to support a customized data management, processing, and analysis workflow. In summary, we have developed a comprehensive quality management program in the laboratory for NGS based tests. This program, which has been implemented in our clinical practice, will help meet regulatory standards as well as assure the integrity and quality of NGS results.

2568T

Non-invasive detection of genomic mutations by targeted sequencing of plasma cell free DNA. *J. Namkung, K. Seo, Y. Lee.* Bioinformatics Tech Lab, SK Telecom, Sungnam, South Korea.

Cell free DNA (cfDNA) offers a non-invasive diagnostic approach to a wide range of clinical disorders. Next-generation sequencing (NGS) has enabled the detection of unknown fetal genomic variations from cfDNA of maternal peripheral blood. However, due to the lengthy sequencing time, some platforms are still not suitable for clinical application. The relatively low concentration of cfDNA in the blood has presented many challenges as well. By using targeted sequencing, only a subset of genes or a defined region in a genome are sequenced, which allows high sequence coverage critical for identifying rare genetic variations. The purpose of our study was twofold, first, to sequence and analyze the genomic coverage of cfDNA using NGS technologies and second, to test the sensitivity and accuracy of detecting the genomic mutation from cfDNA by using Ion AmpliSeq™ Inherited Disease Panel (IDP), which enables multiplexed target selection of exons of 328 genes implicated in genetic disorders. Whole blood (6 mL) was collected from healthy donors, and plasma was separated by centrifugation. The cfDNA and genomic DNA (gDNA) were extracted using column-based methods. The concentration of cfDNA was 8.9 ± 0.5 ng/µl (30 ng/ml of blood), which was in agreement with reported values in healthy controls (5-30 ng/ml). Libraries were prepared accordingly: 1) Ion Xpress ™ Plus gDNA Fragment library kit was used for sequencing with the Ion Torrent PGM™ platform with 316 chips; 2) ThruPLEX™-FD Prep Kit (Rubicon Genomics) was used for Illumina® NGS platform. Result showed that the genomic coverage of cfDNA sequencing was 97% of that of the genomic DNA, given the same number of reads. The results were similar in both Illumina® and Ion Torrent PGM™ platforms. The study also showed that the cfDNA present in the blood stream is representative of the global content of the gDNA. To study the feasibility of detecting the genomic variation of cfDNA, semiconductor sequencing will be performed by using IDP. To mimic the condition of maternal blood, cfDNA samples will be mixed in the range of 5 to 20%, which is the ratio of cell free fetal DNA in the maternal blood. Through this study, we will determine the possibility of using cfDNA from blood for detection of genomic mutations. This suggests that the use of cfDNA in conjunction with accurate and rapid semiconductor sequencing technologies could be the next step forward in developing non-invasive diagnostic testing.

2569F

A systematic approach to assessing the clinical significance of genetic variants. *H. Duzkale[1,2], J. Shen[1,2], H. McLaughlin[1,2], A. Alfares[1,2], M.A Kelly[2], T.J Pugh[1,2], B.H Funke[1,2], H.L Rehm[1,2], M.S Lebo[1,2].* 1) Harvard Medical School, Boston, MA; 2) Partners HealthCare Center for Personalized Genetic Medicine, Cambridge, MA.

Molecular genetic testing can improve the accuracy of diagnosis, prognosis, and risk assessment for patients and their family members. Recent advances in low-cost, high-throughput DNA sequencing technologies have enabled the rapid expansion of genetic tests, as well as an expansion of variant- and gene-level data and their associations with human disease. The number of variants assessed in our laboratory has tripled in the past two years through launching next generation sequencing (NGS) gene panels. While NGS panels have increased the analytical and clinical sensitivity of our assays, the increased content has also added a significant burden of interpretation and higher rate of variants of uncertain significance (VUS). Our laboratory has developed a systematic approach to accurate, efficient and timely assessment of variants for pathogenicity over the past decade. Using our semi-automated tool, the average time for a clinical variant assessment has been reduced to 22 min. We first gather and validate variant information from publications and clinical notes, from internal, collaborative and public variant databases, and from various bioinformatics resources; we then perform statistical analyses, evaluation of research and functional data, and computational predictions on the data to determine the likelihood of pathogenicity; finally, we weigh all the evidence to reach an overall interpretation on the potential for each variant to be disease-causing. In this report, we highlight the principles of variant assessment, address the caveats and pitfalls, and provide customizable tools and examples to illustrate the process. We also demonstrate the importance of variant reassessment, as we recently downgraded 11 of 106 (10%) pathogenic or likely pathogenic cardiomyopathy variants to VUS, mostly due to their presence in large population studies. Our laboratory has evaluated 245 genes in 53 diseases in a total of 22,490 cases since its inception. 17,245 variants have approved clinical classifications and 7,955 were validated and reported in patients. We have recently submitted 7,129 variants to ClinVar database, an initiative to publicly share genetic test results as well as phenotype information of patients. Of these variants, 40% have associated rsIDs in dbSNP, 20% have been reported in the literature, and 40% were novel. By sharing our experience, we hope to bring the clinical and research communities together to build a framework for variant assessment.

2570W

Assessment Of Detection Of Proviral DNA and RT (MET 184 VAL) Gene Resistance Mutation in HIV-1 Identified by Multiplex PCR and Restriction Fragment Digestion Assay. *R. SHRESTHA[1,2], S. KHADKA[1], S.R. WAGLE[1], A. SAPKOTA[1].* 1) Center for Molecular Dynamics Nepal (CMDN), Intrepid Nepal, Pvt. Ltd. Thapathali-11, Kathmandu, Nepal; 2) Department of Laboratory Medicine, Nobel Hospital and research Institute, Kathmandu, Nepal.

ABSTRACT Proviral DNA and ART resistance forms the corner stone of a short chemotherapy course for Post exposure prophylaxis. Potent antiretroviral therapies that suppress cell-free plasma viral RNA levels below the limit of current assay detection necessitate other complementary approaches for assessing viral burden, such as quantification of cell associated proviral DNA.The quantification of human immunodeficiency virus type-1 (HIV 1) RNA is the cornerstone for monitoring the effectiveness of antiretroviral therapy. For the majority of therapy naive patients, three to six months of potent antiretroviral therapy usually suppresses cell-free HIV 1 RNA levels to less than 50 copies/mL of plasma. Objective: To rapidly identify the proviral DNA and To study mutation in specific part (meth184val; ATG - GTA substitution) of M184V gene of HAART resistance in HIV-1 Reverse Transcriptase. Method: An analytical study was design to explore the role of proviral DNA and RT (M184V) gene mutation identified by PCR and RFDA. Results and Discussion: The male patients outnumbered female. Among 13 male subject 2(15.4%) were proviral DNA positive and 11(84.6%) were proviral negative. Among 2 female subject 1(50.0%) were proviral DNA positive and 1(50.0%) were proviral negative. All isolates were only digested by CViAII restriction enzyme and confirmed as wild type. No mutation was detected in the analyzed sample. Conclusion: In summary, we demonstrated here that in contrast to Proviral detection drug response was good as proviral DNA load was below the limit of detection in patients. Since, we can say that the incidence of developing of resistance virus is in increasing order. In addition, Potent antiretroviral therapies suppress cell-free plasma viral RNA levels below the limit of current assay detection necessitate other complementary approaches for assessing viral burden, such as quantification of cell associated proviral DNA. Therefore, it is recommended to use this technique for the diagnosis of Drug Resistance Mutation in HIV-1 patients and the response of ART for their Better Health Care. Keywords: HIV/AIDS, HAART, Drug resistance, mutation, env gene, RT gene,.

International external quality assessment for diagnostic Next Generation Sequencing. *S. Abbs[1], J. Coxhead[2], P. Westwood[3], K. Thomson[4], H. Scheffer[5], S. Bhaskar[6], G. Taylor[7], Z. Deans[8], S. Patton[9].* 1) Genetics Laboratories, Cambridge University Hospitals, Cambridge, United Kingdom; 2) Newcastle University, Newcastle, UK; 3) Western General Hospital, Edinburgh, UK; 4) Oxford University Hospital, Oxford, UK; 5) University Medical Center Nijmegen, Nijmegen, the Netherlands; 6) Central Manchester Foundation Trust, Manchester, UK; 7) University of Melbourne, Victoria, Australia; 8) UK National External Quality Assessment Scheme for Molecular Genetics, Edinburgh, UK; 9) European Molecular Genetics Quality Network, Manchester, UK.

Next Generation Sequencing (NGS) is increasingly being introduced into clinical genetics laboratories worldwide. The huge amount of data generated by NGS cannot be duplicated by alternative methods for laboratories to internally validate all results, therefore external assessment of data is required. The UK National External Quality Assessment Scheme (UKNEQAS) for Molecular Genetics and the European Molecular Genetics Quality Network (EMQN) have developed a joint EQA scheme for NGS, with the aims to: (a) assess and improve quality; (b) enable laboratories to benchmark their NGS service against others and against best practice; (c) work towards consistency of reporting clinical results generated by NGS; and (d) contribute towards best practice. EMQN and UKNEQAS offer numerous disease specific EQA schemes, and the challenge for developing NGS EQA was to ensure it does not duplicate what is already available, making it generic (independent of genes, diseases, and platforms) and applicable to as many users as possible. A survey of 1020 labs worldwide in Dec 2011 generated replies from 52% about methods, platforms, and loci being tested. Diagnostic experience of NGS varied from less than a year (76% labs) to over 3 years (1.9%). All respondents expressed an interest and need for NGS EQA. The survey results were used to develop a follow-up survey to a subset of labs, and then establish a pilot EQA. 30 labs were selected on the basis of diagnostic experience with NGS and covering a variety of technology platforms. These labs were sent a genomic DNA sample and asked to sequence either the smallest gene panel or largest single gene which the lab tested, submit technical details, and genotypes at known SNPs. The DNA was validated in 3 diagnostic labs and by 3 NGS platform manufacturers. The number of genes sequenced per lab varied from 1-625. 1011 variants were reported against reference sequences, in a total of 145 genes. 30 genes were sequenced by more than one lab, allowing comparison of results between participating labs and the validation data. The minimum acceptable depth of coverage required by labs for reporting results varied from 16x to 100x. Disease specific EQA has drastically improved the quality of results and consistency in diagnostic reports. This NGS EQA will play an important role in enabling labs to benchmark this new technology, assess the accuracy of data and facilitate high quality reporting for patient benefit.

Development of a rapid and comprehensive genetic testing service for nephrotic syndrome using next generation sequencing. *E.J. Ashton[1], D. Bockenhauer[2], N.J. Lench[1].* 1) NE Thames Regional Genetics Service, Great Ormond Street Hospital, London,WC1N 3BH United Kingdom; 2) Department of Nephrology, Great Ormond Street Hospital for Children, London, WC1N 3JH.

Nephrotic syndrome is a renal disorder presenting with proteinuria, oedema and hyperalbuminemia. Mutations in at least 18 different genes are known to be responsible for nephrotic syndrome and genetic testing has been a long and time consuming process as each gene would be sequenced independently until a mutation could be identified. Identification of a genetic basis provides an explanation for the disease, enables genetic and prognostic counselling and increasingly affects management of the disease. The advent of next generation sequencing has meant that it is possible to screen a large number of genes simultaneously, which would previously have been impractical and unaffordable. We have developed a targeted re-sequencing screen comparing two different library preparation methods (the Haloplex™ target enrichment system from Agilent and TruSeq Custom Amplicon from Illumina) and used these to screen for mutations in up to 18 genes known to be involved in nephrotic syndrome. Sequencing was carried out using the Illumina MiSeq system using both 2x150 bp and 2x250 bp sequencing chemistries and data analysis was performed using NextGENe® software from SoftGenetics. All mutations detected by Next Generation Sequencing were confirmed using Sanger sequencing. We have screened over 60 patients so far who were referred with a clinical diagnosis of steroid-resistant nephrotic syndrome aged from new-born to adulthood, using a combination of the two different library preparation methods, with the majority of mutations so far being identified in the NPHS1 gene. In cases where we were unable to identify a definite pathogenic mutation (or mutations) we considered that this may be due to mutations in regions of a gene not covered by our design, an uncertain clinical diagnosis or mutations in genes yet to be identified as being involved in nephrotic syndrome and therefore not included in our designs. The flexibility of the library designs means that it is simple to add in genes newly associated with nephrotic syndrome. We have developed a rapid and comprehensive genetic testing service for patients and families with nephrotic syndrome. This well lead to improved detection rates combined with a much reduced cost and turn-around time. The low rate of identified mutations may indicate that the majority of cases of steroid-resistant nephrotic syndrome are not due to monogenic mutations in currently known disease genes.

2573W

Diagnostic exome sequencing can alter a primary clinical diagnosis. *F. Taylan[1,2], M. Kvarnung[1], A. Lindstrand[1], T. Bui[1], A. Nordgren[1], E. Blennow[1], M. Nordenskjöld[1], D. Nilsson[1,2].* 1) Department of Molecular Medicine and Surgery and Center of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Science For Life Laboratory (SciLifeLab), Solna, Sweden.

Whole exome sequencing (WES), which is now feasible and clinically available, allows us to identify disease causing variants in rare diseases. Advancements in bioinformatic tools also make the data produced by WES more interpretable and easy to handle. As part of our effort to use WES as a diagnostic tool, we have collected samples from distinct families with consanguineous marriages and at least two affected children with complex phenotypes. Whole exome sequencing was performed for all available family members, such as parents, affected and healthy children. The family case presented here has two affected children with a clinical diagnosis of Bardet Biedl Syndrome (BBS; MIM209900), a multisystemic ciliopathy characterized by retinal degeneration, obesity, intellectual disability and renal dysfunction. The major findings observed in the affected children were retinal dystrophy, obesity, hypogonadism, eczema, small teeth and flat feet. Whole exome sequencing revealed no mutation in any of the seventeen known BBS genes and genome wide array comparative genomic hybridization did not detect any deletion or duplication at the chromosomal level. We then expanded our analysis to other ciliopathy genes associated with phenotypes similar to BBS. A novel homozygous stopgain mutation was detected at position 2437 of the ALMS1 (ALMS1:NM_015120:exon8:c.C7310A:p.S2437X) in both of the affected children, and the mother, the only parent available, was found to be a carrier of this mutation. The ALMS1 has been known to cause Alström Syndrome, an autosomal recessive ciliopathy with a clinical picture partly overlapping with BBS. This finding demonstrates how exome sequencing can alter a clinical diagnosis and reveal differential diagnoses of phenotypically similar syndromes. As the sequencing technologies become cheaper and bioinformatic tools improve further, whole exome sequencing for clinical diagnostic purposes finds its place in routine medical practices.

2574T

The importance of considering autosomal genes for the diagnosis of Non-Syndromic Intellectual Disability. *C. Tan[1], S. Topper[1], V. Nelakuditi[1], K. Arndt[1], F. Kobiernicki[1], D. del Gaudio[1], N. Meeks[2], J. Saari[2], V. Misra[3], S. Sastry[3], S. Levesque[4], L. Russell[4], G. Sillon[4], S. Das[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Pediatrics, Section of Genetics, University of Colorado, Aurora, CO; 3) Division of Genetics and Metabolic Disorders, Children's Hospital of Michigan, Detroit, MI; 4) Department of Medical Genetics, Montreal General Hospital, Montreal, QC.

Intellectual Disability (ID), with a prevalence estimated to be between 1-3% of the general population, is a lifelong disability typically presenting in infancy or early childhood. It is estimated that mutations in the genes on the X chromosome may account for about 10% of all cases of ID, thus molecular investigations into the X chromosome in elucidating the etiology of an individual with ID have been routinely suggested. Due to the genetic and phenotypic heterogeneity of patients with non-syndromic ID, multi-gene testing, the concurrent analysis of multiple genetic loci, can be beneficial. The utilization of high throughput, massively parallel sequencing, or next generation sequencing (NGS), has greatly improved the ability to simultaneously analyze multiple genetic loci, and X-linked ID (XLID) panels including analysis of a large panel of X-linked genes can be used for diagnosis. We performed next generation sequencing analysis of a total of 95 genes implicated in non-syndromic ID. The 95 genes included 61 X-linked genes, 20 Autosomal Recessive genes and 14 Autosomal Dominant genes. Genes were selected based on a criterion of 'non-syndromic ID' although some syndromic genes were also included, as a range of mutations in a single gene can sometimes confer both syndromic and non-syndromic phenotypes. As more genes are identified and implicated in non-syndromic ID, it seems appropriate to consider the inclusion of autosomal genes in multi-gene panel testing. To date, we have studied 10 patients and have identified pathogenic mutations in 3 out of the 10 patients. All three mutations are novel and include two frameshift mutations in *SYNGAP1* (c.1783del and c.2602del) and one splicing mutation in *TCF4* (c.991-2A>G). All genes in which mutations were identified are autosomal, typically de-novo in inheritance. Phenotypic information was collected on all three patients. Both patients identified with the *SYNGAP1* mutations were non-dysmorphic and were characterized as having global development delays. The patient identified with the *TCF4* mutation had global developmental delays and minor facial dysmorphisms that were possibly suggestive of a spectrum of monogenic conditions. Our three mutation positive cases provide further evidence supporting the utility of including autosomal genes in multi-gene panel analysis of patients with intellectual disability.

2575F

Clinical usefulness of copy number variants detected by affymetrix high-resolution genome-wide array. *E. Cho[1], E. Lee[1], J. Jang[1], H. Kim[2].* 1) Green Cross Laboratories, Yongin , South Korea; 2) Gachon University, Gil Medical center, Incheon, South Korea.

Background: Recently, chromosomal microarray has proven to be an effective tool for detection of submicroscopic chromosome abnormalities causing congenital disorders and has been adopted for clinical applications. Here, we investigated the usefulness of chromosomal microarray, as a first-tier tool in detecting the etiology of developmental delay, intellectual disability, autism spectrum disorders and multiple congenital anomalies in a large number of Korean pediatric patients. Methods: We applied Affymetrix Cytogenetics Whole Genome 2.7M array and Affymetrix Cytoscan 750K array in 333 patients (2.7M array: 200 cases and 750K: 133cases) to assess CNV detection and evaluated the clinical significance of detected CNVs. Results: We found 103 cases (30.9%) with known pathologic CNVs (64 cases: 19.2%) and CNVs of uncertain clinical significance (39 cases: 11.7%). 3 cases(1.0%) of uniparental disomy were detected. 70% (45/64) of known pathologic CNVs were <5Mb and would likely not be detected by G-banded chromosome analysis. 50 cases with copy number losses, 45 cases with copy number gains, 6 cases with both copy number gain and loss and 2 cases with mosaic copy number gain (12p mosaic gain) were detected. The smallest pathologic CNV detected was 23Kb. 2.3 Mb gain at 8p23.2 found in 7 cases was revealed as a probably benign CNV by parental study. Conclusions: We concluded microarray analysis significantly improves the diagnostic yield than G-banded chromosome analysis.

Performance analysis of saliva generated genomic DNA used for genotyping on the Affymetrix DMET Plus array as part of the Coriell Personalized Medicine Collaborative. *N.P. Gerry, N.C. Weiner, D.E. Lynch, L.A. Swanson.* Coriell Institute for Medical Research, Camden, NJ.

The use of saliva as a source of genomic DNA for research and clinical studies has grown in popularity due to the ease of collection and participant compliance. The Coriell Personalized Medicine Collaborative (CPMC) has been using Oragene collection kits for the past six years as the source of genomic DNA, initially for genotyping on the Affymetrix Genome-Wide Human SNP Nsp/Sty 6.0 array, and for the past four years, also for genotyping on the Affymetrix DMET Plus array. Although multiple studies on the SNP 6.0 array have utilized saliva as the source of DNA, the CPMC is one of the first large scale studies to also use that DNA on the DMET Plus array. To date, the study has successfully processed more than 4000 samples on the DMET Plus array with an average call rate of 99.5%. This was similar to the 99.4% call rate achieved on the SNP 6.0 array. The genotyping results from saliva generated genomic DNA have also proven to be highly reproducible on DMET Plus. Independent extractions from individual Oragene kits as well as across multiple kits for 4 samples used as processing controls have resulted in average call rates between 99.5% and 99.8% across thirty or more replicates of each control. Furthermore, in the control replicates, the concordance rates in a set of 166 variants of interest to the CPMC study ranged between 99.7% and 99.9 %. Finally, because the genomic DNA samples were run on both Affymetrix arrays, it was also possible to examine the performance of 212 SNPs that are present on both platforms. For a set of 1920 samples, the average concordance was 98.2%. When excluding SNPs where either or both arrays had a No Call, the average concordance increased to 99.5 %. The use of saliva generated genomic DNA in the Affymetrix DMET Plus assay has proven to be very successful and has allowed the CPMC to expand its genotyping options while maintaining a single DNA source.

2577T

Improved diagnosis of mitochondrial disorders by next generation sequencing approach. *V.W. Zhang, J. Wang, Y. Feng, X. Tian, L-J. Wong.* Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background: Step-wise analyses of the genetically and clinical heterogeneous mitochondrial disorders are time consuming and cost ineffective. Next generation sequencing (NGS) technology allows simultaneous sequence analysis of any number of target genes. **Method:** The intact circular mitochondrial genome is enriched by long range PCR as a single amplicon and sequenced with captured target nuclear genes on HiSeq2000. **Results:** At an average coverage of 20,000X and 1,000X for the mtDNA and nuclear genes respectively, heteroplasmic mtDNA point mutations and large deletions can be detected, quantified, with breakpoints determined. Poorly covered coding regions of nuclear target genes are filled in by specific PCR/Sanger sequencing to ensure 100% coverage. Our results demonstrated that NGS-based analysis improved the diagnostic yield of mtDNA disorders to 30% using muscle specimen. The detection rate in nuclear genes varies from 10 to about 25%. About 25% of complex deficient samples had mutations in mtDNA, and 16/19 (84%) samples with mtDNA depletion in liver had mutations identified in one of the genes causing mtDNA depletion syndrome. **Conclusion:** The NGS approach greatly improves the diagnosis of mitochondrial disorders. Due to the extreme clinical heterogeneity, it remains challenging to diagnose atypical cases despite the technical advance.

2578F

Detection of Disease-Causing Mutations in the Ashkenazi Jewish Population Using a BioFilm Microarray. *M. Procter[1], C. Smith[2], R. Mao[3].* 1) Research and Development, ARUP Laboratories, SLC, UT; 2) AutoGenomics, Vista, CA; 3) Department of Pathology, University of Utah School of Medicine. SLC, UT.

Background: Jews of eastern European descent, referred to as Ashkenazi Jews, are at a higher risk of carrying certain genetic diseases at greater frequencies than the general population. The American College of Obstetricians and Gynecologists (ACOG) recommends genetic testing for people of Ashkenazi Jewish descent for mutations associated with the following conditions: Tay-Sachs disease, Canavan disease, and Familial Dysautonomia. Further ACOG recommendations include testing be offered to these same individuals for mutations associated with the following diseases: Gaucher disease, Bloom syndrome, Fanconi Anemia group C, Neimann-Pick disease type A, and Mucolipidosis type IV. These autosomal recessive diseases occur 20-100 times more frequently in the Ashkenazi Jewish population, and are associated with life-threatening conditions. DNA-based carrier screens for the above conditions in this ethnic group are sensitive due to a number of common shared mutations. Materials and Methods: The assay involves multiplex PCR of DNA at 30 ng/μL, followed by analyte specific primer extension (ASPE) prior to hybridization of the ASPE primers to a BioFilm microarray. The microarray chip with bound ASPE product is washed repeatedly before optical scanning with signal detection and analysis. Steps subsequent to PCR were performed in the Infiniti™ bioanalyzer. For our evaluation, 31 samples representing all 30 mutations and 1 polymorphism were run in the assay to determine accuracy. We utilized DNA purchased from Coriell Cell Repositories and known-positive and known-negative samples from ARUP's clinical Molecular Genetics laboratory as well as samples acquired from collaborators. Results: Twenty-six mutations were detected with 100% concordance with expected results using clinical samples, Coriell samples, and samples from collaborators. The remaining 5 variants were detected with 100% concordance using a commercially available 'supercontrol' containing all AJ variants included in this assay. Conclusions: We found this assay to be reliable in the detection of a large number of mutations associated with Ashkenazi Jewish diseases. The microarray format of this test allows simultaneous detection of many mutations in a single reaction. Automation of all steps subsequent to the PCR step in the Infiniti™ instrument allows for high throughput with minimal hands-on time.

2579W

Comprehensive mutation analysis by next generation sequencing in patients with neonatal intrahepatic cholestasis. *T. Togawa, T. Sugiura, K. Ito, T. Endo, S. Saitoh.* Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan.

Next generation sequencing (NGS) technology has revolutionized genomic and genetic research. Neonatal intrahepatic cholestasis is a heterogenetic disorder and caused by mutations in a number of genes, making genetic diagnosis challenging. We developed a diagnostic panel of causative genes for neonatal intrahepatic cholestasis using AmpliSeq (LifeTechnologies) and the Ion Torrent PGM technology. DNA samples were obtained from 12 individuals with neonatal intrahepatic cholestasis; 4 patients with Alagille syndrome (AS), 2 patients with neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD), 4 patients with progressive familial intrahepatic cholestasis (PFIC), and 2 patients with unknown etiologies. One patient with AS, 2 patients with NICCD and 2 patients with PFIC had known mutations detected by conventional Sanger sequencing, and were invited as positive controls. A panel of genes included *JAG1*, *NOTCH2*, *SLC25A13*, *ATP8B1*, *ABCB11*, *ABCB4*, *AKR1D1*, *HSD3B7*, *CYP7B1*, *TJP2*, *BAAT*, *EPHX1*, *ABCC2*, and *VPS33B*. NGS was performed on Ion Torrent PGM and variant call and annotation were performed with CLC Genomics Workbench version 6.0 (CLC bio). We detected disease-causing mutations in 6 patients; one JAG1 mutation in one patient with AS, two SLC25A13 mutations in one patient with NICCD, and 4 ABCB11 mutations in 3 patients with PFIC as well as one patient with AS. For positive controls, five single nucleotide variants (SNVs) detected by Sanger sequencing were all detected, while only one out of three small insertions/deletions was identified. This study showed clinical usefulness of comprehensive mutation analysis by NGS for neonatal intrahepatic cholestasis. However, improvement on detection of small insertion/deletion remains to be fulfilled.

CIGMA (Clinical Impact of Genetic Mutational Analysis): a new approach to mutational classification in large-scale clinical genetic testing. *C. Turnbull[1, 2], R. Sultana[1], S. Mahamdallie[1], E. Ruark[1], H. Hanson[2], N. Rahman[1,2].* 1) Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, United Kingdom; 2) Royal Marsden NHS Foundation Trust, London, UK.

The evolution of Next-Generation sequencing (NGS) technologies has rendered dramatic expansion in the delivery of germline genetic testing for cancer predisposition both affordable and technically viable. To deliver such large-scale expansion, germline genetic testing for cancer predisposition will likely increasingly be undertaken by oncologists non-specialist in genetics. In the current model of low volume clinical genetic testing, classification of variants represents a sizeable challenge to both those who report the tests and clinicians who manage the patients. Currently, the majority of rare variants detected are classified as 'variants of uncertain significance' and these are detected in 5-10% of many individual cancer gene tests. This classification can confer substantial ambiguity with regard to communication of risk and management implications. Large-scale gene panel testing will identify significant numbers of rare variants per test, potentially scaling up this ambiguity to a level rendering large-scale non-specialist delivery of these tests unfeasible. Hence, a new era of expanded genetic testing will require commensurate new approaches to classification and reporting of mutational data. Most current approaches to variant classification are largely informed by mutational data from disease cases, which enables clear classification as pathogenic or non-pathogenic for only a small minority of variants. We have undertaken large-scale analyses of population mutational data from cancer predisposition genes and integrated these with case mutational data and gene-specific parameters relating to mechanisms of pathogenicity and the clinical relationship between gene and phenotype. Through large-scale bioinformatic integration of these data sources superimposed with clinical interpretation and decision-making, we have developed a novel system of variant classification to deliver clear, robust, consistent classification of mutational results into categories defined by clinical impact and management. We have developed an NGS panel comprising 97 cancer predisposition genes (Illumina TruSight Cancer panel) and are piloting a new model of expanded delivery of genetic testing by oncologists. The application of the CIGMA system for variant classification and reporting of mutational data is central to successful delivery of this programme (www.mcgprogramme.com). The CIGMA design principles and pilot data from our first 100 tests will be presented.

A comprehensive genetic analysis of Japanese patients with Charcot-Marie-Tooth disease using a Next-Generation Sequencing System. *A. Hashiguchi, A. Yoshimura, S. Nozuma, Y. Higuchi, Y. Sakiyama, T. Nakamura, Y. Okamoto, E. Matsuura, H. Takashima.* Neurology and Geriatrics, Kagoshima University Graduate School of Medical and Dental Science, Kagoshima, Japan.

[Background and Objective] Our objective was to perform genetic analysis in Japanese patients with Charcot-Marie-Tooth disease (CMT) and identify the molecular epidemiology. A DNA microarray consisting of 28 known CMT-causative genes has been applied for mutation screening since 2004. However, the positive rate of mutation detection was as low as 10%-20%. Therefore, in May 2012, we increased the number of target genes to 60 using a next-generation sequencing (NGS) system (Illumina MiSeq). [Methods] We conducted a genetic test of 182 Japanese patients with CMT from May 2012 to April 2013. Based on the median nerve motor conduction velocity (MCV), patients with CMT were broadly classified into demyelinating type (MCV < 38 m/s) and axonal type (MCV > 38 m/s). For demyelinating type CMT, the presence of the PMP22 duplication mutation was excluded using FISH before this study. When novel suspected mutations were detected, a segregation study was performed to identify the pathogenicity. The negative cases, filtered by the NGS system, proceeded to exome sequencing. [Results and Discussion] Using the NGS system, we identified pathogenic mutations in 42 (23%) of 182 patients. Thirteen mutations were identified in MFN2 (CMTX1) and GJB1 (CMT2A2). We also discovered mutations in MPZ (6/182), NEFL (4/182), SH3TC2 (2/182), GDAP1 (2/182), PRPS1 (1/182), and TRPV4 (1/182). However, segregation study data were not available for 20 variants, although they were suspected as causative mutations. If we considered these variants, the positive rate would be improved to 34% with the NGS system.

Multiplex-PCR coupled to Next-Generation Sequencing (NGS) and SNP array technologies greatly improve molecular diagnosis of Usher syndrome. *C. Bonnet[1,2], S. Chantot-Bastereaud[3], I. Sliesoraityte[1,4,9], A. Fakin[5], F. Testa[6], L. Martorell Sampol[7], S. Gherbi[2,3], S. Dad[8], S. Marlin[2,3], S. Kohl[4], D. Zobor[4], S. Mohand-Saïd[1,2,9], F. Simonelli[6], S. Banfi[6], J. Rodriguez Jorge J[7], L. Birk Moller[8], A. Kurtenbach[4], M. Hawlina[5], A. Aurricchio[6], JA. Sahel[1,2,9], I. Audo[1,2,9], E. Zrenner[4], C. Petit[1,2,10].* 1) Institut de la Vision, Paris, France; 2) UPMC, INSERM, Paris, France; 3) Hôpital Trousseau, Paris, France; 4) Institute For Ophtalmic Research University of Tübingen, Tübingen, Germany; 5) Eye Hospital University Centre Ljubljana, Ljubljana, Slovenia; 6) Department of Ophthalmology, Second University of Naples, Naples, Italy; 7) Genetica Molecular Hospital Sant Joan de Deu, Barcelona, Spain; 8) National Research Center for Genetics, Glostrup, Denmark; 9) Hôpital des XV-XX, Paris, France; 10) Institut Pasteur, Collége de France, Paris, France.

Usher syndrome (USH) is the most prevalent cause of hereditary deafness-blindness in humans. Three types of USH (USH1, USH2, and USH3) have been distinguished clinically. These are defined according to the severity of the sensorineural hearing impairment, the presence or absence of vestibular defects, and the precocity of retinitis pigmentosa onset. To date, 12 USH loci have been characterized and ten causative genes identified. In order to improve molecular diagnosis and to minimize its cost, we here developed multiplex PCR coupled to Next-Generation Sequencing (NGS) technologies. By using this unique approach in a large cohort of 400 diagnosed Usher patients, biallelic mutations were detected in 83% of patients, monoallelic mutations were detected in 13% of them and no mutation was found in 4% of patients. SNP array was performed for patients with no mutation or with only one pathogenic mutation. Remarkably, large rearrangements (deletion and/or duplication) were observed in 25% of the Usher patients with only one pathogenic mutation. The patients with no mutation found, were examined by whole exome sequencing. Of note, one patient carried a homozygous nonsense mutation in USH2A and one pathogenic nonsense mutation in USH1G. Another patient carried two pathogenic mutations (nonsense and deletion) in USH2A and two predicted pathogenic mutation (splice site variation and predicted pathogenic missense mutation) in CDH23. These observations are crucial in the perspective of gene therapy. An early and reliable diagnosis is one critical step to develop specific and adapted therapies to cure this disorder.

Panel Diagnostics for Deafness Disorders using Next-Generation Sequencing. *I. Vogl, S.H. Eck, S. Datter, S. Küçük, D. Wahl, I. Rost, S. Chahrokh-Zadeh.* Molecular Genetics, Center of Human Genetics and Laboratory Diagnostics, Martinsried, Germany.

Hearing impairments can be classified in many different ways and have an incidence rate of approximately one in 1000 births and additionally affect 50% of the population at age 80 or higher. There are multiple genetic or non-genetic causes for hearing loss. The non-genetic factors include ototoxic drugs, perinatal infections or traumas. In most cases both exogenous factors and mutations in one or more genes contribute to the phenotype. 80% of all familial, non-syndromic deafness cases are inherited in an autosomal recessive manner. In half of them mutations in the GJB2 (gap junction protein connexin 26) are responsible for the phenotype. Sometimes heterozygous mutations in the GJB2 can occur in combination with a heterozygous deletion del(GJB6-D13S1830) in GJB6 (gap junction protein connexin 30). Furthermore there are over 70 genes known which can cause different types of deafness (autosomal dominant, autosomal recessive, X-linked recessive or mitochondrial). In a pilot study we designed a deafness gene panel comprising 75 nuclear genes and 6 mitochondrial genes associated with hearing impairment. In addition to 3 positive and 7 negative controls we sequenced 2 related patients with non-syndromic deafness. Conventional diagnostics by GJB2 sequencing and GJB6 deletion analysis was exhausted and yielded no results. Sequencing was performed on the Illumina MiSeq Next-Generation Sequencing platform. Data analysis was performed using CLCbio workbench (v6.0) and custom developed Perl scripts. The target regions, in total encompassing 413,454bp and 16,569bp, were enriched via in-solution oligonucleotide hybridization and capture (Illumina TSCE). On average, 40-70% of the reads could be mapped to the human genome (build hg19) and 30-60% to the mitochondrial genome, of which between 55-60% and 96-97%, respectively were on target. On the basis of the above mentioned controls a variant calling pipeline was established and validated. Using that pipeline the 2 patients (mother and daughter) were analyzed and the A7445G mutation of the mitochondrial genome was detected. This mutation is known in the literature to be associated with deafness induced by ototoxic drugs or independent of them. Any intake of ototoxic drug was not investigated. The mutation was confirmed independently by Sanger sequencing.

2584F

Next-Generation Sequencing in the Molecular Diagnostics of Rare Diseases using a Gene Panel Approach. *S.H. Eck, I. Vogl, S. Datter, S. Kuecuek, W. Rupprecht, B. Busse, J. Hoefele, S. Chahrokh-Zadeh, C. Marschall, K. Mayer, I. Rost, HG. Klein.* Molecular Genetics, Center for Human Genetics and Laboratory Diagnostics, Dr. Klein, Dr. Rost , Martinsried, Germany.

The implementation of Next-Generation Sequencing (NGS) in clinical diagnostics opens vast opportunities through the ability to simultaneously sequence all genes contributing to a certain disease at lower cost and higher speed compared to traditional sequencing approaches. In rare and heterogeneous disorders NGS may lead to a significant improvement of the diagnostic yield. On the other hand, the practical implementation of NGS in a clinical diagnostic setting involves a variety of new challenges which need to be overcome. Among these are the generation, analysis and storage of unprecedented amounts of data, strict control of sequencing performance, validation of results, interpretation of detected variants and reporting. Here we present a panel approach for the molecular diagnostics of rare disorders. Exonic regions of more than 250 custom selected genes are enriched in parallel by oligonucleotide hybridization and capture (Illumina TSCE) and sequenced on the Illumina MiSeq instrument. During analysis, only genes from the requested indication (grouped in subpanels) are selected to limit analysis to relevant genes, while simultaneously minimizing the possibility of incidental findings. Data analysis is performed using the CLC Genomics Workbench (v.6.0.3, CLCbio) and custom developed Perl scripts. Target regions which fail to reach the designated coverage threshold of 20X are reanalyzed by Sanger sequencing and candidate mutations are independently confirmed in a seperate reaction. All detected variants are imported into an in-house relational database scheme which can be queried via a web interface for dynamic data analysis and filtering. Information from all 250 genes is used in an anonymized way for internal variant frequency calculation, quality control and the detection of potential sequencing artifacts. We have applied this approach to more than 150 samples from a variety of different disorders. In particular we use the outlined approach for the diagnostics of arrythmogenic cardiac disorders (LQTS, HCM, DCM), connective tissue disorders (EDS, TAAD), rare kidney disorders (Nephrotic Syndrome, CAKUT), neurological disorders (Noonan syndrome, Microcephalies), metabolic disorders (MODY diabetes) and pharmacogenetics.

2585W

Sequencing *CFTR* in a clinical diagnostic setting using the ion torrent personal genome machine. *L.Y. Lau[1], M. Eliou[2], J. Orr[2], C.R. Marshall[1,3], T.L. Stockley[2], S.W. Scherer[1,3], P.N. Ray[1,2,3].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Ontario, Canada.

The advent of Next Generation Sequencing (NGS) technologies offers a rapid and low cost approach to replace traditional gene sequencing in the diagnostic setting. Until whole genome sequencing (WGS) becomes affordable as a diagnostic approach, the current strategy involves targeted sequencing of known disease genes. The diagnostic lab at The Hospital for Sick Children (Toronto, Canada) currently uses Sanger sequencing of *CFTR* to screen patients with cystic fibrosis (CF). In collaboration with Life Technologies™, we examined the feasibility of using targeted *CFTR* amplification followed by sequencing with the Ion Torrent Personal Genome Machine (PGM) as a Cystic Fibrosis diagnostic test. Following PCR amplification with Ion Ampliseq™ we sequenced 40 individuals to an average depth of 3500X using the PGM. On average, 25.1Mb sequenced data were obtained per sample with average read lengths of 120 bases and 354,454 reads on target. With the exception of exon 10, all 27 exons and flanking splice sites were sequenced to a read depth of over 500X. For exon 10, we were only able to obtain coverage above 15X for 58% of the exon with uniquely mapping reads because there is a high sequence similarity to a region on Chromosome 20. Using Ion Torrent Suite 3.4 for alignment and variant calling, we were able to detect 39 out of 42 (93%) known mutations of *CFTR*. We had difficulties in reliably identifying the remaining 3 mutations which included changes of the homopolymer T track on intron 8, a duplication of a G on exon 22 c.4028dupG (p.Gly1343fs), and a SNP, c.-8G>C located in the promoter region. The SNP was seen in the alignment file; however, it was not called by the software. When using the updated Ion Torrent Suite 3.6, again on default parameters, we lost the ability to detect the deletion on intron 6a c.744-33GATT[6]+[7]. The updated software also missed a SNP upstream of exon 9 c.1210-13G>T but it is seen in the alignment file. We believe we can improve the results by optimizing the parameters of the updated software. Our data suggest that the PGM can be used as a reliable diagnostic tool for clinical screening of *CFTR*.

Reproducibility of Fetal Fraction Estimates in Maternal Plasma using the Harmony™ Prenatal Test. *E. Wang, C. Struble, T. Musci, A. Batey, J. Schmidt, K. Song, A. Oliphant.* Ariosa Diagnostics, Inc, San Jose, CA.

Introduction: Fetal cell-free DNA (cffDNA) in maternal plasma enables techniques for screening for fetal aneuploidies using next generation sequencing technologies. It is known that the power to detect fetal aneuploidy is directly related to the amount of cffDNA, regardless of whether the approach employs sequencing random DNA fragments using a shotgun method or a directed analysis of targeted DNA fragments. Here, we demonstrate that Digital ANalysis of Selected Regions (DANSR™) assays for single-nucleotide polymorphisms (SNPs) on chromosomes 1-12 and chromosome Y accurately and reproducibly measure the fraction of cffDNA in maternal plasma (fetal fraction). We present data showing fetal fraction measurements using SNPs or chromosome Y alone are highly correlated, and these measurements are reproducible, as evidenced using two blood tubes from a single blood draw. **Objective**: To report clinical reproducibility results on Harmony Prenatal Test's ability to measure fetal fraction. **Methods**: This study included 11,024 maternal plasma samples containing observable counts on the Y chromosome. Samples were processed between 15 March 2013 and 17 May 2013 from pregnant women carrying a fetus at least 10 weeks in gestational age. A separate set of 1,266 research samples, in which both blood tubes were drawn at the same time but processed on different dates, were used to study the reproducibility of the fetal fraction estimates. Samples were processed as previously described (Norton et al., 2012). Fetal fraction was assessed simultaneously by assays against a set of 192 SNP loci on chromosomes 1-12 (FF-SNP) and a set of Y assays (FF-Y). **Results**: In the first study of 11,024 samples, the FF-SNP and FF-Y were correlated with an r-squared of 0.99. Among the duplicated blood tubes, the median processed time difference between a pair of blood tubes was 80 calendar days. Despite this large time difference and various possible reagent, robotic, and operator differences, the fetal fraction calculated between tubes were strongly correlated with an r-squared of 0.99 and a slope of 1. The median absolute relative difference between fetal fractions measured by the tube pairs was 4.5% (S.E. 0.2%). This implies a fetal fraction of 0.04, on average, may result in either 0.038 or 0.042 on a repeated measure from a different blood tube. **Conclusions**: Fetal fraction computed from the Harmony Prenatal Test is accurate, precise, and reproducible.

Fast STR-PCR protocol enabling rapid and high quality chimerism analysis after allo-HSCT. *W. Teng[1], H. Liu[1], F. Wang[1], Y. Wang[1], X. Chen[2], J. Fan[1], P. Zhu[2].* 1) Molecular Medicine Lab., Hebei Yanda Hospital, Sanhe, Hebei, China; 2) Department of Hematology, Peking University First Hospital, Beijing, China.

Background: Chimerism analysis based on STR-PCR is the standard method for chimerism analysis after allogeneic hematopoietic stem cell transplant (allo-HSCT). The cycling time needs about 3.5 hours, and incomplete adenylation of PCR products often become a problem. Here we aimed to develop a fast PCR protocol enables rapid and high quality chimerism analysis. Methods: Peripheral blood and fingernail samples were collected from healthy donors and patients. Simulated mixed chimerism samples were prepared by fold dilution. The AB Identifiler Kit with 15 STR loci was used. AmpliTaq Gold polymerase and standard PCR cycling program were used as contrast. Newly bio-engineer modified fast polymerase MyTaq, Phusion and Q5 were tested with rapid cycling programs. The PCR products were capillary electrophoresed and chimerism was analyzed using AB3500XL and GeneMapper IDX software. Results: All the four kinds of polymerase can be successfully used for STR-PCR and genotyping. The STR-PCR cycling time for MyTaq, Phusion and Q5 were about 30 minutes, considerably less than 3.5 hours when using AmpliTaq Gold. For the 3 kinds of fast polymerases, the Q5 polymerase showed the best balanced amplification efficiency among the 15 STR loci. The PCR product of Phusion and Q5 don't have non-template addition 'A' tail due to lack of adenylate activity, yet the allelic ladders without 'A' tail must be specially made. The MyTaq has extremely efficient of adenylate activity and showed complete adenylation even using crude DNA samples extracted from fingernail, thus actually fully resolved the problem of incomplete adenylation. Conclusion: The STR-PCR cycling time got a drastic reduction and the problem of incomplete adenylation was resolved by using the novel MyTaq and rapid PCR program, thus enabling rapid and high quality chimerism analysis after allo-HSCT.

New method for detecting mutation with high sensitivity using capillary electrophoresis DNA sequencer. *T. Yokoi, M. Yoshida, T. Anazawa.* Central Research Laboratory, Hitachi.Ltd, Tokyo, Japan.

By recent progress in NGS technologies, a genomic era for cancer studies is growing rapidly. In this era, automated capillary electrophoresis (CE) DNA sequencer by sanger dideoxy terminator is still a widely used for validating gene sequences, and is considered gold standard for target gene Analysis. However, CE DNA sequencers cannot detect low-frequency mutation, because sequencing workflow and subsequent signal processing of CE DNA sequencers are optimized for detecting germline mutation (50% existence). To address this issue, we developed a new method for detecting mutation with high sensitivity using CE DNA sequencers. In the method, we first modified sequencing workflow, namely, measuring four kinds of bases in separate capillaries, to reduce to crosstalk-fluorescence signal. Second, we implemented a procedure of extracting relative intensity of each peak to a neighbor peak of the same kind of base in a raw fluorescent signal data. Dispersion of relative intensity of each peak was found to be small enough to detect mutation with high sensitivity by comparing with relative intensity of reference data. This developed method successfully detected 5% existence mutation in EGFR and KRAS without visual inspection. The proposed method shows a possibility to detect mutation of much lower existence, and is promising for practical use to detect genetic mutations.

Whole-genome prenatal sequencing and integrative genomics: Detection of structural variation from invasive and non-invasive approaches. *M.E. Talkowski[1,2,3], V. Pillalamarri[1], H. Brand[1], I. Blumenthal[1], M.Z. Ordulu[5], S. Pereira[5], J. Kitzman[6], J. Shendure[6], J.F. Gusella[1,2,3,4], C.C. Morton[4,5].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Department of Neurology, Harvard Medical School, Boston, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute, Boston, MA; 5) Departments of Obstetrics, Gynecology and Reproductive Biology and Pathology, Brigham and Women's Hospital and Harvard Medical School; 6) Department of Genome Sciences, University of Washington, Seattle, WA.

Technical innovation has had a dramatic impact in prenatal genetic diagnostics, particularly for congenital anomalies where de novo structural variations (SV) represent a major source of risk but are not considered by non-invasive cell free fetal DNA ($_{cff}$DNA) studies that are limited to detection of aneuploidy. We recently performed the first example of prenatal clinical diagnosis from whole-genome sequencing (WGS) using large-insert 'jumping libraries' at a cost and timeline comparable to karyotyping. Here, we present real-time clinical sequencing and integrative genomic interpretation of fetal DNA from four individuals (one twin pair) referred for advanced maternal age harboring *de novo* balanced SVs. In two subjects, DGAP247 and DGAP248, protein-coding genes were disrupted (*KHDRBS3* and *RCF3*, respectively) but interpretation from large independent datasets suggested a variant of unknown significance (VOUS) for each. The parents of DGAP247 chose to receive these findings and carried DGAP247 to term resulting in a well newborn examination. The parents of DGAP248 chose not to receive the findings. We also performed deep WGS on cffDNA isolated from maternal plasma of DGAP247 during the third trimester. We generated 53X genome coverage from 1.72 billion reads, finding a fetal DNA composition of ~25% of reads. We used a split read algorithm to detect the inversion from 14% of reads (~28% fetal coverage at the locus), demonstrating feasibility of SV detection from very deep WGS of $_{cff}$DNA. Transcriptome studies are ongoing. In the twins (DGAP258) we identified a pericentric inversion that rearranged the known copy number morbid 6p25.3 locus, as well as an independent cryptic inversion, but neither disrupted genic sequence. The consequences of inverting a recurrent copy number morbid region but not disrupting genic sequence are unknown, but the twins were recently born with a well newborn examination. These data highlight the power of prenatal WGS by jumping libraries to detect pathogenic SVs of all classes, however they are reliant on invasive methods that carry substantial risk to the fetus. They also show the potential feasibility of SV detection by non-invasive methods, though costs and analytical effort were exorbitant. Collectively, our studies emphasize the unique challenges facing development of a comprehensive prenatal genetic screening strategy that accesses the entire pathogenic mutational spectrum but minimizes risks to the fetus.

2590F

A novel and rapid digital PCR-based method for the identification of 22q11.2 Deletion Syndrome in large population screening. *V. Hwang[1], D. Maar[2], J. Regan[2], T. Simon[3], F. Tassone[1, 3].* 1) Department of Biochemistry and Molecular Medicine, UC Davis, Davis, CA; 2) Digital Biology Center, Bio-Rad Laboratories, Pleasanton, CA; 3) MIND Institute, UC Davis Medical Center, Sacramento, CA.

22q11.2 Deletion Syndrome (22q11DS), the most common microdeletion syndrome in humans, is characterized by a wide range of clinical manifestations including craniofacial defects, developmental delay, neurological and psychiatric problems, autism spectrum disorders and congenital heart defects. 70-80% of individuals have a 3 Mb deletion, 15-30% have a nested 1.5 Mb deletion, and the remainder have atypical deletions within the 22q region. Because the syndrome is associated with over 100 different diagnostic findings that range from mild to severe and life-threatening conditions, diagnosis is often delayed or missed. Therefore, due to this high variability, propositions to include 22q11DS in newborn screening panels have been suggested.

The currently accepted method for diagnosis is fluorescent in-situ hybridization (FISH). This approach, however, is expensive, labor intensive, and requires special technique and equipment. We have developed an inexpensive, rapid, sensitive and specific test that can identify newborns with 22q11DS. The approach uses a droplet digital PCR (ddPCR) that processes samples collected on blood spot cards and provides accurate and rapid diagnosis while keeping costs at a minimum-the ideal premise for large population screenings, such as newborn screening. We performed a validation study where we blindly screened over 500 anonymous blood spots collected from the general population that included a small number of 22q11DS samples. We demonstrate that ddPCR definitively assesses DNA copy number variation from DNA isolated from 903 blood spot cards and provide evidence that this methodology is highly specific and reliable. A large population screening is needed to establish the prevalence of 22q11DS in the general population, which has not been well assessed to date. In addition, the need for newborn screening for 22q11DS is highly sought as diagnosis at birth allows for immediate mediation of symptoms that leads to a better disease prognosis. To our knowledge, this study is the first to demonstrate the efficacy of ddPCR in large population screening studies, an advent that holds great promise for families and clinicians alike.

Detection of 22q11.2 deletion syndrome in Colombian patients with isolated congenital cardiopathy by MLPA. *T. PINEDA[1], O. MORENO[2], I. ZARANTE[3].* 1) Medical Genetics Resident, Genetics Institute, Pontificia Universidad Javeriana, Bogotá, Colombia; 2) Biol, Msc. Genetics Institute, Pontificia Universidad Javeriana. Bogotá, Colombia; 3) Md, Phd. Genetics Institute, Pontificia Universidad Javeriana. Bogotá, Colombia.

22q11.2 deletion syndrome is one of the most common genetic syndromes and it has a wide phenotypic spectrum, abnormalities can include cardiac defects, immunodeficiency, hypocalcaemia, speech and language impairment, cleft palate, development delay and learning difficulties. The aim of this study was to detect the 22q11.2 deletion by MLPA (kit SALSA MLPA Probemix P250 B1 DiGeorge) in Colombian patients presenting with isolated congenital cardiopathy in order to establish the prevalence of this syndrome in this group of patients. The study included 26 patients with congenital cardiopathy that were enrolled from different hospitals in Bogotá (23 patients with contruncal cardiopathy, 1 patient with VSD and Coarctation of the aorta, 1 patient with VSD and overriding aorta and 1 patient with ASD and PDA), the group of patients range from 1 day old to 13 years old. Exclusion criteria included cleft lip or cleft palate, mental retardation and any other major anomaly. The results showed that the classical 22q11.2 deletion is present in the 15,3% of the patients (4/26), we did not find any atypical deletion in this group. With this study we can conclude that MLPA is a very useful molecular method that provide an accurate diagnosis and that it should be implemented in all patients presenting with isolated congenital cardiopathy related to 22q11.2 deletion syndrome.

2592T

A comparison of CNV endpoint accuracy between CytoScan® Dx assay and Next Generation Sequencing. *A. Roter[1], B. Eynon[1], S. Close[2], K. Kwiatkowski[1], D. Ballinger[3], S. Yang[3], R. Duttagupta[1], C. Chen[1], K. Suyenga[1], A. Singh[1], T. Chen[1], M. Chadha[1], E. Fung[1].* 1) Affymetrix, Inc., Santa Clara, CA; 2) Indiana University School of Medicine, Division of Clinical Pharmacology, Indianapolis, IN; 3) Complete Genomics, Mountain View, CA.

Background: The genome-wide distribution of ~2.7 million markers enables CytoScan® Dx assay to determine copy number state with very high resolution. To assess the resolution of CytoScan Dx assay, the accuracy in determining the genomic location of the endpoints of copy number variation (CNV) regions was evaluated. Endpoint location was compared between next generation sequencing and CytoScan Dx assay for 1,387 concordant CNV endpoints in post-natal samples.

Materials & Methods: 137 samples (blood and cell-line derived DNA samples) were selected to maximize variation across the genome. The CytoScan Dx assay was run at Affymetrix and next generation whole genome sequencing was independently performed and analyzed in a blinded fashion at Complete Genomics. Endpoint agreement was pre-specified as the sequence-defined endpoint of ± 12 markers for loss CNVs and ± 25 markers for gain CNVs, translating into an effective resolution of 25kb for losses and 50kb for gains. In addition, copy number accuracy was assessed by comparing results with those determined by routine patient care methods such as FISH or karyotype.

Results: The overall endpoint agreement was 93.4% and was similar for copy number loss regions (92.5%) and for copy number gain regions (94.7%). The median absolute endpoint difference was 1 marker across all comparable endpoints. Additionally, CytoScan Dx assay and routine patient care methods agreed 100% of the time on copy number variation.

Conclusions: The CytoScan Dx assay is highly accurate in detecting copy number variation. For those copy number variation regions of 25kb and 25 markers for loss segments and 50 markers and 50kb for gain segments, CytoScan Dx assay was able to determine the genomic location within ± 1 marker of the sequence determined endpoint demonstrating very high resolution and a high degree of accuracy in determining the copy number variation endpoint locations.

Accurate detection of small and large copy number events from targeted next generation sequence data. *K.B. Jacobs, J.P. Paul, G. Nilsen, M. Mikhaelian, R. Hart, M. Johnson, S.E. Lincoln, J.M. Sorenson.* InVitae Corporation, San Francisco, CA.

Germline copy number variants (CNVs) can be detected from next-generation sequencing (NGS) data generated using targeted DNA capture technologies (e.g. exomes and other panels), however methods for doing so must overcome many technical challenges. Several algorithms have been published to detect CNVs in such data, though they may not yet be adequate for use in diagnostic testing laboratories, particularly for detection of small single-exon CNVs. Thus, diagnostic testing laboratories often resort to expensive and low-throughput methods such as MLPA to discover and confirm small CNVs. As a result, clinicians must carefully decide whether to order both a sequencing test and a deletion/duplication test for their patients. A single test that can accurately assay both types of alterations would improve patient access to comprehensive genetic testing.

We present a new method, CNVitae, which is designed to detect single-exon CNVs as well as larger regions sequenced using NGS. CNVitae is based on a statistical model for read counts and employs model-based segmentation algorithms optimized for use with sparsely distributed and highly variable targets across the genome. This framework estimates the most likely copy number for all segments, and, critically for clinical use, each called segment is assigned a robust quality score indicating confidence in the copy number determination.

We evaluated CNVitae on high-depth targeted NGS data generating using Agilent SureSelect capture and Illumina MiSeq 2x150 paired-end sequencing. Under a simulation model, altering the observed laboratory data *in silico*, we achieved a sensitivity and specificity of >99% to detect single exon hemizygous deletions at a strict confidence threshold of Q25 (probability of error < 0.5%). We saw 97% sensitivity and >99% specificity to detect single exon duplications (CN=3) while four exon duplications were detected with sensitivity of >99%. In 40 patients independently known to carry clinically relevant CNVs, we detected all 37 of the single-exon or larger events with high confidence, although three sub-exon scale CNVs were not detected by the current algorithm. Additional validation results will be represented, including results on additional clinical samples, the Get-RM Copy Number Variation Reference Panel, and a re-analysis of a subset of exome data from the 1000 Genomes Project.

2594W

Assessing Common Maternal Copy Number Variation during cfDNA Analysis for Non-Invasive Prenatal Testing using Digital Analysis of Selected Regions (DANSR™) Assays. *C. Struble, E. Wang, J. Schmidt, A. Batey, T. Musci, K. Song, A. Oliphant.* Ariosa Diagnostics, Inc. San Jose, CA.

Objective: To report on Harmony™ Prenatal Test's ability to provide accurate results in the presence of a maternal CNV. **Method**: As previously described, DANSR assays were used to analyze common trisomies in maternal samples. The DANSR assays were selected to target nucleic acid regions unique to the chromosomes of interest in a maternal sample, and to avoid common copy number variations (CNVs) (Sparks et al, 2012). Fetal fraction was assessed in the maternal samples simultaneously with the trisomy analysis using DANSR assays against a set of 192 single nucleotide polymorphism (SNP)-containing loci on chromosomes 1-12. Using the estimated fetal fraction, a sample specific expectation is determined to evaluate if increased chromosomal counts using the DANSR assay are consistent with fetal aneuploidy and/or other clinical factors such as maternal CNV. **Results**: In approximately 64,000 samples, 35 (0.05%) putative maternal CNVs were observed. Sixteen of these 35 (47%) belong to a 1.5 mega base maternal duplication on chromosome 21q21.3. Of these 16 cases, there was one case of a high-risk for trisomy 21 result, and 15 cases of low-risk results in the presence of this maternal CNV. The case of high-risk for trisomy 21 was subsequently confirmed by amniocentesis. Genes in this duplicated region includes two secreted metelloproteases, ADAM metallopeptidase with thrombospondin type 1 motif (ADAMTS1) and ADAM metallopeptidase with thrombospondin type 5 motif (ADAMTS5). ADAMTS1 has been reported to play a critical role in follicular rupture. ADAMTS5 has been reported to degrade aggrecan, which is a proteoglycan of the cartilage and is associated with inflammation and arthritis. An additional gene in this region include the Cysteine and typrosine-rich 1 (CYYR1) with high conservation among vertebrates and high expression in cells belonging to the diffuse neuroendocrine system. **Conclusion**: DANSR's design allows for efficient and uniform sequencing across the chromosome loci with enough depth to evaluate the risk for fetal aneuploidy in the presence of previously unreported maternal CNV.

2595T

Generating High Confidence Next-Generation Sequencing Variant Calls for Clinical Diagnostic Use. *P.J.B. Sabatini[1], L. Lau[2], M. Eliou[1], J. Orr[1], P. Ray[1], T. Stockley[1].* 1) The Hospital for Sick Children, Toronto, Canada; 2) The Centre for Applied Genomics, Toronto, Canada.

Using next-generation sequencing for clinical diagnostic testing poses significant challenges associated with analytical sensitivity and specificity. Discovery of false positive variants lead to misdiagnoses and false negatives neglect clinically relevant ones. Understanding the properties of false variant calls from next-generation sequencing platforms will assist with tailoring the variant calling programs to generate high confidence sequence variants important for clinical diagnostics. The molecular genetics laboratory at the Hospital for Sick Children in Toronto, Canada is developing next-generation sequencing panels using the Ion Torrent platform. To observe the properties of false variant calls, three separate runs were performed using a known genotyped sample - J. Craig Venter - with the Inherited Disease Panel from Life Technologies. The Inherited Disease Panel targets the coding regions of over 300 genes associated with human genetic conditions and covers a wide variety of sequencing contexts that is important in understanding the properties of variant calling and their genotypes. After sequencing on the Ion Torrent the reads were mapped to the human reference genome sequence (hg19) using TMAP 3.4.3 and variant calls were made using the Ion Torrent Variant Caller's (3.4.2) default settings with an average read length of 135 base pairs. Of the known 1,005 SNPs present in the area targeted from the Venter sample an average of 74 variants were called incorrectly (93% sensitivity) and of the 150399 known references bases sequenced 74 were missed (99.9% specificity). The average read depth for correct homozygous calls was 347 (s.d=312) versus 157 (s.d=173) for false positives and for true heterozygous calls the read depth was 374 (s.d=325) versus 312 (s.d= 230) for false positive heterozygous calls. The ratio of the alternative allele was 1.00 (s.d.=0.02) for correct homozygous calls and 0.81 (s.d.=0.15) for false homozygous calls. Average heterozygous alternative allele ratio was 0.49 (s.d.=0.07) for correct calls and 0.30 (s.d.=0.27) for false positives. There were no significant differences in strand bias. Limiting the analysis to read depths over 350 improved the positive predictive value from 93% to 96%. By designing testing strategies that generate read depths above 350 and narrowing the filtering range of the allelic ratios we can improve the confidence of the variant calls important for clinical diagnostics.

2596F

Validation and implementation of a 19-gene 2nd tier Rett/Angelman syndrome next generation sequencing panel. *J.R. Jones, M.J. Basehore, S. McGee, K. Kubiak, J. Butler, K. King, J.A. Lee, M.J. Friez.* Greenwood Genetic Center, Greenwood, South Carolina, USA.

Angelman and Rett syndromes are common genetic disorders that share many similar features, including developmental delay, intellectual disability and seizures. The genetic heterogeneity among these two syndromes and many other similar disorders make it challenging to determine the appropriate second tier of diagnostic testing once the most common causes have been ruled out. In an effort to provide a more rapid, comprehensive and cost-effective analysis for patients with features overlapping those of Rett and Angelman syndromes, the Molecular Diagnostic Laboratory at the Greenwood Genetic Center (GGC) has designed and validated a 19-gene panel which utilizes RainDance™ Technologies microdroplet enrichment and SOLiD™ Next Generation Sequencing (NGS). The panel includes *MECP2* and *UBE3A* along with 17 additional genes known to cause conditions that often present with clinical features similar to Rett and Angelman syndromes. The coverage of the panel includes all exons for each gene as well as flanking intronic regions. Thus far, 38 samples have been submitted for clinical testing. Of the 17 completed analyses, eight patients had normal results, and six patients had at least one variant of unknown clinical significance. We identified pathogenic changes in three patients (~18%). Interestingly, one of these patients was found to have a one basepair deletion in *MECP2* (c.271delC). *MECP2* sequencing had not been previously requested for this patient since she does not have a classic Rett phenotype. Unlike most patients with Rett syndrome who have microcephaly, short stature and cachexia, at seven years of age this patient has a normal head circumference (47th percentile), height (90th percentile) and weight (75th - 80th percentile). She is ambulatory and non-verbal with severe intellectual disability. Therefore, this panel may also be useful in detecting *MECP2* and possibly *UBE3A* mutations in individuals with atypical presentations of Rett and Angelman syndromes, in addition to being a second tier test for *MECP2* and *UBE3A* mutation-negative patients. Our initial findings indicate that this expanded Rett/Angelman panel will provide a cost-effective method for testing the genes believed to be of the highest diagnostic priority for individuals who fall into this clinical spectrum.

2597W

High-throughput screening for *SMN1* copy number loss by next-generation sequencing. *E. Boyden, G. Porreca, M. Umbarger.* Good Start Genetics, Cambridge, MA.

Spinal muscular atrophy (SMA) is a lethal autosomal recessive neuromuscular disorder caused by functional loss of the *SMN1* gene. The high carrier rate of ~1 in 40 is attributable primarily to *SMN1* copy number loss produced by either deletion of part or all of *SMN1*, or conversion of *SMN1* to *SMN2*, a linked paralog that encodes an identical protein but is poorly expressed due to a silent non-coding variant that disrupts proper splicing. Clinical SMA carrier screening is currently performed via methods such as multiplex ligation-dependent probe amplification (MLPA) that enable the assessment of the copy number status of *SMN1* in a manner that distinguishes between *SMN1* and *SMN2*, typically by interrogating the exon 7 variant. Such methods are sensitive and specific, but relatively low-throughput.

We have developed a method by which the copy number status of *SMN1* and *SMN2* can be measured directly by next-generation sequencing. Our approach uses molecular inversion probes to capture loci specific to *SMN1* and *SMN2*, and subsequently employs ratios of normalized sequence read depths to infer copy number status. Our method shows sensitivity and specificity for detection of *SMN1* copy number loss similar to that of MLPA, but has the advantage of being compatible with automated high-throughput screening. Furthermore, because our method uses sequencing as the readout, it can detect deleterious *SMN1* point mutations and indels that would be missed by MLPA and related approaches. Thus, our new SMA carrier screening assay represents a significant improvement over standard SMA carrier screening methods.

2598T

Establishing Performance Specifications for Clinical Whole Exome Sequencing. *M.O. Dorschner[1,2], S.J. Anover-Sombke[2], J. Gasper[2], S. McGee[2], T. Shaffer[2], K. Patterson[2], J.D. Smith[2], G.P. Jarvik[2,3], D.A. Nickerson[2].* 1) Psychiatry & Behavioral Sciences; 2) Genome Sciences; 3) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle WA.

Whole exome sequencing (WES) is rapidly becoming an effective tool for the molecular diagnosis of rare genetic disorders. WES is particularly well suited for disorders in which the genes are known but diagnostic assays are unavailable or those conditions with closely, difficult to distinguish phenotypes. Prior to launching WES as a clinical test, laboratories must establish performance specifications in accordance with regulations set forth by the Clinical Laboratory Improvement Amendments (CLIA) or College of American Pathologists (CAP). Sanger-based sequencing tests have typically been validated by the examination of a small set of known, mutation-positive and negative samples. The ability to detect these variants accurately, serve as the basis for analytical sensitivity, specificity and reproducibility of the test. Testing only a small number of variants, from a limited set of samples is not adequate to represent the performance of large-scale assays such as WES and whole genome sequencing. To validate our WES protocol, we chose to examine 12 well-characterized HapMap samples, in duplicate. All samples were previously genotyped using the Illumina 1M array, and >60,000 markers overlapping the exome were examined for concordance with exome sequence data. With a mean coverage of 120X (90% of the exome covered at >20X), we calculated the sensitivity and accuracy of our WES protocol at >99% for single nucleotide substitutions. Poorly covered exons were largely the result of high GC content and/or low read mapability. We believe that comparing a much larger set of variants, more accurately reflects the true performance characteristics of our WES assay. With such high accuracy, we have developed an algorithm based on coverage and sequence quality to eliminate the need for Sanger confirmation. Only those variants exhibiting sub-optimal coverage, quality or strand bias are routinely Sanger confirmed. Sequencing technology continues to evolve at a rapid pace necessitating an organized procedure for re-validation of WES protocols as changes are incorporated into clinical workflows. Scalable quality control measures will be required for wider implementation of genomic medicine.

Development and validation of a synthetic, single-reagent, positive control for comprehensive high-throughput carrier screening. *A.M. Fedick[1,2], C. Jalas[3], N.R. Treff[1,2].* 1) Department of Microbiology and Molecular Genetics, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 2) Reproductive Medicine Associates of New Jersey, Basking Ridge, NJ; 3) Bonei Olam, Center for Rare Jewish Genetic Disorders, Brooklyn, NY.

Carrier screening tests that offer parallel analysis of multiple mutations, genes, and diseases are in high demand. Contemporary platforms include testing for hundreds of pan-ethnic mutations at once using methods such as TaqMan allelic discrimination, DNA microarrays, or next generation sequencing. One of the greatest challenges in developing new carrier screening assays is obtaining positive controls. Furthermore, there is no single reagent that can be used as a positive control for all mutations being evaluated, particularly given that there are no individuals who naturally carry the mutant allele for all mutations tested. As a proof-of-principle, we set out to develop a novel synthetic control to provide a single reagent suitable for routine quality control during the development, validation, and performance of TaqMan-based comprehensive carrier screening. A set of 29 ACOG recommended Ashkenazi mutations, for which TaqMan assays had been previously developed and validated using known carriers, were included in designing a synthetic control solution. The synthetic component of the reagent involved the creation of gBlocks (Integrated DNA Technologies). Each gBlock consisted of sequence covering the entire TaqMan amplicon and incorporated sequence for the mutant allele. Multiple amplicons were included in a single gBlock with the maximum size reaching 500 basepairs to enhance cost efficiency. A total of 8 gBlocks were designed, ordered, and pooled together. Initial validation was performed on a 7900 HT real-time PCR instrument using 384 well plates. Two synthetic controls failed to amplify and were excluded from further analysis. The remaining controls were added at a 1:1 ratio with DNA from an individual known to possess normal alleles for all mutation sites. The final mixture was used as template in conventional TaqMan allelic discrimination analysis using first a 7900 and then a QuantStudio 12K Flex Real-Time PCR System for high-throughput genotyping. Successful genotypes were made for 96.3% (26/27) of the synthetic controls on the 7900 and for 92.6% (25/27) on the QuantStudio. The two failed controls both involved mutations in the GBA gene, which has a known pseudogene, and are now being redesigned to achieve 100% coverage. In conclusion, this proof-of-principle study demonstrates a novel strategy to provide a single reagent suitable for routine quality control for high throughput carrier screening.

Limited clinical utility of Whole Exome Sequencing in the diagnosis of hereditary neuropathies. *O. Jarinova[1], J. Warman[1,2], J. Schwartzentruber[3], C. Goldsmith[1], N. Carson[1], E. McCready[1], G. Yoon[4], S. Baker[5], A.M. Innes[6], C. Beaulieu[1], A. Smith[1], T. Hartley[1], K. Boycott[1].* 1) Children's Hospital of Eastern Ontario, Ottawa; 2) Division of Neurology, Department of Medicine, The Ottawa Hospital; 3) McGill University and Genome Quebec Innovation Centre, Montréal, Québec; 4) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto; 5) Department of Medicine, Divisions of Physical Medicine and Rehabilitation, McMaster University, Hamilton; 6) Department of Medical Genetics, Faculty of Medicine, University of Calgary, Alberta.

Hereditary neuropathies comprise a distinct group of inherited disorders in which peripheral nerves undergo progressive degeneration, leading to significant physical disability of the hands and lower legs. While autosomal recessive and X-linked forms have been described, hereditary neuropathies predominantly show autosomal dominant inheritance. Causative mutations can reside in any of a number of genes responsible for various aspects of maintenance of peripheral nerves and result in an overlapping clinical spectrum for these disorders. Currently available molecular diagnostic options only allow the sequential analysis of a limited number of these genes. Therefore determining the genetic cause for a specific patient/family is often time-consuming and expensive.

We questioned whether Whole Exome Sequencing (WES) could facilitate the identification of causative mutations in patients with hereditary neuropathies. We sequenced the exomes of twelve unrelated patients without molecular diagnoses after mutations in the four common neuropathy genes (*PMP22*, *GJB1*, *MPZ*, *MFN2*), which account for over 70% of molecular diagnoses, had been ruled out. We screened the sequence data for the presence of likely damaging coding and splice-site variants using an in-house analysis pipeline and manual review of variants. While this approach has proven to be successful for diagnosis of other genetic disorders, it failed to identify obvious causative mutations in our patients. Our findings suggest that at this time using WES for the diagnosis of patients with hereditary neuropathies is challenging. This study emphasizes the need for refinement of analysis methods and further assessment of clinical utility of WES for the diagnosis of autosomal dominant heterogeneous conditions.

2601T

Comprehensive massive parallel DNA sequencing strategy for the genetic diagnosis of the Neuro-cardio-facio-cutaneous syndromes. *A. Justino[1], P. Dias[2], M.J. Pina[1], C. Ribeiro[1], S. Sousa[1], L. Cirnes[1], A.B. Sousa[2], J.L. Costa[1], J.C. Machado[1,3].* 1) Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal; 2) Department of Genetics, Hospital de Santa Maria de Lisboa, Portugal; 3) Medical Faculty of the University of Porto, Porto, Portugal.

Background: The Noonan, Cardio-facio-cutaneous, Costello and LEOPARD syndromes are members of the Neuro-cardio-facio-cutaneous syndromes group (NCFCS). Mutations in 11 genes have been causally linked to these disorders (*PTPN11, SOS1, BRAF, RAF1, MEK1, MEK2, NRAS, KRAS, HRAS, SHOC2 and CBL*). Recently, an exome sequencing study also associated the gene *A2ML1* with this syndrome. Due to the genetic and clinical heterogeneity of these disorders it is challenging to define straightforward strategies of sequential gene analysis for their molecular diagnosis. Therefore, the aim of this study was to develop and validate a massive parallel sequencing (MPS) based strategy for the molecular diagnosis of NCFCS. Methods: A multiplex PCR-based strategy for the enrichment of the 12 genes and a dedicated variant prioritization pipeline (VPP) was established. Two sets of genomic DNA samples of clinically defined cases of NCFCS were studied using the Ion PGM: a training set (15 cases) used to optimize the strategy and a validation set (20 cases) used to validate and evaluate the power of the new methodology. Sanger sequencing was performed to confirm all variants and fill in regions with insufficient read coverage. Results: All variants identified by Sanger sequencing were detected with our MPS approach. The most frequent mutated gene was *PTPN11* (n=8). Other known disease causing mutations were found in *BRAF* (n=1), *SHOC2* (n=1) and *RAF1* (n=2). Additional genetic alterations of unknown significance were identified in *SOS1* (n=2), *CBL* (n=3) and the novel *A2ML1* (n=10). The methodology resulted in an experimental approach with a specificity of 99.4% and a maximum analytical sensitivity ≥98.1% with a confidence of 99%. The analysis of the 12 genes incremented in 15% the diagnostic yield of the strategy currently used by our laboratory for the molecular diagnosis of NCFCS. Conclusions: Here we present a workflow that provides a comprehensive genetic screening strategy for patients with NCFCS in a fast and cost-efficient manner. This approach demonstrates the potential of a combined MPS-Sanger sequencing based strategy as an effective diagnostic tool for heterogeneous diseases.

Blood Group Genotyping on the TaqMan® OpenArray®. *M. Laig[1], C. Colvin[2], M.A. Keller[2], E. Grigorenko[3], T. Horn[2], J. Crowley[2], D. Fantin[1].* 1) Life Technologies, South San Francisco, CA; 2) American Red Cross, Philadelphia, PA; 3) Diatherix Laboratories, Inc, Huntsville, AL.

Transfusion patients depend on well characterized blood donations. Incompatible blood types can cause severe hemolytic reactions. Blood group antigens have a genetic basis, in most instances they are based on a single nucleotide polymorphism (SNP). Genotyping is more accurate than serology based tests since polyclonal antibodies may miss detection of low expression of antigens. For some blood group antigens, no antibodies are available at all. We developed a high-throughput screening panel on the TaqMan® OpenArray® covering 28 markers across 14 blood groups: Colton Co(a), Cromer Cr(a), Diego Di(a/b), Dombrock Do(a/b), Hy, and Joa, Duffy Fy(a/b), Fy(x) and GATA Silencing, Kell Js(a/b), K/k, and Kp(a/b), Kidd Jk(a/b), Knops Kn(a/b), Landsteiner-Wiener LW(a/b), Lutheran Lu(a/b), MNS MN (GYPA nt59, GYPA nt71/72) and MNS Ss and U (Intron5, nt143, nt230), Rh RHCE C/c, E/e, L245V, M238V, G336C, Scianna Sc(a/b), Yt(a/b). Challenges overcome with this panel are extensive homologies in the MNS group between Glycophorin A, B, and E genes and in the Rh group between the RHCE and RHD genes that pose challenges to assay development. The OpenArray plates are run on the QuantStudio™ 12K Flex with a throughput of roughly 400 samples in 3.5 hours. Genotypes were successfully validated on control samples. Blood Group Genotyping on the OpenArray platform provides an accurate tool for high-throughput screening of blood units which can be a complementary approach to existing serology tests.

2603W

Clinical Validation of Noninvasive Prenatal Screening for Fetal Sex Chromosome Aneuploidies in Maternal Plasma using Direct ANalysis of Selected Regions (DANSR™) Assays. *T. Musci, C. Struble, E. Wang, J. Hooks, J. Schmidt, K. Song, A. Oliphant.* Ariosa Diagnostics Inc., San Jose, CA.

Introduction: Fetal cell-free DNA(cffDNA) in maternal plasma enables techniques for screening for fetal aneuploidy using next generation sequencing technologies. We have previously described a method using DANSR assays for biochemical analysis of chromosomes 13, 18, and 21, combined with the Fetal fraction Optimized Risk for Trisomy Evaluation (FORTE™) algorithm to compute the risk of trisomy based on the DANSR assay results with high sensitivity and specificity. Both components are integral parts of the commercially-available Ariosa Harmony Prenatal™ Test. In this study, we have developed additional DANSR assays for the X and Y chromosomes and have applied the FORTE algorithm on a blinded set of samples. The set contained samples with and without sex chromosome aneuploidies (SCA). **Objective**:Report clinical validation results on Harmony Prenatal Test's ability to detect fetal SCA. **Methods**: 432 subjects were selected. Participants provided informed consent under an IRB approved protocol. All subjects underwent invasive testing. Resulting karyotypes were used to confirm the Harmony Prenatal Test results. Samples were processed as previously described with lab and analysis personnel blinded to the fetal karyotype. FORTE models were built against monosomy X, XXX, XXY, XYY, and XXYY genotypes. Results were compared against the fetal karyotypes. **Results**:Of the 414 plasma samples that passed standard QC metrics for the Harmony Prenatal Test, all generated a sex chromosome result (100%; 95% CI: 99.1-100%). All samples were concordant with the fetal karyotyping result for fetal sex (100%; 95% CI: 99.1-100%). 26 of 27 monosomy X samples classified as high risk agreed with karyotype (sensitivity 96.3%; 95% CI: 81.7-99.8%), with two discordant high risk results (specificity 99.5%; 95% CI:98.1-99.9%). One XXX sample classified as high risk was concordant with karyotype with two discordant high risk results (specificity 99.5%; 95% CI:98.1-99.9%). All of six XXY calls were concordant (sensitivity 100%; 95% CI:61-100%; specificity 100%; 95% CI:99.0-100%). **Conclusions**:Directed analysis of cffDNA with DANSR assays allows for risk assessment of non-mosaic fetal SCA. While this is the largest fetal SCA validation study done to-date, due to the complex nature of SCAs, and possible maternal mosaicism, future larger studies are warranted. This study also demonstrates the ability to expand the Harmony Prenatal Test to genetic conditions other than trisomies 13,18 and 21.

2604T

Comparative Study For The Evaluation Of A New Technology For Cystic Fibrosis Screening. *M.CA. Rongioletti[1], F. Papa[1], C. Vaccarella[1], MB. Majolini[1], A. Luciano[1], C. Centrone[2], B. Minuti[2], V. Mazzucchi[1], M. Belli[1], I. Giotti[2], C. Giuliani[2], F. Torricelli[2], G.M. Liumbruno[1].* 1) Clinical Pathology Department, San Giovanni Calibita Hospital, Rome, Italy; 2) SOD Diagnostica Genetica, AOU Careggi, Florence, Italy.

Introduction Cystic fibrosis (CF) is one of the most frequently diagnosed autosomal-recessive diseases in the Caucasian population. Screening for Cystic Fibrosis Transmembrane conductance Regulator (CFTR) gene mutations, including poly T, is strongly recommended in infertile couples planning a pregnancy by assisted reproductive technology (ART). This study evaluated the performance of the new Nanochip CF70 kit (Savyon Diagnostic, Israel), a microarray assay, and compared it with the Innolipa kits (Innogenetics, Belgium) **Methods** From January to July 2012 we analyzed 392 blood samples with Innolipa and Nanochip technologies that identify respectively 70 and 56 CFTR mutations. Both tests include the most common Italian mutations and the poly-T screening. Discordant results were analyzed with the Devyser CFTR Core Kit (Devyser, AB, Sweden) based on PCR allele specific technology, MLPA (MRC Holland), Direct Sequencing (DS) on the 3730 DNA Analyzer (AppliedBiosystems), and Sequenom's MassArray system (Diatechpharmacogenetics, Italy) **Results** Innolipa and NanoChip were concordant for 371/392 samples although some samples were repeated several times on Nanochip because of no call and low signal results. 21/392 (0.5%) discordant results were tested with the aforementioned technologies: DS confirmed Innolipa results in 18/21 samples and Nanochip results in 1/21, while Devyser and Sequenom did not recognize some mutations not included in their panels. DS was essential for the identification of two different homozygous deletions; although they were not present in Innolipa panels, in 2/21 samples Innolipa indicated a mutation with the warning *no interpretation possible* **Conclusions** In this study the Innolipa assay confirmed its reliability and Nanochip showed that it could become competitive with slight changes to the software.

Next Generation ABO Genomics: the NHLBI Exome Sequencing Project (ESP). *K. Fox[1], I. Stanaway[1], M.B. Bamshad[1,2], P.L. Auer[3,4], A. Gordon[1], D. Crosslin[1], M. Fornage[5], D. Green[6], S. Rich[7], A.P. Reiner[3,8], D.A. Nickerson[1], J. Johnsen[9,10].* 1) University of Washington, School of Medicine, Department of Genome Sciences, Seattle, WA, USA; 2) University of Washington, School of Medicine, Department of Pediatrics, Seattle, WA, USA; 3) Fred Hutchinson Cancer Research Center, Public Health Sciences Division, Seattle, WA, USA; 4) University of Wisconsin-Milwaukee, Zilber School of Public Health, Milwaukee, WI, USA; 5) The University of Texas Health Science Center at Houston, Institute of Molecular Medicine, Research Center for Human Genetics, Houston, TX, USA; 6) Northwestern University, Feinberg School of Medicine, Chicago, IL, USA; 7) University of Virginia, School of Medicine, Center for Public Health Genomics, Charlottesville, VA, USA; 8) University of Washington, School of Public Health, Epidemiology, Seattle, WA, USA; 9) University of Washington, School of Medicine, Hematology Division, Seattle, WA, USA; 10) Puget Sound Blood Center, Research Institute, Seattle WA, USA.

Cardiovascular Disease (CVD) is the leading cause of death in the United States and worldwide. ABO blood type plays a significant role in determining risk for CVD. ABO phenotypes are the result of genetic variation in the coding portion of the ABO gene on 9q34.2. The influence of ABO subtypes (e.g., the A1 and A2 haplotypes) on CVD risk has yet to be fully explored. Previous studies have genotyped SNPs that tag ABO rather than defining the haplotype sequence necessary for subtype detection. We have developed an accurate ranking method to assign ABO haplotype using exome sequence data. This new method uses a matrix-based scoring approach to compare phased sequencing data to reference A, B, and O haplotypes from the Blood Gene Mutation Data Base (BGMUT). We applied our method to phased exome data from ~5,600 individuals of European and African ancestry derived from the ESP. We observed 100% concordance between predicted and actual phenotype in those ESP participants with serological phenotype data (n=80). We identified common variants known to influence function, including a common exon 6 indel that leads to the O genotype, and another common indel that results in the A2 subtype. We have also identified rare coding variants within ABO (single nucleotide/missense variants (n=18), insertion/deletions (n=4) and structural variation spanning multiple exons (n=1)) that segregate on known haplotype blocks. This method has the potential to improve the specificity of blood typing at both the clinical and research level and to reveal novel associations between CVD and previously unidentified rare ABO haplotypes.

2606W

Genome Analysis of iPS Cells for Regenerative Medicine. *A. Watanabe[1], N. Amano[1], M. Nakamura[1], A. Fukuhara[1], P. Unyanee[1], Y. Tokunaga[1,2], M. Yamaguchi[2], T. Aoi[1], K. Okita[1], K. Takahashi[1], S. Yamanaka[1].* 1) Center for iPS Cell Research and Application, Kyoto University, Kyoto, Japan; 2) Amelieff.

Pluripotent stem cells are now suggested as an artificial source of tissues, and consequently it is necessary to be able to guarantee their safety in the human body after transplantation. However, both embryonic stem (ES) cells and induced pluripotent stem (iPS) cells are produced after long-term culture, and thus harbor clone-to-clone variations in their DNA sequences and copy numbers as well as epigenetic profiles. It is therefore important to validate the quality of ES and iPS cells by genomic analyses. We aim to establish the standard method for evaluating iPS cells as a clinical-grade cell source by genome and epigenome analysis. We built the pipeline for both single-nucleotide variations (SNVs) and DNA copy number variations (CNVs), and performed exome and whole genome resequencing and compared between the original somatic cells and established iPS cells. We found not only clone-to-clone variations in iPS cell clones but also the heterogeneity in original somatic cells, indicating that comparison between original cells and established cells is essential for evaluating plulipotent stem cells. One of the iPS clones shows no non-synonymous mutations in exonic region. We also performed DNA methylation analysis by sequence-capture-based deep sequencing and identified novel DNA methylation sites specific for iPS cells. We introduce the strategy of genome and epigenome analysis for evaluating iPS cells for regenerative medicine using iPS cells.

Utility of targeted inherited disease panels for the diagnosis of rare congenital, potentially genetic syndromic disease. *A. Khromykh[1, 2], D. Thach[1, 2], M. George[1, 2], J. McCutcheon[1, 2], W. Wong[1, 2], R. Baveja[3, 4], R. Iyer[1, 2].* 1) Inova Translational Medicine Institute, Inova Health System, 3300 Gallows Road, Falls Church, VA 22042; 2) Inova Fairfax Hospital, Inova Health System, 3300 Gallows Road, Falls Church, VA 22042; 3) Inova Fairfax Children's Hospital, Inova Health System, 3300 Gallows Road, Falls Church, VA 22042; 4) Fairfax Neonatal Associates, 2730-B Prosperity Avenue, Fairfax, VA 22031.

Specific and accurate diagnostic tests are available for almost 3000 genetic disorders. Nevertheless, for many children with rare, potentially genetic syndromic disease, clear diagnosis remains elusive, and the diagnostic odyssey continues. Recently, next generation sequencing has been used to discover genes involved in rare Mendelian disease and for their diagnosis. However, there are significant barriers for equal and widespread accessibility to these tests, including high cost of testing and reimbursement issues, lack of clearly defined, validated, available algorithms to identify clinically relevant results and the need for multidisciplinary expertise to interpret the results. A short term and partial solution to some of these issues may be to implement a tiered testing modality. This includes 1st tier testing on commercially available, cheaper, targeted disease-gene panels which provide less complex and easier to interpret results using algorithms provided by the manufacturer or developed in-house. Though such testing will not identify new genes for Mendelian disease, it could help in the elucidation of new phenotypes associated with targeted genes present in the panel, reduction of further complex and expensive testing, and elimination of the diagnostic odyssey for some families. In this study, we are analyzing our expanding cohort (currently 40+) of families with a proband afflicted with severe multiple congenital malformations that are not consistent with any known clinical diagnosis using targeted gene panels. The probands are negative by currently available standard genetic testing including arrays (when indicated and performed); most of these have not been analyzed on clinically available next generation panels, and have no clearly relevant family history. Targeted sequencing of the coding exons of >800 mendelian disease genes associated with rare and ultra-rare neuromuscular, cardiovascular, developmental, metabolic and other inherited disease, is performed using the Ion Ampliseq and TruSight inherited disease panels (by Life Technologies and Illumina respectively). We expect that our study will provide useful information regarding the analytical and clinical sensitivity, specificity and utility of these panels that could provide support for the deployment of such tiered testing strategies in the clinical laboratory, using these and/or other enhanced targeted gene panels.

Towards a medical grade exome: Use of a gold standard to evaluate and enhance exome sequencing for diagnosis. *M. Pratt[1], G. Bartha[1], S. Luo[1], J. Harris[1], S. Garcia[1], G. Chandratillake[1], S. Chervitz[1], R. Chen[1,4], M. Clark[1], M. Snyder[1,2,3], J. West[1], R. Chen[1].* 1) Personalis Inc, Menlo Park, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Stanford Center for Genomics and Personalized Medicine, Stanford University, Stanford, CA; 4) Icahn School of Medicine, Mount Sinai, New York, NY.

Exome sequencing is increasingly utilized in clinical genetics practice to diagnose cases where other genetic testing has been unsuccessful or would be cost-inefficient. However, diagnostic yield estimates from clinical exome testing remain low (~25%). Furthermore, standards for exome sequencing have not converged with respect to content inclusion and minimum coverage requirements to achieve clinical sensitivity and specificity on that content. We have assembled a broad content set over which we assess and optimize exome performance to significantly improve coverage of medically interpretable content with the aim of increasing diagnostic yield. To assess absolute performance of exome sequencing approaches, we have developed internal gold standards based on genomic sequencing. As an accuracy standard, we use a reference comprising more than 3 Tb of next generation sequencing data over multiple technologies on a large pedigree to develop a thorough set of confirmed inherited variants comprising single nucleotide, indel, and structural variants. We also compute coverage standards across samples at nucleotide and exon resolution over whole genomes and exomes. Using these standards, we determined sensitivity and specificity over the interpretable exome at varying mean sequencing depths in order to develop coverage targets by region and content type to ensure analytic validity over the most interpretable regions. We further assessed performance on additional functional subsets, e.g. UTRs, intronic variants and regulatory regions. Through examining coverage and accuracy shortfalls over interpretable content, we developed additional pull-down targets and protocols to augment commercial exomes in regions of low (<20x) or absent coverage with the aim of creating a finished medical-grade exome. We also targeted regulatory regions and other non-exonic regions known to contain disease and pharmacogenetic-associated variation. This approach greatly increases the number of biomedically-relevant genes finished at our medical coverage target (>99% of bases at >20X) from 2700 to >3800. Such increased coverage enables sensitive and specific variant detection including at an additional 4854 loci having previously reported deleterious variants. Assessing accuracy on a larger set of biomedical variants including regulatory region variants and those associated with complex disease, we increase sensitivity from 58% to 90% while reducing the error rate.

Genetic Research and diagnostic using Fluidigm Integrated Fluidic Circuits (IFCs). *D. Bercovich[1], Y. Plostky[2], S. Allon-Shalev[3].* 1) Human Molecular Genetics & Pharmacogenetics, Migal- Tel Hai, Kiryat Shmona, Galile, Israel; 2) Galil Genetic Analysis - GGA lab, Kazarin, Israel; 3) The Institute for Genetics, Ha'Emek Medical Center, Afula 18101, Israel.

The flexibility of the BioMark Real-Time PCR System, allow us to preform genetic research using different types of nano-fluidic (48.48 or 96.96) chips setup, in the thermal cycle of these chips and image the data in real time for quantity determination of DNA copy numbers (CNV) or mRNA expression in multiple loci locations or genes, and can also to be used as an endpoint image reader for analyzing different allelic genotyping frequencies in a panel of 90 common mutations, in the Israeli populations, for 42 different mono genetic disorders revile there frequency of 15% in screening over 250 indeviduals general Israeli population , and 15-14 common mutations in Breast/ Ovarian and Colon cancers revile there frequency of 3-4% in the Israeli population. A panel of 47 novel Canis (dogs) SNPs was used, for the determination of a phylogenetic tree in 45 different Canis DNA samples. Digital-PCR gene chip were used to determine the number of a human gene which were incorporated in a plant cells for the production of this protein to treat human disease.

Whole Exome Sequencing is a sensitive cost-effective method of detecting mutations in Osteogenesis Imperfecta and Marfan syndrome.
A.M. McInerney-Leo[1], M. Marshall[1], B. Gardiner[1], P. Coucke[2], B. Loeys[2], J. West[3], M. West[3], B.P. Wordsworth[4], A. Zankl[5], P.J. Leo[1], M.A. Brown[1], E.L. Duncan[1]. 1) University of Queensland Diamantina Institute, Woolloongabba, Queensland, Australia; 2) Department of Medical Genetics, MRB, 1st floor Ghent University, Hospital De Pintelaan 185, B-9000 Ghent, Belgium; 3) School of Medicine, The University of Queensland Coordinator, Cardiovascular Genetic Clinic, The Prince Charles Hospital, Rode Road, Chermside QLD, Australia; 4) Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, Nuffield Orthopaedic Centre, Windmill Road, Headington, Oxford England; 5) Bone Dysplasia Research Group, UQ Centre for Clinical Research (UQCCR), The University of Queensland, Building 71/918, Level 3 Royal Brisbane and Women's Hospital, Herston, QLD Australia.

Osteogenesis imperfecta (OI) and Marfan syndrome (MFS) are amongst the commonest Mendelian disorders. Both are normally diagnosed clinically without genetic testing, as conventional sequencing is expensive due to the size and number of potentially causative genes and mutations. However, genetic testing benefits patients, at-risk family members and individuals with borderline phenotypes; improves genetic counselling; and allows critical differential diagnoses. We assessed whether whole exome sequencing (WES) is a sensitive method for mutation detection in OI and MFS. Methods: WES was performed on genomic DNA from 13 participants with OI and 10 participants with MFS, all of whom had known mutations, with massive parallel sequencing of multiplexed samples. SNPs and small indels were called using Genome Analysis Toolkit (GATK) and annotated using ANNOVAR. CREST, exomeCopy and ExomeDepth were used to detect larger deletions. Results were compared with the previous data. The target capture of the currently available exome capture platforms was also compared. Results: All 13 mutations in the OI cohort and 9/10 in the MFS cohort were detected (overall sensitivity = 95.6%) which included non-synonymous SNPs, small indels (<10bp), and a large UTR5/exon 1 deletion. One mutation was not detected by GATK due to strand bias. Capture platforms and analysis programs differed considerably in their ability to detect mutations. Costs for WES were lower than the available commercial sequencing services. Conclusion: WES is both sensitive and cost-effective for mutation detection in patients with OI and MFS. Careful selection of platform and analysis programs is necessary to maximise success.

Rapid and high mutation detection rate using ion torrent technology and inherited disease panel.
N. Al Tassan[1,2], A. Almostafa[1,2], D. Khalil[1,2], J. Shinwari[1,2], R. Kattan[1,2], A. Alissa[1,2], A. Tahir[1,2], M. Abouelhoda[1,2]. 1) Department of Genetics, King Faisal Specialist Hospital, Riyadh,11211, Saudi Arabia; 2) Saudi Genome Project, King Abdulaziz for Science and Technology, P.O Box 6086, Riyadh 11442, Saudi Arabia.

Ion Torrent semiconductor™ is a chip based sequencing technology (Life technologies, Guilford, CT) that performs sequencing-by-synthesis accompanied by electrochemical detection of base incorporation. In addition to Whole genome and exome sequencing, the technology is being applied in a heavily multiplexed PCR -based approach (Ampliseq) for targeted gene panels. The Ion Ampliseq™ Inherited Disease Panel (IDP) uses >10,000 primer pairs divided into 3 PCR pools to amplify the exons of 328 genes associated with approximately 700 inherited diseases. We applied Ion Torrent sequencing and this gene panel to study 100 samples having a Sanger sequencing validated mutation in one of the genes covered by the panel. 10ng of each sample was used to the Ampliseq PCR, the 3 PCR products were pooled and the library was purified, amplified and quantified. 20 pmoles of each library was used for emulsion PCR, followed by enrichment and sequencing on the medium scale 316 Chip for single samples and the high scale 318Chip for multiplexed samples. Specificity and sensitivity was 100% for all homozygous single point mutations. Several indels required manual review of to identify the mutation which was not identified using the current variant caller. Given consanguinity of the study population and consequent frequency of homoallelic mutations, we also examined exclusion of genes based upon presence of heteroallelic SNPs. Ion Torrent technology and sequencing of highly multiplexed panels offers an efficient screening/diagnostic option for inherited diseases commonplace in consanguineous populations.

High-throughput molecular genetic analysis in 92 patients with steroid resistant nephrotic syndrome applying Fluidigm Access Array™ technology.
E.A. Otto, V. Vega-Warner, M. Sampson. Dept Ped, 8220A, MSRB III, Univ Michigan, Ann Arbor, MI.

Background: Steroid resistant nephrotic syndrome (SRNS) is a genetically heterogeneous kidney disease characterized by heavy proteinuria, hypoalbuminemia, and edema. In most SRNS cases the kidney function declines over time, resulting in end-stage renal disease which necessitates renal replacement therapy. Mutations in more than 20 genes are implicated in the pathogenesis of SRNS rendering mutational analysis tedious and costly when applying conventional Sanger sequencing. Here, we screened for mutations in 21 established SRNS genes in 92 mostly pediatric patients recruited at the University of Michigan with SRNS. **Methods:** We implementing the PCR-based Fluidigm Access Array™ approach established previously in our lab [1]. We screened for mutations in all coding regions (424 exons) of 21 established monogenic SRNS genes (*NPHS1, NPHS2, PLCE1, COQ2, COQ6, LAMB2, WT1, PDSS2, CD2AP, SMARCAL1, PTPRO, CFH, CUBN, SCARB2, INF2, MYO1E, NEIL1, TRPC6, ACTN4, LMX1B,* and *ITGA3*) in a cohort of 92 mostly sporadic childhood cases with SRNS. We applied the Fluidigm Access Array™ nanofluidic technology followed by barcoding and next-generation sequencing on an Illumina HiSeq2000 platform. Bioinformatics analysis was performed using CLC Genomics Workbench™ software and significant variants were validated by Sanger sequencing. **Results:** We established the molecular diagnosis in 12 out of 92 patients (13%) and detected pathogenic mutations in the genes *NPHS1, NPHS2, WT1, PLCE1, LAMB2,* and *ACTN4*. Moreover, we discovered novel mutations in the genes *NPHS1* (p.Tyr638Cys, p.Gly601Ala), *WT1* (p.Thr225Met, p.Cys393Tyr), *PLCE1* (p.Ser1190Gly), *LAMB2* (p.Ile992Thr, p.Arg697Trp), and *ACTN4* (p.Arg65Gln). **Conclusion:** Fluidigm Access Array high-throughput mutation analysis allows screening of a large patient cohort for multiple genes in parallel at low cost and helps to find mutations in those genes which are rarely implicated in SRNS. Mutaome Profiling and Retrospective Mutaome Profiling Using Archived Bone Marrow or Peripheral Blood Smear in AML.
H. Liu[1], F. Wang[1], W. Teng[1], Y. Wang[1], X. Chen[2], Q. Yin[1], M. Wang[1], P. Zhu[2]. 1) Molecular Medicine Lab., Hebei Yanda Hospital, Sanhe, Hebei, China; 2) Department of Hematology, Peking University First Hospital, Beijing, China.

Background: Acute myeloid leukemia (AML) is a heterogeneous disease with respect to presentation and clinical outcome. In recent years, more and more somatic mutations and their clinical significance were identified in AML. Herein we recommend using the novel word "mutaome' for representing the repertoire of somatic gene mutations in a specific tumor tissue, and aimed to establish a panel of mutation profiling protocol for clinical use in AML. Methods and Cases: Mutation profiling protocol for CEBPA, DNMT3A, FLT3, IDH1, IDH2, KIT, NPM1, PHF6 and TET2 by PCR and Sanger sequencing was established, with the detection sensitivity about 15% to 20%. Bone Marrow (BM) or peripheral blood (PB) was collected form patients with newly diagnosed or relapsed. Archived BM or PB smear on glass slides at the time of newly diagnosed were used for retrospective mutation analysis. Results: 1) Totally 46 archived smear, 50 fresh BM or PB and 1 paraffin-embedded pathological specimen from 91 patients were analyzed. Age ranged from 1 to 77 years old, with the median age of 32 years old. 2) 68 samples carrying at least one mutation, 33 of them each carrying 2 or more mutations. The number of mutated sample for each gene is 18 for CEBPA, 6 DNMT3A, 25 FLT3, 5 IDH1, 6 IDH2, 2KIT, 15 NPM1 , 3 PHF6, and 14 TET2. 3) Both archived smear and relapsed samples were analyzed for 5 cases, 2 of them showing a difference. One patient carrying FLT3 H811Q, FLT3 D839G, IDH1 A51D and CEBPA A295T in archived BM smear, but only carrying FLT3 D839G in relapsed BM and swelling testicular biopsy specimens, another patient carrying FLT3 G822W, TET2 P208H and TET2 R447S in archived BM smear, but only carrying FLT3 G822W in relapsed BM sample. Conclusions: Panel testing for mutations is effective method for detection of AML molecular markers. Archived BM or PB smear can be used for retrospective mutation analysis.

2614F

Mutaome Profiling and Retrospective Mutaome Profiling Using Archived Bone Marrow or Peripheral Blood Smear in B-ALL. *F. Wang[1], H. Liu[1], W. Teng[1], Y. Wang[1], X. Chen[2], L. Guo[1], M. Wang[1], Q. Yin[1], H. Yang[1], P. Zhu[2].* 1) Molecular Medicine Lab., Hebei Yanda Hospital, Sanhe, Hebei, China; 2) Department of Hematology, Peking Univerity First Hospital, Beijing, China.

Background: B-cell acute lymphoblastic leukemia (B-ALL) is a heterogeneous disease with respect to presentation and clinical outcome. In recent years, more and more somatic mutations and their clinical significance were identified in B-ALL, including point mutations and large genomic sequencing deletion mutations. Herein we recommend using the novel word "mutaome" for representing the repertoire of somatic gene mutations in a specific tumor tissue, and aimed to establish a panel of mutation profiling protocol for clinical use in B-ALL. Cases and Methods: Bone Marrow (BM) or peripheral blood (PB) was collected form patients with newly diagnosed or relapsed. Archived BM or PB smear on glass slides at the time of newly diagnosed were used for retrospective mutation analysis. Mutation profiling protocol for JAK1, JAK2 (Exon16, 20), PAX5, PHF6 and TP53 by PCR and Sanger sequencing was established, with the detection sensitivity about 15% to 20%;. IKZF1 exon deletion, PAX5 exon deletion and MLL partial tandem duplication (MLL-PTD) were detected by RT-PCR, electrophoresis and sequencing of the aberrant bands, which didn't applied to archived smear specimens. Results: 1) Totally 24 archived smear, 29 fresh BM or PB samples from 53 patients were analyzed. Age ranged from 2 to 81 years old, with the median age of 14 years old. 2) Totally 15 out of 29 fresh BM or PB samples carrying one or more mutations. The number of mutated cases for each gene is 5 for TP53, 3 PHF6, 1 FLT3, 3 PAX5 exon deletions and 4 IK6 exon deletions. Totally 6 out of 24 archived smear specimens carrying one or more mutation, 2 with TP53 mutations, 3 with PAX5 point mutations, 1 with FLT3 and 1 with PHF6 mutations. Conclusions: Panel testing for mutations is effective method for detection of B-ALL molecular markers. Archived BM or PB smear samples can be used for retrospective mutation analysis.

2615W

Molecular characterization of children with severe autism spectrum disorders. *A.C. Tsai.* OHSU, Oregon, OR.

From April 2012 to May 1013, 10 pts with severe autism spectrum disorder ascertained in the autism and general genetic clinic in the CDRC/DCH were characterized by CMA and molecular panels. the clincial features of the pateitns in his cohort fall in the Angelman/Rett syndrome-like phenotype: patient either present with severe seizure at birth, severe hypotonic, being non-verbal after 7 years of age, some with history of sleep apnea, unique hand mannerism, ataxia, fascination about the water or inappropriate laughter. Method: All patients receive Rett/Angelman-like panel followed by microarray if negative. The panel includes CDKL5 , SLC9A6, TCF4 and FOXG1, UBE3A and MECP2. When the results of the above tests are normal, additional testing based on clinical finding were added including FLNA, RAI1 and seizure panels, as well as SNP plus 400K CMA. Results: 7 Patient were found to have remarkable findings which include c.409T>C heterozygousmutation of UBE3A, MECP2 (Zappella variant), duplication of MECP2, FOXG1 1-bp deletion, PQBP1 1-bp insertion, and 2 with 1p36 deletion, sized from 2.0-2.4 Mb and a 13Kb deletion of 14q13.2 with iatrogenic deletion of the RALGAPA1 (aka TULIP1; aka GARNL1) Discussion: the significance of c.409T>C heterozygous mutation of UBE3A is still unknown ; this girl is non-verbal but has significant signing, the rest of the testing were normal MOC carries this mutation but cannot determine the parental origin as maternal grandfather is not available for testing. The TULIP1 deletion is inherited from the father who has autistic features but clinically is less involved than the proband. This child also received a seizure panel which were negative. The child with PQBP1 mutation was originally thought to have angelman syndrome but detected by the seiszure panel which include the AS/Rett panel. the diagnosis was subsequently changed. Conclusion:This small study highlight the clinical utility of panel assay which is perfect to characterize conditions with a spectrum of presentation in a gene and overlapping phenotype among the genes on the pathway. This study also demonstrate the importance of proper pre-testing genetic counseling, as the test result might detect unexpected genetic syndromes.

2616T

Establishment of a next-generation sequencing protocol for genetic testing of tuberous sclerosis complex. *P. Chen[1,2,3,4].* 1) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 2) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 3) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan.

Tuberous sclerosis complex (TSC) is a characteristic disease drawing high clinical and research attention. It is an autosomal dominant disorder characterized by tumors in different body organs, including brain, kidney, liver, skin, lung, heart and eye. TSC is caused by dysfunction of the critical biological pathways related to mammalian target of rapamycin (mTOR). About 400 different causative variants have been identified in the two known genes (*TSC1* at chromosome 9q34 and *TSC2* at chromosome 16p13). However, routine genetic testing for TSC patients using traditional Sanger sequencing method is too expensive and labor intensive because there are a total of 64 exons of these 2 genes. We decided to apply the NGS technology for the cost-effective diagnosis of TSC. We have focused on the whole genomic regions containing all exons, all introns and 10 Kb upstream and 10 Kb downstream of the *TSC1* (hg19, chr9:135761735-135830020, 68285 bp) and *TSC2* (hg19, chr16:2087990-2143712, 55722 bp) genes. A Roche NimbleGen customized capture library was designed for enrichment of the targeted sequences. A reasonably good coverage (97% of the intended regions; and 100% of the exons) can be achieved. The enriched libraries were then pair-end sequenced on the Illumina HiSeq2000 Genome Analyzer. The whole bioinformatics analysis was processed in a computer cluster with more than 50 nodes at the High Performance Computing (HPC) center at National Taiwan University. We used BWA for initial read mapping, GATK pipeline for realignment and SNP/indel calling. Aggressive filtering was applied to further reduce false positive results. Biological significance of the genetic variants was then predicted using bioinformatics tools, mostly SIFT and PolyPhen2. The integrative genomics viewer (IGV) was used for visualization of the results. Among the 61 TSC patients we tested, 50 (82%) of them could be assigned causative variants. We demonstrated that our method could detect not only simple variants (such as single nucleotide substitution and small indels) but also difficult genetic variants (such as a big deletion of ~15 Kb size, and mosaicism). This serves as a single stop for TSC genotyping and waive the necessity of both Sanger sequencing and multiplex ligation-dependent probe amplification (MLPA). We consider this new protocol a cost-effective diagnostic test for TSC, and may be applied to other diseases in the future.

Magnitude of effect of reported common allele risk from clinical genome sequencing and conventional decision factors in therapeutic equipoise: initial comparison in The MedSeq Project. *C.A. MacRae[1, 2], S. Kong[3, 8], J. Krier[4, 5], I. Leshchiner[1, 5, 7], I.H. Lee[3, 8], H.M. Maclaughlin[4, 7], W.J. Lane[4, 5], D. Metterville[7], A.L. Hernandez[7], BH. Funke[4, 7, 8], M. Lebo[4, 5, 7], P. Kraft[9], I.S. Kohane[3, 6], R.C. Green[1, 2], H. Rehm[4, 7] for the MedSeq Project.* 1) Medicine, Brigham and Women's Hospital, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, Massachusetts, USA; 3) Department of Pediatrics, Harvard Medical School, Boston, Massachusetts, USA; 4) Department of Pathology, Harvard Medical School, Boston, Massachusetts, USA; 5) Department of Pathology, Brigham and Women's Hospital, Boston, MA, USA; 6) Department of Pediatrics, Childrens Hospital Boston, Boston, Massachusetts, USA; 7) Laboratory for Molecular Medicine, Partners Center for Personalized Genetic Medicine, Cambridge, Massachusetts, USA; 8) Department of Pathology, Massachusetts General Hospital, Boston, Massachusetts, USA; 9) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA.

Genome wide association studies have defined the common risk alleles for numerous human traits, but to date these findings have not impacted clinical practice. The MedSeq Project is a randomized clinical trial that aims to develop standards and procedures for the evaluation and reporting of genome sequencing data and will directly assess the impact of integrating genome sequencing into clinical medicine. MedSeq participants in the sequencing arm of the study will receive both a General Genome Report and a Cardiac Risk Report (CRR), the latter featuring a summary of variants in a targeted panel of 102 monogenic cardiac disease-associated genes, a polygenic predicted fasting lipid profile, and common allele risk information for eight core cardiovascular phenotypes. To define a rational basis for including common alleles in the CRR, we estimated the effect sizes for rigorously validated common risk alleles across all published loci for all phenotypes directly or indirectly related to cardiovascular disease and compared these with the estimated effect sizes of non-genetic risk factors commonly used in clinical decision-making, but which have no randomized clinical trial support. For the eight phenotypes in the current CRR, (abdominal aortic aneurysm, atrial fibrillation, coronary heart disease, type 2 diabetes, hypertension, obesity, platelet aggregation and QT prolongation) the genetic risk, even from a limited number of small effect loci, was comparable in magnitude to that of non-genetic factors used in routine therapeutic decision making in situations of equipoise. We will present a summary of the quantitative approach taken in the evaluation of traits for inclusion in the CRR, discuss the role of small effect-size risk in clinical decision making and describe the evaluation of the effects of CRR disclosure on additional testing and equipoise in both primary care and cardiology clinics within the MedSeq study. Our experience highlights important parallels between the utilization of traditional non-genetic evidence in clinical practice and the practical implementation of complex trait risk results from clinical genome sequencing.

2618W

Translating results of the Australian and New Zealand Registry of Advanced Glaucoma (ANZRAG) into clinical practice. *E. Souzeau[1], K.P. Burdon[1], B. Ridge[1], A. Dubowsky[2], J.E. Craig[1].* 1) Dept of Ophthalmology, Flinders University, Flinders Medical Centre, Adelaide, SA, Australia; 2) SA Pathology, Flinders Medical Centre, Adelaide, SA, Australia.

Purpose: Glaucoma is the leading cause of irreversible blindness worldwide, and is a complex disorder with genetics playing a crucial role. Adequate monitoring and interventions at the early stages can prevent glaucoma blindness. Genetic testing is a promising strategy to identify at risk individuals and reduce the impact of glaucoma blindness through prevention. The Australian and New Zealand Registry of Advanced Glaucoma (ANZRAG) has established a biobank of severe glaucoma cases to identify novel genetic risk factors for the worst glaucoma outcomes, and to establish genetic testing protocols for known glaucoma genes. Methods: Advanced Open-Angle Glaucoma (OAG) cases defined by central visual field loss or severe peripheral vision loss were recruited. Secondary glaucoma cases were also recruited regardless of severity. Cases with advanced glaucoma and Primary Congenital Glaucoma (PCG) were tested in an accredited pathology laboratory by direct DNA sequencing for known glaucoma genes, *Myocilin* and *CYP1B1* respectively, and results were provided back to the participants with the provision of genetic counseling. Cascade genetic testing was made available for relatives of participants with pathogenic mutations in these genes when clinically relevant. Results: 1570 participants with severe OAG and 960 with other glaucoma subtypes have been recruited. Using genome-wide association studies, new glaucoma risk alleles were identified: *TMCO1* in advanced primary OAG cases, and *CDKN2B-AS1* associated with normal-tension glaucoma. *Myocilin* mutations were identified in 4.2% of advanced primary OAG individuals, compared with 1.6% in non-advanced primary OAG. These mutations were found in individuals with younger age at diagnosis and high-tension glaucoma. *CYP1B1* mutations were found in 18% of PCG cases. Cascade genetic testing has identified highly penetrant *Myocilin* mutations in 35 as yet asymptomatic individuals. The experience of tested asymptomatic individuals has been evaluated to help health professionals in providing better support to patients. Outcome: The ANZRAG provides a comprehensive approach to reducing glaucoma blindness by unraveling the genetic complexity of glaucoma, providing accredited genetic testing and genetic counseling, and translating research findings in better clinical care.

2619T

ClinVar: Improving Access to Clinically Relevant Variants for the Research and Clinical Genomics Communities. *M.J. Landrum, J. Lee, G. Riley, R. Tully, S. Chitipiralla, M. Halavi, D. Hoffman, J.B. Holmes, W. Jang, K. Katz, M. Ovetsky, A. Sethi, R. Villamarin, D.M. Church, W.S. Rubinstein, D.R. Maglott.* National Center for Biotechnology Information, NLM, NIH, Bethesda, MD.

Advances in technology for genomic testing, particularly whole exome and genome sequencing, are identifying thousands of new variants. However, determining the clinical relevance of variants can be challenging, especially for rare variants. To increase the access to such data, ClinVar (http://www.ncbi.nlm.nih.gov/clinvar/) maintains a freely available, public repository for the relationships between variants and phenotypes along with supporting evidence. The database can be used interactively or incorporated into variant analysis pipelines. The public release of the database in April 2013 largely included curated data from OMIM and GeneReviews, as well as submissions from some LSDBs, testing labs, and ClinSeq. Within the first two months, submitters also included additional testing labs, research groups, and expert panels and professional societies. Each ClinVar record includes a variant and an assertion of clinical significance for the variant in the context of an observed phenotype, with a review status indicating the level of support. Submitters retain ownership of submitted data, and each record is assigned an accession and version number to allow updates by the submitter as the variant interpretation is refined over time. For submitters who maintain their own website for variants, such as LSDBs, ClinVar links to the submitter's site for each submitted variant, allowing users who start at ClinVar an awareness of the LSDB's curated variants and access to more information on the variant that may be available at the LSDB. ClinVar supports standardization of terms, such as those for variant nomenclature, phenotypes, and pathogenicity, to lessen data ambiguity and aid comparison of information from multiple sources. ClinVar also provides related variant data, such as HGVS expressions mapped across molecule types and allele frequencies. As part of the submission process, ClinVar provides feedback to submitters. This feedback includes HGVS expressions that are invalid and whether a submission has a conflict in clinical significance with an existing record for the same variant and phenotype, alerting submitters to records that may warrant further curation. When multiple submitters provide an assertion for the same variant/phenotype pair, ClinVar collects the data into an aggregate record, allowing clinical labs to more easily identify high-confidence variant associations and to organize curation efforts around variants with conflicting interpretations.

2620F

Molecular diagnostic approach for limb-girdle muscular dystrophy using both multi-gene panel sequencing and Sanger sequencing. *H. Park[1], S. Lee[1], S.H. Seo[1], S. Park[2], S.I. Cho[1], M.W. Seong[1], S.S. Park[1].* 1) Department of Laboratory Medicine, College of Medicine, Seoul National University Hospital, Seoul, Korea; 2) Department of Laboratory Medicine, College of Medicine, Konkuk University Medical center, Seoul, Korea.

Introduction: Limb-girdle muscular dystrophy is genetically heterogeneous disease, with clinical involvement typically limited to skeletal muscle. Because more than 20 genes identified, it is not easy to find the causative mutations by conventional PCR and direct sequencing for individual patient. Here we present a molecular diagnostic strategy combing multi-gene panel sequencing and Sanger sequencing. Methods: Seventeen patients who were suspected of limb-girdle muscular dystrophy were screened for sixteen genes using TruSeq Custom Enrichment Kit (Illumina) and MiSeq (Illumina). All previously reported mutations and probable pathogenic variants including novel nonsynonymous ones were confirmed by Sanger sequencing. Also all low-coverage regions with coverage depth under 10X were resequenced by Sanger sequencing. Results: Among 17 patients, five ones were molecularly confirmed as limb-girdle muscular dystrophy. Two patients had a *LMNA* gene mutation (c.1357C>T and c.1366A>C), which was inherited autosomal dominant manner. Another two patients had compound heterozygous mutations in *DYSF* gene (c.[2248C>T(;)5668-7G>A] and c.[2494C>T(;)4200delC]) and the other one patient had two mutations in *CAPN3* gene (c.[439C>T(;)1076C>T]) which were inherited autosomal recessive manner. Conclusion: Our multi-gene panel detected pathogenic mutation(s) in five limb-girdle muscular dystrophy patients. Multi-gene panel sequencing using next generation sequencing technology can be a cost efficient and fast method for diagnosis of genetically heterogeneous disease like limb-girdle muscular dystrophy.

Coding mutations and variations in the 3'UTR of *CYP21A2* gene in heterozygous females associate with hyperandrogenism. *V. Neocleous[1], C. Shammas[1], AAP. Phedonos[1], M. Picolos[2], TC. Kyriakides[3], M. Toumba[4], N. Skordis[5], LA. Phylactou[1].* 1) Molecular Genetics, Function & Therapy, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) Alithias Endocrinology Center, Nicosia, Cyprus; 3) Department of Epidemiology & Public Health, Yale University, USA; 4) Iasis Hospital, Paphos, Cyprus; 5) Paediatric Endocrine Unit, Makarios III Hospital, Nicosia, Cyprus.

Congenital adrenal hyperplasia (CAH) is a common autosomal recessive disorder primarily caused by mutations in the *CYP21A2* gene. Heterozygosity for *CYP21A2* mutations in females increases their risk of clinically manifesting hyperandrogenism. The present study was designed to seek evidence on the association between the mutations in the *CYP21A2* gene and the biochemical/clinical findings on heterozygous children, adolescents and women with hyperandrogenemia. Moreover, the implication of variants in the 3'UTR region of the *CYP21A2* gene was investigated. The hormonal response to ACTH was evaluated in heterozygous females with clinical signs of hyperandrogenism along with direct DNA sequencing and MLPA analysis for mutations in the *CYP21A2* gene. The suspicion of heterozygote state was based on the median plasma 17-OHP before and 60 minutes after ACTH stimulation. The most frequent mutations among the 66 carriers were the mild p.V281L (53.0%), followed by p.Q318stop (18.2%), p.P482S (10.6%), p.V304M (6.1%), p.P453S (6.1%), p.A391T (1.5%), large deletion/conversion exons 1-4 (1.5%), large deletion/conversion exons 6-8 and 8bpdelE3 (1.5%). Higher values of stimulated 17-OHP levels were found in the carriers of the p.V281L mutation, compared with carriers of other mutations (mean = 22.1 nmol/L vs 15.9 nmol/L). The haplotype of the *52 C>T, *440 C>T, *443 T>C in the 3'UTR was found *in cis* in all heterozygous females with p.V281L. In a similar fashion the haplotype *12 C>T, *52 C>T was found *in cis* in all heterozygous females with the p.Q318stop. Conclusions: Females with heterozygous *CYP21A2* mutations may develop hyperandrogenism. Therefore, systematic evaluation of 17-OHP values in combination with the molecular testing of *CYP21A2* gene may be beneficial. Finally, the identification of variants in the 3'UTR of the *CYP21A2* gene in combination with the heterozygous mutation may be associated with the mild form of the disease and reveal the importance of analyzing the *CYP21A2* untranslated regions to better characterize and treat this category of patients.

2622T

Detection of deleted D4Z4 locus in turkish patients with facioscapulohumeral muscular dystrophy. *S. Berker Karauzum[1], OB. Sahan[1], H. Uysal[2].* 1) Med Biol& Gen, Akdeniz University Faculty Med, Antalya, Turkey; 2) Dept. of Neurology Akdeniz University Faculty Med, Antalya, Turkey.

Facioscapulohumeral Muscular Dystrophy(FSHD) which is characterized by progressive weakness of muscles in the face, schoulder girdle and upper arms is the third must common muscular disease. FSHD is caused by deletions of the D4Z4 repeats in the 4q35 region. In this autosomal dominantly inherited disease, more than 95% patents have only 1-10 repeats instead of 11-100 repeats observed in healthy controls. In this study, 24 individuals (11 male, 13 female) from 6 unrelated Turkish families with FSHD were handled after the preclinical diagnosis by the Akdeniz university medical faculty, department of neurology. Three healthy individuals were studied as a control group. In order to show the deletion of D4Z4 tandem repeats at the q35 locus on chromosome 4, Southern blot method was performed. While D4Z4 repeats of control group was found to be in the normal range(more than 11 repeats), 20 FSHD patients' repeat numbers were observed to be the under the normal range(less than 11 repeats) as concordant to clinical findings. Our results show that, Southern blot was observed as a suitable method for determining the D4Z4 repeat deletions on chromosome 4 and also, because of in all the affected cases displayed D4Z4 repeat deletions, this analysis could be performed in patients with myopathies similiar to FSHD, especially for prenatal diagnosis and genetic councelling.

2623F

Investigating the carrier screening potential of the MPL c.79+2T>A transversion, a known cause of congenital amegakaryocytic thrombocytopenia for individuals of AJ descent. *S.R. Birkeland, J. Sugalski, C. Holland, J. Stoerker, J. Buis.* Progenity, Ann Arbor, MI.

Mutations in the thrombopoietin receptor c-MPL cause a rare inherited disease known as congenital amegakaryocytic thrombocytopenia (CAMT). This disease presents as severe thrombocytopenia at birth, reduced megakaryocytes and progression to bone marrow failure. The only known effective treatment for this is a bone marrow transplant, which presents significant risk. Recently, a founder mutation in the c-MPL gene known as the c.79+2T>A transversion has been shown in the Ashkenazi Jewish population. Carrier screening for other disease alleles within this community has met with great success, reducing the numbers of new disease-affected individuals across a number of syndromes. Here, we present data from a blinded and random screening of individuals of AJ descent and compare this with a cohort of non-AJ individuals. In concordance with the previously studies, we find a significant carrier rate for the c.79+2T>A mutation amongst the AJ population. Our preliminary findings indicate that out of the first 358 tested, 6 are carriers for c.79+2T>A which have been confirmed via Sanger sequencing. We will plan on screening a total cohort of ~1000 individuals. The ability to screen for the c.79+2T>A mutation has been included in our validated AJPNxt carrier screen. Our data presented here along with previous studies and the severity of CAMT supports the value of including testing for this mutation in future AJ population screening.

2624W

Screening of gene mutation in hyperphenylalaninemia using Ion Torrent sequencing. *Y. Cao, F. Song, Y. Qu, J. Bai, Y. Jin, H. Wang.* Department of Medical Genetics, Capital Institute of Pediatrics, Beijing, China.

Hyperphenylalaninemia (HPA) is a very common autosomal recessive genetic disease. It has been verified that the metabolic pathway of phenylalanine involves five pathogenic genes: PAH, GCH1, PTPS, QDPR, and PCBD1. Rapid and accurate genetic diagnosis is very crucial for a clear diagnosis of disease types, choosing the right treatments in a timely manner, and for genetic counseling and prenatal diagnosis. To evaluate the feasibility of gene screening in children with HPA using Ion Torrent Personal Genome Machine (PGM), the CDS and UTR regions of PAH, GCH1, PTPS, QDPR, and PCBD1 in 3 patients with HPA and one healthy control were amplified using Ion AmpliseqTM PCR and then sequenced by PGM. Meanwhile, a set of mutant sample mixture representing common mutations in patients with HPA in China was used as a positive control to determine the accuracy of the PGM. All of known mutation sites were correctly identified in the positive control. In addition, we detected 22 variations in the patients and the healthy control. Compared with database and verified by the Sanger sequencing method, it was confirmed that 6 were pathogenic mutations, 18 were polymorphisms and 4 were false-positive calls. Based on our study, the PGM sequencing might be suitable for screening gene mutation in HPA via metabolic pathways, which could meet the medical need for individualized diagnosis and treatment. However, mutations suspected for false-positive calls should be discriminated by other method.

2625T

Comparison of Seven Commercial DNA Extraction Kits for the Isolation of Listeria monocytogenes DNA from Whole Blood Samples. *M. El-Mogy[1], M.AK Abdalla[2], L. Graziano[3], T.A Haj-Ahmad[4], Y. Haj-Ahmad[4,5].* 1) Molecular Biology Department, National Research Center, Dokki, Cairo, Egypt; 2) Department of Biochemistry, Faculty of Science, Alexandria University, Egypt; 3) Department of Biomedical Sciences, University of Guelph, Guelph, Ontario, Canada; 4) Brock University, 500 Glenridge Avenue, St Catharines, ON, L2S 3A1; 5) Norgen Biotek Corp., 3430 Schmon Parkway, Thorold, Ontario, Canada, L2V 4Y6.

Listeriosis is an important public health concern in North America; it is mainly transferred by food contaminated with the bacterium Listeria monocytogenes. The majority of susceptible individuals are pregnant women, newborns, older adults and those who are immunocompromised, with a mortality rate of about 30% among infected individuals. In this study we compared the recovery as well as the limit of detection of L. monocytogenes DNA from whole blood using seven commercial blood DNA isolation kits (QiaAmp DNA Blood Mini Kit, Norgen Genomic DNA Isolation Mini Kit, MoBio UltraClean DNA BloodSpin Kit, Macherey-Nagel NucleoSpin Blood Kit, Gentra Puregene Blood Kit, Norgen Non-enzymatic DNA Blood Kit and Norgen Enzymatic DNA Blood Kit). Human whole blood samples were spiked with known copy numbers of L. monocytogenes. Total genomic DNA was isolated and compared both qualitatively and quantitatively among the various kits; the concentration as well as OD260/280 and OD260/230 were measured spectrophotometerically. The isolated DNA was used in a real-time PCR reaction using specific primers. We determined the limit of detection for every kit as well as the linearity of pathogen recovery at different concentrations. Also we investigated the presence or absence of contamination and ease of handling of the used methods. Our results show that the column-based methods have higher consistency than alcohol precipitation methods with higher yield and purity from procedures utilizing proteinase K.

2626F

A comprehensive low-cost diagnostic test for hundreds of inherited conditions. *J. Garcia, J. Sorenson, M. Sommargren, J. Westbrook, E. Hare, Y. Kobayashi, M. Anderson, J. Major, R. Hart, K. Jacobs, E. Oliveras, J. Hagenkord, S. Lincoln, M. Cargill, R. Scott.* InVitae, San Francisco, CA.

Historically, diagnostic tests using DNA sequencing have only been offered for a limited set of genes to patients with specific clinical indications. The high cost of de facto standard assays (Sanger sequencing, MLPA, etc.), and more importantly, the high cost and challenges in clinical data interpretation have been cited among the reasons for this. Thus, many genetic diseases and clinically important genetic conditions often go undiagnosed. We have developed an in-house infrastructure for NGS-based diagnostic assay development, validation, and operation in a CLIA environment. To date, we have conducted a thorough scientific review of the literature for over 500 genes and their associated conditions, storing validated gene sequences, transcripts, risk models, and over 32,000 clinically characterized variants in a database used both to optimize assay design and to help interpret results. We have a hybrid calling and data QC pipeline employing GATK, Freebayes, and custom algorithms for different variant classes. Preliminary reports for known and novel SNVs, indels, and CNVs are automatically generated for review, and a team of medical specialists then classifies variants according to ACMG guidelines given the patient's indication and signs-out finalized clinical reports. To date, validation has been performed on over 200 clinical, Get-RM and HapMap samples. 100% of clinical SNV and indel genotypes reported agreed with the results of established, traditional diagnostic assays on those samples. Importantly, pathogenicity assessments in the clinical reports agreed as well. In collaboration with other labs and patient advocates, we have launched an effort to expand the publicly available set of unpublished clinical variants that we believe will be critical in diagnostic settings. Most importantly, we believe these processes are highly scalable, allowing the assay to grow to report on the vast majority of genetic conditions with high accuracy. For the HapMap samples specifically we performed a comparison against a combination of 1000 Genomes Project and Complete Genomics data. For all 2172 coding sequence SNVs in the 211 genes assayed in the HapMap samples, 99.7% sensitivity and greater than 99.99% specificity was demonstrated. For all 66 coding indels, 98.3% sensitivity and greater than 99.99% specificity was demonstrated.

2627W

A Case in Point: When is Extended Genotyping of AAT (SERPINA1) Indicated? *S. Kwong[1, 2], J. Stoller[2], F. Mularo[2], F. Lacbawan[2].* 1) Case Western Reserve University School of Medicine, Cleveland, OH; 2) Cleveland Clinic, Cleveland, OH.

Alpha-1 antitrypsin deficiency (AATD) (OMIM #613490) affects 1 in 2,000 to 1 in 5,000 individuals, but is clinically under-recognized. AATD is associated with mutations of SERPINA1 (or alpha-1 antitrypsin), a serine protein-ase inhibitor that functions as a major inhibitor of neutrophil elastase. AATD typically manifests with liver disease and/or early-onset emphysema. Patients who present with early-onset or unexplained (without typical risk factors) emphysema, unexplained liver disease, or more rare symptoms such as necrotizing panniculitis or vasculitis have alpha 1-antitrypsin serum levels measured. Abnormally low levels are followed up with S/Z genotyping or phenotyping with thin-layer isoelectrofocusing (IEF), the gold standard, to look for aberrant SERPINA1 alleles. The most well-understood and most common alleles are M (wild-type); S and Z (dysfunctional mutant alleles). However, the Q0 (or null alleles), which have nonsense or frameshift mutations leading to absent or truncated mRNA transcripts or proteins that are incompletely characterized. Null alleles are typically not detected with conventional gold-standard methods and may require direct DNA sequencing. Even then, the function of only a few null alleles has been well described, thus making predictions about their phenotypic manifestations difficult. The current report presents a case of an asymptomatic 48-year old female patient who had only chronically elevated AST and was found to have an AAT enzyme level of 54 mg/dL (normal range: 100-220 mg/dL). DNA sequencing showed heterozygous M1V (c.710 T>C) and S (c.863 A>T) alleles with heterozygous Q0_cairo (c.847A>T). Extended genotyping by subcloning demonstrates a trans relationship between the alleles. This explains how the compound heterozygote state produces the unexpected phenotype. To our knowledge, the Q0_cairo and S combination has never been described to date. Neither allele has been associated with liver manifestations, only with lung manifestations. This case demonstrates that direct DNA sequencing and extended genotyping are necessary to help uncover rare alleles associated with AATD and to offer accurate genetic counseling information to the proband and family members. This newly described allelic combination extends the approximately 120 alleles described to date and permits better phenotypic characterization of individuals with unusual variants of AATD.

The NIH Genetic Testing Registry: 2013 status report on genetic testing. *W.S. Rubinstein[1], B.L. Kattman[1], A.J. Malheiro[1], J.M. Lee[1], D.R. Maglott[1], V. Hem[1], M. Ovetsky[1], G. Song[1], C. Wallin[1], K.S. Katz[1], R. Villamarin-Salomon[1], C. Fomous[2], J.M. Ostell[1].* 1) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD; 2) Office of Biotechnology Activities, National Institutes of Health.

The NIH Genetic Testing Registry (GTR; http://www.ncbi.nlm.nih.gov/gtr/) is a free, centralized, international registry of comprehensive genetic test information covering clinical and research tests for Mendelian disorders and drug responses. As of early June 2013, submitters in 37 countries have voluntarily provided detailed information on over 6400 registered tests for over 2700 conditions and 5600 genes. Active submitter participation coupled with GTR's rich data structure enables many questions to be answered about the current status of genetic testing. Methods: Extensive stakeholder input and consultation with advisory boards determined concepts to be represented and ongoing feedback is elicited to enhance utility of GTR. All registered tests provide details about methodology, tested conditions, and targets (genes and variants, chromosomal or mitochondrial regions, proteins or analytes). Clinical tests have fields for purpose, test performance characteristics, target population, ordering information, AMA molecular pathology CPT codes, proficiency testing, and regulatory information. Research tests provide a study description, eligibility criteria, consent form, and enrollment information. GTR staff augment content with practice guidelines, position statements and recommendations from expert sources and the website integrates information from authoritative sources. Results: As of June 2013, a total of 352 laboratories have registered 6465 tests employing molecular (N=6146; 95%), cytogenetic (N=154; 2.4%) and biochemical (N=287; 4.4%) methods (combinations included). Next-generation sequencing is a component of 6.0% of molecular tests. Eighteen registered labs offer whole genome or whole exome sequencing services. All clinical tests have analytical validity statements. Submitted data include statements with supporting citations [in brackets] about clinical validity (for 686 tests [281]), target population (for 1005 tests [305]) and clinical utility (632 total statements [329]). Among tests registered by US labs, 0.2% report FDA status cleared/approved. A total of 158 practice guidelines, position statements and recommendations pertaining to 289 conditions have been assembled by GTR staff. These results will be updated at the time of presentation. Conclusions: GTR enables informed selection of tests by clinicians, provides a snapshot of genetic testing, and helps identify knowledge gaps of interest to professional societies and regulatory agencies.

2629F

Diagnostic exome sequencing beneficial among patients with a prior diagnosis. *L.M. Shahmirzadi, K.D Gonzalez, S. Tang, E. Chao, S. Gandomi, B. Trippin, S. Nahas, W. Zeng.* Ambry Genetics, Aliso Viejo, CA.

Clinical diagnostic exome sequencing (DES) provides data on all the coding exons of the genome and is currently indicated when prior tests have been negative, when the phenotype fits with the clinical spectrum of multiple genes, and/or when the phenotype is not consistent with any known clinical picture. DES has not only identified pathogenic alterations in genes not previously associated with the disease, but it has also revealed broader phenotypes not previously considered as part of the clinical spectrum within genes with well-established disease-associations. Even in cases where the patient has been provided with a clinical diagnosis or appropriate differential diagnosis, DES may still be pursued to identify the underlying molecular etiology when a single gene test was not available or when DES is more cost- and time-effective than the sequential gene-by-gene approach. A retrospective analysis of the first 200 reported patients undergoing DES at one laboratory revealed that prior to testing, 10% had a clinical diagnosis. Among the 20 clinical diagnoses made prior to DES testing, 3 (15%) were associated with 1-3 genes, while multiple genes could be implicated in the rest (85%). DES provided a definitive molecular diagnosis (including characterized and novel genes) in 53% of patients with a prior clinical diagnosis. The detection rate was lower (33%) in cases those with only 1-3 genes associated with the diagnosis, than those with multiple suspected genes (75%), thought to be attributed to the low overall clinical detection rate of the suspected gene(s). Gene coverage was greater than 95% for all of the cases associated with 1-3 genes. These results highlight the clinical utility of DES, even among patients with a prior diagnosis, as it may reveal the underlying molecular etiology of the disease of interest when multiple genes may be involved.

2630W

A retrospective analysis of discrepancies between genotypes and phenotypes on next generation sequencing colon cancer panels (ColoNext NGS): Implications for clinical diagnosis. *S. Tandy, A. Stuenkel, T. Pesaran, H. LaDuca, E. Chen, S. Keiles, V. Speare, C. Radford, W. Zeng.* Ambry Genetics, 15 Argonaut, Aliso Viejo , CA 92656.

The launch of Ambry's cancer NGS panels in early 2012 has led to unexpected genotype-phenotype discrepancies among patient results. We reviewed 38 ColoNext NGS cancer panels that had mutations detected in genes associated with cancer syndromes with established clinical criteria. Of those, a significant percentage of patients with pathogenic mutations did not meet the correlating clinical criteria based on their personal and family history: 50% (3/6) with biallelic MUTYH mutations, 50% (2/4) with SMAD4 mutations, 50% (1/2) with PTEN mutations, 14% (1/7) with APC mutations, 40% (2/5) with MSH6 mutations, 28.5% (2/7) with MSH2 mutations, and 57% (4/7) with PMS2 mutations. Here we discuss specifics in twelve of these cases. Biallelic MUTYH gene mutations were detected in three unrelated individuals with early onset colon cancer and less than 20 adenomatous colon polyps. A SMAD4 mutation was detected in a proband with gastric cancer at age 35 who was later found to have 20-99 colon/GI polyps of varying pathology types, none of which were juvenile, by age 50. Another SMAD4 mutation was found in a proband diagnosed with colon cancer at age 30 with normal tumor MSI and IHC testing. A PTEN mutation was identified in a 65 year old individual with over 100 adenomatous colon polyps and no family history of cancer. An individual with 2-5 adenomatous polyps and colon cancer at age 39 was found to carry an APC mutation. A 16 year old with colon cancer and a reported heavy polyp load was found to carry two MSH6 mutations. A 36 year old unaffected individual with a MSH2 mutation was tested due to a paternal family history of sarcoma, endometrial, and late onset colon cancers. An intronic MSH2 mutation was found in a patient with endometrial cancer at age 48 but whose family history was not suggestive of Lynch Syndrome. A single exon PMS2 deletion was found in a proband with 2-5 colon polyps, colon cancer at age 49, and normal MSI and IHC tumor testing. A proband meeting Cowden syndrome clinical criteria was found to carry a PMS2 mutation. Since these results reveal that genotype-phenotype discrepancies clearly exist among individuals carrying mutations in well-known cancer syndrome genes, we propose continued evaluation of the clinical features associated with each condition. We encourage the continued reporting of additional cases with uncharacteristic correlations in order to further expand upon the clinical criteria utilized in current diagnostic processes.

2631T

Pre-publication sharing of exome/genome variant and phenotype data to resolve rare disease. *J. Den Dunnen, I.F.A.C. Fokkema, M. Vermaat, J.F.J. Laros, M. Kriek, P.E.M. Taschner, G.W.E. Santen.* Center for Human and Clinical Genetics, Leiden University Medical Center, Netherlands.

We have built a system facilitating sharing of unpublished data from whole exome (WES) and whole genome sequencing (WGS) studies. The system should help to speed up gene discovery by assisting researchers to find the critical 'second case'. The main hurdle in current studies using WES/WGS is to find sufficient evidence to prove causality. Roughly studies give a yield of 1/3 proven causality, 1/3 likely causality and 1/3 unresolved cases. An obvious way to improve overall yield would be reaching out to colleagues world-wide to find additional positive or negative evidence for the candidate variants remaining. An important obstacle here is, for several reasons, the desire and demand to publish in peer-reviewed journals which works against pre-publication data sharing. The approach is built around the gene variant databases (LSDBs) using version 3 of the LOVD platform (Leiden Open-source Variation Database, http://www.LOVD.nl) to collect and share information about genes, variants and phenotypes (diseases) and facilitate the analysis of exome and genome sequence data. Within the databases curated by us we have implemented a so-called **VIP-status** for both variants and phenotypes demanding specific attention. People can submit both phenotype descriptions and/or gene variants with the request to assign these a **VIP status**. **VIP-phenotypes** are those for which WES/WGS studies were performed but for which insufficient evidence was gathered to prove causality with variants in a specific gene. **VIP-variants** are those remaining after stringent filtering that could not be linked to nor excluded as causative in WES/WGS. The submitter decides whether the submission is named or anonymous. Others studying **VIP-phenotypes** or identifying **VIP-variants** are invited to contact the submitter to collaborate. For anonymous submissions the LOVD-curator will act as an intermediate to bring researchers into contact. We believe this option is effective regarding sharing data while at the same time protecting peoples' interest to ultimately publish their findings.

The Human Variome Project has granted LOVD the recommended system status for variant collection.

2632F

Multiplex mutation panel for molecular diagnostics of increased nuchal translucency with normal karyotype. *P. Tavares[1], J. Sá[2], A. Lopes[2], L. Lameiras[2], L. Dias[2], A. Palmeiro[2], P. Rendeiro[2].* 1) CEO/Clinical Dir, CGC Genetics, Porto, Porto, Portugal; 2) CGC Genetics, Porto, Portugal.

Introduction: Increased fetal nuchal translucency (NT) is usually associated with chromosomal abnormalities, therefore, cytogenetics in amniotic fluid or CVS are offered. In the absence of chromosomal abnormalities, increased NT is associated with fetal malformations, dysplasias, deformations and genetic syndromes resulting in poor perinatal outcome. The most prevalent genetic abnormality associated with increased NT and normal karyotype is Noonan Syndrome. The molecular characterization of genes involved in Noonan syndrome is extremely important for establishing a precise diagnostic evaluation, specifically during the prenatal period. Method (max 200 words) We developed a multiplex mutation panel that allows the molecular identification of Noonan Syndrome as well as the major diseases in the same metabolic pathway - Costello, Cardiofaciocutaneous and LEOPARD Syndrome. This panel test for 80 point mutations on genes PTPN11, RAF1, SOS1, KRAS, HRAS, BRAF, MAP2K1 and MAP2K2. Results: Between 2009-2012 we analyzed 53 prenatal cases with increased nuchal translucency and normal karyotype using the described multiplex mutation panel. Two cases were positive for mutations on PTPN11 gene, establishing the molecular diagnosis of Noonan Syndrome. Results were obtained, in average 10 days, between 11-16 weeks gestation, allowing early detection of an affected fetus. Conclusions: In the presence of ultrasonographic findings such as cystic hygroma, increased nuchal translucency or hydrops fetalis, Noonan syndrome may be suspected. This new molecular diagnostics panel can be applied in prenatal diagnosis, especially in situations with increased nuchal translucency and normal karyotype, allowing an early molecular diagnostics (before week 14) and thus reducing the couple's anxiety and allowing a faster decision process. A broader clinical spectrum and a 10 days diagnosis window are achieved, at a small fraction of the cost of the traditional approach.

2633W

Clinical Interpretation Accuracy of CytoScan® Dx Assay.

J. Tepperberg[1], S. Schwartz[1], A. Roter[2], C. Du[2], R. Duttagupta[2], G. Mamtora[2], J. Danzer[2], J. Wallace[2], S. Close[3], K. Kwiatkowski[2], E. Fung[2], R. Pfundt[4]. 1) Dept Cytogenetics, Lab Corp America, Res Triangle Pk, NC; 2) Clinical Applications, Affymetrix, Santa Clara, CA; 3) GenEngine, Carlsbad, CA; 4) Radboud University Medical Centre, Nijmegen, Netherlands.

Background: Identification of pathogenic copy number variants (CNVs) by cytogenetic microarrays has demonstrated a higher diagnostic yield as compared to conventional methods, such as karyotyping and FISH and are recommended by the American College of Medical Genetics for use as first tier tests in the assessment of patients exhibiting developmental delay, intellectual disability, and congenital anomalies/dysmorphisms. This study's objective was to characterize the clinical interpretation accuracy of CytoScan® Dx assay compared to samples which were assessed for developmental delay and/or intellectual disability using routine patient care (RPC) methods (excluding any Affymetrix array) in post-natal samples. The study also assessed the average number and size of copy number variation (CNV) regions uncovered in patients with a clinical laboratory diagnosis, which included a syndrome, as well as in phenotypically normal individuals. Materials & Methods: The clinical performance of the assay was evaluated in 153 samples across a broad range of syndromes, of which 149 were included in the analysis, and in 110 presumed phenotypically normal samples. The samples were run on CytoScan Dx assay and the results were sent to a cytogeneticist, not involved in the original analysis for interpretation. The results were compared to the original clinical laboratory diagnosis that accompanied the patient's sample. Results: CytoScan Dx assay identified 15.4 ± 11.5 copy number variation regions per syndromic sample and 10.4 ± 3.40 CNVs per phenotypically normal sample. Diagnostic accuracy in pathogenic samples using the clinical interpretation based upon routine patient care as reference was measured as Positive Percent Agreement (PPA). The Positive Percent Agreement was 145/149 = 97.32% (95%CI 93.30-98.95%). Conclusions: This study demonstrated the ability of the CytoScan Dx assay to achieve high clinical accuracy, as measured by PPA at 97.32% as compared to routine patient care methods.

2634T

Clinical application for gene disorders in children using bench top sequencer.

T. Naruto[1,2], Y. Kuroda[1], I. Ohashi[1], K. Kurosawa[1,2]. 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Japan Science and Technology Agency, CREST.

Objectives: Next-generation sequencing (NGS) has transformed genomic research by decreasing the cost of sequencing and increasing the throughput which overcome the limitations of Sanger sequencing methods used to sequence the disease causing genes. Routine clinical use of NGS technologies is appealing, but there are a number of the genes for analysis. We have performed mutation analysis of single gene disorders using the long range PCR based method, and multi gene disorders using the target enrichment method. Methods: The PCR products were purified using a QIAquick column. Libraries were created using the Nextera DNA Sample Prep kit (Illumina) or HaloPlex Custom Kits (Agilent Technologies), then sequenced on a MiSeq. The alignments were performed and compared the Miseq Reporter, SureCall and BWA + GATK based pipeline. Detected mutations were confirmed by Sangar sequence. HGMD, ANNOVAR and SnpEff were used for annotating variants. Results: We identified the novel and new mutation in gene disorders. (1) Single gene disorders analysis can be identified pathogenic mosaic mutations present at low allele frequencies. The mean coverage is over 1,000 of MLL2, TCOF1 and NIPBL multiplex sequencing. (2) Multi gene disorders analysis can be identified CNVs. Sequencing data were scanned for gains and losses using a comparison of normalized coverage data between samples. The 5× and 20 × coverage were 98.4% and 95.6% in 29genes (target size was 140,417 bp) Conclusion: Our method detected mutations, mosaics and CNV, and had a low false-positive rate. In this study, we showed that these gene multiplexing sequence and multi-targeted sequence will be invaluable in small-scale experiments can be done even for small scale individual projects with bench top sequencer.

Cancer Risk Assessment Using Genetic Panel Testing: Considerations for Clinical Application.

S. Hiraki[1], E. Rinella[2], F. Schnabel[2], R. Oratz[2], H. Ostrer[1]. 1) Albert Einstein College of Medicine, Bronx, NY; 2) NYU Langone Medical Center, New York, NY.

Background: With the completion of the Human Genome Project and the development of high throughput technologies, such as next-generation sequencing, the use of multiplex genetic testing is growing rapidly. The development of genetic cancer panels to assess multiple cancer risks represents one way in which multiplex testing is being applied clinically. There are a number of unique issues to consider when conducting genetic panel testing for cancer risk assessment that differ from the traditional single-gene approach. **Methods:** To address an emerging need for multiplex sequencing panels, we set out to design a cancer panel comprised of genes that confer high or moderately increased risks for breast, ovarian, and colon cancers. Through this process we addressed the following issues: determination of genes to include in the panel, determination of risk estimates and how to convey them to the patient, review of surveillance and management guidelines for increased risk, the genetic counseling process, and return of results. Literature review, cancer gene databases, and existing cancer gene panels were used to inform the development of this panel. **Results:** Our cancer gene panel consists of 26 genes that confer high or moderate risks for breast, ovarian, and colon cancers, with some genes conferring risks for additional cancers. Many of the genes share molecular pathways such as the FANC-BRCA, CHEK2, and MMR pathways. Risks were generally found to cluster at 2 levels: Moderate risk genes, such as those in the FANC-BRCA and CHEK2 pathways for breast cancer, confer a 2-4 fold increased risk while high risk genes, such as CDH1 and PTEN, confer a 10-20 fold increased risk. Established management guidelines for those with increased risk based on family history and clinical factors can be applied to those with comparable risk levels conferred by moderate penetrance genes. **Conclusions:** Cancer panel testing enhances the benefits of genetic risk assessment by 1) extending testing to a wider population beyond those who meet standard genetic testing criteria and 2) broadening the number of gene targets to assess risk, providing a more comprehensive risk assessment. By examining and integrating the data and tools currently available, we can maximize the clinical utility of panel testing and identify the gaps in our knowledge that warrant further investigation.

Sex determination using free fetal DNA at early gestational ages: A comparison between a modified mini-STR genotyping method and Real-Time PCR.

HReza. Goodarzi[1], MReza. Aghanouri[2], Yasaman. Yazdani[3], G. Mohammadzadeh Shahriary[4], Salman. Abbas Zadeh[5], Saman. Yazdani[6]. 1) Department of Medical Genetics, Shiraz University of Medical Sciences, Shiraz, Iran, MD Ph.D; 2) Department of Medical Genetics, Shiraz University of Medical Sciences, Shiraz, Iran, M.Sc; 3) Department of Medical Genetics, Shiraz University of Medical Sciences, Shiraz, Iran; 4) Department of Genetics, Chamran University, Ahvaz, Iran; 5) Cancer Research Institute, Medical University of Vienna, Vienna, Austria; 6) Department of Laboratory Medicine, Lund University, Sweden.

Introduction: Free fetal DNA in maternal blood can be utilized for noninvasive prenatal genetic screenings. In this study, a new algorithmic base Conventional Polymerase Chain Reaction (PCR) genotyping method and also Real-Time (RT) PCR technique for detecting fetal X and Y chromosome sequences in maternal plasma was applied to determine fetal sex in pregnant women in early gestational period (5-13 weeks). Finally the efficiency of the methods in sex determination was compared to verify which method can be more applicable in clinical settings. Materials and methods: DNA was extracted from 106 pregnant women and their husband's blood samples. Fetus mini-Short Tandem Repeats (STR) genotyping was accomplished through amplification of 19 mini-STRs and three non-STR markers using conventional PCR followed by Poly Acrylamide Gel Electrophoresis (PAGE) analysis. Simultaneously, RT-PCR was carried out by using DYS14 specific primers and probe. Results: In conventional PCR method, 47 cases were diagnosed as male and 49 as female. In comparison, RT-PCR amplified DYS14 (Y-marker) sequences in 45 pregnant women plasma samples. Sensitivity and specificity were calculated as 95.9% and 98% for conventional PCR and 91.8% and 100% for RT-PCR respectively. Conclusion: Conventional PCR technique has revealed a higher level of sensitivity rather than RT-PCR technique and could be employed in future clinical diagnosis singly or in combination with RT-PCR. Prospectively, our future studies will be focused on designing and optimizing an algorithm-based RT-PCR method to avoid any non-accurate results and also on advanced methods for extracting and separating high yields of cell-free fetal DNA (cffDNA) from maternal plasma. Keywords: Sex determination, Free-fetal DNA, Maternal plasma, Mini-STR genotyping, Real-Time PCR, DYS14.

Exome sequence of genetic disorders in consanguineal family. *G. Atzmon[1], D. Ben Avraham[1], B. Pode-Shakked[2], Y. Anikster[2].* 1) Departments of Medicine and Genetics, Albert Einstein College of medicine, Bronx, NY, USA; 2) Metabolic Disease Unit, Edmond and Lily Safra Children's Hospital, Sheba Medical Center, Tel Hashomer, Israel.

Consanguinity, is common in certain minority populations in Israel, naturally encompasses a greater risk for autosomal recessive disorders. In order to reveal the molecular mechanism and polygenic predisposition of two cases (same family) with autosomal recessive disorders (Osteogenesis imperfecta and Congenital Disorders of Glycosylation (CDG)), we employed an unbiased screening approach by using Exome sequence capture arrays followed by next generation sequencing (HiSeq2000). We Exome sequenced (due to the polygenic anomaly of the investigated diseases) of 6 members of the family, the 2 cases kids their parents and one sibling of each of the parent, as the primary diagnosis of both disorders is of great significance for future family planning. Of the 154,432 sequence variants (available from the 6 samples) 28,487 variants passed the various QC filtering stages with 15 reads/variant. Of which 316 and 216 sequence variants, displayed heterozygosity in the unaffected samples and homozygosity in the effected ones (Osteogenesis imperfect and CDG, respectively). While, forty missense mutation in the Osteogenesis imperfect case demonstrated the homozygosity pattern of inheritance, were the OR4 (olfactory receptor, family 4) gene's subtype exhibit the highest number of variants, among the CDG case 24 were of missense mutation with substantial prevalence of the FANCA gene (which encoded Fanconi anemia). In conclusion, Exome sequencing was demonstrated herein as a powerful tool for Molecular diagnosis of specific mutations and is therefore extremely necessary in such cases. Primary care physicians should be alert to the possibility of more than one autosomal recessive disorder in consanguineous families and evaluate them promptly with the use of such tool.

2638F

Whole exome sequencing for cancer - is there evidence of clinical utility? *A. Malhotra, L. Cushman-Spock, L. Wieselquist, S. Levine, D. Allingham-Hawkins.* Hayes, Inc., Lansdale, PA.

Objective: To assess the evidence behind the use of whole exome sequencing (WES) to identify genetic changes in cancer. **Context:** Next-generation sequencing technologies are advancing at a rapid rate, allowing the generation of a large amount of data in a relatively short period of time. Genetic changes in cancer are increasingly used for diagnosis and may guide treatment decisions. There are often more than 1, and sometimes many, different genes contributing to the clinical presentation of the disease. Given that the exome encompasses < 2% of the genome, variants affecting the cancer being studied may potentially be missed by WES; however, WES allows detection of 85% of disease-causing variants, thereby providing a less expensive method to detect variants when compared to whole genome sequencing. Nevertheless, the question remains: is there evidence that WES impacts patient outcomes in cancer? **Methods:** Proprietary methodology that combines the ACCE (Analytical validity; Clinical validity; Clinical utility; Ethical, legal and social implications) model for genetic test evaluations with internationally accepted health technology assessment methodology was used. Conclusions were based on peer-reviewed published studies of > 10 patients. **Results:** While WES has been conducted in > 10 patients for a number of different cancers (e.g., colon, prostate, and ovarian cancer), breast cancer has been evaluated most extensively (7 studies to date). Studies evaluating somatic alterations showed high intratumor and intertumor heterogeneity. In addition, both novel and previously implicated variants were identified, with varying frequencies based on the breast cancer subtype (e.g., luminal A or B, basal-like, or HER2-enriched). To date, only 2 studies with > 10 individuals (with breast cancer or ovarian cancer) have shown potential for clinical utility of WES, whereby variants identified through WES may determine response to drug treatment. **Conclusions:** Despite evidence for clinical *validity* of WES in cancers, clinical *utility* is very limited and needs to be further evaluated in large clinical studies. In addition, WES results may have ethical implications (e.g., incidental findings); while recent recommendations suggest that such findings must be provided to physicians/ patients, the appropriate way to communicate this information is not completely clear.

2639W

Recognition of Disease-Associated Alleles in the Reference Sequence is Critical for Accurate Disease-Risk Assessment through Genome Sequencing. *G. Chandratillake[1], S. Garcia[1], R. Chen[1, 2], M. Clark[1], S. Chervitz[1], D. Newburger[1], H. Lam[1], J. West[1], R. Chen[1].* 1) Personalis, Inc., Menlo Park, CA; 2) Icahn School of Medicine, Mount Sinai, New York, NY.

The public reference genome sequence (GRCh37) contains minor alleles at >1 million positions. The presence of minor alleles in the reference negatively impacts both sequence read alignment and variant calling. For example, an individual who is homozygous for a minor allele present in the reference will not be reported as variant at that locus, resulting in failure to apply any medical interpretation relevant to that variant to the individual. On the other hand, individuals heterozygous or homozygous for major alleles absent in the reference are reported as variant at such loci, resulting in an increased burden of variant interpretation. To address the issue of rare alleles in the reference, we extended previous work (PMID 21935354) to create an enhanced human reference sequence. We revised 1.1 million positions in GRCh37 where the reference allele is the minor allele by frequency in four different populations. To assess the impact of this enhanced reference on disease-risk assessment, we interrogated GRCh37 for the presence of medically relevant minor alleles, identifying rare/minor alleles associated with Mendelian disease, pharmacogenetics, and complex disease. We found 38 variants in GRCh37 previously reported to be involved in Mendelian disease (HGMD designation DM/DM?) e.g. rs4784677 in *BBS2* associated with Bardet-Biedl Syndrome and rs1529927 in *SLC12A3* associated with Gitelman Syndrome and hypertension. An additional 217 variants designated disease-associated polymorphisms with functional evidence (DFP) were identified, e.g. the Factor V Leiden allele, rs6025. Furthermore, we identified 4 novel presumed-deleterious alleles (nonsense, frameshift, splice-site) in HGMD genes e.g. rs276936 in *DSC3* and rs9959632 in *PIGN*. Whilst it is unlikely that all of these variants are pathogenic, they warrant in-depth review. Such variants would be completely missed in homozygous individuals and likely filtered out due to population frequency in heterozygous individuals due to recognition of the major allele as variant. In addition, we identified 77 variants with pharmacogenetic associations listed in PharmGKB, e.g. rs1954787 involved in citalopram response, and 985 variants associated with complex disease in our extensive manually curated Disease Variant Database. The use of our enhanced human reference sequence facilitates more complete variant discovery~critical for accurate disease-, carrier- and pharmacogenetic-risk assessment through exome/ genome sequencing.

Autism associated with an Xq12 deletion involving the gene OPHN1 - importance of pursuing a genetic etiology for an Autism Spectrum Disorder (ASD). *E. Elias*. Dept Genetics & Pediatrics, Children's Hosp Colorado, Aurora, CO.

Introduction: ASD's are prevalent, occurring at a rate of 1:88 children per recent CDC report. Many children with an ASD never undergo genetic evaluation. However,current technology allows the determination of a more definitive underlying genetic diagnosis for children with an ASD, especially if accompanied by intellectual disability (ID).

Case Report: A 9 year old boy presented for genetic evaluation of an ASD, and severe ID. Past medical history was notable for strabismus requiring surgical repair and a seizure disorder requiring medication. His exam revealed mildly dysmorphic features, including down-slanting palpebral fissures and a prominent chin. Head MRI was notable for inferior cerebellar hypoplasia, a Dandy-Walker variant and mild ventriculomegaly. Previous genetic testing included normal karyotype and negative Fragile X testing. Family history was notable for a normal brother, and healthy parents.

Genetic Testing: A 191 kb region of loss involving chromosome Xq12 was detected on a Cytochip 180K Oligo microarray panel, which partially overlapped the OPHN1 gene. Similar patients have been reported with either deletions of Xq12, or molecular mutations of the OPHN1 gene. Oligophrenin-1 (OPHN1) encodes a Rho-GTPase-activating protein, the first Rho-linked protein identified in patients with X-linked ID. Rho-GTPase proteins are critical for normal neuronal development and function, particularly regarding dendritic growth and genes affecting glutamate receptors.

Conclusions: This patient had a constellation of problems including strabismus, seizures, and cerebellar anomalies, markedly similar to other patients who have been reported with this rare chromosome deletion syndrome affecting the OPHN1 gene, and is further confirmation of the importance of this gene in CNS morphogenesis. Updated genetic evaluations can be revealing for patients with ASD, especially for those presenting with ID, dysmorphic features, and anomalies. Establishing a definite genetic diagnosis also allows appropriate genetic counseling for this X-linked ID disorder.

2641T

CELL MALIGNITATION ASSOCIATED TO CHROMOSOME TRANSLOCATIONS. CLINICAL MANIFESTATIONS IN TWO PEDIATRIC PATIENTS 46,XY,t(1;4)(q11q11) AND 46,XY,t(6;9)(p21;q34). *J. Aparicio[1, 3], M.L. Hurtado H[2], S. Chatelain M[4].* 1) Dept Gen; 2) Cytogenetics, Hosp para el Nino Poblano, Puebla; 3) Estomatology, benemerita Universidad Autonoma de Puebla; 4) Biotechnology, Universidad Autónoma Metropolitana Mexico DF.

Chromosome aberrations are considered alterations in the chromosome number or structure. They are mainly considered due to gametogenesis inborn error or during the zygote first cellular divisions. Among 4617 chromosomal studies performed during 19 years (from 1992 to 2011), at Hospital Para El Niño Poblano in México, 34.6% (1596 patients) had chromosomal alterations. Among these studies population, 0.23% (11) chromosome translocations were observed. From this data, two male pediatric patients are described, with 1;4 and 6;9 chromosome translocations. Chromosome changes are classified as structural or numeric alterations respectively, and abnormal cell development has been associated with these two specific chromosomal translocations. Both cases were described in this study analyzing their hematological, clinical features, medical treatments and prognosis.

2642F

A Balanced Chromosome Translocation Reveals Involvement of a Predicted Lipase in Weight Gain, Hearing Loss and Tumor Suppression. *B.B. Currall[1,2], K.E. Wong[1], N.G. Robertson[1], T. Hoyos[3,2], A.E. Hickox[4], Y. Yin[5,2], B.J. Quade[1,2], M.C. Liberman[5,2], E.C. Liao[3,2], C.C. Morton[1,2].* 1) Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Purdue University, West Lafayette, IN; 5) Massachusetts Eye and Ear Infirmary, Boston, MA.

The Developmental Genome Anatomy Project (DGAP; www.dgap.harvard.edu) systematically examines subjects with balanced chromosomal rearrangements to identify genes involved in congenital disorders. DGAP056 is an archetypal case with a constellation of symptoms including profound congenital hearing loss, early onset prostate cancer, mild craniofacial abnormalities (coloboma, exotropia, blepharophimosis, and low-set posteriorly rotated ears), mitral valve prolapse and hypospadias. Genomic analyses of DGAP056, using karyotyping, fluorescence *in situ* hybridization (FISH) and genomic sequencing, revealed a balanced translocation involving chromosomes 2 and 13, t(2;13)(p24.1;q22.3)dn, which disrupts a poorly annotated gene designated *C2orf43*. Linkage and genome-wide studies have associated SNPs in and around *C2orf43* with prostate cancer, coronary heart disease and other phenotypes associated with lipid deregulation. Phylogeny and tertiary structure modeling indicate that *C2orf43* encodes a conserved protein related to the alpha/beta hydrolase clan of proteins and likely functions as a serine-based ester hydrolase involved in lipid metabolism. In animal models, *C2orf43* orthologs are expressed in a variety of tissues including adipose tissues, inner ear and prostate. Mouse knockout models have increased weight, high frequency hearing loss and increased rates of tumors (particularly in the prostate). *C2orf43* expression is also down-regulated in human prostate tumors. While it is yet unclear the biochemical role of *C2orf43*, this gene appears to be necessary for proper lipid metabolism and, when disrupted, leads to a variety of diseases including obesity, hearing loss and prostate cancer. DGAP056 demonstrates the power of the DGAP approach using *de novo* genetic lesions, well characterized phenotypes and convergent data to annotate clinically important regions of the genome.

2643W

Genitourinary Defects Associated with Genomic Deletions in 2p15 Involving OTX1. *C. Jorgez[1,2], J. Rosenfeld[6], N. Wilken[2], V. Vangapandu[2], A. Sahin[2], D. Pham[2], C. Carvalho[4], A. Bandholz[6], A. Miller[7], D. Weaver[7], B. Burton[8], D. Babu[9], J. Bamforth[9], T. Wilks[10], D. Flynn[11], E. Roeder[12], S. Cheung[4], J. Lupski[4,5], D. Lamb[1,2,3].* 1) Center for Reproductive Medicine, Baylor College of Medicine, Houston, TX; 2) Scott Department of Urology, Baylor College of Medicine, Houston, TX; 3) Department of Molecular and Cell Biology, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA; 7) Department of Medical and Molecular Genetics Indiana University School of Medicine, Indianapolis, IN; 8) Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL; 9) University of Alberta, Edmonton, Alberta, Canada; 10) Madigan Army Medical Center Department of Pediatrics, Tacoma, WA; 11) Department of Children's Endocrinology, St. Luke's Children's Specialty Center, Boise, ID; 12) Department of Pediatrics University of Texas Health Science Center at San Antonio, San Antonio, TX.

Normal development of the genitourinary (GU) tract is a highly complex process that frequently goes awry, causing malformations of GU structures. In male children the most frequent congenital anomalies are GU defects such as cryptorchidism (1% to 4% of full term newborns), hypospadias (1%), micropenis (0.35%) and vesicoureteral reflux (VUR) (1%). Other congenital urologic malformations, such as bladder-exstrophy-epispadias (BEE) (1:47000), occur less frequently but significantly impact patients' lives. Array comparative genomic hybridization (aCGH) identified seven individuals with deletions in the 2p15 region (66.0kb-5.6Mb). These deletions encompass the transcription factor orthodenticle-homolog-1 (OTX1) gene. Subject 1 (with BEE and VUR) had the smallest deletion (66kb), encompassing only OTX1, and was identified among 30 BEE patients screened by aCGH. Male subjects 2-5 were identified among 30,183 subjects submitted to Signature Genomics for clinical aCGH testing, and male subjects 6 and 7 were identified among 18,734 subjects analyzed at Baylor Genetic Laboratories for clinical aCGH testing. Subjects 2-7 had large de novo CNVs (2.39-6.31 Mb) and exhibited features similar to the 2p15p16.1 and 2p15p14 microdeletion syndromes including developmental delay, short stature, facial abnormalities, and variable GU defects. Breakpoint analysis indicated that the deletion in subject 1 was at chr2: 63,130,672-63,196,654, and thus it only included the gene OTX1. Our subjects with GU defects included four with testicular, three with penile, two with kidney, one with bladder, and one with VUR abnormalities. Otx1-/- null mice suffer from seizures and have prepubescent transient growth retardation and gonadal defects. Similarly, two of our subjects have short stature, two suffer from seizures, and five have gonadal defects. The presence of GU defects in six of our cohort and in eight patients of the thirteen reported with deletions within 2p14p16.1 (including two with deletion of OTX1) suggests that this region encodes genes important for GU development. Thus, impairment of OTX1 function or expression may lead to GU abnormalities that range from the commonly observed cryptorchidism to the rarely observed BEE.

2644T

6q24.3-q25.1 deletion syndrome. *Y. Nishi[1], M. Tominaga[1], H. Ueda[2], Y. Kuroda[1], I. Ohashi[1], T. Saito[3], J. Nagai[3], K. Kurosawa[1,4].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Department of Cardiology, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Clinical Labolatory, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Japan Science and Technology Agency, CREST.

6q24-q25 deletion syndrome is a rare and newly recognized syndrome characterized by congenital heart defects, growth retardation, and variable degree of intellectual disability. The phenotype varies with the range of deletion and the genes involved. Nowaczyk et al. (2008) reported three patients with paternal deletion of 6q24.4. Two of the patients shared a 2.5 Mb region of overlap and similar facial features including a triangular face, frontal bossing, short and up-slanting palpebral fissures, asymmetry of upper eyelids, shallow orbits, and long and flat philtrum. The cardiac defects include the anomaly in the outflow tract and atrioventricular defect. Thienpont et al. [2010] demonstrated that the cardiac defect of the syndrome was caused by haploinsufficiency of TAB2 gene harbored on 6q25.1. Here we present an additional case of 13-year-old girl with the 6q24.3-q25.1 deletion. She was born to nonconsanguineous healthy parents at 40 weeks of gestational age after uneventful pregnancy. Her birth weight was 2780 g. Recurrent episodes of pneumonia were noted during the infantile period. Her developmental mile stone was delayed; head control at 4 months, walking alone at 1 year and 6 months, speaking comprehensive words at 2 years and 6 months. At age of 6 years, G-banded chromosome analysis was performed due to her mild developmental delay, but the result was normal karyotype. Her intelligence quotient was 51-75 at age of 12 years. She had short stature due to the deficiency of growth hormone and the GH therapy was started at her age of 7 years. Since the age of 8 years, she had precocious puberty and treated with GnRH antagonist. At age of 12 years, atrial premature contraction and severe mitral regurgitation was noted. Because of uncontrollable attacks of arrhythmia, she had catheter ablation therapy repeatedly. To elucidate the cause of these clinical episodes, cytogenetic microarray was performed. The results showed interstitial deletion of 4.2 Mb from 6q24.3-q25.1. The present patient shared several features including the facial appearance, the degree of intellectual disability, growth phenotype, and characteristic cardiac defect. Together with these results and previous reports, the deletion of 6q24.3-q25.1 represents distinctive microdeletion syndrome caused by haploinsufficiency of the genes in the interval. Further analysis is required to elucidate the phenotype-genotype correlation in the syndrome.

2645F

An infant with 49,XXXXY syndrome and congenital cataract. *C. Vinkler[1], A. Ben Sasson[2], A. Singer[3].* 1) Inst Med Genetics, Wolfson Med Ctr, Holon, Israel; 2) Child Developmental Center, Maccabi Health Service; 3) Inst Med.-Genetics Barzilai Medical Center , Ashkelon, Israel.

49,XXXXY syndrome is one of the rarest sex chromosome abnormality in humans, showing an incidence of 1: 85,000 to 1: 100,000. It is described to be the most severe variant of Klinefelter syndrome however it is categorized as a separate syndrome by many authors. Clinical features of the syndrome are: coarse face, microcephaly, distinct dysmorphic features, short stature and an IQ ranging between 20 to 60 points. Recently, increased rates of brain anomalies were also described in this group of patients. We present a patient with 49,XXXXY syndrome and congenital cataract. The proband is a 2y and 3m old boy referred to our clinic because of severe hypotonia, developmenatal delay and dysmorphic features. This male patient was born at term to healthy parents. There is no description of cataracts in the family. Pregnancy and delivery were normal with a birth weight of 2.7 kg. Right after birth hypotonia and dysmorphic features were noticed. Cardiac echo revealed small PFO and PDA Eye examination revealed Lt anterior polar cataract of 1 mm and another posterior subcapsular cataract. Brain ultrasound was normal. Chromosome karyotyping showed a karyotype of 49,XXXXY. On examination at the age of 2y and 3m his head circumference is 46cm (3rd centile) height is 75cm (-4 SD) and weight 9kg (-3.5 SD). He has a coarse facial appearance with hypertelorism, epicanthal folds, upslanting palpebral fissures and a broad nasal bridge. He has small penis and small retractile testes. He is diagnosed with global developmental delay. This is the first report of congenital cataract in a patient with 49,XXXXY syndrome. Congenital cataract has been described previously, in one case of 46,XXY syndrome. The molecular basis for the combination of congenital cataract in sex chromosome polysomy is not known. It had been previously suggested that it may be explained by an increased BCOR gene dosage due to the patient's extra X chromosome. Mapped to chromosome X, mutations of the BCOR gene can result in cataracts, and other ocular abnormalities. X inactivation may explain the variable phenotype and rare expression of cataracts in these patients. Further investigation in model systems is needed to verify this hypothesis. Eye examination is recommended in all patients with sex chromosome polysomy.

Aiding the interpretation of CNV and sequence variation in DECIPHER using the Genoverse genome browser. *E. Bragin, E.A. Chatzimichali, G.J. Swaminathan, A.P. Bevan, C.F. Wright, M.E. Hurles, H.V. Firth.* Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom.

DECIPHER (https://decipher.sanger.ac.uk) is a web-accessible database and consortium that facilitates the identification and interpretation of genomic variation in patients with developmental disorders. Over 250 academic departments in genetic medicine contribute phenotype-linked variation data into the DECIPHER database for analysis and interpretation. Following informed consent, shared anonymized patient data enables the identification of clusters of patients with similar phenotype-linked genomic findings and encourages collaboration and contact between member centers. DECIPHER also facilitates contact between external users and consortium members making it an invaluable collaborative resource for genomic research and clinical diagnosis. Driven by decreasing costs and improved technologies, sequencing is now increasingly being used in clinical diagnosis alongside arrayCGH. In order to facilitate the combined analysis and interpretation of phenotype-linked copy-number (CNV) and/or sequence variation we have extended and improved DECIPHER to encompass all forms of genomic variation. New features include informative summary and gene tables, variant-effect predictions as well as a purpose-built genome browser (Genoverse: http://genoverse.org) to visualize and interpret copy-number and sequence variation. Genoverse was developed at the Wellcome Trust Sanger Institute in collaboration with Ensembl. The Genoverse browser utilizes modern web technologies to visualize data 'on-the-fly'. Some of the salient features include customizable views, interactive scroll and zoom, as well as visualization of local files by 'drag n' drop'. Genoverse is currently the visualization engine behind DECIPHER and Ensembl. The design of Genoverse allows easy integration into any website and connection with various data formats and sources. In our presentation we demonstrate our implementation of all recent developments in DECIPHER including the integration of sequence and CNV data, managed data access, inclusion of research data and the new genome browser.

The Diagnostic Yield of Chromosomal Microarray Analysis in a Large Multidisciplinary Craniofacial Clinic. *K. Dipple[1], J. Peredo[1], J.P. Bradley[2], R. Jarrahy[2], F. Quintero-Rivera[3].* 1) Dept Hum Gen, Gonda 5506B, Univ California, Los Angeles, Los Angeles, CA; 2) Dept Surgery, Division of Plastic and Reconstructive Surgery, Univ California, Los Angeles, Los Angeles, CA; 3) Dept Pathology and Laboratory Medicine, Univ California, Los Angeles, Los Angeles, CA.

We report on 100 children tested in the UCLA Craniofacial Clinic using chromosomal microarray in an effort to locate significant areas of the genome and candidate genes associated with craniofacial anomalies. Abnormalities included isolated defects (cleft lip/palate, cleft palate alone, hemifacial microsomia, microtia, Pierre Robin sequence and Tessier clefts), known complex conditions (VATER, CHARGE [without CHD7 mutations or deletions], Nager, OAV/Goldenhar) and individuals with the above isolated defects plus multiple abnormalities, developmental delay and/or intellectual disability. We excluded those patients who had previously identified chromosomal abnormalities by standard G-banded karyotyping. Patients were tested from September 2007 to May 2013 using BAC arrays and later high density oligonucleotides (with and without single nucleotide polymorphism, SNP) arrays once that platform became available. The clinical positive rate of microarray testing in the UCLA Craniofacial Clinic was 10% (n=10/100). Four patients had large regions of homozygosity (ROH) that ranged from 10 Mb to 389 Mb, (one case was 2nd degree relationship). One patient had a duplication of 224 kb, partly overlapping ARL13B, which has been linked to Joubert syndrome type 8 in single-copy form. One patient had a partial tetrasomy/deletion where the gain was not associated with a supernumerary chromosome; the deletion, in Xp11.1, has been linked with autism. Four patients had deletions that ranged from 335 kb to 2.38 Mb. One patient had a microdeletion of 17q24.3 upstream of SOX9 associated with isolated Pierre Robin Sequence (Amarillo et al., AJMG, 2013). Another patient has a 5q35.2-q35.3 microdeletion associated with Sotos syndrome. (Peredo J, et al., Cleft Palate Craniofac J. 2012). We did not find any overlap with previously reported candidate genes for isolated cleft lip/palate or Goldenhar syndrome. Our experience with microarray testing indicates that those children with cleft palate and hemifacial microsomia plus multiple abnormalities (congenital heart defects, encephalopathies, seizures, muscle tone abnormalities) and developmental delay are the most likely to have deletions/duplications that can be detected by CGH array. We did not find deletion/duplications in patients whose craniofacial abnormalities were isolated.

2648F

Effects of up-regulation of the SHH pathway on Ts65Dn, a mouse model of Down Syndrome. *T. Dutka[1], N. Singh[2], J.T. Richtsmeier[2], R. Reeves[1,3].* 1) Institute Of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Anthropology, Pennsylvania State University, University Park, PA; 3) Department of Physiology, Johns Hopkins School of Medicine, Baltimore, MD.

Down Syndrome (DS) is caused by a triplication of human chromosome 21 (Hsa21). DS consists of a constellation of over 80 phenotypes. Three characteristics found in all individuals with DS are some level of craniofacial dysmorphology, brain structural and functional changes, and cognitive impairment. Ts65Dn, a mouse model of DS, contains a freely segregating extra chromosome consisting mostly of the distal portion of mouse chromosome 16 (Mmu16), a region orthologous to part of Hsa21. Previous work has demonstrated that Ts65Dn recapitulates aspects of the craniofacial defects, brain dysmorphology, and intellectual disability seen in DS. Moreover, some aspects of each of these 3 traits have been linked to a reduced response to Sonic Hedgehog (SHH). If all trisomic cells show a similarly reduced response to SHH, then up-regulation of the pathway in affected cells might ameliorate the phenotypes in multiple tissues. To investigate this hypothesis, Ts65Dn mice were crossed with $Ptch1^{tm1Mps/+}$; mice in which the canonical SHH pathway is up-regulated in every SHH-responsive cell through the loss of function of one *Ptch1* allele; this should affect every cell that signals through the canonical HH pathway throughout development. Ts65Dn; $Ptch1^{tm1Mps/+}$ mice were compared to Eu; $Ptch1^{tm1Mps/+}$, Eu; $Ptch1^{+/+}$ and Ts65Dn; $Ptch1^{+/+}$ for craniofacial, behavioral and brain phenotypes. Morphometric assessment of the skull demonstrated specific affects on craniofacial morphology. Evaluation of motor learning was accomplished using an increasing speed rotarod trial; working memory was assessed with a Y-maze; and hippocampal function (contextual learning and visiospatial integration) was explored using fear conditioning and Morris Water Maze. The brain morphology was assessed for cerebellar granule cell density, cerebellar size compared to brain size, foliation and Purkinje cell density with mid-sagittal sections. Comparisons of the effects of reduced Ptch1/increased SHH pathway signaling on all of these phenotypes will indicate if consistently lowering the threshold for SHH stimulation can improve multiple DS phenotypes and clarify roles of the SHH pathway in the overall presentation of DS.

46,X,del(X)(p11.2) Turner syndrome patient with severe keratoconus. *L. Gabriel[1, 2], L. Junior[4], T. Oliveira[1], I. Silva[1], L. Chaves[1], C. Sousa[1], L. Elias[1], L. Mendonça[1], R. Filho[1], L. Lavigne[1, 2, 5], J. Filho[3], J. Jaime[3], M. Avila[1, 2].* 1) Ophthalmologia, CEROF-HC-UFG, Goiania, GO, Brazil; 2) Brazilian Center for Eye Surgery, BCES, Goiania, GO, Brazil; 3) APAE, Anapolis, GO, Brazil; 4) Centro de Diagnostico por Imagem, CDI, Goiania, GO, Brazil; 5) Hospital Geral Roberto Santos, Salvador, BA, Brazil.

A 19-year-old female with amenorrhea, short stature, and severe keratoconus on both eyes was investigated for the diagnostic hypothesis of Turner syndrome. After an extensive laboratory work-up we found: uterus and ovaries with reduced dimensions, anteverted and anteflexed uterus, elevated follicle-stimulating hormone (FSH), elevated dehydroepiandrosterone (DHEA), and a G-banding karyotype showing the X chromosome partial deletion 46, X, del(X)(p11.2) confirming our suspicion of Turner syndrome.

2650T

Heterotaxy in a woman with mosaic Turner syndrome. *P. Kannan[1], A.E. Lin[1], N.S. Scott[2], I. Sahai[1].* 1) Medical Genetics, MassGeneral Hospital for Children, Boston, MA; 2) Department of Cardiology, Massachusetts General Hospital, Boston, MA.

BACKGROUND: Heterotaxy refers to an abnormal arrangement of the thoracic and abdominal organs due to a failure to establish left-right asymmetry during embryogenesis. Important clinical findings include complex cardiovascular malformations, abnormal inferior vena cava (IVC) relationship to the spine, spleen defects, transverse liver, and intestinal malrotation. Heterotaxy is genetically heterogenous. Not all causative genes are known. Chromosomal abnormalities are uncommon. Turner syndrome is a chromosomal disorder occurring in 1 in 2500 live female births. Short stature, ovarian dysgenesis and heart defects are common findings. Turner syndrome is caused when an entire X chromosome is missing (45,X) or is structurally abnormal. In mosaic Turner syndrome 45,X/46,XX, a milder clinical presentation is typically observed. CASE: We report a 29 year old woman with a history of Total Anomalous Pulmonary Venous return into coronary sinus status post surgical repair in infancy, left sided IVC, polysplenia, left of midline liver and intestinal malrotation. Her karyotype is 45,X[3]/46,XX[27]. Sequencing of the 10 known genes associated with heterotaxy did not reveal any variants. Heterotaxy in Turner syndrome is extremely rare and has been reported in two cases previously; our case is the only one in which known heterotaxy genes were analyzed.

2651F

Dilated cardiomyopathy in a patient with Pallister Killian Syndrome while on a ketogenic diet. *J. Lazier[1], J. Harder[2,3], M.A. Thomas[1,2].* 1) Department of Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Department of Pediatrics, Alberta Children's Hospital, Calgary, Alberta, Canada; 3) Department of Pediatric Cardiology, Alberta Children's Hospital, Calgary, Alberta, Canada.

Pallister Killian Syndrome (PKS) is caused by mosaic tetrasomy of chromosome 12p. It is characterized by multiple congenital anomalies, characteristic craniofacial anomalies, and intellectual disability. Seizures are common and often poorly controlled with medication. Up to 40% of patients with PKS have congenital heart anomalies, including atrial septal defects, patent ductus arteriosus and bicuspid aortic valves. Cardiomyopathy is a rare association, with only one reported case of hypertrophic cardiomyopathy. There are no previously reported PKS patients with dilated cardiomyopathy as seen in our patient. *Vogel et. al.* (2009) reported a case of a combined hypertrophic/dilated cardiomyopathy reported in a patient with hexasomy 12p, and Parasuraman *et. al.* (2011) reported a case of severe dilated cardiomyopathy reported prenatally in a fetus with mosaic trisomy 12. These cases suggest that upregulation of genes in this area may contribute to dilated cardiomyopathy.

Ketogenic diets are commonly used to treat children with severe refractory epilepsy, such as that seen in PKS. While they are generally considered safe, long term use has been associated with metabolic changes, including selenium deficiency, which is present in up to 20% of patients on this diet. Rare cases of dilated cardiomyopathy and long QT syndrome have been seen in these selenium deficient patients.

We present the case of a four year old girl with PKS who presented with a long QT syndrome and acute dilated cardiomyopathy. An echocardiogram done 15 months previously had been normal. At the time of presentation, she was on a ketogenic diet for medically refractory epilepsy and had low selenium levels. Despite cessation of the ketogenic diet, medical treatment of her heart failure, and initial improvement of her cardiomyopathy, the patient died from congestive heart failure two months after the initial presentation. Dilated cardiomyoapthy has not been previously reported in PKS. Given that there is a low risk of cardiomyopathy in all patients who are selenium deficient secondary to a long term ketogenic diet, this was likely the explanation for her cardiomyopathy. It is possible, that based on their genetic background, PKS patients are at increased risk of this rare complication and close monitoring of selenium levels may be even more important.

2652W

Clinical and cytogenomic evaluation in two siblings with an 8.5 Mb 6q24.2q25.2 deletion inherited from a paternal insertion. *M.I. Melaragno[1], S.S. Takeno[1], M. Migliavacca[1], A.L. Pilla[1], N.L.M. Sobreira[2], C.B. Mello[3], V.A. Meloni[1].* 1) Genetics Division, Universidade Federal de Sao Paulo, Sao Paulo, Brazil; 2) McKusick Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, USA; 3) Psychobiology Department, Universidade Federal de Sao Paulo, Sao Paulo, Brazil.

Interstitial deletions of the long arm of chromosome 6 are rare. Recently, a clinical 6q microdeletion syndrome was identified as being associated with intellectual disability (ID), microcephaly, characteristic facies, minor dysmorphic features, and multiple organ anomalies. We present two siblings, male and female, with a 6q24.2q25.2 deletion studied in detail by different molecular methodologies. Both patients had global developmental delay, ID, microcephaly, short stature, characteristic facial dysmorphisms, and multiple organ anomalies. Different from the previous cases described in literature, our patients had moderate skin laxity in hands and the female patient had stenosis of the thoracoabdominal aortic junction and atrial septal defect. They differ concerning ID level since the female has moderate, and the male has mild ID. Both patients' karyotype analyses were normal; however, SNP array showed an 8.5 Mb interstitial deletion on chromosome as follows: .arr 6q24.2q25.2(144,444,361-152,966,111)x1. FISH-BAC using the probe RP11-632J15 (6q24.3 region) confirmed the deletion in both siblings, and revealed normal signal in the mother and the older sister. Furthermore, the father has an insertion of a chromosome 6q segment into the long arm of chromosome 8 (8q13), which results in a high recurrence risk for the disease. Our study confirms SNP-array as a powerful method in the identification of cryptic deletions, and underlies the essential role of BAC-FISH in assessing the position of the chromosomal segment involved in the deletion, and detecting balanced carriers. Thus, in our study both methods were important in defining patients' clinical follow-up and genetic counseling. Financial support: FAPESP and NHGRI (1U54HG006542).

2653T

Developmental and Growth Delays, Dysmorphic Features and Microcephaly in a Child With Microduplication 12q13.12. *C. Melver, A. Archbold.* Pediatrics, Div Gen, Akron Children's Hosp, Akron, OH.

We report the case of a 9-year-old boy with a duplication within band 12q13.12 which is de novo and not previously described. He presented for genetics evaluation for developmental delay and dysmorphic features. His medical history was otherwise significant for small size, microcephaly, and undescended testis. An unknown congenital cardiac condition reportedly resolved in infancy, and he is now followed by cardiology for mildly increased triglycerides and total cholesterol. He had mild motor delays, walking around 18 months, but more significant delays in speech. He said his first words after his second birthday and did not use sentences until age four. At the time of his visit he was in the third grade but doing what his mother described as kindergarten-level work. On review of family history his mother reported removal of a unilateral cataract at age 5 thought to be secondary to toxoplasmosis. The remainder of the family history was significant only for a distant cousin on each parent's side of the family thought to have diagnoses on the autism spectrum. On physical exam his height and weight were at the 3rd percentile and his head circumference was less than the 3rd percentile and 50th percentile for 3 years of age. His face was significant for upslanting palpebral fissures without epicanthic folds, double cowlicks and an overall impression of mild facial asymmetry and mild microagnathia. Previous genetic workup at that time included normal karyotype, FISH for SNRPN and testing for Fragile X syndrome. A whole-genome oligonucleotide array CGH with SNP was done which revealed a de novo duplication of at least 417 kb within band 12q13.12. This duplication has not been previously described to vary in its entirety in the general population. It contains 4 genes with known clinical associations, including TUBA1A and MLL2 associated with neurodevelopmental phenotypes. Heterozygous mutations in these two genes are associated with lissencephaly type 3 and Kabuki syndrome type 1, respectively. The clinical consequences of having three copies of these genes are not known. Based on the de novo occurrence the laboratory has now classified this as a positive result representing a possible new microduplication syndrome.

2654F

DIAGNOSTIC AND MANAGEMENT CHALLENGES OF GENETIC DISEASES IN RWANDA. *L. Mutesa[1,2], A. Uwineza[1,2], J. Hitayezu[1], S. Murorunkwere[1], E.K. Rusingiza[3], L. Tuyisenge[3], R. Teteli[3], J. Mucumbitsi[4], N. Muganga[3], A.C. Hellin[2], M. Jamar[2], V. Bours[2].* 1) Medical Genetics, National University of Rwanda, Huye, Huye-Butare Southern Province, Rwanda; 2) Center for Human Genetics, University of Liege, Belgium; 3) Department of Pediatrics, Kigali University Teaching Hospital, Rwanda; 4) Department of Pediatrics, King Faysal Hospital, Kigali, Rwanda.

Background: Genetic diseases refer to genetic disorders caused by defects or abnormalities in chromosomes or genes. Chromosome disorders include numerical anomalies (e.g. monosomies, trisomies, etc) and chromosomal rearrangements mainly characterized by unbalanced translocations, inversions, duplications or deletions. In addition, molecular defects affecting gene expression represent a high proportion of monogenic or polygenic genetic diseases. Methods: In the present study, we conducted a survey aiming at assessing clinical aspects and genetic diagnostic patterns of Rwandan patients presenting with clinical phenotype suggestive of genetic disease. This survey was a compilation of several genetic studies so far conducted within a six-year-period starting from 2006 to 2012. Most of patients were selected based on clinical features suggesting of a specific genetic disease. Cytogenetic studies including karyotype, Fluorescent In Situ Hybridization (FISH) analysis were performed in the majority of these patients. In addition, molecular tests such as Polymerase Chain Reaction (PCR), gene sequencing or Multiplex Ligand Probe Amplification (MLPA) analysisand CGH-array were done for better diagnostics' characterization of monogenetic or chromosomal disorders. Results: In total, we identified a considerable number of chromosomal abnormalities including trisomy 21, trisomy 13, trisomy 18, Turner syndrome, Cat Eye syndrome, Williams symdrome and others. Furthermore, monogenic disorders such as cystic fibrosis-like disease, sickle cell anemia, spinocerebellar ataxia type 2 (SCA2), Hunter syndrome, Hutchinson-Gilford Progeria syndrome were also found. In addition, seven patients showed microdeletion and microduplication syndromes. Other polygenic disorders including holoprosencephaly, meningomyelocele, cyclopia syndrome, and encephalocele sydrome were also identified. Conclusion: this survey revealed a large number of genetic diseases in Rwanda. The cytogenetic and molecular tests should be mandatory for diagnosis assessment. Nevertheless, their management is still a challenging situation in our African settings. However, genetic counselling should be provided to all families at high risk of a recurrent autosomal dominant, recessive or X-linked diseases.

2655W

Neonatal Management of Trisomy 13: Clinical Details of 12 Patients Receiving Intensive Treatment. *E. Nishi[1,2], M. Takasugi[3], T. Hiroma[3], T. Nakamura[3], Y. Fukushima[2], T. Kosho[1,2].* 1) Department of Medical Genetics, Nagano Children's Hospital, Azumino, Japan; 2) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Department of Neonatology, Nagano Children's Hospital, Azumino, Japan.

Trisomy 13 is one of the most common autosomal trisomy syndrome, characterized by multiple congenital anomalies, severe developmental delay, and a short life span with the 1-year survival rate as 5-10 % and the median survival time as 7 days through population-based studies. Management of neonates with trisomy 13 is controversial, palliative care or intensive treatment, supposedly due to the lack of precise clinical information of the syndrome especially on efficacy of treatment. To delineate the natural history of trisomy 13 managed under intensive treatment, we reviewed detailed clinical data of 12 patients with full trisomy 13 admitted to the neonatal intensive care unit of Nagano Children's Hospital, providing intensive treatment to those with trisomy 13, from 2002 to 2012. Two patients had prenatal karyotyping through amniocentesis. Five were delivered by a cesarean. Major clinical findings included congenital heart defects (92%), cryptorchidism (83% of male), cleft lip or cleft palate (75%), polydactyly (67%), tracheomalacia or laryngomalacia(58%), prolonged hypoglycemia(50%), gastroesophageal reflux (50%), and biliary tract disease (50%). 10 patients (83%) received resuscitation by intubation. Mechanical ventilation was required by 10 (83%), two (20%) of whom were extubated and six of whom needed tracheostomy. Surgical operations included tracheostomy, abdominal operation for umbilical hernia, ileostomy, hepatic portenterostomy, plastic operation for cleft lip, plastic operation for polydactyly, cataract surgery, were performed on 10 (83%), of the patients. Enteral feeding was accomplished in all, four of whom were fed orally. Three patients could be discharged home and are still alive. Common final modes of death were congenital heart defects and heart failure (67%). The survival rate at age 1 day, 1 week, 1 month, and 1 year was 100%, 100%, 92%, and 17%, respectively. Median survival time was 229.5 days (range, 22-2334). These date have a resemblance to the date about the patients with trisomy 18 in our hospital. [Kosho et al., 2006] The current study, though the sample size is small, has demonstrated improved survival through neonatal intensive treatment, which would be helpful for clinicians to offer the best information on treatment options to families of patients with trisomy 13.

2656T

Estimation of live birth prevalence of Down syndrome in Japan. *I. Ohashi[1], Y. Kuroda[1], M. Masuno[2], Y. Kuroki[2], K. kurosawa[1].* 1) Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 2) Kawasaki University of Medical Welfare, Kurashiki, Okayama,-Japan.

The live birth prevalence of Down syndrome is determined by several factors including the rates of advanced maternal age, prenatal diagnosis, and policy for the prenatal screening. The maternal ages have steadily increased from 1970s in most of the developed countries. However, the rate of live birth prevalence of Down syndrome varies between countries and geographical status. According to the data from International Clearinghouse for Birth Defects Surveillance and Research (ICBDSR) Annual Report 2011, the peak of the incidence of Down syndrome was observed at 2008 in Japan. The most recent data of the prevalence during the last 4 years has not been presented for the time lag of the epidemiological study. To elucidate the trend of live birth prevalence of Down syndrome in Japan, we used three sets of data from the Kanagawa Birth Defects Monitoring Program (KAMP) during the period 1981-2008, the clinical records of patients with Down syndrome in Kanagawa Children's Medical Center (KCMC), and demographic data in Kanagawa Prefecture. KAMP is a population-based monitoring system, covering about half of total births in Kanagawa Prefecture including 40,000 births annually. KCMC is a tertiary children's hospital in Kanagawa Prefecture. The prevalence of Down syndrome in KAMP was correlated with the numbers of the patients with Down syndrome at KCMC during the study period. The rate of Down syndrome was decreased or stationary from 2009 to 2012. Despite of the fact that the rise of maternal ages would lead to increase of the prevalence of DS, our data showed opposite results. The total number of prenatal diagnosis was stationary or slightly increased, but the rate of mothers over 35 increased two fold from 1998 to 2008 in Japan [Sasaki et al. 2011]. These results suggest that the prenatal diagnosis focused on the advanced maternal ages have had the impact on the birth prevalence of DS since 2009 in Japan. Non-invasive prenatal testing (NIPT) is a screening test to identify pregnancies at risk for common aneuploidies (trisomy 13, 18, and 21). In Europe and United States, the NIPT has been introduced as a routine first screening from 2011. In Japan, NIPT was started as a research framework for clinical trial since April 2013. Further analysis for the prevalence of DS is required for the estimation of the use and spread of prenatal diagnostic techniques and elucidating the impact of elective termination on DS.

2657F

National Institutes of Health Activities in Down syndrome Research: From Creation of a Consortium to Support of a Patient Registry, DS-Connect. *MA. Parisi[1], S. Bardhan[1], L. Kaeser[1], ML. Oster-Granite[1], V. Rangel Miller[2], YT. Maddox[1].* 1) IDD Branch, NICHD, NIH, Bethesda, MD; 2) PatientCrossroads, San Mateo, CA.

Down syndrome (DS) is one of the most common genetic causes of intellectual disability worldwide. The National Institutes of Health (NIH) has a longstanding program of research in DS to improve understanding of this chromosomal disorder, with the goal of developing effective treatments to improve quality of life for those with DS. In 2007, the Trans-NIH Down Syndrome Working Group (DSWG) published *The NIH Research Plan on Down Syndrome* identifying long- and short-term research goals. An NIH DS portfolio review demonstrates progress in DS research; needs remain in several longer-term objectives, and some new goals need development. For example, recognition of the high prevalence of Alzheimer's disease in aging individuals with DS prompted the NIH to sponsor a workshop in April 2013 on *Advancing Treatments for Alzheimer's Disease in Individuals with Down Syndrome*; the outcomes of this workshop will inform the upcoming revision of the research plan.

In December 2010, the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development (NICHD) and the Global Down Syndrome Foundation co-sponsored a conference on patient registries, research databases, and biobanks. One of the recommendations was to create a forum for ongoing discussions about research in DS. To that end, the NICHD convened a DS Consortium composed of ~20 members including self-advocates and family members, DS researchers, leaders of professional DS organizations and foundations, and members of the DSWG. The Consortium explored options for creating a Down syndrome patient registry. In September 2012, NICHD awarded a contract to create *DS-Connect: The NIH Down Syndrome Consortium Registry* to facilitate information sharing among families, persons with DS, researchers, and parent groups. Family members and those with DS will be able to enter contact and health information into an online, confidential, and secure database. A researcher and professional portal willl allow evaluation of aggregated de-identified data. If a participant is eligible for a research study, Registry staff will invite them to contact the investigator for potential participation in the study. DS-Connect is planned for launch within the coming year. These activities highlight progress and remaining challenges in DS research. With new therapeutics being developed to treat the cognitive deficits in DS, the need for these resources is timely.

2658W

Phenotype correlation of a patient with a large 16q23.2 to 16q24.3 duplication and a patient with a 16q23.3 to 16q24.3 duplication and small 16p13.3 deletion. *J. Richer[1,2], J. McGowan-Jordan[1,2].* 1) Genetics Department, CHEO, Ottawa, Canada; 2) University of Ottawa, Department of Pediatrics, Ottawa, Canada.

Patients with large duplications involving the long arm of chromosome 16 are extremely rare. A limited number of patients with large duplications of chromosome 16 with additional rearrangements are described in the literature; descriptions in the literature of patients with isolated large interstitial duplications are rare. We present a girl who has a de novo pure duplication of the long arm of chromosome 16 arising from a derivative chromosome 15. We also present an older patient with a similar duplication in conjunction with a deletion of the short arm of chromosome 16 consistent with the better described 16p13.3 deletion syndrome. Case 1: The patient, now 21 months of age, presented with dysplastic kidneys, failure to thrive with all growth parameters below the 5th percentile, dysmorphic features and cognitive impairment. There were also concerns about recurrent upper respiratory infections and about the child's ability to tolerate vaccination. Genomic 180,000 oligonucleotide array showed a 9.8 Mb duplication of 16q23.2 to the terminus at 16q24.3. Case 2: The patient is a 16 year old female. She has failure to thrive (height at the 5th percentile and a weight below the 5th percentile, but head circumference just above the 50th percentile), severe cognitive impairments (still non-verbal and non-continent), idiopathic thrombocytopenic purpura requiring a splenectomy, low immunoglobulins (IgG), alpha-thalassemia trait and dysmorphic features. Genomic SNP microarray showed a large terminal 16q duplication of 16q23.3 to 16q24.3, as well as a 16p13.3 terminal microdeletion. In conclusion, the dysmorphic features associated with the 16q duplications in our patients are similar with those described in the literature in patients with duplication of the entire long arm of chromosome 16. Based on our results, we postulate that the phenotype of pure large duplications of 16q23.2-q24.3 includes heights and weights which remain at or below the 5th percentile and head circumference near or just above the 2nd percentile. Severe developmental disabilities with more pronounced delays in verbal skills than in motor skills characterize our older patient. Finally, it remains to be established whether low IgG may be part of the phenotype.

2659T

Predicting Obstructive Sleep Apnea in People with Down Syndrome.
B. Skotko[1, 5], M. McDonough[1], L. Voelz[2], D. Rosen[2, 5], A. Ozonoff[2, 5], E. Davidson[2, 5], V. Allareddy[2, 5], N. Jayaratne[2], R. Bruun[2, 5], N. Ching[2], G. Weintraub[4], L. Albers Prock[2, 5], R. Becker[2, 5], D. Gozal[3]. 1) Medical Genetics, Massachusetts General Hospital, Boston, MA; 2) Boston Children's Hospital, Boston, MA; 3) The University of Chicago, Chicago, IL; 4) David Geffen School of Medicine at University of California, Los Angeles, CA; 5) Harvard Medical School, Boston, MA.

Obstructive sleep apnea (OSA) in individuals with Down syndrome is associated with multiple morbidities: systemic and pulmonary hypertension, glucose intolerance, cardiovascular and cerebrovascular disease, and behavioral problems. The prevalence of OSA in this population is very high, with estimates ranging between 55-97%. Currently, an overnight polysomnogram (sleep study) is the gold-standard diagnostic test for patients with Down syndrome. Yet, this testing is cumbersome, poorly tolerated by these children, costly, and not widely available around the country. In this study, we looked to identify predictive factors for OSA in persons with Down syndrome. We enrolled ~100 subjects, ages 3-35 years, who already participate in the Down syndrome Program at Boston Children's Hospital. For each patient, we collected subjective and objective measurements using validated parental survey instruments, standardized physical exams, lateral cephalograms, 3D-digital photogrammetry, and urine samples. Afterwards, all participants underwent standardized polysomnography at the Boston Children's Hospital Sleep Laboratory where objective measurements were collected on OSA. We analyzed which combination of our assessment methods best predicted OSA, as ultimately determined by polysomnography. This will be the first time presenting the results of our data. Our final screening tool will hopefully allow physicians to avoid ordering polysomnograms for those individuals with Down syndrome at lowest risk of OSA. Further, those patients with Down syndrome and clear predictors for OSA can proceed directly toward adenotonsillectomy, the current treatment.

2660F

Diamond Blackfan Anemia due to a RPS17 gene deletion in a child with previously detected `balanced' 15,16 translocation.
J. Sullivan, S. Barry, J. Luty, M-A. Abbott. Baystate Medical Ctr, Springfield, MA.

Diamond-Blackfan anemia (DBA) is a rare congenital anemia due to arrested maturation of erythrocytes. Classic cases present as profound anemia in the first 1-2 years of life. Diagnosis is made with complete blood count demonstrating macrocytic anemia and reticulocytopenia in the setting of bone marrow deficient in erythroid progenitors. There may be associated physical malformations including thumb abnormalities, urogenital defects, craniofacial dysmorphisms, low birth weight, growth and developmental delay. There is also a modest increase risk of acute myeloid leukemia, osteogenic sarcoma, and other malignancies. In the majority cases of DBA there is no family history and the causative gene mutations are de novo; however, in 10-25 percent of cases there is a positive family history with autosomal dominant inheritance and variable expressivity. Approximately 50 percent of DBA individuals possess mutations in genes coding for ribosomal proteins (DBA1-10); DBA4 due to mutations in the RPS17 gene at 15q25.2, accounts for less than 1 percent of cases. We report a 4 year old boy who initially presented with upper respiratory illness and low blood counts thought to be related to viral suppression. Symptoms (pallor, shortness of breath and leg pain) continued and he was referred to pediatric hematology where a repeat CBC showed persistent low Hgb and elevated ferritin. A previous work-up for developmental delays revealed a de novo 46,XY, t(15:16)(q26.1;q13) karyotype. Although this reciprocal translocation appeared cytogenetically balanced, whole genome oligonucleotide array was performed to rule out a cryptic imbalance of genetic material and revealed a 3.3 Mb de novo intersitial deletion extending from cytogenetic band 15q25.1 to 15q25.2. The deleted region contains more than 25 genes including the RPS17 gene associated with DBA4. Recurrent microdeletion of 15q25.2 has been described in association with a variable presentation that can include DBA; anomalies including congenital diaphragmatic hernia, VSD, and cryptorchidismm; developmental and behavioral abnormalities; and short stature. Our patient with DBA4 has mild physical dysmorphisms, no birth defects, and resolving developmental delays.

Gusella[2,3,6], D.J. Harris[7], E.C. Liao[4], R.L. Maas[8], B.J. Quade[5], M.E. Talkowski[2,4,6], C.C. Morton[1,5,6]. 1) Department of Obstetrics, Gynecology, and Reproductive Biology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Departments of Psychiatry, Neurology, and Genetics, Harvard Medical School, Boston, MA; 4) Department of Plastic and Reconstructive Surgery, Center for Regenerative Medicine, Massachusetts General Hospital, Harvard Stem Cell Institute, Harvard Medical School, Boston, MA, USA; 5) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 6) Program in Medical and Population Genetics, Broad Institute, Boston, MA; 7) Division of Genetics, Boston Children's Hospital, Harvard Medical School, Boston, MA, USA; 8) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

DGAP (www.DGAP.Harvard.edu) is a collaborative effort to identify genes critical in human development and disease pathogenesis through study of genes disrupted by balanced chromosomal rearrangements. Since 2001, 263 subjects have been enrolled, with recurring phenotypes that include craniofacial abnormalities (64%), symptoms of neurodevelopmental disorder (NDD) (70%) - 45%; comorbidity of both traits -, and other anomalies, including hearing loss (11%). Detection of breakpoints have migrated from FISH mapping and Southern blotting to next-gen sequencing, and 165 candidate genes and 21 non-coding RNAs have been elucidated. Sequencing of 99 genomes from different individuals harboring a *de novo* balanced rearrangement has identified a rich landscape of chromosomal reorganization previously undetectable by cytogenetic methods. We detected complex chromosomal exchanges in ~20% of breakpoints at sequence resolution (previous estimates using cytogenetics predicted a rate of 2.8% complex exchanges), 90% of which contained microinversions, predominantly repaired through non-homologous end joining, and defined that highly complex localized chromosome 'shattering', or chromothripsis, resolves to largely balanced germline states in individuals with congenital anomalies. To date, 26 animal models have been acquired or created for functional analysis of candidate genes. DGAP provides a unique opportunity to annotate the human genome from an 'n of one' perspective with exciting gene discoveries including a component of the BRAF-histone deacetylase complex as the critical intellectual disability gene in the Potocki-Shaffer syndrome region (*PHF21A*), a histone/lysine demethylase/methyl-transferase in a profound debilitating phenotype (*KDM6A*), genes for traits such as height (*HMGA2*), a noncoding RNA in a severe developmental disorder (*LINC00299*), a chromodomain protein associated with autism spectrum disorder (*CHD8*), and single gene contributors to previously defined regions of genomic disorders (*CDK6*, *MBD5*, *KIRREL3*, *EHMT1*, *SATB2*, and *SNURF-SRPN*). Although largely a basic research endeavor, DGAP methods have recently been implemented as clinical diagnostic tests, particularly for counseling dilemmas encountered with prenatal detection of *de novo* balanced rearrangements. With research results returned to physicians, DGAP offers a wealth of information on poorly annotated, clinically relevant areas of the genome and is actively seeking enrollments and collaborators.

2662T

Establishing a reference group for distal 18q-: clinical description and molecular basis. *J. Cody[1,3], M. Hasi[1], B. Soileau[1], P. Heard[1], E. Carter[1], C. Sebold[1], L. O'Donnell[1,2], B. Perry[4], R. Stratton[1], D. Hale[1].* 1) Dept Pediatrics, Univ Texas Hlth Sci Ctr, San Antonio, TX; 2) Dept. Psychiatry, Univ Texas Hlth Sci Ctr, San Antonio, TX; 3) The Chromosome 18 Registry and Research Society, San Antonio, TX; 4) Ear Medical Group, San Antonio, TX.

Although constitutional chromosome abnormalities have been recognized since the 1960s, clinical characterization and development of treatment options have been hampered by their obvious genetic complexity and relative rarity. Additionally, deletions of 18q are particularly heterogeneous, with no two people having the same breakpoints. We identified sixteen individuals with deletions that, despite unique breakpoints, encompass the same set of genes within a 17.6 Mb region. This group represents the most genotypically similar group yet identified with distal 18q deletions. As the deletion is of average size when compared with other 18q deletions, this group can serve as a reference point for the clinical and molecular description of this condition. We performed a thorough medical record review as well as a series of clinical evaluations. Common functional findings included developmental delays, hypotonia, growth hormone deficiency, and hearing loss. Structural anomalies included foot anomalies, ear canal atresia/stenosis, and hypospadias. The majority of individuals performed within the low normal range of cognitive ability but had more serious deficits in adaptive abilities. Of interest, the hemizygous region contains 38 known genes, 26 of which are sufficiently understood to tentatively determine dosage sensitivity. The data suggest that 20 are unlikely to cause an abnormal phenotype in the hemizygous state and five are likely to be dosage sensitive: *TNX3, NETO1, ZNF407, TSHZ1*, and *NFATC*. *ATP9B* may be conditionally dosage sensitive. Not all distal 18q- phenotypes can be attributed to these six genes; however, this is an important advance in the molecular characterization of 18q deletions.

2663F

Dysmorphological Characteristics of Mosaic 4q31 Terminal Deletion: A Case Report. *D. Torun, Y. Tunca.* Dept. of Medical Genetics, Gulhane Military Medical Faculty, Ankara, Turkey.

Terminal deletion of the long arm of chromosome 4 is a rare condition and the clinical findings may vary depending on the region that is missing. Developmental, craniofacial, digital, skeletal and cardiac involvements are the most common anomalies observed in these patients. Most of the common clinical findings which described for 4q terminal deletion syndrome are restricted to the 4q33----qter. A 7 year old male patient from non-consanguineous healthy parents has been evaluated for the psychomotor developmental delay and multiple congenital anomalies. He had been operated for cleft soft palate, macroglossia, undescended testicles and inguinal hernia. Broad forehead, arched eyebrows, upslanted palpebral fissures, telecanthus, depressed nasal bridge, anteverted nostrils, down-turned corners of the mouth, retrognathia, micrognathia, high palate, bifid uvula, protruding and dysplastic ears and clinodactyly has been observed on his physical examination. Abdominal ultrasound, brain magnetic resonance imaging and hearing tests were normal. Echocardiography showed atrial septal defect. Cytogenetical analysis of patient revealed 46, XY [20%]/46, XY, del (4)(q31qter) [80%]. In this study, we made a literature review and compared the clinical findings between mosaic and complete 4q31 terminal deletion. As we know, this study is the first report of deletion of chromosome 4 (q31qter) in mosaic pattern and gives a further delineation for the clinical features.

2664W

Monozygotic twins with Turner syndrome and discordant phenotypes but concordant genotypes due to in utero chimerism. *A. O'Donnell[1], T.L. Toler[2], J. Krier[1], S.E. Dukhovny[3], S. Eggert[4], S. Weremowicz[4], F. Bieber[4], A.E. Lin[2].* 1) Genetics, Boston Children's Hospital, Boston, MA; 2) Genetics, Massachusetts General Hospital for Children, Boston, MA; 3) OB/GYN, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Pathology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

The chromosome basis of Turner syndrome includes complete 45,X in 40% and mosaicism in 20-30% of affected women, usually with phenotypic correlation. We report on monozygotic twins diagnosed with mosaic Turner syndrome (45,X / 46,XX) with discordant phenotypes, where only one of the twins has features of Turner syndrome. The twins were the product of a triplet IVF pregnancy where two embryos were implanted and resulted in live births of one male and twin female infants.

The phenotypically affected twin had characteristics of classic Turner syndrome *in utero* and postnatally, including coarctation of the aorta requiring surgical repair, webbed neck, and hand and pedal lymphedema. A buccal karyotype on DOL 2 showed 92% 45,X cells. She developed growth delay for which she receives growth hormone. The phenotypically unaffected twin had a blood karyotype performed at 3 months of age that unexpectedly showed 33% 45,X cells. She did not manifest any obvious features of Turner syndrome. Blood karyotyping repeated at 9 years of age showed approximately 1/3 of the lymphocytes were 45,X in both of the twins. We performed skin biopsies and fibroblast karyotypes on the now 11-year-old twins. The affected twin's karyotype was 100% 45,X while the unaffected twin's karyotype was 100% 46,XX.

We hypothesize that twin-to-twin blood mixing *in utero* led to seeding of the hematopoietic stem cell pools during development and resulted in both twins having lymphocytic mosaicism for Turner syndrome. Twin-to-twin blood mixing through placental anastomoses is a common occurrence for monozygotic twins. If the loss of the X chromosome occurred at or after the twinning event, both twins would have isolated hematopoietic chimerism. This is distinct from mosaicism where the loss of the X chromosome occurred prior to the twinning events, in which case the unaffected twin received a smaller proportion of 45,X cell. In mosaicism, there are expected to be some 45,X cells in the fibroblast lineage of both twins. The mechanism of chimerism, especially in contrast to mosaicism, has implications for the risk of ovarian competency for the unaffected twin. This case highlights the importance of using a non-hematopoietic cell line for any genetic testing of discordant twins, given the risk of both false positive results for the unaffected twin and false negative results for the affected twin.

2665T

Detection of an FMR1 Deletion by Chromosomal Microarray Analysis. *J. Smith[1], A.E. Scheuerle[2], L. Ellis[1], S. Peacock[1], P. Fang[1], A. Patel[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Tesserae Genetics, Dallas TX.

Fragile X syndrome, one of the most common etiologies of intellectual disability, is typically caused by expansion of CGG repeats silencing the FMR1 gene. However, silencing of FMR1 by deletion has been reported in a few cases with variation in size and gene content; the phenotypic picture is still evolving. A 2 year 4 month old male was referred for microarray analysis and Fragile X testing due to moderate developmental delay and mildly dysmorphic features. The patient and his dizygotic twin brother, whose development is reportedly normal, were conceived through in vitro fertilization due to unexplained infertility. General health is normal. Motor development was delayed; he sat at 9 months, crawled at 1 year, walked at 19 months and had 2-4 words at 28 months. He was minimally interactive. He was non-verbal but had constant loud vocalizations, tonation changing with mood: happy/angry/sad. The patient was reported to have repetitive habits of rocking and pacing. Physical exam revealed length at 50th centile and head circumference of 25th centile. He had mild dolicocephaly, long palpebral fissures with mild lateral ectropion, flattened midface and periorbital area, large ears, wide nose, patulous lips with downturned mouth, and thick, short toes and fingers. MRI of the brain at 18 months was normal except for a small pineal cyst. Cytoscan HD (Affymetrix) array revealed an 89.48 kb deletion including the FMR1 and FMR1-AS1 genes; the proximal breakpoint was approximately 47 kb upstream of FMR1 and the distal breakpoint approximately 3.5 Mb downstream. The deletion was confirmed by PCR and Southern analyses, which detected no FMR1 allele. While microarray analysis showed three other CNVs, none are considered causative of disease. Thus the patient's phenotypic features are most likely due only to the small deletion affecting FMR1. The presence of moderate developmental and speech delay is in agreement with a previously published report [PMID:22890812 subject 3] of a male patient with a 265 kb deletion; however, at age 4, that patient had relative macrocephaly (75th centile). The couple's infertility is of interest in light of premature ovarian failure suffered by some Fragile X carriers; microarray analysis of both parents to assess the status of all CNVs is pending. This case further shows haploinsufficiency of FMR1 leads to altered dosage resulting in developmental delay. CMA is a sensitive method to detect copy number changes in FMR1.

2666F

Microcephaly associated with duplication of chromosome 15q24. *Y. Wang[1], Y. Zhou[2], D. Shrestha[1], E. Carter[1]*. 1) Dept Pathology, Univ South Alabama, 600 Clinic Dr. TRP IV, 278, Mobile, AL 36688; 2) Dept. of Biology, Baylor University, Waco, TX 76706.

An 11-month-old African American female was born with microcephaly, and she has developmental delay. The physical examination shows an OFC of 43.5 cm (2nd percentile); height is 76 cm (90th percentile); and weight 11.9 kg (above the 95th percentile). The features previously noted for a child with craniofacial dysmorphism including narrow bitemporal diameter and sloping forehead with associated microcephaly. She has no associated anomalies or significant dysmorphisms, otherwise. A brain MRI revealed evidence of simplified gyral pattern with shallow sulci and a fewer gyri as well as thin corpus callosum. These findings are consistent with the diagnosis of microcephaly with simplified gyral pattern (MSGP). A detailed analysis of the constitutional chromosomal changes in the patient was conducted by microarray comparative genomic hybridization (array CGH), and linkage analysis using 6 short tandem repeat (STR) markers on chromosome 15. Array-CGH revealed microduplication with 1.265 Mb on chromosome 15q23-q24.1 (chr15: 72023070-73288923 hg19 coordinates). Linkage analysis confirms this duplication. Human chromosomal region 15q24-26 harbors a high density of chromosome-specific duplicons. Consistent and recognizable clinical phenotypes of microduplication for distal 15q are minor craniofacial anomalies, congenital heart disease, mental retardation, and genital anomalies. Clinical phenotypes may vary in patients, depending on the size and location of duplication portion of chromosome 15q. Duplications in this region had been reported to be associated with neurodevelopmental disorders. However, microcephaly or brain malformation had not been reported in the 15q24 microduplication syndrome. This patient presents microcephaly and developmental delay caused by 15q24 microduplication.

2667W

Elevation of Insulin-Like growth Factor Binding Protein 2 Level in Pallister-Killian Syndrome: Implications for the Postnatal Growth Retardation Phenotype. *K. Izumi[1,2], E. Kellogg[1], M. Kaur[1], A. Wilkens[1], I. Krantz[1]*. 1) Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Research Center for Epigenetic Disease, Institute of Molecular and Cellular Biosciences, The University of Tokyo, Tokyo, Japan.

Pallister-Killian syndrome (PKS) is a multi-system developmental disorder caused by tetrasomy 12p that exhibits tissue-limited mosaicism. The spectrum of clinical manifestations in PKS includes craniofacial dysmorphia, cleft palate, ophthalmologic, audiologic, cardiac, musculoskeletal, diaphragmatic, gastrointestinal, gentiourinary, cutaneous anomalies, intellectual disability and seizures. Probands with PKS often demonstrate a unique growth profile consisting of macrosomia at birth with deceleration of growth postnatally. Since the insulin-like growth factor signaling (IGF) pathway plays a critical role in normal growth physiology, we hypothesized that dysregulation of IGF pathway is involved in the pathogenesis of PKS. Genome-wide expression array analysis performed on cultured skin fibroblasts from PKS probands revealed significantly elevated expression of insulin-like growth factor binding protein 2 (IGFBP2). The amount of IGFBP2 secreted from cultured skin fibroblast cell lines was measured. About 60% of PKS fibroblast cell lines secreted higher levels of IGFBP2 compared to the control fibroblasts, although the remaining 40% of PKS samples produced comparable level of IGFBP2 to that of control fibroblasts. Serum IGFBP2 level was measured in PKS probands, and in 40% of PKS probands, IGFBP2 level was elevated. No correlation was seen between mosaic ratio and the IGFBP2 level. PKS probands with elevated IGFBP2 manifested with severe postnatal growth retardation. IGFBPs are the family of related proteins that bind IGFs with high affinity, and IGFBPs are typically thought to attenuate IGF action, and mouse models of IGFBP2 overexpression demonstrate a postnatal growth attenuation phenotype. Hence, we suggest the possibility that elevated IGFBP2 levels might play a role in the growth retardation phenotype of PKS. Since IGFBPs functions in an endocrine/paracrine fashion, dysregulated IGF signaling pathway should manifest its effects not only on tetrasomic cells, but also on the chromosomally normal cells in PKS probands.

2668T

Aetiology of Moderate Mental Retardation. *A. KUMAR, M. VASHIST.* DEPARTMENT OF GENETICS, M.D.UNIVERSITY, ROHTAK, INDIA.

Mental retardation is a common disorder which imposes a large medical, psychological and social burden .It is grouped into four classes on the basis of IQ scores by ICD-10. Individuals with IQ (35-50) were placed in the moderate mental retardation (MMR) category. Two hundred moderately mentally challenged patients were studied from Pandit Bhagwat Dayal Sharma University of Health Sciences, Rohtak and other rehabilitation centers across Haryana. In our study the outdoor patients reaching the local medical care services were between age group from 1 month of child to 50 years. Age group showed peak values below 16 years and a sharp decline after 50 years of age. Nearly 80% excess of affected males in the present study strongly suggested contribution of non specific X linked mental retardation. Higher percentage of males can also be an indication of the community based bias towards a male child. There were 44% cases from lower socio economic classes like agriculture laborers, construction laborers and other daily wages workers. 72% cases of urban population with lower socio-economic status is an indication of some certain specific risk factors associated with moderate mental retardation. Poverty and nutritional deprivation are environmental conditions which also seem to be relevant predisposing risk factors. Various Non Government Organization and Social Welfare Departments must be intervened to produce more impactful programs in addition to existing schemes in the State of Haryana. The initiation of various health care programmes may limit occurrence of moderate mental retardation. . Retrospective analysis revealed prenatal risk factors in 60% patients, neonatal in 40.35% and postnatal risk factors in 30.53% MR patients. Ninety four percent MR patients showed delayed developmental history. Malnutrition at prenatal stage was the main risk factor.

2669F

A dyslexia case with de novo der(14)t(Y;14)(q10;q10). *E. Kirat, G. Güven, M. Seven, M. Özen, E. Yosunkaya, H. Ulucan.* Medical Genetics, Istanbul University Cerrahpaşa Medical Faculty, Fatih, Istanbul, Turkey.

Dyslexia is a neuropsychiatric syndrome which has historically been called as ‘congenital word blindness’ and contemporarily it is defined as developmental analogue of acquired selective impairment in reading and writing ability due to neuronal damage in certain regions of the brain. The etiology of dyslexia, whether it is a single trait or a cluster of subtypes which are likely to involve different subsets of genes, is an ongoing debate. Also in some of chromosomal abnormalities like XYY syndrome, dyslexia could be a symptom. XYY syndrome is a chromosomal aneuploidy with a predisposition to learning disability, tall stature, behavior disorder and long ear. Here we report a case that has a minor facial dysmorphism and dyslexia with an extra Y chromosome, translocated to the 14th chromosome with a karyotype of 46, XY, der(14) t (Y;14)(q10;q10). The relationship between this translocation and this XYY-like phenotype is under investigation.

2670W

Computer-aided facial recognition of individuals with Angelman Syndrome.
L. Wolf[1,2], W.H. Tan[3,4], L. Karlinsky[1], M. Shohat[1,2,5], L.M. Bird[3,6]. 1) FDNA Ltd., Herzlyia, Israel; 2) Tel Aviv University, Tel Aviv, Israel; 3) 3.NIH Rare Diseases Clinical Research Network~Angelman, Rett, & Prader-Willi Syndromes Consortium, USA; 4) Division of Genetics, Boston Children's Hospital, Boston, MA, USA; 5) 5.Schneider Children's Medical Center of Israel, Raphael Recanati Genetics Institute, Rabin Medical Ctr and Felsenstein Medical Research Center, Petah Tikva, Israel; 6) Division of Genetics/Dysmorphology, Rady Children's Hospital San Diego, San Diego, CA, USA.

Angelman syndrome (AS) is a neurodevelopmental disorder characterized by severe developmental delay, intellectual disability, speech impairment and a unique behavior with an inappropriate happy demeanor. AS patients also commonly present unusual facies that may include deep set eyes, prognathism, thin vermilion of the upper lip, wide mouth, and strabismus.

In this study we examined whether a computer-based dysmorphologic analysis can help distinguish between AS patients and non-AS patients. We used a collection frontal facial images of genetically and clinically verified AS cases (n=210) and compared them to two separate control sets: (i) normal individuals (n=520); and (ii) individuals affected with other syndromes with dysmorphic facial features (n=808). The latter control set is added to verify that the system distinguishes not only between dysmorphic and non-dysmorphic populations, but can also identify the specific facial abnormality associated with AS.

A novel facial dysmorphology analysis system based on 2D photographs (FDNA®) was used. The system is fully automatic and starts by localizing hundreds of facial fiducial points and taking various measurements. The final classification is based on these measurements, as well as on a global "gestalt" detector that estimates the probability of the subject having AS based on the appearance of the entire facial image. A cross validation technique was used to estimate the recognition capability of the computer system. At each one of 20 rounds, the data was split randomly to training and testing data, each comprising of 50% of the individuals.

The system was able to distinguish AS from normal controls with 95.67% specificity and 95% sensitivity, but it was able to distinguish AS from dysmorphic controls with 98.02% specificity and 95% sensitivity. The gestalt of the face as captured by multiple local patterns of facial texture contributed significantly to the correct recognition of the individuals affected with AS.

Overall, we have demonstrated that computer-based analysis can be successfully to support the correct recognition of patients affected with AS.

2671T

Computer-aided detection of Down syndrome from facial photography.
Q. Zhao[1], K. Rosenbaum[2], D. Zand[2], L. Kehoe[2], R. Sze[1,3], M. Summar[2], M. Linguraru[1]. 1) Sheikh Zayed Institute for Pediatric Surgical Innovation, Children's National Medical Center, Washington, DC; 2) Division of Genetics and Metabolism, Children's National Medical Center, Washington, DC; 3) Department of Radiology, Children's National Medical Center, Washington, DC.

Purpose To develop an automatic computer-aided detection (CADe) tool from simple facial photography to allow for instant, remote and accurate diagnosis of Down syndrome. **Methods** A method of automated detection of Down syndrome was developed based on 2D facial image analysis. A dataset consisting of 130 frontal facial photographs with 50 Down syndrome pediatric patients and 80 healthy individuals was collected with a variety of cameras and lighting conditions. The subjects are from multiple ethnicities including 98 Caucasian, 20 African American and 12 Asian and both genders (88 males and 42 females). The age of patients varies from 0 to 3 years. After image acquisition, 44 clinically-relevant anatomical landmarks are defined in the face region. A hierarchical statistical face model is built to locate these landmarks automatically on patient images. Patients of Down syndrome present with special morphology that relates both to geometry (upward slanting eyes and small nose) and texture (flattened philtrum and prominent epicanthal folds). To analyze the facial information, geometric and texture features are extracted. Geometric features are defined via interrelationships among anatomical landmarks to incorporate morphological clinical criteria. There are a total of 27 geometric features, including horizontal and vertical distances normalized by the face size, and corner angles between landmarks. The 132-dimensional local texture features are extracted from square patches around each inner facial landmark to describe the pattern of the facial region such as epicanthal folds and philtrum. Then the most representative 97 features are selected by maximizing the area under ROC curve (AUC) with respect to diagnosis accuracy. Finally, a support vector machine classifier is employed to discriminate Down syndrome and the healthy group by analyzing the selected features. The performance is evaluated using accuracy, sensitivity and specificity with a leave-one-patient-out strategy. **Results** For Down syndrome detection, the CADe system achieved 95.9% accuracy, 100% sensitivity and 93.6% specificity. The AUC was 0.99. **Conclusion** The automatic CADe system demonstrated high accuracy for detecting Down syndrome from simple home photography of variable quality. While access to modern testing for Down syndrome remains limited by geography, cost and physician access, this tool could potentially create an affordable solution for doctors worldwide to detect genetic disorders.

2672F

Tetraploid/diploid mosaicism as a potential cause of hypospadias.
J.C. Giltay[1,3], A.J. Klijn[2,3], M. van Breugel[1,3], L. van der Veken[1,3], R. Hochstenbach[1,3]. 1) Department of Medical Genetics; 2) Pediatric Renal Center; 3) University Medical Center Utrecht, Netherlands.

Both environmental and genetic factors have been implicated in the etiology of hypospadias. Environmental factors include placental insufficiency and pre-existing diabetes, genetic factors include several genes involved in the formation of male external genitalia. Monogenic etiology has mainly been proposed in cases with posterior hypospadias whereas the functional consequences of the mutations identified usually remain unclear. Since in the vast majority of the published reports genomic DNA isolated from blood has been used we hypothesized that mosaic chromosomal abnormalities present in genital tissues might be responsible for hypospadias in some cases. Thus, in a patient with penoscrotal (posterior) hypospadias, micropenis and scrotal testes, who was initially suspected to have partial androgen insensitivity syndrome (PAIS) we cultured fibroblasts from a genital skin biopsy, obtained during surgical correction of the hypospadias. Karyotyping revealed a 92,XXYY/46,XY mosaicism in 53 and 43 cells respectively. Interfase fluorescence in situ hybridization (FISH) with probes for chromosomes 18, X and Y confirmed this distribution of tetraploid and diploid cells. SNP array analysis on DNA from these genital cells gave no indication of chimerism. Karyotyping and/or interfase FISH in blood lymphocytes (n= 600), buccal mucosa cells (n=100) and cells from a urine sediment (n=100) was consistent with 46,XY in all cells. Tetraploidy mosaicism is an extremely rare chromosomal abnormality reported in at least 15 live born patients with growth retardation and developmental delay. Only one of them had renal/urinary tract abnormalities (Stefanova et al 2010). Complete tetraploidy is even rarer and reported in 9 live born children who had a very limited life expectancy (Stefanova et al 2010). In at least 7 out of 9 cases abnormalities of the urogenital tract were reported so these abnormalities seem to be a near consistent finding in tetraploidy. The lack of these abnormalities in patients with mosaicism may be due to ascertainment bias since tetraploid cells in our patient were only found in genital skin fibroblasts. We conclude that tetraploid/diploid mosaicism is a rare cause of hypospadias and perhaps other congenital anomalies of the urogenital tract which can only be diagnosed if cells from these organs are karyotyped.

2673W

Domains of histone marks in monozygotic twins discordant for trisomy 21.
X. Bonilla[1,2], A. Letourneau[1,2], F.A. Santoni[1], M.R. Sailani[1,2], M. Guipponi[3], C. Gehrig[3], S.E. Antonarakis[1,2,4]. 1) Department of Genetic Medicine and Development, University of Geneva Medical School and University Hospitals of Geneva, Geneva, Switzerland; 2) National Center for Competence in Research Frontiers in Genetics, Geneva Switzerland; 3) Department of Genetic Medicine and Laboratories, University Hospitals of Geneva, Switzerland; 4) iGE3 institute of Genetics and Genomics of Geneva, Switzerland.

The use of samples from twins offers the opportunity to study epigenetic modifications that may be associated with phenotypic discordance. The availability of samples of monozygotic twins discordant for trisomy 21 has allowed us to study the effects of the trisomy in gene expression and genome organization in a unique model free of inter individual variability. When the expression level of all protein-coding genes was compared between fibroblasts of the twins, we found that the differential expression is organized in chromosomal domains with regions of upregulated or downregulated expression in the T21 twin. These domains correlated well with previously described replication domains and lamina associated domains (LADs). However we demonstrated that LAD topology is not altered in T21 cells, suggesting the possibility that the differences in expression between the twins are the result of changes in histone marks density or DNA methylation. In order to test the eventual effect of histone methylation on differential gene expression, ChIP seq for H3K4me3 was performed in the twins' fibroblasts. HTS libraries for input and IP chromatin of both twins were sequenced in a HiSeq2500 36bp single read, 41 million reads per sample on average. Peaks were called using HOMER. 18,895 and 22,017 peaks were identified for the T21 and the euploidic twin, respectively. The twins have 18,219 peaks in common. Those significantly enriched in the euploidic (46) are within or near genes related to embryonic development and morphogenesis according to DAVID. Notably, 3,788 peaks are unique to the euploidic twin. They are significantly enriched within or near genes involved in morphogenesis, axogenesis, axon guidance and neuron morphogenesis. Furthermore, we estimated the fold change difference in H3K4me3 density between the twins for each gene. Remarkably, we found a strong correlation between the H3K4me3 differential distribution and the chromosomal gene expression domains. We have studied the DNA methylation differences between the twins and they do not correlate with expression domains. These results suggest that the differences in H3K4me3 levels and not the LADs topology or overall DNA methylation are likely responsible for the changes in gene expression pattern between the twins. More histone marks are currently being investigated to better understand the dynamics of gene expression dysregulation.

2674T

Wolf-Hirschhorn syndrome: natural history into adulthood. A preliminary study of twenty-one individuals. *A. Battaglia[1], V. Doccini[1], T. Filippi[1], A. Lortz[2], JC. Carey[3].* 1) Dev Neurosciences, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) 4p- Support Group, USA; 3) Division of Medical Genetics, Dept. of Pediatrics, University of Utah Health Sciences Center, Salt Lake City, UT, USA.

Information on long-term survival in Wolf-Hirschhorn syndrome (WHS) is very limited. Only five adult WHS are described in the medical literature, with age range between 24 and 37 years. We report on twenty-one WHS individuals (17 females; 4 males), aged between 21ys 7 m and 48ys 9m. Fourteen were personally observed at the Stella Maris Clinical Research Institute by A.B., and 7 were recruited from the 4p- Support Group-USA. All are described as being happy, friendly, outgoing adults; liking to be around family and friends. 11/21 are close to total care with needs to be assisted in feeding, diapering, bathing, dressing/undressing, and when walking needing assistance on unlevel ground or transitioning from carpet to tile. 9/21 are partly self independent, being able to feed and dress themselves, but needing supervision and some assistance with personal hygiene, and, at times, with walking on unlevel ground. 1/21 is fully independent. All had variable degrees of developmental delays, with a moderate-severe cognitive deficit. 18/21 enjoy a good health, whereas 1/21 has diabetes type II, diagnosed at age 13; 1/21 has Raynaud disease, diagnosed at age 18; and 1/21 had esophagitis at age 19. All but one are seizures free. All are enrolled in a personalized rehabilitation program. Knowledge of the medical and developmental aspects of adults with WHS will inform health supervision.

2675F

Prader-Willi syndrome and oculocutaneous albinism due to a 5;15 translocation and hemizygous OCA2 mutation. *A.C.E. Hurst[1], C.R. Haldeman-Englert[2], T.H. Stamper[2], M. Hanna[3], M.J. Pettenati[2], P.P. Koty[2].* 1) Dept. of Pediatrics, Wake Forest School of Medicine , Winston-Salem, NC; 2) Department of Pediatrics, Section on Medical Genetics, Wake Forest School of Medicine, Winston-Salem, NC; 3) Wake Forest School of Medicine, Winston-Salem, NC.

Prader-Willi syndrome (PWS), characterized by infantile hypotonia and feeding difficulties followed by later onset of hyperphagia and obesity with delayed motor milestones, distinctive behavioral phenotype, hypogonadism, short stature, and characteristic facial features, is caused by the absence of imprinted genes on the paternal 15q11.2-q13 region. Oculocutaneous albinism type 2 is diagnosed based on the clinical findings of skin and hair hypopigmentation, nystagmus, and reduced iris and retinal pigment with decreased visual acuity. This condition is due to mutations of OCA2 (previously called the P gene), located within the same region of 15q11.2-12. These two conditions have been described together previously in a limited number of patients. We present here an African-American female, born at 41 weeks gestation, who was noted at birth to have decreased cutaneous pigment, fine curly yellow hair, blue eyes, and hypotonia. Her karyotype revealed a 5;15 translocation: 45,XX,der(5)t(5;15)(q35.3;q11.2). FISH analysis for a PWS deletion was positive, and confirmed the deletion to be on the translocated chromosome 15. A cytogenomic microarray analysis clarified the loss of chromosome 15 material, showing a heterozygous 5.8-Mb deletion of 15q11.2q13.1 that involved OCA2 (chr15:22,770,421-28,547,716; Build 37/hg19), with no gain of material from chromosome 5. Sequencing of OCA2 revealed a previously reported hemizygous mutation: c.819_822delCTGGinsGGTC (p.Asn273_Trp274delinsLysVal). Parental studies are pending, but it is likely that the translocation involves the paternal chromosome 15 and is de novo, and the hemizygous OCA2 mutation involves the maternal chromosome 15 and is carried by her mother. Review of the literature revealed three reports of a chromosome 5;15 translocation associated with PWS, but none of those patients had albinism. Therefore, our patient's findings are a novel cause of the PWS plus albinism phenotype.

2676W

Comparing serum calcium tests in 22q11DS and other genetic conditions: ionized vs. total calcium. *E. Chow[1,2], T. Leung[1], M. Torsan[1], C. Stefan[3].* 1) Clinical Genetics Service, Centre for Addiction & Mental Health, Toronto, ON, Canada; 2) Department of Psychiatry, University of Toronto; 3) Clinical Laboratories and Diagnostics Services, Centre for Addiction & Mental Health, Toronto, ON, Canada.

Background: Hypocalcemia is common in 22q11.2 deletion syndrome (22q11DS) and can occur or recur throughout the life, making its detection an important part of routine monitoring. While the more expensive serum ionized calcium test is often recommended, no scientific research has been conducted on whether it has advantages over the cheaper and more easily performed total serum calcium test for patients with 22q11DS or other genetic conditions. This study aims to compare the detection of hypocalcemia by these two tests. Methods: A simultaneous set of serum calcium tests (pH-normalized ionized calcium and albumin-corrected total calcium) was performed 47 times in 26 individuals (9 male) with 22q11DS and 17 times in 16 individuals (9 male) mostly with other genetic conditions. All subjects were patients at the Clinical Genetics Service of CAMH in Toronto. Mean age at testing was younger for the 22q11DS group [24.9 (SD 6.6) years vs. 31.5 (SD 8.2) years, p=0.006] but the two groups did not differ in the proportion of male subjects or subjects with psychosis. Measured hypocalcemia was defined as having one or both calcium test results below the lower limit of the reference range for the test. The number of times results from the two tests were discordant for measured hypocalcemia was recorded and compared. Results: Rate of measured hypocalcemia was higher in the 22q11DS group (36.2% vs. 11.8%), but at a trend level (p=0.07). For the 22q11DS group, test results were discordant in 9 of the 17 instances of measured hypocalcemia: 7 times only in the ionized calcium test and twice in the total calcium test. 22q11DS subjects had neuromuscular symptoms in 2 out the 7 times when only the ionized calcium was abnormal, but none when only the total calcium was abnormal. On the other hand, both instances of measured hypocalcemia in the other group were found only in one test, and both times in the ionized calcium test. Although neither of these two subjects was symptomatic, the one with Rett Syndrome had a significantly elevated PTH. Conclusions: The increased instances of hypocalcemia detected by pH-normalized ionized calcium appear to represent true hypocalcemia as subjects were more likely to have symptoms of hypocalcemia and/or an elevated PTH. Thus the pH-corrected ionized calcium test was a more sensitive and superior test in detecting hypocalcemia in 22q11DS and other genetic conditions than the albumin-corrected total calcium test.

Scoliosis and Vertebral Anomalies: Additional Abnormal Phenotypes Associated with Chromosome 16p11.2 Rearrangement. *H. Al-Kateb[1], G. Khanna[1], I. Filges[2], S. Kulkarni[1], M. Shinawi[1].* 1) Pathology and Immunology, Washington University School of Medicine, St. Louis, MO; 2) University of British Columbia, Vancouver, BC.

16p11.2 rearrangements are estimated to occur at a frequency of approximately 0.6% of all samples tested clinically and have been identified as a major cause of autism spectrum disorders (ASD), developmental delay, behavioral abnormalities, and seizures. Careful examination of patients with these rearrangements revealed association with abnormal head size, obesity, dysmorphism and congenital abnormalities. In this report, we extend this list of phenotypic abnormalities to include scoliosis and vertebral anomalies through detailed characterization of phenotypic and radiological data of seven new patients, 5 with 16p11.2 deletion and 2 with duplication corresponding to chromosomal coordinates: chr16: 29 528 190-30 107 184 (hg19) with a minimal size of 579 kb. We discuss the phenotypic and radiological findings in our patients and review 5 previously reported patients with 16p11.2 rearrangement and similar skeletal abnormalities. The results show male to female (M:F) ratio of 2:1, strikingly different from the known 1:10 ratio in the general population for idiopathic scoliosis. Interestingly, we found that males have more severe spinal deformities than females. We discuss the implications of these findings on the diagnosis, surveillance and genetic counseling of patients with 16p11.2 rearrangement.

2678F

MED13L haploinsufficiency in isolated delayed neuromotor development: further delineation of the phenotypic spectrum. *B. Callewaert[1], A. Dheedene[1], B. Menten[1], B. Delle-Chiaie[1], E. Snauwaert[2], K. Decaestecker[3], F. Roelens[4], O. Vanakker[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Ghent, Belgium; 2) Department of Pediatrics, Ghent University Hospital, Ghent, Belgium; 3) Department of Pediatrics, Stedelijk Ziekenhuis Roeselare, Roeselare, Belgium; 4) Department of Pediatrics, Heilig Hart Ziekenhuis Roeselare, Roeselare, Belgium.

A decade ago, a chromosomal translocation disrupting the MED13L (Mediator complex subunit 13-like) gene was found in a patient with transposition of the great arteries (TGA) and intellectual disability (ID). Three rare MED13L variants were subsequently identified in a cohort with isolated TGA. More recently, MED13L haploinsufficiency was detected in 2 patients with ID and conotruncal heart defects, while a copy number gain resulted in a ventricular septal defect, hypotonia and learning problems. We report 2 novel patients with a de novo intragenic MED13L deletion and further delineate the phenotype of this rare ID syndrome. Results: Both patients, respectively a 2-year old girl (patient 1) and a 3-year old boy (patient 2), presented with moderately delayed neuromotor development, generalized hypotonia, hypermetropia and a typical facial gestalt including a broad forehead, telecanthus, epicanthal folds, a bulbous nasal tip, rather small and low-set ears with a slight uplift of the earlobe. Staturoponderal evolution and head circumference were normal as was echocardiography. Brain MRI showed slightly delayed myelinisation in both patients. In addition, patient 1 had an episode of acute pyelonephritis. Abdominal ultrasound revealed a normal urogenital tract, but three small subdiaphragmatic liver cysts were noted. Patient 2 had a surgically corrected unilateral cryptorchidism. ArrayCGH analysis (180k Agilent array) revealed a 300kb deletion on chr. 12q24.21, deleting exons 2-22 of the MED13L gene in patient 1 and a 150kb deletion on chr. 12q24.21 deleting exons 2 and 3, likely resulting in a shift of the open reading frame in patient 2. Conclusion: We further document the clinical phenotype of intragenic MED13L deletions with moderate ID and consistent dysmorphic features. Particularly the morphology of the ear and earlobe should prompt MED13L analysis, even in the absence of cardiovascular defects. Hypermetropia in both patients suggests that refractive errors may also be part of the phenotypic spectrum. Besides this clinically recognizable ID syndrome, the mutation rate of the MED13L gene in patients with isolated neurodevelopmental delay remains to be determined.

2679W

Ear anomalies, mild intellectual disability, delayed growth and orodental development in a boy with a 5 Mb microduplication within 20q13.12q13.2. *J.R. Helle[1,2], M. Fannemel[2], T. Barøy[1,2], S. Axelsson[3], A.B. Karstensen[4], E. Frengen[1,2], D. Misceo[1,2].* 1) Department of Medical Genetics, University of Oslo, Oslo, Norway; 2) Department of Medical Genetics, Oslo University Hospital, Ullevål, Oslo, Norway; 3) TAKO Center, Lovisenberg Hospital, Oslo, Norway; 4) Department of Pediatrics, Akershus University Hospital, Norway.

Duplications within 20q13.12q13.2 are rare, and most imbalances previously reported were associated with deletions, resulting from an unbalanced segregation of translocation chromosomes from one parent. In these cases, the contribution to the phenotype of the duplication and the deletion was challenging to assess. More recently, isolated micro-duplications were reported in this region. However, mapping the boundaries and the gene content in these duplicated regions was difficult, mainly due to limited resolution of the investigation methods used, even in recent reports. We present a boy born post-term, presenting with large, cupped ears. He showed delay of developmental milestones, intellectual skills, growth and dental development. From childhood on he showed a mild intellectual disability, delayed loss of deciduous teeth and growth of permanent teeth, height and weight 2,5 standard deviations below mean and protrusion of the tongue. By the age of 20 years, dental status was normal. Array comparative genomic hybridization revealed a de novo 5 Mb duplication on chromosome 20q13.12q13.2, which was shown by FISH to be in situ. The duplication contains 30 RefSeq genes. To the best of our knowledge, the present micro-duplication is one of few duplications in the 20q13.12q13.2 region characterized at high resolution, allowing a precise identification of its gene content. We provide the first clinical report on the long-term development from birth until young adulthood in a patient with a 20q13.12q13.2 duplication, as followed by a multi-disciplinary team of clinicians. We compare the clinical findings in our patient with previously reported patients with overlapping duplications. Our patient's phenotype appears as relatively mild, considering the large number of genes duplicated. This contrasts with the severe phenotype in previously reported patients and suggests a high degree of clinical variability. Further clinical studies and expression studies will likely give information about the phenotypic impact of altered expression of specific genes in the 20q13.12q13.2 region.

2680T

A novel interstitial microdeletion in 2q37 refines critical region and candidate genes for microcephaly, myelination and developmental delay expressed in human neural progenitors. *J. Imitola[1], D. Khurana[2], A. Legido[2], K. Carvalho[2].* 1) Brigham and Women's Hospital Harvard Medical School; 2) 2Section of Pediatric Neurology, St Christopher Hospital for Children's, Drexel School of Medicine. Philaldelphia.

2q37 microdeletion syndrome is characterized by bone, cardiovascular alterations, neurodevelopmental delay, microcephaly and seizures. This syndrome is associated with loss of genetic material approximately 100 genes in the 2q37 band. However, the genes associated with neurodevelopmental phenotype in this syndrome are still unknown. A novel 496 kb deletion was discovered by whole genome array CGH in a patient who fulfilled the criteria for 2q37 microdeletion syndrome with additional features of hand wringing, toe walking and seizures. The abnormal segment contains 10 genes based on UCSC 2006 hg18, including SEPT2, FARP2, HDLBP, STK25. Pathway analysis of these genes revealed links to neural development,myelination, ciliogenesis and interaction with genes associated with neural function, gene expression analysis revealed that these genes are highly expressed in cortical plate, human neural progenitors areas in vivo and in vitro. Our report narrows the genomic region for 2q37 microcephaly, myelination and neurodevelopmental delay to 10 candidates genes and suggests that this segment may represent an important locus for human forebrain development. Haploinsufficiency of this region may lead to human microcephaly, seizures and neurodevelopmental delay.

2681F

Deep White Matter Brain Abnormalities in a Patient with Chromosome 15q11-q13 Deletion and Angelman Syndrome Phenotype. *N. Sekhri[1], G. Scharer[1,2].* 1) Dept. of Pediatrics, Genetics Center, Children's Hospital of Wisconsin, Milwaukee, WI; 2) Advanced Genomics Laboratory, Medical College of Wisconsin, Milwaukee, WI.

While Angelman syndrome (AS) is a neurodevelopmental disorder with a known genetic basis that is characterized by severe intellectual disability, lack of speech, ataxia, seizures, and specific behavioral patterns, leukodystrophy is not a typical finding. Subtle changes to white matter pathways detected by DTI (diffusion tensor imaging) have been described by *Peters et al, 2011*. We describe a 22-month old male patient with more overt leukodystrophy (detected on standard 1.5T brain MRI), childhood onset complex partial seizures and borderline microcephaly. MRI showed symmetric long TR hyperintensity in the periventricular and deep white matter involving the fronto-temporal and parieto-occipital white matter without evidence of abnormal enhancement. Diagnostic work-up initially focused on the white matter abnormalities and seizures; Angelman syndrome was not considered high in the differential diagnosis. Chromosomal microarray analysis was included in the work-up, but not methylation studies. Subsequently, the patient was found to have a 4.9 megabase deletion on microarray analysis (Affymetrix®6.0 oligo/SNP array) at chromosome 15q11.2-q13.1 encompassing the Prader-Willi syndrome (PWS)/(AS) region, while the remainder of genetic tests were negative. After review, the patient's behavioral pattern and clinical presentation was felt to be consistent with a diagnosis of AS. This case highlights a potential emerging problem in the approach to confirming a suspected genetic diagnosis. The availability of clinical exome/genome analysis and sequencing of disease-targeted gene panels based on Next-Generation Sequencing (NGS) technologies still leave gaps in the detection of common disorders due to methylation defects, triple repeat expansion or small CNVs. Clinicians should keep these limitations in mind when evaluating patients with varied genetic disorders.

2682W

Deletion 2q37: Cognitive-Behavioral Profiles, Developmental Trajectories, and IQ Related to Deletion Size. *G.S. Fisch[1], S.T. South[2,3], A. Rutherford[3], R. Falk[4], J. Carey[2].* 1) New York University Dept. Epidemiology & Health Promotion New York, NY; 2) University of Utah Dept. Pediatrics Salt Lake City, UT; 3) Institute for Clinical and Experimental Pathology ARUP Laboratories Salt Lake City, UT; 4) Medical Genetics Institute Cedars-Sinai Medical Center Los Angeles, CA.

2q37 deletion syndrome is typically described as encompassing, among other clinical features, mild to moderate intellectual disability, behavioral problems, short stature, hypotonia, characteristic craniofacial anomalies, and a high proportion of affected individuals with autism. Deletions involving 2q37 occur most often as a de novo mutation although instances of inversions and unbalanced translocations have been observed. We report on 8 cases with deletion of 2q37, the largest single multicenter study to date of individuals with this genetic anomaly. We examined clinical features, cognitive and behavioral abilities from 5 females and 3 males, previously diagnosed cytogenetically with del2q37, and ranging in age from 4 - 18 years at the time of their first cognitive-behavioral assessment. Each participant was administered a comprehensive neurocognitive battery consisting of the Stanford-Binet (4th Ed; SBFE), Vineland Adaptive Behavior Scales [VABS], Conners Parent Rating Scale [CPRS], Child Behavior Checklist [CBCL], and the Child Autism Rating Scale [CARS]. Of the 8 participants, 3 lacked expressive language and could not be assessed by the SBFE. Intellectual disability for the 5 tested with the SBFE ranged from severe to mild [IQ Range: 36 - 59], with relative strength in Quantitative Reasoning. Adaptive behavior composite scores from the VABS were much below adequate levels, ranging from a floor value ['19'] to 55. Based on the CPRS, 7/8 [87%] could receive a diagnosis consistent with ADHD. Scores on the CARS ranged from 22 [non-autistic] to 56 [extremely autistic]; 5/8 [63%] children received scores in the autism range. Deletion size based on microarray analysis using Cytoscan HD or Affymatrix 6.0 was determined for 4 subjects from whom DNA was obtained. Curiously, participants with the largest deletions, 10.1 Mb and 9.5 Mb, achieved the highest IQ and DQ scores; whereas, those with the smallest deletions, 7.9 Mb and 6.6 Mb, attained the lowest IQ and DQ scores. Previously, the CENT2 gene [now known as AGAP1] was thought to be a candidate gene for autism. In our study, the 3 individuals with the largest deletions were haploinsufficient for AGAP1 but not autistic. However, the subject with the smallest deletion in which AGAP1 was extant, was extremely autistic. Conventional doctrine relating deletion size and phenotype severity is discussed further.

2683T

Identification of 22q11.2 deletion in patients from adult congenital heart disease clinic - a missed burden in the transition care in Hong Kong. *B. Chung[1], P. Chow[1], A. Liu[1], P. Lee[1], K. Chan[2], M. Tang[2], E. Lau[2], Y.F. Cheung[1], K.T. Chau[1], Y.L. Lau[1].* 1) Paediatrics & Adol Med, The University of Hong Kong, Hong Kong, N/A, Hong Kong; 2) Prenatal diagnosis unit, Dept of O&G, Tsan Yuk Hospital, The University of Hong Kong.

22q11.2 deletion syndrome (22q11DS) is a common genetic diagnosis in patients with congenital heart disease (CHD). It is multi-systemic with both congenital and later-onset features with lifelong consequences. Variable clinical expression and limited awareness contribute to its under-diagnosis. With low childhood mortality, there is an increasing number of diagnosed/undiagnosed adults, posing a hidden challenge in the transition care for patients with CHD. Our objective is to determine the prevalence of 22q11DS in adult patients with conotruncal defects and to delineate their extra-cardiac manifestations. We enrolled patients through an adult CHD clinic by active screening, using fluorescence-PCR and FISH. We have recruited 156 with conotruncal defects in 2012-2013(on-going recruitment). Results: Eighteen patients are diagnosed with 22q11DS, which translates into a missed diagnosis of 1 in every 10 adults with conotruncal defects. Eleven had the cardiac diagnosis of tetralogy, 6 had pulmonary atresia and ventricular septal defect, 1 had interrupted aortic arch. Our approach of screening by molecular testing has increased the detection rate of 22q11.2DS by at least 4 times.Screening by cardiologists using dysmorphology assessment only may miss 40 percent of patients. Our cohort of patients with 22q11.2DS previously undiagnosed have less extra-cardiac manifestations that the other reported series, presumably due to lack of medical surveillance appropriate for patients with 22q11.2DS.Conclusion: This study will provide important information on the disease burden of 22q11DS and may highlight an important and actionable gap in the transitional care of patients with CHD.

2684F

Diagnosis of atypical 22q11.2 deletion and a recurrent Herpes Zoster virus infection in a man with T cell immunodeficiency. *L.P. Barragan Osorio, G. Giraldo, J.C. Prieto.* Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogota, Bogota, Colombia.

Individuals with the 22q11.2 deletion have a range of findings, including cardiovascular malformations consisting predominantly of conotruncal heart defects, palatal abnormalities characteristic facial dysmorphic features, learning difficulties, mild to moderate immune deficiency, hypoparathyroidism, among other. About 90% of patients with the 22q11.2 microdeletion have a common ~3 Mb deletion, whereas 7% of the patients have a smaller, proximally nested ~1.5 Mb recurrent deletion and other atypical deletions, nested, overlapping or adjacent to the typically deleted region (TDR). However, to date, only a limited number of atypical deletions in 22q11.2 have been reported and only a few are located distally to TDR. In this paper we report a male 47 years old patient who had been studied for primary immunodeficiency with recurrent Herpes Zoster infection which onset 9 years ago. The patient had a history of delayed developmental milestones, mild learning difficulty at school, hypothyroidism and unilateral sensorineural hearing loss. At the first consultation the patient display slight facial dysmorphism, including hooding of the lower lids, long pointed nose, velopharyngeal voice, left ocular Herpes Zoster infection with fourth nerve palsy and mild cognitive deficiency. He had a 46, XY normal karyotype. Immunological profile reported remarkable decrease of immunoglobulin and CD3, CD4 and CD8 deficiency. His IQ total score was 72.These finding suggested a DiGeorge Syndrome, therefore was performed an array-based comparative genomic hybridization (aCGH). It reported a ~1.8 Mb deletion within chromosomal band 22q11.21-22q11.23 that matched with distal 22q11.2 microdeletion. This result was confirmed with an MLPA analysis (kit SALSA MLPA probemix P250 B1 DiGeorge).Here we report one of the few atypical microdeletions in the distal 22q11.2 deletion region with a barely phenotype and an important cellular immunodeficiency leading to recurrent Herpes Zoster infection that has not been described previously. The phenotypic spectrum of 22q11.2 deletion depends on multiple dosage-sensitive genes located in this region. Non-overlapping atypical deletions have showed significantly overlapping phenotypes, suggesting either, a positional gene effect in 22q11.2, the involvement of several candidate genes or a common developmental pathway.

2685W

Clinical characteristics of a newly identified microdeletion syndrome involving chromosome region 16q22.1. *L. Dupuis[1,3], M. Helal[1,3], D.J. Stavropoulos[2,3], R. Mendoza-Londono[1,3].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) University of Toronto, Toronto, Ontario, Canada.

We describe two unrelated cases of a de novo microdeletion of chromosome 16 at band q22.1 that present with distinctive and recognizable features. Patient 1 was first evaluated at 17 months of age because of a history of intrauterine growth retardation, failure to thrive, developmental delay, and congenital heart defect. At her last assessment at 4 years of age, the patient met criteria for autism spectrum disorder, had significant global intellectual disability and was G-tube fed. She also had hearing and visual impairment. Microarray analysis (44,000 oligos platform) revealed an estimated 0.444 Mb deletion of chromosome 16q at band 22.1, which included 25 RefSeq genes. Patient 2 presented at birth with microcephaly, dysmorphic features and hypoplastic deep set nails. At 14 months of age he had mild expressive language delay and distinctive facial features. Microarray analysis (180,000 oligos platform) revealed a larger but overlapping deletion of chromosome 16q22.1. The deletion was approximately 0.833 Mb in size and included 39 RefSeq genes. In both patients, the deletion comprised 4 OMIM genes (*HSF4, HSD11B2, NOL3 and AGRP*) (UCSC Genome Browser, hg 18). Mutations in *HSF4* have been implicated in autosomal dominant and recessive forms of cataracts. Mutations in *NOL3* have been shown to cause adult onset familial cortical myoclonus syndrome in the Menonite population. *HSD11B2* mutations and polymorphisms have been reported in apparent mineralocorticoid excess syndrome and as a risk factor for hypertension. *AGRP* is involved in the regulation of body weight. A thorough review of the medical literature revealed that these two cases are the first report of this particular microdeletion of chromosome region 16q22.1. The patients presented with distinct and recognizable symptoms characterized by failure to thrive and dysmorphic facial features. The two patients had between 25 and 39 genes deleted in this region but less than 4 have been associated with recognized disorders. Deletion of the disease-associated genes does not explain all the features present in our patients. Further work to understand the function of the remaining deleted genes will provide further insight into their role in this newly identified microdeletion syndrome.

2686T

Microarray Comparative Genomic Hybridization analysis (array-CGH) as a diagnostic tool for the investigation of patients with ID/DD/ASD with or without MCA. *M. TZETIS, S. KITSIOU-TZELI, H. FRYSIRA, V. OIKONOMAKIS, K. KOSMA, K. GIANNIKOU, A. SYRMOU, E. KANAVAKIS.* Medical Genetics, University of Athens, Athens, Attica, Greece.

Clinical characteristics of patients are not always related to specific syndromes. Array comparative genomic hybridization (aCGH) is used to detect submicroscopic copy number variants (CNVs) within the genome not visible by conventional karyotyping. The clinical application of aCGH has helped the genetic diagnosis of patients with unexplained developmental delay (DD)/ intellectual disability (ID), autism spectrum disorders (ASD), with or without multiple congenital anomalies (MCA). We have implemented aCGH using the 244K & 4x180K Agilent platform, since 2008 on 581 patients with various degrees of DD/ID, seizures, ASD, MCA and normal previous conventional karyotype. Many of the patients had also received a variety of other genetic tests (FRAX, RETT, single FISH tests or metabolic screens), which were normal. Clinically significant submicroscopic imbalances with aCGH were detected in 164 (28.15%) patients. CNV sizes ranged from 10Kb to>10Mb (155 deletions & 67 duplications). In 120/164 patients one CNV contributed to their phenotype while in 44 two or more explained their clinical phenotype (34: with 2CNVs, 9: with 3CNVs, 1: with 4CNVs and 1: with 5CNVs). A total of 51 patients presented with ASD, some of which also presented: seizures (8/51), hypotonia (1/51), obesity (2/51), mental retardation (9/51), hearing loss (1/51) and dysmorphic features (2/51). CNVs detected in ASD patients were in loci at high risk for autism: 2q37.2, 2p16.3, 5p15.32p14.3, 7p22.3, 10q26.3, 12q24.22q24.3, 15q11.2q11.3, 16p11.2, 18q22.3q23, 21q22.3, Ψq21.31. Genes associated with autism or ASD which were identified included: NRXN1, SHANK3, DOCK8, ZNF92, ASMT, HSFX1, KCNH7, CHRFAM7A, CHRNA7, KCND2, CNTNAP3, MAA, MAOB, STS, VCX. In total 64 different microdeletion and 22 microduplication syndromes were detected, the majority (80%) found de novo in the patients. We were able to define the smallest region of overlap (SRO) for known syndromes, detect a novel microduplication (3q13.2q13.31) and confirm haploinsufficiency of KANSL1 in 14 patients as responsible for Koolen de Vries syndrome albeit with reduced penetrance in 3/14. aCGH is proving to be a powerful tool for the identification of novel chromosomal syndromes, allowing thus accurate prognosis and phenotype-genotype correlations.

2687F

Mortality in patients with 22q11 microdeletion syndrome. *G.M. Repetto[1,2], M.L. Guzman[1], M. Palomares[3,4], G. Lay-Son[1,2], C. Vial[1], K. Espinoza[1], H. Loyola[1].* 1) Center for Human Genetics, Clin Alemana Univ Desarrollo, Santiago, Chile; 2) Hospital Padre Hurtado, Santiago, Chile; 3) Hospital Dr. Luis Calvo Mackenna, Santiago, Chile; 4) Fundación Gantz, Santiago, Chile.

22q11 microdeletion syndrome (22q11DS) is one of the most common genomic alterations in humans, having an estimated incidence of 1/4000 live births. It accounts for approximately 10% of cases of congenital heart disease (CHD) and is also a recognizable cause of palatal anomalies, learning disabilities, immunodeficiency and psychiatric disease. Early mortality has been attributed to the presence of CHD, and diminished life expectancy has also been described in adults. The purpose of this study was to analyze demographic and clinical factors associated with mortality in a large cohort of 22q11DS patients from Chile. Through surveys of clinical cytogenetics laboratories, we found that 419 patients have had molecular confirmation of the deletion from years 1998 to 2012. Their current ages range from 6 months to 50 years. Of them, 58 (13.8%) are deceased, 25 males and 33 females. The average age at death was 1.15 y (1 sd =4.52), with a median of 4 months and ranging from newborns to 32 years. The primary cause of death was recorded in 43 cases, of which CHD and sepsis accounted for 21 cases each (48.9%). The main factors associated with mortality were the presence of CHD resulting in an OR of 5.11 (95% CI of 2.11-15.23) and airway malacia with an OR of 13.44 (95% CI 1.81-151.31). A non-significant trend for association was found with palate abnormalities (OR 0.37, 95% CI 0.05-2.84) or with the presence of gastrointestinal (OR 6.53, 95% CI 0.72-79.23) or renal (OR 8.57, 95% CI 0.16-95.44) anomalies. Patients with 22q11 are at an increased risk for early mortality, mostly due to CHD or infection. In addition to CHD, abnormalities of the airway are a relevant risk factor for early death. Funded by Fondecyt-Chile grants #1061059/1100131/1130392.

Array-CGH: known syndromes, private variants and new syndromes. *E. Biamino[1], E.F. Belligni[1], E. Di Gregorio[2], C. Molinatto[1], A. Calcia[2], A. Mussa[1], E. Grosso[2], A. Zonta[2], M.T. Ricci[2], L. Sorasio[1], G. Mandrile[3], G. Gai[2], V. Naretto[2], P. Pappi[2], F. Talarico[2], A. Guala[4], P. Vigliano[5], G. Restagno[1], E. Savin[2], N. Migone[2], G.B. Ferrero[1], M. Silengo[1], A. Brusco[2].* 1) Pediatrics Dept, University of Turin, Turin, Turin, Italy; 2) Dept of Genetics, Biology and Biochemistry, University of Turin, Italy; 3) Dept of Genetics, AO S. Luigi Gonzaga, Orbassano, Turin, Italy; 4) Dept of Pediatrics, Ospedale Castelli, Verbania, Italy; 5) Dept of Pediatric Neurology, Ospedale Martini ASL2, Turin, Italy.

Array comparative genomic hybridization (array CGH) is widely used as a first-tier clinical diagnostic test in unexplained developmental delay/intellectual disability (DD/ID) and/or congenital anomalies cases. We have tested by array-CGH (Agilent 60 K) a cohort of 513 patients affected by DD/ID associated with congenital malformations and/or dysmorphisms. The detected CNVs, unlisted in the Database of Genomic Variants, were assigned to one of the following four groups: 1) known microdeletion/microduplications syndromes or CNVs encompassing a disease-causing gene: 46/513 patients (8.9%), including del 22q11.21 (n=6), del/dup 15q13.3 (n= 2+2), del/dup 16p11.2 (n=3+4), del 17p21.31 (n=2), del 1p36 (n=2), del 1q21.1 (n=1), del 3q29 (n=1), del 7q11.23 (Williams-Beuren syndrome, n= 2), dup *NSD1* gene, del *CREBBP* gene (Rubinstein-Taybi syndrome), del *NF2* gene, del *PITX2* (Rieger syndrome), del *ANKRD11* gene (KBG syndrome); 2) deletion/duplications extending more than 7 Mb (range 7.5-29 Mb): 23/513 patients (4.5%), including 2 cases of mosaicism (>30%). The remaining CNVs involved chromosomal regions of challenging study by standard karyotype. Five of 23 cases derived from a parental balanced translocation; 3) 'likely pathogenic' deletion/duplications (150 Kb-1.4 Mb): 15/513 cases (2.9%), resulting de novo in 5/15 and inherited in 10/15. Interestingly we detected an atypical deletion of 1,3 Mb in 3q29 (encompassing 13 known genes), a deletion of 500 Kb in 5q12.3 (5 known genes) and a deletion of 1,4 Mb in 16p13.12p12.3 (14 known genes); 4) CNVs of unclear relevance (110-900 kb): 52/513 (10.1%). These results restate the effectiveness of array-CGH analysis as first-step test in patients presenting with complex phenotypes, not only to reach a clinical diagnosis but also to identify new candidate genes for DD/ID.

2689T

Heterozygous microdeletion of 16q covering *SALL1* and *RPGRIP1L* could be a novel contiguous gene syndrome with renal impairment. *N. Morisada[1], M. Taniguchi-Ikeda[1], S. Ishimori[2], T. Ninchoji[1], H. Kaito[1], K. Nozu[1], M. Adachi[2], Y. Takeshima[1], T. Sekine[3], K. Iijima[1].* 1) Pediatrics, Kobe University Graduate School of Medicine, Kobe, Hyogo, Japan; 2) Pediatrics, Kakogawa West City Hospital, Kakogawa, Hyogo, Japan; 3) Pediatrics, Toho University Ohashi Hospital, Tokyo, Japan.

Background. Microdeletion of 16q is a rare chromosomal abnormality. Nonsense mutation of *SALL1* at 16q12.1 causes Townes-Brocks syndrome (TBS, OMIM #107480) with branchiogenic anomalies, imperforate anus, and mild to severe renal impairment. The patients with *SALL1* heterozygous entire gene deletion develop milder clinical symptoms. Renal impairment in the patients with *SALL1* heterozygous entire deletion has not been reported. Homozygous mutation of *RPGRIP1L* at 16q12.2 cause Joubert syndrome (OMIM #611560) with nephronophthisis. There are few case reports with the deletion of both genes. Moreover, these several reported cases did not develop renal impairment. **Case reports.** Case 1: A 15-year-old Japanese boy had hearing loss, external ear malformation, mild developmental impairment and moderate renal impairment. Although his symptom was compatible with the category of branchio-oto-renal syndrome (OMIM #113650), no mutation was detected in *EYA1*. An array comparative genome hybridization (aCGH) analysis revealed a 5.2Mb deletion in 16q including *SALL1* and *RPGRIP1L*. Case 2: A 13-year-old Japanese boy had multiple anomalies such as bilateral renal hypoplasia leading to end stage renal failure, severe developmental delay, imperforate anus, congenital heart defect, and low set ears. He was diagnosed as TBS. Fluorescence *in situ* hybridization (FISH) analysis revealed entire gene deletion of *SALL1*. A subsequent aCGH analysis revealed 6Mb deletion in 16q including *SALL1* and *RPGRIP1L*. **Discussion.** Most of 16q heterozygous microdeletion cases with only one gene either *SALL1* or *RPGRIP1L* have no renal impairment. However, our cases with both heterozygous gene deletions had severe to moderate renal impairment. Therefore, we suggest that there may be some interactions between *SALL1* and *RPGRIP1L* gene, and our cases may be a new contiguous gene syndrome.

2690F

Fetal Alcohol Syndrome and Pitt-Hopkins Syndrome in four maternal-half siblings. *A. Asamoah[1], K.E. Jackson[1], Y. Senturias[2], K. Goodin[1], G.C. Gowans[1], K. Platky[1], J.H. Hersh[1].* 1) Dept Pediatrics, Univ Louisville, Louisville, KY; 2) Dept Pediatrics, Carolinas Medical Ctr, Charlotte, NC.

Fetal alcohol syndrome (FAS) is identified by the presence of growth impairment, characteristic facial features and central nervous system abnormalities in the background of prenatal alcohol exposure. Fetal Alcohol Spectrum Disorders (FASD) is an umbrella term for the group of conditions arising from prenatal alcohol exposure that results in physical, intellectual, developmental and behavioral disabilities in the affected individual. Disorders on the spectrum include Alcohol-Related Neurodevelopmental Disorder (ARND), Partial FAS (PFAS) and Alcohol-Related Birth Defects (ARBD). Pitt-Hopkins syndrome is caused by haploinsufficiency of TCF4 gene either due to a point mutation or a deletion of the chromosomal region 18q21.2. Affected individuals have distinctive facial features, developmental delay/intellectual disability, and hyperventilation and/or breath-holding episodes while awake. We present four maternal half siblings diagnosed with FAS based on maternal history of alcohol abuse during pregnancy and physical examination who on chromosomal microarray analysis were found to have 18q21.1 deletion that includes the TCF4 gene. The finding of TCF4 deletion in these 4 maternal half-siblings suggests their mother has a germ line deletion or is mosaic for the deletion herself. These findings suggest considering chromosomal microarray analysis in patients with FASD to determine if there are no concomitant chromosomal abnormalities contributing to the phenotype.

2691W

Normal appetite and BMI in a 9 year old girl with haploinsufficiency of SIM1 due to a 2.2 MB deletion at 6q16.2-q16.3. *G.A. Bellus, K. Zegar.* Pediatrics, University of Colorado, Aurora, CO., USA.

Many patients with interstitial deletions involving 6q16 are reported to have phenotypic features that resemble Prader-Willi syndrome with obesity, short hands and feet, hypotonia and developmental delays. Several genotype-phenotype studies have implicated haploinsufficiency of *SIM1* (homologue of Drosophila single minded /OMIM 603128) as a candidate gene for obesity and developmental delays in these individuals. In Drosophila, *sim* is a transcription factor that is considered to be a master regulator of neurogenesis. In the mouse, *Sim1* is required for the development of the paraventricular nucleus of the hypothalamus and *Sim1* heterozygous knock-out mice exhibit hyperphagia, early onset obesity and increased linear growth. On the other hand, individuals with obesity and developmental delays have been reported with deletions at 6q14.1-q15 that do not involve *SIM1*. This suggests that *SIM1* hapolinsufficiency may not be necessary to cause obesity and development delays in some individuals with deletions in this region. We report a 9 year old girl with a history of hypotonia and mild intellectual disabilities with a normal appetite and normal BMI who was found to have a 2.2 MB deletion at 6q16.2-q16.3 involving *SIM1*. Together these results suggest that haploinsufficieny of *SIM1* may be neither necessary nor sufficient to cause hyperphagia and obesity in individuals with 6q deletions.

2692T

Lack of Nablus mask-like facial syndrome phenotype in a patient with a de novo microdeletion of chromosome 8q21.2q22.1. *D. Cherukuri[1], B. Crandall[2], S. Kantarci[1].* 1) Department of Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 2) Departments of Pediatrics and Psychiatry, UCLA.

Nablus mask-like facial syndrome (NMLFS) is associated with deletions of 8q22.1 chromosomal region. The clinical manifestations of this rare microdeletion syndrome include tight appearing glistening facial skin, blepharophimosis, telecanthus, sparse arched eyebrows, flat and broad nose, long philtrum, distinctive ears, upswept frontal hairline, short and broad neck, and developmental delay. Happy disposition is a typical behavioral trait of NMLFS [MIM: 608156]. Here, we report a 2-year old girl with a history of developmental delay and dysmorphic features. This girl was born post-term to a healthy nonconsanguineous couple of European descent. The delivery was vaginal and uncomplicated. At birth, the birth weight was 7 pounds 8 ounces, and there were no particular concerns postnatally and she was discharged in 2 days. She had delay in sitting at 9 months of age and sat alone at about 13-14 months period. Head circumference was 10 to 25th percentile, weight was 75th to 90th percentile, and height was 25th percentile at 22 month. Physical examination revealed lower limb hypotonia, trigonocephaly and dysmorphic facial features, including hypertelorism, depressed broad nasal bridge, low lying columella, mild prognathism, deep philtrum, wide mouth, thin upper vermillion border with prominent cupid's bow, and broad and short neck. Her ears were normal. Currently, she had speech delays and distinctive happy and social personality. SNP-chromosomal microarray testing (SNP-CMA) with Affymetrix CytoScan HD array revealed a de novo 10.9 Mb deletion of chromosome 8q21.2q22.1 ranging from genomic position from 86,840,946 to 97,724,672 (GRCh37/hg19). This deletion interval includes 51 RefSeq genes and overlaps with the reported NMLFS critical region (93.98-96.22 Mb (hg19)). Our patient does not present with the characteristic facial features of this syndrome. However, her happy personality is a common behavioral trait observed among the NMLFS patients. Similar to our findings, there are a few reported patients, without the NMLFS clinical features, with overlapping microdeletions with the NMLFS critical region. In conclusion, our report supports that deletions of chromosome 8q22.1 region result in variable phenotypes with and without the NMFLS syndrome.

2693F

MECP2 deletion a in patient with Rett Syndrome. *S.S. Costa, D. Villela, C. Rosenberg.* Genetics and Evolutionary Biology Dpt, , University of Sao Paulo, Sao Paulo, SP, Brazil.

Rett syndrome (RTT) is a neurodevelopmental disorder caused by mutations in the X-chromosome MECP2 gene. Approximately 95% of the girls with classic RTT have a MECP2 mutation. Over 250 specific mutations are associated with RTT: missense mutations, nonsense mutations and few deletions. We report a case of a child who at 18 months initiated neuropsychomotor regression, and developed microcephaly, epilepsy, stereotypical hand movements, irritability and autistic behavior. Karyotype and sequencing of MECP2 did not reveal alterations. Array-CGH (60K - Oxford Gene Technology) disclosed a deletion of 23 Mb encompassing exons 3 and 4 of the MECP2 gene. Array-CGH was performed in the phenotypically normal mother, and exposed a duplication in Xp22.31 of ~ 1.6 Mb. X-chromosome inactivation (XCI) pattern in blood leukocytes was assessed both in the patient and in her mother by methylation-sensitive restriction digestion followed by PCR amplification across the androgen receptor (CAG) repeat region: the mother showed 19:81 proportion and her daughter 72:28. Mother and daughter were tested on a high-resolution genomic array platform (Illumina 850K array). The profile suggests that the MECP2 alteration in the patient is not a contiguos deletion but rather a deletion of exons 4 e 3 without deletion of the intronic region in between them. The possible connection between the X-chromosome alterations in mother and daugher is still unclear, but two similar cases have been reported. The mechanisms associated with the chromosomal rearrangements is discussed.

2694W

Case report of a 17q21.31 microdeletion associated with EFTUD2 mandibulofacial dysostosis with microcephaly identified by comparative genomic hybridization. *S.K. Gandomi[1], D.M. Reeves[3], M. Parra[1], C.L. Gau[1], V. Yap[2].* 1) Ambry Genetics, 15 Argonaut, Aliso Viejo, CA 92656; 2) University of Arkansas for Medical Services, Arkansas Children's Hospital, 1 Children's Way, Slot 512-5, Little Rock, AR 72202; 3) University of Arkansas for Medical Services, Department of Neonatal-Perinatal Medicine, 4301 West Markham, Slot 512-5B, Little Rock, AR 72205.

Mandibulofacial dysostosis with microcephaly (MFDM) is a rare, sporadic malformation syndrome manifesting with severe craniofacial abnormalities, microcephaly, developmental delay, and additional dysmorphic features. Although most cases of clinically diagnosed MFDM remain genetically unexplained, recent sequencing studies have linked this condition to heterozygous EFTUD2 mutations in 15 probands in the literature. In this case report, we present a previously undescribed dizygotic female twin proband (Twin A) born at 36 weeks gestation with severe microcephaly, microcrania, cleft palate, severe retrognathia, oral and pharyngeal dysphagia, bilateral proximal radioulnar synostosis, 11 thoracic ribs, abnormal MRI findings, high-pitched cry due to unilateral vocal cord paralysis, and additional dysmorphic features. Newborn screening and a series of additional biochemical investigations were diagnostically negative. The proband's twin sister (Twin B) was born healthy and shows no phenotypic similarities. Family history is unremarkable for any known genetic syndromes, and the twins' parents are both reportedly in good health. Array comparative genomic hybridization (aCGH)+SNP analysis was performed on Twin A to assess for chromosome rearrangements and regions of homozygosity. Results of this assay identified a small de novo pathogenic deletion on chromosome 17q21.31, encompassing the EFTUD2 gene. The deleted region also included 13 additional genes considered unlikely to be responsible for the proband's phenotype. No regions of homozygosity were identified in the 400K array, which would also confirm a non-consanguineous family history. Of the total 15 reported MFDM-associated EFTUD2 mutations described to date, all alterations resulted in genetic haploinsufficiency, consistent with our proband's microdeletion pathomechanism. In addition, our proband's phenotypic features both overlap and expand on the clinical features of previously reported probands in the literature. As a result, we encourage continued genetic investigation and reporting of other individuals with EFTUD2 mutations and clinical MFDM to better delineate genotype-phenotype correlations for more accurate diagnosis of this complex condition.

2695T

Nablus mask-like facial syndrome: 3 additional cases add support that del 8q22.1 is necessary but not sufficient to cause the classic phenotype. *S.S. Jamuar[1], H. Duzkale[1], N. Duzkale[2], C. Zhang[1], F.A. High[1], L. Kaban[3], S. Bhattacharya[4], J.M. Stoler[5], A.E. Lin[6].* 1) Harvard Medical School Genetics Training Program, Boston, MA; 2) Dept of Medical Genetics, Osmangazi University School of Medicine, Eskisehir, Turkey; 3) Oral Maxillofacial Surgery, Massachusetts General Hospital, Boston, MA; 4) Dept of Anesthesia, Massachusetts General Hospital, Boston, MA; 5) Division of Genetics, Boston Children's Hospital, Boston, MA; 6) Genetics Unit, Massachusetts General Hospital, Boston, MA.

BACKGROUND: Deletion (del) 8q22.1 has been reported in patients (pts) with Nablus mask-like facial syndrome (NMLFS) with its striking craniofacial and dermatologic anomalies. 9 pts reported by Allanson et al. [AJMG 2012] with overlapping deletions, but without the complete NMLFS phenotype suggest that del 8q22.1 is necessary but not sufficient. We report 3 additional pts with del 8q22.1, 2 of whom had NMLFS; one is undergoing complex oral maxillofacial surgery (OMFS). CASES: Pt. 1: 14 yo white male with jaw ankylosis, cleft soft palate, blepharophimosis, small ears, conductive hearing loss and shiny tight facial skin. NMLFS was suspected clinically and a 2.7 Mb del 8q22.1 was confirmed by chromosome microarray (CMA). Procedures prior to diagnosis included distraction osteogenesis, tracheostomy and cleft palate repair. Surgery after diagnosis included curvilinear osteogenesis distraction. Pt. 2: 2 yo white male from Turkey with microcephaly, shiny tight facial skin, blepharophimosis, telecanthus, arched eyebrows, low set dysplastic ears, frontal upsweep, and a small atrial septal defect. CMA confirmed a 3.7 Mb del 8q21.3-q22.1. Pt. 3: 16 yo female with unilateral cleft lip and palate, bilateral moderate to severe hearing loss, scoliosis, cognitive and behavioral issues without NMLFS. CMA showed a 4.6 Mb del 8q22.1. RESULTS: We summarize 22 cases of del 8q22.1, 11 of whom had NMLFS. Craniofacial features reported in NMLFS include shiny tight facial skin, expressionless face, blepharophimosis, telecanthus , bulbous nasal tip (100% each), upswept frontal hair pattern (91%), high arched sparse eyebrows (82%), abnormal ear shape (82%) and micrognathia (82%). In contrast, only a minority of the individuals with del 8q22.1 but without NMFLS had tight facial skin (30%), blepharophimosis (10%), telecanthus (20%), bulbous nasal tip (27%), sparse eyebrows (30%), abnormal ear shape (10%) and micrognathia (40%), and no pts had expressionless face or frontal upsweep. Developmental delay was noted in most pts in both groups. In addition to Pt 1, 7 others had a single surgical procedure. CONCLUSION: These 3 new pts confirm that del 8q22.1 is necessary, but additional factors contribute to the NMLFS phenotype. Complex OMFS can be achieved with intensive multidisciplinary care, especially techniques for airway management (micrognathia, restricted neck movement, small mouth); tracheostomy is done as a last resort.

2696F

In the shadow of *MEF2C*: Genotype-phenotype correlation for 5q14.3q21 deletions. *J.A. Rosenfeld[1], K. Stoate[2], A. Asamoah[2], R.R. Lebel[3], S. Raskin[4], L. Russell[5], J.W. Ellison[1], L.A. Schimmenti[6].* 1) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA; 2) University of Louisville, Louisville, KY; 3) SUNY Upstate, Syracuse, NY; 4) Pontificia Universidade Catolica do Parana, Curitiba, PR, Brazil; 5) Department of Medical Genetics, McGill University Health Centre, Montreal, Quebec, Canada; 6) University of Minnesota, Minneapolis, MN.

High resolution microarray analysis for genomic deletions and duplications has continued to provide ongoing delineation of genomic syndromes and generation of novel hypotheses regarding gene function in human development. We report further delineation of the phenotypic consequences of genomic deletions within 5q14.3q21.1. Microarray-based comparative genomic hybridization was performed on a sample from a 5.5-year-old male with developmental delay, severe expressive speech delay, visual impairment, bilateral incomplete coloboma of the iris, bilateral sensory hearing deficits, and seizures. The results identified four small interstitial deletions within 5q14.3q21.1, distal to *MEF2C* and totaling 2.1 Mb. These findings suggest that genes distal to *MEF2C* may also cause epilepsy and neurodevelopmental impairment. A review of the literature showed that some of the specific features in our patient have been occasionally reported with deletions extending to 5q15q21, including iris colobomas, hearing loss, and urogenital anomalies. To further delineate phenotypes associated with deletions in this genomic region we conducted a survey of patients in our database of clinical microarray cases and identified additional incidences of these features, though they were not fully penetrant. A comparison of our patients to those previously reported supports possible roles for developmentally important genes in these phenotypes, specifically *NR2F1*, with roles in neural, optic, and otic development, and *RGMB*, with roles in BMP2/4 signaling. In particular, *NR2F1* haploinsufficiency is likely associated with hearing loss, optic nerve atrophy, and hypoplastic corpus callosum observed in our proband. This report represents the importance of ongoing delineation of genomic syndromes through case identification and comparison to past cases through a robust clinical database.

2697W

Overlapping Phenotype of Silver-Russell-like and 14q32 Microdeletion Syndromes in a Child with Submicroscopic 11p15.5 Duplication and 14q32 Deletion. *H.J. Mroczkowski[1], D.B. Lowenstein[2], H. Abdel-Hamid[2], D.N. Saller[1], A. Rajkovic[1,3,4], S.A. Yatsenko[1,3].* 1) Department of Obstetrics, Gynecology and Reproductive Sciences, Magee-Womens Research Institute, University of Pittsburgh School of Medicine, Pittsburgh, PA; 2) Department of Pediatric Neurology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Department of Human Genetics, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Paternally and maternally derived duplications of the 11p15.5 region are rare abnormalities associated with overgrowth and growth restriction syndromes: Beckwith-Wiedemann syndrome (BWS) and Silver-Russell syndrome (SRS), respectively. Chromosome 11p15.5 harbors a cluster of imprinted genes, paternally expressed *IGF2* and *KCNQ1OT1*, and the maternally expressed *CDKN1C*, *KCNQ1*, and *H19* genes. Duplications, deletions and translocations of 11p region have been shown to result in distinct syndromes depending on genetic alteration and breakpoint positions relatively to imprinted 11p15.5 domains.

Herein, we present a case of a 7 month old girl who initially exhibited core hypotonia, developmental delay, alternating exotropia, prominent frontal bossing, and dysmorphic facial features. She was hospitalized one month later for new onset seizures. EEG demonstrated infrequent left temporal sharp waves during sleep indicating focal cerebral hyperexcitability with a tendency to have seizures of partial onset from the left temporal region. Magnetic resonance imaging of the brain revealed a hypoplastic corpus callosum, gray-white blurring in the right posterior cingulate gyrus, and diffusion restriction in the right thalamus consistent with a postictal state. Array comparative genomic hybridization showed alterations in DNA copy number involving subtelomeric regions of chromosomes 11p and 14q, suggestive of a complex rearrangement, including a duplication of ~2.4 Mb segment of 11p15.5-pter, an ~0.16 Mb triplication of the proximal 11p15.5 region, and a 1.8 Mb terminal deletion of the 14q32.3 region. The 11p15.5 duplication encompasses the *IGF2* and *H19* genes, and exons 1-2 of the potassium voltage-gated channel (*KCNQ1*) gene, but does not involve maternally expressed *CDKN1C*. The complex chromosome abnormality in our patient is not associated with abnormal growth, but includes a clinical phenotype with SRS features. These features may therefore be partially attributed to a 14q microdeletion syndrome characterized by microcephaly, high forehead, lateral hypertrichosis, dysmorphic facial features, muscular hypotonia, intellectual disability, developmental delay, and seizures. Additional studies on patients with small duplications are required to further delineate the phenotype of imprinted genes in the 11p15.5 region.

2698T

SNP Arrays in Idiopathic Intellectual Disability. *E. Utine[1], G. Haliloglu[2], B. Salanci[1], A. Çetinkaya[3], P.O. Kiper[1], Y. Alanay[1], D. Aktaş[3], B. Anlar[2], M. Topçu[2], K. Boduroğlu[1], M. Alikaşifoğlu[3].* 1) Pediatric Genetics, Hacettepe Univ, Ankara, Turkey; 2) Pediatric Neurology, Hacettepe Univ, Ankara, Turkey; 3) Medical Genetics, Hacettepe Univ, Ankara, Turkey.

Intellectual disability (ID) has a prevalence of 3% and is classified according to its severity. An underlying etiology cannot be determined in 75-80% in mild ID, and in 20-50% of severe ID. After it has been shown that copy number variations involving short DNA segments may cause ID, genome-wide SNP microarrays are being used as a tool for detecting submicroscopic copy number changes and uniparental disomy. This project was performed to investigate the presence of copy number changes in patients with ID of unidentified etiology. Affymetrix® 6.0 SNP microarray platform was used for analysis of 100 patients and their parents, and data were evaluated using various databases and literature. Etiological diagnoses were made in 12 patients (12%). One novel finding of homozygous GRID2 deletion has been reported recently. Homozygous deletion in NRXN1 gene, duplication in IL1RAPL1 gene were detected for the first time. Two separate patients had deletions in FOXP2 and UBE2A genes, respectively, for which only several patients have recently been reported. Interstitial and subtelomeric copy number changes were described in 6 patients, in whom routine cytogenetic tools revealed normal results. In one patient uniparental disomy type of Angelman syndrome was diagnosed. SNP microarrays should be considered as a first-tier genetic test in the evaluation of patients with ID; being a screening test able to detect very small genomic changes, with a high etiological yield even in patients evaluated using traditional cytogenetic tools; offering analysis for uniparental disomy and homozygosity; and thereby being helpful to find novel disease-causing genes.

2699F

Bilateral cleft lip and bilateral thumb polydactyly with triphalangeal component in a patient carrying two de novo deletions on chromosome 4q32 and 4q34 involving *PDGFC, GRIA2* and *FBXO8* genes. *A. Brusco[1,2], A. Calcia[1], G. Gai[2], E. Di Gregorio[1,2], F. Talarico[2], V.G. Naretto[2], N. Migone[1,2], E. Pepe[3], E. Grosso[2].* 1) Dept. Medical Sciences, Univ Torino, Torino, TO, Italy; 2) A.O. Città della Salute e della Scienza, S.C.d.U. Medical Genetics, Torino, Italy; 3) A.O. Città della Salute e della Scienza, Dipartimento Chirurgia Generale e Specialistiche, Torino, Italy.

We report a newborn male with bilateral clefts of the primary palate, a duplicated bilateral triphalangeal thumb, and a patent foramen ovale. At 4 yr., he presented moderate psychomotor developmental delay with normal brain MRI. The association of clefts of the lip/palate (CL/P) and triphalangeal thumbs, per se an extremely rare finding, has never been reported so far. In our case, the array-CGH analysis revealed two de novo deletions (~1.2 Mb and ~400 Kb) on the long arm of chromosome 4, containing four genes: platelet-derived growth factor C (PDGFC), glycine receptor beta subunit (GLRB), glutamate receptor ionotropic AMPA 2 (GRIA2), and F-box protein 8 gene (FBXO8). PDGFC codes for a mesenchymal cell growth factor already associated with clefts of the lip. Pdgfc -/- mice have skeletal anomalies, and facial schisis resembling human cleft/lip palate; GRIA2 codes for a ligand-activated cation channel that mediates the fast component of postsynaptic excitatory currents in neurons, and may be linked to cognitive dysfunction. FBXO8, a gene of unknown function, is member of the F-box gene family, among which SHFM3 is mutated in human split-hand foot malformations type 3. The presence of overlapping deletions in patients who do not share the same phenotype of our case suggest an incomplete penetrance, with a possible effect of modifier genetic factors.

2700W

Normal intelligence and features of Bardet-Biedl syndrome in a family with a duplication of chromosome 20p13-p12.1. *S.M. Nikkel, A.G. Hunter.* Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

Pure duplications of chromosome 20p have been reported rarely in the medical literature. We presented a family with a duplication of chromosome 20p13-p12.1 of 9.2 Mb in size. The proband was initially referred in childhood for a submucous cleft palate with bifid uvula and unilateral high-grade myopia. She was later found to have a didelphic uterus, bilateral renal cysts, and cervical and thoracic vertebral anomalies. Her mother has a bicornuate uterus, bilateral high-grade myopia, and cervical anomalies. Physical features are shared with a maternal uncle, who has a VSD, and the maternal grandmother. The mouths are small, the columella are low hanging and the nasolabial creases are deep. There is brachydactyly and tapering of the digits. The voice quality is marked by hypernasality. Family members have pursued post-secondary education with success. The proband has significant anxiety, and this is seen to a lesser extent in her mother. Duplications of 20p are reported to be associated with cognitive impairments, but the regions involved are larger than what we describe. Vertebral anomalies are common in trisomies of this region and may reflect dosage effects of the *JAG1* gene. The *MKKS* gene is known to cause a recessive phenotype due to loss of function mutations. However, this family demonstrates features of Bardet-Biedl syndrome (uterine anomalies, high palates, renal cysts, and anxiety), despite having an increase in copy number. They do not have polydactyly or retinitis pigmentosa, although ocular problems are present with extremely high myopia. In summary, large 20p duplications are associated with a number of anomalies, but a normal cognitive outcome is possible.

2701T

Inherited Yq12ter Deletion Associated with Congenital Cataracts, Microphthalmia and Autistic Spectrum Disorder in 3 Brothers. *P. Bitoun[1], A. Delahaye[2,3], B. Benzacken[2,3], E. Pipiras[2,3].* 1) Gen Med, CHU Paris-Nord, Hopital Jean Verdier, BONDY, France; 2) Embryo-Cytogenetics, CHU Paris-Nord, Hopital Jean Verdier, Bondy, France; 3) INSERM 676, Robert Debre Hospital, Paris, France.

Purpose: We screened a cohort of 65 patients with syndromal ocular disorder for CNV by microarray analysis after informed consent. We identified a family of male twins and an older brother with congenital cataract and possibly secondary microphthalmia associated with autistic spectrum disorder with cognitive delay, absent speech, introverted affect and severe communication disorder respectively aged 29 and 30 years old and a novel CNV. Methods We used an Illumina microarray platform with Human Hap 300, Human Cyto SNP 12, with 300k whole genome markers upon DNA extracted from lymphoblastoid cell lines. Illumina Software with Genome Studio 2010.3 , CNV partition 3.1.6 was used for analysis and NCBI build 36 (hg18) as reference. Patients were screened with brain MRI, and screened for mutation of SOX2, OTX2, RAX and PAX6 using Sanger sequencing. DNA was extracted from lymphoblastoid cell lines form all patients and cultured cells were used for FISH confirmation of CNV. Results A 296.8 Kb deletion in the Yq12ter region was identified and confirmed by FISH on metaphase lymphoblastoid cells using the amplitech subtelomeric Yq/Xq probe in all 3 boys and healthy father. Three brothers had normal brain MRI as well as negative SOX2, OTX2, RAX and PAX6 mutation analysis by Sanger sequencing. This Yq12ter deletion is within the Pseudo-Autosomal Region PAR2 identical to the Xq28 region. The possible role of the 3 deleted genes from the region in the autistic spectrum disorder will be discussed and the fact that the deletion was inherited from father cannot clearly exclude its pathogenic role. Discussion: The fact that there is a history of cataract in father's as well as mother's family without either parent being affected raises the possibility that the cataract is a separate trait unrelated to the autistic spectrum disorder and inherited from carrier parents in a recessive or even possibly dominant fashion. The deletion CNV identified contains 3 genes and it is difficult without further functional analysis to ascertain causality of this novel CNV in the pathogenesis of the autistic spectrum disorder in the 3 brothers.

2702F

MALFORMATION VARIABILITY ASSOCIATED TO CHROMOSOME TRISOMIES. CLINICAL AND PHENOTIPICAL IMPLICATIONS IN SEVERAL PATIENTS AT A PEDIATRIC HOSPITAL IN MEXICO. *M. Barrientos[1], J.M. Aparicio-Rodriguez[2,6], M.L. Hurtado-Hernandez[3], M.A. Cubillo-Leon[4], S. Chatelain-Mercado[5].* 1) Endrocrinology; 2) Genetics; 3) Cytogenetics; 4) Rehabilitation Therapy, Hospital para el Nino Poblano, Puebla, Puebla; 5) Biotechnology; 6) Estomatology.

Chromosome trisomies are considered alterations in the chromosome number or structure. A trisomy is therefore a type of polysomy in which there are three chromosome copies, instead of the normal two. A trisomy is considered an aneuploidy or abnormal number of chromosomes. There are two different trisomy types; Full trisomy" where an entire extra chromosome has been copied. "Partial trisomy" means that there is an extra copy of part of a chromosome. Depending on the chromosome, a trisomy is named as 'Autosomal trisomies" (trisomies of the non-sex chromosomes) and "Sex-chromosome trisomies." In this study both Autosomal and Sex-chromosome trisomies are described in differents patients, depending on the affected chromosome. Among 4617 chromosomal studies performed during 19 years (from 1992 to 2011), at Hospital Para el Niño Poblano in México, 34.6% (1596 patients) had chromosomal alterations. Among these studies population, a male and female pediatric patients are described, with different chromosome trisomies, were chromosome changes are classified as structural or numeric alterations. All trisomies patients were described in this study analyzing their phonotypical and clinical features, medical treatments and prognosis.

2703W

Congenital primary microcephaly and type B-like brachydactyly , a new syndrome? *A. Lavillaureix[1], J. Masliah-Planchon[1,2], S. Passemard[1,2], S. Drunat[1,2], A. Verloes[1,2].* 1) Department of genetics, Robert Debré Hospital, Paris, France; 2) INSERM U676, Robert Debre Hospital, PARIS, France.

We report a 10 year-old girl with primary microcephaly and brachydactyly . Microcephaly was suspected during the pregnancy by echography. At birth, at term, head circumference was 29cm (-5 SD), weight 2770g, length 50cm . Pregnancy was normal (no drug nor alcohol) and there were no perinatal problems and no feeding difficulties. She is the first child of unrelated parents none of the members of this family have brachydactyly or microcephaly. She started walking at 8 month-old, first words were around 1 year. She followed mainstream schooling. In 2nd grade, problems with motricity and writing fatigability were observed. Clinical examination at 8 year-old: showed a child of medium stature with generalised amyotrophy and microcephaly 41,5cm (-8 SD). Neurological examination was normal. She had facial dysmorphism with upslanted palpebral fissures and microdontia. She has bilateral brachydactyly ressembling type B of hands and feet, respecting thumbs but involving halluces, discovered at birth. On X rays, the terminal phalanges were missing on most digits, intermediate phalanges were hypoplastic or aplastic, with anonychia and cone-shaped epiphyses. MRI revealed a brain of reduced volume but normal structure and gyration. CGH array (180 k), caryotype and mitomicyn-induced chromosome breakage test were normal. To our knowledge it is the first described case of severe congenital microcephaly with normal IQ associated with brachydactyly and anonychia. This disorder is clinically distinct from Jawad syndrome (due to mutations in RBBP8/CTIP - currently under sequencing), which shows mental retardation and ungual hypoplasia, and Teebi anonychia-microcephaly syndrome, which has much milder anomalies.

2704T

Microrearrangements in individuals within the Holoprosencephaly spectrum. *L.A. Ribeiro-Bicudo[1], B.F Gamba[1], C. Rosenberg[2], A.L.B. da Rocha[1], A.L.C. Gaspar[1], R.M.C.S. Sandri[1], A. Richieri[1].* 1) Genetics Department, Hospital for Rehabilitation of Craniofacial Anomalies, Bauru, Sao Paulo, Brazil; 2) Human Genome Center, Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, São Paulo, SP, Brazil.

Holoprosencephaly (HPE) is a malformation sequence where the cerebral hemispheres fail to separate into distinct left and right halves. It can be associated with midline structural anomalies of the central nervous system and/or face. The etiology of HPE is complex, with both environmental and genetic factors being implicated. Numerous different heterozygous mutations have been identified in HPE patients and include missense, nonsense, deletion, and frameshift mutations that are located throughout the gene. Chromosomal abnormalities have been attributed as the main commonly identified cause and high frequency of rearrangements have been reported in studies with array CGH. In the present work we found rearrangements trough Multiplex Ligation-dependent Probe Amplification (MLPA) and arrayCGH analysis in eight non related individuals who presented within the holoprosencephaly (HPE) spectrum previously screened for mutations in some HPE determinant genes such as SHH, GLI2, SIX3, TGIF, and PTCH. Molecular findings showed microdeletions and a microduplication involving SHH, TGIF and ZIC2 genes in five non related individuals, and three individuals presented chromosomal microrearrangements consisting in two duplications, one in a critical region harboring the SIX3 gene (2p21) and other in a region not related with HPE genes (13q14); and a third individual presented a microdeletion (8p23), which is also not associated to HPE phenotype. Because the clinical and genetic heterogeneity existing in patients with HPE and the increasing survival of these patients we concluded that these analysis are indicated in those cases where the search for mutations in main causative genes were negative providing a better tool for genetic counseling.

2705F

Maternal consumption of clay during pregnancy: an unexpected cause of recurrent congenital microcephaly with intracranial calcifications in babies from French Guyana (pseudo-Aicardi-Goutière syndrome). *A. Verloes[1], S. Passemard[1], V. Lambert[2], G. Carles[2], J. Goullé[3], A. Laquerrière[4]*. 1) Departmen,t of Genetics, Robert DEBRE University Hospital and INSERM UMR 676, Paris, France; 2) Department of Obstetrics , Regional Hospital, Saint-Laurent du Maroni, French Guyana, Fance; 3) Department of Toxicology, Rouen University Hospital, Rouen, France; 4) Department of Pathology, Rouen University Hospital, Rouen, France.

Eating clay ("pemba") during pregnancy is a traditional behavior in the Bushinengue population living on the border of the Maroni river, in the French department of Guiana. Clay consist in aluminium silicate. It is a powerful chelator of iron, and this practice (linked to traditional medicine), is responsible for a high incidence of severe anemia of pregnancy in this area. We report on two sibs born to a pemba-eater mother. The first child was born at term with IUGR severe microcephaly. Intracranial "calcifications" were observed by ultrasound screening during the second trimester. CT scan confirmed massive radio-opaque deposits in the brain basis. The clinical diagnosis of TORCH or Aicardi-Goutières syndromes were suggested initially. The child survived with major developmental delay. At age 7y, she has an OFC of 39 cm (-10 SD) and a height of 10 cm (-4SD). CSF interferon and TORCH screening were negative. Recurrence of microcephaly during the second pregnancy lead to TOP, after diagnosis of a similar microcephaly. Neuropathological examination confirmed severe microcephaly, with extensive microcalcifications dispersed throughout the brain. Electron microscopy made it possible to visualize intraneuronal aluminium silicate deposits, resembling aluminium deposition observed in post-vaccinal myofasciitis. The most likely mechanism to explain this recurrence is an association of IUGR secondary to severe maternal anemia combined with accumulation of exogenous silicates in the neural cells. This appears to be the first description of fetal brain disruption secondary to ingested clay. The syndrome superficially mimics Aicardi-Goutières syndrome, and convey a high risk of recurrence.

2706W

Cystic lymphangioma in a 9-year-old boy with Sotos syndrome: review of the tumoral risk in this overgrowth syndrome. *O. Cracco[1], G. Jedraszak[1], T. Dery[1], B. Devauchelle[2], V. Strunski[3], L. Burglen[4], .JF. Ikoli[5], B. Demeer[1], M. Mathieu[1], A. Leke[6], G. Morin[1]*. 1) Genetic department, Amiens University Hospital, Amiens, France; 2) Maxillofacial surgery, Amiens University Hospital, Amiens, France; 3) Otolaryngology, Amiens University Hospital, Amiens, France; 4) Genetic department, Trousseau Hospital, Paris, France; 5) Pathology service, Amiens University Hospital, Amiens, France; 6) Pediatric Reanimation, Amiens University Hospital, Amiens, France.

Background Overgrowth syndromes (OGS) form a heterogeneous group of disorders in which the main characteristic is a weight, height or head circumference over +2 standard deviations. Benign tumours and neoplasms are not exceptional in OGS. Sotos syndrome (SS) (OMIM 117550), one of these OGS, is characterized by cerebral gigantism, distinctive craniofacial appearance, and variable learning disabilities. Haploinsufficiency of the NSD1 gene was identified as the cause of the disorder. From its first description by Sotos in 1964, more than 25 malignancies and 10 benign tumours were reported in the approximately 500 known patients worldwide. Material and method The case of a patient with SS and cystic lymphangioma is retrospectively described. A Pubmed research crossing 'Sotos syndrome or cerebral gigantism' and 'tumour or tumor or cancer or neoplasm or malignancy' was realized. Results are reported. Case report This male patient was the third child of related healthy parents. Pregnancy was unremarkable. Delivery occurred by caesarian section at 37 weeks of amenorrhea in a context of acute foetal suffuring and umbilical cord procidence. Neonatal period was difficult with prolonged tracheal ventilation, E Coli sepsis and ulcero-necrotizing enterocolitis. In the first years of life he developed psychomotor retardation, hyperactivity, advance stature (+3SD), weight (+4SD), and macrocephaly (+2.5SD). Diagnosis of SS was made at the age of 4, and a heterozygous mutation of NSD1 gene was identified (c.3659_3660delAG / p.Glu1220AlafsX5 - Burglen L). At the age of 9 years, a subcutaneous tumour of the neck was discovered. Ultrasound examination and TDM confirmed the presence of a well delimited mixed tumour. This tumour was surgically removed and pathological examination confirmed the diagnosis of cystic lymphangioma. Discussion To our knowledge, this is the first reported case with SS and cystic lymphangioma. This association could be coincidental. However, with an approximate tumoral risk of 7% (at least 35 cases of tumours for above 500 reported cases), SS is really a tumour associating disease. Tumours are often embryonal, but various other kinds of tumours have been reported. Age at time of tumour detection varied greatly, from birth to adulthood. The tumoral predisposition in SS probably requires an attentive clinical follow-up, but the variety of tumour types and localisations makes targeted investigations difficult.

2707T

Cromosome 4 Deletions and Translocations Among 4617 Cariotype Studies at a Third Level Pediatric Mexican Hospital. 4p-, 4q-, T (1; 4), T (3; 4), Six Cases Report. *R. Zamudio[1], J.M. Aparicio-Rodriguez[2,5], M.L. Hurtado-Hernandez[3], F. Cuellar-Lopez[4], H. Chavez-Ozeki[5], S. Chatelain-Mercado[6]*. 1) Cardiology; 2) Genetics; 3) Cytogenetics; 4) Urology, Hospital para el Nino Poblano, Puebla; 5) Estomatology, Benemérita Universidad Autónoma de Puebla; 6) Biothecnology, Universidad Autónoma Metropolitana, Mexico.

Chromosome aberrations are considered changes in the chromosome number or structure. The etiology factor is due to gametogenesis inborn error (meiosis) or during the zygote first cellular divisions. It might occurs during metaphase from the cellular cycle, where DNA loses are seen (clastogenic processes) due to DNA repair processes deficiency o total absence, among others. Six genetic patients associated to chromosome 4 aberration were analyzed; three Wolf-Hirschhorn syndrome patients, a deletion of long arm 4 chromosome and two 1;4 and 3;4 chromosome translocations among 4617 Karyotype studies performed during 19 years period of time (from 1992 to 2011) at a Pediatric Hospital in Mexico. These chromosome changes are classified as structural alterations where these six patients from different families were chosen to evaluate their clinical characteristics, medical or surgical treatments according to their different genetic aberration.

Bench to bedside... The role of clinical genetics in the age of genomic medicine: The shifting paradigm. *T. Bardakjian[1], A. Slavotinek[2], A. Schneider[1]*. 1) Dept Peds/Genetics, Albert Einstein Med Ctr, Philadelphia, PA; 2) Dept. Pediatrics, Univ California, San Francisco, CA.

Advances in molecular diagnostics are catapulting genetics into all areas of medicine. The classic paradigm of clinical geneticist as dysmorphologist collecting phenotypic information to identify a syndrome or differential diagnosis and then ordering diagnostic testing is changing. New technology enables identification of gene mutations which are not associated with well-described phenotypes. While new diagnostic technologies offer great potential to provide a genetic diagnosis, when mutations are not accompanied by clinical prognosis or syndromic information the utility of the diagnosis for the patient is in question. The molecular diagnosis is not the end of the involvement of the clinical geneticist but rather a pivotal moment when genetics really becomes the key to best practices of medical care by a knowledgeable team with regular follow-up and monitoring. This paradigm shift is exemplified in the case of gene identification in the rare birth defect anophthalmia/microphthalmia (A/M). Molecular diagnosis is possible in up to 40% of individuals. Numerous eye development genes can now be tested for, but the natural history of these mutations have not been established. SOX2 as an example, was identified as a causative gene in 2005 and was termed SOX2 anophthalmia syndrome. Collection of clinical data has identified a wide variety of ocular findings and systemic issues not initially described. Testing is routinely ordered by a variety of physicians. However, there is limited knowledge of long term issues and it is not possible for most physicians to offer accurate anticipatory guidance for these patients. The A/M Registry at Einstein Medical Center Philadelphia has collected 30 cases of individuals with SOX2 syndrome. Combining these cases with others reported in the literature, the Registry has been able to develop a natural history and phenotypic spectrum to provide some guidance. It is import to note that given the infancy of this diagnosis, ongoing follow-up is essential. As more eye development genes are identified and clinical findings broaden the spectrum for each gene, the collection of clinical data over time will be critical to the provision of optimal medical care. Long term clinical and outcome data collection and analysis by clinicians is essential to accurately describe the phenotypes which correspond to identified gene mutations. This will enable more accurate genetic counseling and support for families with rare disorders.

2709W

Targeted next-generation sequencing for the molecular genetic diagnostics of mandibulofacial dysostosis. *Y. Kuroda[1], I. Ohashi[1], T. Saito[2], J. Nagai[2], K. Ida[1], T. Naruto[1], M. Masuno[3], K. Kurosawa[1].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 2) Department of Clinical Laboratory, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Genetic Counseling Program, Kawasaki University of Medical Welfare, Kurashiki, Japan.

Mandibulofacial dysostosis (MFD) is a clinically and etiologically heterogeneous group of conditions characterized by significant malar and mandibular hypoplasia. Conductive hearing loss, lower eyelid anomalies, dysplastic ears and cleft palate are frequent associated features. Although many distinct MFD have been described clinically, phenotypic overlap makes it difficult to distinguish syndromic MFD and other craniofacial conditions. Causative mutations have only been identified for syndromic MFD, including TCOF1, POLR1D, and POLR1C in Treacher Collins syndrome, DHODH in Miller syndrome, SF3B4 in Nager syndrome, and EFTUD2 in Mandibulofacial dysostosis with microcephaly (MFDM). We performed targeted next-generation sequencing for MFD. Five patient samples were sequenced by MiSeq (Illumina). DNA libraries were enriched for sequences by capture-based approach. (HaloPlex, Agilent Technologies) Amplicons were designed for mixed panel of six MFD genes (TCOF1, POLR1D, POLR1C, DHODH, SF3B4, EFTUD2) and 69 ciliopathy genes, covering all coding regions and UTRs, in total, 398,456bp. Mean depth of coverage over all samples was 336× and bases covered by at least 15 reads were 97.5% of CDS. Data were analyzed by BWA ver.6 + GATK pipeline. Calling CNV was based on log ratio and z-score of read depth on each exon. CNVs were found in two of five patients and confirmed by array CGH. No mutation considered likely to pathogenic was found in all patients in MFD genes. Patient 1 was 2-year-old boy, the first child of nonconsanguineous and healthy parents. He had esophageal atresia, bronchomalacia, external ear atresia, cleft palate, microcephaly, and mild developmental delay. He had also microtia, mandibular hypoplasia, and slightly hypoplastic zygomatic arches. NGS analysis revealed deletion of exon 16 to end in EFTUD2 gene. Array CGH (Agilent 400k) revealed 37kb deletion at 17q21.31 encompassing EFTUD2 (5' part) and qPCR confirmed the deletion. Parents had no deletion of EFTUD2 gene. The final diagnosis was MFDM. Patient 2 was older brother of siblings with mandibulofacial dysostosis. Their parents were nonconsanguineous and healthy. NGS analysis revealed deletion of all exons of POLR1D. Array CGH (Agilent 400k) revealed 470kb deletion at 13q12.1 encompassing POLR1D gene, causative gene of Treacher Collins syndrome. Targeted next-generation sequencing is an efficient approach for detecting CNVs or intragenic deletions as well as pathogenic mutations.

2710T

FATCO syndrome: Report Nine Cases in Peru and Case Review. *H. ABARCA-BARRIGA[1, 2], B. GALLARDO[1], M. TRUBNYKOVA[1].* 1) Genetic, Instituto Nacional de Salud del Niño, IIMA, LIMA, Peru; 2) Centro de Investigación de Genética Humana Wiñay.

FATCO syndrome is characterized by the presence of Fibular Aplasia, Tibial Camptomelia (tibial arched), Oligosyndactyly (finger/toes absent and union of one or more) (MIM 246570). It's describe for Hecht and Scott at 1981; but Courtens at 1985 coins the term FATCO syndrome. We present nine children evaluated at the Department of Genetics, Instituto Nacional de Salud del Niño of Peru in the last four years with clinical features of the syndrome FATCO. Seven are males and two females; none familiar background, non-consanguinity, all patients do not come from any specific region of Perú. None of patients had development delay. They have normal anthropometry. The most affected leg is the right, two patients showed upper limb malformations only. We believe that there are some genetic and environmental factors in Peru own predispose to FATCO syndrome in more frequently than in other regions. To date, eleven cases have been published worldwide, excluding the nine cases reported in this edition.

2711F

A Novel Mutation in the MASP1 Gene Causes Autosomal Recessive Multiple Congenital Anomaly Syndrome. *H. Boulos[1], Y. Bejaoui[1], N. Khattab[1], Y. Al-Sarraj[1], M. Kambouris[1,2], H. El-Shanti[1,3].* 1) Shafallah Medical Genetics Center, Doha, Qatar; 2) Yale University School of Medicine, Genetics, New Haven CT, USA; 3) University of Iowa, Pediatrics, Iowa City, IA, USA.

Three patients from two related and consanguineous sibships of Pakistani ethnic origin are affected by a recognizable pattern of multiple congenital anomalies. The clinical picture includes increased inner canthal distance, hypoplastic upper lid with ptosis, blepharophemosis, maxillary hypoplasia, facial asymmetry, cleft lip/palate, high arched palate, irregular dentition, low set ears and low posterior hairline, mild scoliosis and decreased carrying angle of elbow. The apparent clinical characteristics overlap, but do not identify solely, with the individual Malpuech, Michels, Mingarelli or Carnevale syndromes, or what has been collectively referred to as the 3MC syndrome; hence, the referral to the phenotype as Multiple Congenital Anomaly syndrome. The family was studied by homozygosity mapping, and Whole Exome Sequencing of a single affected individual performed on ABI SOLiD4. A novel homozygous mutation [c.G542A] affecting the evolutionary conserved residue p.C181Y was identified at 3q27 in the MASP1 encoding a mannose-associated serine protease 1. The variant was confirmed by Sanger sequencing, segregates with the phenotype in the family and is predicted to be damaging by PolyPhen and SIFT. MASP1 functions as a component of the lectin pathway of complement activation. Mutations in the MASP1 gene and another gene (COLEC11) involved in the same pathway have been associated with human craniofacial malformation indicating an impending role for complement pathway elements in vital developmental processes during embryogenesis. The identified autosomal recessive variant extends further support to this hypothesis.

2712W

Diagnostic Criteria in Gomez-Lopez-Hernandez Syndrome: Contribution of brazilian patients. *C.H.P. GRANGEIRO[1], L.B. MESQUITA[1], J.A. JOSAHKIAN[1], C.M. LEVEPROST[1], M.L.M. CASTRO[1], N.R. QUARE-SEMIN[1], L.A.F. LAUREANO[2], A.C. SANTOS[4], J.M. PINA-NETO[1,3].* 1) 1 Serviço de Genética Médica - Hospital das Clínicas da Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 2) Laboratório de Citogenética - Hospital Das Clínicas da Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 3) Departamento de Genética - Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 4) Divisão de Radiologia do Departamento de Clínica Médica da Faculdade de Medicina de Ribeirão Preto da Universidade de São Paulo, Centro de Ciências das Imagens e Física Médica.

Gomez-Lopez-Hernandez syndrome (GLHS) or cerebello-trigeminal-dermal dysplasia is a rare neurocutaneous disorder (so far, 34 sporadic cases have been reported), whose etiology is unknown. It is characterized by the triad of rhombencephalosynasis (RES), trigeminal anesthesia (TA) and bilateral scalp alopecia (SA). Based on the description of new patients and other clinical findings, subsequent reported cases have expanded the spectrum of craniofacial, neurobehavioral and cognitive phenotype. According to data, rhombencephalosynasis and bilateral scalp alopecia constitute obligate criteria. Brachycephaly/turribrachycephaly and midface retrusion are major craniofacial criteria. Strabismus, widely spaced eyes, plagiocephaly and lambdoid craniosynostosis are minor craniofacial ones. Motor delay, ataxia, hypotonia, intellectual disability and head shaking or other stereotypic movement are the neurological criteria. After identifying a new patient with GLHS in our service, totaling seven patients (20% of all cases worldwide), we decided to characterize our patients according to the proposed standard criteria and propose some adjustments. Our sample consists of 7 sporadic cases, 4 boys and 3 girls, one of them born from consanguineous parents (second cousins). The G-banding karyotypes were normal. We believe that trigeminal anesthesia must be considered a mandatory criteria since, not only all patients have this finding, they also had corneal opacity (a complication). All our patients presented broad forehead, upslanting palpebral fissures and low-set ears so major craniofacial criteria must include these dysmorphic features. Prognathism and post natal short stature should also be considered minor criteria. Neurological findings in our sample are consistent with the literature, including intellectual disability in variable degrees. We did not evaluate the presence of stereotyped head movements. Diagnostic criteria are essential for clinical reasoning construction, search of new patients and discovery of etiologic factors, especially in disorders which underlying mechanisms are not yet known.

2713T

New syndrome: brain malformations, Peters anomaly and multiple intestinal atresias. *J.G. Pappas[1], A.L. Shanske[2].* 1) Dept Pediatrics, Clin Genetic Scvs, New York Univ, Sch Med, New York, NY; 2) Children's Hospital at Montefiore, Albert Einstein College of Medicine, Bronx, NY (retired).

We present a newborn girl with brain malformations, bilateral Peters anomaly and multiple intestinal atresias and we compare this case with the only other similarly affected case reported in the medical literature (Shanske AL et al, 2002). Our case was born at 31.3 weeks vaginally without complications to a 34yo primigravida mother who was prenatally followed for mild fetal ventriculomegaly. The family history was not significant. Our clinical examination revealed weight, length and head circumference at about the 50% for gestational age. She had short palpebral fissures, two skin tags in place of the left tragus, a skin tag on the left cheek, corneal opacities and normal tone and activity. Feeding intolerance prompted an abdominal x-ray that suggested proximal jejunal atresia. Exploratory laparotomy revealed proximal jejunal atresia 5 cm distal to the ligament of Treitz, multiple discrete atretic segments of jejunum, a 5 cm segment of atretic distal ileum, and colonic atresia in the mid transverse colon. The atretic segments were resected, a mucous fistula constructed, and a gastrostomy tube placed. Brain MRI demonstrated bilateral schizencephaly communicating with large biparietal extra-axial cysts, partial absence of corpus callosum, ventriculomegaly, small areas of polymicrogyria and generally immature sulcation and myelination pattern for age. Ophthalmology concluded that the corneal opacities were part of Peters anomaly. Whole genome chromosome SNP microarray using the Affymetrix Cytoscan HD platform was reported normal. DNA sequence test of the exons, flanking regions and exon-intron boundaries of the *B3GALTL* gene to evaluate for Peters Plus syndrome revealed no mutations. Seizures started on day 12, and episodes of respiratory depression and bradycardia on day 19. She expired on day 20. Shanske AL et al, 2002 described a male newborn with extensive neuronal migration defect, bilateral Peters anomaly, multiple stenotic and atretic lesions in the jejunum and normal karyotype. At 21 months, he was severely microcephalic and developmentally delayed. The authors concluded that the abnormalities were due to a vascular disruption sequence. Both our case and the case reported in the medical literature present with migration defects, bilateral Peters anomaly and multiple intestinal atresias. This phenotype does not fit a recognizable pattern of malformation and we suggest that it may represent a new syndrome.

2714F

Richieri-Costa and Pereira Syndrome: severe phenotype. *S. RASKIN[1,2], M. SOUZA[3], M.C. MEDEIROS[3], M. MANFRON[2], DC. CHONG E SILVA[2].* 1) Group for Advanced Molecular Investigation, Graduate Program in Health Science, Health and Biosciences School, Pontifícia Universidade Católica do Paraná (PUCPR), Curitiba, Parana, Brazil; 2) Hospital Pequeno Príncipe, Curitiba, Parana, Brazil; 3) Health and Biosciences School, Pontifícia Universidade Católica do Paraná (PUCPR), Curitiba, Parana, Brazil.

Richieri-Costa/Pereira syndrome (RCPS, OMIM 268305) is a rare autosomal recessive disorder characterized by short stature, Robin sequence (micrognathia, glossoptosis, and cleft palate), cleft mandible and limb malformations. We report on a new case with a very severe phenotype. The patient was the first born of a 1st cousin consanguineous marriage, with no familial history of genetic disorders. Prenatal care and ultrasound exams showed no fetal morphological alterations. Delivery was at 38.5 weeks of gestation, the infant weighed 2,805 g, was 44 cm long, with a OFC of 31 cm and an Apgar score of 5 at 1 and 5 minutes, respectively. Malformations included: radial dysgenesis and finger anomalies, club feet, short limbs, toe anomalies, micrognathia, thoraccic deformity with severe sterno-clavicular chondral bilateral dysfunction, fatty hyperplasia of the anterior and posterior surface of the neck, webbed neck, low-set ears, ear deformities, and cranio-facial pansynostosis evolving to craniosynostosis. He had prolapse of base of tongue over the larynx and agenesis of the epiglottis; facial CT scan showed mandibular agenesis and deviated nasal septum. Limb radiographs showed radial agenesis, hypoplastic ulna, malformations of hands and fingers, hyperplasia of the tibia, agenesis of fibulae and toe deformities. Tube feeding was necessary from the time of birth, due to anomalies of the air ways. Three-dimensional CAT scan showed agenesis of the anterior mandible arch and epiglottis. Cranial CAT scan showed prominence of extra-axial space of the frontal convexity. Alterations were observed in skull formation with overriding of lambdoid sutures. To the present, 32 Brazilian and one non-Brazilian case have been described, with a great variability in the expression, but none reported the same degree of severity as the present case. Absence of Robin sequence and cleft mandible have been previously reported in several cases, but their absence particularly in a patient with a severe phenotype is unexpected. The recent finding of a causative genetic alteration at the 5̀ UTR of the EIF4AE gene as the mutation leading to RCPS may generate information on the variability of expression and further elucidate the basis of severe phenotypes such as that reported in the present study.

Goldenhar syndrome (GS), also known as oculo-auriculo-vertebral syndrome, is a congenital defect from anomalous development of first and second branchial arches. Its etiology includes unknown genetic factors, different chromosome aberrations and environmental factors, like maternal vasoactive medication, thalidomide and maternal diabetes. Several candidate genes have been proposed but none have been confirmed as causative of the phenotype. It's a disease with genetic heterogeneity and variable expressivity, commonly underdiagnosed. The majority of cases are sporadic so an environmental contribution to the phenotype cannot be excluded. Only a few familial cases have been reported so far. We studied a large family with GS, with three patients presenting classic signs of Goldenhar syndrome such as facial asymmetry, hemifacial microssomia, microtia or anotia and pre-auricular tags. Other family members exhibited mild malformations: mild facial asymmetry, hyperfolded ear helix and pre-auricular pits. These signs though common in the normal population when observed in family members of Goldenhar syndrome patients may be indicative of an inherited form of the syndrome. Financial support: CAPES, FAPDF/PPSUS.

Wiedemann-Beckwith syndrome associated with pre- and postnatal supraventricular tachycardia. *M. Willems[1], F. Brioude[2], S. Guillaumont[3], P. Amedro[3], M. Vincenti[3], O. Pidoux[5], N. Fries[4], L. Begue[4], C. Dumont[4], P. Sarda[1], P. Blanchet[1], L. Pinson[1], E. Haquet[1], J. Puechberty[1], G. Lefort[1], C. Coubes[1], I. Netchine[2], D. Genevieve[1].* 1) Genetics Dept, INSERM U844, Hopital Arnaud de Villeneuve, Montpellier, cedex 5, France; 2) Explorations Fonctionnelles Endocriniennes, Hopital Armand Trousseau, Paris, cedex 12, France; 3) Service de Cardiopédiatrie, hopital Arnaud de Villeneuve, Montpllier, cedex 5, France; 4) Service de Gynécologie Obstetrique, hopital Arnaud de Villeneuve, Montpellier, France; 5) Service de Pédiatrie et Néonatalogie, hopital Arnaud de Villeneuve, Montpellier, cedex 5, France.

We describe a baby who has Wiedemann Beckwith syndrome due to ICR2 (CDKN1C/KCNQ1OT) loss of methylation, associated with severe fetal and postnatal supraventricular tachycardia. The patient is the third child born from unrelated parents after in vitro fertilization with donor sperm. It was a bichorial biamniotic pregnancy with an early vanishing twin. Prenatal ultrasound screening at 14 WG revealed an omphalocele, leading to perform an amniocentesis. Karyotype analysis was normal. At 29WG, the mother was referred to the Genetic Department for the association of fetal macrosomia, macrostomia, nephromegalia, hepatomegalia and hydramnios. Wiedemann-Beckwith syndrome was suspected. At 30 WG, fetal supraventricular tachycardia was identified, requiring a maternal treatment with flecainide during late pregnancy. Diagnosis of Wiedemann Beckwith was confirmed at birth by clinical features and identification of an isolated ICR2 loss of methylation. Echocardiography was normal but supraventricular tachycardia recurred, requiring a treatment with digoxin and amiodaron which is ongoing at four months of age. Ectopic atrial tachycardia was reported only in two patients with Wiedemann Beckwith syndrome in 1985, associated with a focal cardiomyopathy. Conversely, a few patients with Wiedemann-Beckwith syndrome have congenital long QT associated with KCNQ1 expression defect but pathophysiology of these rhythmic troubles are unrelated. Fetal supraventricular tachycardia occurs in less than 1/2000 pregnancies. It can be associated with structural abnormalities of the heart or isolated. Two thirds of all patients with prenatal tachycardia will develop postnatal arrhythmia. We think that infraclinical focal cardiomyopathy could explain this rare but recurrent complication of Wiedemann-Beckwith syndrome.

Amyoplasia with congenital eye malformations and wrinkled skin: a new syndrome.
D.F.G.J. Wolthuis[1], E.V. van Asbeck[1], H.C. Andersson[2], E. Morava-Kozicz, MD, PhD[1,2]. 1) Pediatrics, Radboud University Nijmegen Medical Centre, Nijmegen, Gelderland, Netherlands; 2) Human Genetics, Tulane School of Medicine, New Orleans, LA.

Amyoplasia is characterized by the congenital absence of muscle tissue, and the most common underlying condition in arthrogryposis multiplex congenita. Patients present with typical symmetrical contractures, including internal rotation of the shoulder, extension of the elbow, flexion of wrists and hands, equinovarus feet and variable contractures of knees and hips with additional supra-articular dimples. Midline hemangiomas are also a common. All published amyoplasia cases are sporadic. Compared to the genetically heterogeneous distal arthrogryposis (DA) syndromes, no associated organ malformations have been described in amyoplasia patients. DA syndromes describe conditions of contractures in 2 or more body parts in the absence of a primary neurologic or muscular disease. We evaluated 2 patients diagnosed with muscle biopsy and imaging-proven amyoplasia in combination with unusual symptoms. Both patients showed eye abnormalities in addition to absent muscle: patient 1 had macular abnormalities and patient 2 had cataract. Feeding problems were present in both patients as well as spontaneous bone fractures, excessive skin in the nuchal region and typical facial features. Patient 1 also had diaphragmatic paresis. Amyoplasia has never been described in combination with eye abnormalities in the medical literature. However, retinal abnormalities are a feature that is commonly seen in DA, especially in type 5 and 5D. In DA5D a genetic defect was identified in *ECEL1*, encoding endothelin-converting enzyme-like 1. Mutation in this endopeptidase leads to reduced terminal branching of motor neurons resulting in decreased development of neuromuscular junctions, which was ruled out in our patients. The underlying pathomechanism in amyoplasia has not yet been discovered. Infectious and autoimmune causes, muscle dystrophy, spinal motor neuropathy and congenital disorders of glycosylation, affecting both muscle and eye development, were ruled out in our patients. Immune histology of extracellular matrix components, however, was abnormal. We suspect the role of genetic factors, like genes involved in collagen synthesis, affecting the extracellular matrix, and development of both the muscle tissue and eye structures, underlying the unique phenotype in our patients.

The contribution of discrepant DNA variations in discordant monozygotic twins with Esophageal Atresia/ Tracheo-esophageal Fistula.
E. Brosens[1,2], R.W.W. Brouwer[3], D. Veenma[1,2], D. Tibboel[1], W.F. van IJcken[3], A. de Klein[2]. 1) Pediatric Surgery, Erasmus MC-Sophia, Rotterdam, Zuid-Holland, Netherlands; 2) Clinical Genetics, Erasmus MC-Sophia, Rotterdam, Zuid-Holland, Netherlands; 3) Centre for Biomics, Department of Cell Biology, Erasmus MC, Rotterdam, Zuid-Holland, Netherlands.

Esophageal Atresia with/or without Trachea-esophageal Fistula (EA/TEF) is a congenital anomaly that can either be present as isolated anomaly or in association with other birth defects. EA/TEF is believed to have a multifactor etiology, is associated with known (genetic) syndromes and can occur in combination with specific chromosomal aberrations, Copy Number Variations (CNV) or mutations. Although suspected, there is not much known about the genetic factors underlying EA/TEF. Twin studies can help to find potential causal or predisposing genetic factors of a disease. Monozygotic (MZ) twins typically share their genetic content and environment during development. We hypothesize that de novo mutations arisen early in embryonic development could explain the discordant phenotypes found in MZ twins. In order to detect these, complete or mosaic, DNA discrepancies six Monozygotic Twins (MZ) discordant for EA/TEF were characterized with SNP array and Exome-NGS. Hundreds discrepant SNPs and InDels were revealed using SNP-array genotyping and exome-NGS. Visual inspection of these events with Illumina's Genomestudio and the integrated genome viewer (IGV) indicated that most discrepancies were actually false positive differences caused by technical limitations, analysis settings (thresholding) and/or limitations of the variant calling. We compared the results obtained with multiple exome capturing techniques (Agilent Human 50 Mb All Exome v2, v4 and HaloPlex Exome), and analysis pipelines (GATK, CLC-bio read-mapper, CLC-bio®, SAMtools mpileup) and down-stream analysis strategies (CLC-bio® reference filter, an in-house developed comparison tool, Cartagenia®, Ingenuity® Variant Analysis) to determine if we could distinguish these false positive differences from actual discordant variants. Currently, we are evaluating whether these remaining discrepancies are true differences and could contribute to the disconcordant phenotype.

A case with single deletion of 17q21.31 involving KANSL1 gene and phenotype of CHARGE association.
ym. chan[1], kw. choy[1], ty. leung[1], ca. bacino[2]. 1) Obstetrics and Gynaecology, The Chinese University of Hong Kong, Hong Kong , Hong Kong; 2) Department of Molecular and Human Genetics Baylor College of Medicine.

We describe a single case with prenatal ultrasound showing increased fetal nuchal translucency and features suggestive for CHARGE association with a small deletion in 17q21.31 involving the KANSL1 gene. On routine first trimester screening ultrasonography performed at 13 weeks of gestation, nuchal translucency was increased to 4.53mm. Chorionic villi sampling was performed. Conventional karyotype was normal. Array CGH detected 573kb single deletion at 17q21.31 involving the KANSL1 gene region, but not included other genes like MAPT and CRHR1. The clinical significance of the deletion at this region was not well known at that juncture. Anomaly scan was unremarkable. Multiple abnormalities were noted after delivery including bilateral membranous choanal atresia, bilateral coloboma involving fovea and optic nerve, bilateral malformed pinna with bilateral severe-profound hearing loss, patent ductus arteriosis compatible with CHARGE association. CHD7 sequencing analysis was normal with no CHD7 mutation identified. Patients with KANSL1 related intellectual disability may present with dysmorphgic features resemble those seen in CHARGE association. However, no reports of choanal atresia or colobomas were previously reported so this is the first report for these malformations in a patient with a KANSL1-related intellectual disability deletion.

Femoral-facial syndrome: long term follow-up and associated array CGH abnormalities.
A. Jacquinet[1], H. Valdes-Socin[2], C. Libioulle[1], J.H. Caberg[1], A. Verloes[1,3]. 1) Center for Human Genetics, CHU & University of Liège, Liège, Belgium; 2) Department of Endocrinology, CHU & University of Liège, Liège, Belgium; 3) Department of Medical Genetics and INSERM U676, APHP-Robert Debré University Hospital, Paris, France.

The femoral-facial syndrome is usually sporadic and its aetiology remains unknown. Non-genetic factors as maternal diabetes mellitus have been associated. Reports of familial cases have otherwise suggested autosomal dominant inheritance. We report the 20 years clinical follow-up of a girl with femoral-facial syndrome diagnosed at birth. Recently, array CGH investigation identified a 1400 kb duplication at 9q31.1, including the gene SMC2, and a 343 kb deletion at 12q24.33 including the genes CHFR, ZNF26, ZNF140, ZNF10 and ZNF268. Moreover, the patient presents a Mayer-Rokitansky-Kuster-Hauser syndrome diagnosed at puberty. Femoral-facial syndrome and Mullerian agenesis may reflect different defects in the primary axial mesodermal development, being the consequences of same environmental or/and genetic factors during blastogenesis. Among these genetic factors, we suggest the possible involvement of the two copy number variants reported here.

Identification of Mosaic Activating Mutations in Overgrowth Syndromes Using a Customized Next Generation Sequencing Panel on both Prenatal and Postnatal Samples. *L. Liu[1], F. Chang[1], E. Fang[1], G. Zhang[1], M.M. Li[1,2].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dan Duncan Cancer Center, Baylor College of Medicine, Houston, TX.

Overgrowth Syndromes are genetically heterogeneous diseases caused by both germline and somatic mutations of different genes. Recent studies have showed that a group of overgrowth syndromes, such as CLOVES and Proteus syndromes, are caused by postzygotic activating mutations in the genes involved in the PI3K-AKT signaling pathway, such as PIK3CA and AKT1. In addition, both germline and somatic mutations of PI3K-AKT pathway genes have been reported in two overlapping disorders, megalencephaly-polymicrogyria-polydactyly-hydrocephalus (MPPH) and megalencephaly-capillary malformation (MCAP). Non-syndromic overgrowth features, such as isolated macrodactyly, have also been reported to be associated with PIK3CA mutations. Due to the low-abundance nature of these mutations, routine Sanger sequencing often yields negative results. We developed a next generation sequencing (NGS) test that targets all known mutations in multiple genes involved in the PI3K-AKT pathway. For differential diagnosis purposes, we also included a few other genes associated with overgrowth syndromes, such as PTEN and GNAS. Four patients including two prenatal cases, an amniotic fluid and a POC samples, and two postnatal cases suspected of CLOVES or Proteus syndromes were tested in our laboratory using the NGS panel. All four cases are positive for PIK3CA somatic mutations including one G542K, one H1047L, and two H1047R. These mutations are only present in the affected tissues. In the amniotic fluid case, the G542K mutation is positive in the DNA extracted from cultured amniocytes but negative in uncultured fluid of the same specimen. These results suggest that the mutant allele is present in the direct amniotic fluid sample at a very low frequency beyond the detection limit of the test. The activating mutation may render growth advantages to the cells carrying the mutation in culture, resulting in the enrichment of mutant allele. To the best of our knowledge, this is the first case of prenatal diagnosis of CLOVES syndrome. Our experience demonstrates that cultured amniocytes can be used for prenatal diagnosis of these overgrowth syndromes. In summary, the custom-designed NGS panel shows high accuracy and sensitivity for the detection of causal mutations in the overgrowth syndromes and facilitates clinical diagnosis both prenatally and postnatally.
