Background: Congenital heart diseases (CHDs) usually refer to abnormalities in the heart's structure or function that arise before birth. Although the exact mechanism behind this cardiac abnormality is not known, transcription factors play an important role in embryonic heart development. GATA4 is one of the candidate transcription factors and GATA4 mutation may leads to different types of CHD such as ASD, VSD, TOF and Single ventricle (SV). The aim of this study is to find the genetic association of CHD with GATA4 mutations from south Indian CHD patients. Method: GATA4 gene was genotyped in 100 CHD patients (ASD, VSD, TOF and SV) and 200 control samples in a case control study using sangers di-deoxy chain terminator cycle sequencing. Genotyping and mutational analysis was carried out with DNA star software. Functional significance of the GATA4 mutation was analyzed by in-silico software like polyphen, Sift, Pmut and other bioinformatics tools. Results: In this study we identified one 5' UTR (ptomoter region -490 to 100 bp) mutation i.e., 620 C>T(rs61277615 ,p>0.0007) and two coding region mutations i.e., c.1734 C>A (Pro394Thr) and c.1827 G>A (Asp425Asn). We also found five 3'UTR mutations i.e., 2400 T>C(rs884662), 2415 T>C(rs904018), 2470 A>G(rs804291), 2446 C>G (rs12825), 3139 A>T (rs12458). All mutation present in the CHD patients are absent in 200 healthy volunteers. Our 'In silico' data also provide evidence that all mutations reported above are pathological or alter the gene expression through micro RNA binding. Conclusion: The present study found that GATA4 genetic variations are associated with CHD in South Indian patients. Our bioinformatics study provide further evidence that those GATA4 mutations observed in Indian patients mutations may alter the function of the transcription factor binding and micro RNA binding , may leads to disease.

2723F

Trying to unravel the etiology of multiple midline congenital anomalies misdiagnosed as VACTERL. *E.M. Pereira[1], M.P. Ramos[2], J.M. Greally[2], R.W. Marion[1].* 1) Division of Medical Genetics, Department of Pediatrics, Children's Hospital at Montefiore, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; 2) Division of Computational Genetics, Department of Genetics, Albert Einstein College of Medicine, Bronx, NY.

A 13 year old girl presented to genetics clinic with a diagnosis of VACTERL. She was the product of a Mexican union with a nonsignificant family history. The patient was noted to have esophageal atresia at birth. In childhood, her medical condition was complicated by right kidney reflux which required nephrectomy. She developed scoliosis though there were no vertebral anomlies; surgical correction was necessary to correct the spinal curvature. The patient was never found to have cardiac or limb abnormalities. She was in stable condition until a few months prior to presentation when she had several days of hematuria. A pelvic MRI showed a malformed, dilated uterus, an atretic/absent vagina, and a cystic structure that may represent a portion of the cervix; her ovaries were structurally normal. The patient has no cognitive defects and does exceptionally well in school.

Though the patient was originally given a diagnosis of VACTERL, her multiple congenital anomalies do not fit clinical criteria for this association. Mayer-Pokitansky-Küster-Hauser syndrome can lead to absence of the vagina and uterus in the most extreme cases, but it would not explain the rest of her abnormalities. Interestingly, the patient has many midline defects from various embryological origins.

The patient's multiple congenital anomalies warranted a microarray. The results revealed a 0.91 Mb duplication at chromosome 6q11.1 (61,971,892 - 62,877,253) of unknown significance. Two genes in the area, KHDRBS2 and MTRNR2L9, have not been associated with any of the abnormalities seen in the patient. Given her unique combination of congenital anomalies, our division selected this patient for whole exome sequencing. Results are currently pending.

2724W

Associated malformations among patients with urinary congenital anomalies. *C. Stoll, B. Dott, Y. Alembik, MP. Roth.* Faculte de Medecine, Strasbourg, France.

Infants with urinary congenital anomalies (UCA) often have other associated malformations. The purpose of this investigation was to assess the prevalence and the types of associated malformations in children with UCA in a defined population. The associated malformations in infants with UCA were collected in all livebirths, stillbirths and terminations of pregnancy during 26 years in 347,810 consecutive births in the area covered by our population based registry of congenital malformations. Of the 1703 infants with UCA born during this period, 563 (33 %) had associated malformations. There were 119 (7%) patients with chromosomal abnormalities including 33 trisomies 18, and 168 (10%) nonchromosomal recognized dysmorphic conditions. There were no predominant recognised dysmorphic conditions, but VA(C)TER(L) association, Meckel-Gruber syndrome, and prune-belly syndrome . Two hundred seventy six (16 %) of the patients had multiple congenital anomalies, non syndromic, non chromosomal (MCA). Malformations in the musculoskeletal, the digestive, and the cardiovascular, and the central nervous systems were the most common other malformations. Prenatal diagnosis was performed in 70 % of the fetuses with UCA. The molecular basis of UCA remains unknown. However, mutations of certain genes have been associated with UCA including HNF1 beta, GDNF, RET, TCF2, PAX2, EYA1, SIX1, SIX2, SIX5, AGT, REN, ACE, AGTR1, BMP4, UPIIIA, FRAS1, FREM1, ROBO2, SOX17, HPSE2, CHRM3, and SALL1.The overall prevalence of associated malformations, which was one in three infants, emphasizes the need for a thorough investigation of infants with UCA. A routine screening for other malformations may be considered i infants and in fetuses with UCA.

A new case of Crane-Heise syndrome with comparative review of literature. *A. Handel[1], K. Fay[1], M. Costaldi[2], R. Lebel[1].* 1) SUNY Upstate Medical University, Syracuse, NY; 2) Pathology Associates of Syracuse, Crouse Hospital, Syracuse, NY.

Crane-Heise syndrome is a lethal constellation of dysmorphic features described in only 9 cases (first reported in 1981). The syndrome is notable for 1) poorly mineralized calvarium, 2) facial anomalies including cleft lip, cleft palate, low-set ears, hypertelorism, and 3) skeletal abnormalities including dysplastic clavicles, vertebral anomalies, and talipes equinovarus. We present the tenth case of this syndrome. The G4P2012>2022 Caucasian 35-year-old woman had one ectopic pregnancy and two surviving daughters; one said to be affected by autism and seizures, the other by ADHD and Asperger syndrome. Ultrasound at 7 weeks provided gestational dating. Repeat ultrasound at 13 weeks revealed gastroschisis, scoliosis, dangling choroid plexus, and left clubbed foot. Ultrasound at 16 weeks confirmed those observations and added cleft lip and palate, and bilateral ventriculomegaly. Amniocentesis revealed a 46,XX karyotype and normal oligo-microarray. Alpha-fetoprotein was elevated with a faintly positive acetylcholinesterase band. Ultrasound at 21 weeks showed fetal demise, apparently three weeks earlier by measurements, and delivery was induced. Autopsy revealed many features seen in Crane-Heise syndrome: markedly under-mineralized calvarium, cleft lip, cleft palate, hypertelorism, soft tissue syndactyly of one hand, low-set ears, and left clubbed foot. Our patient also had a large gastroschisis with extracorporeal viscera; abdominal wall defects have been described in 2 of the 9 previous cases. The patient had renal hypoplasia, not described in previous cases. There was also scoliosis, a narrow thorax, and markedly hypoplastic lungs (each described in only one previous case). Features commonly reported in the previous cases, but absent in the present case are: IUGR, agenesis of vertebral bodies, micrognathia, absent corpus callosum, absent pubic bone, cardiac abnormalities, and hypoplasia of phalanges. This fetus had findings that did not fit together unless one considers very rare syndromes. London Morphology Database offered Crane-Heise syndrome as a strong candidate. We propose that Crane-Heise syndrome should be considered in the differential diagnosis for prenatally discovered gastroschisis. There is strong evidence that this syndrome has autosomal recessive etiology, and our case does not contradict that hypothesis.

2726F

Pathogenic CNVs and causative gene analysis by SNP arrays as the third screening for 646 patients with intellectual disability and multiple congenital anomalies of unknown etiology. *D.T. Uehara, S. Hayashi, J. Inazawa.* Department of Molecular Cytogenetics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan.

In order to identify genetic factors responsible for congenital disorders of unknown etiology in the Japanese population, we have investigated 646 subjects presenting with clinically uncharacterized multiple congenital anomalies and intellectual disability for eight years. We first performed a two-stage screening using two types of in-house bacterial artificial chromosome (BAC)-based arrays, which have allowed the identification of pathogenic copy number variants (CNVs) in 130 cases (20%). Next, we performed a third screening in 432 negative cases using a single nucleotide polymorphism (SNP) arrays platform (Illumina HumanOmniExpress BeadChips) to identify smaller causative CNVs undetected in the previous screenings. Besides the high resolution, this type of array has an additional advantage of detecting uniparental disomy (UPD) through the analysis of copy-neutral loss of heterozygosity (LOH). A preliminary analysis of the results revealed around 10% of the cases with CNVs comprising known pathogenic genes, for example, a deletion in the NRXN1 gene. So far, we have identified five cases with possible pathogenic CNVs that might reveal novel candidate genes for intellectual disability, and one case with uniparental disomy affecting chromosome 20. We are currently focusing on these cases by carrying out functional analyses, and we also plan to further elucidate the mechanisms that originated these rearrangements. Our goal is to finally determine the causative genes delineating these pathologies through a reliable correlation between genotype and phenotype.

The oculoauriculovertebral spectrum: refining the estimate of birth prevalence. *M.T. Gabbett.* Genetic Health Queensland, Royal Brisbane & Women's Hospital, Herston, Queensland, Australia.

The oculoauriculovertebral spectrum (OAVS) is a pattern of congenital malformations characterized by hemifacial microsomia and/or auricular dysplasia. However, the birth prevalence of OAVS is poorly characterized. Figures ranging from 1 in 150,000 through to 1 in 5,600 can be found in the literature. This study aims to evaluate the reasons behind such discrepant figures and to refine the estimated birth prevalence of OAVS. Published reports on the incidence and prevalence of OAVS were systematically sought after. This evidence was critically reviewed. Data from appropriate studies was amalgamated to refine the estimate of the birth prevalence for OAVS. Two main reasons were identified why birth prevalence figures for OAVS are so highly discrepant: differing methods of case ascertainment and the lack of a formal definition for OAVS. This study refines the estimate of birth prevalence for OAVS to between 1 in 40,000 and 1 in 30,000. This number needs to be confirmed in a prospective study using a formally agreed-upon definition for OAVS.

Initial data for benign CNVs distribution in Bulgarian patients. *S.P. Hadzhidekova[1], D.M. Avdjieva-Tzavella[2], B.B. Rukova[1], D.V. Nesheva[1], R.S. Tincheva[2], D.I. Toncheva[1].* 1) Medical Genetics, Medical University - Sofia, Sofia, Sofia, Bulgaria; 2) Section of Clinical Genetics, State University Pediatrics Hospital 'Queen Evdokia', Medical Faculty, Medical University-Sofia, bul. 'Iv. Geshov' 11, Sofia 1660, Bulgaria.

Introduction: Molecular karyotyping is coming up as an extremely suitable method for genetic diagnosis of patients with unclear dysmorphic syndromes and intellectual disability. In this study we present our results from microarray analysis of 52 patients with developmental delay and congenital malformations. Methods: Oligo array-CGH (BlueGnome CytoChip oligo 2× 10^5K, v1.1, 35kbp backbone resolution) was applied in 52 patients with developmental delay and multiple congenital anomalies. Results: A total of 247 CNVs were detected, of which 15 pathogenic, 108 with unknown clinical significance and 124 benign - mean number of CNVs per patient - 4,5. All pathological findings were validated by FISH analysis. In addition, the majority of the patients tested (41 patients) showed normal variations in the number of copies and variations of unknown clinical significance (34 patients). Analyses of the type and distribution of the different variations was performed and the clinical significance of variants of unknown nature was discussed. Conclusion: Our results show the advantages of high resolution microarrays for clinical diagnosis of patients with intellectual disability and congenital malformations, but also highlight the need for extensive population studies revealing the molecular nature and clinical significance of different CNVs and the necessitate for creation of detailed maps of variations in the Bulgarian population. This would facilitate the interpretation of unknown genomic imbalances in clinical aspect. Besides, it would help the widespread introduction of CGH microarray in diagnostic practices - postnatal and prenatal genetic diagnosis. Novel autosomal-recessive syndrome with short stature, distinct facial appearance, myopia, retinitis pigmentosa, bilateral hearing loss, and mild intellectual disability. *E. Schrock[1], T.M. Neuhann[2], I. Neuhann[3], A. Bier[4], B. Novotna[5], N. Di Donato[1].* 1) Institut fuer Klinische Genetik, Medizinische Fakultaet Carl Gustav Carus, Technische Universitaet Dresden, Germany; 2) Medizinisch Genetisches Zentrum, Munich, Germany; 3) MVZ Prof. Neuhann, Munich, Germany; 4) Gemeinschaftspraxis fuer Humangenetik, Dresden, Germany; 5) Sozialpaediatrisches Zentrum am Universitaetsklinikum Carl Gustav Carus, Dresden, Germany.

Retinal anomalies in combination with progressive hearing loss accompany a variety of genetic syndromes. We report here on three patients with retinitis pigmentosa, bilateral hearing loss, peculiar facial phenotype and an unusual combination of other clinical findings incompatible with any of the known genetic conditions. Patient 1 (3 years) presented with short stature (-2, 5 SDS), distinct combination of minor facial anomalies (prominent forehead, short palpebral fissures, deep-set eyes, bulbous nasal tip with broad columella, thin upper lip with accentuated cupid's bow), brachydactyly, high myopia (-3dp) and progressive bilateral hearing loss. Her motor development is mildly delayed. Patient 2 (40 years) is the paternal aunt of patient 1. Her brother, the father of patient 1, is unaffected. Like her niece patient 2 shows a short stature (-3, 5 SDS), brachydactyly and strikingly similar facial anomalies. She has progressive bilateral hearing loss with deafness at the age of 35 years. The complex eye involvement includes progressive myopia, retinitis pigmentosa (onset in the 2nd decade), glaucoma and corneal dystrophy (both started in the 4th decade). Patient 2 attended a regular school but needs support in her daily life. Both patients have normal findings in their brain MRI. Patient 3 (28 years) is a male patient, not related to patients 1 and 2. His family history is unremarkable. He presented with short stature, brachydactyly, progressive bilateral hearing loss, high myopia and retinitis pigmentosa (onset in the 2nd decade). His facial minor anomalies are remarkably identical to patients 1 and 2. The only additional clinical finding not present in the first family is alopecia areata of the scalp. Patient 3 shows mild intellectual disability. Comprehensive genetic tests (conventional and molecular karyotyping in all patients; sequencing of LTBP2, ADAMSTS17 and ADAMTS10 in patient 2, and ERCC8 and ERCC6 in patient 3) were all normal. Taken together we report on an apparently new genetic syndrome associated with short stature, distinct facial anomalies, myopia, retinitis pigmentosa, progressive hearing loss and mild intellectual disability. Based on the pedigrees we suggest an autosomal recessive inheritance. This condition is distinctive from Usher syndrome and from Weill-Marchesani syndrome. Exome sequencing is ongoing to clarify the molecular cause of the disease.

2730W

The use of exome sequencing to disentangle complex phenotypes. *H.J. Williams[1], C. Baccheli[1], J. Hurst[2], F. Lescai[1], L. Ocaka[1], C. James[1], C. Pao[3], E. Rosser[4], P. Beales[1].* 1) The Centre for Translational Genomics - GOSgene, Institute of Child Health, UCL, London, UK; 2) Royal Free Campus, UCL Medical School. London, UK; 3) Respiratory and General Paediatrics, Barts and The London Children's Hospital, London, UK; 4) Clinical Genetic, Great Ormond Street Hospital, London, UK.

The success of whole-exome sequencing (WES) to identify mutations causing single gene disorders has been well documented. However, WES has had limited success in the identification of more complex phenotypes resulting from the disruption of multiple genes. We describe a family where two offspring from healthy consanguineous parents present a complex congenital nonsyndromic phenotype consisting of peripheral neuropathy and bronchiectasis that has not been described previously. Through the use of WES we were able to simplify this complex phenotype and identified a causative mutation (R1070X) in the gene PRX, a gene previously shown to cause Charcot-Marie-Tooth Syndrome 4F and Dejerine-Sottas syndrome when this mutation is present in a homozygous state. For the bronchiectasis phenotype there was no single mutation or compound heterozygote identified which was deemed to be causal, reflecting the heterogeneous nature of this phenotype. This study highlights the potential utility of WES to disentangle complex phenotypes where multiple contributing loci in combination with environmental factors make it difficult to assign a clinical diagnosis; this then has further implications regarding the clinical management and use of therapeutics for such patients. In conclusion we show that WES has the power to improve patient diagnosis and therapy by disentangling complex phenotypes through the identification of causative genetic mutations for distinct clinical disorders that were previously masked.

2731T

Association study of genetic polymorphisms in DNA repair genes APE1/Ref-1 and DNA oxidative damage with the risk of neural tube defects. *J. Wang[1], X. Han[1], J. Guo[2], X. Wang[1], F. Wang[2], C. Ji[1], Z. Guan[1], Q. Xie[1], Z. Zhu[1], B. Niu[1], T. Zhang[2].* 1) Department of biotechnology, Capital Institute of Pediatrics, Beijing, China; 2) Department of molecular immunology, Capital Institute of Pediatrics, Beijing, China.

Neural tube defects (NTDs) are one of the most common human birth defects. Folate deficiency is closely related to NTDs. However, the mechanism remains unclear. Folate can prevent the effect of homocysteine on oxidative stress. Apurinic/apyrimidinicendonucleasee 1/redox-factor 1 (APE1/Ref-1) plays critical roles in DNA oxidative damage repair, oxidative stress. Previous study found the gene polymorphisms were associated with NTDs in a Californian population. In order to investigate the association of APE1/Ref-1 gene polymorphisms and oxidative stress with NTDs among the folate deficiency population in the high-risk area, a case-control study of 335 NTDs fetuses and 336 normal fetuses was conducted in Lvliang areas of Shanxi province with a high prevalence of NTDs. Total 36 single nucleotide polymorphisms (SNPs) in APE1/Ref-1 gene were genotyped by Sequenom MassARRAY Genotyping. The Superoxide dismutase (SOD) activities of fetal liver and maternal plasma were detected by the Cu-Zn/Mn-SOD assay kit and the numbers of apurinic/apyrimidinic sites (AP sites) in DNA of fetal brain tissues were measured by the DNA Damage Quantification Kit. The allele and genotype frequencies of 36 polymorphisms showed no statistically associated with NTDs. After stratifying subjects by NTD phenotype, we observed 4 polymorphisms statistically associated with NTDs subtypes. As to rs1130409, compared with TT genotype, GG genotype of was associated with the decreased risk for spina bifida, in female TG genotype was associated with higher risk of encephalocele compared with those harboring the TT genotype. Allele C of rs3136817 was associated with an increased risk for single encephalocele compared with those harboring allele T. In male, allele T of rs77794916 had a 1.547-fold increased risk for NTDs compared with allele C. GG genotype of rs1760944 was associated with an increased risk for cephalic malformations compared with those harboring the TT genotype. The SOD activity of fetal liver tissue in the control group was significantly higher than that of the case group. In male, the numbers of DNA AP sites in the NTD group were significantly larger than control group and statistically different among the three rs1760944 genotypes in female spina bifida. The results of this study imply that the APE1/Ref-1 gene polymorphisms were correlated with susceptibility to NTDs, oxidative stress and DNA oxidative damage was associated with NTDs in a high-risk area of China.

2732F

Whole exome sequencing of a girl with Rubinstein-Taybi syndrome. *H. Yoo[1,2], K. Kim[3], I. Kim[1], S. Rho[4], J. Park[1], S. Kim[5], N. Kim[3].* 1) Department of Psychiatry, Seoul National University Hospital, Seongnam, Gyeonggi, Korea; 2) Seoul National University College of Medicine, Seoul, Korea; 3) Korean Bioinformation Center, Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea; 4) Softmatter Research Center, Goyang, Gyeonggi, Korea; 5) Department of Pharmacology, Eulji University College of Medicine, Daejon, Korea.

Objectives: The Rubinstein-Taybi syndrome(RSTS) is a rare condition with a prevalence of 1 in 125,000~300,000, with dysmorphic features of face, hands & feet(Rubinstein et al., 1963). The genetic mutations of RSTS are not confirmed, though *CREBBP* or *EP300* mutations have been reported (Tsai et al., 2011). The purpose of this study is to evaluate the genetic causes of RSTS with Whole Exome Sequencing(WES). **Methods**: A 6-year-old Korean girl with RSTS was clinically phenotyped and behaviorally assessed with WPPSI, VABS, Leiter-R, ADOS, ADI-R, CBCL & Pittsburgh Sleep Quality Index(Park et al., 1996; Sparrow et al., 1994; Gale et al., 1997; Lord et al., 1994; LeCouteur et al., 2003; Achenback et al., 1991; Buysse et al., 1989). Blood samples are drawn from the proband and both biological parents. Read mapping, duplicate removal, local re-alignment, SNP and short indel genotyping have been performed by BWA, Picard, and GATK. Gene annotation and variant filtering is done by in-house bioinformatics pipeline and control database comprised of 54 normal Korean individuals. **Results**:(1)Phenotype: The proband is the only child of a healthy non-consanguineous couple. Her features include; 1) Typical facial dysmorphism: highly arched eyebrows, long eyelashes, down-slanting palpebral fissures, beaked nose with the nasal septum extending below the alae, dental crowding & micrognathia; 2) Broad & angulated thumbs & halluces, thickening of the soft tissue of the phalanges & persistent fetal pads; 3) Microcephaly, growth retardation(head circumference, Wt & Ht<3 percentile); 4) Congenital cataract; 5) Skin problems; 6) Swallowing difficulty; 7) EEG abnormality; 8) Mental retardation(IQ=37, PIQ=45) with severe language delay, motor delay & hyperactivity; 9) Autistic disorder fulfilling diagnostic criteria in all domains. (2) WES: In depth quality statistics, we obtained mean read depth coverage of 120x over the targeted genomic regions. We had found candidate mutations; 3 for de novo, 1 for homozygous, 9 for compound heterozygous models. Sanger sequencing validated 3 de novo variants; A frameshift mutation of *CREBBP*(c.2199delG) and missense mutations of *TNC*(c.323G>A) & *IGFALS*(c.1415C>T). **Conclusion**: We observed de novo mutations of *CREBB-BP, TNC* & *IGFALS* in WES of a girl with RSTS. It is the first report of *TNC* & *IGFFALS* as possible causative genes for RSTS. We presume that the mutation of *TNC* might be related to its neurological phenotypes, and *IGFALS* to growth retardation.

2733W

A *de novo* deletion at 16q24.3 involving *ANKRD11* in a Japanese patient with KBG syndrome. *S. Miyatake[1], A. Murakami[1], N. Okamoto[2], M. Sakamoto[3], H. Saitsu[1], N. Miyake[1], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University, Yokohama, Japan; 2) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 3) Takarazuka Municipal Center for Handicapped Children, Takarazuka, Japan.

KBG syndrome is a rare autosomal dominant congenital syndrome comprising developmental delay with various neurological involvements, macrodontia of the upper central incisors, characteristic facial dysmorphism, and skeletal anomalies. *ANKRD11* was recently identified as the gene responsible for this syndrome. To date, there have been only several KBG syndrome families described, each carrying a single base substitution or a small deletion of this gene. Here we present a Japanese patient with clinically confirmed KBG syndrome carrying a de novo deletion at 16q24.3 disrupting *ANKRD11*. He had characteristic facial appearance, macrodontia of the upper central incisors, hand anomalies, delayed bone age and intellectual impairment without autistic features. Hypoplasia of cerebellar vermis was pointed out by brain Magnetic Resonance Imaging. Copy number analysis using an Affymetrix Cytogenetics Whole-Genome 2.7M Array and Quantitative real-time PCR on the patient and his parents revealed that he had a *de novo* 690-kb deletion at 16q24.3 involving part of *ANKRD11*. Interestingly, the deleted region overlaps with the critical region for 16q24.3 microdeletion syndrome, featuring autosomal dominant intellectual impairment and autism spectrum disorder. We compared the clinical aspects of KBG syndrome to those of 16q24.3 microdeletion syndrome. Although dental information is scarce among the patients with 16q24.3 microdeletion syndrome, the other clinical features, such as facial dysmorphism or skeletal abnormalities, are similar. However neurological involvement seemed to be different. In 16q24.3 microdeletion syndromes, intellectual impairment is relatively mild and autistic spectrum disorders are frequently observed , while in KBG syndrome, intellectual disability range from mild to severe, and common behavioral disturbances are hyperactivity, attention deficit or easy frustration rather than autistic features. Our patient was very significant in that he had 16q24.3 microdeletion, but his neurological symptoms are more close to those of KBG syndrome. The other specific finding of our patient was hypoplasia of the cerebellar vermis, which had been reported as a rare complication of KBG syndrome, and not of 16q24.3 microdeletion syndrome. Our patient is significant for considering whether these two syndromes are different. It is necessary to study further patients with these two syndromes to clarify this issue.

2734T

Molecular investigations of Polish patients with Beckwith-Wiedemann syndrome. *D. Jurkiewicz[1], M. Kugaudo[1, 2], A. Tańska[1], E. Ciara[1], D. Piekutowska-Abramczuk[1], M. Pelc[1], S. Łuczak[1], J. Trubicka[1], M. Borucka-Mankiewicz[1], P. Kowalski[1], A. Jezela-Stanek[1], A. Cieślikowska[1], K. Chrzanowska[1], M. Krajewska-Walasek[1].* 1) Department of Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland; 2) Department of Child and Adolescent Psychiatry, Medical University of Warsaw, Warsaw, Poland.

Beckwith-Wiedemann syndrome (BWS) is characterized by overgrowth, macroglossia, abdominal wall defects and a high risk of childhood tumors. BWS is caused by various 11p15 genetic or epigenetic defects leading to defective expression of imprinted genes. The genes in 11p15 region are organized into two imprinted domains controlled by two Imprinting Centers: IC1 (H19DMR) and IC2 (KvDMR). Molecular defects of the region resulting in BWS phenotype include loss of methylation at IC2 (50%), paternal UPD of 11p15 (20%), gain of methylation at IC1 (5%), mutations in *CDKN1C* gene (5%), and chromosomal rearrangements (2%). In ~20% of the patients a molecular alteration is unknown. Forty-nine patients with clinical symptoms of Beckwith-Wiedemann syndrome were investigated. Molecular analysis was performed by methylation sensitive multiplex ligation-dependent probe amplification (MS-MLPA) on leukocyte DNA. Hypomethylation in IC1 region was found in 23 patients including 2 monozygotic twins. Two patients had hypermethylation in IC2 region. Paternal UPD was identified in 8 patients and was subsequently verified by microsatellite analysis. Two patients carried duplications involving both IC1 and IC2 regions, that were confirmed by arrayCGH. Overall the study revealed the presence of mutations in 35 patients (71%). The molecular background of ~30% of studied cases is still unknown. In this group of patients the presence of mutations in the *CDKN1C* gene is possible (the analysis is under way). Moreover, failure to detect UPD in leukocytes due to somatic mosaicism associated with this etiology can not be excluded. There is also a possibility of the presence of molecular alterations in other genomic loci. The presented study is a first complex molecular characterization of a significant group of Polish BWS patients. The pattern of identified genetic defects is comparable with other western populations. The study was financed by National Science Centre, project no. 1149/B/P01/2011/40 (NN407114940) and EU Structural Funds, project POIG.02.01.00-14-059/09.

2735F

Gynecologic Issues in patients with Smith-Lemli-Opitz Syndrome. *M.A. Merideth[1], S.K. Conley[2], F.D. Porter[2].* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Program in Developmental Endocrinology and Genetics, NICHD, NIH, Bethesda, MD.

Objective: To evaluate the gynecologic issues in females with Smith-Lemli-Opitz Syndrome Background: Smith-Lemli-Opitz Syndrome (SLOS) is a rare autosomal recessive multiple anomaly syndrome of abnormal cholesterol metabolism that is caused by mutations in 7-dehydrocholesterol reductase (DHCR7). Though the clinical spectrum is varied, manifestations include microcephaly, growth retardation, moderate to severe intellectual disability, postaxial polydactyly, 2-3 toe syndactyly and characteristic facial features. Current treatments include cholesterol supplementation, early intervention referral and physical/occupational/speech therapy. Despite an expanded phenotypic description of patients with SLOS, there is little information available about the gynecologic issues in this patient population. Methods: Seven females with SLOS were evaluated at the National Institutes of Health Clinical Center. Testing included gynecologic history, laboratory testing, review of outside records, physical examination and pelvic imaging if indicated. Results: The patients ranged in age from 3-36 years. Six patients had normal external genitalia; 1 had redundant perineal tissue. One patient had premature pubic hair development at age 3.5 years. Median age at menarche was 12.5 years (range 10-14 years). Four patients had irregular menstrual cycles and 5 had significant premenstrual mood swings/behavioral problems. Four patients were on hormones to regulate their cycles or help with premenstrual symptoms. One patient had to discontinue hormone use due to elevated liver transaminase levels. Two patients underwent hysterectomy due to difficulties managing menstrual periods. Dysmenorrhea was reported in 3 patients and suspected by parents in 2 patients. No patients had recurrent vaginal infections. No pregnancies were reported. Four patients underwent pelvic imaging with normal findings in all patients. Conclusions: There is a paucity of information in the literature about gynecologic issues in females with SLOS; families and physicians often have questions about puberty, management of menstrual periods and premenstrual behavioral issues. Questions also arise regarding vulnerability in this patient population. Gaining a better understanding of the range of gynecologic problems in SLOS will expand the phenotype and is the first step toward developing gynecologic therapeutic strategies for this patient population.

2736W

Maternal Uniparental Disomy 16 in an infant with intrauterine growth retardation, dysmorphic features, multiple congenital anomalies and dermatoglyphics features suggestive of chromosomal abnormalities: A neglected consideration. *Y. Lacassie[1], M. Narayanan[2].* 1) Dept Ped/ Div Clin Gen, LSU Hlth Sci Ctr and Children's Hospital, New Orleans, LA; 2) LSU School of Medicine in New Orleans.

At the 47th Annual Meeting of the ASHG in 1997, the first author reported that the absence of 'd' triradius predicted a 50% chance of a chromosomal abnormality. At the 59th meeting in Hawaii in 2009, he presented how dermatoglyphics, usually ignored in the examination, provide a clue to suspect cryptic chromosomal disorders, including microdeletions and duplications. We present a 3-month-old male with history of intrauterine growth restriction born to a 38yo mother at 366/7 WGA weighting 1,342g. On day 1 of life, the patient experienced severe respiratory distress. After appropriate intervention and stabilization, a complex congenital heart defect (CHD) and bilateral pulmonary hypoplasia were diagnosed and various dysmorphic features were noticed. Abnormally high levels of plasma amino acids, urine organic acids, and carnitine were found; however, the newborn screen was negative. Initial chromosomal analysis (450-500 bands resolution level) and aCGH (180,000 probes, 300kb resolution) were normal. The patient was transferred to Children's Hospital New Orleans at 53 days of life. Further work up showed multiple cardiovascular anomalies, including malaligned VSD, PFO, left pulmonary artery stenosis, non-compacted LV, hypoplastic aorta, and left SVC. Also, posteriorly rotated ears, anteverted nostrils, first degree hypospadias, cryptorchidism, right inguinal hernia, severe growth retardation, the presence of vertical crease in the soles secondary to gap between the hallux and second toe, single palmar flexion creases (type II at right), minor mesobrachydactyly of 5th fingers and absence of the right axial triradius with a radial arch on the hypothenar area were detected. Suspecting a cryptic chromosomal microdeletion, SNP microarray was requested. This showed normal dosage but two extended contiguous regions of allelic homozygosity restricted to 16p13.3p13.12 (13.4 Mb) and 16q21q23.3 (16.5 Mb), suggestive of UPD 16. Parental study (LabCorp) demonstrated the maternal origin of UPD. A literature review of 54 cases reveals that the major clinical features of patients with mat UPD 16 are highly variable. They may include moderate to severe IUGR, CHD, pulmonary hypoplasia, inguinal hernia, TEF, anal atresia, and dysmorphic facies. This patient shows that UPD 16 should be considered in the differential diagnosis of apparent chromosomal microdeletions or duplications as they may present similar phenotypic findings, including dermatoglyphics.

Audiovestibular findings in Myotonic dystrophy type 1 (DM1) patients from the National Rehabilitation Institute (INR). *M. Arenas-Sordo[1], B. Rivera-Mercado[2], D. Gutierrez-Tinajero[2], A. Martínez-García-Ramos[2], M. Trujillo-Bracamontes[2], O. Hernandez-Hernandez[1], J. Magaña-Aguirre[1].* 1) Genetics, INR, Mexico DF, Distrito Federal, Mexico; 2) Audiology, INR, Mexico DF, Distrito Federal Mexico.

Introduction.Myotonic dystrophy type 1(DM1)is a progressive and multisystemic degenerative neuromuscular disease, characterized by myotony and muscular weakness,secondary to an unstable mutation of CTG repeats in the DMPK gen locus 19q13.3. Precocious presbyacusis has been reported in DM1 patients,indicating a compromise of the auditory system. Purpose.The present work shows the results from audiological and vestibular evaluation in Mexican patients with DM1 from the National Rehabilitation Institute (INR).Methods.42 patients with molecular diagnosis for DM1 were analyzed. An extensive audiological evaluation was performed. Audiograms classified the range, nature and degree of hearing loss and speech, detected the sensorial or conductive nature of hearing loss. Tympanometry, acoustic reflex threshold, and transient otoacoustic emissions were part of the evaluation. The impact of the vestibular disease in daily life was evaluated by the Dizziness Handicap Inventory (DHI)test.Falling in patients with balance deficiency and vestibular disorders was measured by the dynamic gait index-(DGI).Results.From 84 ears analyzed, 26 showed normal hearing (30.95%),58 presented several degree of affectation(69.05%), being the most prominent effect the mild-sensorial hearing loss on low frequencies (22.62%)and mild sensorial hearing loss on high frequencies (19.05%).Most of the patients showed auditory alteration in both ears.High frequency audiometry revealed falls from 40 to 50 dB in 57% of the ears. The most prevalent timpanometry curves were that of type 'A' and 'As' with absence of acoustic reflex thresolds in the 60% of them. Transient otoacoustic emission revealed an inadequate response in 60% of ears. The emotional scale of vestibular evaluation indicated no disability in the 78.26% of the patients and moderate disability in 21.73%. Functional scale showed 21.73% and 8.69% of moderate and severe disability respectively. Physycal scale evaluation showed a 13.04% of moderate and severe disability respectively. Finally the DGI revealed a high risk of falling in 34.78% of the evaluated patients.Conclusions. Hearing loss in low and high frequencies indicate an affection of the base and apex of the cochlea where the outer hair cells play a key role in sound perception through a contractile-like movement. Future research efforts focused on the cells in the context of CTG repeats should be done to understand the pathophysiology of the disease at this level.

2738F

A case of Nonsyndromic hearing-impairment whit S199F GJB2 Homozygous mutation. *G. Giraldo, LP. Barragan Osorio, J.C. Prieto.* Instituto de Genètica Humana, Pontificia Universidad Javeriana , Bogotà , Bogotà D.C, Colombia.

Hearing impairment (HI) affects 1 in 650 newborns which makes it the most frequent congenital sensory impairment. Nonsyndromic HI is very heterogeneous and 37 different genes with a wide variety of functions have been identified. Mutations in GJB2 are the most common genetic etiology of prelingual non-syndromic sensorineural hearing loss. Rikkert et al reported in 2005 a total of 83 different mutations in GJB2; they found that 35delG mutation was the most common with an allelic frequency of 72.44%; they also found a reduced allelic frequency of 0,3% for the S199F mutation. In the study of Olarte M et al in Colombian population they reported that the most common mutations were 35delG and S199F; the allelic frequency for S199F mutation was 42.1%. In this paper we report a case of a Colombian 8 years old female child with a history of bilateral sensorineural hearing loss diagnosed at 5 years old. Her parents were non-consanguineous and her family history was unremarkable. She was born at term after a normal pregnancy. Mother denied exposure to teratogens or infections during pregnancy. In order to establish the etiology of her sensorineural hearing loss a sequence analysis of the gene GJB2 and GJB6 was performed, the report showed S199F homozygous mutation in GJB2 and a normal sequence in GJB6. Most patients with mutations in GJB2 present a prelingual hearing loss but in this case our patient has a S199F mutuation in GJB2 with a non classical postlingual bilateral sensorineural hearing loss and an atypical audiometry pattern.

2739W

Somatic CTNNB1 mutation in hepatoblastoma from a patient with Simpson-Golabi-Behmel syndrome and germline GPC3 mutation. *R. Kosaki[1], T. Takenouchi[2], N. Takeda[3,4], M. Kagami[5], K. Nakabayashi[6], K. Kosaki[2,7].* 1) Div Med Genet, Natl Ctr Child Hlth & Dev, Tokyo, Japan; 2) Dept of Pediatrics, Keio Univ Sch Med, Tokyo, Japan; 3) Dept of Surgery ,Natl Ctr Child Hlth & Dev, Tokyo, Japan; 4) Dept of Surgery ,Kitasato Univ,Kanagawa,Japan; 5) Dept of Molecular Endocrinology, Natl Research Institute of Child Hlth & Dev, Tokyo, Japan; 6) Dept of Maternal-Fetal Biology, Natl Research Institute of Child Hlth & Dev, Tokyo, Japan; 7) Ctr Med Genet, Keio Univ Sch Med, Tokyo, Japan.

Simpson-Golabi-Behmel syndrome is a rare overgrowth syndrome caused by the GPC3 mutation at Xq26 and is clinically characterized by multiple congenital abnormalities, mental retardation, pre/postnatal overgrowth, distinctive craniofacial features, macrocephaly, and organomegaly. Although this syndrome is known to be associated with a risk for embryonal tumors, similar to other overgrowth syndromes, the pathogenetic basis of this mode of tumorigenesis remains largely unknown. Here, we report a boy with Simpson-Golabi-Behmel syndrome who had a germline loss-of function mutation in GPC3. At 9 months of age, he developed hepatoblastoma. A comparison of exome analysis results for the germline genome and for the tumor genome revealed a somatic mutation, p.Ile35Ser, within the degradation targeting box of beta-catenin. The same somatic mutation in CTNNB1 has been repeatedly reported in hepatoblastoma and other cancers. This finding suggested that the CTNNB1 mutation in the tumor tissue represents a driver mutation and that both the GPC3 and the CTNNB1 mutations contribute to tumorigenesis in a clearly defined sequential manner in the propositus. The current observation of a somatic CTNNB1 mutation in a hepatoblastoma from a patient with a germline GPC3 mutation supports the notion that the mutation in GPC3 may influence one of the initial steps in tumorigenesis and the progression to hepatoblastoma.

Establishment and validation of iPS cells and knockout mice for dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos syndrome (DDEDS). *T. Kosho[1,2], F. Yue[3], S. Saka[2,4], N. Tsumita[2,4], Y. Kasahara[2], T. Okada[2], S. Mizumoto[5], M. Kobayashi[6], J. Nakayama[7], N. Miyake[8], Y. Nomura[4], T. Era[9], A. Hatamochi[10], F. Fukushima[1], N. Matsumoto[8], K. Sugahara[5], K. Sasaki[3], S. Takeda[2].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 2) Department of Molecular Therapy, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Japan; 3) Department of Histology and Embryology, Shinshu University School of Medicine, Matsumoto, Japan; 4) Scleroprotein and Leather Research Institute, Tokyo University of Agriculture and Technology, Faculty of Agriculture, Fuchu, Japan; 5) Laboratory of Proteoglycan Signaling and Therapeutics, Hokkaido University Graduate School of Life Science, Sapporo, Japan; 6) Miya Kobayashi: Department of Food and Nutritional Environment, College of Human Life and Environment, Kinjo Gakuin University, Nagoya, Japan; 7) Department of Molecular Pathology, Shinshu University Graduate School of Medicine, Matsumoto, Japan; 8) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 9) Department of Cell Modulation, Institute of Molecular Embryology and Genetics, Kumamoto University, Kumamoto, Japan; 10) Department of Dermatology, Dokkyo Medical University, School of Medicine, Mibu, Japan.

Dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos syndrome (DDEDS), caused by recessive loss-of-function mutations in CHST14, is a recently delineated form of EDS [Kosho et al., 2011], characterized by a unique set of clinical features consisting of progressive multisystem fragility-related manifestations (skin hyperextensibilty and fragility, progressive spinal and foot deformities, large subcutaneous hematoma) and various malformations (facial features, congenital multiple contractures). Multisystem connective tissue fragility is caused by impaired assembly of collagen fibrils through loss of dermatan sulfate (DS) replaced by chondroitin sulfate in the decorin glycosaminoglycan sidechains. Complete loss of DS in patients' urine was also detected. Because the patients suffer from progressive multisystem fragility-related complications, appropriate disease modeling is indispensable in view of developing etiology-based therapy. In this study, we report establishment and validation of induced-pluripotent stem cells (iPSCs) and knockout (Chst14-/-) mice. Cultured skin fibroblasts were obtained from a patient and transduced into iPSCs. Morphologically, patient-derived iPSCs (P-iPSCs) had a smaller size and more vacuoles than control iPSCs (C-iPSCs) derived from a healthy individual. Apoptosis, undifferentiation status, or pluripotency were not different between these iPSCs. Decorin staining on teratoma samples derived from P-iPSCs using human decorin antibody was weaker than that from C-iPSCs, similar to the results from patients' skin specimens. Neural progenitor cells and neurons were differentiated, and neural differentiation potency was weaker in P-iPSCs than that in P-iPSCs. Frozen sperm from Chst14+/- male mice were obtained from the Mutant Mouse Regional Resource Center. After reproducing Chst14+/- mice, Chst14-/- mice were generated and preliminary phenotypic studies were undertaken. Complete loss of DS in urine from Chst14-/- mice was demonstrated, suggesting these mice to reflect glycobiological abnormalities in DDEDS. Although postnatal weight gain was smaller in Chst14-/- mice than in Chst14+/- or WT mice, no apparent congenital multiple contractures or multisystem fragility-related manifestations were noted. Further studies to delineate pathophysiological features of cells from other systems differentiated from iPSCs and longitudinal physical features including pathological abnormalities of Chst14-/- mice are necessary.

Report of a Colombian case of Werner Mesomelic Syndrome with eight fingers in both hands and feet. *J.C Prieto[1,2], G. Giraldo[1], T. Pineda[1].* 1) Inst de Genetica Humana, Univ Javeriana, Bogota, Colombia; 2) Hospital La Victoria. Secretaria Distrital de Salud Bogota, Colombia.

Werner mesomelic syndrome (WMS) is an autosomal dominant disorder first described by Werner in 1912. It is characterized by hypo or aplasia of the tibiae with remarkable short stature associated with preaxial polydactyly of the hands and feet and/or five-fingered hand with absence of thumbs. Wieczorek et al identified the molecular basis of the syndrome in 2010; they established that this condition is caused by a specific point mutation in the ZRS (the sonic hedgehog regulatory region) at position 404. In this paper we report the case of a Colombian 1 year old infant patient with Werner mesomelic syndrome. She was the first daughter of non-consanguineous young parents and her family history was unremarkable; she presented with rizomelic and mesomelic shortening of the lower limbs with bilateral hypoplasia of the tibiae, right femur hypoplasia and bilateral absence of the hallux; she also presented bilateral triphalangeal thumb and preaxial polydactyly with 8 fingers in both hands and feet. This is the first case of Werner mesomelic syndrome reported in Colombia and we describe new phenotypic findings.

A Novel WNT7A Mutation Causes Autosomal Recessive Al-Awadi/Raas-Rothschild/Schinzel Phocomelia Syndrome. *Y. Sahin[1], PO. Simsek-Kiper[2], A. Cetinkaya[1], GE. Utine[2], K. Boduroglu[2].* 1) Department of Medical Genetics, Hacettepe University, Ankara, Turkey; 2) Department of Pediatrics, Department of Pediatric Genetics, Hacettepe University, Ankara, Turkey.

Al-Awadi/Raas-Rothschild/Schinzel Phocomelia Syndrome is a very rare autosomal recessive disease presenting with pelvic hypoplasia, thoracic dystrophy and severe limb defects, especially affecting ulnae and fibulae. A 2-year old girl with several features of this syndrome including bilateral ulnar aplasia, hand defects, fibular aplasia, pelvic hypoplasia and rib fusion anomalies sought medical advice in our genetics clinic. Her limb abnormalities were noticed in the prenatal ultrasound study. She had normal psychomotor development, but she had growth delay. Her abdominopelvic ultrasonography revealed left kidney agenesis which was also confirmed by scintigraphy. She had no other systemic abnormalities. Her parents are from Southeastern part of Turkey and are first cousins. In the light of these clinical findings, Sanger sequencing of patient blood DNA was performed for all 4 exons of WNT7A, which revealed c.713T>G mutation in homozygous state while her parents and two sibs carried this mutation in heterozygous state and were healthy. This mutation is not reported in dbSNP database and is not one of the 6 mutations previously linked to Al-Awadi/Raas-Rothschild/Schinzel Phocomelia Syndrome. This mutation is predicted to cause a missense mutation substituting valine in the 238th position to glycine [p.Val238Gly]. This site is conserved among vertebrates and mutation prediction programs, Mutation Taster and Polyphen-2, predict that this mutation is disease causing. WNT7A is an effector of wnt/β-catenin signalling pathway. It is suggested that this specific type of wnt protein is involved in limb and genitourinary development. The phenotypic features of the patient presented here are in compliance with reported effects of WNT7A deficiency in human. To our knowledge, this patient represents the second case of unilateral renal agenesis reported in this syndrome, emphasizing the role of WNT7A in renal development. In addition, the case of this patient adds c.713T>G mutation to the spectrum of WNT7A mutations causing Al-Awadi/Raas-Rothschild/Schinzel Phocomelia Syndrome.

2743T

Three generation family with kyphomelic dysplasia suggests autosomal dominant inheritance. *O. Vanakker[1], U. Fränkel[2], B. Callewaert[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Paediatrics, Zorgsaam Hospital, Terneuzen, The Netherlands.

Kyphomelic dysplasia (KD) is a rare skeletal dysplasia belonging to the group of bent bone dysplasias. It represents a heterogenous group of disorders, with at least three distinct entities identified: Schwartz-Jampel syndrome (SJS), Cartilage Hair Hypoplasia (CHH) and 'true' KD. For the latter, the genetic background is unknown and autosomal recessive inheritance is presumed based on several sporadic cases with parental consanguinity. We report a three-generation family presenting with a true KD phenotype. The proband was born at term after an uneventful pregnancy. Her length and weight at birth were 37cm and 1578g respectively. She had severe rhizomelic shortening of upper and lower limbs and radiographs showed stubby femora which were extremely curved. Iliac wings were short and widened; the humeri were also short and dumbbell-shaped. The mother of the proband has a similar disproportionate short stature phenotype. Radiographs taken at birth revealed severe femoral bowing, though less prominent compared to her daughter. Follow-up radiographies in the mother demonstrated a gradual decrease of the bowing over several years. The maternal grandfather of the proband had an identical phenotype. All had a normal neuromotor development. There were no signs of myotonia or ocular problems (SJS) nor evidence for immune deficiencies or anaemia (CHH). This family, suffering from true KD, suggests that at least a subtype of KD has an autosomal dominant mode of inheritance. This observation has important consequences for genetic counselling of patients with KD, and identification of other families may allow clarification of the genetic background.

2744F

Further evidence of brain anomalies related to ALX4 mutations: possible genotype-phenotype correlation. *T. Almeida[1], M. Valente[1], G.L. Yamamoto[2], C.A. Kim[1], M.R. Passos-Bueno[2], D.R. Bertola[1,2].* 1) Genetic Unity, Children's Institute, São Paulo, São Paulo, Brazil; 2) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, São Paulo, Brazil.

Brain anomalies has been found in patients with loss-of-function mutations in ALX4, either in the homozygous state, with the frontonasal phenotype, showing abnormalities in corpus callosum and cerebellar hypoplasia, or in the heterozygous state, with parietal foramina, presenting polymicrogyria, high insertion of the tentorium cerebri, bilateral choroid plexus cysts, corpus callosum agenesis and mild cerebellar hypoplasia. Here we describe the cranial MRI of four cases with ALX4 mutations. Patient 1, with a homozygous missense mutation in the homeodomain (p.R215W) and a frontonasal phenotype, showed occipital and cerebellar hypoplasia, high insertion of the tentorium cerebri, agenesis of the septum pelucidum and occipital simplified gyra, with no abnormalities in corpus callosum, previously described for all patients with the frontonasal phenotype. Patient 2, heterozygous for the same mutation, showed no brain anomalies. Patients 3 and 4 (mother and son) with a heterozygous frameshift mutation after the homeodomain (p.D326fs*21) and a frontonasal phenotype, showed no structural anomalies. Contrary to what is observed in the literature for the frontonasal patients, our study describes two individuals with this phenotype without brain anomalies. We believe that this could be related to the preservation of the homeodomain since this is the only family with a mutation that does not encompass that region. The investigation of brain anomalies in the heterozygotes for the ALX4 mutations with parietal foramina were carried out just for a small number of patients. Brain malformations were described in a family with a missense mutation at the homeodomain and in some patients with a microdeletion of this region. On the other hand, a patient harboring a frameshift mutation in ALX4 before the homeodomain, associated with microdeletion in the region 22q11, showed no brain anomalies. This could lead to the conclusion that the brain phenotype has an incomplete penetrance in the heterozygous state and cannot be related to the presence of the parietal foramina, or the position and type of the mutations. This study is a preliminary investigation about the association of the ALX4 gene with brain malformations and requires further studies to establish the real extension and genotype-phenotype correlation of the brain anomalies.

2745W

Further occurrence of "TMCO1 defect syndrome` in a non-Amish population: the first South American patient presenting the same p.R87X mutation recently found in a Turkish individual. *W.A.R. Baratela[1], G.L. Yamamoto[1], M.R. Passos-Bueno[2], D.R. Bertola[1,2].* 1) Unidade de Genética, Instituto da Criança - Hospital das Clínicas - Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Centro de Estudos do Genoma Humano - Departamento de Genética e Biologia Evolutiva - Instituto de Biociências - Universidade de São Paulo.

Autosomal recessive syndrome of craniofacial dysmorphisms (brachycephaly, flat face, arched bushy eyebrows, synophrys, orbital hypertelorism, wide nose bridge, high-arched palate, cleft lip and palate, microdontia of primary teeth, gingival hyperplasia and low-set ears), skeletal anomalies (Sprengel deformity, pectus excavatum, rib anomalies, vertebrae fusions and club foot), and developmental delay/mental retardation associated with TMCO1 defects was first diagnosed in 11 individuals, all from the Old Order Amish of northeastern Ohio. TMCO1 homozygous nonsense mutation in the coiled coil region of the protein was found in all 9 tested patients, with a carrier frequency in the community of 0,7%. Recently a similar case from Turkey was published, with a different mutation in TMCO1, but in the same protein region, with a rather more profound developmental impairment. We describe a 28 yo lady, daughter of a first cousin Brazilian couple, with normal birth measurements. She presented with tall stature, bushy and arched eyebrows, synophrys, ocular hypertelorism, divergent strabismus, cleft lip and palate and gingival hypertrophy. She also had polydactyly, presented in other members of the family in an autosomal dominant pattern. She walked at 2y4mo, first words with 1y6m, attended special education from the beginning. At 3yo developed seizures and started with antiepileptic drugs. Skeletal survey showed rib fusions and scoliosis. Ecocardiogram, and abdominal ultrasound were normal. Molecular studies with exome sequencing found a homozygous mutation in TMCO1, c.C259T (p.R87X), the same reported in Turkey. We describe a further occurrence of 'TMCO1 defect syndrome' in a non-Amish population: the first South American patient, indicating that this disorder is probably more widespread. The family of our patient is from a small city in the Northeast of Brazil, in which there was Portuguese colonization. It is therefore plausible to consider that this mutation has European origin, shared by the Turkish patient. This far, the clinical findings seem quite homogenous, but as this is a new disorder, its full spectrum remains to be depicted.

2746T

Sibs with Hydrops fetalis, arthrogryposis multiplex congenital, neuronal migration disorder, adrenal and pulmonary hypoplasia and renal abnormalities associated with a mutation in the FAT4 gene, encoding a giant cadherin. *D. Chitayat[1,2], T. Uster[1], P. Shannon[3], M. Srour[4], S. Robertson[5], J. Michaud[4].* 1) Prenatal Diag & Med Gen, Mount Sinai Hosp, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Ste-Justine Hospital Research Center, Montreal, Quebec, Canada; 5) Department of Pediatrics and Child Health, Dunedin School of Medicine, University of Otago, New Zeland.

The human FAT gene family consists of the FAT1, FAT2, FAT3 and FAT4 genes. Human FAT family genes encode large proteins with extracellular cadherin repeats, EGF like domains, and laminin G like domain(s). FAT4 is involved in the maintenance of planar cell polarity and inhibition of cell proliferation. FAT4 gene has been reported to be mutated in several types of human cancers, such as melanoma, pancreatic cancer, gastric cancer and hepatocellular carcinoma. However, so far no human condition has been reported to be caused by germline mutations in this gene. We report a male and female sibs, born to a consanguineous Turkish couple, with hydrops fetalis (HF), neuronal migration disorder, joint contractures, pulmonary and adrenal hypoplasia and renal abnormalities. To our best knowledge this is a hitherto new, autosomal recessive condition. The parents were healthy and first cousins of Turkish descent. Patient A, a male, was born at 31.8 weeks gestation following a pregnancy complicated with hydrops fetalis, mild ventriculomegaly, misalignment of the skull bones and lumbar lordosis. He died shortly after delivery and autopsy showed HF, cleft palate, ambiguous genitalia, bilateral talipes equinovarus, camptodactyly of the fingers and clenched fists. There was a butterfly T5 vertebra and hypoplastic lungs, kidneys and adrenal glands. The brain showed megalencephaly, abnormal gyration and an unusual pattern of cytoarchitectural disturbance in the cerebral cortex. The karyotype was 46, XY. Patient B, a female, the product of the couple's second pregnancy, was found to have an increased nuchal translucency and body edema on 12 weeks ultrasound. Ultrasound at 20 weeks gestation showed bilateral talipes equinovarus, flexed wrists, echogenic kidneys, pericardial effusion and an abnormal cerebral configuration. The pregnancy was terminated at 21 weeks gestation and the autopsy showed the same findings as in her late brother apart from her female internal and external genitalia. Microarray analysis was normal and female. Extensive investigation done on the two failed to identify etiology. Exome sequencing showed a homozygous mutation in the FAT4 gene.

2747F

Genetic heterogeneity in Mabry syndrome: a novel phosphatidylinositol glycan (GPI) anchor deficiency disorder. *D. Cole[1], T. Roscioli[2], M. Nezarati[3], E. Sweeney[4], P.N. Krawitz[5], H. van Bokhoven[6], C. Marcelis[6], B. DeVries[6], D. Andrade[7], W.M. Burnham[8], A. Munnich[9], M. Thompson[1].* 1) Dept Laboratory Medicine, Univ Toronto, Toronto, ON, Canada; 2) Dept of Women's and Children's Health, Sydney Childrens' Hospital and University of New South Wales; 3) Dept of Genetics, North York General Hospital, Toronto, Canada; 4) Royal Liverpool Children's Hospital, Liverpool, UK; 5) Inst für Medizinische Genetik, Charité Universitäts Medizin, Berlin, Germany; 6) Dept of Human Genetics, University Medical Centre St. Radboud, Nijmegen; 7) Division of Neurology, Toronto Western Hospital, Toronto, Canada; 8) Department of Pharmacology, University of Toronto; 9) INSERM U781-Université Paris Descartes-Hôpital Necker-Enfants Malades, Paris.

Mabry syndrome (hyperphosphatasia with developmental disability) was first described in 1970 (OMIM#239300). At first considered rare, improved phenotyping has led to recruitment of more than twenty families world-wide. Salient features of the disorder include: characteristic facial dysmorphology (hypertelorism, a broad nasal bridge and a tented mouth); variable shortening of middle and distal phalanges; and neural abnormalities on biopsy (plaques disrupting Schwann cells). Like many infantile metabolic storage disorders, seizures associated with Mabry syndrome have an onset in the first year of life. Persistently elevated serum alkaline phosphatase (ALP) levels are now known to be associated with abnormalities of the phosphatidylinositol glycan (GPI) anchor due to mutations in the PIGV, PIGO and PGAP2 genes. Lysosomal storage material detected in some patients with Mabry syndrome has been putatively identified as glycolipid in nature - possibly resulting from changes in lipid raft functions that result from GPI anchor disruption. Not all patients with a clinical diagnosis of hyperphosphatasia with neurologic deficit result from known GPI disruptions. We present data on patients that suggest there are further subtypes of the disorder.

2748W

Exome sequencing of the X-chromosome in Aicardi syndrome. *C. Lund, H.S. Sorte, Y. Sheng, M.D. Vigeland, O. Røsby, K.K. Selmer.* Oslo university Hospital, Oslo, Norway.

Exome sequencing of the X-chromosome in Aicardi syndrome C. Lund 1, H. S. Sorte2, Y. Sheng2, M. D. Vigeland2, O. Rosby 2, K. K. Selmer2. 1) National Centre for Rare Epilepsy-related Disorders, Oslo University Hospital, Norway, 2) Department of Medical Genetics, Oslo University Hospital, Norway. Background: Aicardi syndrome is a rare neurodevelopmental disorder, a well-defined syndrome since its first description in 1965. The main diagnostic features are agenesis of corpus callosum, chorioretinal lacunae and infantile spasms. The etiology is unknown. However, it is only seen in females and 47, XXY males in healthy families. Therefore, it is assumed to be caused by de novo mutations on the X-chromosome, inherited in a dominant manner with hemizygous lethality in males. Methods: To search for disease-causing mutations, we performed whole exome sequencing on seven patients with Aicardi syndrome. The exome was enriched by using the Agilent SureSelect Human All Exon Capture kit (50 Mb, v3). Sequencing was performed with 100 bp PE reads on an Illumina HiSeq2000, yielding an average coverage of 25x-135x. We identified 17 000-22 000 genetic variants per patient. The filtering process was focused on identifying rare, protein-altering and heterozygous variants, shared by multiple patients. Results: After the filtering process, none of the remaining variants appeared in more than one patient. Conclusions: With the method of exome sequencing of the X-chromosome of seven patients, we were not able to reveal the etiology of Aicardi syndrome. Assuming that the hypothesis of X-linked dominant inheritance is correct, the results of this study suggest that the causal locus lies in a non-coding region or in a gene poorly covered by the exome sequencing kit. However, further studies of these patients will involve trio testing and examination of the autosomal chromosomes.

2749T

Mutations in extracellular matrix genes NID1 and LAMC1 cause autosomal dominant Dandy-Walker malformation and occipital cephaloceles. *V. Mahajan[1], B. Darbro[2], L. Gakhar[3], J. Skeie[1], E. Campbell[2], S. Wu[2], X. Bing[2], K. Millen[4], W. Dobvns[4], J. Kessler[5], A. Jalali[5], J. Cremer[6], A. Segre[6], J. Manak[2,7], K. Aldinger[4], S. Suzuki[8], N. Natsume[8], M. Ono[8], H. Background The Dandy-Walker spectrum of disorders including autosomal dominant Dandy-Walker malformation and occipital cephaloceles (ADDWOC) are characterized by variable cerebellar hypoplasia, meningeal anomalies, and occipital skull defects. We have previously reported deletions that encompass FOXC1 or ZIC genes in rare familial and sporadic cases of Dandy-Walker spectrum disorders, but ADDWOC families do not have mutations in these genes. Thus, we aimed to identify the genetic etiology underlying ADDWOC. Methods We previously characterized the phenotype of a family with ADDWOC of Vietnamese origin, and a second family with a similar phenotype from India. Whole exome sequencing was performed to identify candidate mutations in the larger Vietnamese pedigree, and whole exome sequencing followed by protein interaction network analysis was performed to identify a mutation in the Indian pedigree. A known X-ray crystallography structure of the interacting proteins was used to elucidate the effect of the mutations on the interacting proteins. Findings We identified a mutation in the extracellular matrix protein encoding gene NID1 in the original Vietnamese pedigree. In the Indian family, protein interaction network analysis identified a mutation in LAMC1, which encodes a NID1 binding partner. Structural modeling the NID1-LAMC1 complex demonstrated that each mutation disrupts the interaction. Interpretation These findings implicate the extracellular matrix in the pathogenesis of Dandy-Walker spectrum disorders.

2750F

Mapping a new locus for autosomal dominant nonsyndromic comitant strabismus.
M. Patel[1,3], X. Ye[1,2,3], C. Shyr[2,3], Z. Zong[1,3], M. Thomas[1], P. Power[1], N. Roslin[4], S. Narasimhan[5], D. Giaschi[5], W. Wasserman[1,2,3]. 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Centre for Molecular Medicine and Therapeutics; 3) Child and Family Research Institute; 4) FORGE Canada Consortium; 5) Ophthalmology and Visual Sciences, University of British Columbia, Vancouver, BC, Canada.

Strabismus, defined as a lack of parallel gaze, is a common problem found in 1-4% of the general population yet little is known about its genetic basis. Strabismus is found at an elevated frequency in a large number of different syndromes, precluding the use of syndromology to unravel the genetic basis of this common disorder. The lack of common molecular or cell biologic features between all the syndromes featuring strabismus may also suggest that there are many possible disruptions that can result in an interruption of parallel gaze. One way to address this complexity is to study families with Mendelian inheritance of the trait of interest. We report here a 7 generation pedigree with many affected family members in an autosomal dominant pattern. Affected members had isolated esotropic or hypertropic comitant strabismus that was nearly always congenital and of varying severity. No other ocular or neurological abnormalities segregated in the pedigree and there were no minor anomalies that segregated with the trait. A high density genome-wide mapping study was undertaken in parallel with exome sequencing. Results will be reported at the meeting. Study of this rare family provides an opportunity to uncover a molecular entry point into the biology of nonsyndromic strabismus.

Exome sequencing identifies mutations in a gene not previously related to skeletal dysplasias in patients with spondylometaphyseal dysplasia.
G.L. Yamamoto[1,2], W.A.R. Baratela[1], T.F. de Almeida[1], C.A. Kim[1], M.R.S. Passos-Bueno[2], D.R. Bertola[1,2]. 1) Genetica Medica ICR-FMUSP, Universidade de Sao Paulo, Sao Paulo SP, Brazil; 2) Centro de Estudos do Genoma Humano IB, Universidade de Sao Paulo, Sao Paulo, SP, Brazil.

We report on four cases, two cousins, 12yo and 15yo and two siblings, 2yo and 17yo, from two distinct Brazilian consanguineous families. The families are from two different, small cities in the Northeast of Brazil. The proband in the first family was born at term, with normal birth measurements. She developed progressive bowing of the lower limbs at 1yo. Skeletal survey showed platyspondyly and marked metaphyseal flaring since early infancy, with normal to mildly enlarged epiphysis. No other abnormalities were observed, including normal ophthalmologic evaluation. Skeletal findings in the second family were strikingly similar to the previous family, however, the siblings also presented progressive visual impairment with macular pigmentary changes. Exome sequencing identified a region of loss of heterozigozity in chromossome 3q29 in both families. Two new homozygous mutations, a frameshift in family one and a missense in family two, never before described in control populations, were identified in a single gene within 3q29 that we believe to be associated with the skeletal phenotype. We further hypothesized that a second gene in region 3q29 could be responsible for the visual impairment in family 2, since a homozygous, possibly pathogenic, missense mutation was also identified in a vitamin A metabolism related gene.

2752T

A novel missense mutation in PRPS1 leads to PRS-I deficiency in females displaying retinitis pigmentosa and variable expression of a neurologic phenotype.

Phosphoribosyl pyrophosphate synthetase I (PRS-I) is a key enzyme in nucleotide metabolism. Missense mutations in PRPS1 may lead to PRS-I deficiency and cause three different phenotypes: Arts Syndrome (MIM 301835), X-linked Charcot-Marie-Tooth (CMTX5, MIM 311070) or X-linked non-syndromic sensorineural deafness (DFN2, MIM 304500). All three have in common to be rare, X-linked recessively inherited and to display variable levels of central and peripheral neuropathy in males affected. In the current study, we have identified a novel missense mutation in PRPS1 leading to PRS-I deficiency in 4 affected females across 3 generations of a family with a phenotype consisting of retinitis pigmentosa (RP) and variable expression of optic atrophy, ataxia, peripheral neuropathy and hearing loss. Four members from the family were subjected to whole exome sequencing. After variant filtering analysis assuming dominant inheritance, a novel missense variant in PRPS1 was selected among 107 nonsynonymous variants segregating in the family. Sanger sequencing in 12 members of the family showed complete segregation of the mutation with the disease. PRS-I enzymatic activity in erythrocytes from three affecteds evidenced variable levels of deficiency, with severity correlating with the age of onset of ophthalmologic manifestations. Further assessment of X inactivation skewing confirmed different patterns of X inactivation in the four affecteds, which may be also responsible for the variable phenotypic expression in the females. However, since no male was found affected, a lethal effect of the mutation in males cannot be ruled out. In addition to the observation of PRS-I deficiency in females, this is the first time that RP is part of the myriad of symptoms these syndromes display, being in this family the first and only common manifestation to all affecteds. Visual cycle is especially sensitive to GTP levels, which are expected to be low in the family, and that may lead to an eventual death of photoreceptor cells and would explain the RP phenotype. However, further functional studies are needed in order to elucidate the mechanism underlying RP. This study also highlights the enormous phenotypic variability observed in PRS-I related syndromes inter and intra family.

Mutation analysis of androgen receptor gene: A complementary molecular approach in management of androgen insensitivity syndrome.
F. Baghbani-arani[1], A. Shojaei[2], F. Behjati[3], R. Ebrahimzadeh-Vesal[2], J. Tavakkoly-Bazzaz[2]. 1) Genetics Dept, Varamin-Pishva Branch,Islamic Azad University, Varamin, Iran, varamin, Iran; 2) Department of Medical Genetics, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; 3) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Androgen receptor gene mutations are the leading cause of sex development disorders exhibited by sexual ambiguity or sex reversal. In this study, seven families containing patients clinically diagnosed as androgen insensitivity syndrome (AIS) were genetically evaluated through cytogenetic and molecular analysis including karyotype, polymerase chain reaction (PCR) and sequencing of SRY and AR genes. Two brothers and their mother were hemizygous and heterozygous respectively for c.2522G>A variant, while one of their healthy brother was completely normal hemizygous. Family 2 assessment demonstrated the c.639G>A (rs6152) variant in two siblings who were reared as girls. The SRY gene was intact in all of the study's participants. We could not find any mutation or polymorphism in neither AR nor SRY genes of the other five patients from five families. Our findings in family 1 could be a further proof for the pathogenicity of the c.2522G>A variant. Given the importance of AR mutations in development of morbidities such as disabling sex life and in particular prostate cancer in AIS patients, definitive diagnosis based on molecular genetic approaches accompanied by comprehensive genetic counseling could have promising impacts in clinical management and also in prenatal diagnosis of prospect offspring.

2754W

Ocular Findings in the Marfan Syndrome. *I.H. Maumenee[1], S. Wehrli[2], WW. Xu[2], S. Rahmani[2], S. Kurup[2], I. Kassem[1], M.K. Durbin[2], N. Azar[1], A.A. Fawzi[2], A. Lyon[2], M.B. Mets[2], Chicago Marfan Eye Consortium.* 1) Ophthalmology, University of Illinois Eye and Ear Infirmary, Chicago, IL; 2) Lurie Children's Hospital of Chicago, Chicago, IL.

Purpose: To identify diagnostic criteria and risk factors for vision loss in Marfan patients based upon clinical examination, biometry and OCT imaging of the posterior segment. Material and Methods: 73 patients were seen at Children's Hospital Ophthalmology Clinic in Chicago during the 2012 National Marfan Foundation Conference. Fifty-six patients fit diagnostic criteria for Marfan syndrome and underwent the following examinations: slit-lamp, indirect ophthalmoscopy, biometry, OCT measurements using the Macular Cube 512x128 and Optic Disc Cube 200x200 of the Cirrus HD-OCT (Carl Zeiss Meditec, Dublin, CA). Criterion for OCT inclusion was signal strength ≥ 6 out of 10 without artifacts; the data were analyzed using Cirrus software. Retinal examinations were performed by a vitreoretinal specialist. Color ultra-widefield retinal images were obtained using the Optos 200Tx on 54 patients (108 eyes). The ultra-widefield images were evaluated by a masked vitreoretinal specialist. The color composite images were analyzed with Optos imaging review software. Results were analyzed using Pearson's correlation, 2-tailed tests or one sample t-test. Results: Mean age of patients was 20.7 y (range 2 to 56). Keratometry obtained on 54 eyes showed flattening of the cornea (mean K=41.58D; SD=2.09), ↑corneal thickness, (mean=542.2 µm; SD=42.25); deepened anterior chamber, (mean=3.6mm; SD=0.61), reduced lens diameter (mean=3.84mm; SD=0.48); and increased axial length, (mean=25.39mm; SD=1.91). A dislocated lens was observed in 32% of patients. OCT data showed that 27% of eyes had RNFL thickness <5% of population, suggestive of RNFL loss. There were less significant macular OCT changes. RNFL thickness and macular volume were negatively correlated with axial length but not correlated to age, IOP, or C:D ratio. Peripheral retinal pathology (e.g.: lattice, scars, RD, holes, white without pressure) was identified in 20% of eyes on clinical examination compared with 24% of eyes analyzed using Optos 200 TX. Corneal curvature, AC depth, lens thickness and axial length of the globe (p<.05) can contribute significantly to the diagnosis of Marfan syndrome. 27% of eyes had RNFL thickness <5% suggestive of RNFL loss; 24% had peripheral retinal pathology, both indicative of need for close patient observation.

2755T

Peace Sign Craniosynostosis: A Novel Presentation in Association with Saethre-Chotzen Syndrome. *D.M. McDonald-McGinn[1, 2], N. Bastidas[3], A. Santani[2, 4], C. Stolle[2, 4], C. Bergfield[5], S. Bartlett[2, 3], E.H. Zackai[1, 2].* 1) Div Human Gen, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Perelman School of Medicine, The University of Pennsylvania, Philadelphia, PA; 3) Div Plastic & Reconstructive Surgery, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Dept Path, The Children's Hospital of Philadelphia, Philadelphia, PA; 5) Div Plastic Surgery, Seattle Children's Hospital Seattle, WA.

The combination of metopic, bicoronal and sagittal sutural synostosis produces a severe turribrachycephaly, hypotelorism, bitemporal and biparietal constriction which we have coined 'Peace Sign Craniosynostosis' given the resemblance to the iconic symbol. Saethre-Chotzen syndrome (SCS) is an autosomal dominant condition typically characterized by bicoronal craniosynostosis, ptosis, downslanting palpebral fissures, prominent ear crus, hearing loss, syndactyly, broad laterally deviated halluces, and +/- intellectual disability. Mutations, deletions or duplications of the TWIST1 gene, a basic helix-loop-helix transcription factor located on chromosome 7p21.2, are thought to be responsible for osteodifferentiation and thus premature suture fusion and limb anomalies associated with SCS. To date, over 100 abnormalities involving the TWIST1 gene have been causally related to SCS and although insertions, deletions, nonsense and missense mutations have been described, no genotype-phenotype correlation has been established, suggesting that sequence alterations lead to a loss of functional TWIST1 protein irrespective of the mutation type. Precise penetrance data is not available, however wide phenotypic variability and incomplete penetrance are well described. Here we report the novel association of Peace Sign Craniosynostosis in five patients with SCS. A retrospective review of all patients with bicoronal, metopic and at least partial sagittal synostoses at The Children's Hospital of Philadelphia and Seattle Children's Hospital was performed. Five patients with Peace Sign Craniosynostosis and SCS were identified. 4/5 were found to have TWIST1 abnormalities including a frame shift duplication, two deletions, and a novel point mutation. Results are pending on the 5th child. In terms of management, Patient I underwent three intracranial procedures and required a VP shunt. All other patients had posterior cranial vault distraction as the initial procedure and are awaiting anterior cranial vault remodeling. A second child also required a VP shunt. Thus, synostosis of the metopic, bicoronal and sagittal sutures appears to be associated with SCS and produces a unique yet characteristic skull morphology which we are terming Peace Sign Craniosynostosis. Early long-term data suggests a high rate of reoperation and increased necessity for a VP shunt. Most notably, neither this distinctive presentation nor the etiology has been reported previously.

2756F

Characterization of three families with provisional diagnosis of autosomal dominant retinitis pigmentosa using whole exome sequencing. *L. Vazquez[1], J. Liang[2], B. Almoguera[1], X. Liu[2], P. Fernandez[3], Y. Guo[1], M. Corton[3], B. Keating[1, 4, 5], X. Xu[2], C. Ayuso[3], H. Hakonarson[1, 4, 5], J. Wang[2, 6, 7, 8].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) BGI-Shenzhen, Shenzhen 518083, China; 3) Department of Genetics and Genomics. IIS-Fundacion Jimenez Diaz Hospital. Madrid, Spain; 4) Division of Human Genetics, The Children's Hospital of Philadelphia, 19104 Philadelphia, PA, USA; 5) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA; 6) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 7) King Abdulaziz University, Jeddah, Saudi Arabia; 8) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Denmark.

Introduction: Retinitis pigmentosa (RP) is a clinically and genetically heterogeneous disease with a prevalence of approximately 1 in 4,000. Many modes of inheritance have been described, and more than 60 gene variants have been identified to date. These loci explain ~50% of all cases, and genetic characterization and diagnosis of this condition is complex. Methods: Six families (A-F) with a provisional diagnosis of autosomal dominant RP (adRP) were included in the study. Common adRP variants were previously discarded. A total of 38 individuals (10 affected, 28 unaffected members across families) participated in whole exome sequencing (WES) using the SureSelect Human All Exon kit (Agilent Technologies) and HiSeq 2000 (Illumina). Alignment and variant-calling was performed using standard methods and custom scripts. We filtered variants: 1) in coding regions, 2) segregating in the family under an adRP model, 3) at non-synonymous, splice sitedisrupting, and frameshift sites, and 4) with a MAF<1% in 1000 Genomes Project; NHLBI GO Exome Sequencing Project, and our in-house whole-exome repository. Information on genes associated with RP was retrieved from Retinal Information Network Database and Sanger sequencing was used for variant validation. Results: In three out of the six families, we identified a previously described mutation: two missense mutations in PRPH2 (NP_000313.2, p.D186N, family A) and C1QTNF5 (NP_056460.1, p.S163R, family E), and one frameshift deletion in RPGR (NM_000328.2: c.485_486delTT, family D). Sanger sequencing confirmed the complete segregation of variants in the three families. Discussion: Notably, the only adRP locus identified was PRPH2. This gene had previously been screened in the family but the mutation was missed. In the case of C1QTNF5, p.S163R is a rare mutation responsible for late-onset retinal degeneration (LORD, MIM# 605670), which in the latest phases can mimic RP phenotype. Similarly, RPGR is associated with X-linked RP instead of adRP - an inheritance model not initially considered due to the complete expression of RP in 3 females in the family. Conclusions: WES enabled the characterization of 3 families that had been misclassified in terms of inheritance model and/or phenotype, which is critical for calculating familial risk, and providing adequate genetic counseling.

2757W

Unexplained persistently elevated liver transaminase levels - a presenting feature for Duchenne/Becker muscular dystrophy.
J.A. Wilkinson, M. Martin, B. Hay. Pediatrics - Genetics, UMass Memorial Medical Center, Worcester, MA.

Duchenne/Becker muscular dystrophy (DMD/BMD) occurs due to mutations in the DMD gene. Patients with the more severe DMD phenotype generally present with progressive muscle weakness in early childhood, causing them to be wheelchair bound by adolescence, and an associated cardiomyopathy. Patients with the milder BMD phenotype generally present later in childhood with less severe or even subclinical muscle weakness and longer preservation of ambulation. The majority of affected males will be found to have elevated serum creatinine kinase (CK) levels. Dystrophin staining on muscle biopsy is usually absent in DMD and low to normal in BMD. Due to the invasive nature of muscle biopsy as well as the possible false negative results of dystrophin staining, molecular genetic testing of the DMD gene is the preferred method confirming a suspected clinical diagnosis. We describe four families identified in our clinic as having DMD/ BMD. All four probands presented with persistently elevated liver transaminases of unknown etiology and were referred for possible metabolic/genetic liver disease. In all four patients, findings of elevated liver transaminase levels were incidental. Two patients presented with rash/fevers, one patient presented with new onset seizures, and one patient had undergone routine laboratory surveillance while on stimulant medication. Liver transaminase levels remained elevated despite resolution of the acute illness in three of the cases and discontinuation of the stimulant medication in the fourth case. Two of the patients underwent liver biopsy, which revealed increased hepatic glycogen stores. Upon presentation to the Genetics clinic, CK levels were found to be >10x normal in all four patients, prompting molecular testing of the DMD gene. Three patients were found to have in-frame deletions and one patient was identified as having a complex out-of-frame duplication. At the time of diagnosis, none of the patients had obvious symptoms of muscular dystrophy, although mild findings were noted following the diagnosis in at least two of the probands. Three of the four families underwent targeted DNA analysis and maternal inheritance was confirmed in all three. Based on our clinic's experience with these cases, we suggest that CK levels should be considered in patients with unexplained persistent elevated liver transaminase levels, and molecular genetic testing of the DMD gene be offered in those cases in which the CK is found to be elevated.

2758T

Phenotypic Evolution in Börjeson-Forssman-Lehmann Syndrome: Serial Photos, Endocrine Findings and Dermatologic Observations.
G. Graham[1,3], N. Carson[1,3], D. Picketts[2,3]. 1) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) Ottawa Hospital Research Institute, Ottawa, ON, Canada; 3) University of Ottawa, Ottawa, ON, Canada.

Borjeson-Forssman-Lehmann syndrome (BFLS) is an uncommon X-linked recessive condition caused by mutations in the PHF6 gene. First described in 1962, there are only 51 related publications, a paltry average of one per year. The exact number of reported individuals who have bona fide BFLS is difficult to ascertain but likely between 50 and 75. Many were described prior to the attribution of the gene in 2002, so their diagnosis is not molecularly proven. Some reports do not include photographs; some include photographs that are not convincing and some lack essential clinical details. BFLS is characterized by intellectual disability, epilepsy, central obesity, gynaecomastia, hypogonadism, distal extremity findings and facial dysmorphism, including deep-set eyes and large ears. We present the evolution of this phenotype in half-brothers with a PHF6 mutation, now 13 and 18 years of age, originally felt to have mild BFLS as a result of a splicing mutation that generates an internal deletion of 34 amino acids. Although neither has epilepsy and their intellectual outcome remains more favorable than is often described, one has developed marked facial coarsening and both have developed the obesity, gynecomastia and hypogonadism that is typical of BFLS. We present serial photographs of these brothers as a diagnostic aid. We also present their endocrine profiles, the latter being relatively neglected in the literature. Finally, we highlight what we believe to be unrecognized dermatologic features of BFLS. Both brothers developed multiple pigmented cutaneous nevi over the lateral face and neck and to a lesser extent over the torso and extremities. These are also present in their mother and maternal grandmother, who are manifesting carriers. Both brothers have also developed keloid scars; in one of the two brothers these were severe and disfiguring. We reviewed all published photos of individuals with BFLS. Where photos allow this determination to be made, we noted that the majority of patients have multiple pigmented nevi. We also note keloid scars in at least one of two published patients whose photographs included surgical incision sites. In light of what is understood about PHF6 gene function, we discuss the possibility that these dermatologic findings are a feature of this syndrome and caution against cosmetic surgery in individuals with this diagnosis.

2759F

Identification of a Missense Mutation in the MBTPS2 Gene as the Causeof X-Linked Form of Olmsted Syndrome.
A. Haghighi[1,2], C. Scott[3], D. Poon[3], R. Yaghoobi[4], N. Saleh-Gohari[5], V. Plagnol[6], D. Kelsell[3]. 1) UNiversity of Oxford, Oxford, UK; 2) Department of Genetics, Harvard Medical School, Boston, MA, USA; 3) Centre for Cutaneous Research, The Blizard Institute, Barts & The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 4) Department of Dermatology, Jundishapur University of Medical Sciences, Ahvaz, Iran; 5) Genetic Department, Kerman University of Medical Sciences, Kerman, Iran; 6) Darwin Building, University College London Genetics Institute, University College London, London, UK.

Olmsted syndrome is a very rare severe keratinization disorder characterized by a combination of bilateral mutilating palmoplantar keratoderma and periorificial keratotic plaques. Other reported associated features include corneal lesions, diffused alopecia, digital constriction, diffused alopecia, nail dystrophy, high-tone loss of hearing, infections and squamous cell carcinomas. Treatment of Olmsted syndrome includes topical keratolytics, surgical removal of the keratotic palmoplantar masses followed by autograft, and use of systemic retinoids. However, the outcome is often disappointing and recurrence rate is very high. We investigated the genetic basis of Olmsted syndrome in a consanguineous extended kindred with Olmsted syndrome using whole exome sequencing. Exome sequencing revealed a mutation, which to our knowledge is previously unreported: c.1391T>C (p.F464S) in exon 11 of the X-chromosome gene membrane-bound transcription factor protease, site 2 (MBTPS2) (NM_015884.3) in both male probands. Immunohistochemical staining indicated that MBTPS2 is mainly expressed in the upper granular layer in normal skin, as previously shown; however, in OS skin, MBTPS2 was expressed throughout the epidermis. There was no apparent difference in MBTPS2 localization in the skin of a KFSD patient with the p.N508S mutation. This expands our knowledge about the genetic basis and pathology of Olmsted Syndrome and has applications in genetic counseling.

2760W

Exudative Retinopathy, Cerebral Calcifications, Duodenal Atresia, Preaxial Polydactyly, Micropenis, Microcephaly and Short Stature: A New Syndrome?
B. Isidor[1], A. David[1], Y. Crow[2]. 1) CHU Nantes, Nantes, France; 2) Manchester Academic Health Science Centre, University of Manchester, Genetic Medicine, Manchester, UK.

The association of Coats disease with intrauterine growth retardation, intracranial calcification, leukodystrophy, brain cysts, osteopenia, and gastrointestinal bleeding defines Coats plus syndrome caused by mutations in the CTC1 gene, encoding conserved telomere maintenance component Here, we report on a child with exudative retinopathy, cerebral calcifications, duodenal atresia, preaxial polydactyly, micropenis, microcephaly, and short stature, in whom no mutations in CTC1 were found. Our patient shares some features seen in other diseases associated with telomere shortening including Hoyeraal-Hreidarsson and Revesz syndromes. We therefore measured telomere length by Flow-Fish which was normal. The association of duodenal atresia and microcephaly also suggested a diagnosis of Feingold syndrome. However, direct sequencing ofMYCN was normal, and we did not detect any hemizygous deletion of the miR-1792 polycistronic miRNAcluster.To our knowledge, the phenotype we report on has not been described previously, leading us to speculate that this conditionmay represent a new syndrome.

2761T

Psychological and cognitive profile in four new patients with MOMO syndrome. *C. Passalacqua, M. Garcia, L. Dueñas.* Hospital Carlos Van Buren, Valparaiso, valparaiso, Chile.

MOMO is an acronym for macrosomia, obesity, macrocephaly and ocular abnormalities (OMIM 157980). The first patients were presented in 1993 by Moretti-Ferreira et al. with a total of seven patients published thus far. All the cases presented mental disabillity and in one case austism was described. We present four new cases with a neuropsycologycal profile, there were referal to geneticist and then to psychologist and child psychiatry. All parent patients signed a consent form to participate in the study. All patients were seen by child psychologist who performed WISC III (adapted for Chilean population) and also with child psychiatrist who did the MINI-KID test, used to assess the presence of 24 DSM-IV child and adolescent psychiatric disorders as well as the risk of suicide. The patients are three male (11, 12 and 17 years old) and a female of 13 years old. The four patients fulfill the criterias of macrocephaly, obesity and ophtalmological abnormalities; macrosomia at birth was seen in one patient (male, birth weight: 4985 g >>P99) and another had tall stature to date (male, 11 years, height 159 cm +1.81SD). The karyotype and the Prader Willi methylation test were normal in three patients, in the remain patient are still in process. The four patients had an history of developmental delay, after the psychological evaluation two had ranked as intellectual disability (IQ 51 and 58) and the others as borderline intellectual functioning (IQ 77 and 72). The subscales showed in two patiens asymmetry between verbal skills and execution functions, in three patients the lower skills were assimilate information and cubes assembly. The MINI-KID demostrate that three had psychiatric comorbilities (ansiety, phobia and behavior conduct disorder) the other patient (17 years old) had borderline intellectual functioning, without psychiatric comorbilities and he is more independent in the living day activities. Patient 3 and 4 are siblings from a healthy non consanguineous couple, Moretti-Ferreira suggested an autosomal dominant inherence, while Di Donato theorized an autosomal recessive trait. We think that are still few patients to propose an inherence trait, but the existence of brothers with healthy parents is more suggestive to an autosomal recessive inherence. This is the first neurocognitive evaluation of MOMO patients and we agree with Di Donato who proposed change the M from Macrosomia to Mental (intellectual) disability.

2762F

Pregnancy in Autosomal Recessive Polycystic Kidney Disease/Congenital Hepatic Fibrosis (ARPKD/CHF). *N. Banks, J. Bryant, R. Fischer, M. Huizing, W. Gahl, M. Gunay-Aygun.* Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

ARPKD/CHF is characterized by dilated renal collecting ducts resulting in renal insufficiency and CHF often complicated by portal hypertension. It is caused by mutations in *PKHD1*, which encodes fibrocystin, a protein on the primary cilia-basal body/centriole. The consensus clinical diagnostic criteria for ARPKD/CHF require characteristic kidney and liver involvement, family history consistent with autosomal recessive inheritance, and absence of congenital anomalies. Little is known about pregnancy outcomes for patients with ARPKD/CHF. Patients with other causes of chronic kidney disease are at risk of pregnancy-related decline in renal function, preeclampsia, and impaired fetal outcomes, including higher rates of intrauterine growth retardation and pre-term delivery. Pregnancy with portal hypertension poses similar risks for the mother and baby.

In the ongoing NIH study on ARPKD/CHF and other ciliopathies (www.clinicaltrials.gov, trial NCT00068224), we evaluated 78 patients who fulfilled the clinical diagnostic criteria including 12 females over 18 years of age. Six had children; 4 carried pregnancies and delivered, 1 used assisted reproductive technology with a surrogate, and 1 adopted. Patient 1 is a 61 year old who received kidney-liver double transplantation at age 59. She was unaware of her condition until age 46 when she was diagnosed with Caroli's syndrome (CS) and subsequently with ARPKD/CHF; she had an uneventful pregnancy and delivery at age 33 via cesarean section. Patient 2 was diagnosed with ARPKD/CHF at age 6 months. She became pregnant at age 22 and was initially normotensive with a creatinine of 1.15 mg/dL and an eGFR of 63.9 mL/min/1.73m^2. Her pregnancy and vaginal delivery were clinically uncomplicated, but by delivery creatinine had increased to 1.78 mg/dL and eGFR was 36 mL/min/1.73m^2. Patient 3 was diagnosed with CHF at age 7, underwent splenic embolization at age 13, and delivered vaginally at age 23 following an uneventful pregnancy. Patient 4 was diagnosed with ARPKD/CS at age 24, 3 months after an uncomplicated pregnancy and delivery.

Patients with ARPKD/CHF are at risk of pregnancy-related worsening of kidney and liver disease. Outcomes are likely influenced by pre-pregnancy renal function and severity of portal hypertension. Appropriate preconception counseling is critical to inform patients of pregnancy risks and alternative reproductive options.

X-linked Joubert Syndrome: neuroimaging and clinical features associated with a novel mutation in OFD1. *B. Hashemi[1], H.M. Branson[2], M. Moharir[3], G. Yoon[1, 3].* 1) Division of Clinical Genetics, Hospital for sick children, Toronto, ontario, Canada; 2) Division of Pediatric Neuroradiology,Hospital for sick children, Toronto, ontario, Canada; 3) Division of Neurology,Hospital for sick children, Toronto, ontario, Canada.

Oral-facial-digital syndrome type1 (OFD1; OMIM#311200) is a rare developmental disorder characterized by craniofacial, oral, skeletal abnormalities, cystic kidneys and neurological involvement including mental retardation. The syndrome is caused by mutations in the OFD1 gene and results in male lethality in the first or second trimester. The spectrum of phenotypes associated with mutations in OFD1 continues to expand, and genotype-phenotype correlations are beginning to be recognized. The spectrum includes Simpson-Golabi-Behmel syndrome type 2 (SGB2, OMIM#300209), and X-linked Joubert syndrome (JBS type10) phenotype in addition to the classical OFD1 phenotype with early male lethality. We describe the clinical and neuroimaging findings in a 17 year old male with a clinical diagnosis of Joubert syndrome associated with a novel mutation in the OFD1 gene (JS-10). Our case confirms the reported association of OFD1 gene mutation with X-linked recessive Joubert syndrome. This family is the fifth reported with X linked Joubert syndrome, associated with a novel mutation in exon 17 of the OFD1 gene. We describe unique neuroimaging and clinical features associated with OFD1 mutations and highlight the utility of advanced neuroimaging techniques in characterizing the phenotype.

2764T

Xq11.1-11.2 deletion involving *ARHGEF9* in a girl with autism spectrum disorder. *G. Bhat[1, 2], D. LaGrave[3], A.N. Lamb[4], R. Matalon[2].* 1) Pediatrics, New York Medical College, Valhalla, NY; 2) Medical genetics, Pediatrics, University of Texas Medical Branch, Galveston, TX; 3) Department of Cytogenetics, ARUP laboratories, Salt Lake City, UT; 4) Department of Pathology, University of Utah, Salt Lake City, UT.

We report a de novo *ARHGEF9* deletion in a 6 year old girl presenting with autism spectrum disorder, ADHD, severe speech delay, developmental delays and cognitive impairment. Our patient was born at term without any known complications. She walked at 16 months and started speaking at 2 years of age; she is still unable to make two word sentences. Her hearing is normal and she receives speech therapy at school. There is no history of seizures or sensory hyperarousal and she is not dysmorphic. She was diagnosed with ASD and ADHD by a behavior specialist and is currently receiving therapy. Cytogenomic microarray, using the CytoScan HD platform, demonstrated a de novo 82 Kb deletion involving the X chromosome from Xq11.1 to Xq11.2. This deletion includes a single exon and the 5' end of each of three isoforms of the gene *ARHGEF9*, as well as the micro-inhibitory RNA 1468. X-inactivation studies on peripheral blood did not indicate the presence of significant skewed X-inactivation. *ARHGEF9* codes for collybistin, a brain-specific GEF which interacts with gephyrin, a key protein of the scaffolding system of inhibitory synapses, that is essential for postsynaptic clustering of both GABA and glycine receptors. Gephyrin has been implicated in genetic risk for autism, schizophrenia and epilepsy. Point mutations, disruptions, and deletions of *ARHGEF9* have been reported previously in five patients and are associated with developmental delay, intellectual disability, epilepsy, hyperekplexia and mild dysmorphic features. In our patient, the given clinical features are consistent with the deletion of *ARHGEF9* associated with haploinsufficiency in the presence of non-skewed X inactivation. Our patient is the first reported case of *ARHGEF9* deletion with autism spectrum disorder. This case strengthens the role of *ARHGEF9* in cognitive development and its involvement in a subset of patients with neurodevelopmental disorders. The single gene deletion affecting collybistin may lend itself to benefit by treatment with GABA analogues in these patients. In conclusion, *ARHGEF9* deletion should be considered in patients with autism spectrum disorder, further investigative studies are warranted to explore the treatment options.

2765F

A four generation family with a novel *HRAS* mutation and predominantly ectodermal findings of Costello syndrome.
D. Earl[1], S. Wallace[1, 2]. 1) Genetic Medicine, Seattle Children's Hospital, Seattle, WA; 2) Department of Pediatrics, University of Washington, Seattle, WA.

Costello syndrome is characterized by feeding issues and failure to thrive in infancy, short stature, developmental delay, coarse facial features, sparse curly hair, and loose and/or thickened skin. Cardiac findings include congenital heart defects, cardiac hypertrophy, and arrhythmia. Individuals have a 15% lifetime risk for malignant tumors. *HRAS* is the only gene currently known to be associated with Costello syndrome. Germline mutations leading to amino acid substitutions of the glycine residue at positions 12 or 13 are typical. Most probands have a *de novo* mutation. We present a four generation family with a novel missense *HRAS* mutation and predominantly ectodermal findings. The patient presented at 2 ½ years of age with short stature (-2 SD) and failure to thrive (-2.7 SD). Her head circumference was normal (0.3 SD). Birth parameters were normal. Video swallow study showed oral phase dysphagia, microaspiration, and gastroesophageal reflux. She had mild obstructive apnea and mild central apnea. Bone age was mildly delayed. Her IGF-1 was borderline low. IGF BP-3 and thyroid function studies were normal. She walked and used her first words at 1 year of age. At 5 years of age, she continues to meet normal developmental milestones. Physical examination revealed proportionate short stature, woolly hair, sparse and kinky eyebrows, ptosis with downward eyelashes, epicanthal folds, a wide nasal root, hypoplastic nails, and an eczematous rash involving cheeks, eyebrows and extremities. On ophthalmologic evaluation she had mild anisometropia and possible left amblyopia. Echocardiogram showed a patent foramen ovale and no evidence of hypertrophic cardiomyopathy at 4 years of age. Abdominal imaging has been normal. Platelet function assay was normal despite a report of easy bruising. The patient's mother, maternal grandfather, maternal great-grandfather, maternal uncle and his son have woolly hair, inflammatory skin findings with hyperkeratosis, nail abnormalities, and normal stature. The patient's mother was diagnosed with unilateral breast cancer at 30 years of age. There were no other reported cancers in the family. A novel heterozygous *HRAS* mutation in exon 3, c.175G>A (p.Ala59Thr), was found in the proband, her mother, and maternal grandfather. This family may represent a mild Costello phenotype or a new autosomal dominant disorder characterized by woolly hair and cutaneous findings of ulerythema ophryogenes, eczema, hyperkeratosis, and dysplastic nails.

2766W

Muenke syndrome: phenotype variability of P250R mutation in FGFR3 gene.
T. Felix[1], T.W. Kowalski[1], J. Ferrari[1,2], L.T. Souza[1], M.T.V. Sanseverino[1], M.V. Collares[1], V.S. Mattevi[2]. 1) Serviço de Gen Medica, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Universidade Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, RS, Brazil.

Craniosynostosis is the premature fusion of cranial sutures. It has a prevalence of 1 in 2000 newborns. The FGFR3 gene mutation P250R is responsible for Muenke syndrome. It is an autosomal dominant mutation and it has been shown that accounts for 8% of all craniosynostosis cases. The aim of this study was to analyze P250R mutation in FGFR3 gene in subjects with apparently isolated craniosynostosis. Twenty five subjects with isolated craniosynostosis were included in the study. Of the twelve cases with coronal synostosis, four cases (33%) were positive for P250R mutation. Of the 4 cases with sagittal synostosis, one (25%) was positive for the mutation. None case presenting metopic or lambdoid suture synostosis was diagnosed with the mutation. Radiological evaluation of hand and feet did not showed carpal or tarsal synostosis in all positive cases. Analysis of parent of origin of the mutation showed maternal inheritance in 2 cases and a de novo mutation in one case. Both mothers with P250R mutation also had coronal craniosynostosis. In one of these families, a brother had macrocephaly and ADHD and P250R mutation was diagnosed. The mother of the case with sagittal synostosis had normal head shape but a history of Klippel-Fiel anomaly requiring surgery in infancy. Klippel-Fiel was described previously in the literature in one single family with the P250R mutation, suggesting this anomaly should be part of the phenotype. In conclusion, our study showed the high prevalence of P250R mutation in apparently isolated craniosynostosis and also the variable clinical expressivity of this disorder.

2767T

Investigations on the molecular genetic etiology of Mayer-Rokitansky-Kuster-Hauser syndrome in two cousins using exome sequencing.
M. Herlin[1], S.P. Jonstrup[1], A.T. Højland[1], I.S. Pedersen[2], P.H. Madsen[2], A. Ernst[2], H. Okkels[2], V.Q. Le[2], H. Krarup[2], M.B. Petersen[1]. 1) Department of Clinical Genetics, Aalborg University Hospital, Aalborg, Denmark; 2) Section of Molecular Diagnostics, Department of Clinical Biochemistry, Aalborg University Hospital, Aalborg, Denmark.

Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome (OMIM #277000) is a congenital disorder characterized by aplasia of the uterus and the upper two-thirds of the vagina in females showing normal secondary sex characteristics and a 46,XX karyotype. The MRKH syndrome is often first diagnosed during adolescence where patients present with primary amenorrhoea, but they are also troubled with sexual dysfunction and infertility. MRKH syndrome is classified as type 1 (typical/isolated MRKH), type 2 (complex MRKH with renal, skeletal, or auditory malformations), and MURCS association (Müllerian duct aplasia, renal aplasia, and cervical somite dysplasia). The incidence of MRKH syndrome is estimated to 1 in 4,500 live female births. For a long time, the MRKH syndrome was thought to occur sporadically, but cases of familiar clustering led to the hypothesis of an autosomal dominant inheritance with incomplete penetrance. Several candidate genes involved in early embryonic development, such as WNT4, LHX1, WT1, TCF2 (HNF1β) and homeobox genes (HOXA7-HOXA13), have been investigated in earlier studies, but the molecular genetic etiology of the MRKH syndrome remains unknown. We present a familial case of two female cousins (aged 27 and 19) both with type 2 MRKH (with unilateral renal agenesis) that supports the idea of an autosomal dominant heredity. According to basic Mendelian genetics both their mothers, who are siblings, must be carriers of the MRKH causing mutation. The normal uterus and vagina of both mothers can be explained by incomplete penetrance. Interestingly, the two cousins' late grandfather also had unilateral renal agenesis and one of the cousins had a brother, who died shortly after a preterm birth having complete renal agenesis. It indicates that an MRKH causing mutation could be inherited in a family where males also have renal abnormalities. To reveal the etiology of the two cousins' MRKH syndrome and renal abnormalities, we use a genome-wide approach by carrying out Next-Generation Sequencing of their exomes. We also analyse the exomes of the relatives participating in the study. By using a genome-wide approach, we analyse all candidate genes earlier investigated and furthermore have the opportunity of finding new genes associated with MRKH syndrome. We present one of the first studies using a genome-wide approach and the first study using exome sequencing in the investigation of MRKH patients.

2768F

Novel patient with cutis laxa, fat pads and retinopathy due to ALDH18A1 mutations and review of the literature.
E.V. van Asbeck[1], D.F.G.J Wolthuis[1], M. Mohamed[1], T. Gardeitchik[1], E. Morava[1,2]. 1) pediatrics, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands; 2) pediatrics and human genetics, Hayward Genetics Center, Tulane University Medical School, LA, USA.

Autosomal recessive cutis laxa (ARCL) is a connective tissue disorder characterized by wrinkled, inelastic skin; frequently associated with a multisystem disease. We performed next generation sequencing in genetically unsolved patients with progeroid features, neurological and eye involvement to assess the underlying etiology. Here, we describe one of our patients; diagnosed with a novel, homozygous nonsense mutation in exon 18 of the ALDH18A1 gene, and review all reported P5CS patients. Our patient had dysmorphic, progeria-like facial features and severe, generalized sagging skin with visible veins on the abdomen and thorax. In addition, the patient had severe neurological symptoms, including seizures and spasticity. MRI showed microcephaly and hypoplastic corpus callosum. The patient also had a late closing fontanel, adducted thumbs, salt and pepper retinopathy and failure to thrive. The skin abnormalities were comparable to those described in congenital glycosylation defects (CDG). He had abnormal fat pads on the buttocks and upper legs, and the excessive skin wrinkling, late closing fontanel and seizures are also well known features of CDG. However, ATP6V0A2-CDG and COG7-CDG were ruled out on a molecular and biochemical basis. The adducted thumbs, late closing fontanel, blue sclerae and parchment-like skin could be due to a PYCR1 mutation, although the parchment-like feature of the skin is typically more severe in PYCR1 compared to our patient. PYCR1 too, was ruled out on molecular basis. However, a mutation in ALDH18A1 was found. So far 7 patients with mutations in ALDH18A1 were described. All patients had failure to thrive, five had short stature, three had inguinal hernia, five had cutis laxa on hands and feet, five had visible veins on thorax and abdomen, three had cataract, five were microcephalic and six had joint laxity. Four never learned to walk and four never to speak. Unique features included IUGR, corneal clouding, scoliosis, tremor and dystonia. Our patient is unique due to his abnormal fat distribution, retinal abnormalities, undescended testis, late closing fontanel and severe neurological presentation. Retinitis pigmentosa has never been described in ALDH18A1. In conclusion, the clinical phenotype caused by ALDH18A1 mutations is widely variable. Therefore it is difficult to decide who to screen for P5CS. We suggest genetic testing for possible ALDH18A1 mutations in patients with cutis laxa, FTT, microcephaly and joint laxicity.

2769W

Missense mutation of *MAF* in a Japanese family with congenital cataract. *Y. Narumi[1,6], S. Nishina[2], M. Tokimitsu[3], Y. Aoki[4], R. Kosaki[5], T. Kosho[1], T. Murata[3], F. Takada[6], Y. Fukushima[1].* 1) Department of Medical Genetics, Kitasato University Graduate School of Medical Sciences, Sagamihara, Kanagawa, Japan; 2) Division of Ophthalmology, National Center for Child Health and Development, Tokyo, Japan; 3) Department of Ophthalmology, Shinshu University School of Medicine, Matsumoto, Japan; 4) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 5) Division of Medical Genetics, National Center for Child Health and Development, Tokyo, Japan; 6) Department of Medical Genetics, Kitasato University Graduate School of Medical Sciences, Sagamihara, Japan.

Congenital cataract is defined as a crystalline severe blinding disease and onset within the first year of life. One-fourth patients with bilateral cataracts have inherited trait. More than 40 causative genes of cataracts are encoding structural, cytoskeletal, gap junction channel, membrane associated and cell signaling proteins. It considered difficult to establish phenotype-genotype correlations due to genetic heterogeneity. Therefore, comprehensive mutation analysis using whole exome sequencing (WES) is suitable for the diagnosis of inherited cataracts. We report a family with congenital cataract and *MAF* mutation who were identified by WES. All affected family showed congenital cataract and some members had with coloboma and microcornea. Male family members revealed autism spectrum disorder and hernia inguinalis. It was initially considered that the family had an X-linked semi-dominant inheritance pattern. WES was conducted for 3 DNA samples and *MAF* was included of segregated variants. The *MAF* mutation in the family was not reported previously. The mutations have not been identified in 200 alleles in Japanese control and other unaffected members. These data indicated that the mutation in *MAF* is likely the causal mutation in this family. *MAF* mutation had been reported of only 5 families. The family members which were previously reported had shown various type of cataract and rapidity of onset. The patients with *MAF* mutation shared not only cataracts but also anterior segment abnormalities. Our recent data strongly support that congenital/juvenile cataracts with *MAF* mutations showed microcornea and coloboma.

2770T

Clinical and Mutational Spectrum of Type II Collagenopathy Patients in Korea. *E. Ra[1], H. Park[1], S.H. Seo[1], S.I. Cho[1], T.J. Cho[2], N. Park[1], M.W. Seong[1], S.S. Park[1].* 1) Department of Laboratory Medicine, College of Medicine, Seoul National University Hospital, Seoul, Korea; 2) Division of Pediatric Orthopaedics, Seoul National University Children's Hospital, Seoul, Korea.

Introduction: Type II collagen is a helical molecule which is found in cartilage and the vitreous humor of the eye. Due to its wide distribution, type II collagenopathies show a spectrum of significantly variable conditions. Here we present the phenotypic spectrum of Korean type II collagenopathy patients whose diagnosis was confirmed by the mutation analysis of *COL2A1* gene. Methods: Twenty Korean patients who were suspected of type II collagenopathy were screened for the *COL2A1* gene. DNA was extracted from peripheral blood leukocytes, and *COL2A1* gene mutations were screened via direct sequencing of all 54 exons and multiplex ligation-dependent probe amplification (MLPA). Results: Heterozygous *COL2A*1 mutations were detected in 15 of 20 patients. Among 15 detected mutations, 4 were known (c.823C>T, c.1510G>A, c.2659C>T, c.3121G>A) and 11 were novel (c.619G>A, c.835G>C, c.1519G>T, c.1537G>T, c.1574G>A, c.1826G>T, c.1916G>A, c.2267G>A, c.2833G>A, c.3265G>A, c.3490G>A). Two of them were nonsense mutations and 13 were missense mutations, substituting glycine to other amino acid in triple helix domain. Variable skeletal phenotypes were observed; Czech dysplasia, spondyloepiphyseal dysplasia, spondyloepimetaphyseal dysplasia Strudwick type, Legg-Calve-Perthes disease, and Stickler syndrome. Spondyloepiphyseal dysplasia was diagnosed in 9 cases, which was the most common finding in this study. In 2 cases, diagnoses were not clearly categorized. Interestingly, a nonsense mutation which had been previously reported in a case of Stickler syndrome was found in a patient with Legg-Calve-Perthes disease. In addition, five cases with no mutation of *COL2A1* include one patient with Legg-Calve-Perthes disease, another with family history of early onset osteoarthritis and three with suggestive findings of spondyloepiphyseal dysplasia and brachydactyly. Conclusion: Variable phenotype may occur even within the individuals sharing a same mutation in *COL2A1* gene. This may be due to the effect of other genetic factors related in the developmental process. Confirming the diagnosis of a type II collagenopathy by mutation analysis is important in predicting the possible complications of the condition as well as providing an accurate genetic counseling for other family members.

2771F

Clinical spectrum of eye malformations in 4 new patients with Mowat Wilson syndrome. *A. BOURCHANY[1], I. GIURGEA[2], J. THEVENON[3], A. GOLDENBERG[4], G. MORIN[5], D. BREMOND-GIGNAC[6], P-O. LAFONTAINE[1], D. THOUVENIN[8], J. MASSY[9], A. MASUREL-PAULET[3], C. THAUVIN-ROBINET[3], S. EL CHEHADEH[3], S. LYONNET[7], L. FAIVRE[3].* 1) CHU Hôpital d'Enfants, University of Burgundy, Dijon , Burgundy, France; 2) Department of Genetics, Hôpital Henri Mondor, University of Paris Est Creteil, Paris, France; 3) Department of Genetics and Rare Diseases and Development Abnormalitiies and Malformative Syndroms ,CHU Hôpital d'Enfants, University of Burgundy, Dijon, France; 4) Department of Clinical Genetics, Hôpital Charles Nicolle, University of Rouen, Rouen, France; 5) Department of Oncogenetics and Clinical Genetics, hôpital Nord, University of Picardie Jules Verne , Amiens, France; 6) Pediatric Ophtalmology Saint Victor Center, University of Picardie Jules Verne, Amiens, France; 7) Department of Medical Genetics , Hôpital Necker-Enfants Malades, University of Paris 5 René-Descartes, France; 8) Jean Jaurès Ophtalmogic Center, Toulouse, France; 9) Hôpital Charles Nicolle, University of Rouen, Rouen, France.

Mowat-Wilson syndrome (MWS) is a multiple congenital anomaly syndrome characterized by a distinct facial phenotype, intellectual deficiency, Hirschsprung disease and multiple malformations caused by mutations or deletions in the zinc finger E-box-binding homeobox2 gene (ZEB2). To date, nearly 200 cases have been reported in the literature. ZEB2 encodes for Smad-interacting protein 1, a transcriptional co-repressor involved in the transforming growth factor β (TGFβ) signaling pathway and is strongly transcribed at an early stage in the developing central and peripheral nervous system in mice. Eye abnormalities have been rarely described in patients with this syndrome (4% in literature). Herein, we describe 4 patients (2 males and 2 females) with MWS and eye malformations, with a mean age of 7 years. Eye malformations included microphtalmy, iris/retinal colobomas, atrophy or absence of optic nerve, absence of optic disc, total hyphema, and deep refraction troubles, sometimes with severe visual consequences. Malformations were asymmetric in all cases and often unilateral. This spectrum of manifestations, affecting all eye segments, was superimposable with the 8 previous cases mentioned in the literature (iris/chorioretinal/optic disc coloboma, optic nerve atrophy, retinal epithelium atrophy, cataract, korectopia), as well as expression data of ZEB2 in human embryo. With the help of the literature data, we questioned whether or not the presence of eye manifestations could be due to specific type or locations of mutations. We conclude that the presence of eye malformations, although a rare feature in MWS, should not rule out the diagnosis.

2772W

A case of Autosomal Dominant Cutis Laxa within a familial context of cansanguinity. *M.B. DUZ[1], A. GEZDIRICI[1], E. KOPARIR[1], E. YOSUNKAYA[1], H. ULUCAN[1], M. SEVEN[1], A. DE PAEPE[3], P.J. COUCKE[3], B. CALLEWEART[3], M. OZEN[1,2].* 1) Istanbul University Cerrahpasa Medical Faculty, Istanbul, Turkey; 2) Department of Pathology & Immunology Baylor College of Medicine, Houston, TX, 77030, USA; 3) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Autosomal Dominant Cutis Laxa is a rare connective tissue disorder characterized by loose, redundant skin folds that may be apparent form birth or appear later in life. Most severely affected areas are the neck, axillar regions, trunk, and groin. Typically, patients presents with characteristic facial features including a premature aged appearance, long philtrum, high forehead, large ears, and a beaked nose. Cardiovascular and pulmonary complications include bicuspid aortic valves, aortic root dilatation, and emphysema. Sporadically, these complications have been documented to cause premature death. Most patients harbor frameshift mutations in the last 5 exons of the ELN gene (ADCL1, OMIM#123700), while one patient was described to have a tandem duplication in the FBLN5 gene (ADCL2, OMIM#614434). We report on a two year-old female patient with severe generalized cutis laxa also affecting the limbs. The skin was mildly hyperexensible. She further presented with sagging checks, large ears, a pectus excavatum, mild thoracolumbar scoliosis, a right inguinal hernia and mild joint hypermobility. Motor development was normal but she had a mild speech delay. She is the first child of consanguineous parents (first cousins). Despite the consanguinity, the clinical phenotype, ADCL seemed more likely and was confirmed by ELN mutation analysis showing a previously undescribed c.2156del (p.Gly719Glufs*36) mutation in exon 30 of the ELN gene. In conclusion, this novel case of ADCL emphasizes that careful clinical assessment remains essential in the evaluation of a patient with cutis laxa, and that consanguinity does not preclude the dominant form in this rare pathology.

2773T

Weaver Syndrome: Variable expression and natural history in a three generation family with documented EZH2 mutation. *H. Hoyme[1], A.R. Mroch[1], P.L. Crotwell[1], Y.E. Hsia[2], L. Hasegawa[2], S. Lee[2], L.H. Seaver[2].* 1) Sanford Research/Office of Academic Affairs, Sanford Health, Sanford School of Medicine of the University of South Dakota, Sioux Falls, SD; 2) Kapiolani Medical Specialists, University of Hawaii John A. Burns School of Medicine, Honolulu, HI.

Weaver syndrome is an autosomal dominant condition characterized by tall stature, macrocephaly, round face in infancy, broad forehead, hypertelorism, large ears and early developmental delay. Recently, mutations in the EZH2 gene have been identified as the cause of Weaver syndrome. The purpose of this report is to provide detailed information on the natural history and intrafamilial phenotypic variability in six individuals in a 3 generation family with Weaver syndrome, including the oldest reported patient, a 53 year old female. Our proband, a 10 year old girl, was evaluated for overgrowth at 10 months with a family history of Sotos syndrome. By age 2.5 years, her features were noted to be more typical of Weaver syndrome. Her mother and sister were evaluated at ages 26 and 2 years, respectively, for overgrowth. The mother is 188 cm tall with an OFC of 59 cm. As an adult, the proband's sister is 183 cm tall and has 4 children, 3 with overgrowth and features suggestive of either Weaver or Sotos syndrome. The two eldest had normal NSD1 testing. EZH2 testing on the two youngest children (both clinically affected) revealed a previously identified pathogenic mutation, c.2050C>T, p.R684C. The mutation was confirmed in our proband. Mutation analysis on the two older children, one clinically affected and one clinically normal, is pending. Term birth weights ranged 3.1-5.2 kg. All had excessive linear growth and macrocephaly during infancy, speech delay and articulation difficulties with milder motor delay. The adults graduated from high school. Medical complications include scoliosis, duplicated ureter, avascular necrosis requiring early hip replacement, pulmonary embolism, tonsillectomy for airway obstruction, cholecystectomy, umbilical hernia repair and neonatal tachyarrhythmia. Behavioral and psychiatric concerns were common. None have had malignancy. Several of the children demonstrated a phenotype more compatible with Sotos syndrome in infancy, progressing to a Weaver syndrome phenotype as they aged. Data from this family further enlarge the phenotype of the Weaver syndrome and highlight the difficulty in differentiating Weaver from Sotos syndrome in isolated cases. The identification of EZH2 mutation as causative for Weaver syndrome will help differentiate the two disorders and allow for more accurate phenotypic characterization of both.

2774F

Xeroderma pigmentosum complementation group B / Trichothiodystrophy spectrum in two siblings with ERCC3 mutations. *M. Migliavacca[1], N. Sobreira[2], S. Bragagnolo[1], M. Ramos[1], D. Valle[2], A. Perez[1].* 1) Clinical Genetics, Federal University of São Paulo, São Paulo, São Paulo, Brazil; 2) Institute of Genetic Medicine , Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Nucleotide excision repair (NER) is the main cellular repair pathway by wich a wide range of DNA lesions are eliminated from the genome.The importance of DNA repair is demonstrated by the existence of at least 15 human genetic disorders associated with defects in DNA repair and defects in approximately 35 different genes. In most cases, there is a greatly elevated cancer incidence and multi-system defects. Xeroderma pigmentosum (XP, OMIM 278700-278780), Cockayne syndrome (CS, OMIM 216400, 133540) and Trichothiodystrophy (TTD, OMIM 601675) are autosomal recessive disorders caused by defects in the repair of DNA, remarkable clinical heterogeneity exists within these diseases. The ERCC3 gene (Excision-Repair Cross-Complementing group 3 gene) is related to them and encodes a DNA helicase that acts in the NER pathway and a component of the transcription factor BTF2/TFIIH that initiates transcription of class II genes. Inactivation of the NER pathway can result in the classic phenotype of XP, while inactivation of transcription can lead to photosensitivity phenotype like XP, CS and TTD. Here we describe a sister and a brother born to a non consanguineous 26 years old mother and a 22 years old father, both with developmental delay, recurrent pneumonia, cutaneous xerosis, moderate sensorineural hearing loss, and retinitis pigmentosa. The sister had head circunference of 53 cm (-1DP), her weight was 47kg (p3-5) and height was 1,56 cm (p10), she had dry hair, sparse eyebrows, and a skin lesion in the right anterior cervical region with a descamative aspect. The brother's head circunference was 53 cm (<p3), his weight was 67 kg (p25-50) and height was 1,67 cm (p10), he had microcephaly, dry hair and ichthyosis. To date no skin tumors were diagnosed in neither one of them. WES was performed in the brother and compound heterozygous mutations were identified in exons 11 (c.1763_1764insG; p.E588fs) and 7 (c.C1004T: p.S335L) of ERCC3. Sanger sequencing showed that the mother was heterozygous for the p.S335L mutation, the father was heterozygous for the p.E588fs and the affected sister was compound heterozygous for both mutations. Our results imply the ERCC3 gene as the responsible for the phenotype in this family. Up to now only six families have been described in the literature with mutations in ERCC3. The absence of skin cancer in our patients may be explained by compensation through an alternative process and by the nature of the compound heterozygous mutation.

Craniofacial phenotypes in cutis laxa. *Z. Urban[1], C. Lorenchick[1], T.E. Parsons[2], K. Levine[1], S. Madan-Khetarpal[3], S.M. Weinberg[2].* 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) Department of Oral Biology, University of Pittsburgh School of Dental Medicine, Pittsburgh, PA; 3) Department of Pediatrics, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Cutis laxa (CL) is a rare connective tissue disorder. Anecdotal reports suggest that individuals with CL may have distinctive craniofacial features, but no quantitative analysis of the craniofacial phenotype has been carried out on this population. Our goal was to apply objective methods to this problem. 23 subjects with cutis laxa were included in this study. Participants underwent physical examination and the medical history and results of the examination were collected using a questionnaire. 3-dimensional (3D) images of the head and face were acquired using a 3DMD portable stereophotogrammetry system. 24 facial landmarks were identified on each subject's 3D facial image, and a geometric morphometric analysis was performed to quantify facial shape. A subset of 6 CL subjects were compared to 18 sex and age-matched controls by principal components analysis. The first principal component captured 39% of the total variation and separated CL subjects from controls. CL patients had significant narrowing and elongation of the face as well as mandibular hypoplasia. Our studies define and quantify craniofacial traits in CL and implicate CL genes as regulators of craniofacial development.

2776T

Expanding the RAD21 mutational spectrum: report of the first intragenic deletion and frameshift mutation in two patients with a mild form of Cornelia de Lange Syndrome. *A. Minor[1], M. Shinawi[2], J.S. Hogue[3], D.R. Hamlin[3], C. Tan[1], K. Donato[1], L. Wysinger[1], S. Botes[1], S. Das[1], D. del Gaudio[1].* 1) Human Genetics, University Chicago, Chicago, IL; 2) Department of Pediatrics, Division of Genetics and Genomic Medicine, Washington University School of Medicine, St. Louis, Missouri; 3) Department of Pediatrics, San Antonio Military Medical Center, Fort Sam Houston, Texas.

Cornelia de Lange syndrome (CdLS) is a developmental disorder characterized by limb reduction defects, characteristic facial features and impaired cognitive development. In the majority of cases mutations in NIPBL can be identified. However, additional genes have been implicated in the disorder. Recently, missense mutations and whole gene deletions in RAD21 have been identified in children with growth retardation, minor skeletal anomalies, and facial features that overlap findings in individuals with CdLS. We expand the RAD21 mutational spectrum by reporting the first intragenic deletion and the first frame shift mutation identified in two patients presenting with a mild form of CdLS. Patient 1 is a 2 ½ year old boy with developmental delay, hypospadias, inguinal hernia and some dysmorphic features that included mild synophrys, coarse facial features, 5th finger clinodactyly and overlapping of toes two over three. Patient 2 is a 12 year old boy who was diagnosed with CdLS at around a year of life on the basis of developmental delays, characteristic facial features, hirsuitism, and hand and feet anomalies. In patient 1, an intragenic deletion involving RAD21 exon 13 was identified by exon-targeted array comparative genomic hybridization. Breakpoint junction sequence analysis identified a five base pair region of microhomology around the deletion breakpoints, suggesting that the deletion arose through a microhomology-mediated repair mechanism. In patient 2, sequence analysis of the RAD21 coding region revealed a two base-pair duplication in exon 6, c.592_593dup. This frameshift duplication causes premature stop codon at amino acid position 203. mRNA sequences that contain a premature stop codon may be targeted for nonsense mediated decay. The single exonic deletion and the frame shift mutation of RAD21 identified in our patients were associated with a mild presentation of CdLS. As supported by previous literature reports, our data confirm that RAD21 mutation analysis is indicated in patients presenting with milder phenotypes of CdLS.

2777F

Two Novel Mutations in a Patient with Rhizomelic Chondrodysplasia Punctate Type 1. *H. Onay[1], M. Saka Guvenc[1], T. Atik[2], A. Aykut[1], O. Cogulu[1,2], F. Ozkinay[1,2].* 1) Medical Genetics, Ege University Faculty of Medicine, Izmir, Turkey; 2) Pedsiatrics, Ege University Faculty of Medicine, Izmir, Turkey.

Rhizomelic chondrodysplasia punctate (RCDP) is an autosomal recessive peroxisome biogenesis disorder characterized by prominent skeletal manifestations, such as proximal shortening of the long bones, multiple punctate epiphyseal calcifications and multiple joint contractures. Additionally, these patients have congenital cataracts, severe mental deficiency and postnatal growth retardation. Dismorphic features such as hypertelorism, midface hypoplasia, small nose and full cheeks are seen in these patients. Three clinically indistinguishable forms of RCDP have been defined up to now and mutations in three different genes are responsible for these specific forms. PEX7 gene is responsible for the most common form of the disease, Type 1 RCDP. Only a few patients survive beyond first decade and death usually results from generalized neurologic impairment and respiratory complications. PEX7 gene, which comprises 10 exons is located on 6q21-q22. Due to mutations of this gene, transportation of PTS2 containing proteins including peroxisomal 3-ketoacyl-CoA thiolase and PTS2-EGFP protein to the surface of the peroxisomes is impaired. Herein we present a case with dismorphic features such as depressed nasal bridge, short philtrum, high arched palate, anteverted nares; shortened femur, tibia, humerus and fibula which were diagnosed radiologically, multiple punctate epiphyseal calcifications and congenital cataract. There is consanguinity between parents. Mutation screening in the PEX7 gene revealed two new mutations that were never identified before. p.D308Y mutation which is located in exon 10 was inhereted from mother and IVS6 -2 A>G was inhereted from father. In silico analysis indicated that these two mutations were harmful. We present this case to demonstrate two novel mutations detected in PEX7 gene and to remind the importance of having two different mutations in consanguineous families.

2778W

Hereditary multiple osteochondromas. Molecular characterization of three Cypriot families and report of two novel *EXT1* gene deletions. *G.A. Tanteles[1], V. Neocleous[2], C. Shammas[2], E. Ellina[1], L.A. Phylactou[2], C. Sismani[3], V. Anastasiadou-Christophidou[1].* 1) Clinical Genetics, The Cyprus Institute of Neurology and Genetics, Nicosia, Nicosia, Cyprus, Cyprus; 2) Department of Molecular Genetics, Function and Therapy. The Cyprus Institute of Neurology & Genetics, 1683, Nicosia, Cyprus; 3) Department of Cytogenetics and Genomics, The Cyprus Institute of Neurology & Genetics, 1683, Nicosia, Cyprus.

The disorder hereditary multiple osteochondromas (HMO) - previously called hereditary multiple exostoses (HME) - is characterized by the development of multiple osteochondromas (benign cartilaginous bony tumors which grow outward from the metaphyses of long bones) which can lead to a reduction in skeletal growth, bony deformities, restricted joint motion, short stature, premature osteoarthrosis, and compression of peripheral nerves. The risk for malignant transformation (typically osteochondrosarcoma) increases with age, although the lifetime risk is low (~1%). HMO is inherited in an autosomal dominant manner and is caused by mutations in either the *EXT1* or the *EXT2* genes, which account for approximately 60-70% and 20-30% of cases, respectively. This study presents the molecular characterization of three Cypriot HMO patients and their families who underwent genetic analysis of the *EXT1* and the *EXT2* genes. Mutation analysis was performed by direct sequencing of the entire coding regions of both genes. In an attempt to identify deletions or duplications, MLPA and array-CGH analyses were also used. Two novel *EXT1* gene deletions and the previously known *EXT1* p.R701stop mutation were respectively identified in three probands and members of their families. The two novel *EXT1* large deletions ranged from 4.64kb to 0.16Mb. The breakpoints of the first deletion were located within the coding region of exon 1 of the *EXT1* gene while the second deletion removed exons 2 to 11 of the same gene. These observations provide additional evidence of the variability in phenotypic expression and mutational spectrum which is characteristic of HMO, and represent the first genetic analysis of Cypriot HMO patients. Hopefully this analysis can help towards effective diagnosis, improved genetic counseling and be used as a future potential therapeutic platform for patients affected with HMO in Cyprus.

2779T

First molecular study of Kindler syndrome in three Iranian families: novel and recurrent mutations in the FERMT1 gene. *H. Vahidnezhad[1,2], L. Youssefian[2], A. Yazdanfar[3], AM. Kajbafzadeh[4], F. Agha-Hosseini[5], M. Tabrizi[2].* 1) Biotechnology Research Center, Department of Molecular Medicine, Pasteur Institute of Iran, Tehran, Iran; 2) Medical Genetics, Tehran University of Medical Sciences, Tehran, Tehran, Iran; 3) Department of Dermatology, Hamedan University of Medical Sciences, Hamedan, Iran; 4) Pediatric Urology Research Center, Pediatric Center of Excellence, Tehran University of Medical Sciences, Tehran, Iran; 5) Department of Oral Medicine, Dental Research Center, Dentistry School, Tehran University of Medical Sciences, Tehran, Iran.

Bullous acrokeratotic poikiloderma or Kindler syndrome (OMIM 173650) is a rare autosomal recessive genodermatosis characterized by dysphagia, extensive diffuse poikiloderma, minimal trauma-induced blisters, acrokeratosis and cutaneous atrophy. Kindler syndrome is caused by various mutations in the FERMT1 gene encoding kindlin-1, a component of focal adhesions in keratinocytes in which less than 60 mutations have been reported so far. In contrast to most other countries, the burden of this disease seems to be higher in Iran due to consanguineous marriages. For the first time, we conducted a molecular analysis of three separate families from different ethnic populations in Iran toward better genetic characterization and better management of this unique population. After obtaining written informed consent from families, extensive family history was documented and DNA was extracted from patient blood samples. PCR reaction was set up for 15 exons and nearby intronic regions of the FERMT1 gene. PCR products from eight patients in three separate families were bidirectionally sequenced and analyzed. Two affected brothers from central Iran harbored the c.328C>T (p.Arg110X) homozygous mutations in exon 3. Carrier testing was also performed for four other siblings in this family, and in genetic counseling sessions the available reproductive options and recurrent risks for the heterozygotes were discussed. From Azerbaijan, two affected brothers presented with the least severe clinical manifestations with only cutaneous and no extra-cutaneous involvement. The two Azerbaijani brothers seem to be homozygotes for a probable missense mutation c.1577G>A (p.Arg526Lys) after sequencing and analysis of the entire length of the gene. This variant, in heterozygous form, is classified as a polymorphism and non-pathogenic. This is the first report of homozygosity and pathogenicity of this variant. A third family from western Iran with four severely affected siblings were found to harbor a novel mutation c.1383C>A (p.Tyr461X). In conclusion, we provide evidence for novel mutations in the FERMT1 gene from Iran and expand the existing spectrum of mutations in humans. This data also allows us to provide genetic testing to affected individuals and propose the possibility of using PCR and sequencing as a cheap and quick screen of the heterozygotes in the population. Genetic counseling, education, and follow-up could reduce the burden of this disease in Iran.

2780F

Genotype-Phenotype Relationships in Freeman-Sheldon Syndrome. *A.E. Beck[1,2], M.J. McMillin[1], H.I.S. Gildersleeve[1], K.M.B. Shively[1], M.J. Bamshad[1,2,3].* 1) Department of Pediatrics, Division of Genetic Medicine, University of Washington School of Medicine, Seattle, WA; 2) Seattle Children's Hospital, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

The distal arthrogryposis (DA) syndromes are a group of ~10 disorders characterized by multiple congenital contractures such as camptodactyly and clubfoot. DA type 2A (i.e., Freeman-Sheldon syndrome) is the most severe of the DA syndromes as it is also manifest by contractures of the facial muscles. DA2A is caused by autosomal-dominant mutations in *MYH3*, the gene that encodes embryonic myosin heavy chain, a protein of the contractile apparatus of skeletal muscle. In our cohort of 46 families with DA2A, we found disease-causing mutations in *MYH3* in 43 kindreds (93%). We then characterized the genotype-phenotype relationships in these mutation-positive families with DA2A. Three common *MYH3* mutations accounted for 39/43 (91%) of the DA2A mutation-positive kindreds including: 8/43 (19%) with p.T178I, 11/43 (26%) with p.R672C, and 20/43 (47%) with p.R672H. Using a quantitative phenotype score that we developed based on physical findings and natural history, we found individuals with p.T178I to have a phenotype score that was more severe than individuals with a p.R672C or p.R672H mutation. Specifically, the p.T178I mutation was associated with more severe facial contractures and congenital scoliosis. The p.R672C mutation was associated with less severe foot and facial contracture scores. Of the total 46 cases screened, 11 were familial cases and 35 were sporadic cases. *MYH3* mutations were found in all of the familial cases and in 32/35 (91%) of the sporadic cases. Severe phenotypes were more common among sporadic cases than familial cases. For example, the mutation with the most severe phenotype scores, p.T178I, was observed in only sporadic cases (8/8). The mutation associated with the least severe phenotype scores, p.R672C, was observed in only 3/11 (27%) sporadic cases but 8/11 (73%) familial cases. Collectively, our analysis suggests that *MYH3* genotype is predictive of phenotype and, to a more limited extent, natural history of individuals with DA2A.

2781W

A 24bp deletion in ELN causing a Marfan-like phenotype. *J. Hoyer, C. Kraus, A. Reis.* Institute of Human Genetics, University Erlangen-Nuremberg, Erlangen, Germany.

We report on a 27 year old male presenting with a Marfan-like phenotype. The patient had a mild myopia, a high palate and broad uvula, skin striae, a plain flat foot, a positive wrist sign as well as long fingers and toes and an increased arm span-to-height ratio. Moreover a threefold patellar luxation was reported. Marfan syndrome was suspected three years ago when funnel chest surgery was performed. A cardiological examination was consecutively recommended but revealed no abnormalities. The recently revised diagnostic criteria for Marfan syndrome integrate information from multiple sources including personal medical history and physical examination. Those features are weighted and grouped to derive a 'systemic score'. In the absence of a family history of Marfan syndrome, a systemic score of ≥7 in combination with an aortic root enlargement is sufficient for the diagnosis. Our patient achieved a systemic score of 7 but did not show an aortic dilatation. We used an individual, Multiplex-PCR based Ion AmpliSeq Kit capturing 98,44 per cent of coding regions to analyze the genes FBN1, ACTA2, ELN, CBS, FBN2, MYH11, COL3A1, SLCA10, SMAD3, TGFBR1, TGFBR2 and TGFB2. Surprisingly we identified a small heterozygous in frame deletion of 24 bp (c.1178_1201del24bp) in exon 20 of the ELN gene leading to a loss of 8 amino acids (p.Gly393_Ala401delinsAla). This result was confirmed by Sanger sequencing. We suppose that expression of a mutated protein leads to the disruption of elastic fibre architecture. Up to now mutations in Elastin are only known for autosomal dominant Cutis laxa (ADCL) and as a cause for aortic aneurysms but are not described as causative for other Marfan phenotype features. For further evaluation physical examination and molecular analysis in the patient's parents is planned.

2782T

Multiple pterygium syndrome, Escobar variant, in a patient with a congenital diaphragmatic hernia and prenatally-diagnosed arthrogryposis. *A.L. Sutton, M.D. Descartes.* Department of Genetics, University of Alabama at Birmingham, Birmingham , AL.

Introduction: The multiple pterygium syndromes (MPS) are characterized by arthrogryposis, webbing of the skin (pterygia), dysmorphic facial features, and other congenital anomalies. There are two forms of MPS: the lethal and non-lethal (Escobar) variant. MPS displays significant locus heterogeneity. Some cases are caused by mutations in the gene encoding the gamma-subunit of the acethycholine receptor (*CHRNG*), which is only expressed during fetal life. Case Report: We describe a patient with prenatally-diagnosed arthrogryposis and a congenital diaphragmatic hernia with MPS, Escobar variant, with heterozygous mutations in *CHRNG*. The mother, a 40 year old G3P2, was referred to our fetal diagnosis center at 25 weeks for multiple congenital anomalies. The detailed ultrasound showed multiple joint contractures, skin edema, and polyhydramnios. Amniocentesis returned a normal female karyotype. She was delivered via cesarean section after a failed induction of labor at 39 weeks. After birth, she was found to have a congenital diagphragmatic hernia, which was repaired on day of life 12. Genetic testing revealed two truncating mutations in *CHRNG* (c.459dupA and c.753_754delCT). After serial casting and physical therapy, she started standing at 16 months of age. Discussion: Diaphragmatic hernias are one of the findings in lethal multiple pterygium syndrome. Although diaphragmatic eventrations have been found in patients with MPS, Escobar variant, diaphragmatic hernias have not previously been described in this syndrome. Additionally, homozygosity for these two truncating mutations have been associated with the lethal form of the disorder, while compound heterozygotes for these two mutations with the Escobar phenotype similar to this case have also been described. This case highlights the phenotypic and genetic heterogeneity in the MPS. MPS should be considered in the differential diagnosis in patients with prenatally-diagnosed arthryogryposis and congenital diagphragmatic hernias.

2783F

Congenital Dyserythropoieic anemia type 1 (CDA 1) presenting with blueberry muffin rash and profound anemia. *L. Turner[1], L. Goodyear[2], L. Bowes[2], S. Fernandez[1], A. Hogg[2].* 1) Medical Genetics, Memorial University of Newfoundland, St. John's, NL, Canada; 2) Pediatric Hematology/Oncology, Eastern Health, Janeway Child/Rehab Centre, St. John's, NL, Canada.

The term blueberry muffin rash was first used to describe a non-blanching purpuric rash that can be seen in neonates with congenital infections. Biopsy findings of the lesions seen reveal extramedullary hematopoiesis. The differential diagnosis of blueberry muffin rash includes infection, neoplasms, and hematologic dyscrasias. More recently, Aicardi-Goutieres syndrome and Mucolipidosis 2 have been added to the list of disorders that can present in the neonatal period with blueberry muffin rash. We present a 37 week gestation singleton male born with a blueberry muffin rash and hepatomegaly. He was depressed at birth requiring intubation and ventilation. Initial CBC revealed a hemoglobin of 56 g/L. Physical examination revealed several digit abnormalities including small finger and toenails, 4-5 toe soft tissue syndactyly and a small 3rd toe on the right foot. The infant was also noted to have a short neck with redundant nuchal skin, bilateral epicanthic folds and mild micrognathia. He had significant hepatosplenomegaly. Initial investigations for congenital infection were negative. Karyotype and microarray were normal. Ongoing investigations including repeat blood smear and bone marrow examination showed abnormalities but were not diagnostic of any one condition. Given the hematologic picture and the digit abnormalities CDA 1 was considered. Molecular analysis revealed compound heterozygous mutations in the CDAN 1 gene. Our patient was started on interferon and is doing well. He is the first reported patient with CDA 1 presenting with blueberry muffin rash. CDA 1 should be added to the differential diagnosis of infants presenting with blueberry muffin rash.

2784W

Whole exome sequencing uncovers mutations in MYH9 associated with expanded phenotype spectrum. *C. Kao[1], J. Liang[2], A. Alodaib[3], Y. Guo[1], L. Tian[1], X. Liu[2], L. Dai[2], B. Keating[1,4,5], M. Menezes[3], W. Gold[3], M. Wilson[6], L. Ades[6], J. Zhang[2], A. Kakakios[7], J. Wang[2,8,9,10], H. Hakonarson[1,4,5], J. Teo[11].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia; Philadelphia, PA, USA; 2) BGI-Shenzhen; Shenzhen 518083, China; 3) Genetic Metabolic Disorders Research Unit, Children's Hospital at Westmead; Westmead, New South Wales, Australia; 4) Division of Human Genetics, The Children' s Hospital of Philadelphia; Philadelphia, PA, USA; 5) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania; Philadelphia, PA, USA; 6) Clinical Genetics Dept, Children's Hospital at Westmead; Westmead, New South Wales, Australia; 7) Immunology Dept, Children's Hospital at Westmead; Westmead, New South Wales, Australia; 8) Department of Biology, University of Copenhagen; Copenhagen, Denmark; 9) King Abdulaziz University; Jeddah, Saudi Arabia; 10) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Denmark; Copenhagen, Denmark; 11) Haematology Dept, Children's Hospital at Westmead; Westmead, New South Wales, Australia.

Dominantly inherited deleterious mutations in the human gene MYH9 (myosin, heavy chain 9, non-muscle) have been linked to a range of rare hereditary disorders with the overlapping platelet manifestation of macrothrombocytopenia (MTCP), and they can also cause associated symptoms of hearing impairment, nephropathy, leukocyte inclusion and/or cataract. In the current study, we used whole exome capture followed by next generation sequencing to search for causative mutations in two families with MTCP The proband in the first family presented with MTCP, craniosynostosis and hearing loss and was found to have a MYH9 mutation (amino acid change S96L); the proband in the other family presented with MTCP, severe mental retardation, epilepsy, facial malformations and renal calculi and was found to have another MYH9 mutation (A95T). While these two mutations have been reported before, the presentation of developmental, intellectual and psychiatric abnormalities is atypical and new to the MYH9-related diseases. We validated these mutations by traditional Sanger sequencing and the WES data excluded the possibility of other genetic mutations being causal for the syndromes. These results demonstrate that by providing fast and accurate diagnosis at the molecular level, next generation exome sequencing can help broaden the symptomatic spectrum of an established genetic disorder when the presentation is atypical.

2785T

Mutations in *FAM111B* cause Hereditary Fibrosing Poikiloderma (HFP) with tendon contracture, myopathy and pulmonary fibrosis. *S. Mercier[1,2], S. Küry[3], G. Shaboodien[4], D. Houniet[5], N. Hereditary Fibrosing Poikiloderma (HFP) with tendon contracture and pulmonary fibrosis has been described in a South-African family with autosomal dominant inheritance by Khumalo *et al.* in 2006. Here, we report four sporadic cases affected with this syndrome in two males and two females (ages 6-30). Key features consist of: (i) congenital poikiloderma, hypotrichosis, hypohidrosis; (ii) tendon contracture with feet varus deformation; (iii) progressive muscular weakness and (iv) progressive pulmonary fibrosis. Muscle MRI shows extensive fatty infiltration confirmed by muscle biopsy. Microscopy of the skin reveals a sclerodermiform aspect with fibrosis and alterations of the elastic network. Whole exome sequencing performed in the South African family and in the trio of one sporadic case gives rise to the identification of *FAM111B* gene (NM_198947.3), unreported to date. The involvement of this gene has been confirmed by the detection of variations in the three other cases. In total, three independent patients share exactly the same missense mutation (p.Arg627Gly) and one other patient and the South-African family carry two very close mutations respectively p.Ser628Asn and p.Tyr621Asp. All these mutations are missense variants and are predicted to localize in a loop splitting the trypsin-like cysteine/serine peptidase domain of the protein into two parts. We suggest gain of function or dominant negative mutations resulting in FAM111B enzymatic activity changes. Functional studies are ongoing to better understand the pathophysiology of this entity. *FAM111B* sequencing is also ongoing in a series of *RECQL4* negative patients as this syndrome can be misdiagnosed with Rothmund-Thomson syndrome at first sight. In conclusion, HFP with tendon contracture, myopathy and pulmonary fibrosis, a phenotypically recognisable syndrome, is caused by autosomal dominant mutations in *FAM111B* gene. These findings provide genetic evidence for a new pathogenetic pathway for multisystem fibrosis.

2786F

Identification of Human MALT1 Deficiency and Role of the NF-kappa B pathway in a Novel Autosomal Recessive Immune Deficiency and Dysregulation Disorder. *M.L. McKinnon[1,3], J. Rozmus[2,3], S. Fung[2,3], A. Hirschfeld[2,3], K. Del Bel[2,3], L. Thomas[2,3], N. Marr[2,3], S. Martin[4], C. Senger[3,5], A. Tsang[3,5], J. Prendiville[2,3], A. Junker[2,3], M. Seear[2,3], K. Schultz[2,3], L. Sly[2,3], R. Holt[4], M. Patel[1,3], J.M. Friedman[1,3], S. Turvey[2,3].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pediatrics, British Columbia Children's Hospital, Vancouver, BC, Canada; 3) Child and Family Research Institute, University of British Columbia, Vancouver, BC, Canada; 4) BC Cancer Agency, Genome Sciences Centre, Vancouver, BC, Canada; 5) Department of Pathology, British Columbia Children's Hospital, Vancouver, BC, Canada.

The transcription factor, NF-kappa B (NF-kB) is a chief regulator of lymphocyte activation, survival and proliferation, implicated in immunodeficiency and human inflammatory, autoimmune and neoplastic disorders. Despite its diverse roles, mutations in the NF-kB pathway have not yet been linked to the Hyper IgE syndromes (HIES), a group of primary immunodeficiency disorders characterized by elevated serum IgE, staphylococcal skin infections, eczema and pulmonary infections. Mutations in STAT3 cause autosomal dominant (AD) HIES and mutations in the DOCK8 gene are described in autosomal recessive (AR) HIES. In many HIES cases, the genetic cause remains unknown. Here we describe a novel immune dysregulation phenotype with HIES-like features due to underlying mutations of the MALT1 gene, a key component of NF-kB signaling, highlighting a new role for the NF-kB pathway in human disease. Our patient, a 14 year-old girl born to consanguineous parents, presented in infancy with widespread, treatment-resistant dermatitis. followed by recurrent bacterial and viral skin infections, episodes of pneumonia, chronic lung disease, severe gastrointestinal inflammatory disease, osteoporosis with fractures, chronic granulation tissue of larynx and ears, and severe periodontal disease, along with short stature and non-specific dysmorphic facial features. Laboratory testing showed variable eosinophilia, very low B cell numbers, chronically elevated serum IgE and failure of lymphocyte proliferation upon phytohemagglutinin (PHA) stimulation. By whole exome sequencing, we identified an underlying homozygous missense mutation in the MALT1 gene encoding MALT1/paracaspase, a protein serving dual roles in the NF-kB pathway as caspase-like protease (modifying NF-kB-related substrates), and key scaffold protein of the CARMA1-BCL10-MALT1 (CBM) signalosome complex (critical for CBM-mediated NF-kB signalling). We demonstrate that the MALT1 mutation results in profound deficiency of the MALT1 protein, failure of T-cell receptor-mediated activation of NF-kB and loss of paracaspase proteolytic activity. Characterization of human MALT1 deficiency expands our understanding of the genetic causes of disorders with HIES features and the role the NF-kB pathway in human immune disease. In addition, as MALT1-inhibitors are currently being examined for the treatment of lymphoma and inflammatory conditions, our case provides unique insights to guide the ongoing development of these therapies.

Familial Occurrence of Multiple Isolated Epidermal Inclusion Cysts: evidence for X-linked inheritance? *J. Jenkins, K. Horii, H. Ardinger.* Divisions of Genetics and Dermatology, Children's Mercy Hospitals & Clinics/ University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Epidermal inclusion cysts (EICs) are among the most common type of subcutaneous cysts and are frequently found on the face, trunk, neck and scalp. EICs originate from the infundibular portion of the hair follicle and are characterized by implantation of epidermal elements into the dermis. Most EICs occur as sporadic, isolated lesions and are typically benign with rare malignant transformation reported. EICs are twice as common in males, show no racial predilection, and commonly arise in adulthood. Multiple EICs have been reported in association with underlying genetic syndromes including familial adenomatous polyposis (FAP), pachyonchia congenita, and nevoid basal cell carcinoma syndrome (NBCCS). Autosomal dominant inheritance of multiple isolated EICs has also been suggested (OMIM #131600); although a specific genetic etiology remains unknown. We report a 17 year-old male with a history of multiple subcutaneous cysts involving the trunk, face, neck and buttocks beginning at age 5. The diagnosis of EICs was confirmed on pathology after surgical excision. The family history was notable for early onset of multiple EICs in the patient's mother, maternal aunts, maternal grandfather, maternal great-grandmother, and maternal-great-great grandfather. There was no family history of polyposis, cancers, nail dystrophy, craniofacial dysmorphism or other findings suggestive of FAP, pachyonchia congenita, or NBCCS. The family history could be compatible with either an autosomal dominant or an X-linked inheritance pattern of multiple isolated EICs. All daughters of affected males in this pedigree are affected, males are affected more severely than females, and lack of male-to-male transmission are all factors which could support an X-linked inheritance pattern. The recurrence risk for multiple EICs in the patient's offspring ranges from 50% for either gender in the case of autosomal dominant inheritance, up to 100% in female offspring in the case of X-linked dominant inheritance. While autosomal dominant inheritance has been previously suggested in familial cases of multiple isolated EICs, few families have actually been reported in the literature. To the best of our knowledge, this is the first report of familial multiple isolated EICs that is compatible with X-linked inheritance. The present case underscores the importance of collecting a detailed multi-generational family history for provision of the most accurate recurrence risk information.

2788T

Intragenic deletion of *NPAS3* in a child with developmental delay. *C. Armour[1,2,3], E. Baxter[2], J. McGowan-Jordan[1,3].* 1) Eastern Ontario Regional Genetics Program, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON; 3) Department of Pediatrics, University of Ottawa, Ottawa, ON, Canada.

NPAS3 (*neuronal PAS domain-containing protein 3*) is a basic-helix-loop helix transcription factor expressed in the developing brain and implicated in neurodevelopment as it is thought to function in neuron production and maturation. A number of reports have suggested that disruption of *NPAS3* may result in both cognitive impairment and psychiatric illness. Interestingly, this gene has also been shown to contain the largest number of human-accelerated regulatory sequences (non-coding conserved elements that are unique to humans) and thus postulated to have contributed to human brain evolution. This report describes an 8 year old female with developmental delay and an intragenic deletion of *NPAS3*. She walked at 2.5 years and began speaking at 4 years of age and has additional delays in fine and gross motor skills. She currently attends school in a modified class and overall abilities are currently estimated to be 2 to 3 years behind. Additional medical issues include: daytime intermittent enuresis, an asymptomatic spinal syrinx, obesity (BMI of 34) and an astigmatism. Physical exam reveals macrocephaly of approximately 3 to 4 standard deviations (SD) above the mean and height at approximately 2 standard deviations from the mean. She has a round face with full cheeks, mild ptosis and down slanting palpebral fissures. Family history is notable for a maternal history of learning delay requiring special education. The father has macrocephaly, approximately 3 SD above the mean, and has a historical diagnosis of a Fetal Alcohol Spectrum disorder. High density oligonucleotide array in the proband revealed a 0.111Mb intragenic deletion at 14q13.1 involving only *NPAS3*. Prader-Willi MLPA studies and *PTEN* sequencing were normal. Follow-up studies performed so far indicate that the deletion was maternally inherited, correlating with the mother's own reported learning disability. Family studies are ongoing. This case supports a role for *NPAS3* in neurodevelopment and abnormal NPAS3 function may be involved in other cases of non-specific cognitive impairment.

2789F

Dyggve-Melchior-Clausen syndrome In Three Generation. *B. Bozorgmehr, A. Kariminejad.* Dept Clinical Genetics, K-N Pathology & Genetics Ctr, Tehran, Iran.

Dyggve-Melchior-Clausen(DMC) syndrome is a rare autosomal recessive spondyloepimetaphyseal dysplasia.The main features are short trunk dwarfism,short limbs with intellectual disabilities.Radiological findings are:abnormalities of spine ,epiphyses and metaphyses.We are reporting a 15-year-old boy with afghan origin with short trunk dwarfism,short limbs,characteristic radiological findings and severe mental retardation who had three affected maternal uncles and also his mother had one affected maternal uncle.His parents were first cousin and the others, were from one little village so their pedigree showed a pseudo X-linked recessive pattern.

2790W

Novel de novo SPOCK1 Mutation in a Proband With developmental delay, microcephaly and agenesis of corpus callosum. *R. Dhamija[1], J. Graham[2], E. Thorland[1], S. Kirmani[1].* 1) Mayo clinic, Rochester, MN; 2) Cedars-Sinai Medical Center, Los Angeles, CA.

Introduction: Whole exome sequencing of an affected patient and unaffected parents has now made it possible to identify novel de novo mutations in genes possibly linked to human disease. Here we describe a patient with developmental delay and partial agenesis of corpus callosum with a novel de novo SPOCK1 variant. Mutations in SPOCK1 have not been previously described to cause a human phenotype. Case report: The proband's phenotype included severe global developmental delay with dystonia, structural brain abnormality with partial agenesis of corpus callosum, microcephaly and atrial septal defect with aberrant subclavian artery. Extensive chromosomal, genomic and metabolic studies were unrevealing. At age of 13 years, exome sequencing was performed on the patient and her parents at GeneDX, Gaithersburg, MD, and a de novo novel missense mutation was identified in SPOCK1 (coding for Testican-1) on chromosome 5q31: c.239A>T (p.D80V). This mutation affects a highly evolutionarily conserved area of the gene, replacing a polar aspartic acid with hydrophobic nonpolar valine that changes the chemical properties of the protein product, likely representing a pathogenic variant. Online prediction programs SIFT (http://sift.jcvi.org/) and mutation taster (http://doro.charite.de/MutationTaster/index.html) suggest this variant is a deleterious mutation. Previous microdeletions of 5q31 including SPOCK1 have suggested genes on 5q31 as candidates for intellectual disability. No mutations or variants in other genes potentially linked to the phenotype were identified. Conclusion: Testicans are proteoglycans belonging to the BM-40/SPARC/osteonectin family of extracellular calcium-binding proteins. Testican-1 is encoded by the SPOCK1 gene and in mouse models has been shown to be strongly expressed in the brain and modulate important steps in neurogenesis. In humans the expression is more widespread and also seen in heart, blood and cartilage. We hypothesize that because this gene function is critical in neurogenesis, mutations can potentially lead to a phenotype with developmental delay and microcephaly. Further functional studies are under way to confirm these findings, potentially making this the first reported case of human disease related to SPOCK1.

2791T

FOXP1 mutations cause intellectual disability and a recognizable phenotype. *M.F. Hunter[1,11], A.K. Le Fevre[1,2], S. Taylor[3], N.H. Malek[4], D. Horn[5], C.W. Carr[6], O.A. Abdul-Rahman[7], S. O'Donnell[1], T. Burgess[8], M. Shaw[9], J. Gecz[9], N. Bain[10], K. Fagan[10].* 1) Hunter Genetics, Waratah, NSW, Australia; 2) John Hunter Children's Hospital, Newcastle, NSW, Australia; 3) Core Interventions Occupational Therapy Services, Gosford, NSW, Australia; 4) Speech Pathologist, Lisarow NSW; 5) Institute of Medical Genetics, Charité, University of Berlin, Berlin, Germany; 6) Department of Dermatology, Emory University, Atlanta, GA, USA; 7) Department of Pediatrics, University of Mississippi Medical Center, Jackson, MS, USA; 8) VCGS Pathology, Melbourne, Australia; 9) Department of Paediatrics, The University of Adelaide, SA, Australia; 10) Hunter Area Pathology Service, John Hunter Hospital, Newcastle, NSW, Australia; 11) Faculty of Health, University of Newcastle, Newcastle, Australia.

Mutations in FOXP1, located at 3p13, have been reported in patients with global developmental delay (GDD), intellectual disability (ID) and speech defects. Mutations in FOXP2, located at 7q31, are well known to cause developmental speech and language disorders, particularly developmental verbal dyspraxia. FOXP2 has been shown to work co-operatively with FOXP1 in human development. An overlap in FOXP1 and FOXP2 expression, both in songbirds and the human fetal brain have suggested that FOXP1 may also have a role in speech and language disorders. We report a male child with a 0.19Mb intragenic deletion that is predicted to result in haploinsufficiency of FOXP1. Review of our patient and others reported in the literature reveals an emerging phenotype of GDD/ID with moderate to severe speech delay where expressive speech is most severely affected. Facial features include a broad forehead, down-slanting palpebral fissures, a short nose with broad tip, relative or true macrocephaly, a frontal hair upsweep and persistent fetal finger pads. Autistic traits and other behavioral problems are likely to be associated. Congenital malformations may also be associated with FOXP1 haploinsufficiency.

2792F

CTNNB1 mutation in siblings with intellectual disability, spasticity and microcephaly. *D. Tegay[1,2].* 1) Department of Medicine, NYIT College of Osteopathic Medicine, Old Westbury, NY; 2) Division of Genetics, Nassau University Medical Center, East Meadow, NY.

De novo heterozygous loss-of-function mutations in the beta cadherin-associated protein, beta-catenin (CTNNB1), have recently been identified through whole-exome sequencing in 3 unrelated individuals sharing similar features of intellectual disability, absent or limited speech, microcephaly and spasticity (de Ligt et al., 2012). Beta-catenin is a key downstream component of the canonical Wnt signaling pathway and acts as a negative regulator of centrosome cohesion. While somatic gain-of-function activating mutations in CTNNB1 are found in a variety of tumor types and believed to impart oncogenic activity, animal models suggest germline loss-of-function mutations effect neuronal, particularly cerebellar, development and maturation. We report the first case of siblings, both presenting with variable degrees of unexplained intellectual disability, microcephaly, spasticity and non-specific dysmorphic features, in whom clinical whole-exome sequencing identified a common heterozygous CTNNB1 nonsense mutation (S681X) not detected in either parental sample, suggesting parental germline mosaicism as the likely molecular mechanism. These cases help further delineate and expand the phenotype of CTNNB1 mutation.

2793W

Molecular genetic characterization of *INSR* in a family with Rabson-Mendenhall syndrome. *P. Kantheti[1], S. Agadi[2], Y. Gowda[1].* 1) Centre for Human Genetics, Biotech Park, Electronic City Phase 1, Bangalore, Karnataka, India; 2) Karnataka Institute of Medical Sciences, Hubli, Karnataka.

Rabson-Mendenhall syndrome (RMS) is a rare autosomal recessive disorder caused by mutations in the insulin receptor gene(*INSR*). Sequence analysis of *INSR* in a consanguineous family with all the offspring affected revealed that the two surviving female index cases have a homozygous nucleotide substitution c.768 C > T at the 220th codon of *INSR* predicted to change Proline to Leucine in the cystiene-rich domain of the alpha subunit. The mutation does not appear to affect the transcription of the gene or the binding of insulin to the receptor. Haplotypes inferred from single nucleotide polymorphisms indicated that both siblings inherited identical haplotypes linked to the substitution from the two parents. It is also interesting to note that the affected siblings have inherited homozygous His1085T/T polymorphism from the parents who are heterozygous (His 1085 T/C). This polymorphism may possibly lead to the disruption of an E-box motif (CA**CG**TG) and/or to the disruption of a potential epigenetic signature. This may have relevance to the insulin resistance commonly seen in RMS patients.

2794T

Microarray analysis of a de novo microdeletion involving the Van der Woude Syndrome locus. *E.C. Tan[1], E.C.P. Lim[1], S.T. Lee[2].* 1) KK Research Centre, KK Women's & Children's Hospital, Singapore; 2) Department of Plastic, Reconstructive & Aesthetic Surgery, Singapore General Hospital, Singapore.

Van der Woude syndrome is the most common among syndromes which include cleft lip and/or cleft palate as one of the presentations. This autosomal dominant disorder is usually caused by mutations in the interferon regulatory factor 6 (IRF6) gene, with a few cases of small deletions involving coding sequences in the gene. For larger deletions, there were only four reports of microdeletions in this chromosomal region, one was microscopic while the other three involved microsatellite markers outside the IRF6 gene region. We describe the detection of an interstitial deletion of approximately 2.3 Mb within the 1q32.2 region in a male Chinese patient presenting with typical VWS features using the Affymetrix Human SNP 6.0 Array. Consistent with his negative family history, the same deletion was not present in either parent and his two siblings (a younger sister and a younger brother) were also phenotypically normal. Using microsatellite markers, it had been established that the deletion occurred on the paternal chromosome. Although several known genes (including 11 OMIM genes and several micro RNAs) are deleted, this patient has no other abnormality apart from the orofacial presentations typical of VWS. He has been followed up since birth and there has been no clinically significant abnormality in any other organ system. Other than IRF6, the genes which are deleted in this patient appear to be insensitive to copy number and haploinsufficiency. The deletion in this patient overlaps with another VWS patient which is the only published case with array-CGH data. The female patient is also from this geographical region and her bigger 3 Mb deletion is also de novo. However, she has dysmorphism and some growth retardation in addition to the VWS phenotype. We will present a comparison of the different breakpoints and genes deleted in these two patients and discuss the implications.

2795F

A novel TPM3 gene muation with infantile nemaline myopathy. *S.O. NAM[1], J.H. SHIN[2], Y.J. LEE[1].* 1) Pediatrics, Pusan National University Children's Hospital, Yangsan, Gyeongnam, South Korea; 2) Neurology, Pusan National University Children's Hospital, Yangsan, Gyeongnam, South Korea.

A twelve month-old girl was transferred with respiratory failure. She had no specific perinatal problem with gestational age of 38 weeks 4 days and birth weight of 3,680g. At one month of age, her parents found that her muscle power was decreased. Her parents visited a nearby rehabilitationcenter and the patients had been treated with physical therapy. At 11 months of age, she had caught flu-like symptoms lasting for 2 weeks and progressed to abrupt cyanosis and respiratory failure and visited emergency room. She was admitted to intensive care unit on ventilation therapy after cardiopulmonary resuscitation for 8 minutes. She was tried to be weanedoff her ventilator but failed several times, so she was transferred to the pediatric neurologic clinic of our hospital for the evaluation of underlying disease. There was a family history of motor delay of her mother and her grandfather in her mother's side grown out at adulthood. Physical examination showed elongated face with high arched palate, but had no dysmorphism or visceromegaly. Neurologic examination showed alert mentality and normal cranial nerve function. However, there was marked gross motor delay without involvement of fine motor, language or cognition. Her muscle tone was markedly decreased with frog leg posture, positive head lag sign, and decreased deep tendon reflex. Her laboratory findings including serum creatine kinase and metabolic study were normal. Her brain MRI, electroencephalography, EMG/NCV and cardiac echocardiography were normal. Genetic evaluation including SMN1 gene, DMPK gene, fragile X PCR, and array CGH werealso normal. Light microscopic findings of muscle biopsy revealed selective type 1 fiber atrophy with accumulation of suspicious dense material in modified Gomori trichrome stain. Electromicroscopic findings showed severe loss of myofibrillary structure with nemaline rod accumulation within atrophic fiber. Whole exome sequencing was performed. The results showed 151 variants in genes previously reported to cause neuromuscular disorders. The number of candidate variants was reduced to 22 when screened by normal Korean SNP database. We found a novel missense heterozygous mutation in exon 1 of TPM3 gene (c.32T>A, p.Met11Lys) close to the known pathogenic mutation, compatible with the diagnosis of nemaline myopathy.

2796W

Male infant with Freeman-Sheldon syndrome and an incidental diagnosis of Duchenne/Becker muscular dystrophy. *K. Oishi, E. Quinn, M. Babcock, L. Edelmann, S. Scott, A. Yang, G. Diaz.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Rhabdomyolysis is a condition of rapid breakdown of damaged skeletal muscle triggered from various causes including exercise, hyperthermia, and anesthetic agents. Patients with inherited muscle disorders such as muscular dystrophies are at great risk for malignant hyperthermia and rhabdomyolysis upon using different types of anesthetic agents. This condition can be life threatening and usage of those medications should be avoided for those patients. We report an infant with concurrent diagnosis of Freeman-Sheldon syndrome (FSS) and Duchenne or Becker muscular dystrophies (DMD/BMD), who was admitted to our pediatric ICU for cerebral infarction and elevated CPK after general anesthesia. The patient was a 3-month old male born at full term without complications to non-consanguineous parents from the Dominican Republic with a benign family history. At birth, he had left undescended testis, right inguinal hernia, and developmental dysplasia of the hips. Several days after the cryptorchidism and hernia surgery, he developed a fever, abnormal eye movements, facial nerve palsy and hypertonia. Brain MRI showed watershed cerebral infarction and his CPK was elevated above 45,000 U/L. Physical examination revealed deep-set eyes, low-set ears, high-arched palate, H-shaped cutaneous dimpling of the chin, cortical thumbs, and contractures of wrist and ankle joints. The physical findings supported the diagnosis of FSS, an autosomal dominant disorder due to mutations in *MYH3* gene and characterized by typical facial features, distal arthrogryposis and susceptibility to malignant hyperthermia with rhabdomyolysis following exposure to inhalational anesthetics. Array CGH was done to look for contiguous gene deletion and incidentally identified a *de novo* 74.5-kb deletion on chromosome Xp21.1. The deletion included exons 45-47 of the *DMD* gene, which was predicted to cause DMD or BMD. This is the first reported case of two separate congenital myopathic diseases arising *de novo* in one individual. We speculate that the stroke episode was a complication of malignant hyperthermia with rhabdomyolysis triggered by sevoflurane for general anesthesia. Muscle rigidity has been reported in FSS and malignant hyperthermia with rhabdomyolysis has been described in older DMD/BMD patients, but not in infants. The occurrence of these features in this case, initially thought to be an atypical presentation of FSS, is likely to be a result of the two separate myopathic processes in this patient.

2797T

Whole-exome sequencing identifies a homozygous mutation in the SPG11 gene in patients with Spastic Paraplegia. *V. Adir[1], A. Shalata[2], E. Shahak[1], Z.U. Borochowitz[1].* 1) Simon Winter Institute for Human Genetics, Bnai Zion Medical Ctr., Haifa, Israel; 2) Genetic Institute, Ziv Medical Ctr., Zefat, Israel.

Hereditary spastic paraplegias (HSP) are neurodegenerative diseases which include a heterogeneous group of neurodegenerative diseases. HSP is mainly characterized by lower limb spasticity associated with additional neurological signs in the complicated forms. At least 52 loci and 31 causative genes have been identified. Although mutations in the SPAST gene explain approximately 40%; of the pure autosomal dominant forms, molecular diagnosis can be challenging for the sporadic and recessive forms, which are often complicated and clinically overlap with a broad number of movement disorders. In this study whole-exome sequencing was performed to reveal the genetic cause for the disease in a large family with consanguineous marriage in northern Israel. We sequenced two first cousins patients and the father of one of them. Exome sequencing revealed that both patients carry a novel homozygous nonsense mutation in the SPG11 gene (c.4339C>T; p.Q1447X). The presence of the mutation was confirmed by Sanger sequencing. We developed a PCR RFLP test that would enable easy analysis of the c.4339C>T mutation in the SPG11 gene. The mutation was not found in 100 control chromosomes from the same ethnicity. According to previous studies, the SPG11 encodes the spatacsin protein which is expressed ubiquitously in all tissues. The function of spatacsin remains unknown, but the fact that it is highly conserved among species suggests an essential biological function. Further studies which will reveal the normal function of spatacsin will contribute to the understanding of the pathology of the disease, and better therapy for the patients.

2798F

Identification of a new hypouricemia patient with a pathogenic *GLUT9/SLC2A9* mutation (R380W). *M. Sakiyama[1], H. Matsuo[1], T. Chiba[1], A. Nakayama[1], Y. Kawamura[1], S. Shimizu[1], N. Hamajima[2], N. Shinomiya[1].* 1) Dept. Integrative Physiol. Bio-Nano Med., National Defense Medical College, Tokorozawa, Japan; 2) Dept. Healthcare Admin., Nagoya Univ., Nagoya, Japan.

Renal hypouricemia is a common inherited disease characterized by low serum uric acid (SUA) levels. It is associated with severe complications such as urolithiasis and exercise-induced acute renal failure. We have previously reported that urate transporter 1 (*URAT1/SLC22A12*) and glucose transporter 9 (*GLUT9/SLC2A9*) are causative genes for renal hypouricemia type 1 (RHUC1) and renal hypouricemia type 2 (RHUC2), respectively. In the series of experiments, two families have been revealed to have RHUC2 due to *GLUT9/SLC2A9* missense mutations R198C or R380W. However, there are no reports of other RHUC2 families or patients with these pathogenic mutations until now. Thus, we performed mutational analysis of *GLUT9/SLC2A9* exon 6 (for R198C) and exon 10 (for R380W) in another 50 hypouricemia patients to find other cases of RHUC2. Patients were collected out of more than 2000 samples from J-MICC Study (the Japan Multi-Institutional Collaborative Cohort Study). In this study, one novel hyporuicemia male patient with heterogeneous RHUC2 mutation R380W was identified. His SUA level was 2.6 mg/dL, which is similar to that of our previous case (SUA level: 2.7 mg/dL). Mutation sites in *GLUT9/SLC2A9* (R380W and R198C) locate in highly conserved amino acid motifs in ‘sugar transport proteins signatures’, which is observed in GLUT family transporters. As for glucose transporter 1 (GLUT1) deficiency syndrome which is caused by the corresponding mutations in human *GLUT1* (R333W and R153C), arginine residues in this motif are reported to be an important determinant of membrane topology of GLUT1. The same is probably true in GLUT9 on the basis of membrane topology. In oocyte expression study, their mutants showed markedly reduced urate transport, which would be the result of loss of positive charges of those amino acid motifs. The identification of the new RHUC patient could help to expand the understanding of RHUC pathogenesis and suggest that these *GLUT9/SLC2A9* mutations cause renal hypouricemia by their decreased urate reabsorption on both sides of the renal proximal tubules. In addition, these findings also enable us to propose a physiological model of the renal urate reabsorption and can be a promising therapeutic target for hyperuricemia, gout and associated diseases, such as cardiovascular diseases, cerebrovascular diseases and renal failure.

2799W

The manifestation of Mowat-Wilson syndrome in adult identical twins. *S. Ramanathan[1], S.A. Ashwal[2], R.D. Clark[1].* 1) Pediatric Genetics, Loma Linda University, San Bernardino, CA; 2) Pediatric Neurology, Loma Linda University, San Bernardino, CA.

Mowat-Wilson syndrome (MWS) is characterized by typical dysmorphic facial features, congenital anomalies, including Hirschsprung disease, and moderate to severe intellectual disabilities. Little is known about the features of MWS in adults. We report on 23-year-old monozygotic twin females in whom the diagnosis was recently confirmed. The twins were diagnosed in infancy with an apparently de novo interstitial chromosome 2 deletion: 46,XX,del(2)(q21q23). The parents were seeking re-evaluation for new-onset ‘osteoarthritis’ in the twins when the diagnosis of MWS was made by oligoarray CGH. that showed a 9.7 megabase deletion, including the *ZEB2* gene associated with MWS. The prenatal history was non-contributory and the twins were delivered at 37 weeks with Apgar scores of 8^1 and 9^5. Their developmental delay was initially attributed to the twin gestation and lower birth weight (4lb 11oz, 5lb 2 oz) compared to their siblings. At 14 months, the twins were microcephalic and were not rolling over. MRI of the brain detected agenesis of corpus callosum in both children. Both had recurrent otitis media, upper respiratory infections and urinary tract infections secondary to hydronephrosis with reflux in childhood. Both have epilepsy, which is well-controlled in one. Both have chronic constipation. As adults, they are non-verbal. They babble, follow one-step commands and have some receptive language. They are not toilet-trained. Neither is able to chew food. They need to be restrained at meal-time, as they bat away at spoons. Both have bruxism and bite their wrists. Menarche was at 16 and 18 years and menses are irregular. The twins have had normal echocardiograms, and are awaiting rectal biopsies to rule out Hirschsprung disease. They are being followed by a rheumatologist for swelling of the interphalangeal joints, which has been reported in MWS, but is not well-characterized. Radiographs on the twins do show soft tissue, but no bony changes. Our patients illustrate the value of obtaining a diagnosis, irrespective of age. They add to the meager data on adults with MWS. The authors and the parents of these patients welcome contact with other families who have adults with MWS to collect data on the natural history of this disorder.

2800T

Occurrence of recurrent optic neuritis and cervical cord Schwannoma with Charcot-Marie-Tooth type 4B1 disease: A case report. *P. Scott, F. Almurshedi.* Genetics Dept, Col Med & Health Sci, Sultan Qaboos Univ, Muscat, Oman.

Charcot-Marie-Tooth (CMT) disease is a heterogeneous group of inherited peripheral neuropathies. CMT type 4 is characterized by autosomal recessive inheritance. CMT4B1 due to MTMR2 gene mutations is a rare subtype of CMT4 with reported association of facial weakness, vocal cord paresis, chest deformities, and claw hands. We report the unusual occurrence of recurrent optic neuritis and cervical cord Schwannoma in a male individual with confirmed CMT4B1 disease. This 28-year-old gentleman presented with bilateral, symmetrical limb weakness that started distally and progressed very slowly since the age of 4 years and became wheel chair dependent at the age of 22. Dysphonia with vocal cord paralysis was apparent as he grew. He developed 3 episodes of optic neuritis resulting in a reduced visual acuity. At the age of 27 years, he presented with symptoms suggestive of cervical cord compression with diagnosis of C2/C3 spinal cord Schwannoma. Physical examination was remarkable for facial nerve weakness, chest deformity and claw hands. A positive family history with two affected siblings and the presence of consanguinity suggest autosomal recessive inheritance. The clinical features were consistent with CMT4B1 and MTMR2 gene sequencing revealed a novel nonsense homozygous mutation c.1768C>T (p.Gln590*). The rare association of optic neuritis or Schwannoma with genetically confirmed CMT1A has been individually observed but never with recessive CMT. To the best of our knowledge, the occurrence of recurrent optic neuritis and cervical cord Schwannoma in the same patient has never been reported with any forms of CMT including CMT4B1.

2801F

Novel homozygous missense mutation in the matrix metalloproteinase 2 (MMP2) catalytic domain leading to protein loss of-function in two Italian sibs in the spectrum of Torg-Winchester syndrome. *J. Azzollini[1], D. Rovina[1], C. Gervasini[1], I. Parenti[1], A. Fratoni[2], L. Pietrogrande[3], L. Larizza[1].* 1) Medical Genetics, Department of Health Sciences, University of Milan, Milan, Italy; 2) Pediatrics Unit, G. Salvini Hospital, Rho, Italy; 3) Orthopaedic Division, Department of Health Sciences, University of Milan, Italy.

Torg-Winchester Syndrome (TWS, OMIM #259600) is an extremely rare autosomal recessive disorder characterized by multicentric osteolysis, especially involving hands and feet, subcutaneous nodules, arthropathy with progressive joint contractures and other features such as short stature, hyperpigmented skin lesions, coarse face, corneal opacities and gum hypertrophy. Mutations of MMP2 gene (16q13), encoding Matrix Metalloproteinase 2, have been associated with TWS: only 8 mutations, 3 truncating, 3 missense, 1 splice, 1 in-frame deletion have been described so far in 8 families from different geographic areas. We evaluated two Italian siblings (43♀, 37♂), born to healthy consanguineous parents, who started to display, between age 3 and 6, appendicular osteoporosis and palmar-plantar subcutaneous nodules followed, during adolescence, by tendon retractions, progressive upper limb arthropathies, toes osteolysis and pigmented fibrous skin lesions. The female also suffered from recurrent bilateral eye pterygium after age 30. Based on the clinical presentation and the STRs genotype shared by the sibs at 16q12.2-q21, we performed MMP2 mutation screening on their blood DNA by direct sequencing. Both siblings were found to carry a novel homozygous missense mutation in exon 8, c.1228G>C p.G410R, affecting a highly conserved aminocidic residue within MMP2 catalytic domain. The same mutation was not detected in 260 healthy individuals and is predicted pathological by several bioinformatic tools (Mutation Taster, PolyPhen-2, PMut, Mutation Assessor). Functional assessment was carried out by site-directed mutagenesis on the wild-type MMP2 sequence cloned into an expression vector, trasfection of both wild-type and mutated MMP2 into HEK cell line and gelatin-zymography on the collected conditioned media. As compared to the wild-type MMP2, G410R-MMP2 showed a complete loss of gelatinolytic activity, thus confirming the mutation impact on protein function. Out of 8 described MMP2 mutations, 3 map to exon 8, in the protein catalytic domain (p.E404K, p.V400del, p.G406D), and are associated with Winchester phenotype, mainly characterized by the absence of subcutaneous nodules. p.G410R represents the first inactivating missense mutation, within MMP2 catalytic domain, associated with Torg phenotype, thus reinforcing the complexity of genotype-phenotype correlation in TWS.

2802W

A patient with Simpson-Golabi-Behmel syndrome, Biliary Cirrhosis and successful Liver Transplantation. *B. Demeer[1], G. Guillaume Jedraszak[1], M. Girard[2], A. Mellos[2], D. Djeddi[3], C. Chardot[4], A. Varenterghem[3], M.P. Moizard[5], J. Gondry[6], H. Sevestre[7], M. Mathieu-Dramard[1], F. Lacaille[2].* 1) Genetics Dept, Hopital nord, CHU, Amiens, France; 2) Paediatric Hepatogastroenterology-Nutrition unit, Necker-Enfants-malades Hospital, France; 3) Paediatric hepatogastroenterology-Nutrition unit, C.H.U Amiens, France; 4) Paediatric surgical unit, Necker-Enfants-malades Hospital, France; 5) Service de génétique, INSERM U930, CHRU Tours, France; 6) Prenatal diagnosis unit, Camille Desmoulins maternity hospital / Jules Verne University, C.H.U Amiens, France; 7) Pathology department, C.H.U Amiens, France.

Simpson-Golabi-Behmel syndrome (SGBS) -OMIM 312870-, first reported by Simpson et al in 1975 is a rare X-linked inherited overgrowth syndrome caused by a loss-of-function mutation in the *GPC3* (SGBS type 1) or *GPC4* gene. Patients present a variable phenotype with pre- and post-natal macrosomia, distinctive facial dysmorphism, organomegaly, and numerous congenital anomalies, ie : diaphragmatic hernia, heart or renal defect, genitourinary tract or gastrointestinal malformations, skeletal or hand abnormalities. Intellectual disability is not constant. About 10% of patients develop embryonic tumors in early childhood. A single case of biliary disease (choledochal cyst) has been reported. *GPC3* is localised on Xq26 and encodes for Glypican-3, a glycosylphosphatidylinositol-linked cell surface heparan sulfate proteoglycan, that belongs to the family of glypicans. This report concerns a male infant with Simpson-Golabi-Behmel syndrome type 1, carrier of a *GPC3* mutation. He had neonatal liver disease, and developed early on biliary cirrhosis. Liver transplantation was discussed, considering the risks of cancer and intellectual disability, and performed successfully when the child was 19 months of age. A hypothesis on the role of *GPC3* in this patient's liver disease is proposed.

2803T

Exome Sequencing of a Proband With Bilateral Sensorineural Hearing Loss Furthers Insights into Phenotypic Variability of Waardenburg Syndrome. *A. Wilkens[1], M. Dulik[3], N. Qu[2,4], K. Wang[2,4], J. Brunton[1], V. Jayaraman[1], E. Dechene[1,3], N. Spinner[3], W. Liu[2,4], I. Krantz[1].* 1) Divison of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) BGI@CHOP Genome Center, The Children"s Hospital of Philadelphia, Philadelphia, PA; 3) Division of Pathology, Children's Hospital of Philadelphia, Philadelphia, PA; 4) BGI Health, Shenzhen, China.

Waardenburg Syndrome (WS) is characterized by sensorineural hearing loss and pigmentary differences of the hair, skin and iris with both phenotypic variability, as well as genetic heterogeneity leading to four subtypes. The absence or presence of dystopia canthorum (lateral displacement of the inner canthi) historically has directed clinical testing for two of the four subtypes, as WS type I (presence of dystopia canthorum) is associated with mutations in PAX3, whereas WS type II (absence of dystopia canthorum) is associated with mutations in MITF. We report on a 5-month old proband referred for bilateral sensorineural hearing loss whose physical exam was notable for dystopia canthorum by the presence of a Waardenburg-index of 2.04 (normal being less than 1.95) and whose father was also affected, suggesting dominant inheritance. PAX3 sequencing and deletion analysis was initiated on the proband and was negative. Additional samples from the proband, unaffected sibling, father and mother were obtained and exome sequencing was performed by BGI@CHOP Genome Center on an Illumina HiSeq 2000. Bioinformatic analysis of potentially pathogenic sequence variants shared in the proband and father was completed and led to a single candidate variant as the cause of the phenotype - an MITF p.R255X nonsense mutation previously associated with WS. Initially, this variant was not identified at a read depth coverage of 10x, but was revealed when the read depth coverage was relaxed to 8x. Sanger sequencing was performed to validate the finding and it was present in the proband and father, as well as in the presumed 'unaffected' sibling and was not present in the unaffected mother. This case report of using exome sequencing to aid in the diagnosis for a family with bilateral sensorineural hearing loss highlights the importance of: 1) this technology's ability to identify genetic alterations that would otherwise not have been tested for clinically; 2) amending historically established phenotypes to incorporate a larger clinical spectrum; 3) using lower coverage cut offs in an attempt to decrease false negatives; and 4) how the result of this testing can unearth reduced penetrance in presumed 'unaffected' family members.

2804F

Use of quantitative ultrasound for tibial dysplasia in neurofibromatosis type 1. *D.A. Stevenson, H. Slater, H. Hanson, A. Stevens, J.C. Carey, D.H. Viskochil.* Dept Pediatrics, Univ Utah, Salt Lake City, UT.

Neurofibromatosis type 1 (NF1) is a common autosomal dominant genetic disorder with distinct skeletal manifestations. In particular, tibial dysplasia is a difficult-to-treat morbid manifestation. Tibial dysplasia typically presents with unilateral anterolateral bowing of the tibia with cortical thickening and medullary canal narrowing, with subsequent fracture and non-union. In infancy, physiologic bowing of the lower leg can be confused with pathologic tibial dysplasia in NF1, and early intervention with bracing is thought to improve outcomes. Quantitative ultrasound (QUS) measures speed of sound, avoids radiation, and is reported to be predictive of clinical fracture in the general population. Our aim was to use QUS of the affected and unaffected tibias of individuals with NF1 who presented with suspected tibial dysplasia prior to fracture and pseudarthrosis. Bone quality was assessed on both tibia (the non-bowed and bowed tibia) using the Sunlight Omnisense 7000P scanner (Sunlight Medical, Israel) to measure the speed of sound (SOS) at the mid-shaft. The probe is moved in a sweeping motion, laterally and medially and three to five consecutive measurement cycles are performed, after which the SOS (m/s) is determined and z-scores generated using cross-sectional reference data of the same sex and age provided with the machine. A total of 14 individuals with NF1 with unilateral tibial bowing without fracture/pseudarthrosis were enrolled and both tibia were tested using QUS. The mean SOS z-score for the affected tibia was -2.9. The mean difference in SOS z-score was -2.5 when comparing the bowed tibia versus the individual's contralateral unaffected tibia. One infant with mild anterolateral bowing, radiographically showed no cortical thickening, and the z-score of the 'bowed' bone had a SOS z-score +2.5 difference compared to the other tibia suggesting physiologic bowing rather than pathologic tibial dysplasia. These data show that dysplastic tibia in NF1 prior to fracture and non-union have abnormal bone quality with significant decreases in SOS even though radiographically the tibia show a thickened cortex. These data also suggest that QUS is sensitive to distinguish dysplastic bowing vs. physiologic bowing in infancy in NF1. QUS is an attractive tool as a quantitative outcome measure for future trials aimed at improving tibial bowing to prevent fracture, and potentially for an aid in diagnosis and clinical management in NF1.

New syndrome of ectrodactyly and lethal pulmonary acinar dysplasia associated with homozygous FGFR2 mutation identified by exome sequencing. *C.P Barnett[1,4], N.J Nataren[2,3], M. Klingler-Hoffmann[2,3], Q. Schwarz[2,4], D.L. Bruno[5], J. Lipsett[8], A.J. McPhee[4,7], A.W. Schreiber[3,6], J.H. Feng[3,6], C.N. Hahn[2,4], H.S. Scott[2,3,4,6].* 1) SA Clinical Genetics, Women's and Children's Hospital/SA Pathology, North Adelaide, South Australia, Australia; 2) Department of Molecular Pathology, Centre for Cancer Biology, SA Pathology, Adelaide, SA, Australia; 3) School of Molecular and Biomedical Science, University of Adelaide, SA, Australia; 4) School of Medicine, University of Adelaide, SA, Australia; 5) Cytogenetics Laboratory, Murdoch Children s Research Institute, Royal Children s Hospital, Parkville, Australia; 6) ACRF Cancer Genomics Facility, Centre for Cancer Biology, SA Pathology; 7) Department of Neonatal Medicine, Women's And Children's Hospital , North Adelaide, SA, Australia; 8) Department of Anatomical Pathology, Women's and Children's Hospital/SA Pathology, North Adelaide SA, Australia.

A female infant from a consanguineous union was born at term but died of respiratory failure on day 2. An autopsy revealed severe pulmonary hypoplasia due to acinar dysplasia/congenital pulmonary airway malformation (CPAM) type 0. The infant also had ectrodactyly involving the hands and feet. Ectrodactyly is genetically heterogeneous and acinar dysplasia is a rare lethal congenital lung lesion of unknown etiology. Recessive inheritance has been suggested. SNP array and whole exome sequencing of this infant's DNA identified 22 homozygous candidate causative sequence variants (SV) after filtering against dbSNP and numerous published and in-house exomes. Furthermore, analyses based on prediction of pathogenicity, protein conservation and expression (especially embryonic lung and limb), highlighted one SV in the FGFR2 gene, homozygous missense variant R255Q. Numerous germline FGFR2 mutations have been described in association with human disease, all heterozygous and mostly de novo autosomal dominant mutations associated with craniosynostosis syndromes. Involvement of the hands is classically spared in some (e.g. Crouzon syndrome) while Apert and Pfeiffer syndromes have both craniosynostosis and syndactyly of the hands and feet. Many FGFR2 missense mutations have been described as constitutively activating mutations, mainly in the extracellular ligand binding third Ig-like IgIII domain (D3) domain. Both parents of the affected infant were heterozygous for R255Q and unaffected which may suggest that R255Q is a loss of function allele. However, functional studies show that R255Q is constitutively activating and leads to rapid dimerizaton. Thus a single copy of R255Q may quantitatively and/or selectively (via altered FGF binding) activate FGFR2 downstream signaling in a tissue specific manner compared to other syndromes associated with FGFR2 mutations, possibly explaining this difference. Others have created a knock-in Crouzon syndrome mouse with a recurrent autosomal dominant activating FGFR2 mutation W290R, also in D3. While heterozygous mice show craniofacial malformations, homozygous mice also showed limb and organ (including lung) agenesis and die of respiratory failure. Our case is the first description of a human with homozygous FGFR2 mutations and is the first with profound lung defects. The combination of ectrodactyly and acinar dysplasia has not been described before and we propose it represents a new syndrome caused by homozygous FGFR2 mutations.

2806T

A GC polymorphism associated with serum 25(OH)D level is the risk for hip fracture in Japanese patients with rheumatoid arthritis. *S. YOSHIDA[1, 2], K. IKARI[1], T. FURUYA[1], Y. TOYAMA[2], A. TANIGUHI[1], H. YAMANAKA[1], S. MOMOHARA[1].* 1) Institute of Rheumatology, Tokyo Women's Medical University, Shinjuku, Tokyo, Japan; 2) Department of Orthopaedic Surgery, School of Medicine, Keio University, Tokyo, Japan.

Background: Vitamin D is important for the maintenance of the musculoskeletal system, is positively associated with muscle strength and physical performance, and is inversely associated with fall and fracture risk. The major determinants of serum 25-hydroxyvitamin D [25(OH)D] concentration are sunlight exposure and intake from diet or supplements. However, genetic variants affecting serum 25(OH)D concentration were recently identified in a meta-analysis of genome-wide association studies in Caucasian populations. We investigated the genetic variants associated with serum vitamin D concentration and the occurrence of hip fracture in Japanese patients with rheumatoid arthritis (RA). Methods: DNA samples of 2068 Japanese patients with RA were obtained from the Institute of Rheumatology Rheumatoid Arthritis cohort study (IORRA) DNA collection. Serum 25(OH)D concentration was measured in 932 of 2068 patients in the spring of 2011. Five of the single nucleotide polymorphisms (SNPs) reported in the recent studies were genotyped: rs2282679, in GC; rs3829251, in NADSYN1; rs12785878, rs1790349, near and in DHCR7; and rs10741657, near CYP2R1. The occurrence of hip fractures was determined from the responses to a patient questionnaire every 6 months from October 2000 to October 2010. After confirmed by review of medical records and radiographs, 39 hip fractures in 39 patients were included into this study. Multivariate linear regression analyses adjusted for the non-genetic factors were performed to investigate the association between serum 25(OH)D concentration and each SNP in 932 patients. The SNP showing a significant association with serum 25(OH)D concentration was included into the following prediction analysis for the occurrence of hip fracture by using a multivariate Cox proportional hazards regression model in 1957 patients with no data deficiency. Results: Multivariate linear regression analyses showed that rs2282679 in GC was significantly associated with lower serum 25(OH)D concentration ($P=5.8\times10^{-5}$). A multivariate Cox proportional hazards regression model indicated that rs2282679 in GC was significantly associated with the occurrence of hip fracture [HR (95% CI): 2.03 (1.03 to 5.94); P=0.042]. Conclusion: Our data indicated that a GC polymorphism is the risk for hip fracture in Japanese patients with RA. These results may contribute to a better understanding of the biological impact of genetic variation within the vitamin D metabolic pathway.

2807F

Fetal alcohol syndrome and assessment of maxillary and mandibular arc measurements. *K. Abell[1], W. May[1], P. May[2,3], W. Kahlberg[3], G. Hoyme[4], O. Abdul-Rahman[1].* 1) University of Mississippi Medical Center, Jackson, MS; 2) University of New Mexico, Albuquerque, NM; 3) University of North Carolina, Chapel Hill, NC; 4) University of South Dakota, Sioux Falls, SD.

Fetal alcohol spectrum disorders (FASD) are a range of physical differences and neurologic deficits due to prenatal alcohol exposure. Diagnosis evaluates characteristics like growth deficiency, microcephaly, and cardinal facial features. Other features like midface hypoplasia are also seen. While traditionally judged subjectively, objective measurements of maxillary and mandibular arcs and the ratio between them may be useful in assessing midface hypoplasia. The Fetal Alcohol Syndrome Epidemiologic Research (FASER) project contains dysmorphology assessments of children for FAS. Data are collected during in-school screenings of first-graders for height, weight, and head circumference. Cases are selected by measurements below the 10th percentile, and matched with normal controls. All subjects are evaluated by a dysmorphologist for FASD physical features. Those with possible features undergo neuropsychiatric evaluation and maternal interview for a diagnosis of FAS, partial FAS, alcohol-related neurodevelopmental disorder (ARND), or non-FAS. Using the FASER database, we investigated the size of the maxillary and mandibular arcs and the arc ratio in respect to FAS diagnosis.

We established normative values for the maxillary arc, mandibular arc, and the maxillary-to-mandibular arc ratio for males and females. In our control group of 545 males and 436 females, the mean maxillary and mandibular arcs for males/females were 24.98/24.52cm and 25.91/25.35cm respectively. The ratio was 0.9643 and 0.9676 for males and females respectively. We evaluated the effect of microcephaly, short stature, and low weight, defined as less than 10th centile, individually on arc measurements in the controls. With a few gender-based differences, the arc measurements were reduced significantly but the ratio did not differ. We compared our controls to 138 males and 135 females FASD cases. We noted a significant difference in arc measurements in male and female groups but not the ratio. The trend was greatest for a diagnosis of FAS but also seen in partial FAS and ARND. We compared non-FAS controls with reduced growth parameters to similar cases with a FASD. We did not find a significant difference in the arc or the ratio measurements. Therefore, we conclude the effect of prenatal alcohol exposure on maxillary and mandibular arc measurements is primarily on growth parameters and less directly on maxillary and mandibular growth.

2808W

Genetic analysis of Gonadal Disorders of Sex Development (46,XY DSD) by cytogenetic and molecular methods. *A. Shojaei[1], F. baghbani-arani[2], R. Ebrahimzadeh-Vesal[1], F. Behjati[3], J. Tavakkoly-Bazzaz[1].* 1) Medical Genetics, Tehran University of Medical Science, Tehran, Iran; 2) Genetics Dept, Varamin-Pishva Branch,Islamic Azad University, Varamin, Iran; 3) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Among Disorders of sex development (DSD), 46,XY gonadal dysgenesis is the most complicated, heterogeneous and rare disease.Various genes have been associated with gonadal dysgenesis. Among these, SRY, NR5A1, DHH, DAX1 and WNT4 genes, are clearly known to be associated with these disorders.Mutations of known genes are responsible for only a few percentages of DSD;therefore, there are probably some other potential loci that play an important role in sexual disorders like gonadal dysgenesis. In this study we recruited38 patients that were clinically suspicious for 46,XY gonadal dysgenesis of unknown etiology. Cytogenetic analysis as well as direct sequencing of the SRY, NR5A1and DHH genes was performed. In continue MLPA was used to detect deletions and duplications in DAX1 and WNT4 and subsequent imbalances were confirmed by real time PCR. Additionally, other potential loci were investigated by whole genome Array CGH method.In this study,one new chromosomal rearrangement and SRY deletions were found in one and five patients, respectively. Previously described NR5A1and DHH allelic variants were observed.A heterozygous partial deletion was presented in NR5A1 gene and heterozygous partial duplication was found in WNT4 gene. These deletions/duplications were subsequently confirmed by real time PCR. Array CGH results confirmed the chromosomal abnormality in the patient with abnormal chromosome 13, derived from a maternal translocation between chromosome 7 and 13 and showed the exact region of rearrangements. Also, one partial deletion was detected in the SOX2OTgene. Autosomal chromosome abnormalities could also play a role in disorders of sex developments. SRY gene deletion still has a significant role in these disorders and has a similar incidence in our patients compared with other reports and should be the first gene for testing in GD. Del/dup mutations found to be more common than point mutations in our patients. Therefore, it might be preferred to check Del/dup mutations prior to point mutations.SOX2OT might have a potential role in gonadal dysgenesis and it should be taken into account in molecular approaches to study GD patients.Array CGH is a valuable tool for finding responsible genes in GD and could unravel some potential loci in this regard.

2809T

BECKWITH-WIEDEMANN SYNDROME: A FAMILIAL CASE REPORT.

M.A. Aceves-Aceves[1], I.M. Salazar-Dávalos[1], M.G. González-Mercado[2], R.E. Jiménez-Arredondo[2], S.A. Alonso-Barragán[2], M. Salazar-Páramo[3], N.O. Dávalos[4], D. García-Cruz[4], C. Roa[5], I.P. Dávalos[2]. 1) Instituto de Genética Humana, Facultad de Medicina, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Doctorado Genética Humana, IGH, CUCS, Universidad de Guadalajara, CIBO-IMSS, Guadalajara, México; 3) Depto. Fisiología, Universidad de Guadalajara, Div. Investigación, UMAE, HE, CMNO, Guadalajara, México; 4) Doctorado Genética Humana, Instituto de Genética, CUCS, Universidad de Guadalajara, México; 5) UMAE, Hospital de Pediatría, CMNO, IMSS, Guadalajara, Jalisco, México.

Beckwith- Wiedemann Syndrome (BWS)(OMIM 130650) is a genetic disorder with complex inheritance mode. Possible patterns include autosomal dominant inheritance with variable expressivity, contiguous gene duplication on chromosome 11p15, and genomic imprinting resulting from a defect or absence of the maternal copy gene. BWS has a prevalence of 1 in 13,700 births; it is characterized by overgrowth, macrosomia, macroglossia, organomegaly, exomphalos and predisposition to embryonal tumor development, most common are Wilms tumor or nephroblastoma. Clinical diagnosis is primarly, requiring 3 major criteria or 2 major and 3 minor criteria. OBJECTIVE: To present a familial case of BWS. CASE REPORT: Family data: Mother with antecedent of 4 pregnancies, 2nd correspond to case 1 and 4th to case 2, she presents ear pits. Case 1: 8 years 5 months female, product of the 2nd pregnancy term, obtained by caesarian section from non-consanguineous parents, with 28 years (he) and 29 years (she) at birth time. Apgar 9-10, weight and height >pc97, macroglossia, depressed nasal bridge, posterior helical ear pits and exomphalos surgically corrected, presented neonatal hypoglycemia. During the first year of age presented overgrowth, renal ultrasonography reported right pyelic duplication. At the age of 3 years was performed transversal and anteroposterior reduction glossectomy. Actually weight and height pct 97 and hemihypertrophy was detected.Case 2: Two years 11 months female, product of the 4th pregnancy, obtained by cesarian section at 30 weeks, weight at birth 2500g. Physical examination: weight and height > pct 97, posterior helical ear pits, macroglossia, umbilical hernia; has not required surgical procedure. Renal ultrasonography without abnormalities. Conclusion: Clinical findings of both cases have BWS criteria diagnosis. The treatment consisted of surgical reduction of exomphalos and anterior-transversal reduction glossectomy in case 1. The patient of case 2 has not required surgical intervention. The renal ultrasonography in patient 1 reports right pyelic duplication, meanwhile patient 2 renal ultrasonography was normal. The early diagnosis of BWS allows a complete treatment and a genetic counseling. The early and continuous monitoring of glycemia level in the first days after birth provide an opportune treatment of hypoglycemia and could prevent neurologic complications. The abdominal and renal ultrasonography support early diagnosis of kidney tumor.

2810F

Gastric necrosis and dilation with or without rupture a cause of death in Prader-Willi Syndrome: Three new case reports with a review of the mortality literature and an update in causes of death in PWS.

J.A Gold[1,2], R.T Rivera[3], J. Heinemann[4], A. Scheimann[5,6], P.J Gold[7], S.B Cassidy[8], J.L Miller[9]. 1) Pediatrics, Loma Linda University Medical Center, Loma Linda, CA; 2) Division of Pediatrics, Department of Genetics and Metabolism University California Irvine Medical School, Irvine , CA; 3) Department of Surgery, Providence Tarzana Medical Center, Tarzana, CA; 4) Prader-Willi Syndrome Association (USA), Sarasota, FL; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Department of Pediatrics, John Hopkins School of Medicine, Baltimore, MD; 7) Department of General Surgery, Warwick University Medical School, Warwick, UK; 8) Department of Pediatrics, Division of Medical Genetics, University of California, San Francisco, CA; 9) Department of Pediatrics, University of Florida, Gainesville, FL, USA.

Prader-Willi syndrome (PWS) is a neurodevelopmental disorder. While obesity is only part of the disorder, binge eating and periods of rapid weight gain and weight loss are common. Individuals have a high pain threshold and rarely vomit. A 3% mortality due to gastric necrosis and rupture was previously reported. We report three individual's age range 8-50 year's one female and two males with PWS and death due to gastric necrosis or dilation and rupture in one case with confirmed binge eating in one with suspicion of a binge in another. One of the complications of PWS is constipation and gastroparesis. It has previously been speculated that in individuals with PWS, episodes of food foraging and episodic hyperphagia cause acute dilation. This is likely to result in relative ischemia or occlusion of blood vessels, ischemia and gastric rupture. Stomach muscle integrity due to prior weight loss has also been hypothesized to be contributory factor (Wharton 1997). A thorough literature review was undertaken. Although rare, it appears that gastric necrosis, dilation and gastric rupture is more common in individuals who have an eating disorder such as bulimia and anorexia nervosa. It appears that a low or near normal basal metabolic index (BMI) is more common in those who suffer this complication after a prior episode of obesity, but is not always present. These cases and the literature review support strict adherence to dietary control from birth and prevention of vacillating weights. Vigilance on the part of emergency departments to be aware of the possible complication and need for CT and emergency laparotomy. Future long term outcome studies in PWS and other eating disorders including bulimia and anorexia nervosa is imperative. It would be helpful to determine if the use of growth hormone aids this goal by improving weight management. I hypothesize that a gastrostomy tube (GT) may cause scaring and a weakness making this a complication of GT insertion and should be avoided in individuals with PWS. It will be important to document if individuals who receive gastrostomy tubes in the neonatal period could have a nidus for gastric rupture at a weakened GT site or due to scaring.

2811W

The Coordination of Rare Diseases at Sanford (CoRDS) patient registry for all rare diseases and those undiagnosed.
E.A. Donohue, N.A. Simpson, R.M. Bourscheid, D.A. Pearce. Sanford Children's Heath Research Center, Sanford Research, Sioux Falls, SD.

BACKGROUND Sanford Children's Health Research Center at Sanford Research has established a rare disease registry named CoRDS (Coordination for Rare Diseases at Sanford). CoRDS houses de-identified contact and clinical information for patients who have been diagnosed with any rare disease. CoRDS' mission is to accelerate rare disease research by creating a resource of rare disease data for researchers and a mechanism by which participants can be contacted about research opportunities. METHODS CoRDS serves as a rare disease patient registry with several components. First, there is a data collection component, in which the patient-reported data is collected. Second, data management involves the archiving, collation, and accumulation of data. Third, dissemination of data ensures that researchers can access and utilize information for their research. A Scientific Advisory Board has been established to provide oversight and review applications to ensure that researchers have IRB approval and the research proposal is sound. CoRDS utilizes Velos eResearch, a clinical research information system supporting the collection of data and processes in study design/monitoring/execution, patient recruitment, reporting, data integration, compliance and safety monitoring for its software solution. Participant recruitment is closely tied to the process by which CoRDS partners with Patient Advocacy Groups (PAGs) that support patients diagnosed with rare diseases. PAGs communicate enrollment information to their membership and educate their researchers about the opportunity to utilize CoRDS as a resource. RESULTS CoRDS has 853 participants (446 enrolled, 407 in the screening), representing 127 rare diseases. CoRDS has partnered with 44 PAGs and organizations in the medical and rare disease field. These partnerships help increase participant enrollment and disease numbers. DISCUSSION Collecting and collating data on patients diagnosed with any rare disease offers the opportunity to perform a comparative analysis to better understand and treat the diseases. Many treatments are symptomatic, thus treatment strategies for one disease may be beneficial in application to other diseases with similar clinical profiles. CoRDS serves as a source of data to help researchers better understand the particular disease they are studying and can help them identify potential participants for research studies or clinical trials with the potential to accelerate their timelines.

Homoplasmy of a mitochondrial 3697G>A mutation causes Leigh syndrome.
Y. Negishi[1], A. Hattori[1], E. Takeshita[2], C. Sakai[2], N. Ando[1], T. Ito[1], Y. Goto[2], S. Saitoh[1]. 1) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 2) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Japan.

Leigh syndrome (LS) is a subacute necrotizing encephalomyelopathy characterized by bilateral symmetrical necrotic lesions in the basal ganglia and brainstem. We report that three siblings with LS harbor the m.3697G>A mutation in a homoplasmic fashion. Three siblings from healthy parents are all affected with LS of different severity. Patient 1 is a 9-year-old girl presenting with progressive gait disturbance from 18 months. Currently, she can walk without support, and speak sentences. Patient 2 is a 7-year-old boy. Progressive rigidity of four limbs started at 2 years. Currently, he cannot stand without support and does not have meaningful words. Patient 3 is a 5-year-old girl. She presented with progressive gait disturbance from 18 months. Her condition severely deteriorated after viral infection at 2 years, and has been bedridden with tracheostomy since then. Brain MRI showed necrotic lesions in the bilateral basal ganglia in all patients, but brainstem involvement only in patient 3. Entire mitochondrial DNA sequencing of a biceps brachii muscle specimen from patient 1 revealed that this patient harbored the m.3697G>A substitution (G131S) of the ND1 gene. This mutation was homoplasmic in all three siblings and heteroplasmic in their mother. Heteroplasmic m.3697G>A has been reported in patients with Leber's hereditary optic neuropathy (LHON) and mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS). Since all of our three patients carried m.3697G>A in a homoplasmic fashion and showed LS, it is conceivable that homoplasmy of m.3697G>A causes the LS phenotype. The mechanism by which the three siblings developed homoplasmy while the mother carried the mutation in a heteroplasmic fashion can be explained by the bottleneck theory. This phenomenon should be taken into account for genetic counseling of mitochondrial disorders.

Defining the Undefined Congenital Myopathies: Pathological Findings and Clinical Features.
L.C. Swanson[1], P.D.S.C. Ciarlini[1, 2], A.H. Beggs[1, 2]. 1) Boston Children's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA.

The congenital myopathies are a group of rare and genetically heterogenous neuromuscular disorders that affect skeletal muscle, often causing numerous symptoms including, but not limited to, non-progressive muscle weakness, hypotonia, respiratory insufficiency, scoliosis, facial weakness, and feeding difficulties. The severity of symptoms and age of onset are variable among individuals with the same diagnosis. Mutations in different genes can lead to similar histopathological features, and mutations in the same gene can give rise to variable clinical and pathological phenotypes. Several specific congenital myopathy diagnoses include nemaline myopathy, congenital fiber type disproportion, myotubular/centronuclear myopathy, and central core/multi-minicore disease. The diagnoses are based on histopathological analysis, by which the muscle is reviewed for specific features associated with a congenital myopathy diagnosis, such as central nuclei or nemaline rods. When none of these defining features are present and a distinct congenital myopathy diagnosis cannot be determined based on histopathological analysis, the patient may be said to have an undefined congenital myopathy. We report the retrospective review of 61 patients enrolled in the Beggs Congenital Myopathy Research Program with a diagnosis of undefined congenital myopathy who had pathology reports and muscle biopsies available. After this review, 34 cases were reclassified with a pathological diagnosis of a specific congenital myopathy including centronuclear myopathy, congenital fiber type disproportion, and multi-minicore disease or another neuromuscular condition like congenital muscular dystrophy. Of the remaining 27 patients, 7 patients had varying clinical presentations including myasthenic syndrome, chronic pain, and facial weakness, whereas 20 patients presented with weakness or hypotonia at early age as a unifying feature. Seven of this latter group had additional findings not limited to muscle, including a patient with Vici syndrome. The remaining 13 patients had a clinical history consistent with a congenital myopathy, with delayed motor milestones, feeding difficulties, and diffuse hypotonia, but with normal or nonspecific findings on biopsy. We explore the clinical courses, possible genetic causes, and the pathological findings present in the patients originally classified as undefined congenital myopathy.

2814W

Molecular and clinical study of 30 Angelman syndrome patients with *UBE3A* mutations.
K. Hosoki[1], S. Saitoh[2]. 1) Department of Pediatrics, Hokkaido University Graduate School of Medicene, Sapporo, Japan; 2) Department of Pediatrics and Neonatology, Nagoya City University School of Medical Sciences. Nagoya, Japan.

Angelman syndrome (AS) is a neurodevelopmental disorder related to genomic imprinting at 15q11-q13. Genetically, AS is classified in five genetic groups; approximately 70% are caused by deletion at 15q11-q13, 5% paternal uniparental disomy 15, 5% imprinting defects, 10% *UBE3A* mutations, and 10% unknown etiologies. Deletion positive patients have been reported to show more severe clinical features than those with patients in other genetic groups including *UBE3A* mutation group. In order to delineate molecular and clinical characteristics in AS patients with *UBE3A* mutations, we reviewed identified mutations in the *UBE3A* gene in our series of molecular testing for patients with AS, and tried find genotype-phenotype correlation. We detected 26 *UBE3A* mutations in 30 patients with AS, including 7 familial and 23 sporadic patients. It is of note that 7/26 (27%) mutations were present in exon 16. Frameshift mutations were most predominant (18/26, 69%). Seventy three % of mutations have not been reported previously. Next, we compared clinical features of the patients with *UBE3A* mutations to those of 10 AS patients with typical 5Mb deletions. There were no significant difference between two groups for major clinical features of AS. However, motor developmental milestones including head control, independent sitting and independent walking were significantly less delayed in patients with *UBE3A* mutations than in patients with typical deletions. Therefore, our study indicates that patients with *UBE3A* mutations show milder phenotype than patients with typical deletions. Typical deletion encompasses three genes (*GABRB3*, *GABRA5* and *GABRG3*) encoding subunits of $GABA_A$ receptor. Haploinsufficiency of these genes may explain more severe phenotype in patients with typical deletions.

Stargardt Disease, a Clinical Description. *L. Mora[1], M. Tamayo[1,2], F. Rodriguez[2], M. Valencia[2].* 1) Instituto de Genética Humana, PontificiaUniversidad Javeriana, Bogotá, Colombia; 2) Fundación Oftalmológica Nacional, Bogotá, Colombia.

INTRODUCTION. Stargardt's disease or juvenile macular degeneration, first described in 1909 by Karl Stargardt, is known as a nosologic entity of autosomal recessive (AR) inheritance. It is the most common cause of macular degeneration in childhood, due to accumulation of lipofuscin in the retinal pigment endothelium and limited energy exchange at level of the photoreceptors; clinically evident between 7 and 12, is shown as a progressive deterioration of visual acuity. It has been reported worldwide incidence of 1/10000, but no data are available at the Colombian population. **MATERIALS AND METHODS.** * 10 patients (4 men - 6 women) with clinical diagnosis of Stargardt disease. They were obtained from the database of patients with genetics eye diseases of the National Ophthalmological Foundation (FUNDONAL). * Average age now 39.2 years, range 12-69 years. * The patients were evaluated with a complete medical history, fundoscopy under pupil dilation and best corrected visual acuity using Snell scale and fluorescein angiography. * 6 patients were evaluated with OCT (Optical Coherence Tomography) images, which were performed using 5 lines radiated scanner, manually centered on the fovea. **RESULTS.** * 100% of patients present with best corrected visual acuity of > 20/100. * 80% of those tested were found in stage I / II. * Inverse correlation was found between visual acuity and foveal thickness. * Symptoms start in the first two decades of life in 90% of the patients. * We consider the AR inheritance mechanism as the most likely in the study population. **DISCUSSION.** Stargardt's disease is a progressive disease, affecting individuals in the first decade of life. In the clinical and paraclinical description of 10 individuals in collaboration of the Institute of Human Genetics at the Javeriana University and National Ophthalmological Foundation, it was established that for our population the most frequently reported symptoms in the first decade of life include nictalopia and tunnel vision. Symptoms have slow progression, most patients were in stage I and II, this being compatible with a visual acuity of > 20/100, with an average of evolution of 20 years. The OCT findings showfoveomacular reduced thickness and loss of photoreceptors in the macular area, which can be useful in the diagnosis of Stargardt disease, it was found strong correlation between foveal thickness and visual function in patients sample.

Mixed phenotype of incontinentia pigmenti and anhidrotic ectodermal dysplasia with immunodeficiency in a patient with duplication of the IKBKG gene. *A. Ramalingam, E. van Asbeck, T.J. Chen, E. Morava.* Human Genetics, Tulane University School of Medicine, New Orleans, LA.

/We report on a 30 year old female patient with a mixed phenotype of incontinentia pigmenti and anhidrotic ectodermal dysplasia with immunodeficiency in combination with normal intelligence and a progressive neurologic disease. The patient presented with recurrent benign tumors, multiple hemangiomas and cysts and arteriovenous malformation. She has cysts in her ear canal and neurinoma. Besides fatigue, muscle pain and generalized muscle weakness she also developed rapidly progressive peripheral neuropathy, macrocephaly with absence of seizures and hearing loss. She has experienced sudden visual loss on her right eye due to retinal hemorrhage. She presented with progressive problems with gastric emptying and gastroparesis necessitating a G-tube. Skin symptoms with color changes in a linear pattern, decreased hair growth, patchy alopecia and decreased sweating appeared after puberty. She also has severe and recurrent life threatening infections with compromised immunity but without obvious T or B cell deficiency or low immunoglobulin levels. A duplication of approximately 136 kb at Xq28 was identified by array CGH, and confirmed by qPCR. G6PD and IKBKG genes were fully duplicated while FAM3A and GAB3 were partially duplicated. Deletions, partial duplications and point mutations in IKBKG have been detected in patients with X-linked anhidrotic ectodermal dysplasia with immunodeficiency (XL-EDA-ID). The clinical phenotype of our patient supported our postulation that the fully duplicated IKBKG also played a pathogenic role in XL-EDA-ID patients. Our patient shows a progressive, mixed phenotype of both incontinentia pigmenti and anhidrotic ectodermal dysplasia with immunodeficiency, suggesting more complicated pathogenic mechanisms, such as reported somatic mosaicism, variable expression in different tissues, and skewed X-inactivation. IKBKG is likely to involve in these mechanisms. Further characterization of this duplication and its pathogenic role is in progress.

Single Molecule Targeted Sequencing of Long Fragments (>1kb) for Ovarian Hypersensitivity Syndrome. *F. Orkunoglu-Suer[1,2], A. Harralson[3], D. Frankfurter[4], P. Gindoff[4], E. Hoffman[1,2], T.J. O'Brien[5].* 1) Children's National Medical, Research Institute, Genetics in Medicine, NW, Washington DC, 20010; 2) Dept of Integrated System Biology, Sciences Department, the George Washington University Medical Center, Washington, DC 20037; 3) Department of Pharmacogenomics, Bernard J. Dunn School of Pharmacy, Shenandoah University, Ashburn, VA; 4) Department of Obstetrics and Gynecology, The George Washington University Medical Center, Washington,; 5) Department of Pharmacology and Physiology, the George Washington University Medical Center, Washington, DC 20037.

Targeted resequencing using next-generation sequencing technology is being rapidly applied to the molecular diagnosis of genetic diseases. To identify novel predictive genetic biomarkers for ovarian hyper stimulation syndrome (OHSS) that is multi-genic in nature and requires rapid genomic techniques for the identification of risk alleles we employed targeted single molecule sequencing technology. To perform a proof-of-concept study, we selected four patients with OHSS. We developed a custom Targeted Single Molecule Sequencing (T-SMS) Panel; total 44 loci and 3756 primer pairs using long 1 kb standard fragment size with droplet PCR technology (Rain DanceTM). T-SMS was carried out using single molecule real time (SMRT) DNA sequencing (Pacific BiosciencesTM). Secondary analyses were conducted using the Genome Analysis Toolkit for SNP discovery embedded in Smart Portal followed with ANNOVAR for functional annotations. Filtered functional variants further validated using conventional Sanger sequencing in original samples. Target enrichment PCR yielded amplicons averaging 1 kb fragment size. The total targeted sequence was 3.18 Mb per sample. Mean mapped CCS read accuracy was 97%, with filtering set default >10X CCS. Using this approach, we have identified a non-synonymous variant LHCGR (NP_000224.2:p.Asn291Ser; rs12470652) in two severe OHSS cases. Critically, combining larger fragments and droplet PCR targeted approach helped us to overcome gDNA and other fragments that may occupy unnecessary sequencing cells, and cause reduction of reads. Single Molecule Sequencing technology provided a new resolution by providing significantly longer reads, reads of GC reach sequences, sequencing of many target genes in a short time (45 min on instrument), low error profile that has promises for clinical diagnosis. Best of our knowledge this is the first clinical study reporting effective sequencing of 1 kb size amplicons utilizing droplet PCR technology. This data show excellent utility for follow-up validation and extension studies in ovarian hypersensitive syndrome and, panel that can be further modified and extended to assisted reproductive therapy and infertility genomics.

Myocardial thickness and ventricular Tei index by echocardiography among normal developing fetuses. *Y-H. Zhang[1,2], Q-Y. Cao[1,2], J. Ge[1,2], N. Zhong[1,2,3,4].* 1) Ultrasound, The 4th Municipal Hospital of Shijiazhuang, Shijiazhuang, China; 2) Center of Translational Medicine for Maternal and Children Health, The Maternal Health and Obstetric Hospital, Shijiazhuang, China; 3) Peking University Center of Medical Genetics, Beijing, China; 4) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, New York.

Congenital heart disease (CHD) has become the top list of birth defect in China in the recent years. In order to accurately monitor the fetal heart development, normal developmental parameters are necessary to be established. For which, we have undertook a study to obtain the normal fetal myocardial thickness and ventricular Tei index, and to explore its growth regularities as well as reference ranges of normal fetal growth among 257 normal singleton fetuses. These fetuses were randomly selected from normal pregnancies that underwent prenatal ultrasound screening for birth defect in our hospital. The fetal myocardial thickness of left and right ventricular wall, ventricular septum, and left and right ventricular apex were measured from a four-chamber view during the relaxation period. The blood flow frequency spectrums of left and right ventricular inflow and outflow were obtained respectively using pulse Doppler ultrasound. The corresponding time intervals were measured and corrected by heart rates, and then Tei index was calculated. The fetal myocardial thickness and ventricular Tei index varied in different pregnant weeks. Fetal myocardial thickness grew with the increase of pregnant weeks and there was a linear correlation between them. Right ventricular wall was thicker than other parts. The ventricular Tei index decreased gradually with the increase of gestational age and Tei index of right ventricle was lower than that of the left ventricle. Fetal myocardial thickness and Tei index could be estimated accurately by echocardiography. Reference ranges of normal fetuses with different gestational ages are helpful in early detection and timely management of fetal abnormalities.

Harlequin Ichtyosis: A rare case of two consecutive harlequin ichthyosis in the offspring of a sequindigravida. *O. Franciska, R. Santos.* Obstetric Gynecology department, Jose R Reyes Memorial Medical Center, Rizal Avenue, Manila, Philippines, MD.

ABSTRACT: Harlequin fetus is rare and the most severe form of congenital ichthyosis, inherited as autosomal recessive trait with an incidence of about 1 in 300,000 births. It is characterized by hyperkeratosis and desquamation of the epidermis which begins prenatally. The skin barrier is severely compromised, leading to excessive water loss, electrolyte imbalance, temperature dysregulation and an increased risk of life threatening infection. Here in our institution, we report a case of a pregnant woman with a previously born child affected with Harlequin Ichthyosis. For this second pregnancy, they were expecting to have a normal baby since the congenital sonographic scan done prenatally was unremarkable. However, the mother delivered at 29-30 weeks age of gestation with the fetus showing signs of Harlequin Ichtyosis. The child was a 1200 gram female neonate born prematurely by partial breech extraction. Clinical manifestation of harlequin ichthyosis were present at birth. Furthermore, the fetus suffered from respiratory distress and was very ill, few hours after delivery and died few days after birth. Prenatal Diagnosis of HI is made with the use ultrasound guided fetal skin biopsy, imaging technique with 2D and 3D real time sonography as well as genetic mutational analysis. Prenatal genetic counseling is very essential in her case because of the serious implications to consider for her offspring. The complex management of our patient can be best achieved by using a multidisciplinary approach characterized by strong communication, both among the medical team and with the family. Key words: Harlequin ichtyosis, congenital, prenatal diagnosis, ultrasound.

Prenatal presentation of fetal anemia associated with εγδβ -thalassemia: two new cases. *E. Gagne[1], Y. Sabr[1, 2], M.F. Delisle[1, 2], N. Kent[1, 2], T. Nelson[1, 3], L.A. Brown[1, 3], K. Schlade-Bartusiak[1, 3], P.C. Rogers[1, 4], S. Pritchard[1, 4], L.D. Wadsworth[1,3], N. Au[1,3].* 1) Children and Women's Health Centre of British Columbia, Vancouver, BC, Canada; 2) Department of Obstetrics and Gynaecology, University of British Columbia, Vancouver, BC, Canada; 3) Department of Pathology and Laboratory Medicine, University of British columbia, BC, Canada; 4) Department of Paediatrics, University of British Columbia, Vancouver, BC, Canada.

εγδβ-thalassemia is rare hematological disease caused by either a deletion of the beta-globin gene cluster, or deletion of the upstream β locus control region (LCR). It results in a phenotype of beta-thalassemia trait in adulthood. In the fetal and newborn period, the phenotype can range from self-limiting anemia to life threatening anemia requiring intra-uterine transfusions. Of the 30 εγδβ-thalassemia deletions reported so far, only 4 have been associated with severe congenital anemia requiring intervention or intrauterine transfusion. Here, we report the clinical course and molecular characterization of two new cases. Case 1- A 26 year G1P0, Filipino (Southeast Asian) who presented at 19 weeks and 4 days of gestation with polyhydramnios, fetal pericardial effusion and thickened myocardium. Fetal karyotype was normal. Cordocentesis showed a fetal hemoglobin of 30g/L, which required two intra-uterine transfusions. Delivery was induced at 36 weeks of gestation. Cord blood hemoglobin was 150g/L. Hemoglobin levels improved slowly (Hb at 9 months 96g/L) and the patient did not require further blood transfusion. Alpha and Beta thalassemia molecular genetic testing was normal. Microarray analysis (Affymetrix Cytoscan HD) revealed a deletion of 54 kb encompassing the β LCR, HBE, HBG1 and HBG2 genes. The deletion was confirmed by FISH and shown to be maternally inherited. Case 2- A 42 years G2T1L1, Caucasian (Irish/Scottish) who presented at 33 weeks and 3 days of gestation with polyhydramnios, umbilical cord cyst, thick placenta (7.8cm) and elevated MCA peak systolic velocity (94cm/sec). Patient was delivered by cesarean section at 33 weeks and 5 days gestation because of fetal hydrops. Cord blood hemoglobin was 49g/L, and multiple blood transfusions were needed over a 6 months period. Microarray analysis showed a deletion of 771 kb of the entire beta-globin gene cluster. The deletion was shown to be inherited from the father who had no prior history of anemia. Detailed family history however revealed a paternal aunt previously diagnosed with εγδβ-thalassemia 24 years ago and was reported as the >185 kb Canadian deletion (Diaz-Chico, 1988). In conclusion, we report the first εγδβ-thalassemia deletion diagnosed in a patient of South Asian ethnicity and present evidence of the inter-individual variation in the clinical presentation between carriers of the same deletion. In addition, we show that microarray can be a valuable tool to diagnose these deletions.

Aicardi-Goutières syndrome carrier screening in Ashkenazi Jewish families.
C. Jalas[1], A. Fedick[2,3], C. Landau[1], C. Halberstam[1], A. Shaag[4], W.K. Chung[5], J.G. Pappas[6,7], E.S. Moran[6], J. Roberts[8], N.R. Treff[2,3], M. Szynkiewicz[9], G. Rice[9], Y.J. Crow[9], O. Elpeleg[4], S. Edvardson[4]. 1) Bonei Olam, Center for Rare Jewish Genetic Disorders, Brooklyn, NY; 2) Department of Microbiology and Molecular Genetics, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ; 3) Reproductive Medicine Associates of New Jersey, Basking Ridge, NJ; 4) Monique and Jacques Roboh Department of Genetic Research, Hadassah, Hebrew University Medical Center, Jerusalem, Israel; 5) Department of Pediatrics, Columbia University Medical Center, New York, NY; 6) Center for Children, NYU Hospital for Joint Diseases, New York, NY; 7) Clinical Genetic Services, New York University School of Medicine, New York, NY; 8) Maimonides Medical Center, Brooklyn, NY; 9) Manchester Academic Health Science Centre, University of Manchester, Genetic Medicine, Manchester, UK.

Aicardi-Goutières syndrome (AGS) is a genetically determined disorder, most particularly affecting the brain and the skin. In its most characteristic form, AGS is a remarkable mimic of the sequelae of congenital infection. In such cases, the prominent clinical features consist of subacute onset of a severe encephalopathy, often after a period of apparently normal initial development, characterized by irritability, psychomotor regression, and slowing of head growth. The initial period is followed by apparent stabilization during which appendicular spasticity, truncal hypotonia and dystonic posturing are prominent along with severe cognitive deficits. Imaging is an important part of diagnosis, typically showing calcification of the basal ganglia, particularly the putamen, globus pallidus, and thalamus. White matter calcifications may also be seen. Other common imaging abnormalities consist of dysmyelination, with a predilection for the frontotemporal regions and cerebral atrophy. Laboratory abnormalities observed in most patients are chronic cerebrospinal fluid (CSF) lymphocytosis and increased CSF interferon alpha (IFN-α). Increased CSF neopterin, a marker of cellular immune system activation, has been shown to be prominent in a number of patients. Although the majority of recognized patients conform to the relatively stereotyped 'classical' phenotype just described, there is also now an extensive literature reporting a broader spectrum of disease presentation, progression and outcome encompassing a variety of apparently non-specific 'inflammatory' features. Consequently, it is likely that AGS is underdiagnosed. AGS is caused by mutations in at least six genes, with the SAM domain and HD domain-containing protein 1 (SAMHD1) gene accounting for 10 percent of mutations in an unselected population. We have identified a total of five mutations in SAMHD1 that cause AGS in thirteen Ashkenazi patients among our cohort and published cases. The most common mutation is a deletion of exon 1, which has a carrier frequency of 1/138 derived from genotyping over 1000 healthy Ashkenazim. Based on these findings, and considering the severity of the condition, we recommend including the SAMHD1 mutations on the expanded carrier screening panels for members of the Ashkenazi Jewish population.

Quantification of total and fetal cell-free DNA in patients with abnormal Maternal Serum Screen (MSS) parameters.
I. Manokhina[1, 2], T.K. Singh[2, 3], M. Peñaherrera[1, 2], W.P. Robinson[1, 2]. 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Child & Family Research Institute, Vancouver, BC, Canada; 3) Faculty of Biology, University of British Columbia, Vancouver, BC, Canada.

Determining the relationship between total/fetal cell-free DNA (cfDNA) in maternal plasma and gestational characteristics may help in early detection of fetal abnormalities and the prediction of pregnancy complications. For this purpose 27 plasma samples between 14 and 33 weeks gestational age were collected from women with normal (N=8) or abnormal maternal serum screen parameters (N=19; 9 with low PAPPA and 10 with abnormal hCG, AFP or inhibin A). Placenta and pregnancy outcome data were collected at term: 7/19 women from the abnormal MSS group developed pregnancy complications (1 early-onset preeclampsia, 3 intrauterine growth restriction, 1 placental pathology associated with low birth weight, 1 preterm labour/chorioamnionitis and one trisomy 21). Fetal and total cfDNA was quantified using TaqMan qPCR assays specific to the *SRY* (Chr Y) as these were all male pregnancies and *RPP30* (Chr 10) genomic regions. The mean values of total and fetal cfDNA in the whole population were 2426 genome equivalents (GE)/mL, (range: 357-9767 GE/mL) and 149 GE/mL (range: 18-739 GE/mL), respectively. We investigated possible associations of quantified levels of total and fetal cfDNA with gestational age and pregnancy characteristics, such as abnormal maternal serum screen results, conditions associated with placental insufficiency (preeclampsia, intrauterine growth restriction), and pathological outcomes in total. No significant association between gestational age and the levels of cfDNA was detected, which could be attributed to small sample size. No significant association was detected between total or fetal cfDNA levels in the control and abnormal MSS groups. However, the levels of fetal cfDNA were higher in pregnancies complicated by placental insufficiency (N=4; mean: 321 GE/mL, range: 57-738 GE/mL) relative to uncomplicated pregnancies (N=23; mean: 118 GE/mL, range: 18-488 GE/mL) but this trend did not reach significance (ANOVA, p=0.062). Additionally, total cfDNA was significantly higher in cases with any pathological outcome (N=7; mean: 5691 GE/mL, range: 1372-9767 GE/mL) compared to pregnancies with normal outcomes (mean: 1223 GE/mL, range: 356-2498 GE/mL) (ANOVA, p <0.0001). No significant associations with the available MSS parameters (AFP, PAPP-A, hCG) were detected. We are currently expanding the sample and comparing several approaches for cfDNA quantification to further evaluate these relationships.

***De novo* mutations in embryonic development and early lethality.**
A. Hoischen[1], C. Serra-Juhé[1,2], C. Gilissen[1], M. Steehouwer[1], J.A. Veltman[1], L.A. Pérez-Jurado[2]. 1) Department of Human Genetics, Radboud University Medical Centre, Nijmegen, Netherlands; 2) Unitat de Genètica, Universitat Pompeu Fabra & CIBER de enfermedades raras (CIBERER), Barcelona, Spain.

We and others have recently shown the importance of de novo mutations for rare [1-3] and common [4-6] sporadic disorders by the direct detection of de novo mutations by exome sequencing. This has revolutionized the genetics of congenital malformations, intellectual disability, and clinically defined syndromes. There are however several reasons why (Mendelian) disease genes are not always easily detected, one reason can be early lethality. Pathologic pregnancies are one of the major health burdens of our society, as just 25% of all conceptions lead to a liveborn child. While the role of (de novo) chromosomal aberrations as a cause of pathologic pregnancies has been intensively studied over the last decades, the role of (de novo) point mutations remains largely unexplored, leaving a large proportion of pregnancy losses unexplained. In this study we have selected cases of pregnancy loss exhibiting well-defined malformations (14 fetuses with hypoplastic left heart (HLH), 14 fetuses with neural tube defect and Arnold-Chiari malformation and 10 fetuses with multiple malformations) in order to identify (de novo) mutations that cause embryonic lethality. In a first analysis we e.g. identified de novo mutation in *USP32* and *NCAPD3*, and subsequently private variants in the same gene or pathway in additional cases, allowing to speculate about the role of these genes in human heart development. The systematic study of the role of point mutations in pathologic pregnancies will allow identification of genes with functions crucial for early development in humans, such mutations would remain undiscovered when only studying liveborn patients. In addition this will improve diagnostics and counseling for affected families in the future. References: 1.Hoischen A et al. De novo nonsense mutations in ASXL1 cause Bohring-Opitz syndrome. Non Invasive Prenatal Screening - Are we providing a false sense of security? *S. Klugman[1], B. Suskin[1], K. Erskine[1], N. Kirshenbaum[2], S. Dolan[1].* 1) Reproductive Genetics, Montefiore Med Ctr, Bronx, NY; 2) Maternal-Fetal Medicine, Montefiore Med Ctr Bronx, NY.

Background: HIstorically, a patient who has had a high risk for aneuploidy after first trimester screening was offered invasive prenatal testing via chorionic villus sampling or amniocentesis. In the past year, non invasive prenatal screening has been offered by some in lieu of diagnostic testing. Currently, four companies offer this testing. Case: A 37 year old woman had a first trimester screen at an outside clinic with an increased risk for DS of 1/5 and an increased risk for trisomy 13/18 of 1/25. She was counseled by her primary obstetrics provider and chose to do non invasive prenatal screening. The results were low risk for trisomies 21, 18 and 13. The patient reports she was relieved at that time and chose to continue the pregnancy. The patient was referred to our facility at 19 weeks gestational age for amniocentesis after an anatomy scan showed fetal hydrops and a hypoplastic left heart. The patient was confused because she was told, 'everything was good on the new special blood test.' Amniocentesis revealed a 45XO karyotype. Discussion: This case highlights the limitations of non-invasive prenatal screening. It also reiterates the importance of pre-test counseling and post -test counseling when using non invasive prenatal screening as outlined in the recent ACOG/SMFM and ACMG guidelines. Non-invasive prenatal screening tests for a limited number of chromosomal aneuploidies, and they differ by platform. In this case specifically, choosing a test that included sex chromosome aneuploidy would have been preferred. In addition, this case highlights the fact that in those patients with a positive first trimester screen who undergo invasive testing, the resultant karyotype is not always consistent with the abnormal screening result. A full karyotype and/or microarray, i.e. a diagnostic test, is recommended after a positive screen and will provide more information than a non invasive prenatal screen.

2825W

Two unrelated cases of female fragile X carriers with proximal duplication of non-repetitive DNA sequence within the CGG repeat region of the *FMR1* gene. *J. Skeen[1], J. Coppinger[1], J. McCarver[1], R. Cao[2], S. Filipovic-Sadic[2], L. Schnetzler[3], D. Sevilla[3], J. Weisberger[3], A. Hadd[2], S. Nolin[4], R. Zimmerman[3], G. Latham[2].* 1) Pharmacogenomic and CLIA Service, Asuragen, Austin, TX; 2) Research and Technology Development, Asuragen, Austin, TX; 3) GenPath, BioReference Laboratories, Inc, Elmwood Park, NJ; 4) Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Nearly all individuals with fragile X syndrome have a full expansion mutation of more than 200 CGG trinucleotide repeats in the 5'untranslated region of the *FMR1* gene. Females with fragile X premutations (55-200 CGG repeats) have a risk of transmitting a fragile X full mutation to their offspring. New high resolution PCR methodologies enable precise sizing of the CGG repeat region and reveal non-repeat sequences, such as AGG interruptions. Here, we report two fragile X carrier females with unexpected DNA sequence findings in the CGG repeat region of the *FMR1* gene detected by these novel PCR assays.

Two clinical diagnostic testing laboratories utilizing the same *FMR1* PCR technology independently identified an unusual electrophoretic reading suggesting a non-CGG sequence within the CGG repeat regions of two unrelated, pregnant fragile X carriers. The samples were further analyzed for AGG interruptions and methylation status, and sequenced across the repeat region. Patient #1 is an African American female who underwent fragile X carrier testing and was found to have an *FMR1* allele size consistent with 78 repeats, but with an unusual electrophoretic trace suggesting a segment of non-CGG DNA within the CGG repeat region. Patient #2 is a female of Taiwanese descent identified by fragile X carrier testing to have an *FMR1* allele size consistent with 58 repeats, but also with a pattern consistent with a non-CGG DNA insert in the repeat segment. Sanger sequencing on both maternal DNA samples confirmed the insertion of a unique non-repetitive sequence of 71 nucleotides in Patient #1, and 37 nucleotides in Patient #2. In both cases, the inserted sequence was homologous to a 36 bp sequence within the *FMR1* gene that is directly upstream of the CGG repeat region.

This type of intra-repeat insertion-duplication has not been previously reported in the medical literature to our knowledge. Both patients have reportedly normal health and intelligence, and both are currently pregnant with male fetuses, one of whom has been confirmed to also carry the atypical *FMR1* allele without any expansion. These findings suggest that the increasing use of more sensitive, high resolution PCR technologies will reveal rare genotypes with uncertain clinical consequences, raising new questions and challenges for researchers, clinical providers, and patients.

2826T

Non-invasive prenatal testing (NIPT): Proceed with caution. A case of trisomy 18 mosaicism in a phenotypically normal newborn. *H. Welsh[1,3], H. Ardinger[1,3], M. Begleiter[1,3], L. Zhang[2,3], L. Cooley[2,3].* 1) Department of Pediatrics, Children's Mercy Hospitals and Clinics, Kansas City, MO; 2) Department of Pathology and Laboratory Medicine, Children's Mercy Hospitals and Clinics, Kansas City, MO; 3) University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Prenatal screening is used to identify fetuses with chromosomal anomalies so parents and their physicians are able to make critical care decisions. The newest screening methods use massively parallel sequencing of circulating cell-free fetal DNA in maternal plasma to detect chromosomal aneuploidy. This non-invasive prenatal screening (NIPT) allows for the detection of chromosome anomalies without the risk of miscarriage. However, as a new front line screening test, a positive NIPT result must be confirmed by conventional methods prior to making major or irreversible medical decisions. We present a 41-year-old woman, who had MaterniT21™ testing at 11 weeks gestation due to advanced maternal age. The test was positive for Trisomy 18. Amniocentesis was performed at 15 weeks gestation. FISH analysis of uncultured amniocytes showed three chromosome 18 centromere signals in 2.5% of nuclei. Chromosome analysis found an extra small marker chromosome in one of 15 colonies. FISH analysis of cultured amniocytes found the extra small marker chromosome in 3 of 21 colonies. Serial sonograms were performed with normal fetal anatomy and growth documented. The female child, born at term, weighed 7 pounds 9 ounces, was 19 inches in length, and was non-dysmorphic. Random chromosome analysis of cord blood, cord, membranes and villi found a normal diploid karyotype in 98%, 65%, 100% and 100%, respectively. Two abnormal cell lines were found: one with the extra small marker chromosome (positive with chromosome 18 centromere probe), and one with complete trisomy 18 (positive for chromosome 18 centromere and 18q21 probes). The small extra marker was present in 2% of blood, and 0% of cord, membranes and villus metaphase cells. Trisomy 18 was present in <1% of blood, 35% of cord, and 0% of membranes and villus metaphase cells. FISH analysis found trisomy 18 in 4% and 8% of blood metaphase cells and nuclei, respectively; 15.5% of cord; 24.5% of membranes and 32% of villus nuclei. This case shows NIPT may have high sensitivity for chromosomal aneuploidy and reinforces NIPT as a screening test. Positive NIPT results must be carefully followed up with gold standard prenatal classic cytogenetic diagnostic methods before critical decisions are made. This new methodology may reveal fetuses with mosaic conditions that previously may have gone undetected.

Detection of Carriers of Rare and Novel Mutations using Next Generation DNA Sequencing. *V. Greger, C.J. Kennedy, K. Casey, N. Chennagiri, C. Perreault-Micale, S. Hallam.* Good Start Genetics, Cambridge, MA 02139.

Traditional carrier screening assays can identify only the most common mutations within a gene, typically those recommended by the American College of Medical Genetics, the American Congress of Obstetricians and Gynecologists and societies representing the Ashkenazi Jewish (AJ) population. This methodology can yield high detection rates in specific populations such as the AJ, but a targeted and limited carrier screening approach can miss many mutations prevalent in other ethnicities, as well as any novel or rare mutations. Next generation DNA sequencing (NGS) enables deep gene sequencing in a cost-effective manner, and it is not dependent on an ethnicity-derived panel of mutations. In this study we evaluated the spectrum of mutations found in a pan-ethnic population in the following genes: HEXA, ASPA, BLM, G6PC, FANCC, CFTR, BCKDHA, BCKDHB, DLD, CLRN1, PCDH15, SMPD1, MCOLN1, IKBKAP, and ABCC8. We sequenced the exons and exon-intron junctions of these genes in more than 10,000 patients referred for carrier testing by IVF clinics across the US. To date we have identified a total of 87 unique mutations and 449 carriers. AJ founder mutations or other common mutations, such as the Caucasian Tay-Sachs mutation c.1073+1G>A in HEXA, were often found in multiple carriers. However, we also detected a variety of rare variants, such as ASPA c.2T>C (M1T), ASPA c.79G>A (G27R), and SMPD1 c.1280A>G (H427R) that we observed only once. We also identified novel variants that are predicted to be pathogenic because they are expected to disrupt gene or protein function. Such truncating mutations include nonsense mutations, frameshift mutations and mutations at invariant splice site positions. Examples of some of the novel truncating variants we have identified include: CFTR c.580G>T (G194X), CFTR c.1526delG, IKBKAP c.2128C>T (Q710X), ABCC8 c.579+2T>A, G6PC c.975delG, BCKDHA c.288+1G>A, BCKDHB c.634-2A>G, MCOLN1 c.244delC, CLRN1 c.634C>T (Q212X), BLM c.757C>T (Q253X), BLM c.4076+1delG, and FANCC c.705delC. A significant proportion of the disease mutations we found are rare or novel. Most of these mutations would have not been detected by traditional carrier screening, in particular the novel mutations which are only detectable with comprehensive sequencing. NGS has significant advantages over traditional carrier screening and is expected to yield higher detection rates, irrespective of patient ethnicity, resulting in fewer missed carriers.

2828T

Cree Leukoencephalopathy and Cree Encephalitis Carrier Screening: Retrospective Evaluation of a Population-Based Program.
A.M. Laberge[1-3], J. Leclerc-Blain[1,2], G.A. Mitchell[1-3], B. Wilson[4], A. Bearskin[5], V. Gosselin[6], J. Torrie[6], A. Richter[1-3]. 1) Medical Genetics Division, CHU Sainte-Justine Montreal, QC, Canada; 2) CHU Sainte-Justine Research Center, Montreal, QC, Canada; 3) Department of Pediatrics, University of Montreal Montreal, QC, Canada; 4) Dept of Epidemiology and Community Medicine, University of Ottawa, Ottawa, ON, Canada; 5) Eeyou Awaash Foundation, Chisasibi, QC, Canada; 6) Cree Board of Health and Social Services of James Bay, Chisasibi, QC, Canada.

STATEMENT OF PURPOSE: Cree encephalitis (CE) and Cree leukoencephalopathy (CLE), two severe neurodegenerative autosomal recessive diseases, are found in the James Bay Cree communities (Northern Quebec, Canada). A population-based carrier screening program for CE/CLE (CSP) was developed by local health authorities in collaboration with a community family support group (Eeyou Awaash Foundation). Two groups are targeted: high school students (≥14 years) and women of reproductive age and their partners, mostly in prenatal settings. The CSP has not been evaluated since its start in 2006. OBJECTIVE: To describe screening outcomes using existing data collected by the CSP. METHODOLOGY: We obtained ethics approval to use data collected for management purposes by the CSP (12/2006-04/2013). Available variables include demographic information, carrier screening decision and carrier screening status. We determined uptake of screening and prenatal diagnosis, and carrier rates. Data from school-based and prenatal/preconception screening were analyzed separately. RESULTS: 1340 students were offered screening in school-based CSP. Of those, 650 (48.5%) were screened. Complete data are currently available for 454 screened students. Most had no known family history of CE (98.5%) or CLE (95.8%). 1.2% were screened in the context of an ongoing pregnancy. 22 students were identified as carriers for CE, 48 for CLE, and one for both. For CLE, one potentially at-risk couple was identified; there was no prenatal diagnosis. In the prenatal/preconception setting, 379 individuals were offered screening. Most had no known previous family history of CE (94.7%) or CLE (80.2%). 326 (86.0%) individuals chose carrier screening for CE and/or CLE; 115 (69.3%) women had an ongoing pregnancy. 46 individuals were identified as CLE carriers and 15 as CE carriers, 10 were carriers for both. Of 8 at-risk couples with an ongoing pregnancy, 6 chose prenatal diagnosis. We estimate the population-based carrier rate as 1/11 for CLE and 1/17 for CE, in contrast to incidence-based carrier rates previously calculated at 1/10 and 1/30, respectively. CONCLUSION: High uptake of carrier screening in target populations confirms its acceptability in the communities, as well as individual interest in knowing their carrier status. We plan to evaluate the CSP prospectively to assess screening outcomes and participant knowledge and satisfaction.

2829W

Y-chromosome partial deletions and male infertility in Indian sub-continent.
S. Rajender[1], D. Jaiswal[2], K. Kumar[3], D.S. Rani[4], K. Singh[2], R. Dada[3], K. Thangaraj[4]. 1) Endocrinology, Central Drug Research Institute, Lucknow, UP, India; 2) Banaras Hindu University (BHU), Varanasi, India; 3) All India Institute of Medical Sciences (AIIMS), New Delhi, India; 4) Centre for Cellular and Molecular Biology (CSIR), Hyderabad, India.

Complete AZFc deletions are a proven risk factor for male infertility; however, partial deletions are now emerging as risk factors. No concrete data on AZFc partial deletions in Indian populations are available. We have analyzed 2184 individuals in three cases-control groups from different corners of the Indian sub-continent. Kolkata cohort included 775 infertile and 287 normozoospermic fertile men from Kolkata and adjacent regions. Uttar Pradesh cohort included 547 infertile and 300 fertile control subjects from Lucknow, Varanasi, and adjoining areas. Delhi cohort included 200 cases and 75 control individuals recruited from Delhi and adjacent areas. All subjects were analyzed for complete and partial deletions in the AZFc region using STS and SNV markers recommended by the European Academy of Andrology (EAA). This was followed by meta-analyses on gr/gr and b2/b3 deletions. Classical Y-deletions were observed in a few individuals only. Microdeletions involving the entire AZFc region (b2/b4 recombination) were observed in all cohorts and their presence increased the risk of infertility. Most interesting observation concerned gr/gr deletions, which were observed in all cohorts at comparable frequency and increased the risk of infertility. B1/b3 partial deletions were less common and did not affect infertility risk significantly. Interestingly, b2/b3 deletions were absent in most of our cohorts and were not a risk factor for infertility. In conclusion, partial deletions in the AZFc region are risk factors for male infertility in Indian populations. The data from these cohorts suggest that gr/gr partial deletions are a strong risk factor and that b2/b3 deletions, which are very common and increase infertility risk in Chinese and few other populations, are almost completely absent in Indian populations. Population specific differences in the existence of AZF partial deletions and associated infertility risk are evident from comparison of our data with other populations, particularly Chinese/East Asians. Meta-analysis on partial deletion data suggested that gr/gr deletions are important in infertility and may be considered for inclusion in clinical testing of infertile individuals. On the other hand, meta-analysis on b2/b3 deletions found them to be of least significance for testing in a clinical setting.

2830T

MTHFR C677T POLYMORPHISM IN MEXICAN PATIENTS WITH POLYCYSTIC OVARY SYNDROME.
I.M. Salazar-Dávalos[1], N. Suárez-Magaña[2], J.P. Mena[3], M. Salazar-Páramo[4], E. Chávez[4], M.A. Aceves-Aceves[1], N.O. Dávalos[1], M.G. González-Mercado[3], F. Grover-Páez[4], I.P. Dávalos[3]. 1) Instituto de Genética Humana, DGH, Facultad de Medicina, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) UMAE, HGO, IMSS, Guadalajara, México; 3) Doctorado Genética Humana, CUCS, Universidad de Guadalajara;CIBO-IMSS, Guadalajara,México; 4) Depto. Fisiología, CUCS, Universidad de Guadalajara; Div. Investigación, UMAE, HE, CMNO, IMSS, Guadalajara, México.

Introduction: Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in reproductive age patients and one cause of anovulatory infertility. There are findings of high homocysteine levels in PCOS, the C677T polymorphism of the MTHFR gene have been associated with hyperhomocysteinemia and decrease of folic acid. Objective: To determine the association between MTHFR C677T polymorphism in mexican patients with polycystic ovary syndrome. Material and methods: We included 64 patients with PCOS diagnosis according to Rotterdam criteria and 101 Mexican mestizos as reference group (M). The genotyping was performed by PCR/RFLP technique. The M group presented Hardy-Weinberg equilibrium. Results: In the PCOS group (n=64)the MTHFR C677T genotypic frequencies %(n)were distributed as follows: CC 33 %(21), CT 48 %(31) y TT 19 %(12). The allelic frequency of the C allele was 57 %(73) and T was 43 %(55). The GF in the reference group (n=101) were CC 31 %(31), CT 50 %(51), TT 19% (19) and AF for C allele 56 %(113) and for T allele 44 % (89). The AF comparison between both groups were no statistically different ($p>0.05$). Conclusion: The genotypic and allelic distribution between both groups (group-PCOS vs group-M) were similar. This study showed no association between MTHFR C677T polymorphism and PCOS.

Gene-Environment Interaction in Adverse Reproductive Outcomes.
B.Dev. Banerjee. Biochemistry, University College of Medical Sciences, Delhi, India.

Many human disorders result from a complex interaction between an individual's genetic make-up and environmental stressors Humans are exposed to numerous xenobiotics constantly and unavoidably such as pesticides, metals, PCBs etc. Endocrine disruption, genetic predisposition, altered immune surveillance, inflammation and subsequent oxidative stress may antedate adverse reproductive outcomes and contribute to its pathogenesis. Although environmental factors are important, genetics clearly plays a role in adverse reproductive outcomes. Identification of genetic susceptibility variants will lead to better understanding of the role of variable factors in adverse reproductive outcomes. It has been observed that a lot of women with genetic polymorphism do experience normal delivery while some do not. It can be hypothesized that genetic polymorphism requires the presence of certain environmental stimuli to have consequences of clinical significance. The recent abundance of epidemiologic research examining associations between polymorphic genes that code for enzymes involved in xenobiotic biotransformation and disease has on occasion generated interesting findings. Recent studies from our laboratory clearly showed the importance to assess the role of variations in the human genome (polymorphisms) in modifying the effect of exposures to xenobiotics to define 'Gene-Environment Interaction', which render some individuals or groups in the population more or less likely to develop adverse health effect. Current and future efforts to identify new polymorphisms in genes involved in environmental response with larger sample size will broaden the scope of potential genetic effect modifiers. Currently, our laboratory is involved in studying the role of 'Gene-Environment Interaction' with reference to xenobiotic metabolism and oxidative stress related genes in various diseases and we have reported the association of xenobiotics with many of adverse reproductive outcomes such as preterm birth, intrauterine growth retardation, recurrent miscarriage, etc. Our effort in this area may also lead to the development of possible biomarker(s) to screen individuals, exposed to xenobiotics and preventive measures for safe reproductive outcomes. Determining the effect of these polymorphisms along with xenobiotics burden will be of paramount importance in an early diagnostic strategy and preventive measures for adverse reproductive outcomes with reference to environmental toxins.

Trans-ethnic GWAS of pelvic organ prolapse among African American and Hispanic post-menopausal women of the Women's Health Initiative.
D.R. Velez Edwards[1, 2], R.M. Ward[3], A. Giri[4], K.E. Hartmann[1], A.J. Park[5], C.L. Avery[6], R. Wallace[7], G. Bareh[8], L. Qi[9], M.J. O'Sullivan[10], A. Reiner[11], T.L. Edwards[2,4], .JM. Wu[12]. 1) Vanderbilt Epidemiology Center, Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Department of Obstetrics and Gynecology, Division of Female Pelvic Medicine and Pelvic Reconstructive Surgery, Vanderbilt University Medical Center, Nashville, TN; 4) Institute for Medicine and Public Health, Division of Epidemiology, Department of Medicine, Nashville, TN; Vanderbilt University; 5) Department of Obstetrics and Gynecology, and Urology Georgetown University School of Medicine Staff, Female Pelvic Medicine & Reconstructive Surgery Medstar Washington Hospital Center; 6) Department of Epidemiology, University of North Carolina, Chapel Hill NC; 7) Department of Epidemiology, University of Iowa, Iowa City, IA; 8) University of Texas Health Science Center, San Antonio, TX; 9) Department of Public Health Sciences, University of California Davis, Davis, CA; 10) Department of Obstetrics and Gynecology, University of Miami, Miami, FL; 11) Department of Epidemiology, University of Washington, Seattle, WA; 12) Department of Obstetrics and Gynecology, Division of Urogynecology, University of North Carolina-Chapel Hill, NC.

Pelvic organ prolapse (POP) impacts 40% of post-menopausal women and has a profound negative impact on a woman's quality of life. Despite POP being common and having acute effects, the pathophysiology is not well understood. As much as 40% of POP risk may be attributed to genetic factors. We conducted a genome-wide association study (GWAS) of POP in post-menopausal African-American (AA) and Hispanic (HP) women from the Women's Health Initiative (WHI) SNP Health Associated Resource (SHARe) GWAS. This is the first GWAS of POP in minority populations. WHI POP outcomes were obtained from pelvic exams. WHI data included 1427 participants with POP (stage 1 through 3) and 1274 controls (stage 0). After imputing to the most recent 1000 Genomes reference haplotypes, race stratified single SNP logistic regression on POP outcomes (for POP stage 0 versus 1-3 and stage 0 versus 2&3, respectively) was performed adjusting for continuous axes of ancestry and known POP risk factors (age, parity, BMI [AA] or WHR [HP]). We used fixed effects models to meta-analyze across AA and HP cohorts. We identified one novel locus at chromosome 4q32.3 (carboxypeptidase E [CPE] rs28573326, OR = 2.36, 95% CI 1.78 to 3.15, $p = 3.5\times10$-9) in AAs using POP stage 0 versus 2&3 and another at chromosome 4q34.3 when AA and HP data were meta-analyzed (intergenic, rs113518633, OR = 2.41, SE = 0.16, pHet = 0.722, $p = 2.19\times10$-8) using POP stage 0 versus 1-3. Both associations exceeded genome-wide significance and neither has previously associated with POP. No genome-wide significant associations were observed in HPs, however, we found some suggestive associations at chromosome 11q23.3 (myelin protein zero-like 2 [MPZL2], rs3018366, OR = 0.37, 95% CI 0.25 to 0.55, $p = 4.68\times10$-7) using POP stage 0 versus 1-3. Although neither SNP was previously associated with POP, the CPE SNP associated in the same direction in both AA and HP and the gene has been associated with risk for rectal prolapse in prior studies. These results provide the first evidence of GWAS-associated SNPs with POP in minority populations. We are also evaluating POP in European Americans and AAs participants from BioVU, the Vanderbilt electronic medical record DNA biorepository.

2833W

The Genetic Predisposition for Uterine Leiomyomas in Recently Admixed Populations: A Preliminary Study in Individuals From Electronic Medical Records. *J. Jeff[1], G. Belbin[2], D. Ruderfer[2,3], E. Stahl[2,3], S. Purcell[2,3], E. Bottinger[1], R. Loos[1,4], O. Gottesman[1], E. Kenny[1,2].* 1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Institute for Genomics and Muliscale Biology, Department of Genetics and Genomics, Ichan School of Medicine at Mount Sinai, New York, NY; 3) Division of Psychiatric Genomics, Icahn School of Medicine at Mount Sinai; 4) The Mindich Child Health and Development Institute at The Icahn School of Medicine at Mount Sinai.

Uterine leiomyomas (UL) are common benign tumors of the uterus and are the leading cause of hysterectomies. UL affects 25-77% of women and women of African descent have 2-3 fold increased risk. In addition to African ancestry, risk factors for UL include increased age, obesity, endogenous hormonal factors, and family history. Heritability studies in Europeans suggest 26-79% of UL can be explained by genetic factors. Despite the high heritability, established common genetic variants have yet to be identified. Identifying common genetic risk factors for UL in particular has been a challenge. First, obtaining a large population of UL cases that have been clinically diagnosis has been difficult to achieve in survey based cohort studies. Furthermore, there are few genetic studies that have been performed in UL in minority populations. We aim to address these limitations by using a diverse clinical population to identify and characterize the genetic predisposition of UL in African Americans (AAs) and Hispanics (HAs). Here, we report preliminary findings from a association study using Illumina OmniExpress and Human Exome BeadChip arrays in AAs and HAs from BioMe Biobank Program at Icahn Medical School at Mount Sinai, a clinical care cohort of consented patients with genotype data linkable to their electronic medical records (EMR). Using medical billing codes as a broad preliminary definition of case status, we identified a total of 325 cases and 650 controls from BioMe that were self-reported AA and 306 cases and 606 controls that were self-reported HA. We tested 844,372 common SNPs for an association with UL. All analyses were adjusted for age, body mass index, and informative principle components. While no SNP reached genome-wide significance at the discovery stage, we identified four loci at p<5.0E-6: AASDHPPT on chr11 (OR=1.6, p=1.4E-6) and an intergenic region on chr4 (OR=1.7, p=4.1E-6) in AAs as well as GAB4 on chr22 (OR=1.9, p=3.0E-6) and an intergenic region on chr2 (OR=0.51, p=2.5E-6) in HAs. We then meta-analyzed the results of AAs and HAs and detected six associations at p<5.0E-6. Notably, one locus harbors a tumor suppressor gene, FOXP1 (p=2.9E-6) and trends towards significance in both AAs and HAs (p=1.2E-4 in AAs, p=2.4E-3 in HAs). To expand this limited study, we are expanding the BioMe cohort and developing a robust algorithm to extract UL cases and controls from the EMRs of BioMe participants.

2834T

Role of Shigella in etiology of Endometriosis. *M. Latha[1,2,3], V. Kutala[1], Q. Hasan[3], V. Kodati[2].* 1) Biochemistry, CCMB-NIMS, Hyderabad, Hyderabad, India; 2) Genetics and Molecular medicine,Vasavi hospital , Hyderabad, Hyderabad, India; 3) Genetics and Molecular medicine,Hyderabad Science society,Hyderabad,India.

Endometriosis is defined as a disease characterized by the presence of endometrial cells, gland and stroma at ectopic sites outside the uterine cavity in addition to their normal presence as the innermost lining of the uterus. This is responsible for menstrual related problems, infertility and morbidity in women of reproductive age. There are different etiological factors implicated in the pathogenesis of endometriosis like mechanical, hormonal, environmental, immunological and genetic. In addition, our group has demonstrated the role infection in pathophysiology of endometriosis for the first time particularly identifying the novel DNA sequence obtained from ectopic endometrium which is having 96% homology to the Shigella sps genomic sequence.Present study has demonstrated that the mRNA was isolated from ectopic and eutopic tissues of three endometriosis cases and Differential Display RT- PCR (DD-RT-PCR) revealed sequences which were analyzed using the BLAST search .A 60/65 bp, 96% homology with Shigella dysenteriae, flexineri and sonnei species. (Figure- 13, 17) was obtained.Hence "bacterial hypothesis" provides a novel explanation of the molecular etiopathogenesis of endometriosis.

2835W

Identification of differentially expressed non-peptide metabolomic molecules with metabolomics approach in pregnancy-induced hypertension syndrome. *X-C. Luo[1,2], J. Pan[1,2], X-G. Tao[2,3], X-L. Zhao[2,3], Y. Gu[1,2], Q-X. Shi[1,2], N. Zhong[1,2,3,4].* 1) Lianyungang Maternal and Children's Hospital, Lianyungang, China; 2) Chinese Alliance of Translational Medicine for Maternal and Children's Health, Lianyungang, China; 3) Peking University Center of Medical Genetics, Beijing, China; 4) New York State Institute for Basic Research in DD, Staten Island, NY.

Pregnancy-induced hypertension syndrome (PIH) is the most common medical condition encountered during pregnancy and is reported to affect up to 9.4% ~10.4% of all gestations. PIH is defined as a systolic of 140mmHg or greater or a diastolic of 90mmHg or greater. Earlier studies showed that several risk factors have been described as predisposed to PIH, however, the pathophysiology of the PIH is not clear yet. The most well accepted hypothesis is that placental ischemia/hypoxia results from inadequate utero-placental vascular remodeling, which leads to a decrease in placental blood flow and the most of the data reported earlier were related to large peptide molecule metabolism. In this study, we have applied a metabolomics approach with HPLC-MS to investigate the differential metabolomic molecules presented in HIP. A total number of 537 molecule peaks (fractions) have been detected and computerized at the p<0.01 value. Among which, 84 were identified to be shared by all PIH1 (BP:140-150/95-100), PIH2 (BP: 160-175/105-125), and PIH3 (BP: >180/100) groups, 10 were overlapped between PIH1 and PIH2, 123 between PIH2 and PIH3, and 6 between PIH1 and PIH3. There were 113 peaks were down regulated and 37 up regulated when the group of control was compared against that of PIH1, 259 down regulated and 8 up regulated against PIH2, and 311 down regulated and 16 up regulated against PIH3. Two molecules, one (Feature 897.2/466) from the subgroup PIH-1 that was detected as up regulated and another (Feature 736.1/1870) that was down regulated, from PIH-3 showed excellent separation one from another between the PIH and control groups with a relative narrow intragroup variation within the two comparison groups. These two molecules could be potentially considered as bio-signature candidates for further investigations. Two molecules, Feature 894.2/467 and Feature 418.2/1345, showed a good separation, both intergroup and intragroup, and the remaining 5 showed a fair separation. Our findings justified a prospective assessment of metabolomic technology as a screening tool for PIH, and may lead to an improved method in future to monitor PIH including preeclampsia using non-peptide biochemical markers.

2836T

Admixture mapping study of uterine fibroids finds evidence for fibronectin and diabetes genes. *K.S. Tsosie[1], D.R. Velez Edwards[1,2], T.L. Edwards[1,3].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Vanderbilt Epidemiology Center, Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 3) Vanderbilt Epidemiology Center, Department of Medicine, Vanderbilt University, Nashville, TN.

Uterine fibroids are benign tumorous growths that affect up to 77% of women by menopause and account for $9.4 billion in yearly healthcare costs in the U.S. Fibroids are highly heritable, with up to 69% of risk attributable to genetic factors, as estimated by family history and supported by racial differences in prevalence and severity. Compared to European Americans (EA), African American (AA) women have earlier age-of-onset, more numerous and larger fibroids with a higher lifetime incidence. Here we further evaluated the racial disparities in fibroid risk through admixture mapping. Utilizing the Vanderbilt BioVU DNA databank, which links adult DNA samples with electronic medical records, 1,237 AA and EA subjects (185 cases and 1,022 controls) were identified whose fibroid status were confirmed with pelvic imaging. Admixture mapping was performed among AAs using GWAS data and identified regions were further evaluated in both EAs and AAs for association with fibroid risk. Local ancestry was estimated using LAMP-ANC, and logistic regression models relating local ancestry to fibroids were adjusted for principal components of ancestry. Analyses revealed associations that link uterine fibroid risk and African ancestry on chromosome 3q26 at two novel loci, TRAF2 and NCK-interacting protein kinase (*TNIK*; rs13315469, odds ratio [OR] = 0.41, 95% confidence interval [CI] 0.27, 0.62; $p = 2.6 \times 10^{-5}$) and solute carrier family 2, facilitated glucose transporter member 2 (*SLC2A2*; rs11924032, OR = 0.42, 95% CI 0.28, 0.64; $p = 3.6 \times 10^{-5}$). *TNIK* has an essential role in the Wnt signaling pathway but also phosphorylates *TCF7L2*, which modulates blood glucose homeostasis and is associated with type 2 diabetes. *SLC2A2* has also been implicated as a susceptibility gene for noninsulin-dependent diabetes mellitus. Of note, complex interactions between insulin, insulin-like growth factors (*IGF-I*), estrogen, and progestogen pathways have been shown to lead to fibroid growth. Diabetes has been previously associated with protection from fibroids and has a racial disparity in prevalence, supporting a potential role for *SLC2A2* in fibroid disparity. When models were further adjusted for age, an association was observed in the gene fibronectin type III domain containing 3B (*FNDC3B*; rs6763884, OR = 0.42, 95% CI 0.28, 0.64; $p = 5.6 \times 10^{-5}$). Previous studies have already implicated increased expression of fibronectin in uterine fibroids and *FNDC3B* has a known role in oncogenesis.

2837W

The Kallmann Syndrome gene WDR11 and Binding Partner EMX1 Are Expressed in Hypothalamic and Gonadal Tissues. *EK. Ko[1], SD. Quaynor[1], LP. Chorich[1], HG. Kim[1], SH. Kim[2], RS. Cameron[1], LC. Layman[1].* 1) Institute of Molecular Medicine & Genetics, Georgia Regents University , Augusta , GA 30912; 2) Division of Basic Medical Sciences, St. George's Medical School, University of London, London SW17 0RE United Kingdom.

The hypothalamic-pituitary-gonadal (HPG) axis is regulated by pulsatile secretion of gonadotropin releasing hormone (GnRH). When HPG dysfunction occurs at the level of the hypothalamus, normosmic hypogonadotropic hypogonadism (nHH) results. Patients with IHH manifest absent puberty with low serum levels of sex steroids and gonadotropins. When sense of smell is impaired in IHH patients, it is termed Kallmann Syndrome (KS). Approximately 40% of nHH/KS patients have mutations in a variety of genes that affect GnRH neuron migration and/or GnRH action. One such gene is *WDR11*, which was identified by positional cloning in a KS patient with a 10;12 chromosome translocation. Approximately 3% of nHH/KS patients had mutations in *WDR11*, which interferes with WDR11's binding to EMX1. EMX1 is a transcription factor known to be expressed in the developing forebrain, olfactory sensory neurons, branchial arches, and the embryonic kidney~all of which are affected in KS patients. Recently it was reported that some nHH/KS genes (FGFR1 and NR0B1) could have physiologic effects at both the hypothalamus and gonads. WDR11 is a cytoplasmic protein, which was sequestered in the nucleus following leptomycin B treatment, which inhibits nuclear export. The mechanism of how WDR11 causes KS is not known, but we hypothesize that WDR11 shuttles from the cytoplasm to nucleus, binds with EMX1, and affects expression of downstream genes in GnRH neurons. Therefore, we first wanted to determine if mRNA expression of *Wdr11, Emx1*, and related gene Emx2 were present in hypothalamic GnRH neurons and gonads. RNA was extracted from mouse GnRH neurons (migratory NLT and postmigratory GT1-7 cells), human GnRH olfactory neuroblasts (FNCB4-hTERT cells), testes, and ovaries, and then subjected to RT-PCR with confirmation by DNA sequencing. In mouse GnRH neurons, *Wdr11*, *Emx1*, and *Emx2* were expressed. However, in human GnRH olfactory neuroblasts, *WDR11* was expressed, but *EMX1* and *EMX2* were not detected. In mouse testes and ovaries, *Wdr11* and *Emx1* were expressed. Protein analysis is ongoing. These findings indicate that WDR11 and EMX1 are co-expressed in GnRH neurons, testes, and ovaries. Interestingly, *EMX1* and *EMX2* were not detected in human GnRH olfactory neuroblasts that were derived from an earlier embryological stage than the mouse GnRH neuronal cells used. These findings suggest that WDR11 could have reproductive functions at both the hypothalamus and gonads similar to other nHH/KS genes.

2838T

Understanding the genetics of spermatogenic failure by resequencing the sex chromosomes of infertile men. *R. George[1], J. Hughes[1], L. Brown[1], L. Lin[2], D. Koboldt[2], R. Fulton[2], R. Wilson[2], R. Oates[3], S. Silber[4], S. Repping[5], D. Page[1].* 1) Whitehead Institute, Cambridge, MA; 2) The Genome Institute at Washington University, St. Louis, MO; 3) Boston University School of Medicine, Department of Urology, Boston, MA; 4) Infertility Center of St. Louis, St. Louis, MO; 5) Academic Medical Center, Department of Reproductive Medicine, Amsterdam.

The sex chromosomes harbor a large number of genes involved in spermatogenesis and are hemizygous in males. For these reasons, mutations that cause spermatogenic failure~the production of very few or no sperm~are disproportionately likely to be found on the X and Y chromosomes. While several genetic causes of spermatogenic failure, such as microdeletions of the Y chromosome and large-scale cytogenetic abnormalities (e.g. Klinefelter's syndrome; XXY), have been identified, they only account for 20-30% of cases and the majority of genetic causes remain unknown. To identify new mutations involved in spermatogenic failure, we have captured and sequenced the coding and conserved non-coding regions of the X and Y chromosomes in 300 men with nonobstructive azoospermia and 300 controls. Our targeted regions include 838 and 53 protein coding genes from the X and Y chromosomes respectively, along with 22 Mb of non-coding sequence that contain ncRNAs and putative regulatory regions. We will describe the initial analysis of these sequences, and the identification of putatively causal coding mutations and copy number variants.

Mutations in the Kallikrein related peptidase-3 (KLK3) gene affect semen parameters in Indian men. *N. GUPTA[1], D.V.S. SUDHAKAR[2], S.N. SANKHWAR[3], N. GUPTA[4], K. THANGARAJ[2], S. RAJENDER[1].* 1) ENDOCRINOLOGY, CSIR-CDRI, LUCKNOW, UTTAR PRADESH, INDIA; 2) CENTRE FOR CELLULAR AND MOLECULAR BIOLOGY, HYDERABAD, ANDHRA PRADESH, INDIA; 3) DEPARTMENT OF UROLOGY, KING GEORGE MEDICAL UNIVERSITY, LUCKNOW, UTTAR PRADESH, INDIA; 4) INSTITUTE OF REPRODUCTIVE MEDICINE, KOLKATA, WEST BENGAL, INDIA.

Kallikrein related peptidase-3 (KLK3) is a highly abundant serine protease in the prostatic epithelium and seminal plasma. It has been known to play a role in fragmentation of semenogelins, resulting in the dissolution of semen coagulum and activation of sperm progressive motility. Among male reproductive organs, KLK3 expression was earlier thought to be restricted only to the prostate gland. Recent studies have reported KLK3 expression in adult testis, suggesting its possible participation in the process of spermatogenesis. Genetically compromised activity of KLK3 might alter spermatogenesis, but analysis of KLK3 sequence to identify mutations in infertile men has not been undertaken. Therefore, we have analyzed the coding region of KLK3 in ethnically matched 875 infertile and 290 fertile men. Interestingly, this study identified thirty three substitutions, of which thirteen were novel (not yet available in public databases). None of these substitutions has been studied in correlation with male infertility. Among the thirty three substitutions, nine resulted in non-synonymous changes while rest of them were either in the intronic regions or resulted in synonymous changes. In silico analysis on novel substitutions revealed four to be missense variants, six to be intronic variants, one to be a 5'UTR variant, one to be a 3'UTR variant, and one to be a downstream gene variant with reference to the transcript ENST00000326003. Variant effect prediction analysis on the non-synonymous substitutions identified p.Met139Lys, p.Glu174Lys, and p.Ile179Thr to be deleterious. Statistical comparisons of genotype frequencies showed that six SNPs were differentially distributed between fertile and infertile men. The frequency of genotypes 'CA+AA' (rs266881, OR = 2.92, $P = <0.0001$), 'TC+CC' (rs11573, $P = 0.022$), 'GA+AA' (rs266875, OR= 1.44, $P = 0.016$), and 'TC+CC' (rs174776, OR = 1.91, $P < 0.0001$) were significantly higher in infertile men as compared to fertile controls. However, the genotypes 'TC+CC' at intronic SNPs c.206+235T>C (OR = 0.44, $P = 0.002$) and 'GA+AA' at c.631-74G>A (OR = 0.26, $P = 0.02$) were more frequent in fertile controls as compared to infertile men. In conclusion, our findings suggest that genetic alterations in the KLK3 gene may lead to altered semen parameters and affect male fertility; highlighting the importance of this gene in spermatogenesis/testicular function.

Expression Quantitative Trait (eQTL) Mapping in Mid-Secretory Phase Endometrial Cells Identifies Candidate Genes for Recurrent Early Pregnancy Loss (REPL). *C.L. Kagan[1], G. Kosova[1], K. Patterson[1], M.D. Stephenson[2], C. Ober[1,2].* 1) Dept of Human Genetics, University of Chicago, Chicago, IL; 2) Dept of Obstetrics and Gynecology, University of Chicago, Chicago, IL.

Fertility traits are heritable in humans; however, little is known about the genes that influence reproductive outcomes or genetic variants that contribute to inter-individual differences in these traits. To address this gap in knowledge, we performed an unbiased genome-wide study to identify functional (regulatory) SNPs in endometrial biopsies collected during the mid-secretory phase, the time at which implantation occurs, in 34 women of European ancestry with a history of at least two documented intrauterine miscarriages of less than 10 weeks of gestation. Gene expression was measured in RNA using Illumina Human HT12v4 arrays; DNA samples were genotyped using the Affymetrix Axiom™ Genome-Wide CEU 1 Array, which contains 674,517 SNPs. To identify *cis* eQTLs, we included SNPs within 200kb of each gene and considered an additive model as implemented in Matrix eQTL. Transcripts from 10,191 genes were detected as expressed in these samples. Out of 532,538 association tests, 1,088 *cis* eQTLs in 308 genes were significant at a false discovery rate (FDR) of <5%. We then genotyped the 80 most significant *cis* eQTLs in 256 women with REPL (not included in the eQTL study) and 232 women with at least one successful pregnancy and no history of infertility or miscarriage (fertile controls), and tested for differences in genotype frequencies between the two groups using the Cochram-Armitage trend. 64 of these SNPs were successfully genotyped using iPlex (Sequenom). Nine SNPs had p-values < .05 (based on permutation) when only 3.2 were expected by chance, reflecting a significant enrichment for small p-values (p = 0.0037). The most significant association was with a SNP (rs56274787; p = 0.0087) that is an eQTL for the *TBCD* gene, which encodes a tubulin-folding protein that promotes epithelial cell detachment. Overall, 9 SNPs showed independent evidence both for being functional in the endometrium (i.e., associated with gene expression) and for being significantly associated with REPL patients compared to fertile controls; This study demonstrates that eQTL mapping in a relevant tissue is a promising strategy for identifying genes and associated alleles that are risk factors for REPL, which affects approximately 5% of couples. The eQTLs identified in our study could also serve as candidates for other reproductive disorders such as primary infertility and preeclampsia. Supported in part by NIH grant HD21244.

The Clinical Analysis of Relationship between Sperm DNA Damage and Sperm Parameters. *F. Kaplan[1], S. Aydos[1], B. Altinok Zaim[1], I. Yükselen[1], Y. Yükselten[1], A. Sungurolu[1], K. Aydos[2].* 1) Ankara University Faculty of Medicine,Department of Medical Biology Ankara, Turkey; 2) Ankara University Faculty of Medicine, Reproductive Health Research Center Ankara, Turkey.

Purpose:Although fertilization rate by using intracytoplasmic sperm injection (ICSI) is increasing, the probability of fertilization with DNA damaged sperm creates risk for both pregnancy success and also health of the new born.Recently, disputes about whether sperm parameters give an opinion related to sperm DNA damage or not have become more of an issue.The aim of the study is to investigate the relationship between sperm DNA damage and sperm parameters. Methods: 298 infertile men,between 24-38 years,whose sperm motility percentage and sperm counts are known,were included to the study.140 of them had also sperm morphology records. In all couples,female factor was eliminated.DNA damage was studied with Comet assay. Observations were made at magnification 400 X using an epifluorescent microscope.100 cells were analyzed visually from each 3 slide.Each image was classified according to nucleus scale and tail length given a value of 0,1,2,3 or 4(from undamaged class 0 to maximally damaged class 4),so that the total DNA damage score of the slide could be between 0 and 400 arbitrary units (AU).Sperm DNA damage ratios were correlated with sperm motility,sperm count and sperm morphology.Statistical analysis was made by Mann-Whitney u and Kruskal-Wallis tests. Results:Our results showed a significant negative correlation between the sperm counts ≥ 15 million/ml(p<0.001),progressive motility ≥%32(p<0.05),and total sperm DNA damage score. Total sperm DNA damage scores of the samples with sperm counts ≥15,progressive motility ≥%32 were found 185.3±40.08 and sperm counts ≤15,progressive motility ≤%32 were found 222.4±56.88 respectively.According to our findings there was no correlation between Kruger morphology results and sperm DNA damage scores. Discussion:According to our results,there was no relation between sperm morphology and sperm DNA damage.We found significant relation between sperm count,motility,and total sperm DNA damage score.The significant increase of spermatozoa rates with DNA damage in infertile males comes into prominence due to being overcome obstacles by using assisted reproductive technology(ART) in these infertile males.Indeed,in case of natural fertilization, spermatozoa reached the fallopian tube have much healthier DNA when compared to which cannot.The results of our study emphasize the risk of using sperm cell with DNA damage in males having abnormal sperm parameters,because of randomly chosen morphologically normal sperms during IVF/ICSI.

Quantitative Analysis of Mixtures by Deep Sequencing of HLA Gene Amplicons Using Next Generation Systems. *B.N. Hoglund[1], M. Rastrou[1], D. Goodridge[2], H.A. Erlich[1,3], C.L. Holcomb[1].* 1) Human Genetics, Roche Molecular Systems, Pleasanton, CA; 2) Conexio Genomics, Perth, Australia; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Purpose: The clonal property of next generation sequencing systems allows for the quantitative analysis of mixed samples by simply counting sequences corresponding to the component alleles. Previously, we developed a method using 454 amplicon sequencing and Conexio software for high resolution and high throughput genotyping of the HLA class I and class II loci. This system was used to analyze the blood of a severe combined immunodeficiency (SCID) child and estimate the proportion of maternal cells by counting HLA-C allelic sequence reads corresponding to the non-transmitted maternal allele. Here we report the development of a system that allows us to quantify HLA allelic mixtures in plasma. Methods: DNA from plasma or contrived mixtures of cell lines was amplified using primers that targeted a short region (~150 bp to amplify small DNA fragments in plasma) of HLA DPB1 or DQB1 exon 2. Amplicons were further amplified by emulsion PCR and sequenced on a 454 GS FLX or GS Junior. Sequences were examined using modified Conexio Assign ATF 454 software. This software allowed for rapid digital analysis of each DPB1 or DQB1 allele. We also analyzed mixtures using the Illumina MiSeq. Results: Using the modified Conexio software, minority HLA alleles in a mixture were readily identified and separated from background 'noise' i.e., sequences generated by PCR or sequencing errors. In mixtures of two heterozygous cell lines, the minority HLA alleles could be detected at 0.5% with 1 ng (~140 diploid genomes) DNA input. In one plasma sample from a pregnant woman in the third trimester, fetal HLA alleles were detected at 11.6% of the total of maternal plus fetal alleles. Conclusion: We have developed a system that allows the sensitive and precise analysis of mixtures using either 454 or Illumina MiSeq sequencing technology. This method could be useful in numerous clinical applications; we have demonstrated the quantification of fetal DNA in maternal plasma during pregnancy by detection of HLA alleles. Such quantification has potential uses in noninvasive prenatal diagnostics.

Screening models for early detection of late-onset preeclampsia with various markers in low-risk pregnancy population. *H.J. Park, D.H. Cha, S.H. Kim, S.S. Shim, J.Y. Kim, Y.K. Cho, K.J. Lee.* CHA Gangnam Medical Center, CHA University, Seoul, South Korea.

Objective : Our primary objective was to establish a cut-off value for the soluble fms-like tyrosine kinase 1(sFlt-1)/placental growth factor (PlGF) ratio measured using the Elecsys assay to predict late-onset preeclampsiain low risk women. A second objective was to evaluate the ability of combination models that included Elecys data, second trimester uterine artery (UtA) Doppler, and fetoplacental proteins measurements during Down syndrome screening. Methods:A prospective cohort study was carried of 262 women at low risk for preeclampsia. Maternal plasma samples were obtained for measurement of pregnancy-associated plasma protein-A (PAPP-A),alpha-fetoprotein, unconjugated estriol, human chorionic gonadotrophin, inhibin-A, and the sFlt-1/PlGF ratio. All women underwent UtA Doppler at 20-24 weeks of gestation. Results: Of the 262 women, eight (3.0%) developed late-onset preeclampsia. ROC curves demonstrated that the sFlt-1/PlGF ratio in the third trimester yielded the best detection rate (DR) at a fixed false positive rate (FPR) of 10%. This was followed in rank order by the sFlt-1/PlGF ratio in the second trimester, sFlt-1, and then PlGF. Binary logistic regression was used to determine the five best significant combination models for screening. For a FPR of 5 and 10%, the combination of PAPP-A with the sFlt-1/PlGF ratio in the second trimester yielded a DR of 87.5%, identical to that of serial sFlt-1/PlGF ratios for late PE. The combination of maternal BMI and second trimester sFlt-1 yielded a DR of 87.5% at a 10% FPR. Combining PAPP-A with inhibin-A yielded a 50% DR at a 10% FPR. The combination of PAPP-A and the sFlt-1/PlGF ratio in the third trimester yielded a DR of 62.5% for late preeclampsia at a 10% FPR. Conclusion: The combination of the second trimester sFlt-1/PlGF ratio and PAPP-A data or BMI, and the second trimestersFlt-1 can predict late onset preeclampsia more effectively than any single marker alone.

First live birth in Hong Kong after preimplantation genetic diagnosis on a disease-predisposition mutation carrier with a novel genomic deletion in BRCA2. *Q. Wang[1,2], J. Chow[1,2], W. Yeung[1,2], E. Lau[1,2], V. Lee[1,2], E. Ng[1,2], P.C. Ho[1,2].* 1) Dept. of Obs. & Gyn., The University of Hong Kong, Hong Kong; 2) Dept. of Obs. & Gyn., Queen Mary Hospital, Hong Kong.

Preimplantation genetic diagnosis (PGD) is an option for couples bearing disease-causing mutations to avoid the bearing of an affected child. The use of PGD on disease-predisposition mutation carriers, such as BRCA mutation is controversial. Here we report the first live birth in Hong Kong, after PGD upon a request from a woman with an early onset of breast cancer. She carries a paternally derived mutant allele with an unknown genomic breakpoint. Due to the limited availability of familial data, sperm haplotyping was conducted on the woman's carrier brother, leading to the identification of the mutant haplotype. Embryo biopsy was performed on 8 good-quality embryos on day 3, followed by whole genome amplification and linkage analysis with 4 microsatellite markers and 2 intragenic SNP markers. Among the five unaffected embryos identified, one morula and 1 blastocyst were replaced on day 5, resulting in a singleton livebirth. To increase the diagnostic accuracy in future cycles and to better understand the cancer risk among the family, efforts were made to identify the mutation breakpoint, which was found to be novel. The data showed that a genomic sequence of 2596 nucleotides including exon 15 and 16 was deleted. In conclusion, the first live birth in Hong Kong after PGD on disease-predisposition mutation marked the beginning of a new phase of PGD practice in Hong Kong.

Embryo SNP array genotyping: a model for preimplantation diagnosis in human. *F. Campagnari[1,4], Y.T. Utsunomiya[3], A.S. Carmo[4], J.A. Vinsintin[2], J.F. Garcia[3], C. Rosenberg[1], R.V. Alonso[2,4].* 1) Genetics and Evolutionary Biology Dept , University of Sao Paulo, Sao Paulo, SP, Brazil; 2) FMVZ - University of Sao Paulo, Sao Paulo, SP, Brazil; 3) FMVA - UNESP, Araçatuba, SP, Brazil; 4) Deoxi Biotecnologia, Araçatuba, SP, Brazil.

Preimplantation diagnosis and screening is gradually been incorporated to routine for couples with increased risk of particular disorders or to increase in vitro fertilization (IVF) success by selecting euploid embryos. Developments in animal reproduction biotechnology, such as embryo in vitro production (IVP), micromanipulation and preimplantation genetic diagnosis (PGD) can be used as models for application in human PGD. The aim of this study was to perform PGD in bovine embryos through SNP arrays genotyping (BeadChip BovineLD - 6,909 SNP). The small amount of genomic DNA (gDNA) obtained from embryo biopsy is the main limitation for SNP array analysis. Whole Genome Amplification (WGA) (Repli-g® Mini Kit, Qiagen, Hilden, Germany) was used to increase the amount of gDNA from embryo biopsy and allow the analysis of thousands of SNP simultaneously. Eighty-eight IVP bovine embryos were subjected to micromanipulation by microaspiration, forming three groups based on numbers of biopsied cells: G1) 05-10 (n=28); G2) 10-20 (n=37); and G3) > 100 - hatched blastocyst (n = 23). All samples were subjected to the same WGA protocol, and 4µL of each sample were genotyped on iScan/Illumina platform. The genotyping quality was assessed using the Call Rate (CR), GenCall Score (GC10), Alelle Drop In (ADI) and Alelle Drop Out (ADO). Kruskal-Wallis test was applied to investigate differences in the distribution of variables among the groups. Spearman's rank coefficient was calculated to assess the correlation of each possible variables pair. The results showed a positive correlation between CR and GC10 (0.99/P <0.001), while ADI and ADO rates were negatively correlated with CR and CG10 (ADI/CR: -0.87; ADI/GC10: - 0.88; ADO/CR: -0.87; ADO/GC10: -0.86), P<0.001 for all variables. Kruskal Wallis pointed to significant differences in all variables (CR, GC10, ADO and ADI) among the 3 groups of biopsies (G1, G2 and G3). The CR average was 59.26 percent;, 78.47 percent; and 95.97 percent; for G1, G2 and G3, respectively, revealing that the number of cells recovered from the embryo biopsy is crucial for obtaining satisfactory results in SNP analysis. The development of an algorithm based on Mendel's first law (Law of Segregation) increased CR average to 79.69 percent;, 88.20 percent; and 97.28 percent; for groups 1, 2 and 3, respectively. The present study showed that, based on animal model, it is possible to apply SNP arrays in embryo stage, enabling early genotyping for PGD.

2846T

KaryoLite® - A rapid single cell screening assay to simultaneously detect aneuploidies for all chromosomes from whole-genome amplified DNA from 3 day blastomeres. *S. Dallaire, R. Walker, M. Schermer.* PerkinElmer, Molecular Diagnostics, 940 Winter Street, Waltham, MA. 02451.

Aneuploidy is a genetic defect where the number of chromosomes is either greater or less than 46. Aneuploidies have been detected in a majority of miscarriages. The ability to test for aneuploidies prior to IVF implantation may allow better management and outcome of the pregnancy. The FISH and microarray tests that are used in clinical labs to detect aneuploidy on all chromosomes are impractical for many labs because of cost, labor, and time-to-result. We have developed the KaryoLite® kit, which is a bead-based multiplex assay in PerkinElmer's BACs on Beads® family, which will detect aneuploidies for chromosomes 1-22, X and Y. KaryoLite BoBs utilizes a new concept of composite beads having DNA from three different BAC clones on each bead type. The composite clone format expands the region of chromosomal DNA interrogated by each bead. The assay is fluorescence based and uses encoded multiplex beads which have been coupled to BAC derived DNA from defined loci on all 24 chromosomes. This allows detection of aneuploidies on all chromosomes from a clinical sample in a single well of a 96-well microtiter plate with results in as little as 16 hours. A study was performed using 117 DNA samples derived from blastomeres at day 3. DNA from the biopsied cells was processed by whole genome amplification. 240ng of the amplified DNA from each sample was fluorescently labeled and analyzed. The assay was robust with typical signal/background greater than 4, and the KaryoLite assay was completed within 24 hours. Results indicated 68 female and 49 male samples. Of these, 16 were normal, 87 indicated whole chromosome aneuplodies, 9 with arm specific aneuploidies and 4 were -X and 1 was +Y. These results show KaryoLite to be a sensitive, multiplex, high throughput assay that can detect all aneuploidies on all chromosomes from single cell blastomere samples. This demonstrates KaryoLite as a useful tool in preimplantation genetic screening research.

Quebec perspectives on the medical and social uses of preimplantation genetic diagnosis and on the current service deliveries. *F. Duplain-Laferrière, R. Drouin, C. Bouffard.* Division of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Quebec, Canada.

Since 2010, Quebec's healthcare system has covered costs related to preimplantation genetic diagnosis (PGD) for the purpose of detecting specific chromosomal or single-gene defects. However, this measure has several shortcomings. In order to identify problems and to better understand the situation, we consulted the Quebec geneticists, obstetricians-gynecologists and genetic counselors likely to be involved in PGD. Among the objectives of this study, we wanted to know their positions on the medical and social uses that could justify PGD, and hear their proposals to improve the current conditions of the delivery of services.

Methodology: Qualitative Research Design ~ Online questionnaire containing 34 questions has been completed by 15 obstetricians, 15 geneticists and 17 genetic counselors engaged in activities related to prenatal diagnosis in the province of Quebec. Mixed data analysis: quantitative and descriptive for closed questions; qualitative (inductive) and thematic approach for open questions.

Results: The participants propose to: 1) certify laboratories, 2) restrict PGD to lethal or disabling diseases, 3) proscribe PGD for multifactorial diseases or social uses, 4) direct the decision-making process of the patients, 5) create a provincial discussions table or committee to organize the development and the implantation of PGD 6) regulate, standardize and make PGD more accessible. As for conditions that may justify PGD: 1) obstetricians seem less restrictive, 2) geneticists more conservative and 3) genetic counselors more focused on genetic counseling and the needs of the patients.

Conclusion: Despite certain differences between professionals, there is a clear consensus on the necessity of improving the conditions of PGD services, and of reducing problems of accessibility. All also agree on the need to regulate and standardize PGD and to ensure the availability of knowledge relating to the situation.

***Notchless* Impacts Multiple Signaling Pathways During Pre-Implantation Development.** *C.-L. Lo[1, 3], A.C. Lossie[1, 2], J.B. Sherrill[4].* 1) Department of Animal Science, Purdue Univ, West Lafayette, IN; 2) Dept of Medicine, Indiana University School of Medicine, Indianapolis, IN; 3) PULSe Interdisciplinary Graduate Program, Purdue University, West Lafayette, IN; 4) Department of Biological Sciences, Purdue University, West Lafayette, IN.

Peri-implantation is a critical stage in mammalian development. Genes and genetic pathways that are necessary for establishing and maintaining maternal-fetal interactions play crucial roles in this process. Several members of the WNT pathway are detected in normal embryos and maternal tissues during this transitional stage. Recent studies in our laboratory demonstrated that mutations in *Notchless (Nle1)*, a member of the vast WD40-repeat family and a putative NOTCH signaling molecule, disrupts expression of several genes in the *Wnt* pathway. Mutant embryos also express high levels of *Cdkn1a*, suggesting that they are under severe cellular stress that ultimately leads to caspase-mediated apoptosis at the hatched blastocyst (E4.5) stage. To determine if mutants were undergoing cell cycle arrest prior to apoptosis, we examined expression of *Cdk9*, a downstream target of CDKN1A that promotes cell cycle recovery from replication arrest. At E3.5, mutant embryos showed reduced steady-state levels of Cdk9, suggesting that they were in cell cycle arrest at this stage. Since mutant embryos showed evidence of apoptosis at E4.5 and TRP53 induction often precedes apoptosis, we analyzed *Trp53* expression at the mRNA and protein levels. Although we did not detect altered mRNA levels of *Trp53* by qRT-PCR, immunofluorescence studies using an antibody that detects an active form of TRP53 (Acetyl K376), demonstrates that the acetylated form is only detected in mutant blastocysts at E3.5 and E4.5. Together, these data suggest that at E3.5, Nle1 mutants are undergoing cell-cycle arrest, while at E4.5 the mutants initiate caspase-mediated apoptosis. These two mechanisms are regulated by activation of TRP53. Our data implicate NLE1 in WNT signaling, cell cycle arrest and apoptosis via TRP53-mediated signaling. Intriguingly, WNT signaling is critical for gastrulation in mice. Deletion of Wnt3 leads to failure prior to primitive streak formation, and multiple ligands and receptors are detected in blastocysts and the uterus during peri-implantation. These pathways could provide novel targets for the design of therapeutic interventions for infertility.

The first report of a viable, 35 week gestation pregnancy following the transfer of a genetically normalized blastocyst; embryo normalization can occur during differentiation to the blastocyst stage. *W.G. Kearns[1,2], M. St. Amant[3], B. Welch[4], J. Carter[4], A. Potts[4], P.R. Brezina[5], A.T. Benner[1], K.J. Tobler[2], G.R. Cutting[6], R.P. Dickey[4].* 1) Center for Preimplantation Genetics, LabCorp, Rockville, MD; 2) Department of Gynecology and Obstetrics, Division of Reproductive Endocrinology and Infertility, Johns Hopkins Medical Institutions, Baltimore, MD; 3) Women's Hospital, Baton Rouge, LA; 4) The Fertility Institute of New Orleans, Mandeville, LA; 5) Fertility Associates of Memphis, Memphis, TN; 6) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Medical Institutions, Baltimore, MD.

Case Report. Here we report the progress of a genetically normal 35 week fetus that resulted from the embryo transfer of a genetically normalized blastocyst. A 36 year old female with 9 years of secondary infertility was treated with in vitro fertilization and preimplantation genetic screening (PGS). Two cleavage stage embryos underwent embryo biopsy by laser and a single cell was removed from each embryo for PGS. The single cells underwent lysis and DNA whole genome amplification using a modified random priming method. Following this, comparative genomic hybridization (aCGH) microarray analysis was performed. The single cell from each cleavage stage embryo was aneuploid; embryo one was 48, X, +17, +19, +21 and embryo two was 47, XY, +15. During further embryo culture, only embryo two differentiated to the blastocyst stage of development and then underwent a trophectoderm (TE) biopsy and repeat aCGH analysis. The aCGH results showed embryo two to be euploid, 46, XY. Because no cleavage stage euploid embryo was available, the 'normalized' embryo was transferred after obtaining informed consent from both parents regarding the risk of delivery of an aneuploid baby. A fetal heartbeat was detected at 6 weeks. Amniocentesis performed at 16 weeks; confirmed a normal karyotype: 46, XY. Due to the aneuploidy in the single cell from the cleavage stage embryo, uniparental disomy analysis was performed to confirm that one copy of chromosome 15 came from each parent. Masked aCGH microarray reanalysis of the cleavage stage embryo DNA and the trophectoderm DNA confirmed karyotypes of 47, XY, +15 and 46, XY respectively. The pregnancy is progressing normally at 35 weeks. DNA fingerprinting analysis is ongoing to confirm that the transferred, genetically normalized blastocyst resulted in the viable pregnancy. This report supports the hypothesis that mosaic cleavage stage embryos, with aneuploid cells, can normalize into euploid blastocysts capable of viable pregnancies.

2850T

Stability Testing of a Noninvasive Prenatal Test (NIPT) in a Clinical Setting - the MaterniT21™ PLUS Laboratory-Developed Test. *R.C. Tim[1], J.A. Tynan[2], T.J. Jensen[1], L. Cagasan[1], V. Lu[1], L. Liu[1], S. Sovath[1], M. Riviere[1], P. Oeth[2], M. Ehrich[2].* 1) Sequenom Center for Molecular Medicine, LLC, San Diego, CA; 2) Sequenom, Inc., San Diego, CA.

Excellent clinical performance of a noninvasive test for fetal aneuploidies using next-generation sequencing has been demonstrated by several laboratories. This study demonstrates the robustness of the processes involved in one such assay, the MaterniT21™ PLUS laboratory-developed test, focusing on reproducibility and stability of the results. The study was divided into two portions to determine the robustness of the MaterniT21™ PLUS test. The first was designed to measure reproducibility of chromosomal representation in a pool of circulating cell-free (ccf) plasma DNA isolated from women at increased risk for fetal aneuploidy with a known euploid fetus as determined by fetal karyotyping. For these experiments, ccf DNA obtained from 976 women was combined and used to prepare over 1000 libraries. These libraries were sequenced and analyzed for variability of chromosomal representation. The second portion of the study was designed to investigate the stability of the post-PCR workflow processes. For this part of the study, a set of libraries was generated for use throughout the entire series of experiments, comprised of 44 known euploid and 44 known trisomy 21 samples. For each experimental subset, all factors were kept constant, including operator, reagent lots, and instruments, except for the particular variable of interest. All flow cells from both portions of the study were clustered on the Illumina® cBot in 12-plex and sequenced on the HiSeq™ 2000 (Illumina, San Diego, California). Sequencing reads were de-multiplexed, aligned to the human genome with Bowtie2 and chromosomal representations were determined. Results demonstrate that while library concentrations and raw aligned counts may be variable from plate to plate, chromosomal representation is remarkably stable for the pooled maternal ccf DNA samples processed by multiple operators, across library batches, and measured on multiple sequencing instruments. From the second part of this study, no significant differences in classification z-score values were found across flow cells as a function of library storage time, flow cell storage time, reagent lot, or sequencing instrument. Both sensitivity and specificity for each of these experimental subsets were determined to be nearly 100%. This study demonstrates the stability for use of the MaterniT21™ PLUS test across operators and instruments and reveals the low variability for discrete process steps of the assay.

Identification of Pathogenic CNV by arrayCGH in Prenatal Cases with Oral Clefts. *Y. CAO[1], Z. LI[3], J. ROSENFELD[4], A. PATEL[5,6], J. HUANG[1], X. SUN[3], T.Y. LEUNG[1], S.W. CHEUNG[5,6], K.W. CHOY[1,2].* 1) Department of Obstetrics and Gynecology, The Chinese University of Hong Kong, Hong kong, China; 2) CUHK-Shenzhen Research Institute, The Chinese University of Hong Kong, Shenzhen, China; 3) Third Affiliated Hospital of Guangzhou Medical University, Guangzhou, Guangdong, China; 4) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, Washington, USA; 5) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 6) Medical Genetics Laboratories, Baylor College of Medicine, Houston, TX, USA.

PURPOSE: Oral clefting is one of the most common congenital malformations. With improvements in sonography, it is now being detected more frequently and accurately during routine fetal morphology scan. Prenatal identification of oral cleft raises questions about prognosis, as oral cleft may be part of syndromic presentations, associated with other congenital malformations, possibly detectable by ultrasound; and/or with neurodevelopment problems, which could not be assessed prenatally. Identification of a genetic cause may help clarify the prognosis and improve clinical management. A systematic review showed that up to 7.9% of oral clefts cases which were combined with different cleft categories both detected prenatally and postnatally was identified with chromosomal defects by karyotype. However the role of submicroscopic chromosomal variants (CNVs) still remains in limited knowledge in prenatal oral cleft cases. METHOD: We performed a retrospective multi-centre study of prenatal cases undergoing clinical microarray-based comparative genomic hybridization (aCGH) with different categories of oral cleft. RESULTS: There were 119 isolated oral cleft cases and 159 syndromic oral cleft cases. We further subdivided these cases into these subgroups: isolated cleft lip(CL) (45/278, 16.2%); isolated cleft lip and palate(CLP) (74/278, 26.6%); syndromic CL (46/278, 16.5%); and syndromic CLP (113/278, 40.7%). Cardiac defects, limb defects and brain abnormalies were the most frequently accompanying defects in syndromic cleft. The overall detection rate of pathogenic CNVs was 12.9%. Pathogenic CNVs were more commonly identified among syndromic groups, (29/159, 18.2%), especially in syndromic cleft lip, while less (7/119, 5.8%) among isolated cleft. Four pathogenic CNV regions, 4p16, 15q11.2, 16p12.2, 17p13.3 were recurrent in our cases. CONCLUSION:aCGH is a powerful tool to detect submicroscopic pathogenic CNVs in prenatal cases with oral clefts. It is highly recommended and should be a first-tier test prenatally, especially for suspected syndromic oral cleft cases.

Assessing the utilization and distribution of an evidence-based resource recommended in the 2013 American College of Medical Genetics and Genomics statement on noninvasive prenatal screening for fetal aneuploidy. *S. Meredith[1], B. Skotko[2], C. Brasington[3].* 1) Human Development Institute, University of Kentucky, Lexington, KY; 2) Massachusetts General Hospital Down Syndrome Program, Boston, MA; 3) Down Syndrome Clinic at Carolinas Medical Center, Charlotte, NC.

Introduction and Purpose: The purpose is to share data for the first time on the utilization and distribution of an evidence-based resource as implemented by medical providers delivering a prenatal diagnosis of Down syndrome (DS). "Understanding a DS Diagnosis" (www.lettercase.org) was prepared with assistance from representatives of ACMG, ACOG, NSGC, and the national DS organizations. It is part of the National Center for Prenatal and Postnatal DS Resources at the University of Kentucky and was recently included as a recommended resource in the 2013 ACMG policy statement. Specifically this assessment determines: 1. Trends in US geographic areas 2. Professional discipline trends 3. Referral sources used by medical providers 4. The impact of professional guidelines, professional newsletters, and internet promotions Methods: This study examines the number of medical providers who requested/purchased printed copies of "Understanding a DS Diagnosis." When requesting a free printed book, medical providers are required to submit their name, email, medical practice, address, area of practice, and can optionally indicate how they learned about the book. The data was collected and organized from 681 medical requests/purchases from June 1, 2012-June 1, 2013 to show the number of medical providers from different disciplines requesting books from different regions. Results: The data reveals that the top states where medical providers request/purchase the Lettercase book include Washington(85), California(82), Pennsylvania(57), Minnesota(55), and Illinois(47). The top discipline requesting books is genetic counselors(154) while the least requests come from OB/GYNs(49) and Family Practitioners(20). Data indicates that the majority of medical providers obtain information about patient resources via professional organizations, colleagues, and email. Conclusion: The top states requesting booklets typically include higher population states and states where local Down syndrome organizations and state health departments are conversely less active in distributing books. Genetic counselors are most likely to utilize a patient resource and receive the most DS training. Yet, OB/GYNs and family practitioners are least likely to utilize the book and receive the least training about DS. Data indicates that 'word of mouth' and professional organizations are most influential in the sharing of a patient resource, and online professional newsletters prompt the most requests.

Exploring Placental Gene Expression Pattern in Abnormal Fetal Growth. *A. Sabri[1,2], C.H.M. Ng[1,3], D. Lai[2], A. D'Silva[1], J. Kaur[1], J.A. Hyett[1,3].* 1) Department of Obstetrics, Gynecology and Neonatology, Queen Elizabeth II Research Institute for Mothers and Infants, The University of Sydney, Sydney Australia; 2) Molecular Biology Facility, Bosch Institute, The University of Sydney, Sydney, Australia; 3) RPA Women and Babies, Royal Prince Alfred Hospital, Sydney, Australia.

Objective: Extremes of fetal growth are associated with increased perinatal mortality and morbidity and a higher prevalence of cardiovascular disease, obesity and diabetes in later life. The placenta plays a pivotal role in fetal growth and development. We aimed to identify changes in placental gene expression in term pregnancies with evidence of growth dysfunction and to identify candidate genes that may be used to identify abnormal patterns of growth prior to delivery.

Materials and methods: Placenta samples were collected and classified from pregnancies that were small for gestational age (SGA; <10th centile; n=5), large for gestational age (LGA; >90th centile; n=6) or normal (AGA; 40-60th centile; n=5). All pregnancies were 39 weeks' gestation, with male infants delivered by caesarean section. RNA was extracted from the placental samples prior to microarray gene expression analysis (Affymetrix HG-U219 array). Microarray data were analysed using Partek Express and Ingenuity Pathway Analysis. Significant differential gene expression was defined by >2 fold-change with p<0.05.

Results: Significant differential gene expression was found in both SGA and LGA placentas, with up-regulation in 68 and 18 genes and down-regulation in 9 and 9 genes respectively. Differential expression in SGA placentas was seen in genes involved in embryonic and connective tissue development and in developmental, metabolic and neurological disorders. In contrast, differential expression in LGA placentas involved genes involved in cardiovascular and haematological disease, cell-mediate immune responses, endocrine and developmental disorders. Individual findings of interest include gremlin 2 (*GREM2*) and zinc finger protein 711 (*ZNF711*) (SGA) and leptin (*LEP*) and matrix metallopeptidase 12 (*MMP12*) (LGA), playing important roles in embryonic and organ development, cell proliferation and tissue differentiation.

Conclusions: Dysfunctional growth is associated with differential placental gene expression and affects genes involved with a whole spectrum of developmental and cellular functions. *GREM2* and *ZNF711* appear to be good candidates for prediction of SGA in term pregnancies. *LEP* appears to be decreased in LGA infants, which may be of significance for long term outcome.

2854T

Diagnostic dilemma: fetal cardiomyopathy presenting at a late gestational age. *B. Suskin[1,2], K. Bajaj[1,2], M. Rosner[1,2], P. Dar[1,2], S. Klugman[1,2].* 1) Department of Obstetrics & Gynecology and Women's Health, Montefiore Medical Center, Bronx, NY; 2) Albert Einstein College of Medicine, Bronx, NY.

Background: Cardiomyopathies are diseases of the myocardium that affect the mechanical or electrical function of the heart. American Heart Association has stated that most are due to genetic causes. Elucidating a cause, expediting testing and explaining a prognosis is challenging in the fetal setting. Case: A 30 year-old multiparous woman at 30 weeks with gestational diabetes was referred from an outside clinic for fetal surveillance. Her pregnancy was otherwise uncomplicated and she denied any significant family history. Oligohydramnios was found. At her follow-up ultrasound with fetal medicine specialists, oligohydramnios was seen again. They also found a grossly enlarged heart, a small pericardial effusion and an increased PR interval and suspected cardiomyopathy. The fetus did not have hydrops. Fetal echocardiograms by pediatric cardiologists confirmed these findings. TORCH and Lupus work-ups were sent. The patient was lost to follow-up, but represented in labor. A female infant was delivered at 39 weeks at 3585 grams with apgars 5/6/8 at 1, 5 and 10 minutes respectively. She was intubated and transferred to the pediatric hospital. Echocardiograms show bilateral ventricular hypertrophy and moderately depressed function. The work-up is pending. Discussion: Due to the fact that the patient presented at 30 weeks with sparse prenatal care, the work-up was limited to infectious and maternal causes. Neonatal cardiomyopathies can be seen in high-output failure, anemia, volume overload and myocardial damage. A common non-genetic cause of neonatal cardiomyopathy is hyperinsulinemia secondary to maternal diabetes. There are also many possible genetic causes. These include syndromic, metabolic, neuromuscular, mitochondrial and sarcomere mutations. Despite our abilities to evaluate for many such causes, we are often limited in the prenatal setting by time and cost. It is important to consider both genetic and acquired causes of cardiomyopathy of fetuses during pregnancy. The increased risk of fetal demise is known, especially when hydrops is present. This poster presents the genetic considerations, work-up and limitations of prenatally diagnosed fetal cardiomyopathy.

Improving efficiency and cost of next generation sequencing of maternal cell free DNA for the detection of fetal aneuploidy.
L. Chitty[1,3], J. Weir[2], C. Boustred[3], S. Fielding[3], F. McKay[3], H. White[4], Z. Kingsbury[2], S. Humphray[2], E. Tsogka[2], N. Lench[3], J. Betley[2]. 1) Clinical Molecular Genetics Unit, UCL Institute of Child Health, London, London, United Kingdom; 2) Illumina Inc, Chesterford Research Park, Little Chesterford, Essex, CB10 1XL, UK; 3) North East Thames Regional Genetics Laboratory, Great Ormond Street NHS Foundation Hospital, London; 4) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, Wiltshire SP2 8BJ.

We have recently reported preliminary data describing a new PCR-free method of preparing cfDNA for next generation sequencing (NGS), which may remove PCR-bias and potentially improve accuracy of trisomy 13 and 18 detection as well as decreasing costs and time to results. Before use in clinical practice, it is necessary to ensure that this method is accurate for the detection of aneuploidies, and is not affected by the various protocols used for maternal blood collection. Here we aim to investigate the robustness of this new method in a larger number of normal and trisomic pregnancies with plasma prepared in different ways to inform clinical implementation. Maternal blood was taken into both EDTA and cell-stabilising tubes from women undergoing invasive tests for clinical indications. cfDNA was extracted from plasma double spun at varying time intervals. Samples were prepared for sequencing (HiSeq 2500) using a modified version of Illumina's PCR-free protocol, eliminating amplification bias as a source of variable accuracy. For each sample preparation method, percentages of mapped reads by chromosome were compared to determine whether plasma or library preparation method had a significant effect. Duplicate samples were taken and prepared using a modified version of Illumina's TruSeq PCR workflow for comparison between the two library prep methods. Our results showed that after alignment with iSAAC 1x36 bp (hg19), all 3 collection/spin workflows produced similar standard deviation (SD) values after removing aneuploidy samples from SD values in each case; including for Chromosome 13 all were < 0.03 standard deviation (SD) of the percentage aligned. In addition when the data was combined into a single data set, the standard deviation (SD) values were similar showing robust data when using a combination of collection strategies is possible. The z scores were plotted based on the average and SD of each data set and all the data sets called correctly Trisomy results. We have shown that omitting PCR enrichment of libraries for NGS of cfDNA does not affect sequencing performance for cfDNA collected into EDTA or cell-stabilising tubes, and appears to give reliable results for trisomy calls in plasma separated up to 24 hours after blood draw. Omitting amplification eliminates any possibility of PCR-bias and the results presented here indicate that this approach may improve accuracy as well as decreasing time and costs for NGS of maternal plasma cfDNA.

Cordocentesis: an alternative prenatal procedure for women who missed amniocentesis in developing regions of China.
Q. Cao[1, 2], J. Ge[1,2], Y-Y. Peng[1,2], E.C. Jenkins[4], W.T. Brown[4], N. Zhong[1,2,3,4]. 1) The 4th Municipal Hospital of Shijiazhuang, Shijiazhuang, China; 2) Chinese Alliance of Translational Medicine for Maternal and Children's Health, China; 3) Peking University Center of Medical Genetics, Beijing, China; 4) New York State Institute for Basic Research in DD, Staten Island, NY.

Objective: To assess the efficacy of cordocentesis for rapid karyotyping in a high-risk obstetric population. Methods: Cordocenteses were performed on 64 pregnant women with different indications for prenatal diagnosis in an outpatient setting from November 2009 to September 2012. Fetal chromosome karyotypes were examined. Results: The most frequent indication for cordocentesis was a fetal abnormality on sonography (92.2%). All of the procedures were performed using the free cord loop. The success rate of cordocentesis was 92.2% (59/64) and cell culture was 94.9% (56/59). Transient bleeding was common at the puncture site, but all stopped spontaneously within one minute. Seven chromosomal abnormalities (12.5%) and 4 chromosomal variations (7.1%) were identified among 56 specimens cultured. Six of the seven chromosomal abnormalities (11.8%) were identified among 51 cases with abnormal ultrasound findings. Trisomy, the most prevalent chromosomal abnormality, was present in 6 of the 7 (85.7%) abnormalities detected. One case of 69, XXY was also identified among the 7 chromosome abnormalities. Conclusions: Cordocentesis is a rapid and reliable procedure for prenatal diagnosis, especially for mid and late pregnancies.

2857W

Single nucleotide polymorphism (SNP)-based non-invasive prenatal testing (NIPT) detects triploidy: two case studies.
Z. Demko, M.P. Hall, M. Hill, B. Zimmermann, S. Sigurjonsson, M. Rabinowitz. Natera Inc., San Carlos, CA.

Objective: To report two NIPT cases with evidence of triploidy. **Design:** Two triploid samples were analyzed using the non-invasive prenatal Next-generation Aneuploidy Test Using SNPs (NATUS) algorithm under a commercial protocol (reporting detection of Trisomies 13, 18, and 21, and Monosomy X) or as part of an IRB-approved research protocol. **Materials and Methods:** Cell-free DNA (cfDNA) isolated from plasma from pregnant women was analyzed via sequencing after amplification using a multiplex PCR protocol targeting 19,488 SNPs. Sequencing results were analyzed with the NATUS algorithm. Laboratory personnel (and the NATUS algorithm) were blinded to sample karyotype. **Results:** NATUS analysis identified more than two fetal haplotypes present for multiple chromosomes, indicating twins or triploidy. **Case 1** (fetal fraction: 6.4%): multiple paternal haplotypes on multiple chromosomes (13, 18, 21, X) were detected, indicating either paternally-inherited triploidy or fraternal twins. **Case 2** (fetal fraction: 20.8%): multiple paternal haplotypes on multiple chromosomes (13, 18, 21, X) were detected, similarly indicating either a paternally-inherited triploidy or fraternal twins. Ultrasound with chorionic villus sampling **(Case 1)** or amniocentesis **(Case 2)** confirmed single gestations affected with triploidy. **Conclusions:** This SNP-based approach examines the relative distributions of different alleles at polymorphic loci, thus not requiring a reference chromosome, and therefore offers the unique ability to detect triploidy. Here, this method correctly flagged both triploidy cases. This method is expected to distinguish twins from triploidy based on the presence (in the case of twins) or absence (in the case of triploidy) of an extra fetal haplotype. Detection of paternal triploidy is particularly clinically relevant as it is correlated with partial molar pregnancy, and molar pregnancy (partial or complete) can develop into choriocarcinoma. Studies are ongoing to differentiate all twin and triploidy cases; in the interim ultrasound will be required to confirm which cases may be at risk of triploidy. **Support:** NIH 4R44HD062114-02.

Microduplication 22q11.2 is mainly characterized by a high variable clinical phenotype that ranges from mild dysmorphic features with very moderate learning disabilities to severe malformations with profound mental retardation. One of the main characteristics of this new chromosomal pathology is its extreme phenotypic variability. Therefore genetic counselling is very difficult when a microduplication 22q11.2 is found in prenatal diagnosis. We report twenty three prenatal cases of 22q11.2 duplication mostly diagnosed by new molecular cytogenetic technology: the Prenatal BACs on Beads™. We analysed phenotypic profiles of fetuses with microduplication 22q11.2, including indication of prenatal diagnosis, and outcomes of the pregnancy when available. Several fetuses' DNAs (16/23) were analysed by microarray. Out of the 23 cases, 15 are inherited, 6 are de novo and 2 of unknown origin. Termination of pregnancy was mainly due to ultrasound findings and occurred in 7 cases. We discussed about the difficulty of genetic counseling in this syndrome and about different hypothesis to explain its clinical heterogeneity. We examined in particular, the co-existence of additional CNVs and their contribution to the phenotypic variation in the 22q11.2 microduplication syndrome. In conclusion we report the first prenatal serie of microduplication 22q11.2. Our data are consistent with the extreme variability of this syndrome. New molecular cytogenetics technologies as Prenatal BoBs™ and microarray would probably increase the detection rate of this cryptic chromosomal rearrangement. Moreover the clinical follow-up during childhood of patients with 22q11.2 microduplication diagnosed prenatally would help the understanding of this pathology.

2859W

Validation of epigenetic marker for noninvasive prenatal diagnosis of fetal trisomy 18. *DE. Lee[1], SY. Kim[1], JH. Lim[1], HJ. Kim[1], SY. Park[1], HM. Ryu[1, 2].* 1) Laboratory of Medical Genetics, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Background: The quantification of cell-free fetal DNA by methylation-based DNA discrimination has been used in noninvasive prenatal diagnosis of fetal chromosomal aneuploidy. Maspin (SERPINB5) gene, located on chromosome 18q21.33, is hypomethylated in the placenta and completely methylated in maternal blood cells. The objective of this study was to evaluate the accuracy of noninvasive fetal trisomy 18 detection using tissue specific-methylation of maspin in the first trimester of pregnancy. Methods: A nested case-control study was conducted using maternal plasma samples collected from 66 pregnant women carrying 11 trisomy 18 and 55 normal fetuses. Using real-time quantitative methylation-specific PCR, the concentrations of unmethylated maspin (U-maspin) and methylated maspin (M-maspin) were measured in first trimester maternal plasma. Results: U-maspin concentrations were significantly elevated in women with trisomy 18 fetuses compared with controls (27.2 vs 6.7 copies/mL; P<0.001). M-maspin concentrations were significantly higher in women with trisomy 18 fetuses compared with controls (96.9 vs 19.5 copies/mL, P<0.001). The specificities of U-maspin and M-maspin concentration for noninvasive fetal trisomy 18 detection were 96.4% and 74.5%, respectively, with a sensitivity of 90.9%. In the risk assessment for fetal trisomy 18, the adjusted odds ratios of U-maspin and M-maspin concentration were 325.2 (95% confidence interval: 17.9-5903.8, P<0.001) and 19.0 (95% confidence interval: 2.1-175.6, P=0.009), respectively. Conclusions: Our results suggest that U-maspin and M-maspin concentration may be useful as potential biomarkers for noninvasive fetal trisomy 18 detection in the first trimester of pregnancy, irrespective of the sex and genetic variations of the fetus.

2860T

Highly accurate non-invasive detection of fetal aneuploidy for chromosomes 13, 18, 21, X and Y. *B. Levy[1], S. McAdoo[2], B. Zimmermann[2], M. Banjevic[2], B. Pettersen[2], M. Hall[2], Z. Demko[2], M. Hill[2], M. Rabinowitz[2].* 1) Department of Cell Biology and Pathology, Columbia University, New York, NY; 2) Natera, Inc, 201 Industrial Rd, San Carlos, CA, 94070.

Objective: To develop a non-invasive prenatal test (NIPT) that will detect fetal chromosome 13, 18, 21, X, and Y copy number through analysis of cell-free (cfDNA) isolated from maternal plasma using the Next-generation Aneuploidy Testing Using SNPs (NATUS) algorithm. **Methods:** cfDNA was isolated from 699 maternal plasma samples at ≥9 weeks gestation, including 70 aneuploid samples, under an institutional review board approved protocol. DNA at 19,488 polymorphic loci covering the target chromosomes was amplified in a single multiplex-PCR assay and sequenced. Results were analyzed using the NATUS algorithm, which uses Bayesian statistics to accurately identify copy number. NATUS considers parental genotypes and HapMap data to calculate expected allele distributions for a large number of possible fetal ploidy states. It then compares the predicted allele distributions to the actual allelic distributions as measured in the cfDNA sample, sums the likelihoods of each ploidy state hypothesis (monosomy, disomy or trisomy) based on the sequencing data, and calls the hypothesis with the maximum likelihood as the ploidy state. Unlike other methods, NATUS calculates a sample-specific accuracy without requiring a reference chromosome. **Results:** In samples that passed quality control thresholds (94.2%), 99.8% of calls were correct. The mean confidence calculated by NATUS for these samples was greater than 99%. Samples typically failed to meet the quality control threshold due to poor DNA quality and/or low fetal fraction (less than 4%). **Conclusions:** The NATUS algorithm is the only NIPT method that calculates sample-specific accuracies and detects chromosomally abnormal fetuses from maternal plasma with high accuracy at chromosomes 13, 18, 21, X and Y as early as 9 weeks gestation.

2861W

Disease-specific characteristics of fetal epigenetic markers for non-invasive prenatal diagnosis of trisomy 21. *J. Lim[1], D. Lee[1], S. Park[1], D. Kim[1], H. Kim[1], H. Ahn[2], S. Lee[2], K. Choi[2], M. Kim[2], H. Ryu[1,2].* 1) Laboratory of Medical Genetics, Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Seoul, South Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, South Korea.

BACKGROUND: Non-invasive prenatal diagnosis of trisomy 21 (T21) is being actively investigated using fetal-specific epigenetic markers (EPs) that are present in maternal plasma. Recently, 12 EPs on chromosome 21 were identified based on tissue-specific epigenetic characteristics between placenta and blood, and demonstrated excellent clinical performance in the non-invasive detection of fetal T21. However, the disease-specific epigenetic characteristics of the EPs have not been established. Therefore, we validated the disease-specific epigenetic characteristics of these EPs for use in non-invasive detection of fetal T21. METHODS: We performed a high-resolution tiling array analysis of human chromosome 21 using a methyl-CpG binding domain-based protein (MBD) method with whole blood samples from non-pregnant normal women, whole blood samples from pregnant normal women, placenta samples of normal fetuses, and placenta samples of T21 fetuses. Tiling array results were validated by bisulfite direct sequencing and qPCR. RESULTS: Among 12 EPs, only four EPs were confirmed to be hypermethylated in normal placenta and hypomethylated in blood. One of these four showed a severe discrepancy in the methylation patterns of T21 placenta samples, and another was located within a region of copy number variations. Thus, two EPs were confirmed to be potential fetal-specific markers based on their disease-specific epigenetic characteristics. The MBD results of these EPs were consisted with the results obtained by bisulfite direct sequencing and qPCR. However, the methylation level of these EPs showed inter-individual variability. CONCLUSION: We validated that two EPs have the potential to be fetal-specific EPs which is consistent with their disease-specific epigenetic characteristics. The findings of this study suggest that disease-specific epigenetic characteristics should be considered in the development of fetal-specific EPs for non-invasive prenatal diagnosis of T21.

The concerns of health professionals and pregnant women involving the non-invasive prenatal diagnosis of trisomy 21 in Quebec and in France. *A.K. MAGLO[1], R. DROUIN[1], JM. MOUTQUIN[2], C. BOUFFARD[1].* 1) Division of Genetics, Department of Pediatrics, Université de Sherbrooke, Faculty of Medicine and Health Sciences, Sherbrooke, Quebec, Canada; 2) Department of Obstetrics and Gynecology, Université de Sherbrooke, Faculty of Medicine and Health Sciences, Sherbrooke, Quebec, Canada.

Introduction: In France, the Agence Nationale de Sécurité du Médicament currently assesses the relevance of authorizing the non-invasive prenatal diagnosis (NIPD) through blood testing of trisomy 21 (T21) (PrenaTest®). As Quebec begins to be confronted with this issue, our objective was to identify and compare the concerns of health practitioners, pregnant women and couples involving the NIPD of T21 from probative data available for France and Quebec. Methodology: Qualitative aspect: 1) Systematic narrative review: research through key-words in probative data (scientific publications and gray literature) in databanks: PubMed, ERIC, JSTOR, SCOPUS, etc. 2) Thematic and comparative analysis of the content: coding, categorization and classification of information in themes, allowing for the identification of the variables and relationships established in the texts. 3) Comprehensive synthesis. Results: In Quebec, reflection focuses mostly on the invasive diagnosis of T21. In France, the debate extends to issues related to NIPD. In both countries, health practitioners, pregnant women and their partners are equally concerned with 1) the lack of information on NIPD and 2) the importance attributed to genetic counseling. Finally, health practitioners have questions relating to 3) standards of practices and 4) ethics; pregnant women have questions relating to 5) decision-making autonomy and 6) the attitude of society towards individuals living with T21. Conclusion: Parallel to the evolution of NIPD techniques, we continue to lack probative data that would allow us to establish health policies ensuring that this change in paradigm in the field of prenatal diagnosis does not diminish the quality of services and decision-making autonomy of women, and does not encourage discrimination against people with T21.

2863W

A single nucleotide polymorphism-based approach to non-invasive prenatal testing identifies lingering cell-free fetal DNA in pregnancies with vanishing twins. *S. McAdoo, M. Savage, M.P. Hall, B. Zimmermann, S. Sigurjonsson, Z. Demko, M. Rabinowitz.* Natera, Inc., San Carlos, CA.

Objective: Using single nucleotide polymorphism (SNP)-based non-invasive prenatal testing (NIPT) to analyze cell-free fetal DNA (cffDNA) allows for identification of samples with multiple maternal and/or paternal haplotypes; these additional parental haplotypes distinguish single from multiple gestations. Vanishing twins may confound fetal copy number calling in singleton pregnancies due to cffDNA from the vanishing twin placenta. A SNP-based approach allows detection of vanishing twins in reportedly singleton pregnancies, and may reduce the frequency of incorrect results. We present three such cases. **Methods:** Commercial samples were processed at a single reference laboratory. Isolated cfDNA was amplified using multiplex PCR targeting 19,488 SNPs covering chromosomes 13, 18, 21, X, and Y. Sequencing data was analyzed using Next-generation Aneuploidy Test Using SNPs (NATUS) algorithm that uses Bayesian statistics to analyze multiple copy number hypotheses and determine the Maximum Likelihood hypothesis, calculating chromosome-specific accuracies without requiring a reference chromosome. Follow-up clinical information was sought for cases in which NATUS was suggestive of a vanishing twin. **Results:** Case 1: vanishing twin reported at 6w0d, maternal blood drawn at 14w3d; Case 2: twin loss reported at 6w5d, maternal blood drawn at 13w5d. Neither case had evidence of a second sac at blood draw. Case 3: two sacs but one fetus reported at 12w6d, maternal blood drawn at 19w1d. **Conclusions:** This method detected cffDNA from a vanishing twin as many as 8 weeks after demise. The contribution of cffDNA from a vanishing twin increases the total cffDNA estimate, potentially resulting in analysis of samples with cffDNA levels from the surviving twin below that which is appropriate for accurate detection of aneuploidy. Additionally, residual cffDNA from a vanishing twin could be aneuploid (explaining the cause for the loss) whereas the surviving twin could be euploid. Together, this may result in incorrect results when using non-SNP-based methods, as these are classified as singleton pregnancies at the time of maternal blood draw. This SNP-based NIPT approach identifies these cases, potentially decreasing incorrect results.

A KEY ROLE FOR AMNIOTIC FLUID CITRULLINE ANALYSIS IN THE PRENATAL DIAGNOSIS OF CITRULLINEMIA TYPE I. *M.J. Miller, V.R. Sutton, Q. Sun, S.H. Elsea.* Biochemical Genetics Laboratories, Baylor College of Medicine, Houston, TX.

The urea cycle disorder citrullinemia type I results from argininosuccinate synthetase 1 (ASS1) deficiency and can be diagnosed prenatally using fetal enzymatic and/or molecular testing. Additional analysis of amino acid levels in amniotic fluid (AF-AA) has been suggested to aid in the prenatal diagnosis of multiple urea cycle disorders but in the case of citrullinemia the published experience is limited (PMID#6739433). To assess the clinical utility of AF-AA testing we reviewed the 30 prenatal citrullinemia cases diagnosed with both enzyme and AF-AA assays in our laboratory over the last decade, 16 of which had further molecular testing and all involved mothers with prior affected offspring. To provide additional support to our normal reference range we also quantified the AF-AA levels from 50 mothers receiving prenatal testing unrelated to citrullinemia and for whom no abnormalities were detected. Overall, AF-citrulline values strongly correlated with argininosuccinate synthetase enzyme activity in amniocytes. Consistent with this, AF-citrulline levels for affected fetuses (n=11) were significantly elevated above unaffected/carrier fetuses (n=69). Setting a cutoff of 50 μM AF-citrulline afforded a positive predictive value of 100% with 91% sensitivity. In two instances AF-citrulline confirmed a diagnosis in the face of ambiguous molecular and/or biochemical test results. Taken together our data demonstrate that amniotic citrulline levels serve as an important adjuvant in the interpretation of enzyme and DNA data in the prenatal diagnosis of citrullinemia.

Experience using a rapid assay for aneuploidy and microdeletion detection in over 2900 prenatal specimens. *S. Sulpizio, S.A. Morton, A.M. Bandholz, L.D. McDaniel, R.A. Schultz, B.S. Torchia, J.B. Ravnan, J.W. Ellison, P. Mowery-Rushton, J.A. Rosenfeld.* Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA.

While microarray testing can identify chromosomal abnormalities missed by karyotyping, its prenatal use is often avoided in low-risk pregnancies due to the possible identification of variants of uncertain significance (VOUS). We tested 2971 samples using a rapid, BACs-on-Beads^{TM}-based assay with probes for sex chromosomes, common autosomal aneuploidies, and a panel of 15 microdeletion syndromes and 5 reciprocal microduplication syndromes, designed as an alternative to microarray testing in low-risk pregnancies and an alternative to rapid aneuploidy FISH in high-risk pregnancies that also undergo microarray analysis. Interpretable results were obtained in 2942 cases (99.0%), with 89% receiving results the next business day after sample receipt. Aneuploidies were detected in 7.3%, with the rate dependent on indication for study ($p<0.0001$). Partial chromosome abnormalities were detected in 0.5% (n=14), including six low-risk cases referred for maternal age, abnormal maternal serum screen, or isolated soft ultrasound markers. One VOUS was obtained (0.03%), which was determined to be benign following further characterization by microarray. Abnormalities were confirmed through secondary testing; neither false negatives nor false positives were found, within limitations of the test. Female polyploidy cannot be detected, while polyploidies with Y chromosomes are suspected and confirmed through additional analysis. This assay allows for detection of clinically significant microdeletions and aneuploidy with rapid results. It tests for more conditions than rapid aneuploidy FISH, though cannot detect all polyploidy. When combined with karyotyping, this assay provides increased interrogation of specific chromosomal regions, while limiting the identification of VOUS.

Methods for fetal fraction quantification in circulating cell-free DNA sequencing libraries. *J. Tynan[1], G. Hogg[1], J. Fox[1], P. Iyer[1], M. Ehrich[2].* 1) Sequenom Center for Molecular Medicine, San Diego, CA; 2) Sequenom, Inc., San Diego, CA.

OBJECTIVE: Circulating cell-free (ccf) fetal DNA fraction in maternal plasma can be measured using chromosome Y markers from a male fetus, fetal specific methylation markers, or paternally inherited alleles absent in the maternal genome. Here, we compare the quantification of ccf fetal DNA fraction in maternal plasma sequencing libraries using single nucleotide polymorphism (SNP) allele frequencies, chromosome Y representation by sequencing, and the ratio of chromosome Y and total genomic copies by droplet digital PCR (ddPCR). METHOD: Maternal plasma DNA was isolated and plasma DNA libraries were prepared using TruSeq reagent kits (Illumina, San Diego California), clustered at 12-sample plexing and sequenced on the HiSeq 2000 (Illumina) for 36 cycles. Plasma DNA sequencing reads were aligned to the human genome (hg19) and the proportion of reads derived from chromosome Y were used to estimate fetal fraction. Maternal plasma DNA libraries were also used as template for a multiplexed single-tube PCR SNP panel and a duplex ddPCR assay. The multiplexed single-tube PCR assay amplified 67 high minor allele frequency SNPs and was designed such that a subsequent universal PCR incorporated indexed adapter sequences to allow multiplexed sequencing on the MiSeq (Illumina). The duplex ddPCR assay was designed to quantify SRY copies arising from the male fetal genome and TERT total genomic copies on the QX100 (Bio-Rad, Hercules California). RESULTS: By sequencing 84 plasma DNA libraries for chromosome Y representation, 38 samples passing assay QC metrics were derived from a donor carrying a male fetus. Sequencing based chromosome Y fetal fraction significantly correlated to ddPCR based fetal fraction ($r2 = 0.72$). ddPCR fetal fraction showed significant correlation to SNP based fetal fraction ($r2 = 0.63$). Sequencing based chromosome Y fetal fraction showed significant correlation to SNP based fetal fractions ($r2 = 0.81$). CONCLUSION: These data demonstrate concordance of ccf DNA fetal fraction measurement in sequencing libraries by multiple methods. SNP allele frequencies and chromosome Y representation showed the highest correlation. The ddPCR method likely is negatively impacted by sampling error of SRY copies leading to a higher variability of fetal fraction quantification. Of course, only the SNP allele frequency assay is able to quantify fetal fraction in pregnancies carrying a female fetus.

2867W

Prenatal MLPA screening and aCGH analysis detected cytogenomic abnormalities in four cases with fetal ultrasound anomalies. *J. Xie[1], Z. Xu[1, 2], Q. Geng[1], F. Xu[2], P. Li[2].* 1) Center for Prenatal Diagnosis, Shenzhen Maternity and Child Healthcare Hospital, Shenzhen, Guangdong, China; 2) Department of Genetics, Yale School of Medicine, New Haven, CT.

Ultrasound detected fetal anomalies have been the most important clinical indications for prenatal genetic diagnosis. However, the associations of specific ultrasound findings with most syndromic cytogenomic disorders remain elusive. We have applied rapid MLPA screening and aCGH analysis to high risk pregnancies with abnormal ultrasound findings. Cytogenomic abnormalities were characterized in four cases. The first fetus with ultrasound findings of growth retardation, bilateral cleft lip and palate, right-sided aortic arch and multiple cystic hypoplasia was detected with a 40.701 Mb duplication of 8q22.3-q24.3 and a 23.839 Mb deletion of 7q33-q36.3. Follow up parental study found the father to be a carrier of a balanced 7q33/8q22.3 translocation. The second fetus with single-ventricle heart, transposition of the great arteries and double superior vena cava was diagnosed as Jacobsen syndrome (OMIM#147791) by a de novo 13 Mb distal deletion of 11q24.1-q25. The third fetus with split-hand split-foot malformation and multiple umbilical cord cysts was diagnosed as type 1 split-hand/foot malformation (SHFM1, OMIM#183600) with a de novo 19.971 Mb interstitial deletion of 7q11.23-q21.3. The fourth fetus with pleural effusion, a hypoplastic cerebellum and a large ventricle showed a 699.8 Kb deletion including the TERT gene at 5p15.33 for the diagnosis of Cri du Chat syndrome (OMIM#123450). Post-test genetic counseling was performed with detailed genomic information and well characterized postnatal syndromic features. All parents made an informed decision to elect termination. Prenatal ultrasound findings reported in literature for Jacobsen syndrome, SHFM and Cri du Chat syndrome were reviewed and summarized. Our results demonstrated that comprehensive evaluation of abnormal prenatal ultrasound findings and their association with known cytogenomic disorders will lead to better practice of prenatal genetic testing and counseling.

Chinese Alliance of Translational Medicine for Maternal and Children's Health (CATMMACH): A unique resource for longitudinal cohort study of pregnancies. *J. Pan[1,2], Q-X. Shi[1,2], Y. Gu[1,2], X-C. Lou[1,2], M-F. Hua[1,2], N. Zhong[1,2,3,4].* 1) Lianyungang Maternal and Children's Hospital, Lianyungang, Jiangsu, China; 2) Chinese Alliance of Translational Medicine for Maternal and Children's Health (CATMMACH), China; 3) Peking University Center of Medical Genetics, Beijing, China; 4) New York State Institute for Basic Research in DD, Staten Island, NY.

Globally, 536,000 women died from causes related to pregnancy and childbirth in 2005, and 3.7 million newborn infants died in 2004. Globally, an estimated 15 million infants are born preterm annually, and more than one million infants die annually from preterm birth complications, making these complications the most frequent cause of all deaths worldwide of children younger than 5 years of age. Recent translational research to elucidate the molecular mechanism underlying preterm births is focusing on two major categories: conventional research to explore biomarkers, which may be applied to early prevention of preterm birth, and an integrated systems biology approach with '-omic' technology, to uncover the genetic risk factors, including gene mutation, genetic predisposition or environmental-genetic interaction. However, the molecular mechanisms underlying preterm birth are not yet clearly understood because it is a complex disorder. Many environmental and genetic factors are involved, and gene-gene and gene-environmental interaction(s) likely play key roles. To study these roles, a national network in China, the Chinese Alliance of Translational Medicine for Maternal and Children's Health (CATMMACH), has been developed, comprising eight hospitals and two medical genetics centers. Collection of quantitative specimens from pregnancies, along with detailed clinical information, has become a critical resource to enable the biobanking program of this alliance to conduct a longitudinal cohort study of pregnancy outcomes. Availability and accessibility of the pregnancy specimens from the biobank of the alliance allow international and domestic investigators to perform translational research to uncover the molecular pathophysiology of pregnancy and its outcomes.

Integrative transcriptome analysis reveals dysregulation of canonical cancer molecular pathways in placenta leading to preeclampsia. *R. Moslehi[1], J.L. Mills[2], C. Signore[3], A. Kumar[1], X. Ambroggio[4], A. Dzutsev[5].* 1) Epidemiology and Biostatistics, Cancer Genomics Center, University at Albany, State University of New York, NY; 2) Epidemiology Branch, Eunice Kennedy Shriver National Institutes of Child Health and Human Development, NIH, Bethesda, MD; 3) Pregnancy and Perinatology Branch, Eunice Kennedy Shriver National Institutes of Child Health and Human Development, NIH, Bethesda, MD; 4) Bioinformatics and Computational Biosciences Branch, National Institutes of Allergy and Infectious Disease, NIH, Bethesda, MD; 5) Cancer Inflammation Program, Center for Cancer Research, National Cancer Institute, NIH, Frederick, MD.

Background Based on our clinical observations and subsequent genetic epidemiologic studies of DNA repair disorders, we previously identified associations between specific nucleotide excision repair (NER)/transcription gene mutations in the fetal genome and the risk of placental maldevelopment and preeclampsia, possibly due to impairment of Transcription Factor (TF)IIH-mediated functions in placenta. To identify the underlying mechanisms, we designed an integrative analysis of relevant transcriptome data sources containing gene expression arrays of fetal cell-derived tissue. This novel approach has enabled enrichment of causative mechanisms which underlie the previously-reported associations. **Methods** We conducted meta-analysis of gene expression patterns in placenta from four case-control studies of preeclampsia. A preeclampsia-specific gene list obtained from this meta-analysis was then interrogated in three relevant data sources [normal and time course placentas (i.e., placentas from first, second and third trimester pregnancies), hypoxic trophoblasts and XPD^{TTD} fibroblasts (i.e., cells predisposed to preeclampsia)]. **Results** Our meta-analysis of placental gene expression patterns revealed 419 differentially-regulated genes (136 downregulated and 283 upregulated) at false discovery rate(FDR)<0.05. Genes coding for TFIIH subunits and for components of RNA Pol-II complex were significantly-downregulated in preeclamptic placentas. Interrogation of the preeclampsia-specific gene signature through a filter constructed from the three relevant data sources identified *EGFR* and *ATF3* as key regulators of preeclampsia development. ATF3 upregulation was found as an upstream event to FLT1 and ENG induction. Integrative Gene Ontology(GO) and canonical pathway analyses identified EGF signaling as a key pathway involving the majority of differentially-regulated genes across all datasets. **Conclusion** Our overall integrative analysis suggested that, in the presence of hypoxia and oxidative stress, EGFR signaling deficiency, which can be caused by TFIIH impairment, results in ATF3 upregulation, inducing molecular mediators of clinical symptoms of preeclampsia such as FLT1 and ENG. EGFR- and ATF3-dependent pathways play prominent roles in cancer development. Thus, we propose that dysregulation of these cancer molecular pathways occurs in preeclampsia and delineate the relevance of TFIIH, providing etiologic clues which could eventually translate into a therapeutic approach.

2870T

TLR SNP T399I and early gestational age in a Wisconsin population of black newborn infants. *D. Pillers[1], M. Baker[1], S. Schrodi[2], L. Zyduck[1], J. DeValk[1], B. Pattnaik[1], S. Tokarz[1].* 1) Pediatrics, University of Wisconsin, Madison, WI, United States; 2) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI United States.

Background: Toll-like receptors (TLRs) are present in many cell types and serve as the first point of defense in the innate immune system by initiating the inflammatory cascade in response to infection. Single nucleotide polymorphisms (SNPs) are present in many TLR genes and have been associated with disorders of inflammation. TLR4 D299G and T399I SNPs are associated with increased susceptibility to infection from various pathogens. As inflammation can play a role in the development of preterm labor, TLR SNPs that alter the response to infection may have a different frequency in the preterm population. Objective: Screen a large, diverse population of Wisconsin newborns for TLR4 D299G and T399I SNPs and determine the genotype frequency in relation to gestational age (GA). Design/Methods: Anonymized DNA samples from 3095 infants were obtained in collaboration with the Wisconsin State Laboratory of Hygiene. Race was self-determined by patient as White (hispanic/non-hispanic), Black, Asian, and American Indian. TLR SNP assays (rs4986790, rs4986791) were purchased from Applied Biosystems Inc (ABI) and run on the ABI StepOnePlus™. Data were analyzed using StepOne™ software v2.2.2. Statistical analysis was carried out in collaboration with the Marshfield Clinic and the National Institute of Standards and Technology. Results: We did not find a significant correlation between the 299G and 399I alleles and early gestational age in the total population. However, when adjusting for racial background, we found that among Black infants the 399I allele frequency was 0% in term infants (37+ weeks GA), whereas it was 7.6% in preterm infants <37 weeks GA (P=0.039) and 7.7% in those <33 weeks GA (P=0.020). Conclusions: We show that in a population of Wisconsin infants the TLR4 SNP 299G did not associate with early gestational age. Our data are not consistent with current literature that show a correlation between the TLR4 SNP 299G allele and early gestational age. However, we did show an association between the 399I allele and early gestational age in a cohort of Black infants. Our data suggest that the racial background of an individual may affect the contribution of a specific TLR allele to preterm birth.

Copy number variation of RYR1 locus, which is involved in myomentrial contraction and relaxation, is associated with preterm births. *M. Liu[1], Y. Chen[1,2], N. Zhong[2,3].* 1) Center for Reproduction and Genetics, Suzhou Municipal Hospital Affiliated to Nanjing Medical University, Suzhou, Jiangsu, China; 2) Chinese Alliance of Translational Medicine for Maternal and Children's Health, China; 3) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Preterm birth refers to a life birth before 37 gestational weeks. It is the leading cause of neonatal death. As well, it has been listed as one of the most common causes for under-5 children's mortality and morbidity. Although many risk factors have been identified to associate with preterm birth, genetic deficit is yet unknown. In this study, we have applied a genome wide study to assess the association of copy number variation (CNV) with preterm birth. A cohort of 26 preterm birth samples with gestational age of <32 weeks, for which, common known factors had been excluded, were analyzed with Agilent 1M microarray comparative genomic hybridization (aCGH), compared to the results of 49 normal samples. 639 CNV loci were found from preterm birth samples and 12 CNVs, mainly located on chromosome 1, 17, 19, were associated with preterm birth. Among these 12 loci, three were shown statistically significant. Variation within these loci includes duplication, homozygous and heterozygous deletion. Among 26 preterm birth samples, 3 (12%) at three loci and 8 (31%) at two loci had copy number variations simultaneously. A gene RYR1 located within the significant loci were noticed to be involved in calcium regulation in smooth muscle and most interestingly, in myomentrial contraction and relaxation that indicates this gene may contribute to the premature labor for preterm birth.

2872T

LncRNA Pathways Involved in Premature Preterm Rupture of Membrane (PPROM). *Q. Shi[1], X-C. Luo[1], Y. Gu[1], J. Pan[1], N. Zhong[1,2,3,4].* 1) Lianyungang Maternal and Children's Hospital, Lianyungang, China; 2) March of Dimes Global Network of Maternal and Infant Health, NY; 3) Peking University Center of Medical Genetics, Beijing, China; 4) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Preterm birth (PTB) is a live birth delivered before 37 weeks of gestation (GW). About one-third of which result from the preterm premature rupture of membranes (PPROM). Presently, the pathogenic mechanism underlying PPROM is not yet clearly understood. In this study, we have investigated the differential expression of lncRNAs in placentas of PPROM, compared to controls, and their involvement in the pathogenic pathway of PPROM. A total number of 1954, 776, and 1050 lncRNAs were identified from placentas of PPROM (group A), which were compared to full term (FT) birth (group B), PTB (group C), and premature rupture of membrane (PROM) (group D), respectively. Instead of investigating the individual pathogenic function of each lncRNA involved in the pathogenic mechanism underlying PPROM, we have focused on investigating the metabolic pathways and their functions to explore what is the likely association and how they are possibly involved in the development of PPROM. Six groups, including up-regulation and down-regulation in the comparison of A vs. B, A vs. C, and A vs. D, of pathways were analyzed. Our results showed that 22 pathways were characterized as up-regulated 7 down-regulated in A vs. C, 18 up-regulated and 15 down-regulated in A vs. D, and 33 up-regulated and 7 down-regulated in A vs. B. Functional analysis showed pathways of infection and inflammatory response, ECM-receptor interactions, apoptosis, actin cytoskeleton, and smooth muscle contraction are the major pathogenic mechanisms involved in the development of PPROM, which opened a new avenue for further investigating of the regulation of lncRNAs in PPROM as well as PTB.

Functional validation of severe ciliopathies in a cohort of terminated pregnancies. *F.W. Verheijen, R. Oegema, L.M. van Unen, J.M. Verhagen, K.M. Diderich, M.L. van der Sterre, R.M. Hofstra, G.M. Mancini.* Clinical Genetics, Erasmus Univ MC, Rotterdam, Netherlands.

The wide application of prenatal ultrasound often leads to the detection of multiple congenital anomalies and consequently to termination of pregnancy (TOP) without a definitive diagnosis. Severe congenital anomalies at ultrasounds, such as (cranial) neural tube defects, ventriculomegaly, cerebellar and kidney dysplasia, skeletal abnormalities and heart-loop lateralization defects are frequent in defects of the primary cilium (ciliopathies), mostly recessively inherited, such as Meckel syndrome or hydrolethalus syndrome, but establishing a diagnosis in a fetus can be challenging. Ciliopathies have an incidence above 1 in 1,000 conceptuses and around 2500 genes are expected to be related to function and/or structure of the cilia. We therefore sought to develop a diagnostic screening assay and subsequent workflow for ciliopathies in fetuses of pregnancies, terminated on the basis of the ultrasound findings. Initially, immunostaining of the primary cilium and basal body in cultured skin fibroblasts proved to accurately diagnose patients with known ciliopathies (such as Joubert syndrome, Meckel syndrome, Rotatin mutation). Additionally, Shh-mediated Gli response was used as functional test for cilia-related pathways and confidently detected patients with known mutations, even with minor/no cilia structural anomalies. In a cohort of TOP fetal fibroblasts derived from fetuses with above mentioned malformations, we detected a high percentage of structural and functional cilia abnormalities. In fetuses with undefined ciliopathy, this approach complements the use of targeted NGS panels for ciliopathy genes, useful for both patient selection and confirmation of genomic variants. This approach also detects high recurrence risk pregnancies, offering the possibility of early prenatal diagnosis.

2874T

An Inverse Association Between Telomere Lengths and Gestational Age. *H. Naderi[1], K. Ryckman[2], J. Dagle[3], J. Murray[3].* 1) Carver College of Medicine, University of Iowa, Iowa City, IA; 2) Department of Epidemiology, College of Public Health, University of Iowa, Iowa City, IA; 3) Department of Pediatrics, University of Iowa, Iowa City, IA.

Preterm birth (PTB; defined as birth before 37 weeks of completed gestation) is a complex disorder and is associated with significant neonatal morbidity and mortality rates. Genetic variations between preterm and term infants may provide insights into the pathways involved with PTB. One such genetic variation of interest is telomere length (TL). In humans, telomeres are non-coding TTAGGG repeats located at the end of chromosomes. With each cell division, telomeres shorten. Eventually shortened telomeres lead to cell senescence and serve as one marker of aging. Shorter TL has been associated with cardiovascular disease, cancer, dementia, arthritis, osteoporosis, and hypertension. The main determinants of TL are age, inheritance, and gender. Studies have shown conflicting results regarding a relationship between gestational age (GA) and TL. We tested the association between TL and GA in an initial 260 cord blood samples taken from a cohort of infants with GA between 24-41 weeks. Relative TL was measured using a qPCR method. Primers specific to telomeres (the target of interest) and to the 36B4 gene (a single copy gene on chromosome 12 used as a reference gene) were used to obtain a ratio of telomere to single copy gene length (T/S). This ratio was normalized to control for quantity of genomic DNA. Standard curves were produced as a means to check the efficiency of the assay. Relative quantification was used to analyze the data. The data was stratified into Group 1, GA less than 37 weeks (n=166), and Group 2, GA of 39 to 41 weeks (n=75). The average GA for the first group was 30.7 weeks while that of the second group was 40.0 weeks. The normalized T/S ratio of Group 1 is 3.69 while that of Group 2 is 2.18. This indicates that the TL of the preterm group (Group 1) is about 1.7 times longer than that of the term group (Group 2). A single variable regression of TL on GA yields a beta value of -0.093 (p-value = 0.033) indicating that a one unit increase in GA results in a TL loss of 0.093. The effect of TL on PTB outcome, as well as how TL changes with respect to gestational age, will now be examined with a larger sample size.

Case report of a pregnant woman with inherited thrombocytopenia associated with MYH9 mutation. *O. Samura[1,2], T. Mizunoe[2], S. Kunishima[3].* 1) Dept OB/GYN, Onomichi General Hospital, Onomichi, Hiroshima, Japan; 2) Dept OB/GYN, Kure Medical Center, Kure,Hiroshima,japan; 3) Dept of Advanced Diagnosis,clinical Research Center, Nagoya Medical Center, Nagoya,Japan.

[Introduction] MYH9 disorders are autosomal dominant macrothrombocytopenias with leukocyte inclusion bodies, characterized by giant platelets, thrombocytopenia, and Döhle body-like cytoplasmic inclusion bodies. May-Hegglin anomaly (MHA), caused by mutations of MYH9, is classified as a MYH9 disorder. Here, we report a rare case of a pregnant woman with familial congenital thrombocytopenia and confirmed MHA genetic diagnosis.[Case] A 31-year-old woman was diagnosed with thrombocytopenia when she was 20-year- old, but she did not receive treatment. Her familial history included low platelet levels in her paternal grandfather, father, and younger sister, and during her first pregnancy the platelet count was approximately 5.0 × 104/μL. However, she had a vaginal delivery without excessive bleeding. The patient was referred to our department for the management of her second pregnancy; however, due to her low platelet count (4.7 × 104/μL) and family history, congenital thrombocytopenia was suspected. A blood film revealed giant platelets, disparity in platelet size, and Döhle body-like cytoplasmic inclusion bodies, which were present in almost all segmented leukocytes. By immunofluorescent staining, abnormal myosin aggregation in granulocyte cytoplasm was suspected; therefore, we performed MYH9 testing with the consent of the patient and her father at gestational week 30. Genetic testing revealed an E1841K substitution in exon 38 of MYH9, and MHA was confirmed. Her platelet count ranged from 4-6 × 104/μL during her second pregnancy without the need for blood transfusion. She had a normal cephalic vaginal delivery of a 3148-g female with Apgar scores of 9 and 9 at 1 and 5 min, respectively, at gestational week 40. However, the second child also had thrombocytopenia and the same abnormal morphological findings as our patient. [Conclusion] In pregnancy, thrombocytopenia management in a patient with a family history should be carefully observed by peripheral blood smears because MYH9 disorders are not merely benign abnormalities but serious syndromic disorders that affect the kidneys, inner ears, and lens. Genetic diagnosis of MYH9 disorders is mandatory for accurate nonhematological complication prognosis and pregnancy management.

KIR2DL4 polymorphism and perinatal HIV-1 transmission. *C. Czarnecki[1], E. Rossnagel[2], S. Ramdahin[2], J. Embree[2], F. Plummer[1, 2], M. Luo[1, 2].* 1) National Microbiology Laboratory, Winnipeg, Canada; 2) University of Manitoba, Winnipeg, Canada.

Objectives: Killer cell immunoglobulin like receptor (KIR) 2DL4 is a framework gene located within the leukocyte receptor complex. It can be found in almost all individuals and is believed to play an important role during pregnancy. The only known ligand for KIR2DL4 is HLA-G, which is highly expressed at the maternal-fetal interface and also conducts an important role during pregnancy. We previously examined the effect of HLA-G polymorphism on perinatal HIV-1 transmission and observed HLA-G*01:03 to be associated with a decreased risk of transmission. In this study we analyzed the genetic polymorphism of KIR2DL4 and their epistatic interactions with HLA-G in perinatal HIV-1 transmission. Design: One hundred and ninety nine HIV-1 positive drug treatment naïve mothers enrolled in a mother-child HIV-1 transmission cohort in Nairobi, Kenya were genotyped for 2DL4 using a sequence-based typing method. Associations of major 2DL4 alleles and their epistatic interactions with HLA-G alleles were analyzed by statistical analysis using SPSS 13.0 for 274 mother-chair pairs. Results: A total of 20 2DL4 alleles were identified in this population, with 8 of them uncharacterized. Only 6 alleles had a phenotype frequency of greater than 5%. 2DL4*0010301 was the most common allele with an allele frequency of 42.71% and phenotype frequency of 62.81%. 2DL4*022 was associated with an increased perinatal HIV-1 transmission (p=0.009, OR:2.977 95% CI:1.276-6.942). Epistatic interactions between 2DL4*008 and HLA-G*01:01:02:01 increased the odds of perinatal transmission. The odds ratio for mothers with HLA-G*01:01:02:01 alone was 1.322 (p=0.28, 95% CI:0.826-2.115) and for mothers with 2DL4*008 alone was 1.157 (p=0.617, 95% CI:0.654-2.046). However, in mothers with both of these alleles the odds ratio of transmitting HIV-1 to their children increased to 2.011 (p= 0.035, 95% CI:1.044-3.876). Conclusions: KIR2DL4 polymorphism and its interaction with HLA-G can influence the risk of perinatal HIV-1 transmission.

Genome-Wide Association Study Identifies More Than 10 Loci Associated with Hypospadias. *F. Geller[1], B. Feenstra[1], L. van der Zanden[2], A. Nordenskjöld[3], L. Carstensen[1], I. van Rooij[2], I. Baranowska-Körberg[3], T. Schnack[1], M. Melbye[1].* 1) Statens Serum Institut, Copenhagen, Denmark; 2) Radboud University Medical Centre, Nijmegen, The Netherlands; 3) Karolinska Institutet, Stockholm, Sweden.

Hypospadias is a common birth defect in boys with a prevalence of about 4 cases in 1,000 births in Denmark. Severe cases require surgery and a previous study observed substantial familial aggregation with recurrence risk ratios of hypospadias for male twin pairs, first- and second-degree relatives of a hypospadias case, at 50.8, 11.6 and 3.27, respectively. This motivated us to perform a genome-wide association study based on 1,006 surgery confirmed cases identified from the National Hospital Registry and 5,468 controls, all genotyped on Illumina Omni chips. Twelve loci showed association at P<5/10-8, including the previously described locus on chromosome X close to DGKK. Combined, these genetic variants explain more than 10% of the variance in liability for hypospadias. Currently, independent replication study groups from Denmark, the Netherlands and Sweden are genotyped for these loci. Genes with general roles in development are overrepresented among the identified genomic regions.

2878T

Simultaneous uniparental disomy of chromosome 5 and 16; A case report. *H. Akar, D. Torun, Y. Tunca.* Medical Genetics, Gulhane Military Medical Faculty, Ankara, Turkey.

Uniparental disomy (UPD) describes the inheritance of both homologues of a pair of chromosomes from only one parent. Mechanisms of formation are trisomy rescue, gamete complementation, mitotic duplication, and post-fertilisation errors. Problems associated with UPD are placental or even fetal mosaicism mostly because of formation by trisomy rescue, homozygosity of autosomal recessively inherited mutations and aberrant genomic imprinting describing parent of origin dependent gene expression. A 29 years old healthy mother has come to our notice because of fetal loss. The family was followed up due to recurrent fetal losses before the last abortion and the mother revealed 46,XX, t(5;16)(q22;q24)mat,t(5;16)(q22;q24)pat karyotype. The mother stated as homozygous identical resiprocal translocation carrier. Unconsanguineous father had 46,XY normal constitutional karyotype. Parents of mother was consanguineous and carriying the same translocaticon as heterozygote. The last pregnancy was terminated at 7th week of gestation due to absence of fetal heartbeat. We have performed fetal cell culture to evaluate the cytogenetic abnormalities and karyotype analysis revealed 46, XX, t(5;16)(q22;q24),t(5;16)(q22;q24). We estimated that both of the reciprocal translocations inherited from the mother. This finding suggested that miscarriage resulted from maternal UPD of chromosome 5 and 16. As we know, this is the first report of simultaneous UPD of chromosome 5 and 16 that arise from homozygous identical resiprocal translocation carrier proband.

Proviral loads of human T-cell leukemia virus type 1 in the peripheral blood samples from carrier pregnant women. *N. Fuchi[1], K. Miura[1], T. Tsukiyama[1], D. Sasaki[2], N. Inokuchi[2], K. Yanagihara[2], S. Kamihira[2], H. Moriuchi[3], K. Yoshiura[4], H. Masuzaki[1].* 1) Department of Obstetrics and Gynecology, Nagasaki University Graduate School of Medicine, Ngasaki, Japan; 2) Department of Laboratory Medicine, Nagasaki University Graduate School of Medicine, Ngasaki, Japan; 3) Department of Pediatrics, Nagasaki University Graduate School of Medicine, Ngasaki, Japan; 4) Department of Human Genetics, Nagasaki University Graduate School of Medicine, Ngasaki, Japan.

Objective: Human T-cell leukemia virus type 1 (HTLV-1) is causative virus of adult T-cell leukemia (ATL), which is still intractable against any medical treatments. As the proviral loads of HTLV-1 in blood samples is associated with the risk of ATL later, those in pregnant women may be also a risk factor of maternal-child transmitted infection. However, the information regarding proviral loads of HTLV-1 in carrier pregnant women is still unknown. Therefore, the aim of this study is to clarify the changes of proviral loads of HTLV-1 genome in the peripheral blood samples from carrier pregnant women before and after delivery. Material and Methods: When the pregnant woman was decided as positive or false positive by the first screening test by chemiluminescent enzyme immunoassay (CLEIA), blood sampling before delivery was performed at 28-34 weeks of gestation and the quantitative real-time PCR of HTLV-1 genome (30ng genomic DNA) was done as confirmation test. When HTLV-1 genome was detected in blood sample, pregnant woman was diagnosed as HTLV-1 carrier. After delivery, blood samples of HTLV-1 carrier pregnant women were obtained within 24 hours, and the proviral loads of HTLV-1 were measured by quantitative real-time PCR before and after delivery. PCR primers for HTLV-1genome were located at the pX region, while PCR primers for beta-globin as an internal control were on exon 2. HTLV-1 proviral load was calculated by the formula [(HTLV-1 pX copy number)/(beta-globin copy number/2)] ×10, 000 cells. Result: A total of 36 pregnant women were diagnosed as HTLV-1 carrier. Mean (minimum-Maximum) proviral loads were 83.3 (0.87-502.3)104 cells before delivery, while 34.27 (0-149.37)104 cells after delivery. HTLV-1 proviral loads before delivery was higher than those after delivery (Wilcoxon signed rank test, P<0.001). Conclusion: The proviral load of HTLV-1 genome in blood samples was decreased significantly after delivery, suggesting that the changes of HTLV-1 proviral load may reflect the changes of CD4-positive T cells in pregnant women.

Characterization of placenta-specific microRNAs in fetal growth restriction pregnancy. *A. Higashijima[1], K. Miura[1], H. Mishima[2], A. Kinoshita[2], O. Jo[1], S. Abe[1], Y. Hasegawa[1], S. Miura[1], K. Yamasaki[1], A. Yoshida[1], K. Yoshiura[2], H. Masuzaki[1].* 1) OB/GYN, Nagasaki Univ Hosp, Nagasaki, Japan; 2) Human Genetics Dept, Nagasaki Univ, Nagasaki, Japan.

Objective:The aim of this study was to characterize placenta-specific microRNAs in fetal growth restriction (FGR) pregnancy. Method:Placenta-specific miRNAs were identified by next-generation sequencing analysis. Subsequently, quantitative real-time RT-PCR was used to identify FGR placenta-specific miRNAs whose level of expression was significantly decreased in FGR placenta (n=45) compared with uncomplicated placenta (n=50). FGR pregnancy-associated, placenta-specific microRNAs were identified in maternal plasma after delivery at significantly decreased concentrations, and their circulating levels in maternal plasma was compared between FGR pregnancies (n=10) and uncomplicated pregnancies (n=10). Results: Out of the 10 placenta-specific microRNAs that we identified, seven placenta-specific microRNAs (hsa-miR-518b, hsa-miR-1323, hsa-miR-516b, hsa-miR-515-5p, hsa-miR-520h, hsa-miR-519d and hsa-miR-526b) from the chromosome 19 microRNA cluster were identified as FGR placenta-specific microRNAs. Four FGR placenta-specific microRNAs (hsa-miR-518b, hsa-miR-1323, hsa-miR-520h and hsa-miR-519d) were confirmed as FGR pregnancy-associated, placenta-specific miRNAs, but their circulating levels in maternal plasma showed no significant differences between FGR pregnancy and uncomplicated pregnancy. Conclusion: Our data suggest that reduced expression in placenta of certain FGR placenta-specific miRNAs is associated with FGR, and that the discrepancy between expression in FGR placenta and their circulating levels in maternal plasma will be crucial to understanding how placenta-specific microRNAs are released into the maternal circulation.

2881W

Heritability of cardiovascular diseases in a preeclampsia family cohort. *L.C.V. Thomsen[1,2], P.E. Melton[3], K. Tollaksen[4], I. Lyslo[4], P. Solberg[5], L.T. Roten[6,7], A.S. Gundersen[6,7], M.L. Odland[7], K.M. Strand[7], O.K. Nygård[2,8], C. Sun[1], A-C. Iversen[7], R. Austgulen[7], E.K. Moses[3], L. Bjørge[1,2].* 1) Department of Obstetrics and Gynecology, Haukeland University Hospital; 2) Department of Clinical Science, University of Bergen; 3) Centre of Genetic Origins of Health and Disease, University of Western Australia; 4) Department of Obstetrics and Gynecology, Stavanger University Hospital; 5) Department of Obstetrics and Gynecology, Levanger Hospital; 6) Department of Laboratory Medicine, Children's and Women's Health, Faculty of Medicine, Norwegian University of Science and Technology; 7) Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology; 8) Department of Heart Disease, Haukeland University Hospital.

Purpose: Preeclampsia (PE) is a complex genetic disease of pregnancy with potentially severe outcomes for mother and fetus. Women who develop PE have been observed to have increased risk (2-8x) of developing cardiovascular diseases (CVD) later in life. We aimed to estimate the heritability of CVD phenotypes in well-characterized families with an acknowledged predisposition to PE. Methods: Using information contained in the Norwegian Preeclampsia Family Biobank, a cohort composed of families with an increased occurrence of PE, we classified 496 participants from 138 families according to predefined CVD phenotypes; a) risk factors for CVD (treated hypertension and/or hypercholesterolemia), b) established atherosclerotic vascular disease (subtypes: angina, acute myocardial infartion, stroke, aneurism, thrombosis), or c) no diagnosis of CVD. Heritabilities were calculated using a variance components procedure implemented in the SOLAR software with the inclusion of covariate age, sex, and their interactions. Results: Average age of the participants was 46.9 (range 18-87) years. Heritability estimates (h2r) were statistically significant for PE (h2r=0.54±0.3, p=0.02), non-pregnancy related hypertension (h2r=0.62±0.1, p=2.1×10-3) and hypercholesterolemia (h2r=0.55±0.3, p=0.03). When only the presence or absence of any of the CVD phenotypes was assessed the heritability of CVD was highly significant (h2r=0.31±0.12, p=1.9×10-3). The trait heritability was not significant for the other CVD phenotypes examined. Conclusion: This study represents the first link between hereditary development of PE and specific CVD traits identified in a family cohort. Due to the relative young age of these participants most of the cohort would not yet have experienced manifest atherosclerotic disease in form of acute myocardial infarction or stroke, but rather the established risk factors of CVD. Further identification of genetic variants specific to the affected families will avail us to focus on certain genetic areas potentially regulating biologic functions implicated in development of both CVD and PE.

2882T

Transcriptional profiling analyses of RNA in uncultured amniotic fluid using GeneChip® PrimeView™ Human Gene Expression Array. *D. Cha[1,2], S.H. Sung[2], S.R. Sung[2], M. Chin[2], J. Park[2], S. Kang[2], K. Kang[2], S. Lyu[1].* 1) Dept OB/GYN, Kangnam CHA Hosp, Seoul, South Korea; 2) Genetics Laboratory of Fertility Center.

Amniotic fluid is the only body fluid in direct contact with the the fetal oropharynx, lungs, gastrointestinal tract, skin, and urinary system and amniotic fluid cell-free fetal RNA(AF cffRNA) can provide biological information on developing fetal organ system. The aim of this study is to clarify AF cffRNA profile of normal fetuses in three different gestational periods, 16~17 weeks (group 1), 25~26 weeks (group 2), and 36~38 weeks (group 3). The total 13 AF samples, 5 of group 1, 4 of group 2 and 4 of group 3, were collected. Total RNA was extracted from 10 mL of the amniotic fluid supernatant using the QIAamp Circulating Nucleic Acid Kit. The extracted RNA was hybridized to GeneChip® PrimeView™ Human Gene Expression Array to compare gene expression in amniotic fluid supernatant samples. The data were analyzed with Robust Multi-array Analysis using Affymetrix default analysis settings and global scaling as normalization method. The normalized, and log transformed intensity values were then analyzed using GeneSpring 12.5. In group 1, total 3289 transcripts were identified. We were confirmed 532 transcripts that have been known to be associated with fetal development through a search of pathway analysis software and Medline. We found 1,977 genes to be differentially expressed between group 1 and group 2. Among these genes, 27 genes increased and 1950 genes decreased in group 2. Also, we found 2,039 genes to be differentially expressed in group 3 compared to group 1. 48 out of 2,039 genes increased and 1475 genes decreased in group 3. Our result presented cffRNA profiles in amniotic fluids of pregnant women with normal fetal development in three different gestational periods. This study might contribute to the further studies for the discovery of biomarkers for abnormal fetal growth.

2883W

Recurrent enlarged nuchal translucency: prenatal presentation of a familial 15q26.2→qter deletion syndrome. *R. Reiss[1], D. Ahern[1], M. Sandstrom[2], L. Wilkins-Haug[1].* 1) Center for Fetal Medicine and Prenatal Genetics, Dept of Obstetrics and Gynecology, Brigham and Women's Hospital, Boston, MA; 2) Dept of Pathology, Brigham and Women's Hospital, Boston, MA.

Objective: To elucidate familial recurrence of enlarged nuchal translucency (NT) with chromosomal microarray and FISH techniques. Methods: A patient presented in each of 3 pregnancies with enlarged NT (4.7 mm, 4.0 mm, 7.1 mm). The first pregnancy was terminated when cardiac defect was suspected at 13.1 wks. Products of conception (POC) were karyotyped as 46,XX. In the next pregnancy, chorionic villus sampling at 12 wks showed karyotype 46,XX, and no deletion at 22q11.2. Ultrasound at 17 wks identified talipes. Fetal echocardiogram was normal at 19 wks. Pregnancy continued, complicated by IUGR. Multiple anomalies were identified after birth (micrognathia, malrotated kidney, talipes, brachydactyly). Postnatal growth lag prompted microarray testing at 5 months. In a 3rd pregnancy, septated NT at 11.7 wks again led to pregnancy termination. Chromosome analysis of POC showed 46,XY. Microarray was performed on fetus. Karyotype and FISH were performed on the mother. Results: 6.0 SNP microarray on the liveborn girl showed a 6.53Mb deletion at 15q26.2-q26.3, confirmed by 15q subtelomeric FISH. CGH microarray on fetal DNA from pregnancy 3 showed a 6.49Mb loss of 15q26.2→qter, consistent with the deletion seen in the affected child. FISH using a 15q subtelomere probe confirmed microarray findings. Subtelomeric 15q FISH analysis, performed retrospectively on a destained slide of cultured metaphases of POC from pregnancy 1, confirmed 15q26.2-26.3 deletion. Maternal blood chromosome analysis was normal, 46,XX. FISH using BAC probes from 15q26.2 and 15q26.3, with control probe to 15q11.2, showed no deletion or translocation of the 15q26.2 region. Studies on father and CVS from a recent 4th pregnancy are pending. Conclusions: Terminal microdeletion 15q26.2→qter, an emerging syndrome of pre- and postnatal growth lag and anomalies, can present in 1st trimester with large NT. Our case highlights the importance of offering chromosomal microarray as well as conventional karyotyping when large NT is identified. Retrospective performance of microarray or FISH on DNA/cells from fixed samples can help document a familial syndrome. Based on review of the literature, most cases of terminal 15q deletion are de novo. This is the 2nd report of a familial case. We postulate that the father may carry a chromosome rearrangement involving the 15q terminal region. Alternatively a small inversion in the region of the breakpoints, or germline mosaicism might be present in a parent.

2884T

Gene expression differences between preeclamptic and healthy placentas - an RNA sequencing study. *T. Kaartokallio[1], A. Cervera[2], S. Hautaniemi[2], J. Kere[1,3,4,5], H. Laivuori[1,6].* 1) Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 2) Systems Biology Laboratory, Institute of Biomedicine and Genome-Scale Biology Research Program, University of Helsinki, Helsinki, Finland; 3) Department of Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden; 4) Molecular Neurology Research Program, Research Programs Unit, University of Helsinki, Finland; 5) Folkhälsan Institute of Genetics, University of Helsinki, Helsinki, Finland; 6) Department of Obstetrics and Gynaecology, Helsinki University Central Hospital, Helsinki, Finland.

Objectives: Preeclampsia (PE), a common pregnancy disorder originating from impaired placental development, is responsible for morbidity and mortality to both mother and child. In the present study, we utilized RNA sequencing to identify genes that are differently expressed between preeclamptic and healthy placentas. **Methods:** Placental RNA of nine preeclamptic women and nine healthy controls was sequenced in pools of three with Illumina chemistry. The PE pools 1, 2 and 3 consisted of placental samples from 38-39, 34-36 and 33 weeks of gestation, respectively, and the control pools from 38-39 weeks of gestation. All women delivered by C-section without labor. The data was processed and analyzed with appropriate tools including Tophat, Cuffdiff and CummeRbund. The two groups were tested for differential gene expression by comparing all the case pools as well as subsets of the case pools against the control pools. The results will be validated by qPCR in a sample set of 20 cases and 19 controls including the samples utilized in the RNA sequencing. In this sample set, the cases and controls do not differ significantly for maternal age or body mass index, gestational age, mode of delivery or sex of the child. **Results:** Initially, a total of 58 genes were found to be differentially expressed between PE and control groups. After excluding genes with inconsistent expression pattern within the groups, hemoglobin genes, and genes located in Y chromosome, as the fetal sex distribution between the groups was not equal, we were left with 40 genes. Of these, 15 will be subsequently validated by qPCR. The genes selected for the validation are involved e.g. in immunological processes, placental development and function, invasion, angiogenesis and vasodilation, all of which are processes relevant for the development of PE. Some of these genes have also been previously associated with autoimmune or renal diseases. In addition to our main goal of identifying expression differences between preeclamptic and healthy placenta, we wish to emphasize the importance of taking account of gestational age when studying placental gene expression in pregnancy complications. Therefore, in the qPCR validation, we also aim to demonstrate the effect of gestational age on expression of certain genes. **Conclusions:** By comparing transcriptomes of preeclamptic and healthy placentas, we were able to identify genes that were differentially expressed between the two groups.

2885W

Towards a Mouse Model of Thrombocytopenia with Absent Radius (TAR) Syndrome. *V.L. Horner[1], A. Dodd[1], A. Long[1], C.L. Martin[2], T. Caspary[1].* 1) Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Autism and Developmental Medicine Institute, Geisinger Health System, Lewisburg, PA.

TAR syndrome is characterized by low blood platelet counts (thrombocytopenia) and absence of the radius bone in each forearm. Thrombocytopenia can lead to easy bruising and/or hemorrhage in infancy, which may become less severe over time. The absence of radius bones results in shortened forearms. TAR syndrome is inherited in an autosomal recessive manner and is due to changes in the gene *RBM8A*. Compound inheritance of one *RBM8A* null allele (most often as a large deletion) and one *RBM8A* hypomorphic allele causes TAR syndrome. At present, two hypomorphic alleles have been described. Somewhat surprisingly, both alleles contain the minor allele of a single nucleotide polymorphism (SNP) in a regulatory region of *RBM8A*. These two regulatory SNPs lower *RBM8A* transcription *in vitro*. Further, the level of the *RBM8A* gene product, Y14, is reduced in individuals who carry the SNPs compared to wild-type controls. Together, these results lead to the hypothesis that there is a dose-effect phenomenon, in which a null allele together with a hypomorphic allele brings Y14 levels below some critical threshold to cause TAR syndrome. To determine where, when and how much *RBM8A* production is required during embryonic development, we are generating mouse alleles in which the endogenous *RBM8A* locus is under the control of a tetracycline-dependant transactivator. This system will enable us to control the amount of Y14 protein available during embryogenesis, by varying the amount of tetracycline fed to pregnant mothers. We are generating two strains of mice: the first strain will have the transactivator (TetOn) under the control of the endogenous *RBM8A* promoter. The second strain will have the tetracycline-responsive promoter (tetO) driving *RBM8A* expression. The presence of tetracycline allows the transactivator to bind and drive *RBM8A* transcription. There is a linear relationship between the amount of tetracycline and the amount of transcription, enabling us to define the critical dosage threshold of Y14 that causes TAR syndrome phenotypes as well as the dosage that causes lethality. Ultimately, this system will also allow us to examine the temporal and spatial requirements for *RBM8A* during development, by providing tetracycline to pregnant mothers at various stages of embryogenesis and by driving the transactivator with promoters specific for various tissues. These experiments are the first step to defining the therapeutic level of Y14 for TAR syndrome treatment.

2886T

A single mutant *HTT* allele is sufficient to elicit early alterations to the brain in a knock-in mouse model of Huntington's disease. *M. Kovalenko[1], A.J. Milnerwood[2], S. Tappan[3], J. St.Claire[1], J.R. Guide[1], R.C. Switzer III[4], L.A. Raymond[2], J.-M. Lee[1], V.C. Wheeler[1].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 2) Department of Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada; 3) Microbrightfield laboratories, MBF Labs, Williston VT, USA; 4) NeuroScience Associates, Knoxville, TN, USA.

Huntington's disease (HD) is a dominantly inherited neurodegenerative disease caused by the expansion of a CAG repeat in the *HTT* gene encoding huntingtin (Htt). To increase the chance of identifying early responses to mutant Htt that are relevant to the disease process in patients we are using accurate genetic knock-in mouse models of the HD mutation to delineate phenotypes that result from the expression of a single allele's worth of full-length mutant Htt as occurs in the majority of HD patients.

Here, as part of our ongoing phenotyping effort we report the results of neuropathology and electrophysiology studies in heterozygous $Hdh^{Q111/+}$ mice. We assessed neuropathology in multiple brain regions in $Hdh^{Q111/+}$ mice at 10 and 18 months of age. To probe potential underlying disease mechanisms we also assessed a cohort of 10 month mice that had been fed a high-fat diet. Immunohistochemistry revealed reduced levels of DARPP-32 in $Hdh^{Q111/+}$ striata at 10 months of age, independent of diet, and widespread increased myelin basic protein (MBP) staining in $Hdh^{Q111/+}$ at 18 months. Stereology revealed subtly reduced volumes of striatum, caudate-putamen, cerebrum, cortex and nucleus accumbens and subtly reduced cortical thickness at 10 months of age. Both cortical volume and thickness were decreased to a greater extent in $Hdh^{Q111/+}$ mice on a high-fat diet than on a control diet suggesting that a high-fat diet provides a sensitized background to these measures. Medium-spiny striatal neurons (MSNs) are particularly vulnerable to the effects of the *HTT* CAG mutation. To explore a potential functional deficit at the level of the MSN, as indicated by reduced DARPP-32, we used acute slice electrophysiology to probe very early alterations in glutamatergic transmission from the cortex to the MSNs. As early as 1.5 months of age $Hdh^{Q111/+}$ mice exhibited a slowed decay of evoked NMDA receptor-mediated postsynaptic currents compared to wild-type controls. At 5 months of age $Hdh^{Q111/+}$ mice exhibited elevated extrasynaptic NMDA currents as well as altered AMPA receptor-mediated spontaneous postsynaptic currents.

Together, these data strongly indicate that the expression of endogenous levels of full-length mutant Htt expressed from a single expanded allele is sufficient to elicit phenotypes consistent with neuronal dysfunction at an early age.

From Chromosomal Translocation to Functional Analysis, Identification of ATG4C in Cleft Palate Malformation. *L.J. Rochard, T. Hyos, M. Talkowski, J. Gusella, C. Morton, E.C. Liao.* Massachusetts General hospital, BWH, Harvard Medical School.

Orofacial defects such as cleft lip and palate (CLP) are the most common structural congenital anomalies, affecting 1 out of 700 births. Elucidating the genetic basis of these orofacial clefts is essential to identify risk loci and develop new therapeutic and preventive measures. In an ongoing gene discovery effort, the Developmental Genome Anatomy project (DGAP) has developed whole genome sequencing strategies to characterize genes contributing to such human congenital anomalies. Through this methodology, we discovered a new candidate gene for CLP, ATG4C that encodes an autophagy related cysteine protease. The isolated deletion of ATG4C was identified in a 12 year old Caucasian boy presenting a CLP. Previous studies in our lab have demonstrated conservation of the fundamental molecular pathways and homology of primary palate formation between mammals and zebrafish. Therefore we utilized the model organism zebrafish to study and validate the role of ATG4C in palate development. By whole mount in situ hybridization, we determined that the spatiotemporal expression of atg4c is compatible with a role in craniofacial development. Additionally, knockdown studies performed with morpholino injections resulted in both a shortened and cleft palate, suggesting a strong role for atg4c as the causal gene in the human case of CLP. Our current work is focusing on a mechanistic analysis of ATG4C in craniofacial morphogenesis and autophagy. Our future studies will track migrating cranial neural crest cells and help determine if the failure of upper jaw morphogenesis in atg4c mutants is due to a defect in cell migration, proliferation or convergence extension mechanisms. We also plan to assess effects of atg4c loss of function in a GFP-LC3 (a component of autophagosome) transgenic line. To this end, we are creating mutants for this gene by using the targeted mutagenesis method, CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats). This study goes beyond functional annotation of ATG4C to include detailed biological analysis of gene function, and highlights the utility of the zebrafish model in high throughput and reverse genetics approaches that are important in functional genomics projects.

***Trim37*-deficient mice recapitulate several features of the multi-organ disorder Mulibrey nanism.** *K.M. Kettunen[1, 2, 3], R. Karikoski[4], R.H. Hämäläinen[2], T-T. Toivonen[1, 2, 3], H. Jalanko[5], A-E. Lehesjoki[1, 2, 3].* 1) Folkhälsan Institute of Genetics, Helsinki, Finland; 2) Research Programs Unit, Molecular Neurology, Biomedicum Helsinki, University of Helsinki, Finland; 3) Neuroscience Center, University of Helsinki, Finland; 4) Central Hospital of Tavastia, Hämeenlinna, Finland; 5) Hospital for Children and Adolescents, Helsinki University Central Hospital, Finland.

Objective: Mulibrey nanism (MUL) is a rare autosomal recessive multi-organ disorder caused by mutations in the *TRIM37* gene. The main symptoms include growth restriction, cardiopathy, infertility, increased risk for tumors, metabolic syndrome and type 2 diabetes. The disease mechanisms and the physiological function of TRIM37 are unknown. We characterized thoroughly a *Trim37* knock-out mouse ($Trim37^{-/-}$) to gain understanding of the pathogenesis of MUL. *Materials and Methods:* A congenic C57BL/6JOlaHsd $Trim37^{-/-}$ mouse strain was produced by use of BayGenomics gene-trap ES cells. *Trim37* knock-out mice and wild-type littermates were monitored for fertility and weight development. CT scans were performed to measure the skeletal size of adult mice. Samples of brain, heart, lung, liver, pancreas, spleen, intestine, kidneys, adrenal glands, ovaries / testes, rib, femur and white adipose tissue were collected at the age points 1, 4, 6 and 18 months. Histological samples were stained with hematoxylin and eosin, Oil red O for lipids and specific antibodies when appropriate. Basic laboratory measurements were determined from serum samples collected after a 24h fast in six-month-old mice. *Results and discussion:* $Trim37^{-/-}$ mice were found to have significantly smaller skull size compared to wild-type mice, despite of similar weight development in both genotypes. $Trim37^{-/-}$ mice were infertile due to degeneration of testes and ovaries. On histological level both male and female gonads showed germ cell aplasia and Leydig cell hyperplasia. Common pathological findings in 1.5 year old mice included cardiomyopathy, hepatomegaly and fatty liver, splenomegaly and various tumors. Fat accumulation in liver started already at the age of 16 weeks and increased with age. Adult six-month-old $Trim37^{-/-}$ mice had elevated fasting blood glucose values (4,71 ± 0,7mmol/l vs. 3,79 ± 0,5 mmol/l, p = 0,0047) and low fasting serum insulin values (0,37 ± 0,1ng/ml vs. 0,59 ± 0,3ng/ml, p = 0,065), compared to wild-type mice. Thus $Trim37^{-/-}$ mice have disturbances in glucose metabolism and most likely impaired glucose tolerance or type 2 diabetes. *Conclusion:* $Trim37^{-/-}$ mice recapitulate several features of the human disease phenotype, including growth restriction, infertility, risk of various tumors, cardiomyopathy, disturbances in glucose and lipid metabolism and fatty liver and thus provide a good model to study disease pathogenesis related to TRIM37 deficiency.

2889T

An in vivo mouse model to study the phosphorylation of FMRP. *M. Santoro, S.T. Warren.* Department of Human Genetics Emory University Atlanta, GA.

Fragile X syndrome, the most common form of inherited intellectual disability, results from a lack of Fragile X Mental Retardation Protein (FMRP). FMRP is a selective mRNA-binding protein and plays a key role in synaptic plasticity. In neurons, FMRP represses translation of its target mRNAs but allows translation to proceed upon receipt of specific synaptic signals. In the hypothalamus, activation of mGluR receptors causes FMRP to derepress translation of its target mRNAs, resulting in a burst of local protein synthesis, internalization of AMPA receptors, and long term depression. In vitro experiments indicate that FMRP's activity is regulated by the phosphorylation status of a specific serine (S499 in mice; S500 in humans). In order to more fully investigate the translational regulation of FMRP we have developed a knock-in mouse model with a Ser499Ala mutation. This results in an amino acid replacement that structurally resembles unphosphorylated FMRP. Indeed, using an antibody raised against phosphor-FMRP, no signal is observed on Western blots from Ser499Ala mouse tissue, although normal levels of FMRP are seen with the conventional antibody. Phenotypic studies are underway but preliminary data suggest that the Ser499Ala mouse may not be a complete phenocopy of the FMRP null mouse.

A systematic genome-wide knockout generation and analysis of zebrafish protein-coding gene function. *C.M. Dooley[1], E.M. Busch-Nentwich[1], R.N.W. Kettleborough[1], C. Scahill[1], I. Sealy[1], R.J. White[1], J.C. Collins[1], N. Wali[1], C. Herd[1], R. Gibbons[1], S. Carruthers[1], A. Hall[1], R.C. Clark[1], Z. Pusztai[1], M. Niemi[1], F. van Eeden[2], J.C. Barrett[1], D.L. Stemple[1].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) MRC-CDBG/Department of Biomedical Science, The University of Sheffield, United Kingdom.

Although the human genome sequence was completed a decade ago less than half of the identified vertebrate genes have been assigned a function. Detailed investigations involving model organisms have played a fundamental role in connecting genotype to phenotype and will continue to do so. The ability to thoroughly investigate the role of a gene in various biological processes greatly depends on loss of function analysis which has traditionally been carried out, in vertebrates, on a gene-by-gene basis. The zebrafish is a genetically tractable organism with an external, transparent and rapidly developing embryo offering an in toto model of the complex cellular processes required for the formation of all major vertebrate organs. In recent years it has moved beyond being a model of early development as 70% of all human genes are represented by at least one zebrafish ortholog. This has helped to make zebrafish a first stop choice for human geneticists aiming to assign function to human orthologs or clinicians hoping to develop a model for a particular disease. Enabled by a completed and annotated zebrafish reference genome sequence, high-throughput sequencing and efficient chemical mutagenesis, we describe the active Zebrafish Mutation Project (ZMP) at the Wellcome Trust Sanger Institute which aims to identify and phenotype disruptive mutations in every zebrafish protein-coding gene. Thus far we have identified potentially disruptive mutations in more than 48% of all of the 26,000 known zebrafish protein coding genes. We have developed a multi-allelic phenotyping scheme to efficiently assess the effects of each allele during embryogenesis and have analyzed the phenotypic consequences of more than 1600 alleles. Our phenotyping scheme is also adaptable to phenotypic analysis beyond embryogenesis and we are currently expanding our analysis to encompass a wider array of phenotypes as we set forth to fully functionally annotate the zebrafish genome. To accompany our chemical mutagenesis we have also developed the Cas9/CRISPR system to allow for single as well as multiplexed targeted bespoke knockouts. A further goal is to use our rich collection of knockouts and knockout generation capabilities to model human disease and to work towards the complete functional annotation of the entire zebrafish genome. To this end, all knockout alleles and data are immediately made available to the community via our website http://www.sanger.ac.uk/cgi-bin/Projects/D_rerio/zmp.

Accessing mouse model data for human disease research. *J.T. Eppig, S.M. Bello, H. Dene, A. Anagnostospoulos, H. Onda, R. Babiuk, M.N. Knowlton, M. Tomczuk, C.L. Smith.* Jackson Laboratory, Bar Harbor, ME.

The laboratory mouse is the primary model for human disease based on its extensive genetics, fully-sequenced genome, and large-scale mutagenesis programs that have created ENU (point mutations) and knock-out (null) mutations covering most of its genome. In addition, programs to develop genetically-defined variant populations mimicking human population variation provide new means to study quantitative traits and complexly inherited syndromes. This genomic knowledge, coupled with increasing phenotyping precision and micro-technologies, add exquisite detail to knowledge about morphological and physiological variation in mouse.

The Mouse Genome Informatics (MGI, www.informatics.jax.org) database and resources provide a roadmap to discovery for biologists and clinicians seeking to use the extensive genetic, phenotypic, and disease model data available to correlate mouse phenotypes and human disease. MGI holds data on more than 750,000 mutant allelic variants in 21,400 genes. More than 250,000 phenotypic annotations to genotypes are curated using the Mammalian Phenotype Ontology. Mouse models are annotated to over 1,240 unique human diseases in OMIM.

MGI is developing new interfaces to human disease information to foster use by clinical and human genetics researchers. These interfaces will provide easy access to mouse models via human genes, human genome locations, human disease symptoms, and human anatomy terms. Our aim is to reduce the barriers to use of mouse data and increase the synergy derived from comparative genomics and comparative phenotyping. This will facilitate mining data for common pathways, disease variants, and potential therapeutic interventions. We describe these new human-centric entry points to MGI data and present examples of insights derived from examining human diseases in light of mouse models. We demonstrate the ease of obtaining mouse disease models from repositories, the path to reference collections, and the search for collaborators. Supported by NIH grant HG000330.

Reducing variability in variation data using a common genotype-phenotype model. *N.L. Washington[1], M. Brush[2], A. Bandrowski[3], C. Borromeo[4], K. Eilbeck[7], J. Espino[4], J. Grethe[2], A. Gupta[3], H. Hochheiser[4], S. Hoffmann[2], S.E. Lewis[1], L. Lui[3], M. Martone[3], C.J. Mungall[1], P. Robinson[5], D. Smedley[6], C. Torniai[2], N. Vasilevsky[2], M.A. Haendel[2].* 1) Genomics Division, Lawrence Berkeley National Lab, Berkeley, CA; 2) Library and Dept. of Medical Informatics and Epidemiology, Oregon Health Sciences University, Portland, CA; 3) Center for Research in Biological Systems, University of California San Diego, La Jolla, CA; 4) Department of Biomedical Informatics, University of Pittsburgh, Pittsburgh, PA; 5) Institut für Medizinische Genetik und Humangenetik, Charité - Universitätsmedizin Berlin, Berlin, Germany; 6) Wellcome Trust Sanger Institute, Cambridge, UK; 7) University of Utah, UT.

Investigating the basis of disease requires correlating and integrating genotype, phenotype, and environmental factors. Ideally, we could leverage the depth of knowledge available from model systems. However, choosing an appropriate and sufficient model organism (e.g. genotype) for the study of a disease is a challenge, as it often requires an understanding of the organism-specific vocabularies, nomenclature guidelines, and a whole host of nuances attributed to laboratory animal husbandry, breeding, and maintenance. Though the volume of curated genotype-to-phenotype data is steadily growing, our ability to query across different organisms and data resources is limited. This is due, in part, to a lack of a common genotype and phenotype reporting format, and results from the variety of ways in which this data is reported, including free text, organism-specific vocabularies, nomenclatures, syntaxes. The data is further complicated because phenotypes may be linked to different aspects of a genotype, such as an allele, a QTL, or the complete genome. Despite efforts to standardize human variation through proposed standards such as HGVS many alternatives still exist, leading to difficulties when integrating human phenotype data from different database resources. A first step toward the integration of organism genotypes (including human and model systems) is to translate them to a common genotype model. As part of the Monarch Initiative, we have created a pan-species genotype representation that allows users to access human variation and model organism genotype-to-phenotype data in a uniform way. This permits cross-species querying by genotype components without needing to know about a specific resources' nomenclature, and is the first step in being able to aggregate and attribute phenotype data to different components of a genotype. This standardization enables translational genotype-phenotype hypotheses and analysis of treatment options, and will make model system data available for rare and undiagnosed disease diagnosis and clinical decision support tools.

2893F

MYBPC1 mutations impair skeletal muscle function in zebrafish models of arthrogryposis. *D.M. Alvarado[1], K. Ha[1], J.G. Buchan[2], K. McCall[1], A. Vydyanath[3], P.K. Luther[3], M.I. Goldsmith[4], M.B. Dobbs[1,5], C.A. Gurnett[1,2,4].* 1) Orthopaedic Surgery, Washington Univ, St Louis, MO; 2) Neurology, Washington Univ, St. Louis, MO; 3) Heart and Lung Institute, Imperial College, London, UK; 4) Pediatrics, Washington Univ, St. Louis, MO; 5) St. Louis Shriners Hospital for Children, St. Louis, MO.

Myosin binding protein C1 (MYBPC1) is an abundant skeletal muscle protein that is expressed predominantly in slow twitch muscle fibers. Human MYBPC1 mutations are associated with distal arthrogryposis type 1 and lethal congenital contracture syndrome (LCCS4). Because the function of MYBPC1 is incompletely understood, the mechanism by which human mutations result in contractures is unknown. Here, we demonstrate that *mybpc1* is required for embryonic motor activity and survival in a zebrafish model of arthrogryposis using antisense morpholino knockdown. *Mybpc1* morphant embryos have severe body curvature, cardiac edema, impaired motor excitation and are delayed in hatching. Myofibril organization is selectively impaired in slow skeletal muscle and sarcomere numbers are greatly reduced in *mybpc1* knockdown embryos. To evaluate the effects of human distal arthrogryposis mutations, *mybpc1* mRNAs containing the corresponding human W236R and Y856H MYBPC1 mutations were injected into embryos. Dominant-negative effects of theses mutations were suggested by the resultant mild bent body curvature, decreased motor activity, myofibril disorganization, as well as impaired overall survival compared to overexpression of wild-type RNA. These results demonstrate a critical role for *mybpc1* in slow skeletal muscle development and establish zebrafish as a tractable model of human distal arthrogryposis.

2894W

Scaling up: Integrating high throughput mouse phenotyping data with additional genomic resources for gene discovery. *C.L. Smith, H. Dene, R. Balderelli, S. Gianatto, K. Forthover, J. Kadin, J. Richardson, J.T. Eppig, Mouse Genome Informatics Staff.* Mouse Genome Informatics, Jackson Laboratory, Bar Harbor, ME.

The mouse is the most commonly studied model organism for understanding gene function in human disease and development. Comparative genetics and genomics can assist in prioritization of candidate genes for human disease, and model organisms can be used for confirmation or validation of gene function. However, comprehensive functional and phenotypic annotation of mouse genes is incomplete in many instances and mouse phenotype data are available for only 7770 of of the estimated 33,735 protein coding and RNA only coding genes.

The International Mouse Phenotyping Consortium (IMPC) is gearing up to collect phenotype data on mice made from the large collection of knockout alleles in embryonic stem cells available from the International Knockout Mouse Consortium. The goal is to provide standardized phenotypic data derived from the same battery of tests for every gene in the mouse genome. Mouse Genome Informatics (MGI: www.informatics.jax.org) has already established pipelines to the WTSI and Europhenome pilot phenotyping projects and has developed the infrastructure to integrate and display these initial sets of data with all of the all other genetic and functional information available about these genes in mouse.

Phenotypic representation of genetically engineered mice integrated with other biological data at MGI will aid in model building, understanding biochemical pathways, and determining the underlying mechanisms of human genetic disease. We will show web based query results utilizing query forms designed to search phenotypic, biochemical function and process, subcellular location, expression, pathways and sequence data that may assist in finding novel candidate genes for human disease. Supported by NIH grant HG000330.

2895T

Translational Modeling of Calpain-5 Vitreoretinopathy Mechanisms in Mice. *K.J. Wert[1, 2], J.M. Skeie[3, 4], S.H. Tsang[1, 2], V.B. Mahajan[3, 4].* 1) Department of Ophthalmology, Columbia University Medical Center, New York, NY; 2) Institute of Human Nutrition, College of Physicians and Surgeons, Columbia University, New York, NY; 3) Omics Laboratory, University of Iowa, Iowa City, IA; 4) Department of Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA.

A wide range of human diseases including cancer, multiple sclerosis, Alzheimer's disease, cataract, diabetes, and muscular dystrophy have implicated a role for calpains in their pathogenesis. We previously identified *CAPN5* (calpain-5) as the causative gene for retinal degeneration and autoimmune uveitis in human patients with Autosomal Dominant Neovascular Inflammatory Vitreoretinopathy (ADNIV). To understand the molecular and genetic mechanisms of ADNIV, a human *CAPN5* disease allele was expressed in mouse retinas using a lentiviral vector. Mouse *Capn5* DNA sequence, RNA expression, and protein expression was compared to *CAPN5* in the human retina. Lentiviral vectors were created to express either the wild-type human (*h*) *CAPN5* or the ADNIV mutant *hCAPN5-R243L* allele under a rhodopsin promoter with tandem green fluorescent protein (GFP) expression. Vectors were injected into the subretinal space of perinatal mice, and expression was determined by autofluorescent imaging. Mouse phenotypes were analyzed using electroretinography, histology, and inflammatory gene expression profiling. Mouse calpain-5 shows high homology to its human ortholog with over 98 percent sequence identity that includes the ADNIV mutant residue. In correlation with human expression, *Capn5* RNA was detected in mouse retina. Calpain-5 protein was expressed in the inner and outer segments of both rod and cone photoreceptors and in the inner plexiform layer. Live imaging of the lentiviral GFP reporter showed good uptake and distribution throughout the retina. Electroretinography, retinal histology, and expression of inflammatory genes indicate the *CAPN5-R243L* allele elicits an ADNIV-like disease in mice. Taken together, our studies suggest that ADNIV is due to a *CAPN5* gain-of-function, and retinal expression may be sufficient to generate an autoimmune response. Moreover, genetic models of ADNIV can be developed in the mouse and serve as pre-clinical models for therapeutic testing. Further elucidation of the pathogenic mechanism of *CAPN5* in ADNIV, by examining the effects of *hCAPN5* compared with *hCAPN5* including the single amino acid change R243L, will provide important new insight into causes of irreversible human blindness.

2896F

A primary cell culture model to study an inherited macular degeneration, DHDR/ML. *R. Fernandez-Godino, D. Garland, E. Pierce.* Ophthalmology, Ocular Genomics Institute- MEEI-Harvard Medical School, Boston, MA.

The p.Arg345Trp mutation in the *EFEMP1* gene causes the inherited macular degeneration Doyne Honeycomb Retinal Dystrophy/ Malattia Leventinese (DHRD/ML). The hallmark of DHRD/ML is the formation of drusen at an early stage. Gene targeted *Efemp1*$^{R345W/R345W}$ knockin mice develop extensive basal deposits which are considered precursors to drusen. In previous studies using *Efemp1*$^{R345W/R345W}$:complement *C3*$^{-/-}$ double mutant mice we demonstrated a critical role for complement system in the formation of the basal deposits. The purpose of this study was to use a primary RPE cell culture system to investigate the mechanisms involved in the pathogenesis of basal deposit formation in the *Efemp1*$^{R345W/R345W}$ mutant mice and the role of the complement system in this process. Primary RPE cells from wild type, *Efemp1*$^{R345W/R345W}$ knockin, and *Efemp1*$^{R345W/R345W}$:*C3*$^{-/-}$ double mutant mice were grown on a permeable support under polarizing conditions. Cell phenotype was characterized by electron and fluorescent microscopy. Expression levels of complement genes and *Efemp1* were quantified by qRT-PCR. Protein expression in the RPE cultures was determined by western blot analysis and immunofluorescence using confocal microscopy. As demonstrated by results of qRT-PCR experiments RPE cells from each strain express the following complement components and factors: *C1q, C2, C3, C4, Cfb, Cfd* and *Cfh*. Moreover, the expression of *C3* was significantly higher in *Efemp1*$^{R345W/R345W}$ knockin cells (ANOVA, p=0.0218) than in wild type. Electron micrographs showed that RPE cells from *Efemp1*$^{R345W/R345W}$ knockin but not from wild type or double mutant *Efemp1*$^{R345W/R345W}$:*C3*$^{-/-}$ mice secrete deposit-like material *in vitro*. Immunostaining of the deposits revealed that EFEMP1, C3 and other complement components colocalize in the deposits. The primary RPE cell culture system recapitulates *in vivo* observations. The primary RPE cell culture model is capable of reproducing deposit formation *in vitro*, which provides an excellent approach to investigate the very early effects of the *Efemp1* mutation on RPE dysfunction. The results suggest that complement expressed locally by the RPE is important in basal deposit formation in *Efemp1*$^{R345W/R345W}$ mutant mice. This model may be a useful system to test drugs, such as complement inhibitors, to prevent basal deposit formation in inherited macular degeneration as well as the more common age-related macular degeneration AMD.

2897W

Inactivation of the *miR-183/96/182* cluster gene results in syndromic retinal degeneration. *S. Xu[1,2,3], S. Lumayag[1,2,3], C.E. Haldin[1,2,3], N.J. Corbett[3], K.J. Wahlin[4], C. Cowan[1,2,3], S. Turturro[1,2,3], P.E. Larsen[5], P.D. Witmer[6], D. Valle[6], D.J. Zack[4], D.A. Nicholson[3].* 1) Pharmacology; 2) Ophthalmology; 3) Neurological Sci, Rush Univ Med Ctr, Chicago, IL; 4) Wilmer Eye Institute, The Johns Hopkins University School of Medicine, Baltimore, MD; 5) Biosciences Division, Argonne National Laboratory, Lemont, IL; 6) McKusick-Nathans Institute of Genetic Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD.

The *miR-183/96/182* cluster is highly expressed in the retina and other sensory organs. To uncover its in vivo functions in the retina, we generated a knockout mouse model, designated as *miR-183C*$^{GT/GT}$, using a gene-trap embryonic stem cell clone. Our results showed that inactivation of the cluster resulted in early-onset and progressive synaptic defects of the photoreceptors, leading to abnormalities of scotopic and photopic ERGs with decreased *b*-wave amplitude as the primary defect and progressive retinal degeneration. In addition, inactivation of the *miR-183/96/182* cluster resulted in global gene-expression changes in the retina, with enrichment of genes important for synaptogenesis, synaptic transmission, photoreceptor morphogenesis and phototransduction, suggesting that the *miR-183/96/182* cluster plays important roles in postnatal functional differentiation and synaptic connectivity of photoreceptors. Our data suggest that the *miR-183/96/182* cluster is a new candidate gene for inherited retinal degeneration and susceptibility gene for age-related retinal dysfunction/degeneration. Although the phenotypes and molecular changes in *miR-183C*$^{GT/GT}$ mice are not a perfect match for any known human disease, mutation-negative Usher syndrome-like patients would be good candidates for *miR-183/96/182* loss-of-function mutations. Studies on genetic variation or polymorphisms around the *miR-183/96/182* gene are warranted in patients with age-related, progressive retinal and/or multiple sensory defects, and other neurological conditions.

2898T

The Dhtkd1 Tyr486* knock-in mouse model recapitulates some phenotypes of Charcot-Marie-Tooth disease type 2Q. *M. Gu[1], W. Guo[1], C. Luan[1], Z. Yu[1], Y. Chen[1], S. Dang[1], Y. Kuang[2], Z. Wang[1,2,3].* 1) Department of Medical Genetics, Shanghai Jiao Tong University School of Medicine (SJTUSM), Shanghai 200025, China; 2) Research Center for Experimental Medicine, Rui-Jin Hospital at SJTUSM, Shanghai 200025, China; 3) Shanghai Research Centre for Model Organisms, Shanghai 201203, China.

Charcot-Marie-Tooth disease (CMT) or peroneal muscular atrophy is one of the most common inherited neurological disorders with a prevalence estimated at 1/2500. On the basis of clinical manifestation and electrophysiological properties, CMT has been divided into four main types: CMT1, CMT2, CMT4 and CMTX. CMT2 is an axonal peripheral neuropathy characterized by distal muscle weakness and atrophy, normal or near-normal nerve conduction velocities. Our previous study demonstrated that the nonsense mutation [c.1455T→G (p.Tyr485*)] in exon 8 of DHTKD1 (dehydrogenase E1 and transketolase domain containing 1) was one of disease-causing genes in CMT2 subtype which had been named as CMT2Q (MIM 615025), implicating a significant role for DHTKD1 in the neurological development and mitochondrial energy production (AJHG, 2012, 91: 1088-1094). To identify the molecular mechanisms of mutant DHTKD1 causing CMT2Q, we generated a knock-in mouse model for the Tyr486* mutation in the Dhtkd1 gene. At first, we evaluated the gene expression, energy production and apoptosis of the mutant Dhtkd1 gene in the positive ES cell clones. We found that the gene expression and ATP production were significantly decreased in the heterozygous ES cells. Moreover, mutant cells became easier to apoptosis than wild-type cells under hydrogen peroxide (H_2O_2)-induced oxidative stress. Then, the phenotypes were observed among wild-type mice, heterozygous mice and homozygous mice from two heterozygous parental mice. The results showed the homozygous knock-in mice did not appear embryonic lethality or developmental abnormalities. The sciatic nerve and peroneal muscular of mutant mice at eight month of age also did not appear significant pathological changes. However, we found the ATP production in homozygous mice liver was obviously lower than that of the heterozygous and wild-type mice. The ratio of $NADP^+$/NADPH in homozygous and heterozygous mice was obviously higher than that of wild-type mice. These data demonstrated that nonsense mutation of Dhtkd1 gene led to decline in metabolic capacity in mice. We also found the response for hot in homozygous mice significantly slower than that of in heterozygous and wild-type mice. Taken together, we indicated that the Dhtkd1 Tyr486* knock-in mouse model recapitulated some phenotypes of CMT2Q. Further in-depth studies are underway.

2899F

Comprehensive characterization of a zebrafish model for pseudoxanthoma elasticum reveals a role for the abcc6 transporter in cardiovascular development. *M.J. Hosen[1,2], O. Vanakker[1], A. Willaert[1], P. Coucke[1], A. De Paepe[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Dept. of Genetic Engineering and Biotechnology, Shahjalal University of Science and Technology, Sylhet, Bangladesh.

Pseudoxanthoma elasticum (PXE) is characterized by elastic fiber calcification and fragmentation, resulting from ABCC6 mutations. Recently, up-regulation of the pro-osteogenic BMP2-RUNX2 pathway was demonstrated in patients. Also, recent reports on vascular malformations in patients suggested a possible developmental role for ABCC6. We used 4 zebrafish (ZF) models, targeting 3 abcc6 isoforms and combined knock-down, to assess the developmental phenotype, mineralization and mineralization-associated pathways. In-situ hybridization demonstrated all isoforms to be mainly expressed in the pronephric ducts. Abcc6 knock-down was obtained by injecting translational blocking or splice junction morpholinos (MOs) of abcc6 in 1-4 cell stage embryos. To avoid non-target-related phenotypes due to apoptosis, co-injection of an anti-p53 MO along with the experimental MO was performed. Morphants exhibited a delay in gastrulation. At 3 days post fertilization (dfp), curving and shortening of the tail, variable in severity, pericardial edema, decreased mobility, total body length and body pigmentation as well as underdevelopment of head and eyes were observed. Cardiovascular evaluation, using MO injection on Fli:gfp embryos demonstrated the development of abnormal rudimentary tubular heart with decreased heart beat and blood flow compared to controls, contributing to early demise of the morphants. Further, underdevelopment and delayed sprouting of multiple vessels was noted. Calcein staining of the morphants (5dpf) showed advanced skeletal mineralization compared to controls. QPCR analysis revealed up-regulation of bmp2a, runx2a and msxc. We illustrate a distinct phenotype, affecting longitudinal growth, eye and cardiovascular development. The cardiovascular underdevelopment in the morphants corroborates the hypothesis that ABCC6 may also have an embryological role. Advanced mineralization and confirmation of BMP2-RUNX2 involvement suggest that ZF is a useful model organism for further PXE cell signaling research.

2900W

Impaired viability of muscle precursor cells in muscular dystrophy with glycosylation defects and amelioration of its severe phenotype by limited gene expression. *K. Kobayashi[1], M. Kanagawa[1], C.C. Yu[1], C. Ito[1], S.I. Fukada[2], T. Chiyo[3], T. Okada[3], S. Takeda[3], T. Toda[1].* 1) Neurology/Molecular Brain Science, Kobe Univ Grad Sch Medicine, Kobe, Japan; 2) Molecular and Cellular Physiology, Osaka Univ Grad Sch Pharmaceutical Sciences, Osaka, Japan; 3) Molecular Therapy, National Institute of Neuroscience, NCNP, Tokyo, Japan.

A group of muscular dystrophies, dystroglycanopathy, is caused by abnormalities in post-translational modifications of dystroglycan (DG). To better understand the pathophysiological roles of DG modification and to establish effective treatment for dystroglycanopathy, we generated 2 distinct conditional knock-out (cKO) mice for *fukutin*, the first dystroglycanopathy gene identified for Fukuyama congenital muscular dystrophy. The first dystroglycanopathy model~myofiber-selective fukutin-cKO (MCK-fukutin-cKO) mice~showed mild muscular dystrophy. Forced exercise experiments in presymptomatic MCK-fukutin-cKO mice revealed that myofiber membrane fragility triggered disease manifestation. The second dystroglycanopathy model~muscle precursor cell (MPC)-selective cKO (Myf5-fukutin-cKO) mice~exhibited more severe phenotypes of muscular dystrophy. Using an isolated MPC culture system, we demonstrated that defects in the fukutin-dependent modification of DG lead to impairment of MPC proliferation, differentiation, and muscle regeneration. These results suggest that impaired MPC viability contributes to the pathology of dystroglycanopathy. Since our data suggested that frequent cycles of myofiber degeneration/regeneration accelerate substantial and/or functional loss of MPC, we expected that protection from disease-triggering myofiber degeneration provides therapeutic effects even in mouse models with MPC defects; therefore, we restored fukutin expression in myofibers. Adeno-associated virus (AAV)-mediated rescue of fukutin expression that was limited in myofibers successfully ameliorated the severe pathology even after disease progression. In addition, compared to other gene therapy studies, considerably low AAV titers were associated with therapeutic effects. Our findings indicated that fukutin-deficient dystroglycanopathy is a regeneration-defective disorder, and gene therapy is a feasible treatment for the wide range of dystroglycanopathy even after disease progression.

2901T

Mutations in Sonic hedgehog signaling pathway predispose to fatty liver. *A.F. Martinez[1], R.J. Lipinski[2], M. Guillen-Sacoto[1], S.K. Hong[1], J.L. Everson[3], K.K. Sulik[3], N.S. Trivedi[4], A.G. Elkahloun[5], B.D. Solomon[1], M. Muenke[1].* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Dept. of Comparative Biosciences, School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI; 3) The Bowles Center for Alcohol Studies, University of North Carolina, Chapel Hill, NC; 4) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 5) Cancer Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Holoprosencephaly (HPE) is a severe genetic disorder that affects forebrain and craniofacial development. Several developmental factors implicated in HPE belong to or interact with Sonic hedgehog (Shh) signaling as the central pathway affected in this disorder. In our clinical studies we observed a significantly higher prevalence of fatty liver in HPE patients and unaffected carrier relatives (pediatric: p=0.0023, adult: p=0.0135) compared to the general population. While typically quiescent in the adult healthy liver, the Shh pathway becomes active in alcoholic and non-alcoholic fatty liver disease. The gene-environment studies described here explored the effect of Shh pathway mutations on liver metabolism using a mouse model of fatty liver disease. Along with their wild-type (WT) littermates, heterozygous knockout mice for *Gli2* (a proximal Shh signaling mediator) were fed a high-fat (HF) or a control diet for 12 weeks and their livers removed for gene expression profiling. All animals fed the HF diet showed an increase in body mass and liver steatosis, but $Gli2^{+/-}$ mice gained more weight and showed higher steatosis scores compared to the WT mice. $Gli2^{+/-}$ mice fed the control diet showed a differential expression of genes involved in carbohydrate and lipid metabolism, immune function, oxidative stress and cell cycle regulation, which suggests these mutants have an inherent metabolic defect impacting liver function. Top molecules include *Ctse, Taf1d, Gadd45g, Snora74a, Lcn2, Hsph1, Sult2a1, Sult2a2, Cyp3a5, Cyp2c9, Rnf186, Pdk4 and Rsad2*. Shh pathway genes did not show significant differences in gene expression. Though both $Gli2^{+/-}$ and WT mice fed the HF diet showed changes in genes involved in the same cellular processes, the $Gli2^{+/-}$ mice revealed a higher number of genes and genes associated with more advanced stages of liver disease. These results have key implications for the management of HPE patients and their families. A simple abdominal ultrasound may help identify possible mutation carriers in families with history of HPE. Future studies will involve complete metabolic/endocrinological profiling and histological evaluation of the hypothalamic/pituitary axis of the $Gli2^{+/-}$ mice, and the study of additional animal models (currently, $Shh^{+/-}$ mice). Our ultimate goal is to identify genetic risk factors for idiopathic fatty liver in the general population, a longstanding clinical problem posing a heavy burden on the healthcare system worldwide.

2902F

Imaging disease states using mouse models. *S. Rockwood, M. Osborne, M. Lessard, M. Sasner.* Genetic Resource Science, The Jackson Laboratory, Bar Harbor, ME.

The mouse is a widely used model organism well-suited for the study of mammalian development and physiology, and for elucidating details of disease mechanisms. Recent advances in genetic engineering have greatly expanded the options available to researchers to precisely label specific cellular subsets. The Jackson Laboratory (JAX) Mouse Repository, as part of its mission, facilitates the access of these valuable mouse strains to the research community. The approaches used in designing these genetically engineered mice incorporate both constitutive and inducible strategies, affording researchers a great deal of flexibility in controlling spatial and temporal expression. Numerous models employ a promoter with a well-characterized expression pattern, driving transcription of a reporter molecule. Among this growing set are GFP-expressing reporter lines developed by the Allen Institute for Brain Science (AIBS), various lacZ-expressing lines, and the latest generation of the well-known multi-colored 'Brainbow' models. The 'Confetti' strains are similar in concept to 'Brainbow' lines with the difference being that they can be expressed in any tissue and cell type. A large number of strains that express cre in the brain are available, including sets generated by the NIH Neuroscience Blueprint Cre Driver Network and the AIBS. The cre activity patterns for many of these strains have been characterized in a comprehensive manner at AIBS and JAX. The cre portal database (www.creportal.org) facilitates identification of an appropriate cre-expressing line by providing tools to search by promoter gene or by the anatomical site of expression. In combination with the wide array of cre reporter lines available, these resources enable the user to label the tissue/cell subsets of choice with the preferred fluorescent or other reporter molecule by simply mating the appropriate cre-expressing and cre-reporter lines. These alleles can be used in conjunction with existing mouse models of human disease to address translational questions by providing a way to better image tissues involved in disease pathologies.

Donating a strain to the Jax Mouse Repository is an easy way to fulfill the NIH's requirements for sharing mice. Researchers wishing to have strains considered for inclusion in the Repository are encouraged to submit their strains at: **www.jax.org/donate-a-mouse**.

The cDNA expression pattern in the brain of Long Evans Cinnamon rat, the animal model of Wilson disease. *G. Kim[1], B. Lee[1,2], J. Kim[1], J. Kim[1], S. Heo[1], M. Kang[1], J. Choi[2], H. Yoo[1].* 1) Med Gen Clinic & Lab, Asan Med Ctr, Seoul, South Korea; 2) Dept. Pediatrics, Asan Med Ctr, Seoul, South Korea.

Wilson's disease (WD; OMIM #277900) is one of the most common inborn metabolic disorders, which is caused by a deficiency in the P-type Cu-transporting ATPase (ATP7B). The pathogenic process of WD begins in the liver because ATP7B is primarily expressed in the liver, where it plays a central role in the regulation of intracellular Cu metabolism. As the pathogenic process progresses, the injuries widely extend to extrahepatic tissues, particularly the brain, and the neurological manifestations usually follow those of the liver in an age-dependent manner. The brain damage in WD is expected to be related to diverse molecular processes, including Cu-related toxicity, but the majority of the underlying mechanisms remain elusive. The study investigated the gene expression profiles using RatRef-12 bead array with the brains of WD animal model Long-Evans Cinnamon (LEC) rat at 24 weeks of age in order to identify the important early molecular changes that underlie the development of neurological symptoms in WD. Biological ontology-based analysis revealed diverse altered expressions of the genes related to copper accumulation. Of particular interest, we found altered expression of genes connected to mitochondrial respiration (Sdhaf2 and Ndufb7), calcineurin-mediated cellular processes (Ppp3ca, Ppp3cb, and Camk2a), amyloid precursor protein (Anks1b and A2m) and alpha-synuclein (Snca). In addition to copper-related changes, compensatory upregulations of Cp and Hamp reflect iron-mediated neurotoxicity. Of note, reciprocal expression of Asmt and Bhmt is an important clue that altered S-adenosylhomocysteine metabolism might underlie brain injury in WD, which is directly correlated to the decreased expression of S-adenosylhomocysteine hydrolase in hepatic tissue in LEC rats. This study indicates that diverse molecular changes, both variable and complex, underlie the development of neurological manifestations in WD. Copper-related injuries were found to be the principal pathogenic process, but iron (Fe)- or adenosylhomocysteine-related injuries were also implicated.

2904T

Dube3a expression levels affect axonal propagation and resting potential in fly models of Angelman syndrome and Duplication 15q autism. *L. Reiter[1,2], C. Valdez[1], R. Scroggs[2].* 1) Dept Neurology, UTHSC, Memphis, TN; 2) Dept of Anatomy and Neurobiology, UTHSC, Memphis, TN.

Changes in UBE3A expression levels in neurons can cause neurogenetic disorders ranging from Angelman syndrome (AS) (decreased levels) to 15q duplication autism (increased levels). Here we investigated the effects on neuronal function of varying UBE3A levels using the *Drosophila* neuromuscular junction as a model for both of these neurogenetic disorders. Stimulations that evoked excitatory junction potentials (EJPs) at 1 Hz intermittently failed to evoke EJPs at 15 Hz in a significantly higher proportion of Dube3a over-expressors (*C155*-GAL4>UAS-*Dube3a*) relative to controls (*C155*-GAL4 alone). However, in the Dube3a over-expressing larval neurons with no failures at 15 Hz, there was no difference in EJP amplitude at the beginning of the train, or the rate of decrease in EJP amplitude over the course of the train compared to controls. In the absence of tetrodotoxin (TTX), spontaneous EJPs were observed in significantly more *C155*-GAL4>UAS-*Dube3a* larva compared to controls. In the presence of TTX, spontaneous and evoked EJPs were completely blocked and mEJP amplitude and frequency did not differ among genotypes. These data suggest that over-expression of wild type Dube3a, but not a ubiquitination defective *Dube3a*-C/A construct, compromises the ability of motor neuron axons to support closely spaced trains of action potentials, while at the same time increasing excitability. EJPs evoked at 15 Hz in the absence of Dube3a ($Dube3a^{15b}$ homozygous mutant larvae) decayed more rapidly over the course of 30 stimulations compared to w^{1118} controls, and $Dube3a^{15b}$ larval muscles had significantly more negative resting membrane potentials (RMP). These data suggest that reduced *UBE3A* expression levels may influence factors involved in maintenance of muscle and nerve RMP and neurotransmitter release from motorneurons. Similar affects of under- and over-expression of UBE3A on membrane potential and synaptic transmission may underlie the synaptic plasticity defects observed in both AS and autism.

Dysregulation of inflammatory pathways in a Familial Hemiplegic Migraine 1 mouse model after the induction of cortical spreading depression. *E. Eising[1], B. de Vries[1], R. Shyti[1], L.S. Vijfhuizen[1], L.A.M. Broos[1], N.A. Datson[1], E.A. Tolner[1], P.A.C. 't Hoen[1], M.D. Ferrari[2], A.M.J.M. van den Maagdenberg[1,2].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Department of Neurology, Leiden University Medical Centre, Leiden, The Netherlands.

Familial Hemiplegic Migraine type 1 (FHM1) is a rare monogenic subtype of migraine with aura caused by mutations in the CACNA1A gene. CACNA1A encodes a subunit of voltage-gated CaV2.1 calcium channels that regulate neurotransmitter release in brain synapses. In FHM1 knock-in mouse models these mutations enhance cortical glutamatergic signaling and increase the susceptibility for cortical spreading depression (CSD): a transient wave of neuronal and glial depolarization followed by a prolonged depression of activity that underlies the migraine aura. We used CSD induction as a migraine related trigger to measure gene expression profiles in our FHM1 mouse model under triggered conditions. We induced seven CSDs in the caudal cortex by KCl application onto the dura, which were recorded in the frontal cortex. In sham surgeries NaCl was used instead as it does not induces CSDs. Some 24 hours after surgery, the middle part of the cortex, through which the CSD waves travelled, was isolated and subjected to deep-Serial Analysis of Gene Expression (SAGE) sequencing (a tag-based Next Generation sequencing method for gene expression profiling). Sequencing data was aligned to the mouse genome with Bowtie and analyzed for differential expression using the Bioconductor package EdgeR. Gene expression differences were validated using qPCR. We identified genes differentially expressed; 1) between FHM1 and wild-type mice (genotype effect), 2) between CSD and sham groups (CSD effect), and 3) due to an interaction between genotype and CSD effects (interaction effect). Only few genes showed a genotype effect. The CSD effect comprised more genes, and a gene ontology term analysis identified an enrichment of immune related functions. The largest number of differentially expressed genes showed an interaction effect. Using k-means cluster analysis, we identified a set of genes that showed a CSD effect only in the FHM1 mice. Interestingly, this set is predominantly involved in inflammation and includes a network of interferon-related genes. Whereas the cortical expression profile of our FHM1 mice was previously shown to be relatively stable under basal (untriggered) conditions, numerous gene expression differences were identified between FHM1 and wild-type mice after CSD induction. Our results point towards a stronger immune reaction to CSD in FHM1 mice than in wild-type mice, which highlights a role for disturbed immune function in the pathophysiology of migraine.

2906W

Analysis of the role of GAA repeat expansion instability in Friedreich ataxia pathology in a humanized mouse model. *J. Sarsero[1, 2].* 1) Cell and Gene Therapy, Murdoch Childrens Research Institute, Royal Children's Hospital, Parkville, Victoria, Australia; 2) Department of Paediatrics, The University of Melbourne, Royal Children's Hospital, Parkville, Victoria, Australia.

There is evidence that age-dependent and tissue-specific somatic instability of the GAA repeat expansion may be a determinant of the progressive pathology of Friedreich ataxia (FRDA), and is evident in FRDA patients, FRDA iPS cells and a YAC-based GAA repeat expansion mouse model. Interruptions in GAA repeat sequences can alleviate transcription inhibition and reduce genetic instabilities. We explored the role of instability of the GAA repeat expansion on FRDA pathology using a humanized mouse model containing an interrupted GAA repeat expansion. An interrupted GAA repeat expansion was introduced into the first intron of the human *FXN* gene present on a BAC clone by recombineering. The genomic insert was used to generate humanized transgenic/KO mice. The presence of the introduced interrupted GAA repeat expansion resulted in markedly decreased levels of human *FXN* transcript and frataxin protein in humanized mouse tissues. The region immediately upstream of the interrupted GAA repeat expansion region was found to be almost completely methylated. Somatic instability of the interrupted GAA repeat expansion was not detected using the small pool PCR technique. The assessment of phenotypic symptoms of FRDA by a series of behavioral, neurological, biochemical and histological tests did not reveal any significant phenotypic differences between humanized and wild type mice. The interruption of the GAA sequence contributes to the somatic stability of the repetitive element, which in turn results in the mice lacking an obvious phenotype despite the low levels of *FXN* mRNA and frataxin protein and repressive epigenetic changes.

2907T

Beta-glucosidase 2 (GBA2), which is mutated in inherited spastic paraplegia and cerebellar ataxia, is sensitive to inhibition by conduritol B epoxide. *A.C. van der Spoel[1], C.M. Ridley[1], K.E. Thur[1], N.B. Thillaiappan[2], A.A. Rahim[3], S.N. Waddington[3].* 1) Departments of Pediatrics and Biochemistry & Molecular Biology, Dalhousie University, Halifax, Nova Scotia, Canada; 2) Department of Pharmacology, University of Oxford, Oxford OX1 3QT, UK; 3) Gene Transfer Technology Group, Institute of Women's Health, University College London, London WC1E 6HX, UK.

Genetic diseases caused by defects in the lysosomal degradation of glycosphingolipids are well characterized and their pathophysiologies are increasingly understood. Examples of these lysosomal storage disorders are GM1-gangliosidosis, Sandhoff, Tay-Sachs, Fabry, and Gaucher disease. The latter condition results from deficiencies in glucocerebrosidase, which is an endolysosomal glycohydrolase that cleaves glucosylceramide into glucose and ceramide. Recently, two inherited conditions were found to be caused by defects in the extralysosomal degradation of glucosylceramide. Individuals affected with hereditary spastic paraplegia 46 (SPG46) and autosomal-recessive cerebellar ataxia carried mutations in the β-glucosidase 2 gene (*GBA2*). Similar to glucocerebrosidase, GBA2 cleaves glucosylceramide, but GBA2 is located in the ER and/or at the plasma membrane. GBA2 activity was reported to be drastically reduced in a lymphoblastoid cell live derived from mononuclear white blood cells from an SPG46 patient. Assessment of enzymatic activity of GBA2 is thus clinically relevant. This raises the challenge to distinguish the GBA2 activity from that of glucocerebrosidase, as both β-glucosidases can degrade the same natural and artificial substrates under similar conditions. The first approach proposed to specifically measure GBA2 activity was to use conduritol B epoxide (CBE), which is an irreversible inhibitor of glucocerebrosidase. CBE was thought not to affect GBA2. Nevertheless, we found that CBE irreversibly inactivated GBA2. The extent of GBA2 inhibition depended on the CBE concentration and time of exposure. We propose an alternative strategy to measuring GBA2 activity using *N*-butyldeoxygalactonojirimycin (*N*B-DGJ), which inhibits GBA2, but leaves glucocerebrosidase fully active. Therefore, we redefine GBA2 activity as the *N*B-DGJ-sensitive β-glucosidase. In mouse tissues and cultured cells, the *N*B-DGJ-sensitive β-glucosidase activity was up to 10-fold higher than the CBE-resistant β-glucosidase activity. In fact, instead of representing less than 10% of the total β-glucosidase activity, GBA2 was responsible for the majority of the detergent-independent β-glucosidase activity of most tissues and cell lines. Our results enable a more accurate assessment of GBA2 activity, which will be an asset in evaluating the roles of GBA2 in hereditary disorders, and may be helpful in clinical practice.

2908F

A biological role for impaired BDNF transcription in Familial Dysautonomia. *M. Nilbratt[1,2], G. Lee[3], E. Morini[1,2], S.J. Haggarty[1,2], L. Studer[4], S.A. Slaugenhaupt[1,2].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Institute for Cell Engineering, John Hopkins University, Baltimore, MD; 4) Center for Stem Cell Biology, Memorial Sloan-Kettering Cancer Center, New York, NY.

Familial Dysautonomia (FD), or Riley-Day syndrome, is an autosomal recessive disorder with extensive sensory and autonomic nervous system involvement present at birth. FD is characterized by recurrent episodes of hypertension with tachycardia, nausea and vomiting, impaired thermoregulation, and deceased sensitivity to pain and temperature. The clinical features of FD are due to a genetic mutation in the IKBKAP gene that results in a tissue-specific reduction of IKAP protein. Neuropathological studies show a marked reduction of neurons in the sympathetic and sensory ganglia. All FD patients have an intronic splice site mutation in the IKBKAP gene, the scaffolding member of the Elongator protein complex involved in transcriptional elongation. This mutation results in tissue-specific skipping of exon 20 in the mRNA with aberrant splicing most pronounced in neuronal tissues. The alternative splicing defect leads to reduced production of normal IKAP protein in FD patients. In addition, complete embryonic loss of Ikbkap in mice causes early embryonic lethality, suggesting that this gene is required for effective transcription of genes involved in very early neural development. Neurotrophic factors are implicated in survival and differentiation of several neuronal populations and in the regulation of neurogenesis, synaptic plasticity, learning and memory. Although there is evidence for a role of neurotrophins in various human neuropathies, their relevance to the disease process is not fully understood. Previous studies have indicated reduced neurotrophic activity mediated by nerve growth factor (NGF) in fibroblasts from FD patients. Here we show a functional role of reduced brain-derived neurotrophic factor (BDNF) transcription associated with neurotrophic activity in our induced pluripotent stem (iPS) cell model system of human neural development. We found impaired neurotrophic support from patient fibroblast cells and by inhibition of BDNF activity from normal fibroblasts on the development of iPS cell-derived neurons. Interestingly, the reduced biological activity from patient cells was rescued by increasing the IKAP expression using small chemical compounds. Our data indicate a mechanism underlying FD that may also provide insights for potential new therapeutic interventions.

2909W

Species-specific expression of acidic mammalian chitinase in stomach tissues. *M. Ohno[1], Y. Togashi[1], K. Tsuda[1], K. Okawa[1], M. Kamaya[2], M. Sakaguchi[1], Y. Sugahara[1], F. Oyama[1].* 1) Biotechnology Laboratory, Dept Applied Chemistry, Kogakuin Univ; 2) Enviroment Analytical Chemistry Laboratory, Department of Environmental and Energy Chemistry,Kogakuin Univ.

Two active chitinolytic enzymes, chitotriosidase (Chit1) and acidic mammalian chitinase (AMCase), have been identified in mouse and human, although mammals do not have chitin synthase. Since these chitinolytic enzymes are significantly increased in Gaucher disease and mouse models of asthma, both chitinases have been regarded primarily as a host-defense mechanism against chitin-containing pathogens and/or play important roles in the pathophysiology. Little is known, however, about the mutual regulation of both chitinases between human and mouse. We quantified expression levels of the chitinases to compare the mRNA levels between human and mouse tissues on the same scale using a human-mouse hybrid standard DNA. Our analysis showed that Chit1 mRNA is expressed at similar levels in normal human and mouse lung. On the other hand, AMCase is predominantly overexpressed in mouse but not human stomach. To see whether these mRNA changes are reflecting actual differences in the levels of protein expression, we measured chitinolytic activity at pH 2.0 and pH 5.0 using the synthetic substrate of 4-methylumbelliferyl β-D-N, N'-diacetylchitobiose (4MU-chitobiose) and detected robust chitinolytic activity in mouse stomach extract at pH 2.0 and strong activity at pH 5.0. In contrast, no activity was detected in that of human at pH 2.0 and very low activity was observed at pH 5.0. Furthermore, the anti-AMCase antibodies recognized a robust single protein band in extract from mouse stomach but not from human. Thus, mRNA differences between human and mouse stomach tissues were reflecting differences in the chitinolytic activities and levels of protein expression. Thus, the expression level of the AMCase in the stomach is species-specific.

2910T

Quantitative expression analysis of mammalian chitinases in human and mouse tissues. *F. Oyama, M. Ohno, Y. Togashi, K. Tsuda, K. Okawa, M. Sakaguchi, Y. Sugahara.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Chitinase hydrolyzes chitin, which is an N-acetyl-D-glucosamine polymer that is present in a wide range of organisms, including insects, parasites and fungi. Although mammals do not have chitin synthase, genes encoding chitotriosidase (Chit1) and acidic mammalian chitinase (AMCase) and their translation products have been found in both human and mouse. Recent studies have shown an association between the mammalian chitinases and inflammatory diseases. For instance, Chit1 levels were elevated in the plasma of Gaucher disease and the bronchoalveolar lavage fluid of smokers with chronic obstructive pulmonary disease (COPD). AMCase expression and activity is upregulated in allergic airway responses in mouse models of asthma. Little is known, however, about mutual regulation of gene expression between Chit1 and AMCase in vivo. We established a quantitative PCR system using a single standard DNA and found that both chitinases mRNAs are predominantly expressed in mouse stomach. In stomach, AMCase mRNA is expressed 7-10 fold higher than those of housekeeping genes and expressed comparative level with pepsinogen C (progastricsin) mRNA, a major component of the gastric mucosa. Furthermore, we applied this methodology to the quantification of chitinase mRNAs in human tissues. We found that both chitinase mRNAs were widely expressed in normal human tissues. Chit1 mRNA was highly expressed in the human lung, whereas AMCase mRNA was not overexpressed in normal human stomach tissues. The levels of these mRNAs in human tissues were significantly lower than the levels of housekeeping genes. These results indicate that the Chit1 and AMCase expression levels are relatively low in the human tissues examined and that the AMCase expression level in the stomach differs significantly between human and mouse.

2911F

Molecular basis of a new form of hyperekplexia. *J. Capo-chichi[1,2], S. Boissel[3], E. Brustein[3], F.F. Hamdan[1,4], M. Samuels[1], G.A. Rouleau[4], P. Drapeau[3], J.I. Michaud[1,2].* 1) Centre de Recherche du CHU Sainte-Justine, Montréal, Québec, Canada; 2) Département de biochimie , Université de Montréal,Québec,Canada; 3) Département de pathologie et biologie cellulaire,Université de Montréal,Québec,Canada; 4) Centre de recherche du CHUM, Montréal,Québec, Canada.

Hyperekplexia (HK) is characterized by increased tone with startle reactions inducible upon tactile or auditory stimulations. HK is a genetic condition caused by disruption of glycine signaling in the CNS. Here we report on a consanguineous family from Cambodian origin composed of 4 affected female siblings who, in addition to severe HK, showed small birth weight, microcephaly with simplified gyral structure, and burst suppression on the EEG. They could not breath by themselves and died a few days after birth. We performed homozygosity mapping on all 4 affected siblings followed by exome sequencing on 2 of them and identified, in the shared regions of homozygosity, 1 rare predicted-damaging homozygous mutation in CLPB (p.Ile562fs) that segregated with the disease. CLPB belongs to a subfamily of AAA+ proteins that includes clpb (bacteria) and hsp104/hsp78 (yeast), both of which function in protein disaggregation and resolubilization. Members of this subfamily form homo-hexameric ring. p.I562Ifs truncates the protein upstream of a well-conserved segment that has been shown to be required for hsp104/clpb protein oligomerization. It is thus likely that p.Ile562fs abolishes CLPB function. To investigate the functional consequence of p.I562Ifs, we interfered with the zebrafish ortholog Clpb mRNA translation using a splice-blocking antisense morpholino (AMO). The specificity of the morpholino was confirmed by RT-PCR and western blot. The Clpb KD zebrafish larvae were well formed but presented some morphological deficits (smaller eyes, shorter head and body length) compared to wild-type, non-injected larvae. They also exhibited a motor phenotype characterized by an abnormal touch-evoked response with increased maximum swim velocity and faster tail beat frequency. All larvae co-injected with wild-type human CLPB mRNA and Clpb AMO exhibited restoration of the morphological and motor phenotypes. Conversely, larvae co-injected with mutated human CLPB mRNA and Clpb AMO showed similar morphological and motor deficits to those observed in Clpb KD larvae. These phenotypes due to Clpb KD are reminiscent of the microcephaly, small birth weight and hyperexcitabilty observed in our patients. Taken together, our results suggest that the disruption of CLPB is responsible for the observed HK phenotype.

2912W

A homozygous missense mutation in HSPA9 causes epiphyseal-vertebral-ear (EVE) dysplasia. *J. Amiel[1,2], M. Oufadem[2], A. Linglart[3], D. Lehalle[1], C. Bole[2], P. Nithske[2], A. Munnich[1,2], S. Lyonnet[1,2], C. Gordon[2].* 1) Dept Genetics, Necker Hosp, AP-HP, Paris, France; 2) IMAGINE Institute, INSERM, Paris, France; 3) Pediatric Endocrinology, Bicêtre Hosp, AP-HP, Kremlin Bicêtre, France.

Epiphyseal-vertebral-ear (EVE) dysplasia associates distinctive dysmorphic features and ossification defects. A single family has been reported, with two affected sisters born to healthy, consanguineous parents. Key features were midface hypoplasia, depressed nasal bridge, anteverted nares, symmetrical dysplasia of the helices, epiphyseal dysplasia, mid-coronal clefting of vertebral bodies, odontoid hypoplasia, elbow dislocation and intrauterine growth restriction with post-natal catch-up growth. Similar craniofacial and skeletal features have been noted in cerebral, ocular, dental, auricular, skeletal anomalies (CODAS) syndrome. The genetic causes of EVE and CODAS syndromes have not been reported. We performed exome sequencing of the two affected EVE dysplasia patients, and after filtering for published and in-house SNPs and selecting for deleterious variants, the only deleterious homozygous variant shared between both sisters was the missense mutation p.Thr362Ile in heat shock 70kDa protein 9 (HSPA9). The catalytic activity of HSPA9 is encoded by the ATPase domain, a structure conserved in chaperones from vertebrates to bacteria. Thr362 is absolutely conserved in known orthologues of HSPA9, falls within the ATPase domain and structural modelling of the mutation Thr362Ile indicates disruption of hydrogen bonding, predicted to lead to protein instability. Published transcriptomic data indicates that HSPA9 is highly expressed in human fetal cartilage. This work identifies HSPA9 as a novel regulator of craniofacial and skeletal development, with its mutation causing EVE dysplasia. These findings add specific roles during development to the ones already ascribed to the HSP70 family of chaperones. Whether CODAS syndrome is caused by mutations in HSPA9, a related gene or pathway remains to be explored.

2913T

Autosomal Recessive Congenital Ichthyosis (ARCI) and related disorders: Mutation in *CERS3*, coding for ceramide synthase 3, reveal major puzzle peaces for the understanding of epidermal barrier formation. *K.M. Eckl[1,2], R. Tidhar[3], H. Thiele[4], V. Oji[5], I. Hausser[6], S. Brodesser[7,8], M.L. Preil[9], A. Önal-Akan[2], F. Stock[10], D. Müller[10], K. Becker[2], R. Casper[2], G. Nürnberg[4], J. Altmüller[4], P. Nürnberg[4,8], H. Traupe[5], A.H. Futerman[3], H.C. Hennies[1,2,8].* 1) Center for Dermatogenetics, Innsbruck Medical University, Innsbruck, Austria; 2) Center for Dermatogenetics, Cologne Center for Genomics, University of Cologne, Cologne, Germany; 3) Dept. of Biological Chemistry, Weizmann Institute of Science, Rehovot, Israel; 4) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 5) Dept. of Dermatology, University Hospital of Münster, Münster, Germany; 6) Dept. of Dermatology, University Hospital of Heidelberg, Heidelberg, Germany; 7) Inst. of Med. Krnjaic, Merk, Preil, Schäfer, Ansbach, Germany; 10) Inst. of Human Genetics, University Hospital of Leipzig, Leipzig, Germany.

The barrier function of the human epidermis is supposed to be governed by lipid composition and organization in the stratum corneum. We report on a large German family with multiple consanguinity. The pedigree consists of several branches each with affected and unaffected family members. Using a combined approach of SNP-based autozygosity mapping and exome sequencing in autosomal recessive congenital ichthyosis we identified a homozygous interval of 3.4 Mb on chromosome 15 containing homozygous missense mutations in two genes. Cosegregation analysis pinpointed mutations in *CERS3*, coding for ceramide synthase 3 (CerS3), as underlying the phenotype. Using LC-ESI-MS/MS we demonstrate that the mutation impairs the activity of CerS3, which synthesizes very long chain ceramides in the skin. We show a specific loss of free and bound ceramides with chain lengths from C26 up to C34 in terminally differentiating patient keratinocytes. Reconstructed skin from either healthy control cells or patient fibroblasts and keratinocytes reveals premature epidermal differentiation and a moderate impairment of barrier function in patient skin models. Our findings demonstrate that specific synthesis of very long chain ceramides by CerS3 is a crucial early step for the formation of the epidermal barrier and indicate that disorders characterized by ichthyosis can be attributed to defects in the epidermal metabolism of ceramides and other components of the cornified lipid envelope. With the identification of mutations in *CERS3* a missing link between several genes implicated in congenital ichthyosis has been identified, and we propose a crucial epidermal pathway of the lipid metabolism involving *CERS3* and the ARCI genes *TGM1*, *ALOX12B*, *ALOXE3*, *ABCA12*, *CYP4F22*, but also for *LIPN*, mutated in late onset autosomal ichthyosis; as well as for *FALDH*, *ELOVL4*, *FATP4*, *ABHD5*, which are mutated in syndromic ichthyosis disorders.

2914F

The Centriolar satellite protein AZI1 interacts with BBS4 and is involved in ciliary trafficking of the BBSome. *X. Chamling[1], S. Seo[2], C.C. Searby[4], G.H. Kim[1], D.C. Slusarski[3], V.C. Sheffield[1,2,4].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) Department of Ophthalmology and Visual Sciences, University of Iowa Carver College of Medicine, Iowa City, IA; 3) Department of Biology, University of Iowa, Iowa City, IA; 4) Department of Pediatrics, Howard Hughes Medical Institute, IA.

Bardet-Biedl syndrome (BBS) is a ciliopathy with mutations reported in 17 different genes. Most of the protein products of the BBS genes localize at or near the primary cilium and the centrosome. Near the centrosome, BBS proteins interact with centriolar satellite proteins, and the BBSome (a complex of seven BBS proteins) is believed to play a role in transport of ciliary membrane proteins. However, the precise mechanism by which BBSome ciliary trafficking activity is regulated is not fully understood. We show that a centriolar satellite protein, AZI1 (also known as Cep131), interacts with the BBSome and regulates BBSome ciliary trafficking activity. Furthermore, we show that AZI1 interacts with the BBSome through BBS4. AZI1 is not involved in BBSome assembly, but accumulation of the BBSome in cilia is enhanced upon AZI1 depletion. Under conditions in which the BBSome does not normally enter cilia, such as in BBS3 or BBS5 depleted cells, knock down of AZI1 with siRNA restores BBSome trafficking to cilia. Finally, we show that azi1 knockdown in zebrafish embryos results in typical BBS phenotypes including Kupffer's vesicle abnormalities and melanosome transport delay. These findings associate azi1 with the BBS pathway. Our findings provide further insight into regulation of BBSome ciliary trafficking and identify AZI1 as a novel ciliopathy candidate gene.

2915W

NPHP10 (SDCCAG8) interacts with components of the multi-aminoacyl-tRNA synthetase complex. *K. Weihbrecht[1,2], M. Humbert[1,2], V. Sheffield[1,3], S. Seo[2].* 1) Dept. of Pediatrics, Univ. of Iowa, Iowa City, IA; 2) Dept. of Ophthalmology and Visual Sciences, Univ. of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute, Univ. of Iowa, Iowa City, IA.

Nephronophthisis (NPHP) is a recessive kidney disorder that is the leading cause of early onset, end-stage renal failure. Many proteins mutated in cystic kidney disease have been shown to localize to the primary cilia and centrosomes, providing a coalescing mechanism for NPHP-related ciliopathies (NPHP-RC). Aside from renal failure and kidney cysts, retinal degeneration and dysplasia or degeneration of the cerebellum are also seen in many NPHP-RCs. SDCCAG8 is a nephronophthisis gene (NPHP10), with patients exhibiting retinal and renal abnormalities, obesity, and learning disabilities. Mutations in SDCCAG8 were also found in several BBS patients, making SDCCAG8 the 16th BBS gene (BBS16). However, little is known about the molecular functions of NPHP10 and how loss of NPHP10 function leads to the observed phenotypes. Our goal was to gain insight into the function of NPHP10 by determining its interactors. Here, we show that NPHP10 interacts with components of the multi-aminoacyl tRNA synthetase complex (MSC), including 8 out of 9 aminoacyl tRNA synthetases (ARS) as well as aminoacyl-tRNA-synthetase-complex interacting multifunctional protein 2 (AIMP2). We performed tandem affinity purification using stably transfected HEK293T cells expressing FLAG- and S-tagged NPHP10 and isolated its associated proteins. We further determined that among the MSC components, NPHP10 directly interacts with AIMP2. Co-immunoprecipitation was used to determine interacting domains of these two proteins. Sucrose gradient ultracentrifugation of WT mouse tissues showed that NPHP10 is associated with the MSC in the kidney, brain, and eye, all affected tissues in NPHP10 patients. Lastly, we show that disruption of the MSC through AIMP2 knockdown significantly reduces ciliogenesis. Altogether, these findings suggest that NPHP10 functions through an MSC-mediated mechanism or vice versa, and that the MSC is an important component for ciliary function.

Fragile X Mental Retardation Protein (FMRP) in cell differentiation: The MEG-01 as a new study model. *M. Mc Coy, F. Corbin.* Biochemistry Dept, University of Sherbrooke, Sherbrooke, Quebec, Canada.

Introduction: Fragile X Syndrome (FXS) is the most common form of inherited mental retardation. It is triggered by the expansion of CGG repeats in the 5'UTR of the FMR1 gene, as well as from the methylation of its CpG Island. The latter causes transcriptional silencing of the encoded Fragile X Mental Retardation Protein (FMRP). FMRP is an RNA-binding protein commonly associated with polyribosomes and is thought to play a critical role in the maturation of the synaptic network by repressing translation. Consequently, in the absence of FMRP, deregulated protein synthesis results in the abnormal maturation of neuronal dendritic spines. To investigate the more universal role of FMRP in architecture development during cell differentiation, a new model was established using a megakaryoblastic cell line: MEG-01. **Methods:** MEG-01 cells were activated with PMA and left to differentiate until complete maturation, with the release of platelet-like particles (PLPs). Complementary techniques were employed to study the behavior of FMRP during those changes. In fractionation experiments, cells were lyzed and cellular constituents were separated either by differential ultracentrifugation or on sucrose gradient. Protein content was then revealed by Western Blot analysis. In immunofluorescence experiments, protein expression was analyzed by FACS, while confocal microscopy was performed for subcellular localization and colocalization assays. **Results:** Cell fractionation experiments revealed the redistribution of FMRP and other RNA-binding proteins throughout the cell upon activation. By microscopy, the reorganization of the cytoskeleton and the elongation of filopodial extensions, releasing PLPs was observed. FMRP and other RNA-binding proteins were shown to colocalize with microtubules in the cytoplasmic extensions. **Conclusion:** The regulation of local synthesis appears to be important in the maturation of the cytoplasmic extensions, considering that FMRP and other proteins of the translational machinery accompany mRNPs towards regions of the cell undergoing development. The reorganization of the cytoskeleton and colocalization of mRNPs with microtubules suggests that translational complexes are carried from the core of the cell to filopodial extensions for local synthesis by means of microtubular transport, as is the case in neuronal maturation. FMRP is therefore necessary as part of a complex for regulating the process of maturation of elaborate cellular networks.

2917F

Hypervitaminosis D due to 1,25-(OH)2D-24 hydroxylase (CYP24A1) deficiency causing nephrocalcinosis and nephrolithiasis. *G. Nesterova[1], M. Malicdan[1], T. Sakaki[2], M. Collins[3], D. Adams[4,5], C. Boerkoel[4], W. Gahl[4,5].* 1) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA,; 2) Department of Biotechnology, Faculty of Engineering, Toyama Prefectural University, Toyama, Japan; 3) 3Skeletal Clinical Studies Unit, Craniofacial and Skeletal Diseases Branch, National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD, USA; 4) NIH Undiagnosed Diseases Program, NIH Office of Rare Diseases Research and Human Genome Research Institute, Bethesda, MD, USA; 5) Office of the Clinical Director, National Human Genome Research Institute, NIH, Bethesda, MD, USA.

Background/Objectives: An excess of an active form of Vitamin D1, or 1α,25(OH)2D3, can result in nephrocalcinosis and nephrolithiasis. Nephrolithiasis represents a global health problem with prevalence at 10%; we evaluated the cause of increased 1α,25(OH)2D3 levels in the development of those disorders. Patients and Methods: We measured serum and urine calcium and phosphate, vitamin D metabolites and performed mutation analysis in CYP24A1 gene encoding 1,25$(OH)_2$D-24-hydroxylase in two patients with hypervitaminosis D, nephrocalcinosis or nephrolithiasis enrolled in the National Institutes of Health Undiagnosed Diseases Program. CYP24A1 pathological variants and mutations were evaluated using the dbSNP database and the pathogenicity prediction programs. Results: Both patients exhibited hypercalciuria, low level of 24,25(OH)2D3, elevated 1α,25(OH)2D3, and undetectable activity of 1,25$(OH)_2$D-24-hydroxylase that inactivates 1α,25(OH)2D3. They had biallelic mutations in the CYP24A1 leading to the loss of function of this enzyme. Based upon dbSNP data, the frequency of deleterious biallelic CYP24A1 mutations and variants is estimated to be 1960 per 100,000 in the general population. That would be a significant number contributing to the prevalence of nephrolithiasis . Conclusion/Discussion: We found that CYP24A1 loss of the function mutations is associated with nephrocalcinosis and nephrolithiasis. Our assessment of CYP24A1 gene variants predicted that pathogenic defects in CYP24A1 may account for a significant fraction of nephrolithiasis. Recognition of CYP24A1 deficiency could prompt the recommendation that 1α,25(OH)2D3 levels be determined in such patients and promotes therapy for hypervitaminosis D.

2918W

ARID1B inhibits WNT signaling through interaction with BRG1 and β-catenin. *G. Vasileiou[1], A.B. Ekici[1], S. Uebe[1], J. Behrens[2], A. Reis[1], M.V. Hadjihannas[2].* 1) Inst. of Human Genetics, Universität Erlangen-Nürnberg, Erlangen, Germany; 2) Nikolaus Fiebiger Center, Universität Erlangen-Nürnberg, Erlangen, Germany.

The SWI/SNF chromatin remodeling complex regulates transcription by remodeling chromatin and through interactions with transcriptional regulators. Recently, deleterious mutations in subunits of this complex, which carry enzymatic activity and confer functional specificity, have been found in a diverse spectrum of human cancers, with an overall frequency approaching that of mutations in the p53 oncogene. Likewise, haploinsufficiency due to mutations in various components of the SWI/SNF complex was shown to be a frequent cause of the Coffin-Siris syndrome and intellectual disability. The mechanisms by which mutations in SWI/SNF subunits contribute to cancer and intellectual disability remain poorly understood. Here we show that ARID1B suppresses Wnt/β-catenin signaling and that Wnt/β-catenin target genes are upregulated in intellectual disability patients carrying mutations in ARID1B as compared to normal subjects. We found that ARID1B associates with β-catenin in nuclear puncta through a mechanism involving the SWI/SNF subunit BRG1, a binding partner of both β-catenin and ARID1B. Mutation of ARID1B as seen in an intellectual disability patient leads to partial truncation of its BRG1 binding domain, which reduces the ability of ARID1B to localize β-catenin to nuclear puncta and interferes with the suppressive effect on β-catenin-driven transcription. Aberrant activation of Wnt/β-catenin signaling is a causative feature of many human cancers and has been previously linked to brain development. Our results offer an explanation as to how the tumor suppressive effect of chromatin remodeling complexes is mediated and specifically how mutations in ARID1B lead to some of the clinicopathological features observed in syndromic and non syndromic intellectual disability. Finally, our results indicate that while chromatin remodeling can have both activating and repressive effect on transcription, its repressive function could play an important role in human development and cancer through modulation of developmental/oncogenic pathways.

2919T

Cardiovascular manifestations in a family with GLA nonsense mutation (W162X). *E. Severin[1], C. Dragomir[2], A. Stan[2], G. Sarca[3].* 1) Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania; 2) Genetic Lab, Bucharest, Romania; 3) C. Angelescu Hospital, Bucharest, Romania.

Background: Previous studies reported that different mutations of GLA gene are associated with multiorgan damage. A three-generation Caucasian family with alpha-galactosidase A gene mutation is described. Complete or partial deficiency of alpha-galactosidase A results in the accumulation of globotriaosylceramide in cells throughout the body, leading to severe and progressive cardiovascular manifestations. Despite being recessive X-linked, carrier females are affected by Fabry disease and can express the same cardiovascular symptoms as males. Objectives: To describe and compare cardiovascular findings, to confirm the diagnosis of Fabry disease in male and female family members and to identify the mutation causing variable symptoms of cardiovascular phenotype. Patients and Methods: 2 males and 5 females of the family were enrolled and clinically assessed (including echocardiography); enzyme activity levels were also evaluated. Genomic DNA was isolated from blood samples of all family members and analyzed for GLA gene mutation. Results: Both male patients were found hemizygotes having one copy of GLA gene mutation (c.485G>A) and no enzyme alpha GAL activity. Also, all five females were found carrier of the same mutation and a broader range of residual alpha GAL activity. Despite having the same mutation, they exhibited different cardiovascular phenotypes. One male patient (31-year-old) had no cardiac involvement but his maternal uncle (56-year-old) presented left ventricular hypertrophy, cardiomyophaty and cerebrovascular manifestations. Mild left ventricular hypertrophy and moderate interventricular septum thickening were noticed in females by the third decade of life. None of these females received enzyme replacement therapy (ERT) prior to the study. Conclusions: Cardiovascular abnormalities were described in both male and female family members. Differences between genders were noticed but cardiovascular abnormalities increase with age and alpha GAL deficiency. Early genetic testing should be considered in younger female with a positive family history of Fabry disease. ERT should be instituted at an earlier age, particularly in carrier females with low alpha GAL activity, in order to limit severe expression of Fabry disease.

Analysis of *GH-releasing hormone (GHRH), GHRHR, GH1, PROP1, HESX1* and *GLI2* reveal the etiology of congenital growth hormone (GH) deficiency. *I.J.P. ARNHOLD, M.M. França, M.G.F. Osorio, S. Marui, M.Y. Nishi, L.R. Carvalho, A.P. Otto, F.A. Correa, E.F. Costalonga, A.A.L. Jorge, B.B. Mendonca.* Unidade de Endocrinologia do Desenvolvimento, Laboratorio de Hormonios e Genetica Molecular, LIM42, Divisao de Endocrinologia, Hospital das Clinicas da Faculdade de Medicina da Universidade de Sao Paulo, SAO PAULO, SP, Brazil.

Background: Mutations in transcription factors involved in pituitary organogenesis and in the GHRH-GH axis genes are involved in the etiology of congenital GH deficiency. **Objective:** to diagnose the etiology of congenital GH deficiency by selecting candidate genes based on a) the deficiency of GH alone (isolated GH deficiency, IGHD) or associated to other pituitary hormones (combined pituitary hormone deficiency, CPHD), and b) on magnetic resonance imaging (MRI) studies of the pituitary gland. **Patients and Methods:** Retrospective analysis of genetic results in 207 patients with congenital GH deficiency. GH deficiency was diagnosed by failure to respond to two GH-stimulation tests: clonidine test followed by combined insulin, TRH and GnRH test, which also evaluated other pituitary hormone deficiencies. *GH1, GHRH* and *GHRHR* were studied only in patients with IGHD. *PROP1* was studied in CPHD patients with topic posterior pituitary lobe (PPL). *HESX1* and *GLI2* were studied in patients with IGHD and CPHD irrespective of MRI findings. DNA was extracted from peripheral leukocytes and the coding regions and intronic boundaries of the respective genes were amplified by PCR and sequenced by Sanger method. **Results:** Among 57 patients with IGHD, 8 had homozygous *GH1* mutations, 7 (5 families) homozygous *GHRHR* mutations, all with a PPL in the normal position, but none *GHRH* mutations. Among the 140 patients with CPHD, 11 (9 families) had homozygous *PROP1* mutations, 1 patient a homozygous *HESX1* mutation and 27 patients heterozygous *GLI2* mutations (3 frameshift/stop codon and 24 non-synonymous; 26 CPHD and 18 ectopic PPL). One *GLI2* mutation was associated to GH deficiency in 4 additional family members. In one family *GLI2* mutation was associated to polydactyly and in another to midline facial defects. Holoprosencephaly and septo-optic dysplasia were not present. The pattern of inheritance was autosomal recessive and segregation with phenotype was complete for all genes except for *GLI2* which was autosomal dominant with incomplete penetrance and variable expression. **Conclusion:** Homozygous mutations in *GH1, GHRHR* and *PROP1* explained the etiology of congenital GH deficiency in 13% of patients. Heterozygous *GLI2* variants were the most frequent genetic abnormality (13%) but penetrance was variable. Hormonal testing and MRI of the pituitary are helpful to select candidate genes for the etiology of congenital GH deficiency.

2922T

Somatic mutations in *ATP1A1* and *ATP2B3* lead to aldosterone-producing adenomas and secondary hypertension. *T. Wieland[1], F. Beuschlein[2], S. Boulkroun[3,4], A. Osswald[2], H.N. Nielsen[5], U.D. We started to investigate sporadic endocrine adenomas by sequencing tumor and matched control tissue. Here, we report our investigations in aldosterone-producing adenomas. Primary aldosteronism is the most prevalent form of secondary hypertension and is present in up to 7% of hypertensive individuals. Up to 60% of the primary aldosteronism cases are caused by unilateral aldosterone-producing adenomas (APAs). Recent reports showed that 30-40% of these APAs are caused by mutations in the potassium channel gene *KCNJ5*. To identify further genetic determinants of primary aldosteronism, we performed exome sequencing in APA-tumor and matched control tissue from nine males without *KCNJ5* mutation. We identified multiple somatic variants in two members of the P-type ATPase gene family, *ATP1A1* (encoding an Na^+/K^+ ATPase) and *ATP2B3* (encoding the plasma membrane Ca^{2+} ATPase). We then performed targeted resequencing in 299 additional APAs. The complete collection of APA samples (n=308) contained 16 (5.2%) somatic mutations in *ATP1A1* and 5 (1.6%) in *ATP2B3.* ATPase alterations were predominantly found in males (81%). Mutation-positive cases had significantly higher preoperative aldosterone concentrations (P=0.02) and lower potassium concentrations (P=0.013) compared to cases without mutation. All five identified alterations are either located in the transmembraneous α helix M1 or the juxtaposed α helix M4 in both *ATP1A1* and *ATP2B3.* The recurrence of mutations affecting these highly conserved regions involved in interaction with the transported cations in two paralogs is suggestive of a gain-of-function effect. Functional in vitro studies of *ATP1A1* mutants showed loss of pump activity and strongly reduced affinity for potassium. Electrophysiological ex vivo studies on primary adrenal adenoma cells provided evidence for inappropriate depolarization of cells with ATPase alterations, suggesting cation influx. In summary, gain-of-function alterations in two members of the ATPase gene family result in autonomous aldosterone secretion in roughly 7% of aldosterone-producing adenomas. The same mutational mechanism might be causative for other endocrine tumors. We will present our investigations in further endocrine tumor entities.

2923F

A novel homozygous mutation IVS6+5G>T of CYP11B1 gene of patient with Vietnamese congenital adrenal hyperplasia. *M.T.P. Nguyen[1,2], T.H Nguyen[2], N.D Ngo[1], C.D Dung[1], V.H Nong[2], T.L Nguyen[1], H.H Nguyen[2].* 1) Human Genetics, National Hospital of Pediatrics, Hanoi, Hanoi, Viet Nam; 2) Institute of Genome Research, Hanoi, Vietnam.

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disease which is characterized by a deficiency of one of the enzymes involved in the synthesis of cortisol from cholesterol by the adrenal cortex. More than 90% of CAH cases are due to 21-hydroxylase deficiency (21OHD), whereas 5-8% arise from 11β-hydroxylase deficiency. Mutations in the CYP11B1 gene are the cause of 11β-hydroxylase deficiency. This study performed on a patient with congenital adrenal hyperplasia, with premature development such as enlarged penis, muscle development, high blood pressure, bone age equivalent of 5 years old. Biochemical tests for steroids confirmed the diagnosis of CAH. We used PCR and sequencing to screen for mutations in CYP11B1 gene. Results showed that the patient has a novel homozygous mutation of guanine (G) to thymine (T) in intron 6 (IVS6+5G>T). We analysed this mutation on a MaxEntScan boundary software which showed this mutation could affect the gene splicing during transcription. This CYP11B1 genotype testing is the basis for genetic counseling and prenatal diagnosis in the future.

2924W

Alterations in the PAX8 promoter region cause thyroid dysgenesis.
P. Hermanns[1], M. Morlot[2], M. Donaldson[3], J. Jones[3], P. Pohlenz[1]. 1) Molecular Endocrinology, University Medical Center Mainz, Mainz, Germany; 2) Endokrinologikum Hannover, Centre for Hormone and Metabolic Diseases, Hannover, Germany; 3) 3Department of Child Health, Royal Hospital for Sick Children, Glasgow, Ireland.

Thyroid dysgenesis (TD) is the cause of approximately 80% of patients diagnosed to have congenital hypothyroidism. So far, mutations in five candidate genes (*PAX8*, *TSHR*, *TTF1*, *TTF2* and *NKX2.5*, respectively) have been identified to cause TD. We screened 190 patients with TD for mutations in these genes. Besides previously described and characterized mutations, we detected new so far unreported mutations in the coding regions of *PAX8*, *TSHR*, *TTF1*, *TTF2* and *NKX2.5*. 100 normal individuals did not harbour those mutations. Interestingly, in addition to mutations in the coding region of the known candidate genes we also detected four different base pair exchanges in the *PAX8* promoter region. Very recently, we have found one of these base pair changes in a patient diagnosed with thyroid dysgenesis who was heterozygous for a mutation in the *NKX2.5* gene and heterozygous for a base pair change in the *PAX8* promoter. *In vitro* studies were performed to unravel the mechanisms by which these newly identified promoter base pair exchanges might be causative. Electromobility shift assay (EMSA) studies suggest no specific protein or protein complex binding to the altered promoter elements. Transient transfection studies in different cell lines showed that at least one of these base pair changes leads to a significantly decreased promoter activity and thus to an impaired *PAX8* gene expression. In summary, we identified a new group of *PAX8* promoter sequence alterations that might cause TD. Further studies are needed to prove this hypothesis.

2925T

Shortening the diagnostic odyssey of patients with very early onset inflammatory bowel disease.
S. Drury[1], J. Kammermeier[2,3], L. Jenkins[1], M. Elawad[2], K. Gilmour[4], N. Lench[1], N. Shah[2]. 1) NE Thames Regional Genetics Service, Great Ormond Street Hospital, London, London, United Kingdom; 2) Department of Gastroenterology, Great Ormond Street Hospital for Children, London, WC1N 3JH; 3) Centre for Translational Genomics-GOSgene, UCL Institute of Child Health, London, WC1N 1EH, United Kingdom; 4) Department of Immunology, Great Ormond Street Hospital for Children, London, WC1N 3JH.

Very early onset inflammatory bowel disease (VEO - IBD) results in chronic intractable and therapy resistant inflammation of the gut and severe growth failure. The pervasive nature of the disorder often requires lengthy hospital admission. Despite underlying genetic heterogeneity, clinical presentation is often homogeneous. The differential diagnosis of VEO-IBD includes monogenic conditions with defects in epithelial barrier function, T/B lymphocyte selection and activation and innate and adaptive immune response as well as conditions leading to neutropenia and defective phagocyte killing and hyper- and autoinflammation. We have implemented a next generation sequencing approach to expedite the diagnosis of VEO-IBD patients, by screening 40 genes associated with the disorder. Coverage of the panel overall is 99% at 30x or greater. Thus far 5 positive controls and 6 VEO-IBD patients have been screened. All control mutations were detected and the pathogenic mutation in 1 previously undiagnosed patient has been identified. The subject presented with severe intractable inflammation of the large and small bowel and was diagnosed with autoimmune enterocolitis. Despite lack of diagnosis and due to the severity of the condition the subject has undergone experimental haematopoietic stem cell transplant (HCST), which has a mortality rate of 20%. Subsequent molecular analysis, showed the patient to be a compound heterozygote for mutations in *TTC37* (c.2018G>A p.Gly673Asp and c.2808G>A p.Trp936*), associated with tricho-hepato-enteric syndrome (THES), a very rare disease (1/1,000,000 births). The phenotype of this patient is unlike the characteristic features reported in other cases; thus NGS has enabled a diagnosis of a) a rare disorder not characterised by phenotype alone and b) a genetic test which until now has not been offered clinically. Due to the rarity of THES, it is currently unknown whether HCST is optimal treatment for the condition. Identifying the molecular basis of VEO-IBD has the potential to profoundly affect patient management; e.g. patients with mutations in *IL10* can be successfully treated with HCST. In addition 42 primary immune deficiency genes are also captured with the same panel and analysis can be extended to these genes, offering a comprehensive molecular approach to this complex group of patients. We aim to introduce this extensive genetic screening early on in patient management, to guide medical intervention at the earliest opportunity.

2926F

Patient derived somatic and induced pluripotent stem cells as a model for functional assessment of mutations identified by exome sequencing in congenital diarrheal disorders.
M. Yourshaw[1], A. Vega-Crespo[2], R. Solorzano-Vargas[2], J. Wang[2], S. Stanford[2], C. Sosa[2], S. Nelson[2], J. Byrne[2], M. Martín[2]. 1) Human Genetics, UCLA Geffen School of Medicine, Los Angeles, CA; 2) UCLA Geffen School of Medicine, Los Angeles CA 90024.

Background: Children presenting with intractable diarrhea often have a poor prognosis; after a sometimes fruitless diagnostic odyssey they can end up with prolonged intravenous nutrition and/or intestinal transplant. Morbidity and mortality are high, and medical care costs overwhelming. Our pilot study of the use of whole exome sequencing to diagnose difficult cases of congenital diarrhea found convincing genetic evidence of mutations in genes that are known to cause malabsorptive diarrhea or other conditions, including ADAM17 (inflammatory skin and malabsorptive diarrhea), EPCAM (Tufting enteropathy), MYO5B (diarrhea with microvillus atrophy), NEUROG3 (generalized malabsorptive diarrhea), PCSK1 (PC1/3 deficiency), SI (sucrase isomaltase deficiency), and SLC5A1 (glucose/galactose malabsorption), as well as a number of novel candidate genes. It is now possible to model these disorders in gut epithelium generated from somatic intestinal stem cells and induced pluripotent stem cells (iPSCs). **Methods:** We performed exome sequencing on cases with congenital malabsorptive, secretory, or IBD-like diarrhea having no convincing diagnosis after a conventional medical and genetic workup. To model these disorders we took two approaches: 1) isolate somatic intestinal stem cells from patients' endoscopic biopsies or surgical samples from normal controls, or 2) derive induced pluripotent stem cells (iPSCs) from dermal fibroblasts obtained by skin biopsies, and subsequently direct the iPSCs towards intestinal epithelial fate. We used methods including RNAseq, immunofluorescence, and other assays to assess the functional effect of mutations identified by exome sequencing in patient cell lines, and normal cell lines in which selective genes are depleted using shRNA methods. **Results:** We developed disease-specific somatic intestinal stem cell and pluripotent cells lines, characterized them for reprogramming by assessing their expression of pluripotency markers, their karyotype, and their ability to form representatives of all three germ layers. We have differentiated disease-specific iPSC lines into intestinal epithelium for disease modeling purposes and identified phenotypes caused by mutations in a number of the genes. **Conclusion:** The development of somatic intestinal stem cell and iPSC lines has allowed us to model severe diarrheal disorders within a dish and provides a potential foundation for future personalized cellular therapeutics for digestive system disorders.

2927W

Exome sequencing of a familial trio with a suspected autosomal dominant idiopathic immune deficient syndrome identifies novel candidate mutations in the complement system and two other genes.
R. Golhar[1], J. Liang[2], D. Li[1], C. Kao[1], Y. Guo[1], W. Chen[2], L. Tian[1], F. Wang[1], J. Synder[1], N. Abdel-Magid[1], L. Vazquez[1], B. Keating[1,3,4], J. Zhang[2], H. Hakonarson[1,3,4]. 1) The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) BGI-Shenzhen, Shenzhen 518083, China; 3) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 4) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

We sequenced the exomes of a familial trio with an affected mother and child showing signs of an autosomal dominant idiopathic immune deficient syndrome to determine the potential underlying genetic cause. The affected child suffers from chronic sinusitis, conjunctivitis, constipation, and recurrent skin lesions. The mother suffers from chronic respiratory infections, recurrent bacterial and viral infections. Both probands have a history of bacteremia and maintain a low white-blood cell count during infections without fever. We suspected an autosomal dominant inherited deleterious mutation in one of the Toll-like receptors or within the TLR signaling pathway. The Toll-like receptors detect pathogens by recognizing specific microbial components. Exome sequencing revealed a splice acceptor site mutation in NEMO at chrX:153,792,177 (T>C). The child appeared homozygote, while the mother and father both appeared heterozygote. Knowing the father cannot be heterozygote, we determined the second half of NEMO is duplicated approximately 100kb downstream on the 3' strand. Follow-up Sanger sequencing of NEMO and the NEMO-homolog using long-range PCR show the child has the mutation in both NEMO and the NEMO-homolog, while the father has the mutation in NEMO but not in the NEMO-homolog. As the father is unaffected, this rules out NEMO as a candidate. We performed a more exhaustive variant reduction analysis revealing a novel heterozygote deletion in C2 (chr6:31902193-4, AG) and 2 heterozygote mutations, in LILRB1 (chr19:55143563, A/G) and KIR3DL3 (chr19:55246741, A/T). C2 is part of the classical complement system which interacts with the adaptive immune system to clear pathogens. We suspect the adaptive immune system is attempting to recruit the complement system, however this 2bp deletion renders C2 unable to function resulting in a lack of immune response. LILRB1 is part of the leukocyte immunoglobulin-like receptor family, and is expressed on immune cells. LILRB1 controls inflammatory responses to focus immune response and limit autoreactivity. KIR3DL3 is killer cell immunoglobulin-like receptor expressed by natural killer cells, subsets of T cells and is thought to play a role in regulation of immune response. Both LILRB1 and KIR3DL3 exist in highly variable regions and the genetic variation observed may be normal. All three mutations need further functional validation before we can conclusively attribute them to this idiopathic immune deficient syndrome.

2928T

SNPs associated with cerebrovascular accident in a Brazilian cohort of sickle cell anemia patients.
P.R.S. Cruz[1], G. Ananina[1], F. Menaa[1,2], M.A.C. Bezerra[3], A.S. Araujo[3], G.P. Gil[1], W.M. Avelar[4], F. Cendes[4], F.F. Costa[2], M.B. Melo[1,2]. 1) Center of Molecular Biology and Genetic Engineering (CBMEG), University of Campinas, Campinas, São Paulo, Brazil; 2) Hematology and Hemotherapy Center/HEMOCENTRO, University of Campinas, Campinas, São Paulo, Brazil; 3) Hematology and Hemotherapy Center of Pernambuco (HEMOPE), Recife, Pernambuco, Brazil; 4) Neuroimaging Laboratory, Department of Neurology, UNICAMP, Campinas, São Paulo, Brazil.

Although sickle cell anemia (SCA) results from the homozygosity for a single mutation in amino acid 6 of the β-hemoglobin *locus*, this disease presents high phenotypic heterogeneity. Virtually all organs may be affected by vascular occlusion, with emphasis on the Central Nervous System, where are observed transient ischemic attacks, stroke and cerebral hemorrhage, which affect approximately 25% of patients with SCA. Early identification of patients with sickle cell anemia susceptible to to cerebrovascular accident (CVA) could reduce the risk, possibly preventing the recurrence of infarcts and potentially reducing their incidence. Thus, we proposed to investigate the frequency of Single Nucleotide Polymorphisms (SNPs), using high-density microarrays (Genome-Wide Human SNP Array 6.0) in order to identify genomic regions potentially involved in the increased risk of CVA in sickle cell patients. SCA patients with and without CVA were recruited at two Brazilian centers of hematology: Hemocentro (Campinas, SP) and HEMOPE (Recife, PE). Patients' recruitment and blood collection methods were approved by the Ethics Committee of FCM-UNICAMP (Campinas-SP, Brazil). The genotyping protocol was carried out using Affymetrix® Genome-Wide Human SNP 6.0 Array (Affymetrix Inc., CA, USA) according to manufacturer's recommendations. SNP calling was performed with Affymetrix Genotyping Console software. We filtered SNP data for probe contrast quality (QC call rate > 0.40), excluded individuals with more than 5% of missing genotypes, as well as removed SNPs with call rate less than 95%, minor allele frequency below 5% and/or presenting deviation from Hardy-Weinberg equilibrium. Population structure was assessed by Principal Component Analysis (controlling for linkage disequilibrium) and did not suggest difference in subjects' ancestry. After filtering, the dataset consisted of 26 cases and 25 controls, which together underwent Fisher's exact test for 662,267 autosomal variants. Three intergenic SNPs were associated with CVA (located on chromosome 2, p-value: 4.8e-06; and chromosome 6, p-values: 6.2e-06 and 7.2e-07); chromosome 3 harbored two associated SNPs (on *SLC9A9* gene, p-value: 8.8e-07; and on a lincRNA, p-value: 8.8e-06), while chromosome 14 had a SNP on a serine/threonine kinase (*PRKD1*), suggestively associated to CVA (p-value: 5.3e-07). None of the variants was previously associated with CVA, possibly reflecting the singularity of the Brazilian population.

2929F

Clinical, Immunological, and Molecular Characterization of JAK3 Deficiency causing Severe Combined Immunodeficiency Disease in Saudi Arabia.
A. Hawwari[1], H. Al-Shammari[2], S. Al-Hisi[1], O. A-Smadi[1], H. Al-Dhekri[2], A. Al-Ghonaium[2], S. Al-Muhsen[2], B. AL-Saud[2], R. Arnaout[2], H. Al-Mousa[2,3]. 1) Genetics, Research Center, MBC: 03, King Faisal Specialist Hospital & Research Center, PO Box 3354, Riyadh 11211, Saudi Arabia,; 2) Department of Pediatrics, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; 3) Al-Faisal University, Riyadh, Saudi Arabia.

Molecular defects in IL2Rg gene are the most common genetic cause of T-B+NK- SCID worldwide followed by JAK3. However, no report has been published to describe the genetic defects of T-B+NK- SCID in Saudi Arabia. Due to high consanguinity rate in Saudi society, most cases that we observe in our patient population are mainly due to autosomal recessive pattern of inheritance. Hence, patients with T-B+NK- SCID were screened for mutations in JAK3 gene. Eight patients from 5 families diagnosed with T-B+NK- were screened for mutations in JAK3 gene. The diagnosis of T-B+NK- SCID is based on the profound, characteristic lymphopenia and early clinical presentation of immunodeficiency often with strong family history indicating an autosomal recessive inheritance. Five novel homozygous JAK3 mutations were identified. Three closely related patients (two siblings and a cousin) carry the nonsense mutation (Q305X) ; one patient was found to have a deletion mutation (A338LfsX14) leading to a stop codon 14 amino acid downstream; and two brother patients carry the R403C missense mutation. The remaining two patients carry either E1019K or R103H missense mutations. Contrary to the available data of X-linked IL-2 common gamma chain gene defect of T-B+NK- SCID as the most common, we demonstrate here that in the Kingdom of Saudi Arabia the most common form of T-B+NK- SCID is the autosomal recessive mode of inheritance associated with JAK3 deficiency.

2930W

Likely pathogenic hypomorphic mutation in the perforin 1 gene causing adult-onset familial hemophagocytic lymphohistiocytosis.
L. Massingham[1], J. Walsh[1], N. Shur[1], C. Benson[1], P. Rintels[2], N. Berliner[3], D. Treaba[4], J. Li[4], C. Phornphutkul[1]. 1) Department of Pediatrics, Division of Genetics, Hasbro Children's Hospital and Rhode Island Hospital, Providence, RI; 2) Division of Hematology, Rhode Island Hospital, Providence, RI; 3) Divsion of Hematology, Brigham and Women's Hospital, Boston, MA; 4) Department of Pathology, Rhode Island Hospital, Providence, RI.

Familial hemophagocytic lymphohistiocytosis (FHL) is characterized by fever and hepatosplenomegaly with cytopenias and hyperactivated macrophages and T-lymphocytes. FHL is inherited in an autosomal recessive manner and currently there are five known molecular subtypes (FHL1-5) with overlapping phenotypes. The age of onset is generally in infancy or the first few years of life, but more recently adult-onset FHL has been reported. Distinguishing between FHL and secondary (acquired) hemophagocytic lymphohistiocytosis (HLH) is difficult and treatment recommendations vary considerably. Mutations in the perforin 1 (PRF1) gene account for 80% of patients with FHL. Case: A 30 year old previously healthy man presented with a 2 week history of cough and fever. Initial labs revealed pancytopenia, elevated AST and ALT, low fibrinogen and elevated ferritin. Bone marrow biopsy revealed hypercellularity with megakaryocyte hyperplasia. Flow cytometry did not reveal any T-cell or B-cell clonal populations. IHC staining revealed large clusters of T cells. An extensive infectious evaluation was negative. CT scan revealed splenomegaly and a diffuse pulmonary interstitial infiltrate. He was presumed to have hemophagocytic lymphohistiocytosis and chemotherapy was initiated. A persistently abnormal coagulation profile prompted a repeat bone marrow biopsy, which showed a hypocellular marrow with no clonal populations by T-cell gene rearrangement or B-cell clonality studies. Upon readmission for fever, epistaxis, and pancytopenia, genetics was consulted and FHL testing was sent, which revealed a homozygous change for c.272C>T (p.Ala91Val) in the PRF1 of unknown significance. Conclusion: Our patient meets clinical criteria for HLH and the molecular results support this diagnosis. This missense mutation has been classified by some as a neutral polymorphism, but other functional studies have suggested that the p.Ala91Val variant may be hypomorphic. Our patient's late presentation is consistent with the hypothesis that missense mutations in PRF1 are hypomorphic, whereas, individuals with nonsense mutations typically present much earlier. Studies by the Filipovich group have identified hypomorphic alleles in approximately 15% of adult onset HLH. Molecular results in this patient supports a genetically inherited predisposition to HLH. Unlike acquired HLH, genetic counseling recommendations for patients with adult onset familial hypomorphic HLH is very different.

Ancestry and genetic admixture among sickle cell disease patients in North America.
Z. Wang[1], L. Diaw[1], M. Barr[1], M. Quinn[1], D. Diggs[1], A. Oguhebe[1], D. Darbari[1,2], A. Hutchinson[3], C. Hoppe[4], J.G. Taylor[1]. 1) Genomic Medicine Section, Hematology Branch, NHLBI, NIH, Bethesda, MD, USA; 2) Center for Cancer and Blood Diseases, Children's National Medical Center, Washington, DC, USA; 3) Cancer Genetics Research Laboratory, SAIC-Frederick, Inc., Frederick National Laboratory for Cancer Research, Frederick, Maryland, USA; 4) Oakland Children's Hospital, Oakland, CA, USA.

Genome wide association studies (GWAS) are an important tool for identifying complex human disease loci. An important variable for GWAS is the degree of admixture occurring within study populations. If undetected, admixture can lead to spurious associations, although it may also be exploited as a strategy for mapping by admixture linkage disequilibrium (MALD). As part of our efforts to identify genetic modifiers of sickle cell disease (SCD), we have examined ancestry and genetic admixture in SCD patients living in North America. We first examined ancestry from family histories for 649 adults with SCD recruited to the Bethesda Sickle Cell Cohort Study in the eastern US, where 61% of subjects are African American, 22% African, 12% Caribbean or South American and 1.8% of other origins, suggesting a high degree of population diversity. We further examined these observations with genetic markers by identifying 364 ancestry informative markers (AIMs) from over 4 million SNPs typed in Europeans (CEU) and Yorubans (YRI, Nigeria) available from the Human Haplotype Map. AIMs were typed in 445 of these SCD cohort subjects. Principle components analysis showed African American or Caribbean/South American subjects had the highest degree and a wider range of admixture compared to Africans with SCD or HapMap populations (CEU, YRI and CHB). STRUCTURE analysis showed similar results. We also performed a replication study using 471 anonymous DNA samples from SCD subjects in a western US newborn screen cohort. Similar to the analysis of population ancestry in the Bethesda cohort, the SCD newborns are highly admixed, plotting between YRI and CEU populations. However, the degree of admixture is different when comparing these 2 SCD populations from eastern and western regions of the US. Overall, SCD patients in North America have a high degree of genetic admixture that must be accounted for in candidate gene or GWA studies. Furthermore, the degree of admixture adjustment could vary for SCD subjects from different geographic regions of the US. Finally, these SCD populations may be ideal for mapping by MALD to identify genetic modifiers of this monogenic disease.

Erythropoiesis failure and ribosomal dysfunction in zebrafish model of Diamond-Blackfan anemia.
N. Kenmochi[1], T. Uechi[1], Y. Nakajima[1], G. Yadav[1], T. Sawada[1], M. Ikeda[2]. 1) Frontier Sci Res Ctr, Univ Miyazaki, Miyazaki, Japan; 2) Veterinary Pharmacology Dept, Univ Miyazaki, Miyazaki, Japan.

Ribosomes, the molecular factories that carry out protein synthesis, are essential for every living cell and ribosomal proteins (RPs) play important roles in the formation of a functional ribosome. Defects in ribosome biogenesis have been linked to many human diseases called ribosomopathies, a rare collection of genetic disorders that are associated with increased cancer susceptibility. Diamond- Blackfan anemia (DBA) represents the first and the most extensively studied human disease caused by defects in ribosomal proteins. RPS19 is most commonly mutated in DBA, although some patients show mutations in several other RP genes.

To investigate the molecular pathogenesis of DBA, we have developed a zebrafish model of DBA by knocking down the *Italic rps19* gene in the embryos using a morpholino oligonucleotide (MO). The knockdown embryos displayed a drastic reduction of red blood cells, whereas differentiation of other myeloid cells and endothelial cells seemed to be normal. The anemia phenotype was almost completely rescued by injection of synthesized *rps19* mRNA, but not by mutated mRNAs with patient-type mutations. The DBA model also showed developmental abnormalities in the head and tail regions due to increased cellular apoptosis. Simultaneous inhibition of *tp53* rescued the morphological abnormalities but did not alleviate the erythroid aplasia, suggesting that a TP53-independent but RPS19-dependent pathway could be responsible for defective erythropoiesis in DBA. To evaluate the impact of RPS19 deficiency on mRNA translation, we carried out polysome analyses. The polysome patterns were similar between rps19 morphants and control embryos but the amount of heavier fractions was less in the morphants. Finally, we carried out an RNA-Seq analysis of polysomal mRNAs that were purified from the embryos. We found that translational efficiencies of about 300 genes were significantly changed in rps19 morphants. These data suggest that selected mRNA translation may play an important role for the pathogenesis of DBA.

A family based exome sequence analysis identifies a rare AID deficiency causing mutation enriched in Finland. *L. Trotta[1], H. Almusa[1], M. Lepisto[1], P. Ellonen[1], S. Hannula[1], A. Palotie[1,2], K. Porkka[3], M. Seppanen[4], J. Saarela[1].* 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 3) Hematology Research Unit Helsinki, Department of Medicine, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 4) Immunodeficiency Unit, Division of Infectious Diseases, Helsinki University Central Hospital, Hospital District of Helsinki and Uusimaa. Aurora Hospital, Helsinki, Finland.

Primary immune deficiencies (PIDs) are a large and heterogeneous group of congenital disorders of the immune function due to genetic defects impairing essential branches of the immune system. PIDs predispose affected individuals to increased susceptibility to recurrent and persistent infections and autoimmunity. PIDs are mainly inherited as rare monogenic disorders with more than 200 different genetic etiologies (5670 known mutations in genes with immune function) occurring in ~1:500-10,000 live births, with differences among countries and a much higher prevalence of some disorders in cases with high consanguinity rates or among genetically isolated populations. The molecular mechanisms behind many forms are not yet known and the significant clinical and immunological heterogeneity often delay the diagnosis and make treatment of PIDs challenging. Several cases of PIDs have been described in Finland, and because its unique genetic architecture the Finnish population has been defined as a model population for human genetic studies, especially for monogenic disorders. A founder effect, drifts in subsequent subisolates and rapid regional expansions shaped the gene pool of the population leading to the peculiar enrichment of rare variant responsible for the occurrence of the 'Finnish disease heritage' (i.e. more than 40 rare genetic disorders enriched in Finland). An exome sequencing analysis of a Finnish PID family with 5 affected siblings, characterized by lymphatic hyperplasia, autoimmunity and recurrent respiratory tract infections, as well as missing IgA, IgG, IgE levels and switched memory B cells, led us to identify the p.Met139Thr mutation in the AICDA gene. The gene, previously reported to cause AID deficiency, encodes for a single-stranded DNA-specific cytidine deaminase required for several crucial steps of B-cell terminal differentiation necessary for efficient antibody responses. The identified mutation is a rare variant, not reported in the 1000 Genomes database. We further monitored the frequency of the mutation in ~4000 Finnish individuals with sequence level data (kindly provided by the SISu Consortium) observing it as very rare (0,152%), however 12 fold higher in Finland than in the general European population (NHLBI Exome Sequencing Project data). This suggests an enrichment of the variant in the Finnish population and further studies may provide evidence to merit the disease to be included in the list of 'Finnish disease heritage'.

2934T

Exome sequencing identifies *NFKB2* mutations as a cause of autosomal dominant early-onset common variable immunodeficiency. *K. Chen[1], E. Coonrod[2], A. Kumanovics[2,5], Z. Franks[7], J. Durtschi[2], R. Margraf[2], W. Wu[6], N. Augustine[5], P. Ridge[2], H. Hill[2,3,4,5], L. Jorde[6], A. Weyrich[7], G. Zimmerman[3], J. Bohnsack[1], K. Voelkerding[2].* 1) Dept. of Pediatrics, Allergy & Immunology, University of Utah School of Medicine, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 3) Dept. of Medicine, University of Utah School of Medicine, Salt Lake City, UT; 4) Dept. of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT; 5) Dept. of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 6) Dept. of Human Genetics, University of Utah, Salt Lake City, UT; 7) The Molecular Medicine Program, University of Utah, Salt Lake City, UT.

Common variable immunodeficiency (CVID) is a heterogeneous disorder involving low antibody levels, poor response to antigens, and immune dysregulation. CVID is one of the most common primary immune deficiencies, occurring in approximately 1:10,000 to 1:25,000 people. The genetic defects responsible for CVID have been identified in less than 15% of cases. To investigate the molecular cause of CVID, we studied a family affected by an autosomal dominant form of early-onset CVID. Exome sequencing analysis of four members of this family identified a heterozygous frameshift deletion (c.2563delA; p.Lys855SerfsX7) in the gene that encodes nuclear factor kappa-B2 (*NFKB2*; p100/p52, also known as p100/p49). This mutation is predicted to both truncate the protein and prevent nuclear translocation due to impairment of phosphorylation and proteosomal processing of the C-terminus into the active protein. Using long-range PCR and next-generation sequencing, we then screened for *NFKB2* mutations in a cohort of 33 additional CVID patients and identified a second heterozygous nonsense mutation at the same C-terminal locus (c.2557*C>T; p.Arg853X) in an unrelated CVID patient. All four patients from the two families with *NFKB2* mutations presented with an unusual combination of childhood-onset CVID and adrenal insufficiency. Variant Annotation, Analysis, and Search Tool (VAAST) analysis of the exome sequence data from the index family and an unrelated CVID patient ranked *NFKB2* highest and reached genome-wide significance ($p< 1.56\times10^{-11}$). Western blotting and immunocytochemical analysis of EBV-immortalized B cells from affected subjects demonstrated the presence of mutant NF-κB2 protein and decreased nuclear translocation. NF-κB2 is the principal protein involved in the noncanonical NF-κB pathway, is evolutionarily conserved, and functions in peripheral lymphoid organ development, B cell development, and antibody production. The identification of *NFKB2* mutations will further elucidate the pathogenic mechanisms of CVID and can provide potential targets for treatment. These findings describe the first primary immunodeficiency syndrome caused by a germline mutation in the noncanonical NF-κB signaling pathway.

2935F

Lobar holoprosencephaly (HPE) associated with additional clinical anomalies in two daughters of a consanguineous couple. Comparison of SNP-array analysis results as an attempt to search for a potential causative candidate gene. *P.M. Kroisel[1], B. Plecko[2], M. Brunner-Krainz[3], M.R. Speicher[1], C. Windpassinger[1].* 1) Human Genetics, Medical University of Graz, Graz, Styria, Austria; 2) Department of Pediatrics, University of Zurich, Zurich, Switzerland; 3) Department of Pediatrics, Medical University of Graz, Graz, Austria.

A consanguineous family (both parents are first degree cousins) has five children, three boys and two girls. A lobar holoprosencephaly (HPE) was already diagnosed prenatally in both female pregnancies. Male offsprings are healthy, however one of them shows a mild form of UDP-galactose-4-epimerase deficiency. In the first affected girl by prenatal sonographic investigation HPE was suspected in the 23. gestational week and was confirmed by MRI in the 26. gestational week. Cytogenetic analysis and array CGH performed after birth at term showed normal results but distinct facial features like hypertelorism, a depressed nasal bridge, low set simplified ears and a general increased skin hair density and length were recognized. Beside brain anomalies like the mentioned lobar HPE, a ventriculomegaly and a partial pachygyria was found. Psychomotor development was strongly reduced, and seizures, which became more frequent and severe, finally caused a fatal outcome at an age of 3 years. Her sister, who was born two years later shows a nearly identical clinical phenotype with lobar HPE, very similar facial and skin hair anomalies but also a hypoplastic vermis. Seizures are however clearly less frequent and antiepileptic treatment is more successful. However progress in her neurological development is of course related to her brain anomalies very severely delayed. Cytogenetic and array CGH analysis using a 60k Agilent oligonucleotide array also did not reveal a genomic unbalance or aberration. Based on these findings a monogenic form of HPE appears to be likely in our two patients. At least 14 genes have been implicated in HPE, with 4 major genes including SSH and 10 minor genes. We still had sufficient DNA of the deceased patient and her severely affected sister, who up to now seems to have a slightly better prognosis. Therefore we performed a 250k Affymetrixs SNP-array analysis of both DNA-samples in an attempt by homozygosity mapping and comparison of the results in our two patients to narrow down potential HPE candidate gene regions. By this approach we were able to reduce the number and size of homozygous chromosomal segments shared by both sisters to two chromosomal areas of less than about 2-3 Mb at 10p11 and 11q24. Only to the latter locus a possible minor candidate gene (CDON) has already been mapped. If analysis of this gene would fail to show a homozygous mutation, NGS analysis could be considered to identify a possible new causative gene for HPE.

2936W

Infantile-onset ascending hereditary spastic paraplegia with bulbar involvement due to the novel ALS2 mutation c.2761C>T. *S. Majid[1], R. Abuthuraya[1], K. Ramzan[1], S. Hagos[1], H. Al-Dossari[1], R. Al-Omar[1], H. Murad[2], A. Chedrawi[2], Z. Al-Hassnan[3], S. Bohlega[2].* 1) Department of Genetics, KFSHRC, RIYADH, Saudi Arabia; 2) Department of Neurosciences, KFSHRC, RIYADH, Saudi Arabia; 3) Department of Department of Medical Genetics, KFSHRC, RIYADH, Saudi Arabia.

Mutations in the alsin gene cause three clinically distinct motor neuron diseases, infantile-onset ascending hereditary spastic paraplegia (IAHSP), juvenile primary lateral sclerosis (JPLS), and juvenile amyotrophic lateral sclerosis (ALS2). A total of 23 different ALS2 mutations have been described for the three disorders so far. Most of these mutations are predicted to result in a frameshift leading to premature truncation of the alsin protein. We report the novel ALS2 truncating mutation c.2761C>T detected by homozygosity mapping and sequencing in two infants affected by IAHSP with bulbar involvement. The mutation c.2761C>T resides in the pleckstrin domain, a characteristic segment of guanine nucleotide exchange factors (GEFs) of the Rho GTPase family, which is involved in the overall neuronal development or maintenance. This study highlights the importance of using homozygosity mapping combined with candidate gene analysis to identify the underlying genetic defect as in this Saudi consanguineous family. This study suggests genetic screening and consideration of preimplantation genetic diagnosis in IAHSP families.

2937T

A Mutation in the SCN10A Voltage-gated Sodium Channel Genes Causes a Novel Autosomal Recessive Progressive Neuromuscular Disease and Epilepsy-related Syndrome. *M. Kambouris[1,2], T. Ben-Omran[3,4], Y. Al-Sarraj[1], Y. Bejaoui[1], M. Almuriekhi[3], H. Boulos[1], H. El-Shanti[1,5].* 1) Shafallah Medical Genetics Center, Doha, Qatar; 2) Yale University School of Medicine, Genetics, New Haven CT, USA; 3) Clinical & Metabolic Genetics, Pediatrics, Hamad Medical Corporation, Doha, Qatar; 4) Weill Cornell Medical College, Doha, Qatar; 5) University of Iowa, Pediatrics, Iowa City, IA, USA.

A consanguineous family of Sudanese ethnic origin affected by a putative novel autosomal recessive progressive neuromuscular disease associated with epilepsy was studied by homozygosity mapping and whole exome sequencing of a single affected individual to identify the responsible gene and defect. Clinical characteristics of the two affected siblings include moderate to severe intellectual disability; muscle weakness due to upper motor neuron lesion; -both siblings are non-ambulatory- anhydrosis; recurrent seizures and distinctive facial appearance with prominent forehead, long face & broad nasal bridge. The responsible gene was mapped to four possible intervals genome linkage [[3p, 11p/q, 11q, 14q], as the family structure did not allow the identification of a single interval with a significant LOD score. Whole exome target enrichment sequencing was performed on ABI SOLiD4 for a single-affected individual. A c.C4514T / p.T1505M homozygous mutation affecting a highly conserved amino acid residue was identified in the SCN10A gene -a member of the voltage-gated sodium channel gene family at the 3p22 linkage interval- with damaging effects according to PolyPhen and SIFT protein-modeling software. The variant validated by Sanger sequencing, co-segregates with the disease phenotype within the family and it is absent in 2000 ethnically matched control chromosomes. The affected amino acid residue [1505] is positioned between helices S1 and S2 of domain IV (DIV) of the sodium channel. The mutation is spatially located between the two helices in a putative extracellular position. Since epilepsy is also observed alongside mental retardation and peripheral neuropathy in the mutant SCN10A gene, the mutation probably interferes with normal functioning of this particular sodium channel, resulting in aberrant transmission of nerve impulses. Sodium channels are responsible for the instigation and proliferation of action potentials both in the central and peripheral nervous systems. Mutations, mostly autosomal dominant, affecting sodium channel genes are responsible for a range of epileptic or seizure-related disorders. This is the first autosomal recessive, epilepsy related disease involving a sodium channel gene.

2938F

Duplication of EYA1 causes Branchiootic Syndrome in a Brazilian family. *R. Mingroni-Netto[1], V.G.L. Dantas[1], E.L. Freitas[1], A.M.S.M. Moraes[2], M.C.C. Braga[1], S.B. Ramos[3], C. Rosenberg[1], V.A. Della-Rosa[4].* 1) Centro de Estudos do Genoma Humano, Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 2) Departamento de Medicina, Universidade Estadual de Maringá, Paraná, Brazil. Brazil; 3) Centro Universitário de Maringá, Maringá, Paraná, Brazil; 4) Departamento de Biotecnologia, Genética e Biologia Celular, Universidade Estadual de Maringá, Paraná, Brazil.

Branchiootic syndrome 1 (BOS1; OMIM#602588) is an autosomal dominant disorder characterized by malformations of the outer, middle, and inner ear associated with conductive, sensorioneural, or mixed hearing impairment, branchial fistulae and renal cysts. The penetrance is high, but incomplete and the phenotype extremely variable. A large pedigree with 12 affected individuals presenting with hearing loss and ear malformations was ascertained in the state of Paraná in southern Brazil. After clinical exams and computer tomography (five individuals), malformations of outer, middle and inner ear, auricular and cervical fistulae were detected, albeit without renal abnormalities. Genomic scanning was performed on DNA from 11 affected individuals using 50k microarray technology from Affymetrix (GeneChip® Human Mapping K Array Xba 240). Multipoint lod scores were calculated under an autosomal dominant model with a penetrance estimated to be 90%. Using MERLIN, a peak lod score of 2.6 was obtained for markers in the EYA1 gene region on chromosome 8. Sequencing of EYA1 did not reveal pathogenic mutations. Array-CGH (Oxford Gene Technology, 180k) was then performed with DNA samples from 2 affected individuals and a duplication including the EYA1 gene was detected (hg18 8:72,104,245-72,756,772). No other gene was included in the duplicated segment. In order to confirm this alteration and to investigate the segregation of the duplication, real time PCR was performed. The duplication was present in all 11 affected individuals investigated and absent in the 7 unaffected individuals. Our findings implicate this EYA1 duplication in the BOS1 phenotype observed in this pedigree.

2939W

DNA Copy-Number Variations in Prune Belly Syndrome. *S. Harrison[1], L. Baker[1,2].* 1) Department of Urology, University of Texas Southwestern Medical Center, Dallas, TX; 2) McDermott Center for Human Growth and Development, University of Texas Southwestern, Dallas, TX.

INTRODUCTION: Prune belly syndrome (PBS) is a rare complex of abnormal abdominal wall musculature, urinary tract anomalies, and bilateral cryptorchidism, and is associated with significant morbidity. The cause of PBS is unknown, however a male predominance (95%) and identified families with multiple affected individuals suggests PBS may be an X-linked or sex-limited genetic disease. Disease-causing DNA changes can vary from chromosomal alterations detectable by karyotyping to point mutations detected by DNA sequencing. More recently discovered, copy-number variations (CNVs) are small deletions or duplications that affect the number of copies of a gene. CNVs are missed by DNA sequencing and karyotyping but have been shown to account for previously unexplained genetic diseases by identifying candidate genes or regions involved in various disorders. The purpose of this study was to assess if novel CNVs are present in PBS patients. MATERIALS & METHODS: From 2008-current, blood samples from PBS patients were prospectively tested by whole genome comparative genomic hybridization (CGH) using the array version current (V8.1 or V8.3) at the time of ascertainment (Baylor Medical Genetics Laboratory, Houston TX). When possible, in cases wherein novel genomic CNVs were detected, parental testing (via FISH probes) was performed to identify whether CNVs are de novo or inherited. RESULTS: CGH testing on 12 PBS cases identified 5 (42%) patients with novel CNVs. Two patients have duplication CNVs: one patient has a maternally inherited 0.360Mb duplication on 2q11.2 and one patient has a 0.324Mb duplication on Xq23 of unknown genetic origin. Two patients have deletion CNVs: one patient has a paternally inherited 0.271Mb deletion on 7q31.1 and one patient has a maternally inherited 0.113Mb deletion on Xq22.1. Additionally, one adopted patient has two 0.066-0.151Mb deletions on 6q23.2 and 7q33.2 of unknown genetic origin. CONCLUSIONS: Prune belly syndrome (PBS) is a rare but morbid birth defect and novel CNVs are common in these males (42%). The finding that 2 of the 5 identified CNVs are located on chromosome X supports the hypothesis that PBS is an X-linked genetic disease. Further investigation of these genomic rearrangements may lead to the identification of genetic causes of PBS, thereby aiding prenatal diagnosis and genetic counseling.

2940T

A Mutation at the H2B Histone Family, member W [H2BFWT] gene causes a novel X-linked mental retardation with abnormal head shape syndrome. *V. Chini[1], R. Ali[2], N. Khattab[1], T. Bin Omran[2], Y. Al-Sarraj[1], M. Kambouris[1,3], H. El-Shanti[1,4].* 1) Molecular Genetics, Shafallah Medical Genetics Center, Doha, Qatar; 2) Pediatric Department, Hamad Medical Corporation, Doha, Qatar; 3) Yale University School of MEdicine, Genetics, New Haven CT, USA; 4) University of Iowa, Pediatrics, Iowa City, IA, USA.

A non-consanguineous Arabic family affected by a putative novel seemingly X-linked disease characterized by mental retardation and abnormal head shape was studied by gene mapping, candidate gene mutation screening and whole X chromosome Exome sequencing of a single affected member to identify the responsible gene defect. Clinical presentation includes mental retardation, hyperactivity, hypotonia, turricephaly (in one affected), dolichocephaly (in the other affected), narrow face, downward slanted palberal fissures, large ears, open mouth appearance, long and slender fingers. Neurologic and metabolic evaluations including urine organic acid, lysosomal enzyme analysis, gaunidinocompound, CDG and Fragile-X syndrome were negative. SNP genotyping with the HumanOmniExpress bead chip [Illumina, USA]; analyzed with the GeneMapper software mapped the responsible gene to four possible X-chromosome intervals [p22.33-22.2, p22.2-21.1, p31.1-q22.3, q26.3-28] as the family structure did not allow identification of a single interval with a significant LOD score. Based on the clinical presentation one candidate gene (FGF16) was screened but no pathogenic mutations were identified. Whole Exome target enrichment Next Generation Sequencing for the X chromosome was performed on the ABI SOLiD4 platform for a single affected individual. Three variants were identified within the linkage intervals: AMMECR1 [c.C208T/p.L70F] was excluded as it did not co-segregate with the disease phenotype. A second variant (c.C11T/p.P4L) in the Rab40 GTP-binding protein gene (RAB40AL). Pathogenic mutations within this gene have been associated with Martin-Probst X-linked mental retardation syndrome (MRXSMP) which presents with a different phenotype characterized by hearing loss. The last variant (c.G227A/p.C76Y) at the H2BFWT histone family gene has damaging effects according to PolyPhen and SIFT protein-modeling software, co-segregates to the disease phenotype and is absent in 752 ethnically matched control chromosomes. No known diseases have been associated with mutations in H2BFWT apart from male infertility. Tissue specific H2BFWT expression studies show expression in human fetal brain, making this mutation the likely developmental defect. At present, mutation analyses in additional healthy normal maternal male relatives are underway for the possible exclusion of H2BFWT as the offending gene.

2941F

The Solute Carrier SLC26A9 Accounts for Variability in Biomarkers of Cystic Fibrosis-Related Prenatal Exocrine Pancreatic Damage. *M.R. Miller[1], D. Soave[1,2], W. Li[1,2], T. Chiang[1], J. Gong[1], H. Levy[3,4], L. Sun[2], J.M. Rommens[1,5], F. Accurso[6,7], P. Durie[1,8], M.K. Sontag[7,9], L.J. Strug[1,2].* 1) Research Institute, The Hospital for Sick Children, Toronto, ON, Canada; 2) Biostatistics, University of Toronto, Toronto, ON, Canada; 3) Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 4) Clinical Research Institute, Children's Hospital of Wisconsin, Milwaukee, WI; 5) Molecular Genetics, University of Toronto, Toronto, ON, Canada; 6) Pediatrics, University of Colorado Denver School of Medicine, Aurora, CO; 7) Pediatrics, Children's Hospital Colorado, Aurora, CO; 8) Pediatrics, University of Toronto, Toronto, ON, Canada; 9) Epidemiology, Colorado School of Public Health, Aurora, CO.

In Cystic Fibrosis (CF), exocrine pancreatic damage begins *in utero*. Serum levels of the pancreatic enzyme trypsinogen (IRT) are elevated at birth in CF individuals and form the basis of newborn screening. Postnatally, IRT levels decline rapidly, and reflect pancreatic reserve. IRT levels at birth act as a biomarker of prenatal exocrine pancreatic damage, and are heritable and variable, even in individuals with the same CFTR genotype, indicating a role for modifier genes. On average, IRT is lower in CF individuals with the intestinal obstruction Meconium Ileus (MI). In ~6300 CF individuals from the International CF Gene Modifier Consortium (the Consortium), eight SNPs in three solute carriers, *SLC26A9*, *SLC6A14* and *SLC9A3*, were associated with MI, as was a prioritized gene set corresponding to apical plasma membrane constituents that reside alongside CFTR. We hypothesized that these genetic contributors to MI would be associated with exocrine pancreatic damage, as measured by newborn screened (NBS) levels of IRT. Genome wide data and NBS IRT measures were available on 147 subjects from Colorado and Wisconsin, who were part of the Consortium, but not the MI gene modifier study. Linear regression was used to determine whether any of the eight SNPs in *SLC26A9*, *SLC6A14* and *SLC9A3* were individually associated with IRT. We then used the hypothesis-driven GWAS (GWAS-HD) method (Sun et al. 2012, *Nat Genet 44*:562-9), which uses biologic basis to prioritize genes in GWAS, to determine whether, like MI, constituents of the apical membrane were associated with IRT. SNPs in *SLC6A14* or *SLC9A3* did not provide evidence of association with IRT ($p>0.05$), but all four tested SNPs in *SLC26A9* were significantly associated with IRT after multiple test correction (SNP rs7512462, adjusted $p=3.82 \times 10^{-4}$). Each MI risk allele is associated with a ~53 ng/ml reduction in IRT (95% CI: -81, -28); this SNP explains 11% of the variation in IRT. While not significant at the genome-wide level, the GWAS-HD identified rs7512462 in *SLC26A9* as the top-ranked SNP. The GWAS-HD suggested *SLC26A9* plays the greatest role in exocrine pancreatic damage among all tested constituents of the apical membrane, demonstrating that biologically prioritizing genome-wide data can be a powerful tool in association studies. Together with the previous associations with MI, CF-related diabetes, and reported interaction with CFTR, we propose *SLC26A9* is a therapeutic target to ameliorate CF disease severity.

Anophthalmia and microphthalmia (A/M) are early eye development anomalies resulting in absent or small ocular globes, respectively. A/Ms occur as syndromic or nonsyndromic forms. They are genetically heterogenous with some mutations in some genes responsible for both anophthalmia and microphthalmia. The purpose of this study was to identify the disease gene involved in A/M in a large inbreed Pakistani Family. A combination of homozygosity mapping, exome sequencing and Sanger sequencing, was used to identify the disease mutation in the Pakistani family and to screen the ALDH1A3 gene for mutations in additional unrelated A/M patients. We identified homozygosity for a missense mutation in the gene encoding the A3 isoform of the aldehyde dehydrogenase 1 (ALDH1A3) in the Pakistani family. The screening of the gene is a cohort of A/M patients excluding known A/M genes allowed identifying two additional homozygote ALDH1A3 mutations including another missense change and a splice-site mutation in two consanguineous families. The review of the clinical files of patients showed that patients with ALDH1A3 mutations had A/M with occasional orbital cystic, neurological and cardiac anomalies. ALDH1A3 is a key enzyme in the formation of a retinoic acid gradient along the dorso-ventral axis during the early eye development. Transitory expression of mutant ALDH1A3 cDNAs showed that both missense mutations reduce the accumulation of the enzyme, potentially leading to altered retinoic acid synthesis. While the role of retinoic acid signaling in eye development is well established, our findings provide genetic evidence of a direct link between retinoic acid synthesis dysfunction and early eye development in human.

Congenital myopathy disorders (CMDs) are heterogeneous inherited diseases of muscle characterized by a range of distinctive histologic abnormalities. We have studied a consanguineous family with a non-progressive congenital myopathy. In order to pursue a molecular diagnosis in this family, we performed genotyping on four patients, their parents and a healthy sibling using the Affymetrix GeneChip Human SNP5 array. We determined the genotype calls by using Affymetrix GeneChip Genotyping Analysis Software (GTYPE) and KinSNP software. Based on the consanguinity in the family, we hypothesized homozygosity by descent of a recessive mutation as the likely cause of the disorder. Therefore, we searched for homozygous regions consistent with linkage. Three homozygous blocks (on chromosomes 6, 10 and 14) shared by the three affected individuals, heterozygous in the parents, and not homozygous in the unaffected sib were identified. Exome sequencing revealed a highly suggestive mutation in a gene not previously reported to be associated with myopathy in humans. The variation segregated as expected in the family, it did not appear in dbSNP, evs or the 1000 genome project, nor was it found in 134 Bedouin control individuals.

2945W

Identification of a new locus on chromosome 1 for autosomal dominant retinitis pigmentosa. *K.K. Selmer[1], R. Riise[2], M.D. Vigeland[1], K. Brandal[1], D.E. Undlien[1].* 1) Department of Medical Genetics, Oslo University Hospital and University of Oslo; 2) Department of Ophthalmology, Innland Hospital, Elverum, Norway.

Purpose: The aim of this study was to identify the genetic cause of autosomal dominant retinitis pigmentosa in a large Norwegian family.

Methods: We ascertained 20 members of a Norwegian family with autosomal dominant retinitis pigmentosa in three generations. Maximum possible LOD score was estimated in easyLINKAGE. Peripheral venous blood was drawn and clinical ophthalmological examination performed. We genotyped all 20 individuals using Affymetrix GeneChip® Human Mapping 10K 2.0 array and performed linkage analysis in the software MERLIN. Candidate genes were sequenced using traditional Sanger sequencing.

Results: Assuming full penetrance and no phenocopies, the maximum possible LOD score of this family was estimated to be 3.6. Multipoint linkage analysis revealed a single region achieving this maximum score. The linkage peak spans 5 Mb on the short arm of chromosome 1, and contains more than 100 protein coding genes, of which none are known to cause retinitis pigmentosa. Two candidate genes, the *SLC16A1* and *SLC16A4* were sequenced, but no mutation was identified.

Conclusion: We have identified a new locus for autosomal dominant retinitis pigmentosa on chromosome 1. The linked region is 5 Mb long and contain more than 100 genes. The sequencing of two candidate genes did not lead to the identification of the disease gene.

2946T

Molecular basis of previously uncharacterized mental retardation syndrome. *E. Kaasinen[1,2], E. Rahikkala[3,4], S. Miettinen[3,4], K. Palin[1,2,5], L. Pajunen[3,4], L.A. Aaltonen[3,4].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Haartman Institute, University of Helsinki, Helsinki, Finland; 3) Department of Clinical Genetics, University of Oulu, Oulu, Finland; 4) Department of Clinical Genetics, Oulu University Hospital, Oulu, Finland; 5) The Finnish Cancer Institute, Finland.

We report here a large Finnish family of nine patients with a profound mental retardation syndrome of yet unknown etiology. The family originates from the homogeneous population isolate from Northeastern Finland. Extensive genealogy work revealed that the parents were all distantly related to a common ancestor from the 17th century suggesting a recessive inheritance of a single gene mutation. The clinical features of the patients were not compatible with any previously characterized mental retardation syndrome. The clinical features included also hypotonia, strabismus, retinal pigment atrophy, difficulties to fix the eyes to an object, epilepsy, obesity, joint hypermobility and coarse facial features that develop gradually during childhood. Standard chromosome and array-CGH analysis showed normal results. Also standard metabolic screening including plasma and urine amino acids, urine organic acids and oligosaccharides were normal. We performed whole-genome SNP genotyping with Illumina's HumanOmni2.5 chip from four patients, and whole-genome sequencing with Complete Genomics from one of the four patients included in the SNP genotyping. Homozygous chromosomal regions common in the four patients were combined with variations observed in the whole-genome sequencing data. The longest shared homozygosity was found in 3p22.1-3p21.1 encompassing 11.5Mb. Sanger sequencing of genetic markers revealed that the region was homozygous in all six patients from which we had blood derived DNA available. The parents were healthy heterozygous carriers of the markers, and the homozygous region was segregating with the disease in the family. Single point parametric linkage with SimWalk2 showed logarithm of the odds (LOD) score of 11 for the locus. Four candidate genes (P4HTM, USP4, PCBP4, TKT) within the region had sequence changes that were potentially protein damaging. The changes were found with 0.3-0.7% allele frequencies in 402 whole-genome sequenced controls from Northeastern Finland, and no homozygous were found in these population-based controls, in additional in-house controls or in the 1000 Genomes data. To conclude, we have identified a new mental retardation syndrome and the underlying disease locus. Further functional studies of the candidate genes are needed to show pathogenicity of the identified sequence changes in the locus.

2947F

Novel frameshift mutation of the ADAR1 gene in a Chinese family with dyschromatosis symmetrica hereditaria. *W. Cao[1], J. Zhang[2], X. Chen[3], Z. Zhang[3], H. Wang[2], L. Guo[2], Y. Liu[2], X. Zhao[2], Q. Xing[2], M. Shao[4].* 1) Clinical Research Center, Zhengzhou People's Hospital, Zhengzhou, China; 2) Children's Hospital and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 3) Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 4) Department of Urology, People's Hospital of Henan Province.

Dyschromatosis symmetrica hereditaria (DSH; MIM127400) is a human pigmentary genodermatosis which has been reported predominantly in East Asians. Patients with DSH typically present a mixture of hyperpigmented and hypopigmented macules on the dorsal aspects of the extremities and freckle-like macules on the face. The DSH locus has been mapped to chromosome 1q21.3, and pathogenic mutations were identified in the ADAR1 gene. ADAR1 catalyzes the conversion of adenosine to inosine RNA editing on double-stranded RNA substrates. Human ADAR1 protein includes two translation products due to alternative initiation of transcription: a full-length 150-kDa ADAR1p150 and a shorter 110-kDa ADAR1p110, which is initiated from a downstream AUG at codon 296. In this study, a family with autosomal dominant DSH from Jiangsu province of China was investigated. The pedigree comprised of 13 individuals spanning three generations. The proband was a 9-year-old boy who presented typical hyperpigmented and hypopigmented macules that varied in shape and size on the dorsal aspects of his hands and feet since the age of 5. Direct sequencing of the patient's ADAR1 gene revealed the presence of a novel heterozygous deletion mutation c.271-272delAG (p.R91fsX123) in exon 2. This mutation leads to a frameshift which results in a premature translation peptide consisting of 122 amino acids without translating any functional domains of ADAR1p150 located in exons 2-15. This alteration was not detected in unaffected members or controls. The novel mutation is similar to p.Q102fsX123, p.N205fsX217, p.V211fsX217 and p.H216fsX261 described previously. They all locate and create new stop codons at the upstream of codon 296, thus they cause early stopped ADAR1p150 synthesis in the patients carrying these mutations, but there should be no effect on the synthesis of ADAR1p110 proteins. Moreover, using luciferase reporter assay, for the first time we confirmed that the identified novel mutation has no effect on the synthesis of the p110 protein, although it located in the 5'-UTR of p110. Our data confirmed the dosage of functional p150 is the determinant of DSH.

2948W

Association of genetic marker rs7576183 located downstream of the human Activinβ-B gene with non-syndromic hypodontia. *L.A. Morford[1,2], P.E. DiFranco[1], A.N. Vu[1], K.C. Kirk[2], G. Falcão-Alencar[2], M.S. Gilbey[2], X. Ding[3], D.W. Fardo[3], J.K. Hartsfield, Jr.[1,2].* 1) Dept Oral Health Science, Division of Orthodontics, Univ Kentucky College of Dentistry, Lexington, KY; 2) Center for Oral Health Research, Univ Kentucky College of Dentistry, Lexington, KY; 3) Biostatistics, College of Public Health, Univ Kentucky, Lexington, KY.

Objective: The aim of this case-control study was to determine whether Single Nucleotide Polymorphisms (SNPs) located within or near the Activinβ-A and Activinβ-B genes were associated with non-3rd molar Naturally Missing Teeth (NMT). Materials and Methods: This study was conducted under the approval of the University of Kentucky Internal Review Board for Human Subjects Research. Genomic DNA was isolated from the saliva of 97 orthodontic patients (29 subjects with NMT and 68 controls). The average age ± standard deviation for the subjects with NMT and controls were 16.0 ± 5.5 and 14.5 ± 4.6 years, respectively. Clinical assessment of the dentition, dental histories and radiographic verification were utilized to accurately identify cases of tooth agenesis versus teeth that were missing due to other causes (extractions due to caries, trauma, or orthodontic treatment). Subjects with non-3rd molar NMT were subclassified based on the number of affected teeth as having hypodontia (1 to 6 NMT) or oligodontia (7 or more NMT). Peg-shaped teeth, which represent only partial tooth formation, were also noted. All control subjects exhibited a full complement of adult teeth. Cases of cleft lip and/or cleft palate and other craniofacial syndromes were excluded from the study. The genotypic variation at six SNPs located within or near the Activinβ-A or Activinβ-B genes were assayed using Taqman®-based SNP genotyping. Hardy-Weinberg Equilibrium (HWE) was assessed with the Fisher's test and logistic regression analysis was used for association with significance at $p<0.05$. Results: NMT were identified more frequently in women than men (3.8 to 1). The maxillary lateral incisors were the most common teeth affected by agenesis and/or peg formation, followed by mandibular 2nd premolars and maxillary 2nd premolars. All control genotyping data maintained HWE. The genetic marker rs7576183, located downstream of the ActivinβB gene, was significantly associated with the subjects exhibiting hypodontia ($p=0.033$) under an additive mode of inheritance (MOI). Individuals with hypodontia that were homozygous carriers of the rs7576183 G-allele predominately presented with incisor hypodontia of the maxillary arch. Conclusion: Each rs7576183 A-allele provides a multiplicative reduction of 0.41 (0.17, 0.90) in the odds of hypodontia. Conversely, each copy of the G-allele at rs7576183 confers a 2.44 (1.11, 5.88) increased odds of hypodontia.

2949T

New candidate genes in holoprosencephaly: results from homozygosity mapping in six inbred families. *S. Odent[1,2], M. de Tayrac[2,3], M. Babron[4,5], C. Dubourg[2,3], C. Mouden[3], R. Bouvet[6], S. Gazal[4,5], M. Sahbatou[7], L. Ratié[2], V. Dupé[2], J. Mosser[2,3,6], V. David[2,3].* 1) Genetique Clinique, CHU de Rennes Hosp SUD, Rennes CDX 2, France; 2) UMR 6290 CNRS, IGDR, University Rennes1, Rennes, France; 3) Service de génétique moléculaire et génomique, CHU pontchaillou, Rennes, France; 4) Inserm UMR 946, Genetic variability and human diseases, Paris, France; 5) Institut Universitaire d'Hématologie, Université Paris Diderot, Paris, France; 6) Plateforme Biogenouest, Rennes, France; 7) Fondation Jean Dausset CEPH, Paris, France.

Holoprosencephaly (HPE) is a congenital malformation of the human brain due to an imperfect division of the forebrain during early development. Multiple genetic defects have been identified as involved in this process. It is now currently admitted that HPE is a multihit pathology caused by at least two or more dysfunctional events involving at least 4 major genes (SHH, ZIC2, SIX3 and TGIF) and 10 minor genes belonging to different signaling pathways. However, the mutations and deletions in these genes represent only 30% of HPE cases. Recessive inheritance of HPE can also be suspected in consanguineous families with intrafamilial recurrence. Homozygosity mapping was undertaken in six families with history of consanguineous marriage to search for regions harboring mutations that are identical by descent. Parents and affected children were genotyped on HumanCytoSNP-12 arrays (Illumina). We first determined the population ancestry of each family with OriginMineR [de Tayrac, ASHG 2012] to estimate their specific SNP allele frequencies. Inbreeding coefficients of affected children were estimated from their genomic data by the FEstim method [Leutenegger et al., 2003]. Using the genomic inbreeding coefficient we performed homozygosity mapping without relying on the genealogical information. In parallel we detected the runs of homozygosity across the genome for each individual (PLINK). Three regions of interest were detected by both methods on chromosomes 1, 6 and 10. We applied Endeavor software to prioritize genes in these regions. One of them was previously identified by CGH array on chromosome 6 (DLL1) and other good candidate genes will be presented.

2950F

A frameshift mutation of TBC1D7, a subunit of the TSC1-TSC2 complex upstream of mTORC1, causes a new distinct clinical phenotype with intellectual disabilities. *L. Micale[1], A. Abdullah Alfaiz[2,3], B. Mandriani[1], C. Fusco[1], B. Augello[1], M.T. Pellico[1], J. Chrast[2], L. Zelante[1], A. Reymond[2], G. Merla[1].* 1) IRCCS, Casa Sollievo della Sofferenza Hospital, San Giovanni Rotondo, FG, Italy; 2) Center for Integrative Genomics, Génopode, Lausanne, Switzerland; 3) Swiss Institute of Bioinformatics (SIB), Lausanne, Switzerland.

Mutations in TSC1 or TSC2 cause the tuberous sclerosis complex (TSC), a multisystemic disorder characterized by the development of hamartomas or benign tumors in various organs as well as a high incidence of epilepsy, intellectual disability, and autism. TSC1, TSC2, and TBC1D7 form a complex that inhibits mTORC1 signalling and limits cell growth. Disruption of TBC1D7 has been reported in a family with intellectual disabilities and megalencephaly. Using exome sequencing we identified two sisters with a novel homozygous truncating mutation in TBC1D7: c.18-21delGAGA; p.R7TfsX21. Both siblings are macrocephalic and affected by medium intellectual disabilities. They present myopia, astigmatism, prognathism, osteo-articular defects, behavioural abnormalities, learning difficulties and celiac disease. We assessed the functional consequences of this variant on TBC1D7 mRNA and protein levels in cell lines derived from the affected subjects and their heterozygote unaffected parents. It affects mTORC1 activity, measured by phosphorylation assays of its S6K1 and 4EBP1 substrates and monitoring cellular cell growth and autophagy markers as suggested by the newly described role of TBC1D7 as an upstream regulator of mTORC1. This study reinforces the involvement of TBC1D7 in the regulation of mTORC1 pathway, increases the number and types of TBC1D7 mutations, enlarges the associated phenotypic spectrum, and provide additional proofs about the existence of a new syndrome due to TBC1D7 mutations.

2951W

Exome Sequencing Identifies Novel Genes for Autosomal Recessive Heterotaxy-spectrum Disorders. *A.E. Cast[1], M. Tariq[1], F. Rahim[2,3], M. Jelani[2,4], S.M. Ware[1,5].* 1) Division of Molecular Cardiovascular Biology, Cincinnati children's Hospital Medical center, Cincinnati, OH; 2) Institute of Basic Medical Sciences, Khyber Medical University, Peshawar 25000, Pakistan; 3) Physiology Department Bacha Khan Medical College, Mardan, Pakistan; 4) Princess Al-Jawhara Albrahim Center of Excellence in Research of Hereditary Disorders, King Abdulaziz University, Jeddah 80205, Saudi Arabia; 5) Division of Human Genetics, Cincinnati children's Hospital Medical center, Cincinnati, OH.

Heterotaxy is a rare multiple congenital anomaly syndrome resulting from abnormal left-right (LR) embryonic organ patterning with a prevalence of ~1 in 10,000 newborns. Although heterotaxy is the most highly heritable cardiovascular malformation, the genetic basis is most frequently multifactorial and autosomal recessive inheritance has been described only rarely. In this study, we analyzed whole-exomes of 18 probands with heterotaxy-spectrum disorders. This includes 4 probands belonging to families with obvious autosomal recessive inheritance. Exome analyses identified approximately ~8000 coding variants in each individual which were subsequently filtered using 1000 Genome, dbSNP135 and NIH exome sequencing project (ESP) databases. The remaining variants were further analyzed using regions of homozygosity (ROH) revealed by SNP genotyping and/or inheritance-based exome analysis. This identified suspected disease-causing variants in novel candidate genes in 7 probands as well as in previously known heterotaxy or related phenotype genes in 4 probands. The majority of variants were homozygous and located in ROH (~2Mb-44Mb), supporting the autosomal recessive inheritance in 6 familial cases. Sanger sequencing of probands and available family members confirmed these homozygous mutations and validated their recessive segregation with phenotype. Novel selected candidates (*C21orf59, DNAH6, DNAJB7, MIA3, INTS7, JMJD1C, SORBS2*) were further investigated by expression analyses in mouse, including RT-PCR and whole mount in-situ hybridization, with results suggesting a possible role in LR patterning and early heart development. Knockdown of *c21orf59* via antisense morpholino in *Xenopus laevis* resulted in LR patterning defects and abnormal *pitx2* expression at stage 30, suggesting *c21orf59* is a novel gene involved in laterality. This study proves the importance of exome analysis complemented with ROH segregation revealed by SNP arrays for identification of unknown causes of human laterality defects and these causes will provide insights to understand new molecular mechanisms involved in embryonic LR patterning.

2952T

Age-Dependent Germline Mosaicism of the Most Common Noonan Syndrome Mutation Shows the Signature of Germline Selection. *P. Calabrese[1], S. Yoon[1], S. Choi[1], J. Eboreime[1], B. Gelb[2], N. Arnheim[1].* 1) Mol Comp Biol, Univ Southern California, Los Angeles, CA; 2) Icahn School of Medicine at Mount Sinai, New York, NY.

Noonan syndrome (NS) is among the most common Mendelian genetic diseases (~1/2,000 live births). Most cases (50%-84%) are sporadic, and new mutations are virtually always paternally derived. More than 47 different sites of NS de novo missense mutations are known in the PTPN11 gene that codes for the protein tyrosine phosphatase SHP-2. Surprisingly, many of these mutations are recurrent with nucleotide substitution rates substantially greater than the genome average; the most common mutation, c.922A>G, is at least 2,400 times greater. We examined the spatial distribution of the c.922A>G mutation in testes from 15 unaffected men and found that the mutations were not uniformly distributed across each testis as would be expected for a mutation hot spot but were highly clustered and showed an age-dependent germline mosaicism. Computational modeling that used different stem cell division schemes confirmed that the data were inconsistent with hypermutation, but consistent with germline selection: mutated spermatogonial stem cells gained an advantage that allowed them to increase in frequency. SHP-2 interacts with the transcriptional activator STAT3. Given STAT3's function in mouse spermatogonial stem cells, we suggest that this interaction might explain the mutant's selective advantage by means of repression of stem cell differentiation signals. Repression of STAT3 activity by cyclin D1 might also play a previously unrecognized role in providing a germline-selective advantage to spermatogonia for the recurrent mutations in the receptor tyrosine kinases that cause Apert syndrome and MEN2B. Looking at recurrent mutations driven by germline selection in different gene families can help highlight common causal signaling pathways.

2953F

Clinical spectrum of the families with multiple synostosis syndromes with novel NOG mutations. *J. Kim[1], B. Lee[1,2], G. Kim[1], J. Lee[1], S. Choi[1], J. Lee[1], H. Yoo[1,2].* 1) Medical Genetics Center, Asan Medical Center, Seoul, South Korea; 2) Dept. Pedicatrics, Asan Medical Center, Children's Hospital, Univ. Ulsan College of Medicine, Seoul, South Korea.

Multiple synostosis syndrome (SYNS) is a rare autosomal dominant skeletal disorder, characterized by variable clinical features including facial dysmorphism, progressive fusion of proximal interphalangeal joints, variable degree of fusions of multiple other joints including spine, and conductive hearing loss. Currently, three genes, NOG, GDF5, and FGF9, have been identified as the causative genes of SYNS. According to the haploinsufficiency of the NOG, GDF5, and FGF9 genes, SYNS is classified as SYNS1 (MIM186500), SYNS2 (MIM610017) and SYNS3 (MIM612961), respectively. However, due to its diverse phenotypic and genotypic heterogeneities as well as its extreme rarity, it is difficult to diagnose a patient with SYNS either clinically or genetically. In this report, two unrelated Korean families with SYNS were described. Under the diagnosis of SYNS, genetic testing was done for the NOG, GDF5, and FGF9 genes using genomic DNA from peripheral leukocytes of the patients. Genetic testing revealed two novel NOG mutations: c.452C>A (p.Ser151*) in family 1 and c.261_262insG (p.Pro88Alafs*94) in family 2. The two novel mutations are expected to produce the premature truncated proteins, lacking C-terminal region that is an integral part for its appropriate function. The patients shared the general features of SYNS, but their phenotypic expressivities were different among inter- and intra-family members. In addition, their diversities were irrespective of a patient's age, indicating the importance of surveillance for the full spectrum of SYNS for each affected patient. Our report expands the understanding of this rare condition from the genetic and clinical perspectives.

2954W

***ZFPM2* Mutations in Sporadic and Familial Congenital Diaphragmatic Hernia Patients.** *M. Longoni[1,2], M.K. Russell[1,2], F.A. High[1,2,3], K. Lage[1,2,4], J. Wells[5], C.J. Bult[5], K.G. Ackerman[6], C. Lee[2,7], B.R. Pober[1,2,3], P.K. Donahoe[1,2,4].* 1) Massachusetts General Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Children's Hospital Boston, Boston, MA; 4) Broad Institute, Cambridge, MA; 5) The Jackson Laboratory, Bar Harbor, ME; 6) School of Medicine and Dentistry, University of Rochester, Rochester, NY; 7) Brigham and Women's Hospital, Boston, MA.

Congenital Diaphragmatic Hernia (CDH) is a common birth malformation. CDH is genetically heterogeneous, and evidence points to a multifactorial, possibly polygenic, etiology in many cases. The most prevalent phenotype is isolated left-sided posterolateral hernia, associated with life threatening pulmonary hypoplasia. An intragenic deletion in Zinc finger protein, multitype 2 (*ZFPM2*, also known as *FOG2*), a gene previously implicated in CDH, was identified in a multigenerational family with isolated hernia inherited in an autosomal dominant pattern with incomplete penetrance. Point mutations in *ZFPM2* or in its transcriptional co-repressor C-terminal binding protein (*CTBP2*) were identified in 7 unrelated patients from a cohort of 93 CDH patients by exome sequencing. All tested variants were inherited from an unaffected parent, consistent with the hypothesis that multiple environmental factors or genetic modifiers are necessary for *ZFPM2* haploinsufficiency to display a clinically recognizable diaphragmatic defect. In an effort to identify pathogenic mechanisms of *ZFPM2* mutations resulting in CDH, microarray expression data from the primordial diaphragm of *Zfpm2* null mice at E11.5 were generated from laser captured tissue. The dataset, containing 428 differentially expressed genes (mutant vs. wildtype), was enriched for Mouse Genome Informatics (MGI) Mammalian Phenotype ontology categories such as skeleton, muscle, and respiratory phenotypes. This expression dataset, together with an analogous one from wild type mice collected at three time points during diaphragm development published by Russell and colleagues (2011), was used as a screening tool to identify possible second hits that explain the observed variable penetrance. In most patients with *ZFPM2* deletions or point mutations, we identified additional novel or rare sequence variants, defined as less than 0.1% in control cohorts, mapped to genes deregulated in *Zfpm2* knock-out animals or in genes whose expression levels are highly correlated with *Zfpm2* during ontogenesis. Though further studies are needed to determine that our prioritized second hits are bona fide *Zfpm2* genetic interactors, our results show that developmentally oriented expression studies are a useful tool for the interpretation of exome sequencing data when studying birth defects.

2955T

Whole exome sequencing links TMCO1 with Cerebro-Facio-Thoracic Syndrome. *Y. Bayram[1], E. Karaca[1], D. Pehlivan[1], C.R. Beck[1], C. Gonzaga-Jauregui[1], T. Gambin[1], S.N. Jhangiani[2], H. Aydin[3], W. Wiszniewski[1], A.H. Cebi[4], M.M. Atik[1], D. Muzny[2], R.A. Gibbs[2], J.R. Lupski[1,5,6].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston TX, USA; 3) Department of Medical Genetics, Zeynep Kamil Women's and Children's Hospital, Istanbul, Turkey; 4) Department of Medical Genetics, Karadeniz Technical University, Faculty of Medicine, Trabzon, Turkey; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 6) Texas Children's Hospital, Houston, TX, USA.

Next generation massively parallel sequencing, both Whole Genome Sequencing (WGS) and Whole Exome Sequencing (WES), is a disruptive technology that has changed the course of clinical/human genetics. As a more efficient and cost effective method, WES is now widely used as a diagnostic tool for identifying the underlying gene, mutation(s), and genetics of challenging genetic syndromes. Here we report a case with a clinical diagnosis of Cerebrofaciothoracic syndrome (CFTS) (MIM#213980) in whom we identified by WES homozygous splice site mutations in the transmembrane and coiled-coil domains 1 (TMCO1) gene. Mutations in TMCO1 gene were shown to be responsible for craniofacial dysmorphism, skeletal anomalies, and mental retardation syndrome (MIM#614132), which is characterized by facial dysmorphism, multiple malformations of the vertebrae and ribs, and mental retardation. Our retrospective review revealed that clinical manifestations of both syndromes are remarkably similar. We propose that, mutations of TMCO1 are not only responsible for craniofacial dysmorphism, skeletal anomalies, and mental retardation syndrome, but also for CFTS. In addition, one should keep in mind that these two syndromes might be different spectrums of the same clinical entity, molecularly diagnosed as TMCO1 defect syndrome.

Stormorken syndrome: mutation in STIM1 as a cause or a remarkable coincidence? *G. Morin[1], G. Jedraszak[1], A. Rabbind singh[1], B. Roméo[2], E. Bourges-Petit[3], H. Sevestre[4], D. Brémond-Gignac[5], H. Ouadid-Ahidouch[6], M. Mathieu[1], J. Rochette[1].* 1) Genetic department, EA 4666, Amiens University Hospital, Amiens, France; 2) Pediatric pneumology unit, Amiens University Hospital, Amiens, France; 3) Pediatric cardiology unit, Amiens University Hospital, Amiens, France; 4) Pathology service, Amiens University Hospital, Amiens, France; 5) Ophtalmology service, Amiens University Hospital, Amiens, France; 6) University of Picardie Jules Verne, UFR of Sciences, Laboratory of Cellular and Molecular Physiology EA 4667, SFR CAP-SANTE, Amiens, France.

Background Stormorken syndrome is very rare autosomal dominant disease with associated congenital miosis, thrombocytopenia/thrombocytopathia, tubular aggregate myopathy, asplenia, small stature, ichtyosis, and moderate developmental disabilities. When documented the myopathy is characterized by the presence of tubular aggregates. Additionally, most patients present moderate hypocalcemia. Till now, only 4 families have been reported with a total of 6 patients. The moderate hypocalcemia observed in some patients suggested the deregulation of the calcium homeostasis. Furthermore, mutations in the calcium sensor region of STIM1 were reported in the autosomal dominant form of tubular aggregate myopathy. Methods We describe a family study expending over 2 generations with 2 affected individuals displaying Stormorken syndrome. The disease affected father and son confirming its autosomal dominant inheritance. Both proband and father had marked congenital miosis, moderate thrombocytopenia (lower value: son 28G/L, father 97G/L), muscular fatigue, significant elevation of creatine kinase (higher value: son 769UI/L, father 4412UI/L), moderate hypocalcemia, small stature, moderate learning difficulties and ichtyosis. The father was asplenic. The son presented an increased bleeding time with normal values for clotting factors. In order to investigate the genetic cause of the Sormorken syndrome, we investigated STIM1 based on the presence of hypocalcemia and the result of the muscular biopsy. The STIM1 gene was studied by direct sequencing in the affected and unaffected individuals of the family. Results We identified a novel reported heterozygous missense mutation in exon 7 of STIM1 gene (c.910C>T; p.Arg304Trp) in the father and son, and not in the other members of the family. Restriction enzyme analysis confirmed the presence of the C>T substitution in position 910. The identified mutation lies in the coiled coil 1 domain of the protein (Cα2). This amino acid residue is highly conserved in mammals. Data obtained from in silico analysis show a major change in the secondary structure of the Cα2 domain when compared to the wild type.

2957W

SX10 in the development of the olfactory ensheathing cells. *V. Pingault[1,2,3], W. Watanabe[1,2], S. Marcos[4], V. Baral[1,2], A. Chaoui[1,2], M. Goossens[1,2], J.P. Hardelin[5], C. Dodé[4,6], N. The SOX10 transcription factor plays a role in the maintenance of progenitor cell multipotency, lineage specification, cell differentiation, and is a major actor in the development of the neural crest. It has been implicated in Waardenburg syndrome (WS), a rare disorder characterized by the association of pigmentation abnormalities and deafness, sometimes associated with neurological disorders. We recently found that apart from WS, SOX10 mutations also cause Kallmann syndrome (KS) with deafness. KS is defined by the association of anosmia and hypogonadotropic hypogonadism due to incomplete migration of neuroendocrine GnRH (gonadotropin-releasing hormone)-cells along the olfactory, vomeronasal, and terminal nerves. We provide further study of SOX10 expression in the olfactory ensheathing cells (OECs) during mouse development and of the developmental defects observed in the *So×10^{lacZ}* mutant mouse. This confirms several of the roles previously suspected for these peculiar cells, which are thought to be responsible for the olfactory neurons unique capacity to renew throughout life.

2958T

FGFR1 mutations cause Hartsfield syndrome, the unique association of holoprosencephaly and ectrodactyly. *C. Vilain[1,2], I. Migeotte[3,1], N. Lambert[3,1], C. Perazzolo[3], D. de Silva[4], B. Dimitrov[5], C. Heinrichs[2], S. Janssens[6], B. Kerr[7], G. Mortier[8], G. Van Vliet[9], P. Lepage[2], G. Casimir[2], M. Abramowicz[1,3], N. Simonis[10], G. Harstfield syndrome is the rare and unique association of holoprosencephaly (HPE) and ectrodactyly, with or without cleft lip and palate, and variable additional features. All the reported cases occurred sporadically. Although several causal genes of HPE and ectrodactyly have been identified, the genetic cause of Hartsfield syndrome remains unknown. We hypothesized that a single key developmental gene may underlie the co-occurrence of HPE and ectrodactyly. Using whole exome sequencing in four isolated cases including one case-parents trio, and direct Sanger sequencing of three additional cases, we identified a novel FGFR1 mutation in six out of 7 patients with Hartsfield syndrome. Affected residues are highly conserved and are located in the extracellular binding domain of the receptor (two homozygous mutations) or the intracellular tyrosine kinase domain (four heterozygous de novo variants). Strikingly, among the six novel mutations, three are located in close proximity to the ATP's phosphates or the coordinating magnesium, with one position required for kinase activity, and three are adjacent to known mutations involved in Kallmann Syndrome plus other developmental anomalies. Dominant or recessive FGFR1 mutations are responsible for Hartsfield syndrome, consistently with the known roles of FGFR1 in vertebrate ontogeny and conditional Fgfr1-deficient mice. Our study shows that, in humans, lack of accurate FGFR1 activation can disrupt both brain and hand/foot midline development, and that FGFR1 loss-of-function mutations are responsible for a wider spectrum of clinical anomalies than previously thought, ranging in severity from seemingly isolated hypogonadotropic hypogonadism, through Kallmann Syndrome with or without additional features, to Hartsfield Syndrome at its most severe end.

Cleft lip and palate is one of the most common birth defects, occurring in 1 of 700 live births. The majority of individuals occur in single affected member families. While GWAS studies have identified major loci, there remains an unexplained genetic contribution that we hypothesize is due to rare unidentified mutations. To this end, we have undertaken genomic studies in larger multi-affected families who could be enriched for Mendelian forms of orofacial clefting in order to identify causative high penetrance alleles. A minimum of two exomes have been performed from each family on the Illumina platform in 20 families with patterns of inheritance consistent with dominant, recessive and X-linked traits. The results have identified pathogenic mutations in some known genes, amongst them, ARHGAP29, in approximately 15% of the cohort. The remaining families may harbour mutations in novel genes for which investigations are ongoing, including studies of the collagen family of genes and SOX9. We discuss in addition adjunct methodologies to reduce the number of variants requiring confirmatory Sanger sequencing such as the programs homozygositymapper, dominantmapper and SNP arrays. In conclusion, based on this initial survey, we have identified multiple rare variants which may contribute to isolated cleft lip and palate.

2960W

Identification of a novel mutation Arg118Gly in the TWIST1 gene causing Saethre-Chotzen Syndrome. *M.L.M. CASTRO[1], C.H.P. GRANGEIRO[1], N.R. QUARESEMIN[1], C.M. LEPREVOST[1], J.A. JOSAH-KIAN[1], L.A.F. LAUREANO[2], W.A.R. BARATELLA[1], J. HUBER[1], E.S. RAMOS[1,3], W.A. SILVA JR[3,4], L. MARTELLI[1,3], G.A. MOLFETTA[3,4].* 1) Serviço de Genética Médica - Hospital das Clínicas da Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 2) Laboratório de Citogenética - Hospital Das Clínicas da Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 3) Departamento de Genética - Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 4) Centro de Medicina Genomica - HCFMRP - USP.

Saethre-Chotzen syndrome (SCS) or Acrocephalosyndactyly Type III is a craniosynostosis syndrome characterized by craniofacial and limb abnormalities, complete penetrance with variable expressivity and autosomal dominant inheritance. Its prevalence varies between 1:25,000 and 1:50,000 live births. Since the first description of mutations in the TWIST1 gene causing SCS, about 163 different mutations, deletions and insertions have been detected in affected patients. The TWIST1 gene is located on chromosome 7p21.1 and encodes a transcription factor with a DNA-binding domain implicated in cell lineage determination and differentiation. We report on a novel missense mutation in the TWIST1 gene in a patient with SCS phenotype. The patient was referred to the Medical Genetics Division of the University Hospital when he was 7 months old and his dysmorphological examination showed: short stature, microbrachycephaly due to bilateral coronal synostosis, high forehead, low frontal hairline, flat face, midface hypoplasia, prominent eyes, unilateral eyelid ptosis, a broad and depressed nasal bridge, anteverted nostrils, high vaulted and narrow palate, antihelix prominent and prominent crura helicis, short neck, small hands with brachydactyly, clinodactyly of fifth fingers bilaterally. The development was normal, however, at the age of two years old, in the last evaluation during his follow up at the Genetics Division, he demonstrated sensorineural hearing loss and speech delay. Genomic DNA for the genetic analysis was extracted from peripheral venous blood sample by conventional methods. In order to detect any abnormalities in the TWIST1 gene, we carried out the DNA sequencing method using an ABI Big Dye Terminator Kit (Applied Biosystems, USA), following manufacturer's instructions. The sequences were compared to the TWIST1 Accession Number NM_000474 and it was revealed the mutation Arg118Gly in heterozygosis. In silico bioinformatics analysis using the software MutPred indicated a high score of patogenicity. The MutPred data have also revealed that the Arg118Gly mutation causes loss of MoRF binging, loss of stability, loss of phosphorilation at T121, loss of disorder and loss of solvent accessibility. We suggest that this novel mutation may be responsible for the SCS phenotype, but further complementary functional assays should be applied for confirming the patogenicity of the mutation Arg118Gly in the TWIST1 gene.

2961T

Splice site mutation leads to ataxia and retardation in a consanguineous family. *R.M. Burns[1], W. Peng[2], J. Xu[2], J.Z. Li[2], M. Burmeister[1, 2].* 1) Molecular and Behavioral Neuroscience Institute University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics University of Michigan, Ann Arbor, MI.

The cerebellar ataxias are a heterogeneous group of neurological disorders with onset of symptoms occurring between early childhood and late adulthood. While the genetic causes of several ataxias have already been identified, many more, especially rare recessive forms, are still unknown. Heterogeneity, or the large number of genes that can cause recessive ataxias, is the major reason why many genes for recessive forms are still unknown. Individual families with independent mutations are too small to positively identify a chromosomal region by genetic linkage.

Objective: We are studying a consanguineous Turkish family with a non-progressive, congenital ataxia of unknown etiology. Symptoms include hypotonia, developmental delay, mental retardation, nystagmus, truncal and extremity ataxia and cerebellar hypoplasia that do not progress with age. In this study, we aim to elucidate the genetic cause of a rare recessive ataxia.

Methods: We utilized a combination of exome sequencing with homozygosity mapping and expression analysis to identify candidate genes. Sanger sequencing was used to verify damaging variants. Molecular assays, such as RT-PCR and immunoblotting, were used to determine the functional consequences of gene variants.

Results: We have identified a variant in an obligatory splice sequence (the first base of an intron is changed from GT to AT). This mutation is absent in >13,000 American control DNAs and 200 Turkish control chromosomes. RT-PCR demonstrates that this splice mutation causes skipping of an exon that is present in all isoforms and expression of the gene is lower in patients than controls. Immunoblot demonstrates loss of this protein in the affected individuals.

Conclusion: Our results suggest that we have identified a novel gene causing recessive ataxia. Additionally, we are developing a zebrafish animal model, utilizing morpholino-mediated knockdown, to study this disorder. Our research may help identify causes of other ataxias and may lead to novel therapies to treat ataxias.

2962F

A novel gene for Spinocerebellar Ataxia (SCA) linked to chromosome 6 and involved in fatty acid metabolism. *E. Di Gregorio[1,2], B. Borroni[3], E. Giorgio[1], D. Lacerenza[1], C. Mancini[1], A. Spinocerebellar ataxias (SCA) are a highly heterogeneous group of autosomal dominant neurodegenerative disorders phenotypically characterized by gait ataxia, incoordination of eye movements, speech, and hand movements, and usually associated with cerebellar atrophy. More than 30 SCAs have been identified, whose genes may be classified into two main categories: repeat expansion disorders - among which the most common forms SCA 1-3, 6, and 7 - and genes with conventional mutations. Here we report the identification of a novel SCA gene. Genome-wide linkage analysis identified a 92 Mb region on chromosome 6 in an Italian family affected by a pure form of ataxia with disease onset in the 4th decade of life. Next generation sequencing of all coding genes in the smallest interval identified only one possible mutated gene, with a Gly to Val amino acid change. Screening of over 450 SCA independent patients identified this same mutation in two further unrelated Italian families. Haplotyping proved that at least two of the three families shared a common ancestor. Two further missense variants, in three independent families, affected the same exon involved in the Italian families, suggesting this may be a mutational hot-spot. All changes hit conserved amino acids, and were not common polymorphisms. The gene encodes an ubiquitously expressed enzyme involved in fatty acid biosynthesis. In situ hybridization on mouse and human brain demonstrated that Purkinje cells have a peculiar high expression of the enzyme. In agreement with the function of this gene, we showed a reduced level of a subgroup of fatty acids in the serum of three patients with the Gly to Val amino acid change. Furthermore, we found an increased gene expression at the messenger RNA and protein levels in the patients' lymphoblasts vs. controls. We hypothesize that a positive feedback loop, activated by the functional impairment of the enzyme, may lead to an increase of protein expression that in turn may accumulate within cells leading to a toxic gain of function. In conclusion, we suggest that our mutated gene, highly expressed in Purkinje cells, is a good candidate for a new form of pure autosomal dominant cerebellar ataxia and join the group of CNS diseases involving fatty acids metabolism.

2963W

Targeted exome sequencing with copy number variant detection reveals HSD17B4-deficiency in a male with cerebellar ataxia and azoospermia. *D.S. Lieber[1,2,3,4], S.G. Hershman[1,2,3,4], N.G. Slate[1,2], S.E. Calvo[1,2,3,4], K.B. Sims[2,5], J.D. Schmahmann[5], V.K. Mootha[1,2,3,4,6].* 1) Department of Molecular Biology, Massachusetts General Hospital, Boston, MA 02114, USA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA 02114, USA; 3) Department of Systems Biology, Harvard Medical School, Boston, MA 02115, USA; 4) Broad Institute of Harvard and MIT, Cambridge, MA 02141, USA; 5) Department of Neurology, Massachusetts General Hospital & Harvard Medical School, Boston MA 02114, USA; 6) Department of Medicine, Massachusetts General Hospital, Boston MA 02114, USA.

We describe an adult male with cerebellar ataxia, peripheral neuropathy, hearing loss, and azoospermia. Commercial genetic testing of 18 ataxia and mitochondrial disease genes was negative, but biochemical findings in serum, urine, and muscle biopsy pointed to the possibility of a mitochondrial abnormality. Targeted exome sequencing followed by analysis of single nucleotide variants and small insertions/deletions failed to reveal a genetic basis of disease. We subsequently applied computational algorithms to infer copy number variants (CNVs) from exome data, revealing a heterozygous 12kb deletion of exons 10-13 of *HSD17B4* that was compounded with a rare missense variant (p.A196V). Recessive mutations in *HSD17B4* cause D-bifunctional protein deficiency, a severe, infantile-onset disorder of peroxisomal fatty acid oxidation. Recently, compound heterozygous mutations in *HSD17B4* were reported in two sisters diagnosed with Perrault syndrome (MIM # 233400), who presented with ovarian dysgenesis, hearing loss, and ataxia. Retrospective review of patient records revealed elevated ratios of pristanic:phytanic acid and arachidonic:docosahexaenoic acid, consistent with peroxisomal dysfunction. Our case expands the phenotypic spectrum of Perrault syndrome, representing the first male reported with ataxia, infertility, and HSD17B4 deficiency. Furthermore, our study highlights the importance of exome-based CNV detection in the diagnosis of rare disorders and points to potential crosstalk between mitochondria and peroxisomes in Perrault syndrome.

2964T

Mutations of COQ2 in Familial and Sporadic Multiple System Atrophy. *J. Mitsui[1], T. Matsukawa[1], H. Ishiura[1], Y. Fukuda[1], Y. Ichikawa[1], H. Date[1], B. Ahsan[1], Y. Nakahara[1], Y. Tsuji[1], JAMSAC, JGSCAD, JPDSGC, JaCALS, and NAMSA-SG.* 1) Department of Neurology, The University of Tokyo, Tokyo Japan; 2) Tokyo University of Technology, Tokyo, Japan; 3) Institute of Molecular and Cellular Biosciences, The University of Tokyo, Tokyo Japan; 4) Department of Pathology, Brain Research Institute, Niigata University, Niigata, Japan; 5) Department of Neurology, Brain Research Institute, Niigata University, Niigata, Japan; 6) Department of Neurology, Wakayama Medical University, Wakayama, Japan; 7) Department of Neuropathology and the Brain Bank for Aging Research, Tokyo Metropolitan Geriatric Hospital and Institute of Gerontology, Tokyo, Japan; 8) Hôpital de la Salpêtrière, Département de Génétique et Cytogénétique, F-75013, Paris, France; 9) Department of Neurological Sciences, University Federico II, Napoli, Italy; 10) Department of Neurology, University of Bonn and German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany; 11) University of Sydney at the ANZAC Research Institute, Concord Hospital, Sydney, Australia; 12) Department of Neurology, University of Michigan, Ann Arbor, MI.

Background Multiple system atrophy (MSA) is an intractable neurodegenerative disease characterized by autonomic failure with various combinations of parkinsonism, cerebellar ataxia, and pyramidal dysfunction. MSA is classified into two subtypes: MSA-C, characterized by predominant cerebellar ataxia, and MSA-P, characterized by predominant parkinsonism. MSA-C has been reported to be more prevalent (8.0 per 100,000) than MSA-P in the Japanese population, whereas MSA-P has been reported to be more prevalent in Europe and North America. Furthermore, multiplex MSA families have been identified. These findings strongly suggest involvement of genetic components underlying MSA. Methods In combination with linkage analysis, we performed whole-genome sequencing of an individual with autopsy-proven MSA of a multiplex family. Mutational analysis was further conducted on the patients in five other families, and, furthermore, on Japanese (363 MSA patients and 520 controls), European (223 MSA patients and 315 controls), and North American (172 MSA patients and 294 controls) series. Functional analysis of COQ2, which encodes para-hydroxybenzoate-polyprenyltransferase, an enzyme essential for coenzyme Q10 (CoQ10) biosynthesis, was conducted using a yeast complementation system and by enzyme activity measurement. CoQ10 levels in lymphoblastoid cells and brains were measured by high-performance liquid chromatography. Results We identified a homozygous mutation (M78V-V343A) and compound heterozygous mutations (R337X/V343A) in COQ2 in two multiplex families. Furthermore, we demonstrated that a common variant (V343A) and multiple rare variants of COQ2, both of which are functionally impaired, are associated with sporadic MSA. The V343A variant was exclusively observed in the Japanese population, while other multiple rare variants are observed irrespective of ethnic background. The ratio of MSA-C to MSA-P was significantly higher in COQ2 variant carriers than in noncarriers. Conclusions Functionally impaired variants of COQ2 associated with an increased risk of MSA in multiplex families and sporadic cases, supporting a role of impaired COQ2 activities in the pathogenesis of MSA.

2965F

Late-onset sacsinopathy diagnosed by exome sequencing and comparative genomic hybridisation. *A. Pyle[1], H. Griffin[1], J. Duff[1], S. Zwolinski[2], T. Smertenko[1], P. Yu-Wai-Man[1], M. Santibanez-Koref[1], R. Horvath[1], P.F. Chinnery[1].* 1) Wellcome Centre for Mitochondrial Research, Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom; 2) Northern Genetics Service, Newcastle upon Tyne Hostpitals NHS Foundation Trust, Newcastle upon Tyne, United Kingdom.

The molecular diagnosis of adult-onset autosomal recessive cerebellar ataxias remains challenging because of genetic heterogeneity. However, recently developed molecular genetic techniques will potentially revolutionise the diagnostic approach. Here we set out to define the genetic basis of the ataxia in two brothers with no molecular diagnosis. Clinical evaluation was followed by whole exome second generation sequencing and comparative genomic hybridisation to determine the diagnosis. Whole exome sequencing identified a hemizygous novel spastic ataxia of Charlevoix-Saguenay (SACS) stop-codon mutation in both brothers (c.13048G>T, p.E4350X) which was present in the mother, but not the father. Comparative genomic hybridisation revealed a 0.7Mb deletion on chromosome 13q12.12 in both brothers, which included SACs and was heterozygous in the asymptomatic father. The milder phenotype, caused by a whole gene deletion and a stop codon mutation in SACS, indicates a loss-of-function mechanism in late-onset autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS), and illustrates the importance of chromosomal rearrangements in the investigation of adult-onset ataxia.

2966W

Autosomal-recessive spastic ataxias: systematic whole-exome sequencing of a large cohort reveals novel phenotypes and gene candidates. *R. Schüle[1,2], M. Gonzalez[2], J. Reichbauer[1], A. Caballero Oteyza[1], S. Wiethoff[1,3], M. Dobler[4], U. Gaiser[4], T. Rattay[1], K. Karle[1], L. Schols[1], S. Zuchner[2], M. Synofzik[1].* 1) Department of Neurodegenerative Disease, Hertie Institute for Clinical Brain Research, Tuebingen, Germany; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Florida; 3) Brain Research Trust, UCL, Institute of Neurology, London, UK; 4) Department of Paediatric Neurology and Developmental Medicine, Children's Hospital, University of Tuebingen, Tuebingen, Germany.

Autosomal recessive hereditary spastic ataxias are a clinically and genetically poorly defined group of neurodegenerative disorders characterized by the combined occurrence of ataxic and spastic features. Patients are usually classified as either complicated Hereditary Spastic Paraplegia (HSP) or autosomal recessive spinocerebellar cerebellar ataxia (SCAR), often with a large overlap which makes the respective classification arbitrary in many cases . Few genes are known to cause spastic ataxia as the predominant phenotype and they explain only a small fraction of known cases. Among the most common known causes of autosomal recessive spastic ataxias are mutations in the SACS gene, causing autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS), late onset Friedreich ataxia, caused by repeat expansions in the FXN gene and HSP Type 7 (SPG7). Using a comprehensive whole-exome sequencing approach, we aimed to systematically unravel the genetic basis of spastic ataxias, investigate atypical phenotypes and identify novel gene candidates. We have collected a cohort of 51 index patients with progressive early onset spastic ataxia and a family history compatible with autosomal recessive disease. Mean age of disease onset was 10.8 years. Additional symptoms present in some of the patients included mental retardation, optic atrophy, peripheral neuropathy, epilepsy and dysgenesis of the corpus callosum on MRI. Whole-exome sequencing was performed in all index cases (enrichment: SureSelect Human All Exon 50Mb kit, Agilent; sequencing: Hiseq 2000, Illumina). After alignment to the hg19 version of the human genome (Wurrows-Wheeler algorithm) and variant calling (Genome Analysis Toolkit GATK software package) data was imported into GEM.app, a browser accessible exome database and collaboration tool. Pathogenic mutations in known genes were identified in about one third of cases These include mutations in known spastic ataxia genes like SACS, SPG7, GBA2, or FA2H, but also genes not yet associated with spastic ataxia like e.g. ADCK3, SYNE1, or TACO1 among other genes Clinico-genetic findings in solved families as well as exciting new candidate genes for autosomal recessive spastic ataxias will be presented. These findings not only provide a systematic account of the genetic basis and phenotypic spectrum of spastic ataxias, but also enlarge the genetic spectrum that needs to be considered in spastic ataxias.

A dominantly inherited syndrome of adult-onset tremor, ataxia, parkinsonism, seizures and sensory neuropathy associated with c.970-1 G→A *PolG2* splice site mutation. *L. Van Maldergem[1], R.W. Taylor[2], R. Van Coster[3], G. Stevanin[4], A. Rolfs[5], M. Humble[6], E. Blakely[2], L. He[2], J. Piard[1], B. Depaepe[3], P. Hella[7], F.G. Debray[8], J-J. Martin[9], J. Bergmans[10], P. Laloux[11], A. Durr[4], S. Forlani[4], W.C. Copeland[6], E. Mormont[11].* 1) Centre de génétique humaine, Université de Franche-Comté, Besançon,, France; 2) Pathology Wellcome Trust Centre for Mitochondrial Research, Newcastle University, Newcastle upon Tyne, United-Kingdom; 3) Laboratory of Mitochondrial disorders University of Gent, Belgium; 4) CRICM (INSERM / UPMC 975, CNRS 7225) and neurogenetics laboratory, GHU Pitié-Salpêtrière, Paris, France; 5) Albrecht-Kossel-Institute for Neuroregeneration, University of Rostock, Rostock, Germany; 6) Mitochondrial DNA Replication Group National Institute of Environmental Health Sciences, Durham, NC; 7) Dept Neurology, Regional Hospital, Namur, Belgium; 8) Metabolic Unit, Centre of Human Genetics, University Hospital, Liège, Belgium; 9) Born-Bunge Foundation, University of Antwerp, Belgium; 10) Neurophysiology, private practice, Brussels, Belgium; 11) Dept Neurolgy, CHU UCL Mont-Godinne Dinant, Yvoir, Belgium and Institute of Neuroscience (IoNS), Université Catholique de Louvain (UCL), Brussels, Belgium.

Mutations in an increasing number of nuclear genes involved in the maintenance and replication of mitochondrial DNA (mtDNA) are being described, associated with an extensive spectrum of clinical phenotypes and secondary mtDNA defects that can take two forms: mtDNA depletion syndromes which are characterised by a quantitative loss of mtDNA copy number leading to isolated organ or multi-systemic pediatric mitochondrial disease and multiple mtDNA deletions which are associated with late-onset mitochondrial disease, a mosaic pattern of cytochrome c oxidase (COX)-deficiency and in which progressive external ophthalmoplegia (PEO) is the predominant clinical feature. We describe the clinical, pathological and molecular findings in a large Caucasian family segregating a late-onset (sixth to seventh decade) movement disorder comprising head and arms tremor, cerebellar ataxia, parkinsonism and sensory axonal peripheral neuropathy, complicated after a few years by generalized epileptic seizures and cognitive decline, in seven individuals. Spotty white matter T2 hypersignals were observed in cerebellum, cerebellar peduncles, brainstem and periaqueductal grey matter. Strikingly, PEO was mild or even absent. Muscle biopsy of four affected family members revealed the presence (2-25%) of COX deficient fibers, some of which exhibited 'ragged-red' pathology. Fluorescent imaging of mitochondrial membrane potential in patient fibroblasts revealed a mosaic staining pattern, characteristic of a heterogeneous mitochondrial defect. Long-range and real-time PCR analyses confirmed the presence of clonally-expanded mtDNA deletions as the cause of the focal COX deficiency. Candidate gene screening excluded mutations in POLG, PEO1, RRM2B, SLC25A4 and TK2 whereas sequencing of POLG2 revealed all affected individuals to be heterozygous for a c.970-1G>A splicing mutation. cDNA studies on muscle from two affected individuals indicated 10-15% exon5 skipping and more complex exon6 skipping. By contrast, seven unaffected family members were wild type at this POLG2 locus indicating complete segregation of the clinical phenotype with the novel splice-site mutation. This is the first complex neurological phenotype reported so far due to a mutation in the gene encoding the accessory subunit of human polymerase gamma.

2968F

Successful collaborative data mining for novel neuromuscular genes in Genomes Management Application (GEM.app). *S. Zuchner, F. Speziani, A. Abrams, A. Strickland, A.P. Rebelo, R. Ulloa, R. Acosta, M. Gonzalez.* Department for Human Genetics and Hussman Institute for Human Genomics, University of Miami, Miami, FL.

Many neuromuscular diseases are genetically heterogeneous with hundreds of Mendelian genes identified so far. Because of available exome sequencing analysis new genes are being reported on a nearly weekly basis. Still these genes explain only a portion of all patients for these phenotypes, indicating that a sizable number of new genes are still to be identified. In parallel, exome sequencing broadens the understanding of phenotype/genotype relationships and clinico-genetic overlap between diseases. When analyzing large amount of exome data, we identified a need for novel powerful genomic analysis tools that are seamlessly accessible to medical doctors and molecular biologists, and provide secure data sharing if needed. Over the past two years, we have designed the web-based tool GEM.app that allows for analysis and integration of multiple exome/ genome datasets across the world. GEM.app contains >3,000 exomes with extensive variant annotation from over 160 users in 18 different countries. It represents a fully functional analysis suite for exome data, is fast, yet easy to use. As of today GEM.app is used 250 times each day with a total of >35,000 queries performed by its users. Single exomes or families are queried in < 1 second and searches over hundreds of families typically take less than 4 seconds. Thus, it is especially powerful to search for common genes across several hundred patient exomes with the same phenotype. More than a dozen novel genes have been identified or contributed by GEM.app in the past 12 months. Nearly all of these genes represent collaborative data analyses. Recently published examples of hereditary spastic paraplegia genes include DDHD1, DDHD2, GBA2, CYP2U1, RTN2, B4GALNT1; Charcot-Marie-Tooth disease genes MARS, PDK3, AARS, HARS, HINT1, SLC25A; spinal muscular atrophy BICD2; different syndromes ANKRD11, PNPLA6, SARM1, DNAJC5; and many more in the pipeline. In addition, we have begun to use GEM.app for remote and local clinical genetics case conferences with geneticists, neurologists, genetic counselors, nurse practitioners and students to discuss specific findings in exomes of research cases. Taken together, we have created a new genomic platform for studies of neuromuscular diseases and beyond. Access is available to all investigators with exome/genome datasets at no cost. This platform can be used for a multitude of research and clinical applications and will continue to significantly simplify the interpretation of exomes.

Comprehensive genetic analysis of an Usher I patient cohort. *K.M. Bujakowska[1], M. Consugar[1], E. Place[1], M.F. Farkas[1], D. Taub[1], J. White[1], D. Navarro-Gomez[1], A. Langsdorf[1], M. Sousa[1], C. Weigel DiFranco[2], S. Harper[2], X. Gai[3], E.L. Berson[2], E.A. Pierce[1].* 1) Ocular Genomics, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA; 2) Berman-Gund Laboratory for the Study of Retinal Degenerations, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, Massachusetts, USA; 3) Department of Molecular Pharmacology and Therapeutics, Loyola University Chicago Health Sciences Division, Maywood, Illinois, USA.

Usher syndrome is the most frequently inherited dual impairment of vision and hearing. Usher syndrome type 1 (USH1) is the most severe form characterized by profound congenital deafness, vestibular dysfunction and prepubescent onset of retinal degeneration. Currently, there are six genes associated with USH1: Myosin VIIa (MYO7A), Harmonin (USH1C), Cadherin-23 (CDH23), Protocadherin-15 (PCDH15), Sans (USH1G) and recently identified CIB2. The products of five of these genes have recently been identified to be part of the calyceal processes of photoreceptors. The purpose of the study was to genetically characterize a cohort of 38 USH1 probands. Methods: An USH1 cohort of 38, partially pre-screened for MYO7A mutations, was high-throughput sequenced for targeted exons of genes associated with inherited retinal degenerations. Genetically unsolved samples were subsequently screened for deletions using a comparative genomic hybridization (CGH) array and deep intronic mutations were investigated by sequencing of the targeted whole-gene capture of the known Usher genes. Intronic regions were mapped onto retina transcriptome. When possible, the likely pathogenic variants were confirmed by co-segregation in available family members with Sanger sequencing. The study protocol adhered to the tenets of the Declaration of Helsinki and was approved by Institutional Review Board. Results: Selective exon capture and Illumina sequencing provided excellent coverage of the targeted exons, with >95% of exons having >10X sequence depth. With this sequencing approach, we were able to solve 55% of 38 probands, where mutations in MYO7A and CDH23 were the most frequent (18% each), followed by USH1C (11%). Eleven samples (29%) contained one heterozygous likely pathogenic change in a USH1 gene. The remaining, 16% did not carry mutations in any known USH1 gene. CGH array analyses and Usher whole-gene sequencing is in progress and will be reported. Conclusions: Targeted exon sequencing provides an effective approach for genetic diagnostic testing of patients with Usher syndrome type 1. We report 24 novel variants among 38 probands. This study also shows that there are some USH1 patients presently with an unknown genetic cause of the disease, suggesting possible copy number variation in known genes, deep intronic mutations or additional genetic loci for this condition. This work was supported by grants from the National Eye Institute (EY012910) and the Foundation Fighting Blindness.

SPG11 and SPG15 are the most frequent genotypes causing spastic paraplegia with thin corpus callosum, white matter changes and mental retardation in Italian patients. *C. Gellera[1], V. Pensato[1], B. Castellotti[1], E. Sarto[1], D. DiBella[1], L. Nanetti[1], D. Pareyson[2], E. Salsano[2], M. Eoli[3], C. Ciano[4], C. Mariotti[1], F. Taroni[1].* 1) Unit of Genetics of Neurodegenerative and Metabolic Diseases, Fondazione IRCCS - Istituto Neurologico Carlo Besta, Milan, Italy; 2) Unit of Clinic of Central and Peripheral Degenerative Neuropaties, IRCCS - Fondazione Istituto Neurologico Carlo Besta, Milan, Italy; 3) Unit of Molecular Neuro-Oncology,IRCCS - Fondazione Istituto Neurologico Carlo Besta, Milan, Italy; 4) Unit of Clinical Neurophisiology, IRCCS - Fondazione Istituto Neurologico Carlo Besta, Milan, Italy.

Hereditary Spastic Paraplegias (HSPs) are clinically and genetically heterogeneous diseases characterized by lower limb spasticity and weakness. The genetic of HSPs is complex and at least 38 HSP genes have been identified as causative ones. A subgroup of complicate autosomal recessive HSPs (ARHSP) has been distinguished for the presence, of thin corpus callosum (TCC) and mild white matter lesions (WML). The ARHSP-TCC phenotype has been recognized in association with at least seven genes but causative mutations have been most frequently found in the KIAA1840 (SPG11) and ZFYVE26 (SPG15) genes. We selected a cohort of 53 unrelated Italian patients with complicated spastic paraplegia presenting with at least one clinical/neuro-radiological hallmark (mental retardation, TCC and/or WML). DNA samples from the patients were analyzed for mutations in SPG11 (KIAA1840), SPG15 (ZFYVE26), SPG21 (ACP33) and SPG5A (CYP7B1) genes. Patients included in this survey presented juvenile onset of neurological symptoms (14.6±10yrs). In 10 cases family history was compatible with a recessive inherited disorder, while the remaining were sporadic cases. Molecular investigations allowed the genetic diagnosis in 21 index cases: 15 patients, from 14 families, were found to carry pathogenic mutations in the SPG11 gene, and 7 unrelated patients were found to carry mutations in the SPG15 gene. The remaining 32 cases were negative also for mutations in SPG21 and SPG5A genes. SPG11 mutations were found in homozygous form in 4 cases and in compound heterozygous form in the remaining 10 patients. Overall, we found 19 different mutations with a large prevalence (74%) of nonsense mutations. Only, 7 mutations have been previously reported. SPG15 mutations were all newly identified mutations. They have been found in homozygous form in 6 cases (five carried a stop mutation and one carried a missense mutation), while one patient was compound heterozygous for a frameshift and a stop mutation. In all cases we could demonstrated the segregation of the identified mutations within families. In our cohort of Italian patients with complicated HSP we found SPG11 mutations in 26% of the cases, and SPG15 mutations in 13%. The majority of mutations are predicted to cause absence of the protein and 18 mutations were newly reported. Negative molecular results in at least 60% of cases, suggests further genetic heterogeneity among the patients with similar clinical presentation.

Malformations of Cortical Development (MCD) are important causes of intellectual disability (ID) and account for 20-40% of drug-resistant epilepsy in childhood. A large number of MCD have now been identified and classified using embryology, genetic, and imaging criteria. Contrary to previous assumptions, the majority of these disorders are now thought to have a genetic basis, although environmental causes such as in utero infection or ischemia are still possible. Microdeletions of the 5q14.3-q15 region have been described in patients with abnormal brain development, severe ID and epilepsy. Further delineation of a critical region of overlap in these patients pointed to *MEF2C* as the causative gene. However, we previously reported two patients with a 5q14.3-q15 deletion that did not span *MEF2C* suggesting that other genes may be implicated in these conditions. Here, we investigated 6 additional patients harboring partially overlapping deletions that do not include *MEF2C*. The clinical phenotype includes moderate-to-severe mental retardation, hypotonia, epilepsy and MCD. The minimal critical region shared by all patients spans an interval of approximately 4.2 Mb in the 5q15 region. This interval contains 8 genes: *NR2F1, FAM172A, POU5F2, C5orf36, ANKRD32, MCTP1, FAM81B* and *TTC37*. Among these genes, we considered three of them as the best candidates since they are expressed in human as well as in rodent fetal brain tissues. To identify which gene contribute to MCD phenotype, we developed an experimental approach. Indeed, we used RNAi-based inactivation in rodents, enabling rapid functional evaluation of candidate genes potentially impacting neuronal migration and maturation. Using this approach, we succeeded to confirm that one of the candidate gene mapped to 5q15 is crucial for brain development.

2972W

Evolution of Magnetic Resonance Imaging (MRI) findings in a girl with Megalencephalic Leukoencephalopahty with Subcortical Cysts (MLC). *D.L. Renaud[1], N. Manolakos[2], G.M. Hobson[2].* 1) Div Child/Adolescent Neurology, Mayo Clinic, Rochester, MN; 2) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE.

Background: MLC is characterized by macrocephaly and mild gross motor delay with characteristic MRI findings including diffuse white matter abnormalities and subcortical cysts in the bilateral anterior temporal regions. Mutations in the MLC1 and HEPACAM genes have been described. Objective: To describe the evolution of MRI findings in MLC. Case report: A 7 month old girl presented with macrocephaly (with enlarged anterior fontanelle) and mild gross motor delay. Her MRI revealed diffuse white matter abnormalities with some anterior predominance. The white matter of the brainstem and cerebellum appeared normal. MR spectroscopy was normal. Normal evaluation included thyroid function, lysosomal enzymes, peroxisomal panel, organic acids, lactate, GFAP gene analysis and eye exam. At 10 months, the MRI was unchanged with no new myelin formation suggesting hypomyelination. Lumbar puncture for metabolic studies was normal. At 17 months, the MRI revealed unchanged white matter abnormalities but the new finding of subcortical cysts in the anterior temporal lobes. Molecular analysis revealed two heterozygous mutations in the MLC1 gene and one heterozygous mutation in the HEPACAM gene. At 2 years of age, she continues to have normal intelligence with mild gross motor delay. Conclusion: Subcortical cysts may not be present initially in patients with MLC.

2973T

***De novo* mutations in the autophagy gene encoding WDR45 (WIPI4) cause static encephalopathy of childhood with neurodegeneration in adulthood.** *H. Saitsu[1], T. Nishimura[2], K. Muramatsu[3], H. Kodera[1], S. Kumada[4], K. Sugai[5], E. Kasai-Yoshida[4], N. Sawaura[3], H. Nishida[6], A. Hoshino[6], F. Ryujin[7], S. Yoshioka[7], Y. Kondo[1], Y. Tsurusaki[1], M. Nakashima[1], N. Miyake[1], H. Arakawa[3], M. Kato[8], N. Mizushima[2,9], N. Matsumoto[1].* 1) Yokohama City University, Yokohama, Kanagawa, Japan; 2) The University of Tokyo, Tokyo, Japan; 3) Gunma University Graduate School of Medicine, Gunma, Japan; 4) Tokyo Metropolitan Neurological Hospital, Tokyo, Japan; 5) National Center of Neurology and Psychiatry, Tokyo, Japan; 6) National Rehabilitation Center for Children with Disabilities, Tokyo, Japan; 7) Shiga University of Medical Science, Shiga, Japan; 8) Yamagata University Faculty of Medicine, Yamagata, Japan; 9) Tokyo Medical and Dental University, Tokyo, Japan.

Static encephalopathy of childhood with neurodegeneration in adulthood (SENDA) is a recently established subtype of neurodegeneration with brain iron accumulation (NBIA)1-3. By exome sequencing, we found de novo heterozygous mutations in *WDR45* at Xp11.23 in two individuals with SENDA, and three additional *WDR45* mutations in three other subjects by Sanger sequencing. Using lymphoblastoid cell lines (LCLs) derived from the subjects, aberrant splicing was confirmed in two subjects, and protein expression was observed to be severely impaired in all five subjects. *WDR45* encodes WD repeat protein interacting with phosphoinoside 4 (WIPI4), one of the four mammalian homologs of yeast Atg18, which plays an important role in autophagy4,5. Decreased autophagic activity and accumulation of aberrant early autophagic structures were demonstrated in the LCLs of the subjects. These findings provide the direct evidence that an autophagy defect is indeed associated with a neurodegenerative disorder in humans.

2974F

Alteration of ganglioside biosynthesis responsible for complex hereditary spastic paraplegia, SPG26. *G. STEVANIN[1,2,3], A. Boukhris[4], R. Schule[5], C.M. Lourenço[6], J.L. Hereditary spastic paraplegias (HSPs) form a heterogeneous group of neurological disorders. A whole genome linkage mapping effort was made using three HSP families from Spain, Portugal and Tunisia and it allowed us to reduce the SPG26 locus interval from 34 to 9 Mb. Following this, a targeted capture was made to sequence the entire exome of affected individuals from the three above families, as well as from two additional autosomal recessive HSP families of German and Brazilian origins. Five homozygous truncating (n=3) and missense (n=2) mutations were identified in B4GALNT1. Following this finding, we analyzed the entire coding region of this gene in 65 additional cases, and three mutations were identified in two subjects. All mutated cases presented an early onset spastic paraplegia, with frequent intellectual disability, cerebellar ataxia and peripheral neuropathy as well as cortical atrophy and white matter hyperintensities on brain imaging. B4GALNT1 encodes beta-1,4-N-acetyl-galactosaminyl transferase 1 (B4GALNT1), involved in ganglioside biosynthesis. These findings confirm the increasing interest of lipid metabolism in HSPs. Interestingly, while the catabolism of gangliosides is implicated in a variety of neurological diseases, SPG26 is the second human disease involving defects of their biosynthesis.

2975W

Neurofilament light gene mutation causes hereditary motor and sensory neuropathy with pyramidal signs. *H. Takashima, A. Hashiguchi, M. Nomura, H. Arata, A. Yoshimura, Y. Higuchi, Y. Sakiyama, T. Nakamura, Y. Okamoto, E. Matsuura.* Dept Neurology and Geriatrics, Kagoshima Univ, Kagoshima, Japan.

Objective: To identify novel mutations causing hereditary motor and sensory neuropathy type V (HMSN-V), a variant of Charcot-Marie-Tooth disease (CMT), we screened known CMT and related genes in members of a Japanese family with HMSN-V. Methods: The clinical features, peripheral nerve conduction properties, and MRI findings of four patients from the Japanese family were examined to confirm HMSN-V. We then screened 28 CMT disease-causing and related genes using a custom microarray chip. Results: The clinical features included mild weakness of the distal lower limb muscles, foot deformity, mild sensory loss, and late-onset progressive spastic paraparesis. Electrophysiological studies revealed slower sensory and motor nerve conduction and small sensory and muscle compound action potentials in multiple nerves in limbs, indicating widespread neuropathy. Brain MRI revealed an abnormally thin corpus callosum. In all four patients, microarrays detected a novel heterozygous missense mutation c.1166A>G (p.Y389C) in the gene encoding the light chain neurofilament protein (NEFL).This mutation is segregated with disease and patient phenotype in this family. Conclusion: All members of the Japanese family with motor and sensory neuropathy with pyramidal tract involvement harbored the same novel NEFL mutation, indicating that NEFL mutations can result in an HMSN-V phenotype.

2976T

***KIF5A* gene mutations in patients with spastic paraplegia.** *F. Taroni[1], S. Caldarazzo[1], E. Sarto[1], S. Baratta[1], K. Savio[2], G. Galassi[3], A. Ariatti[3], G. Lauria[4], L. Nanetti[1], E. Salsano[5], D. Pareyson[5], C. Mariotti[1], D. Di Bella[1].* 1) Genetics of Neurodegenerative & Metabolic Diseases, IRCCS Ist Neurol Carlo Besta, Milan, Italy; 2) Neurology Unit, Ospedale degli Infermi, Biella, Italy; 3) Neurology Unit, Ospedale di Modena, Modena, Italy; 4) Neuromuscular Disease Unit, IRCCS Ist Neurol Carlo Besta, Milan, Italy; 5) Neurology 8, IRCCS Ist Neurol Carlo Besta, Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. Pure and complicated forms of the disease have been described. About half of HSP cases result from autosomal dominant (AD) mutations in *spastin* (SPG4), *atlastin-1* (SPG3A), or *REEP1* (SPG31) genes. Mutations in the *KIF5A* gene have been reported to be a relatively frequent cause (approx. 10%) of pure or complicated AD-HSP phenotypes (SPG10) in French and Italian populations. The *KIF5A* gene encodes the neuronal kinesin heavy chain implicated in the anterograde axonal transport. Most mutations identified so far (all missense except one deletion) are located in the motor domain, with the exception of one mutation identified in the neck region and one in the stalk domain of the protein. The motor domain (exons 1-11) of *KIF5A* was analysed by high-resolution melting (HRM) analysis and/or direct sequencing in 350 unrelated HSP index cases, including 185 AD and 165 sporadic cases, negative for SPG4 mutations. We identified 10 different missense mutations, 4 of which are novel, in 11 HSP probands. The novel mutations were not detected in >350 normal alleles. By *in silico* analysis, all mutations are predicted to damage protein structure or function. Six mutations were identified in AD-HSP probands, 3 cases were apparently sporadic while for 2 probands family history was either not available or unclear. Our patients showed a wide range of age-at-onset, with 4 patients exhibiting onset in childhood, 2 patients at >50 yrs, and the remaining patients in the 3rd-4th decade. Interestingly, 9/11 patients had a complex phenotype with axonal neuropathy, parkinsonism, ataxia, and deafness as variably associated symptoms. *Conclusions*: In our study, *KIF5A* mutations account for 3.5% of cases with autosomal dominant inheritance or sporadic occurrence, a frequency lower than that observed in other Italian (Crimella 2012) and French (Goizet 2009) patient series but similar to that (4%) found in a mixed European population (Schüle 2008). Our findings indicate that SPG10 should be considered in the molecular analysis of HSP phenotypes, even in the absence of a clearly positive family history. Clinically, the probands of our SPG10 families present with a rather broad range of phenotypes, with polyneuropathy or Charcot-Marie-Tooth phenotype as the most frequently associated feature. (Partly supported by grant RF-2009-1539841 from Italian Ministry of Health to F.T.).

2977F

A Locus for Autosomal Recessive Congenital Mirror Movement Disorder Maps to 22q13.1. *J.B. Vincent[1], M.A. Rafiq[1], P. John[2], I.A. Balouch[1,2].* 1) Neurogenetics Sect, R30, Ctr Add/Mental Hlth,Clarke Div, Toronto, ON, Canada; 2) Atta-ur-Rehman School of Applied Biosciences (ASAB), National University of Sciences and Technology (NUST), Islamabad-Pakistan.

Mirror Movement (MRMV) disorder is a rare, mainly autosomal disorder, although it is thought that some sporadic cases may be due to recessive inheritance. MRMV refers to voluntary movements on one side of the body being mirrored by involuntary movements on the opposite side. Using a linkage analysis and candidate gene approach two genes so far has been in implicated to MRMV: DCC on 18q21.2, which encodes a netrin receptor, and on 15q15.1, which is involved in the maintenance of genomic integrity. Here, we describe a large consanguineous Pakistani family with cases 11 cases of MRMV reported across 5 generations, with autosomal recessive inheritance likely. We used Sanger sequencing to exclude DCC and RAD51. We then employed microarray genotyping and autozgosity mapping to identify a shared region of homozygosity-by-descent among the affected individuals. We identified a single autozygous region of ~3.3 Mb on chromosome 22q13.1 (Chr22:36605976-39904648). We used Sanger sequencing to exclude several candidate genes within this region, including DMC1. Whole exome sequencing is currently underway to identify the causative mutation in this family.

2978W

The Whole Genome Sequence of a Jack Russell Terrier with Progressive Spinocerebellar Ataxia and Myokymia Contains a Homozygous Disease-Associated KCNJ10 Missense Mutation. *D. Gilliam[1], J.R. Coates[2], G.S. Johnson[1], L. Hansen[1], T. Mhlanga-Mutangadura[1], J.F. Taylor[3], G.C. Johnson[2], R.D. Schnabel[3], D.P. O'Brien[2].* 1) Department of Veterinary Pathobiology, University of Missouri College of Veterinary Medicine, Columbia, MO; 2) Department of Veterinary Medicine and Surgery, University of Missouri College of Veterinary Medicine, Columbia, MO, USA; 3) Division of Animal Sciences, University of Missouri College of Food Agriculture and Natural Resources, Columbia, MO, USA.

A distinct progressive autosomal recessive spinocerebellar ataxia occurs in three related dog breeds: Jack Russell Terriers, Parson Russell Terriers, and Russell Terriers (JRT/PRT/RTs). Affected dogs develop cerebellar ataxia by 2-to-6 months of age. As the disease progresses, most dogs exhibit myokymia and some have seizures. We used Illumina sequencing technology to generate a whole genome sequence (WGS) with 20-fold coverage from an affected JRT and aligned the reads to the canine reference genome sequence using NextGENe software. The detected sequence variants were prioritized according to predicted functionality and filtered to remove variants also present in any of 22 WGSs generated for dogs with other heritable diseases which served as controls. Among the 107 homozygous sequence variants in 89 genes that survived the filter step, a KCNJ10:c.627C>G transversion predicting a p.I209M amino acid substitution was considered most likely to be causal because cerebellar ataxia and seizures are features of SeSAME syndrome caused by mutations in human KCNJ10. In addition, p.209I and surrounding amino acids are highly conserved components of the functionally important inward rectifier potassium channel domain. We used a TaqMan allelic discrimination assay to determine the genotypes of individual dogs at KCNJ10:c.627. The 13 JRT/PRT/RTs in our collection with spinocerebellar ataxia were all homozygous for the KCNJ10:c.627G allele; whereas, only one of the 879 genotyped JRT/PRT/RTs with undetermined phenotype was a KCNJ10:c.627G homozygote. We were unable to ascertain any clinical information for this KCNJ10:c.627G homozygote. The other genotyped JRT/PRT/RTs were either heterozygotes (n = 100) or homozygous for the reference allele (n = 779). One hundred and two dogs from 62 other breeds were all KCNJ10:c.627C homozygotes. There appear to be species differences between human and canine KCNJ10 deficiency diseases. SeSAME syndrome patients are deaf; whereas, the affected JRT/PRT/RTs have normal hearing. In addition, although myokymia is often exhibited by affected JRT/PRT/RTs, it is not considered a feature of SeSAME syndrome. This report illustrates that the mutation responsible for an unmapped disease can be identified from the WGS of a single affected dog plus controls.

2979T

The *Alu*-rich architecture of *SPAST* predisposes to diverse and functionally distinct CNV alleles. *P.M. Boone[1], I.M. Campbell[1], B.C. Baggett[1], J.C. Scull[2], C.J. Shaw[1], M.A. Withers[1], P. Moretti[1,3,4], W.E. Goodwin[5], J.K. Fink[6], A. Ordóñez-Ugalde[7], B. Quintáns[7], M-J. Sobrido[7], S. Stemmler[8], J.R. Lupski[1,2,9,10].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Medical Genetics Laboratories, Baylor College of Medicine; 3) Dept. of Neurology, Baylor College of Medicine; 4) Michael E. DeBakey VA Medical Center, Houston, TX, USA; 5) Children's Medical Center of Dallas, TX, USA; 6) Department of Neurology, University of Michigan, Ann Arbor, MI, USA; 7) Grupo de Medicina Xenómica, Fundación Pública Galega de Medicina Xenómica, SERGAS, IDIS, CIBERER, Santiago de Compostela, Spain; 8) Department of Human Genetics, Ruhr University, Bochum, Germany; 9) Texas Children's Hospital, Houston, TX, USA; 10) Department of Pediatrics, Baylor College of Medicine.

SPAST is the disease gene for autosomal dominant spastic paraplegia, type 4 (SPG4). While disease-causing deletions and duplications (CNVs) in *SPAST* have been described, their origin and molecular consequences remain obscure. We mapped 44 *SPAST* CNVs with nucleotide resolution in subjects with SPG4. A diverse combination of exons were deleted or duplicated, providing insights into the importance of particular exons for spastin function. 75% of CNV breakpoints localized to *Alu* elements, suggesting that the *Alu*-rich architecture of *SPAST* renders this locus susceptible to a variety of small genome rearrangements and potentially explaining why a large percentage of mutations in SPG4 patients are CNVs. Nine deletions overlapped part of *SPAST* and part of a nearby, directly-oriented gene, creating a chimeric gene in these patients' genomes. An additional 10 deletions of the 3' end of *SPAST* suggest that splicing from *SPAST* to *SLC30A6*, the most proximal downstream gene, may occur or that *SLC30A6* expression may be altered; PCR and sequencing of cDNA from a patient with a *SPAST* exon 17 deletion revealed multiple *SPAST*:*SLC30A6* fusion transcripts. As *SLC30A6* has been implicated in Alzheimer disease, these data may explain a report of spastic paraplegia and dementia co-segregating in a family with deletion of *SPAST* exon 17. In summary, we provide evidence that the *Alu* architecture of *SPAST* predisposes to diverse, disease-causing CNV alleles with distinct transcriptional - and possibly phenotypic - consequences. †The authors acknowledge Athena Diagnostics, a subsidiary of Quest Diagnostics, for contributing a cohort of anonymized DNA samples.

2980F

Tank-binding kinase 1 (*TBK1*), autophagy, and glaucoma. *J.H. Fingert[1,2], K. Anfinson[1,2], F. Solivan-Timpe[1,2], B.R. Roos[1,2], A. Khanna[1,2], A.L. Robin[3,4], R.F. Mullins[1,2], B.A. Tucker[1,2].* 1) Ophthalmology and Visual Sciences, Carver College of Medicine, University of Iowa, Iowa City, IA; 2) Institute for Vision Research, Iowa City, IA; 3) Department of Ophthalmology and International Health, Johns Hopkins University, Baltimore, MD; 4) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

Purpose: Retinal ganglion cell (RGC) loss is a key feature of glaucoma. We have previously shown that duplication of the TANK binding kinase 1 (*TBK1*) gene is a cause of normal tension glaucoma (NTG). *TBK1* and other NTG genes (*OPTN* and *TLR4*) have important roles in autophagy. Consequently, we derived RGCs from human skin cells to investigate the effects of *TBK1* gene duplication on autophagy in the most relevant tissue for glaucoma pathophysiology. **Methods**: Adult induced pluripotent stem cells (iPSCs) were generated from human skin cells (fibroblasts or keratinocytes) via infection with a single lentiviral vector, which was designed to drive expression of the Yamanaka factors Oct4, Sox2, Klf4, and c-MYC. Pluripotency was assessed by testing for the induced expression of the Yamanaka factors with RT-PCR. Neuronal cells were produced by differentiating iPSCs via culture in a series differentiation media containing Noggin, Dkk-1, IGF1, bFGF, DAPT, and aFGF. Differentiation into iPSC-derived retinal ganglion-like cells was assessed by testing for production of the RGC markers BRN3B, NF200, and THY1 with immunocytochemistry. Additional immunocytochemistry and Western blot experiments were used to search for altered production or altered localization of key factors in autophagy, including LC3-II (a marker of activated autophagy). **Results**: Generation of iPSCs from skin cells of patients with *TBK1*-related glaucoma and from controls was confirmed by RT-PCR amplification of all four Yamanaka factors. iPSC-derived neurons from both glaucoma patients with a *TBK1* gene duplication and from control subjects were positive for the RGC markers BRN3B, NF200, and THY1. Finally, Western blot analysis showed significantly increased levels of LC3-II in cells from glaucoma patients with a *TBK1* gene duplication. **Discussion**. We have successfully generated cultured neurons that expressed RGC markers and harbor a glaucoma-causing *TBK1* gene duplication. Initial studies show that a key marker of autophagy is greatly increased in cells with a *TBK1* gene duplication. These data provide strong evidence that activation of autophagy may be an important event in the pathophysiology of glaucoma. Further studies of the autophagy pathway using these iPSC-derived RGCs may provide additional insights into the causes of glaucoma at the molecular level and may also suggest new therapeutic interventions.

2981W

Lamin B1 over-expression is associated with nuclear defects and alterations in nuclear structure. *H. Rolyan[1], K. Dahl[2], N. Dahl[3], A. Melberg[4], C.F.M. de Souza[5], F.P. Vairo[5], A. Brusco[6], Q.S. Padiath[1].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Chemical Engineering, Carnegie Mellon University, 5000 Forbes Ave., Pittsburgh, PA, USA; 3) Dept. of Immunology, Genetics and Pathology, Section of Clinical Genetics, The Rudbeck laboratory, Uppsala University Children's Hospital, Uppsala, Sweden; 4) Department of Neuroscience, Neurology, Uppsala University, Uppsala Sweden; 5) Hospital de Clínicas de Porto Alegre & Universidade Federal do Rio Grande do Sul; Brasil; 6) University of Torino, Department of Medical Sciences, Torino, Italy.

Autosomal Dominant Leukodystrophy (ADLD) is an adult onset demyelinating disease caused by duplications of the lamin B1 (LMNB1) gene. LMNB1 is a component of the nuclear lamina and together with providing structural integrity to the nucleus, it also plays an important role in gene regulation and chromatin modification. The mechanism by which LMNB1 duplications cause ADLD is unknown and it is also not known whether LMNB1 duplications lead to altered nuclear structure. To address this question, we have analyzed the nuclear structure in fibroblasts from ADLD patients. We have shown for the first time that patient fibroblasts show a greater number of nuclear abnormalities, alterations in nuclear shape and size and have altered chromatin landscapes. These results were confirmed in mouse fibroblast lines over expressing LMNB1. Our results suggest that alterations in nuclear structure are a functional consequence of LMNB1 over expression that may play an important role in disease causation.

2982T

Mechanisms underlying non-recurrent microdeletions causing neurofibromatosis type-1 (NF1). *J. Vogt[1], K. Bengesser[1], K. Claes[2], K. Wimmer[3], L. Messiaen[4], V.-F. Mautner[5], R. van Minkelen[6], E. Legius[7], H. Brems[7], T. Rosenbaum[8], M. Upadhyaya[9], D.N. Cooper[9], H. Kehrer-Sawatzki[1].* 1) Institute of Human Genetics, Ulm University, Ulm, Baden-Wuerttemberg, Germany; 2) Center for Medical Genetics, Ghent University Hospital, 9000 Ghent, Belgium; 3) Division of Human Genetics, Medical University Innsbruck, Innsbruck, Austria; 4) Medical Genomics Laboratory, Department of Genetics, University of Alabama at Birmingham, Birmingham, USA; 5) Department of Neurology, University Hospital Hamburg Eppendorf, Hamburg, Germany; 6) Department of Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 7) Department of Human Genetics, KU Leuven, Leuven, Belgium; 8) Clinical Centre Duisburg, Children's Hospital, Germany; 9) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, UK.

NF1 microdeletions encompassing the NF1 gene region at 17q11.2 are present in ~5% of patients with NF1. Although the mechanisms underlying recurrent NF1 microdeletions have been investigated in great detail, those underlying non-recurrent (atypical) NF1 microdeletions are not well delineated. NF1 microdeletions with non-recurrent breakpoints are heterogeneous in terms of their size, breakpoint position and number of deleted genes. In this study, we investigated 20 atypical NF1 deletions using high-resolution custom aCGH and performed breakpoint-spanning PCRs with primers located in non-deleted regions closely flanking the deletion boundaries. Sequence analysis of breakpoint-spanning PCR products indicated that 15 deletions exhibit simple breakpoint junctions without further complexities and hence were probably mediated by NHEJ/MMEJ. We therefore conclude that NHEJ/MMEJ is the most common mechanism underlying atypical NF1 deletions. However, two of the 20 deletions investigated exhibited complex breakpoints characterized by SVA-F element insertion at the deletion junctions, as determined by inverse PCR, semi-specific PCR and Genome Walker analysis. Large genomic deletions associated with SVA-element insertions at the breakpoints have not been previously reported. We postulate that SVA insertions, occurring via retrotransposition, that trigger large genomic rearrangements may represent an as yet uncharacterized mechanism responsible for causing CNVs with non-recurrent breakpoints. We noted that 14 (70%) of the 20 atypical NF1 microdeletions displayed proximal breakpoints located within a 38-kb region of the SUZ12P. The enrichment of atypical NF1 deletion breakpoints in SUZ12P is remarkable since the breakpoints of recurrent type-2 NF1 deletions are also located within SUZ12P. However, only two atypical NF1 deletion breakpoints co-localized with the breakpoints of previously analysed type-2 NF1 deletions. Hence, a clustering of breakpoints within a single region of SUZ12P was not observed. Nevertheless, the accumulation of breakpoints associated with recurrent and non-recurrent NF1 deletions within SUZ12P is indicative of its genomic instability. The analysis of FISH, microsatellite markers and insertion/deletion polymorphisms revealed somatic mosaicism in 12 of the 20 (60%) atypical NF1 deletion patients investigated. Thus, not only recurrent type-2 NF1 deletions, but also a considerable proportion of atypical NF1 deletions, are of postzygotic origin.

2983F

West syndrome caused by homozygous mutation in an evolutionary conserved mitochondrial elongation factor. *A.A. Alfaiz[1,2,3], N. Boutry-Kryza[4,5,6], D. Ville[7], N. Guex[2], J. Bellescize[8], C. Infantile spasms (IS), pathognomonic hypsarrhythmia and developmental regression are the triad of features that identify West's Syndrome (WS), a rare epileptic disease affecting about 1:3,500 live births. It occurs either in isolation or as part of a more complex disease syndrome. This heterogeneity often impedes the identification of the etiology of WS within the clinical practice. We identified using exome sequencing a homozygous mutation in the GUF1 gene in three siblings from a consanguineous family affected with isolated West syndrome and severe neurological impairment. The encoded GUF1 protein is a universally conserved GTPase in mitochondria and chloroplasts. Its prokaryote homolog, named EF4 or LepA, encodes a non-essential translational elongation factor able to back-translocate the tRNA on ribosomes. The EF4 gene is essential when suboptimal conditions trigger the formation of aberrant elongating ribosomes probably because the encoded mitochondrial translational elongation factor has the capacity of remobilizing stuck ribosomes under these suboptimal conditions. It was proposed that the strong selective advantage conferred by the presence of this elongation factor both in eu- and prokaryote could explain its ubiquitous distribution, as well as why it is one of the most conserved proteins. The variant we identified and which segregates with WS modifies an Alanine residue conserved in ALL eukaryotic organisms from budding yeast to human. It is positioned within the beta-strand moiety of the GTPase that specifically recognizes the acceptor stem and D-loop of tRNA molecules. Nuclear defects affecting mitochondrial protein synthesis might lead to severe epileptic disorders in infants such as IS/WS. They are, however, easily overlooked possibly because of the difficulty to correctly gauge the activity of the respiratory chain complexes, especially when no lactate and/or pyruvate increase is identified in blood and/or cerebrospinal fluid. We show that exome sequencing is a suitable strategy for identifying causative genes in familial IS/WS since many of the causative nuclear genes are probably yet unknown. We establish a new link between alteration of mitochondrial protein synthesis and IS/WS.

2984W

Gene discovery and high-throughput resequencing of candidate genes in epileptic encephalopathy. *H. Mefford[1], E. Sherr[2], I. Scheffer[3], A. Poduri[4], D. Dlugos[5], Epi4K Investigators.* 1) Pediatrics, University of Washington, Seattle, WA; 2) Neurology, University of California, San Francisco, CA; 3) Neurology, University of Melbourne, Australia; 4) Neurology, Children's Hospital, Boston, MA; 5) Neurology, Children's Hospital of Philadelphia, PA.

Epileptic encephalopathies (EE) are severe childhood epilepsy syndromes characterized by multiple refractory seizure types, developmental arrest or regression and a poor prognosis. In most cases, the cause is unknown, but *de novo* genetic mutations have been identified in some patients. We recently performed exome sequencing in 264 probands and their unaffected parents for two classic EE syndromes: infantile spasms (IS; n=149) and Lennox Gastaut syndrome (LGS; n=115). We confirmed 329 *de novo* mutations in 309 genes and found an excess of *de novo* mutations in the ~4000 genes that are most intolerant to functional genetic variation in the human population (Epi4k & EPGP Investigators, 2013, *Nature*). Notably, we identified four patients with *de novo* mutations in *GABRB3* and two patients with the identical *de novo* mutation in *ALG13*, confirming these two genes as novel EE genes. While many of the other genes in which there were *de novo* mutations are reasonable candidate genes for EE, identification of additional patients with mutations is necessary to confirm the role of each gene in the genetic etiology of EE. Here, we perform targeted capture and high-throughput resequencing of 31 genes in which a *de novo* mutation was identified in one or more patients with IS or LGS in our prior study. We selected genes in which two unrelated probands had a *de novo* mutation (n=4, including *GABRB3* and *ALG13*), genes that are among those intolerant to genetic variation and in which the *de novo* mutation was severe (nonsense, frameshift, splice; n=8), and genes in which mutations have previously been reported in other epilepsy syndromes, brain malformation syndromes, intellectual disability, autism or related phenotypes (n=19). We are screening ~600 patients with a range of EE syndromes, as we anticipate that many of the genes will cause EE disorders other than IS or LGS. We will report the frequency of *de novo* mutations of each candidate gene in our cohort and investigate genotype-phenotype correlations for each gene in which multiple patients harbor mutations.

2985T

Mutations of *TBC1D24* can cause nonsyndromic deafness DFNB86 or unrelated epilepsy disorders. *A.U. Rehman[1], K. Lee[2], R.J. Morell[1], T. Ito[3], M.C. Drummond[1], S. Riazuddin[4], R.L.P. Santos-Cortez[2], S.N. Khan[5], A.J. Griffith[3], S. Riazuddin[5], S.M. Leal[2], T.B. Friedman[1].* 1) Laboratory of Molecular Genetics, NIDCD, National Institutes of Health, Rockville, MD; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 3) Otolaryngology Branch, NIDCD, National Institutes of Health, Rockville, MD; 4) Division of Pediatric Otolaryngology, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH; 5) Allama Iqbal Medical College/Jinnah Hospital Complex, Lahore, Pakistan.

Many nonsyndromic deafness genes remain to be identified. We previously reported that *DFNB86*, a locus for autosomal recessive nonsyndromic deafness, is located on chromosome 16p (maximum two-point LOD score 8.54; Ali and Rehman et al., 2012). We subsequently identified three additional large families segregating nonsyndromic deafness that showed statistically significant linkage to the *DFNB86* interval. To identify the causative gene for DFNB86 deafness, we sequenced the exome of one affected individual from three of the four DFNB86 families. In each exome dataset we identified two to nine homozygous DNA variants in the *DFNB86* interval that were present at an allele frequency of <1% in the public SNP databases and were predicted to be pathogenic by at least one *in silico* prediction program. Assuming there is a single gene responsible for all of the deafness linked to the *DFNB86* locus, we searched for mutations of a single gene across the three exome datasets. We found that affected individuals from two of the three families were homozygous for the same missense mutation, p.Asp70Tyr, of *TBC1D24*. Affected individuals of the third family were homozygous for another missense mutation, p.Arg293Pro, of *TBC1D24*. The fourth DFNB86 family was also segregating the p.Asp70Tyr allele of *TBC1D24*. These missense mutations co-segregated with deafness in the respective families and we did not observe them in 358 control chromosomes from an ethnically matched cohort. Both missense mutations alter highly conserved residues of the wild type TBC1D24 protein and are predicted to be pathogenic by a variety of *in silico* prediction programs including MutationTaster and PolyPhen-2. The splice isoforms, expression patterns and possible functions of *TBC1D24* in the auditory system will be discussed. Enigmatically, mutations of *TBC1D24* were previously reported to cause focal epilepsy and intellectual disability syndrome or familial infantile myoclonic epilepsy, with no reports of hearing loss in any of these patients. Clinical re-evaluations of the affected subjects of our DFNB86 families indicated that deafness appears to be nonsyndromic.

2986F

HIPPOCAMPAL DEFECTS IN THE FMR1 KNOCKOUT MOUSE. *F. Kooy[1], I. Heulens[1], V. Sabanov[2], T. Ahmed[2], A. Popp[3], R. Willemsen[3], R. D'Hooge[2], D. Baltschun[2], L. Rooms[1].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Laboratory of Biological Psychology, KU Leuven, Belgium; 3) Department of Clinical Genetics, Erasmus MC Rotterdam, The Netherlands.

Whole-cell patch-clamp recordings on hippocampal slices from CA1 pyramidal neurons revealed a significant decrease (p=0.0127) of IPSCs in three-week-old Fmr1 knockout mice. Several drugs that modulate the GABA(A) receptor are available for clinical use. Ganaxolone, a positive allosteric modulator of GABA(A) receptors, prevents seizures in Fmr1 knockout mice. To further explore the therapeutic effect of ganaxolone, we evaluated the effect of the drug in the marble burying paradigm. Acute ganaxolone treatment is able to correct the abnormal marble burying behavior of Fmr1 knockout mice without having an effect in wild-type littermates (p<0.001). Previous studies reported enhanced mGluR5-dependent long-term depression (LTD) in Fmr1 knockout mice. We examined NMDA-dependent LTD by induction with low-frequency stimulation. Our data reveal a significant decrease in this form of LTD in Fmr1 knockout mice (p<0.05). Previously, we found a reduced expression of Larg in Fmr1 knockout mice. LARG is a GEF which activates RhoA, involved in actin cytoskeleton remodeling and spine morphology. We show that several genes of the LARG-RhoA pathway are underexpressed in the fragile X syndrome. DiOlistic labeling shows that spine density was significantly increased in the CA1 region of the hippocampus in Larg+/- mice (p<0.01), while spine length remained unchanged. Underexpression of LARG thus results in dendritic spine abnormalities with striking similarities to those observed in the fragile X syndrome. Our findings thus confirmed the importance of the GABAergic pathway as a powerful therapeutic target as well as unveiled novel pathways involved in key aspects of the fragile X phenotype.

2987W

Analysis of Genomic DNA sequence based on new molecular diagnostic strategies for Neurofibromatosis Type I. *S. Choi[1], J. Kim[1], J. Lee[1], J. Lee[1], G. Kim[1], B. Lee[1,2], H. Yoo[1,2].* 1) Medical Genetics Center, Asan Medical center, Seoul, South Korea; 2) Dept. Pediatrics Asan Medical Center, Children's Hospital, University of Ulsan College of Medicine, Seoul, South Korea.

Neurofibromatosis I (NF1, OMIM 162200) is characterized by multiple café au lait spots, axillary and inguinal freckling, multiple cutaneous neurofibromas, and iris Lisch nodules. NF1 is diagnosed based on the constellation of clinical findings. The genetic testing in NF1 is also important for the diagnostic confirmation. More importantly, it is essential for the appropriate genetic counseling. However, the molecular genetic testing is problematic due to the large size of the causative gene, NF1. In addition, the gene has homologous domains such as Cystein-Serine rich domain (CSD), GTPase related domain (GRD), and adenylated kinase pseudogene (AK3). These domains are dispersed in multiple chromosomal loci, leading to false positive results in routine medical sequencing tests in NF1. To avoid interferences by these homologous sequences, labor-intensive RNA-based sequencing methods have been used. To facilitate the genetic diagnostic process with high accuracy, we introduced the new strategy of genomic DNA-based molecular test for NF1. A total of eighteen patients were enrolled. All patients were diagnosed with NF1 on the basis of typical clinical features. Genomic DNAs were isolated from peripheral leukocytes. Homologous sequence domains on NF1 were amplified with the range of 6~13kb size using five NF1-specified primer sets. Nested PCRs were done in the five long-PCR products by exon-by-exon primers of the NF1 gene. The nested PCR products were sequenced using the same nested PCR primers. With this method, pseudo-variants by CSD, GRD, and AK3 regions located on exon9-to-31 of NF1 were excluded in all patients. Subsequently, we identified 18 pathogenic mutations including 11 novel variants in all NF-1 patients studied. Analytical validities of this diagnostic strategy will be evaluated in a large patient cohort with NF1.

2988T

Comprehensive Mutation Analysis for Hereditary Sensory and Autonomic Neuropathy Using a Next-Generation Sequencing System. *J. YUAN, E. Matsuura, Y. Higuchi, A. Hashiguchi, T. Nakamura, S. Nozuma, Y. Sakiyama, A. Yoshimura, H. Takashima.* Kagoshima University 8-35-1 Sakuragaoka, Kagoshima City, Kagoshima, Japan.

Objective To establish an effective diagnostic procedure and identify new molecular mechanism in patients with hereditary sensory and autonomic neuropathy (HSAN). Methods Sixteen Japanese patients with predominant sensory and/or autonomic nervous dysfunctions were enrolled. Nerve conduction studies revealed multiple sensory nerve involvement with or without mild motor nerve abnormalities. Sural nerve biopsy was performed in eight patients, and the specimens were examined by light and electron microscopy. Using a next-generation sequencing system (Illumina, MiSeq), all coding regions and flanking intron sequences of 11 known HSAN disease-causing genes and another five genes (SCN9A, CCT5, PRNP, FLVCR1, and RNF170) that may also generate sensory and autonomic symptoms were screened. Subsequently, the suspected pathogenic mutations and low-coverage domains (depth of less than 10) were confirmed by Sanger sequencing. Cases without pathogenic mutations in these genes proceeded to exome sequencing. Results The mean age of the included patients (11 males and 5 females) was 50.1 years (range, 20-80 years), and the median age at disease onset was 35 years (range, 1-71 years). Six patients (37.5%) displayed central nervous system involvement, whereas hearing loss was detected in five patients (31.3%). Pathological studies of the sural nerve revealed the loss of large and/or small myelinated nerve fibers at variable severity. Using the MiSeq system, 97.6% of target regions were covered in more than 10 reads. A frameshift mutation was discovered in SCN9A in two unrelated patients. Meanwhile, in another two patients, novel missense mutations were detected in DNMT1. Conclusions The next-generation sequencing system proved to be effective and trustworthy for genotyping the HSAN gene panel. However, we could not identify any pathogenic mutation in these 16 genes in 75% patients with the HSAN phenotype. Using exome sequencing, we can expect that more HSAN disease-causing genes will be identified.

2989F

Whole Exome Sequencing Identifies Rare Variants in Turkish Patients with Brain Malformation. *E. KARACA[1], D. PEHLIVAN[1], C. GONZAGA-JAUREGUI[1], T. GAMBIN[1], W. WISZNIEWSKI[1], A.H. CEBI[2], M.M. ATIK[1], V. GELOWANI[1], M. WITHERS[1], D. MUZNY[3], S.N. JHANGIANI[3], R.A. GIBBS[3], J.R. LUPSKI[1,4,5].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) 2.Department of Medical Genetics, Karadeniz Technical University, Faculty of Medicine, Trabzon, Turkey; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston TX, USA; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 5) Texas Children's Hospital, Houston, TX, USA.

Disorders disrupting normal brain development represent a clinically and genetically heterogeneous group. Genomic technologies are being used widely, especially in recent years, and enabling the discovery of many novel genes that are involved in brain development. However, many more are likely waiting to be brought to light. Here we report whole exome sequencing (WES) data from 25 Turkish probands from 22 families, 18 of which are consanguineous, with diagnoses of neurodevelopmental delay with brain malformation. Exome sequencing revealed deleterious mutations in candidate genes that have not been described before as mutated in brain malformation syndromes in 20 probands (80%), while the other 5 probands (20%) had mutations in known genes. Functional studies of the identified variants and genes will be performed in order to elucidate their functional impact in normal brain development. Increasing use of genomic sequencing approaches, along with other genome-wide interrogation technologies are helping to identify causative rare variants not only in disorders of brain development but also in other disorders showing Mendelian inheritance.

2990W

Investigating the genetic basis of amyotrophic lateral sclerosis using next-gen techniques. *J.A. Fifita[1], K.L. Williams[1], G.A. Nicholson[1,2], I.P. Blair[1].* 1) Macquarie University, Sydney, New South Wales, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, New South Wales, Australia.

Amyotrophic lateral sclerosis (ALS) is a fatal form of motor neuron disease characterized by the progressive degeneration of both the upper and lower motor neurons. ALS may occur as familial or sporadic disease. To date, genetic mutations are the only known cause of ALS. ALS is heterogeneous with mutations in over 15 genes now described in both familial and sporadic ALS, including *SOD1*, *TARDBP*, *FUS*, *C9ORF72*, *UBQLN2*, *OPTN*, *PFN1*, *hnRNPA1* and *SS18L1*. Nevertheless, the genes are yet to be identified in 30-40% of familial ALS. We aim to identify novel genes involved in ALS using next-generation sequencing techniques. We performed exome capture (Illumina TruSeq Exome Enrichment Kit) and massively parallel sequencing (Illumina HiSeq2000) on 14 DNA samples from five ALS families that are negative for all known ALS genes. The families used in this study have DNA samples available from either two affected individuals and a 'married-in' control, or more than two affected individuals. Bioinformatic analysis of exome data identified several candidate variants among four families. Additional segregation analysis in one of these families reduced the number of potential causative variants to two. Analysis of large control cohorts is underway to validate these variants. Functional studies will then be undertaken to examine the pathological consequences of these variants in an attempt to further understand the disease mechanisms underlying both sporadic and familial ALS. Using a combination of exome sequencing and Sanger sequencing we have also determined the prevalence of known ALS genes in Australian familial and sporadic ALS cohorts. Mutations in known ALS genes account for 57.2% of familial ALS and 5% of sporadic ALS. The familial mutations comprise of *SOD1* (13.9%, n=26), *TARDBP* (2.1%, n=4), *FUS* (2.7%, n=5) *C9ORF72* (38%, n=71), *OPTN* (0.5%, n=1), *UBQLN2* (1.1%, n=2), and *SS18L1* (0.5%, n=1). Currently, the cause of 40% of ALS families, and 95% of sporadic ALS is still unknown. Additional exome sequencing projects are underway in Australian familial index patients to identify novel ALS genes.

Molecular genetics of primary microcephaly in Indian population: mutations in WDR62, ASPM and STIL genes. *A. Kumar[1], V. Bhat[1], G. Mohan[1], S.C. Girimaji[2].* 1) Molecular Reproduction, Development & Genetics, Indian Institute of Science, Bangalore, Karnataka, India; 2) Child and Adolescent Psychiatry, National Institute of Mental Health and Neuro Sciences, Bangalore, Karnataka, India.

Development of the human brain, specially the cerebral cortex, is an intricate and complex process that involves generation of neural progenitors in periventricular zones, cell proliferation through symmetric and asymmetric cell divisions, and finally the migration of post-mitotic neurons to their final destinations. An understanding of the molecular mechanisms guiding these intricate and complex processes is facilitated by discovery of causative genes for a Mendelian form of the cortical (brain) malformation disorder, primary microcephaly (MCPH), which is characterized by a smaller than normal brain and mental retardation. Interestingly, the brain volume (400 cc) of an MCPH patient is similar to early hominids, such as Australopithecus who lived 2.0-4.4 myr ago. Occasionally, MCPH patients also have other brain malformations, such as pachygyria, polymicrogyria, simplified gyral pattern etc. We have been working on the genetics of MCPH for some time, which led to discovery of the seventh MCPH gene STIL in 2009. So far, a total of nine genes and 10 loci have been identified for MCPH: MCPH1 on ch8p22-ter:MCPH1, MCPH2 on ch19q13.1-q13.2:WDR62, MCPH3 on ch9q34:CDK5RAP2, MCPH4A on ch15q21.3-q13.3:CASC5, MCPH4B on ch15q21.3-q13.3:CEP152, MCPH5 on ch1q25-q32:ASPM, MCPH6 on ch13q12.2:CENPJ, MCPH7 on ch1p32.3-p33:STIL, MCPH8 on ch4q12:CEP135, MCPH9 on ch3q22.2:CEP63 and an orphan locus MCPH10 on ch10q11.23-21.3. We have continued to ascertain MCPH families and collected so far a total of 60 families. Using homozygosity mapping and Sanger sequencing, we have identified mutations in WDR62 (3 families), ASPM (8 families) and STIL (6 families) genes only in our families, with a mutation detection rate of 28.33% (17/60 families) in known nine MCPH genes. Thus, the ASPM gene is found to be the most commonly mutated gene followed by STIL in Indian population. There are still many families in our family dataset which do not harbor mutations in any of the nine known genes, suggesting the discovery of additional novel genes for MCPH in future. We are currently using homozygosity mapping and whole-exome sequencing to identify the novel gene(s). A comprehensive analysis of our molecular genetic analysis of Indian MCPH families will be presented and discussed.

2992F

Genetic background of inner ear malformation. *R. Birkenhager, E. Prera, S. Arndt, W. Maier, R. Laszig, A. Aschendorff.* Otorhinolaryngology H&N Surg, Univ Freiburg, Freiburg, Germany.

Introduction: Hearing impairment is the most common sensory disorder in humans, affecting approximately one to three in 1000 newborns, with 50 % due to genetic causes. The majority of these cases (70 %) are non-syndromic, about 2 % of these are X-linked. So far five different X-linked loci have been mapped, the causative gene POU3F4 (MIM 300039) has been identified for the gene locus DFNX2. This hearing loss is often progressive, with temporal bone abnormalities and stapes fixation. Temporal bone anomalies include dilation of the fundus of the internal acoustic canal (IAC), that can increase the risk of CSF gusher during cochlear implant surgery. During inner ear development, the homologous mouse Pou3f4 gene is exclusively detected in the mesenchymal tissue adjacent to the otic epithelium. Knockout Pou3f4 mice have abnormalities in mesenchyme derived structures including the scala tympani, spiral limbus and spiral ligament fibrocytes of the cochlea as well as variances in the temporal bone. POU3F4 belongs to a sub-family of transcription factors, which are characterized by two conserved DNA binding domains, a POU and a HOX domain, both helix-turn-helix (HTH) structural DNA binding motifs. Several molecular genetic studies have identified mutations in the POU3F4 gene, including partial or complete deletions of the gene, as well as deletions, inversions, and duplications of the DFNX2 genomic region not encompassing the POU3F4 coding sequence. Here we present the clinical characteristics of four patients from independent families. Mutations analysis in the POU3F4 gene was brought by direct sequencing. Methods: Hearing testing BERA/Electrocochleography was only done in the Patient other family members were not tested because they have no hearing impairment or clinical abnormalities. Radiological a high-resolution CT scan was made. Mutational analysis of the affected individual and first degree relatives was performed using direct sequencing of the coding exon and intron transitions of the POU3F4, including deletion analysis. Results: Sequence analyses revealed a novel deletion of 2600 nucleotides [TAG (Stop) +21nt - 2620nt] and two novel missense mutations c.902C>T, (p.P301L) and c.973 T>A, (p.W325R) and in a fourth patient an already known missense mutation c.907C>T, (p.P303S). Conclusions: Until now three novel strongly conserved mutations in the HOX-domain of the POU3F4 transcription factor were identified leading to an effect in the protein function.

2993W

Using whole exome sequencing to diagnose primary microcephaly caused by mutations in ASPM and WDR62. *A.H. Cebi[1], D. Pehlivan[2], E. Karaca[2], M.M. Atik[2], T. Tos[3], W. Wiszniewski[2], Y. Bayram[2], D. Muzny[4], R.A. Gibbs[4], J.R. Lupski[2,5,6].* 1) Medical Genetics, Karadeniz Technical University, Faculty of Medicine, Trabzon, Turkey; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 3) Department of Medical Genetics, Sami Ulus Children's Hospital, Ankara, Turkey; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston TX, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 6) Texas Children's Hospital, Houston, TX, USA.

Whole-exome sequencing (WES) is a new groundbreaking technology that has changed the course of human genetics. As a more efficient and cost effective method, WES is now widely used as a diagnostic tool for identifying genetic disorders. Microcephaly is defined by an occipito-frontal head circumference less than 2 standard deviations (SD) under age and gender-based averages. Mutations in the ASPM and WDR62 genes have been found to cause primary microcephaly. The ASPM gene probably plays a role in the coordination of mitotic processes as well as mitotic spindle regulation and may also have a function in regulating neurogenesis, whereas the WDR62 gene codes for a spindle pole protein that serves in cerebral cortical development. Here, we present two separately consanguineous families, each with two affected individuals with primary microcephaly. We identified homozygous frameshift deletion in ASPM gene in the affected individuals from one family and WDR62 gene in the other family, whereas parents were at heterozygous state for this mutation.

2994T

ZBTB20-dependent transcription regulation imbalance in autism and intellectual disability. *R. Koul[1,2], L. Dukes-Rimsky[1], Y. Luo[1,8], K.A. Jones[3], E. Lemyre[5], S.M. Sowell[1], D.P. Srivastava[3], S. Ladd[1], B.R. DuPont[1], C.M. Wilson[6], C. Skinner[1], F. Gurrieri[7], R.E. Stevenson[1], E. Boyd[6], J.L. Michaud[5], L. Wang[2], P. Penzes[3,4], A.K. Srivastava[1,2].* 1) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, SC; 3) Department of Physiology, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Department of Psychiatry and Behavioral Sciences, Northwestern University Feinberg School of Medicine, Chicago, IL; 5) CHU Sainte-Justine, Centre de recherche, Montréal (QC), Canada; 6) Fullerton Genetics Center, Asheville, NC; 7) Institute of Medical Genetics, Catholic University, Rome, Italy; 8) Present address: Department of Pediatrics, Emory University School of Medicine, Atlanta, GA.

Dendritic spine morphology and dendritic arborization are key determinants of neuronal connectivity, and have been found to be altered in many neurodevelopmental disorders such as autism spectrum disorders (ASDs) and intellectual disability (ID). Several studies suggest that the changes in neuronal gene expression controlled by selective expression of transcription factors (TFs) affect the formation of dendritic spines and synapses. Recently, we identified the disruption of two transcription factor genes, *ZBTB20*, a member of the BTB/POZ (poxvirus and zinc finger) family of transcription factors, and *SOX5*, a member of the SOX (SRY-related HMG-box) family of transcription factors, by a chromosome translocation t(3;12) in a patient with developmental delay and autistic features. In addition, we identified two *SOX5* mutations, one missense and one nonsense, unique to non-syndromic ID, two nonsynonymous *ZBTB20* mutations unique to ASD and or ASD/ID, and a *de novo* intragenic deletion of *ZBTB20* in a patient with borderline intelligence, attention deficit and impulsivity. Recently, several genomic deletions involving either *ZBTB20* or *SOX5* have also been reported in patients with ASD and or ID. Studies in mice brain have shown that Zbtb20 functions as a transcriptional repressor that binds and represses several TF genes, including *SOX5,* which are involved in neurogenesis, dendritogenesis, and neuronal circuit formation. We found that in human brain, *ZBTB20* expression was largely negatively correlated with these co-expressed TF genes and genes enriched with Gene Ontology terms including synapse and synaptic transmission functions. In cultured rat cortical pyramidal neurons, overexpression of *ZBTB20* affected spine morphology and dendritic arborization. Furthermore, overexpression of *ZBTB20* in HEK293H cells resulted in a significantly reduced expression of TF genes such as *TBR1* and *MEF2C*, previously associated with ASD and ID. The ASD/ID-associated *ZBTB20* mutants had no repressor activities and caused no change in the expression of *TBR1* and *MEF2C*. Taken together, our study suggests the association of SOX5 and its transcription regulator ZBTB20 with ASD and ID and provides potential molecular and cellular mechanisms for ZBTB20 physiological actions, and suggests a potential contribution of a ZBTB20-dependent transcription regulation mechanism in neurocognitive and behavioral disorders.

2995F

Rare Deletion of the *DMD* Brain-Specific Promoter Results in ASD without Muscle Findings. *H. Mason-Suares[1], F. Probst[2], M. Hedge[1], B. Coffee[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The *DMD* gene is expressed from eight separate promoters, three of which code for the full length protein with changes in only the first exon. One of these promoters, known as Dp427c or Dp427b, is expressed predominantly in neurons of the cortex and the CA regions of the hippocampus. This brain-specific isoform is identical to the muscle-specific isoform of *DMD* except that the first 11 amino acids of the muscle-specific isoform are replaced with the three amino acids MED. While the function of the brain-specific isoform is unknown, it has been hypothesized that it may be responsible for the intellectual disability defect seen in about one-third of Duchenne muscular dystrophy patients. Supporting this, the brain-specific isoform is associated with the postsynaptic membrane and thought to play a role in synapse structure or function. Here we present the first case of a deletion that only removes the brain-specific promoter, leaving the rest of the *DMD* gene intact including the muscle-specific promoter, in a pair of male twins. The twins presented with developmental delay and an autism spectrum disorder including speech delay and repetitive behaviors. One of the twins also had intellectual disability and intractable epilepsy, which was resolved via left temporal lobectomy. Neither of the twins have had any muscle findings nor a positive Gower's sign consistent with an intact muscle-specific *DMD* transcript. This case suggests that the brain-specific *DMD* transcript is necessary for normal brain function, but does not result in muscular dystrophy.

2996W

Mitochondrial DNA deletions heteroplasmy analysis using the Next Generation Sequencing. *Y. Okamoto, J. Yuan, A. Yoshimura, S. Nozuma, Y. Higuchi, Y. Sakiyama, A. Hashiguchi, I. Higuchi, H. Takashima.* Department of Neurology and Geriatrics, Kagoshima University, Kagoshima, Japan.

Mitochondrial disorders are genetically heterogeneous group of diseases, involving two genomes, the 16.6 kb mitochondrial genome and approximately 1500 genes encoded in the nuclear genome. Mitochondrial myopathy with episodic hyper-creatine kinase-emia (MIMECK) is characterized by episodic or persistent muscle weakness and elevated serum CK levels triggered by infections, drugs, or stressful situations. We previously reported a similar phenotype with same mitochondrial DNA (mtDNA) alterations. However, the pathophysiological mechanism of MIMECK is still unknown. The development of Next Generation Sequencing (NGS) has revolutionized the diagnostic approach. New approaches make genetic analyses much faster, more sensitive and more efficient. The MiSeq personal sequencing system was performed on 30 samples and revealed mtDNA deletions in muscles samples of genetically proven cases, clinically and pathologically suspected cases and MIMECK. We found low rate mtDNA deletions in MIMECK and also found various rate mtDNA deletions heteroplasmy in other mitochondrilal disease including MELAS with 3243A>G mutation. Further study we need to perform analysis for nuclear gene or pathological study to detect pathophysiology. Sanger sequencing does not have the sensitivity to detect heteroplasmic mutations below about 20%. It also does not detect large deletions. Southern blot analysis is not sensitive to detect low levels of heteroplasmic deletions. Low rate mtDNA deletions analysis by NGS could be more sensitive tool before exome-sequence for nuclear mitochondrial related gene or underdiagnosed mitochondrial disease.

Severe Congenital *RYR1* Associated Myopathy: AR and AD *RYR1* Mutations that Expand the Genetic, Clinical and Pathologic Spectrum. *L. Medne[1], D.X. Bharucha-Goebel[1], M. Santi[2], K. Zukosky[3], J. Dastgir[3], T. Winder[4], P.B. Shieh[5], G. Tennekoon[1], R.S. Finkel[6], J.J. Dowling[7], N. Monnier[8], C.G. Bönnemann[3].* 1) Div of Neurology, CHOP, Philadelphia, PA. 19104; 2) Dept of Pathology & Laboratory Medicine, CHOP, Philadelphia, PA 19104; 3) Neurogenetics Branch, NINDA, NIH, Bethesda, MD; 4) Prevention Genetics, Marshfield, WI; 5) Dept of Neurology, University of California, Los Angeles, CA; 6) Division of Neurology, Nemours Children's Hospital, Orlando, FL; 7) Department of Pediatrics, University of Michigan Medical Center, Ann Arbor, MI; 8) Biochimie et Genetique Moleculaire, Institut de Biologie et Pathologie, CHU, Grenoble, France.

RYR1 gene mutations are known to cause central core or minicore myopathy, typically with a static or slowly progressive course, and pharmacogenetic predisposition to malignant hyperthermia (MH). We report a series of 13 patients with early neonatal onset *RYR1* associated myopathy due to both autosomal recessive and dominant acting *RYR1* mutations representing the severe end of the clinical spectrum, thus expanding the genetic, clinical and histological spectrum of *RYR1* associated myopathy. Clinical features associated with the severe neonatal presentation of *RYR1* associated myopathy included decreased fetal movement, hypotonia, poor feeding, respiratory involvement, arthrogryposis, ophthalmoplegia in four patients, and femur fractures or hip dislocation at birth. One patient had a cleft palate, and another a congenital rigid spine phenotype. Muscle biopsy was performed in all patients at ages ranging from 3 weeks of life to 4 years old. Marked type I fiber predominance approaching type I uniformity was common. All dominant cases had cores while recessive cases had extremely diverse pathology including central cores, multi minicores, more subtle unevenness or normal staining on NADH. Centralized nuclei, extensive fatty and connective tissue infiltration, extremely small fibers in the absence of active degeneration and regeneration were also seen as part of this spectrum. Dominant *RYR1* mutations (*de novo* or due to mosaic parent) were present in 4 patients and 9 patients had recessive *RYR1* mutations. Two of the carrier parents showed muscle weakness and one had ophthalmoplegia, thus showing that those mutations can be dominant acting. This series confirms and expands the clinical and histological variability associated with severe congenital *RYR1* associated myopathy. Both dominant and recessive mutations of the *RYR1* gene can result in a severe neonatal onset phenotype, but more clinical and histological heterogeneity has been seen in those with recessive RYR1 gene mutations. Absence of cores on muscle biopsy should not preclude the consideration of *RYR1* associated myopathy. Furthermore, identification of predominantly recessive *RYR1* mutations with severe neonatal phenotype alters recurrence risk counseling for parents and their own medical management suggesting the need for life-long MH precautions in heterozygous carrier parents and siblings given the AD nature of isolated MH predisposition mutations.

2998F

Subtle mutations in the SMN1 gene in Chinese patients with SMA: p.Arg288Met mutation causing SMN1 transcript exclusion of exon7. *Y. QU[1], J. DU[1], E. LI[2], J. BAI[1], Y. JIN[1], H. WANG[1], F. SONG[1].* 1) Capital Institute of Pediatrics, Beijing, China; 2) Children's Hospital Affiliated Capital Institute of Pediatrics, Beijing, China.

Background: Proximal spinal muscular atrophy (SMA) is a common neuromuscular disorder resulting in death during childhood. Around 81 ~ 95% of SMA cases are a result of homozygous deletions of survival motor neuron gene 1 (SMN1) gene or gene conversions from SMN1 to SMN2. Less than 5% of cases showed rare subtle mutations in SMN1. Our aim was to identify subtle mutations in Chinese SMA patients carrying a single SMN1 copy. Methods: We examined 14 patients from 13 unrelated families. Multiplex ligation-dependent probe amplification analysis was carried out to determine the copy numbers of SMN1 and SMN2. Reverse transcription polymerase chain reaction (RT-PCR) and clone sequencing were used to detect subtle mutations in SMN1. SMN transcript levels were determined using quantitative RT-PCR. Results: Six subtle mutations (p.Ser8LysfsX23, p.Glu134Lys, p.Leu228X, p.Ser230Leu, p.Tyr277Cys, and p.Arg288Met) were identified in 12 patients. The p.Tyr277Cys mutation has not been reported previously. The p.Ser8LysfsX23, p.Leu228X, and p.Tyr277Cys mutations have only been reported in Chinese SMA patients and the first two mutations seem to be the common ones. Levels of full length SMN1 (fl-SMN1) transcripts were very low in patients carrying p.Ser8LysfsX23, p.Leu228X or p.Arg288-Met compared with healthy carriers. In patients carrying p.Glu134Lys or p.Ser230Leu, levels of fl-SMN1 transcripts were reduced but not significant. The SMN1 transcript almost skipped exon 7 entirely in patients with the p.Arg288Met mutation. Conclusions: Our study reveals a distinct spectrum of subtle mutations in SMN1 of Chinese SMA patients from that of other ethnicities. The p.Arg288Met missense mutation possibly influences the correct splicing of exon 7 in SMN1. Mutation analysis of the SMN1 gene in Chinese patients may contribute to the identification of potential ethnic differences and enrich the SMN1 subtle mutation database.

2999W

Exome sequencing identifies PINCH2 mutations associated with early-onset autosomal recessive LGMD with severe cardiomyopathy and triangular tongue. *J. Warman Chardon[1], A. Smith[2], J. Woulfe[3], K. Rakhra[4], C. Dennie[4], J. Schwartzentruber[5], C. Beaulieu[2], FORGE. Canada Consortium[6], J. Majewski[7], D.E. Bulman[2], K.M. Boycott[1,2], D. Dyment[1,2].* 1) Genetics, Chidren's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 3) Pathology, The Ottawa Hospital, Ottawa, Ontario, Canada; 4) Medical Imaging, The Ottawa Hospital, Ottawa, Ontario, Canada; 5) McGill University and Genome Quebec Innovation Centre, Montréal, Québec; 6) Canada; 7) Department of Human Genetics, McGill University, Montreal, Quebec.

Limb Girdle Muscular Dystrophy (LGMD) is a heterogeneous group of inherited disorders leading to progressive muscle degeneration often associated with cardiac complications. We investigated affected siblings with a childhood onset LGMD with macroglossia and calf enlargement. The siblings developed decreased ejection fraction with global left ventricular dysfunction in their 3rd decade, severe quadriparesis and relative sparing of the face, with a broad based triangular tongue. After negative genetic evaluation for known LGMD genes, we performed whole exome sequencing of the affected siblings and identified shared compound heterozygous missense mutations in exon 5 (c.C356T; p.Pro119Leu and c.C342G; p.Asn114Lys) and exon 11 (c.T1034C; p.Leu345Pro) of the PINCH2 gene, which segregated appropriately in the family. Both novel variants in exon 5 are in cis. PINCH2 is an important member of the IPP (ILK, Parvin, PINCH) heterotrimeric complex and is essential for signaling through integrin adhesion receptors that regulate cell migration, spreading and adhesion and is found in skeletal and cardiac muscle cells. The IPP complex stabilizes expression of the component proteins by reducing proteasomal degradation. PINCH1 and PINCH2 demonstrate overlapping expression, competitive binding to ILK and functional redundancy. There is evidence in murine models that PINCH1 may compensate for loss of PINCH2 in some tissues, suggesting that a potential therapeutic approach may involve upregulation of PINCH1 to stabilize the IPP complex in patients with PINCH2 mutations. Although well demonstrated in animal models, this is a novel discovery of IPP complex dysfunction implicated in LGMD.

3000T

C19ORF12 Mutations in Neurodegeneration with Brain Iron Accumulation (NBIA). *G. Annesi[1], P. Tarantino[1], M. Gagliardi[1], G. Lesca[2,3], E. Broussolle[4,5], A. Gambardella[1], A. Quattrone[6].* 1) Inst. of Neurological Science, National Research Council, Mangone (CS), CS, Italy; 2) Department of Medical Genetics, Hospice Civiles de Lyon and ClaudeBernard Lyon, University Lyon France, Lyon, France,; 3) CRNL, CNRS UMR 5292, INSERM U1028, Lyon, France, Lyon, France; 4) Université Lyon I; Centre de Neurosciences Cognitives, CNRS UMR5229, Lyon, France,; 5) Service de Neurologie C, Hôpital Neurologique Pierre Wertheimer, Lyon, France, Lyon, France,; 6) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy, Catanzaro, Italy.

Neurodegeneration with Brain Iron Accumulation (NBIA) comprise heterogeneous group of progressive neurodegenerative disorders that present with a progressive extrapyramidal syndrome and excessive iron deposition in the brain, particularly affecting the basal ganglia, mainly the globus pallidus. Genetic defects in PANK2 gene are the most common cause of NBIA, followed by mutations in PLA2G6, few reported NBIA families are known to carry mutations in FA2H, a gene previously associated with familial leukodystrophy and spastic paraparesis. Mutations within C19orf12 have recently been identified in patients with NBIA. This gene C19orf12, codes for a mitochondrial membrane protein and the acronym MPAN (mitochondrial membrane protein-associated neurodegeneration). In this study we report the clinical description of five patients from five families with NBIA and the subsequent molecular genetic investigation. Five patients diagnosed with NBIA by movement disorders specialists. As required by clinical regulations, all provided written informed consent for genetic testing.The initial diagnosis was based on manifestation of progressive movement disorder and demonstration of a hypointense signal in the globus pallidus on T2-weighted MRI scans. The exons of PANK2, PLA2G6, FA2H and C19orf12 were amplified by PCR and sequenced. Results.Sequencing of PANK2, PLA2G6 and FA2H was normal; whereas the molecular analysis of C19orf12 gene revealed a novel homozygous and heterozygous C19orf12 mutations in our patients with NBIA. Further studies are needed to explore the function of C19orf12 in NBIA, and extended genetic analysis of larger patients cohorts will provide more information about the frequency of this disease.

Hypoxanthine guanine phosphoribosyltransferase (HPRT) deficiencies: *HPRT1* mutations in new Japanese families and PRPP concentration. *Y. Yamada[1], N. Nomura[1], A. Yamano[1], K. Yamada[1], R. Kimura[1], D. Fukushi[1], H. Hasegawa[2], M. Nakamura[2], K. Ichida[2], N. Wakamatsu[1].* 1) Dept Gen, Inst Dev Res, Aichi Human Service Ctr, Kasugai Aichi, Japan; 2) Dept Pathophysiol, Sch Parma, Tokyo Univ Pharm and Life Sci, Tokyo, Japan.

Mutation of hypoxanthine guanine phosphoribosyltransferase (HPRT), gives rise to Lesch-Nyhan syndrome, which is characterized by hyperuricemia, severe motor disability, and self-injurious behavior, or HPRT-related gout (Kelley-Seegmiller syndrome). The marked heterogeneity of HPRT deficiency is well known, as reported more than 500 mutations at the HPRT gene (*HPRT1*) locus. We had identified a number of *HPRT1*mutations in Asian patients manifesting different clinical phenotypes. In this study, we clarified the mutations of four new Japanese families with the HPRT deficiencies and observed the increase of erythrocyte PRPP concentrations in the deficiencies. A new mutation of G to TT (c.456delinsTT) resulting in a frame shift (p.152fs154X) in exon 3 has been identified from a Lesch-Nyhan family. In the other Lesch-Nyhan family, a point mutation on intron 7 (c.532+5G>T) causing splicing error (exon 7 excluded) was detected. In two partial deficiency cases with hyperuricemia, two missense mutations of p.D20V (c.59A>T) and p.H60R (c.179A>G) were found, respectively. The mutations of c.532+5G>T and p.D20V were detected firstly in Japanese patients but had been reported in European families. The p.H60R was reported previously as an asymptomatic missense substitution. The PRPP concentrations in erythrocyte from three Lesch-Nyhan patients (18.5; 33.4; 40.8 nmol/mL) were markedly increased compared with those from normal control (0.8 ± 0.3 nmol/mL, n=8). The PRPP concentrations from patients with partial deficiency (1.3 - 7.7 nmol/mL) were also increased, but the degrees were smaller than those of the complete deficiency. The increases of erythrocyte PRPP concentration were correlated approximately with the phenotypic severity. Furthermore, we summarize the spectrum of Asian HPRT mutations.

3002W

PLEKHG5 deficiency leads to an intermediate form of autosomal recessive Charcot-Marie-Tooth disease. *H. Azzedine[1], P. Zavadakova[1], V. Planté-Bordeneuve[2], M. Vaz Pato[3], N. Pinto[3], L. Charcot-Marie-Tooth disease (CMT) comprises a clinically and genetically heterogeneous group of peripheral neuropathies characterized by progressive distal muscle weakness and atrophy, foot deformities, and distal sensory loss. Following the analysis of two consanguineous families affected by a childhood to late-onset recessive form of intermediate CMT, we identified overlapping regions of homozygosity on chromosome 1p36 with a combined maximum LOD score of 5.4. Molecular investigation of the genes from this region allowed identification of two homozygous mutations in PLEKHG5 that produce premature stop codons and are predicted to result in functional null alleles. Analysis of Plekhg5 in the mouse revealed that this gene is expressed in neurons and glial cells of the peripheral nervous system, and that knockout mice display reduced nerve conduction velocities that are comparable to those of affected individuals from both families. Interestingly, a homozygous PLEKHG5 missense mutation was previously reported in a recessive form of severe childhood onset lower motor neuron disease (LMND) leading to loss of the ability to walk and need for respiratory assistance. Together, these observations indicate that different mutations in PLEKHG5 lead to clinically diverse outcomes (intermediate CMT or LMND) affecting the function of neurons and glial cells.

3003T

Characterization of a homologue of the Batten disease protein CLN3 in the model eukaryote Dictyostelium. *R.J. Huber, S.L. Cotman, M.A. Myre.* Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA.

Batten disease refers to a group of mostly childhood neurodegenerative disorders also known as the neuronal ceroid lipofuscinoses (NCL). NCL disorders characteristically display dysregulated lysosomal function and an excessive accumulation of lipofuscin in neurons and other cell types. Juvenile NCL is the most common subtype of Batten disease and results from recessive, loss-of-function mutations in the CLN3 gene. Clinical symptoms of the disease include the progressive loss of motor function and psychological ability, blindness, seizures, and a reduced lifespan. Despite substantial research efforts using a variety of systems, the precise function of CLN3 remains unknown. The social amoebozoan Dictyostelium discoideum is used as a model system for studying a variety of cell and developmental processes and has been successfully used in biomedical research for studying a number of human diseases, including neurodegenerative disorders (e.g., Alzheimer's, Parkinson's, and Huntington's). To better understand the function of CLN3 in humans, we knocked out the CLN3 homologue in Dictyostelium and assayed the mutant cells for obvious and subtle phenotypic abnormalities during Dictyostelium growth and development. CLN3- cells proliferate at an enhanced rate and are able to complete the developmental cycle. However, phenotypes are observed during early, mid-, and late Dictyostelium development suggesting an involvement of CLN3 in cell movement, aggregation, and differentiation. Our current work is focused on expressing human CLN3 in Dictyostelium to see whether its expression can rescue the phenotypes we observe in CLN3- cells. Together, our work has generated a new cellular model for studying CLN3 function, which will provide new insight into the function of CLN3 in normal and diseased human cells. Our work also further validates the use of Dictyostelium for studying the function of proteins linked to neurodegeneration.

Whole exome sequencing identifies a new gene for Charcot-Marie-Tooth Type 2 in a Polish family. *M.L. Kennerson[1,2,3], G. Pérez-Siles[1], A. Kochański[4], A. Kidambi[1], A.P. Drew[1], J. Kosińska[5], M. Gonzalez[7], D. Kabzińska[4], R. Ploski[5], M. Menezes[6], I. Hausmanowa-Petrusewicz[4], S. Zuchner[7], G.A. Nicholson[1,2,3].* 1) Northcott Neuroscience, ANZAC Res Inst, Concord, Australia; 2) Molecular Medicine Laboratory, Concord Hospital, Sydney, Australia; 3) Sydney Medical School, University of Sydney, Sydney, Australia; 4) Neuromuscular Unit, Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland; 5) Department of Medical Genetics, Warsaw Medical University, Warsaw Poland; 6) Kids Research Institute, The Childrens Hospital, Westmead, Australia; 7) Hussman Institute for Human Genetics, University of Miami Miller School of Medicine, Miami, FL, USA.

Charcot Marie Tooth (CMT) disease is the most common inherited peripheral neuropathy affecting 1 in 2500 people. The disorder affects both motor and sensory neurons of the peripheral nervous system resulting in the 'dying back' (axonal degeneration) of long nerves. CMT is both clinically and genetically heterogeneous and is traditionally divided into demyelinating (CMT1) and axonal (CMT2) forms based on electrophysiological and neuropathalogical criteria. For CMT type 2 up to 80% of the causative genes remain unidentified. CMT research in the last 20 years has made significant discoveries that are elucidating the complexities of motor and sensory nerve biology and the pathogenic process of axonal degeneration. The advancement of sequencing technologies is providing affordable tools to identify gene mutations in families too small for traditional positional cloning approaches. The strategy of whole exome sequencing (WES) is therefore a very feasible approach for gene discovery in smaller CMT families. We have previously reported a Polish family with CMT type 2 in which all known CMT2 genes have been excluded (1). The family is a three generation kindred with affected individuals in two generations. We have performed WES on four members of the family (3 affected and one normal). Bioinformatic analysis and variant filtering identified a non-synonymous exonic variant in a member of the tubulin gene family. The variant fully segregates with the affected phenotype and has been excluded in 1400 normal control chromosomes. The variant occurs at a highly conserved amino acid residue of the protein and is predicted to be pathogenic. By querying 164 CMT2 index exomes in the GEMapp database (University of Miami, Miller School of Medicine URL: https://genomics.med.miami.edu/gem.app) we have identified an additional family with a different variant in the same gene. Transient transfection experiments with wild type and mutant expression constructs have shown alteration of the cytoskeleton. Genetic validation and functional studies supporting pathogenicity of the variant will be presented. This study demonstrates the power of WES for gene discovery in small families, further genetic heterogeneity of CMT type 2 and highlights a pathogenic mechanism altering cellular scaffolding. Distributions of Degenerative Myelopathy Associated SOD1 Alleles among Privately Owned Dogs. *A. Kolicheski[1], R. Zeng[1], G.S. Johnson[1], M.L. Katz[2], T. Mhlanga-Mutangadura[1], L. Hansen[1], E. Ivansson[3], K. Lindblad-Toh[3,4], J. Guo[1], D.P. O'Brien[5], G.C. Johnson[5], J.R. Coates[5].* 1) Department of Veterinary Pathobiology, University of Missouri College of Veterinary Medicine, Columbia, MO; 2) Mason Eye Institute, University of Missouri School of Medicine, Columbia, MO, USA; 3) Department of Medical Biochemistry and Microbiology, Uppsala University, Uppsala, Sweden; 4) Broad Institute of Massachusetts Institute of Technology and Harvard, Cambridge, Massachusetts, USA; 5) Department of Veterinary Medicine and Surgery, University of Missouri College of Veterinary Medicine, Columbia, MO, USA.

Canine degenerative myelopathy (DM) is a common neurodegenerative disease in dogs 8 years-old or older. Similar to human amyotrophic lateral sclerosis patients (ALS) patients, dogs with DM show both upper and lower motor neuron signs at end stage. DM-affected dogs may prove useful as a naturally-occurring disease model to investigate ALS pathogenic mechanisms and to evaluate the efficacy of therapeutic interventions. Two SOD1 mutations, SOD1:c.118G>A and SOD1:c.52A>T, are associated with DM. We here report the distribution of alleles at SOD1:c.118 and/or SOD1:c.52 in 33,747 privately owned dogs including cross-bred dogs and representatives from 222 breeds. Members of 124 different dog breeds harbored the SOD1:c.118A allele; whereas, the SOD1:c.52T allele was found exclusively in Bernese Mountain Dogs. Among the 914 genotyped Bernese Mountain Dogs, the SOD1:c.52T allele frequency was only 3.5%, much lower than the 37% frequency of the SOD1:c.118A allele in this breed. Twenty-four Bernese Mountain Dogs were compound heterozygotes, inheriting the SOD1:c.52T allele from one parent and the SOD1:c.118A allele from the other. We ascertained the clinical status of six 8 years-old or older compound heterozygotes Bernese Mountain Dogs. Four of them developed clinical signs consistent with DM. DM was histopathologically confirmed in eight SOD1:c.118A/G heterozygotes from 5 breeds. These eight dogs had no other SOD1 sequence variants, suggesting that heterozygosity at SOD1:c.118A/G increases the risk of developing DM. To estimate the relative risk of developing DM for SOD1:c.118A/G heterozygotes versus SOD1:c.118A homozygotes or SOD1:c.118G homozygotes, we reviewed clinical histories of 104 dogs that were under 8 years old and without signs of DM when their samples were submitted for genotyping but are currently over 10 years old. Sixteen of 26 SOD1:c.118A homozygotes (62%) exhibited DM-like signs; whereas, none of the 40 SOD1:c.118A/G heterozygous dogs and none of the 38 SOD1:c.118G homozygous dogs developed these clinical signs. Because the SOD1:c.118A allele is so common among privately owned dogs, it should be possible to recruit a cohort of homozygotes to test the efficacy of therapeutic interventions.

The *FIG4* gene encodes a phospholipid phosphatase that removes the 5-phosphate from the signaling lipid $PI(3,5)P_2$, a regulator of late endosome/lysosome vesicle trafficking. Deficiency of $PI(3,5)P_2$ in *Fig4* null mice results in enlarged cytoplasmic vacuoles, autophagy defects and neurodegeneration (Ferguson et al, HMG 2012). Hypomorphic mutations of human *FIG4* result in the peripheral neuropathy Charcot-Marie-Tooth type 4J (Nicholson et al, Brain 2012). Yunis-Varón syndrome (OMIM 216340) is an autosomal-recessive disorder with neurological and bone involvement including cleidocranial dysplasia and digital anomalies, as well as enlarged vacuoles in neurons, muscle, and cartilage. Using whole-exome and Sanger sequencing, we identified frameshift and missense mutations of *FIG4* in affected individuals from three unrelated families with Yunis-Varon Syndrome (Campeau et al, AJHG 2013). The *FIG4* genotypes of affected individuals included homozygosity for protein truncation alleles in one family, with heterozygosity for missense and null mutations or homozygosity for missense mutations in the other two families. In a functional assay, the missense substitutions from these families failed to correct the vacuolar defect of *Fig4* null mouse fibroblasts, demonstrating loss of function. We identified previously unrecognized skeletal defects in *Fig4* null mice, including small skeletons, reduced trabecular bone volume and cortical thickness. Comparison of patients with Yunis-Varon Syndrome and CMT4J indicates that complete absence of functional FIG4 results in central and peripheral nervous system dysfunction as well as skeletal anomalies, while retention of as little as 0.2% of normal FIG4 activity protects the CNS and causes peripheral nerve impairment only. Neurological findings in null individuals of both species include degeneration with vacuolization of the cerebral cortex and cerebellar and thalamic nuclei, as well as hypoplasia of the corpus callosum. Our findings demonstrate that null mutations of *FIG4* are responsible for a subset of Yunis-Varon Syndrome, the most severe known human disorder caused by defective phosphoinositide metabolism, and demonstrate a previously unrecognized role for $PI(3,5)P_2$ signaling in skeletal development. Studies in progress include genomic analysis of three Yunis-Varon families lacking *FIG4* mutations, and further investigation of defective bone development in homozygous null mice.

Whole exome sequencing analysis identified a novel homozygous c.1058G>A (p.Arg353Glu) missense mutation in *SLC25A12* that segregated with disease in a consanguineous Indian kindred in which a brother and sister were similarly affected with severely delayed global development, congenital hypotonia, mixed epilepsy, delayed myelination, and notable reduction of the N-acetylaspartate peak on brain spectroscopy. Extensive clinical diagnostic genetic testing was unrevealing, although both affected siblings shared three large homozygous chromosomal regions that were identified by genome-wide microarray analysis. Research-based whole exome sequencing (WES) analysis identified two rare homozygous variants that were predicted to be disease-causing, with only the *SLC25A12* mutation found by Sanger validation to segregate with disease in this family. *SLC25A12* encodes the neuronal aspartate-glutamate carrier 1 (AGC1) protein, which is an essential component of the malate-aspartate shuttle that transfers the reducing equivalents of NADH and H+ from cytosol to mitochondria in neurons. Functional studies demonstrated that the activity of recombinant mutant (Arg353Glu) AGC1 protein from the proband's fibroblasts was reduced to fifteen percent of the wild-type rate when measuring either aspartate or glutamate transport. This is the second reported family in which AGC1 has been shown to be causal of a severe, infantile-onset neurologic disease. An ACG1 mutation was identified in the initial case by candidate gene sequencing with fibroblast validation of absent AGC1 activity following identification of severely reduced brain levels of N-acetylaspartate and hypomyelination. Indeed, AGC1 activity enables neuronal export of aspartate, which is the glial substrate necessary for proper neuronal myelination. In summary, these data confirm that autosomal recessive *SLC25A12* disease impairs neuronal AGC1 activity and highlight the importance of considering *SLC25A12* in the differential diagnosis of infantile-onset seizures, hypotonia, and global developmental delay with abnormal myelination and reduced N-acetylaspartate levels in brain.

Defect of TARG1/C6orf130 gene causing an autosomal form of familial neurodegeneration with seizure.
E. Ozkan[1], B. Chioza[1], M. Patton[1], A.G. Ladurner[2], G. Timinszky[2], I. Ahel[3], R. Sharifi[1]. 1) BMS Genetics, St.George's University of London, London, United Kingdom; 2) Faculty of Medicine, Butenandt Institute of Physiological Chemistry, Ludwig Maximilians University of Munich, Munich, Germany; 3) Cancer Research UK, Paterson Institute for Cancer Research, University of Manchester, Manchester, UK.

The genetic causes of neurodegenerative disorders, a heterogeneous group of chronic progressive diseases, remain largely unknown. Here, we report the discovery of TARG1/c6orf130 gene (NM_145063.2) causing severe neurodegeneration with an autosomal recessive trait. The clinical presentations are; progressive global neural dysfunction and severe neurological development delay, generalized tonic- clonic (grandmal) epilepsy, tetraplegia, absence of tendon reflexes, communication disability, and lack of swallowing reflex. We genotyped the family members on genome-wide SNP microarrays and used the data to determine a single 20 cM homozygosity-by-descent (HBD) locus in region 6p21 (LOD score of 7.4); with performing next generation sequencing we identified the missense change c.227C>T that causes an early stop codon (NP_659500.1:p.R76X) at the conserved C-terminus within TARG1/C6orf130. This gene encodes C6orf130 protein belongs to the macrodomains family which are evolutionarily conserved structural protein involving in adenosine diphosphate (ADP)-ribosylation. Adenosine diphosphate (ADP)-ribosylation is an evolutionarily conserved reversible post-translational protein modification that regulates a wide range of cellular processes, including DNA repair, transcription, telomere dynamics, cell differentiation and proliferation, the inflammatory and immune responses and apoptosis. We identified C6orf130 as a PARP (poly(ADP-ribose) (PAR) polymerase)-interacting protein that removes mono(ADP-ribosyl)ation on glutamate amino acid residues in PARP-modified proteins. Our biochemical analysis of C6orf130 suggests a mechanism of catalytic reversal involving a transient C6orf130 lysyl-(ADP-ribose) intermediate. In human neuron cells, we show that C6orf130 localise to the nucleus. Furthermore, depletion of C6orf130 protein in cells leads to proliferation and DNA repair defects. Collectively, our data suggest that C6orf130 enzymatic activity has a role in the turnover and recycling of protein ADP-ribosylation, and we have implicated the importance of this protein in supporting normal neuron cell function in humans. This is for the first time that we show the importance of C6orf130 protein (newly named Terminal ADP-Ribose protein Glycohydrolase; TARG1) in neuron cells by reversing protein ADP-ribosylation and protein modulation.

Rare diseases, the vast majority of which are genetic in origin, have a particularly detrimental effect on children. More than 50% of rare disease patients are paediatric, and at least 30% of these children will not live to see their first birthday. Additionally, many of these patients will be incorrectly diagnosed (at least 40% according to EURODIS), or will remain without a final diagnosis. For example, it is well established that half of the patients with leukoencephalopathies, rare central nervous system white-matter disorders, remain a diagnostic mystery despite the fact that they are known to have a genetic basis. Here we present a series of studies showing the successful application of high-throughput genome and exome sequencing to paediatric patients with unresolved diagnoses. These include i) identification of the mutations in DARS responsible for an young boy's leukoencephalopathy and the characterisation of a novel disease (HBSL), ii) identification of a de novo TUBB4A mutation responsible for a leukoencephalopathy of unknown genetic aetiology, H-ABC, iii) identification of a novel de novo mutation in KCNT1, a potassium transporter, in a child with non-specific white matter abnormalities and severe epilepsy, which led to treatment with specific channel therapies, and iv) in less than a month, identification of the mutation responsible for an unexplainable case of Leigh disease, which facilitated patient enrolment in an ongoing clinical trial. In collaboration with the Global Leukodystrophy Initiative (GLIA) and others, we are now working with large cohorts of children with rare diseases with the aim of dramatically reducing the number of unresolved cases.

3010F

Rai1 dosage in early development is essential to PTLS-like phenotype development in Dt-Rai1 animals. *L. Cao[1], C. Abad[1], J. Molina[2], J.I. Young[1,3], K. Walz[1,3,4].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, Miller School of Medicine, University of Miami, FL, USA; 2) Centro de Estudios Científicos, CECS, Valdivia, Chile; 3) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, FL, USA; 4) Department of Medicine, Miller School of Medicine, University of Miami, FL, USA.

In humans, duplication of Rai1 is associated with the Potocki-Lupski syndrome, a neurodevelopmental disorder that causes failure to thrive, hypotonia, intellectual disabilities and autism. Previously, we had generated a mouse line carrying a transgene encoding Rai1 under the control of a tTa responsive promoter. By crossing this mouse line with camkII-tTa transgenic mice which express tTa downstream of CamkII promoter, we obtained double-transgenic mice (Dt-Rai1) which express transgenic Rai1 specifically in mouse forebrain neurons. Surprisingly, Dt-Rai1 mice showed most of the PTLS-like phenotypes including underweight, lower abdominal fat content, hyperactivity, and impaired learning and memory ability. Doxycycline administration can inactivate tTA mediated transcription and thus turn off the transgene expression. A critical question for possible therapeutic approaches to PTLS and related disorders concerns phenotypic prevention and reversibility. Here we applied doxycycline treatment to Dt-Rai1 animals at different time points: 3-5 months, to test phenotypic reversibility, 1-3 months to test phenotypic prevention. Our study showed that turning off the transgene expression after the onset of the phenotypes (3-5 month) cannot rescue the phenotypes and turn off the transgene expression before the onset of the phenotypes (1-3 month) cannot prevent the development of the phenotypes in mice either. Interestingly, when the mice were treated with doxycycline from embryonic development to 3 month, some of the phenotypes are rescued as activity in open field and context memory in fear conditioning test. At 3 month of age, Body weight showed an increase of ~3 g compared with mice treated with doxycycline from 1-3 month. Our results showed that Rai1 dosage in early developmental stage is essential to the development of PTLS-like phenotype in mice.

3011W

Role of REEP1 (SPG31) in mitochondrial structure and energetic function. *C. Goizet[1,2], J. Lavie[1], N. Bellance[1], S. Melser[1], G. Solé[3], D. Hannequin[4], S. Lyonnet[5], S. Forlani[6,7,8], A. Brice[6,7,8,9], G. Stevanin[6,7,8,9], A. Durr[6,7,8,9], R. Rossignol[1], D. Lacombe[1,2], G. Bénard[1].* 1) Univ. Mutations in REEP1 cause SPG31, an autosomal dominant form of hereditary spastic paraplegia (HSP). In a previous study, we showed that fibroblasts and muscle biopsies from one SPG31 patient with a heterozygous truncative mutation of REEP1 (c.106delG ; p.V36SfsX4) displayed defective mitochondrial energy production as well as altered structure of mitochondrial network. We now confirme an alteration of mitochondrial function and architecture using fibroblasts from additional patients with missense mutations (c.166G>A, p.D56N and c.124T>C, p.W42R, respectively). Interestingly, we also find that SPG31 patients reveal higher level of mitochondrial DNA (around 3-fold increase) compared to controls. To analyze whether REEP1 is involved in mitochondrial physiology, we have expressed different isoforms of REEP1 in HeLa cells and we demonstrate different localization profiles for REEP1. We observed that one pool of REEP1 strongly locates to mitochondria inducing the organelle fragmentation. Our results validate the role of REEP1 in mitochondrial functions.

3012T

Comprehensive genetic analysis of autosomal dominant spinocerebellar ataxia using a next-generation sequencing system. *Y. Higuchi, A. Yoshimura, J. Yuan, Y. Sakiyama, R. Saigo, R. Hirano, A. Hashiguchi, Y. Okamoto, R. Okubo, H. Takashima.* Neurology and Geriatrics, Kagoshima University Graduate School of Medical and Dental Science, Kagoshima City, Kagoshima, Japan.

Objective: Autosomal dominant spinocerebellar ataxias (AD-SCAs) are a group of clinically and genetically heterogeneous neurodegenerative disorders. Genetic studies revealed at least 20 disease-causing genes in patients with AD-SCA. Concomitant with the increase in the number of genes, labor, and reagent costs for molecular genetic testing has increased significantly. We established a diagnostic procedure for AD-SCA using a next-generation sequencing (NGS) system. Methods: First, 208 patients with AD-SCA were screened for repeat expansions in the genes encoding SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA12, SCA31, and DRPLA. Second, 31 patients who were negative for the first screening were enrolled. Using the NGS system (Illumina MiSeq®), we screened for mutations in nine known AD-SCA disease-causing genes, including SPTBN2, TTBK2, KCNC3, PRKCG, ITPR1, PDYN, FGF14, AFG3L2, and TGM6 (genes encoding SCA5, SCA11, SCA13, SCA14, SCA15, SCA23, SCA27, SCA28, and SCA35, respectively). Results: In the first screening, 171/208 (82.2%) patients received a molecular diagnosis; SCA31 was the most frequent subtype followed by SCA6, SCA3, and DRPLA. Secondly, mutation screening using the NGS system revealed four novel missense variations in SPTBN2, TTBK2, and PRKCG. Conclusion: We established a comprehensive diagnostic procedure for AD-SCA using an NGS system. NGS facilitates target resequencing for rapid, accurate, and low-cost applications. No pathogenic mutations were conclusively detected in approximately 18% patients, suggesting that more causative genes should be related with the AD-SCA phenotype. It is expectable that exome sequencing and whole-genome sequencing will contribute to the identification of the novel causative genes.

3013F

The phenotype associated with *ASPM* mutation expands to severe Seckel syndrome. *D.J. Morris-Rosendahl[1], G. Yigit[2], G. Carpenter[3], R. Colnaghi[3], K. Mueller[1], G. Borck[4], M. Trimborn[5], F. Beleggia[2], M. Leipoldt[1], G. Nuernberg[6], K. Seufert[1], B. Wollnik[2], M. O'Driscoll[3].* 1) Institute of human Genetics, Albert-Ludwigs University of Freiburg Medical Center, Freiburg, Germany; 2) Institute of Human Genetics, University of Cologne, Germany; 3) Genome Damage and Stability Centre, University of Sussex, Brighton, UK; 4) Institute of Human Genetics, University of Ulm, Ulm, Germany; 5) Institute of Medical and Human Genetics, Charité University, Berlin, Germany; 6) Cologne Genomics Center, Cologne, Germany.

ASPM is one of the 10 genes known to be associated with primary autosomal recessive microcephaly (MCPH), characterized by reduced head circumference at birth and varying degrees of intellectual disability (ID). Mutations in ASPM are responsible for 25-50% of MCPH, depending on the ethnic background of the patients. The phenotypes associated with the MCPH genes are continually being re-defined and mutations in the *CENPJ* (MCPH6) and *CEP152* (MCPH9) genes are now known to also cause Seckel syndrome. Clinical findings so far associated with *ASPM* mutation include late-onset seizures, pyramidal tract involvement, simplified gyral pattern of the cortex, ventricle enlargement, partial corpus callosum agenesis, mild cerebellar hypoplasia, focal cortical dysplasia and unilateral polymicrogyria. Non-neurologic abnormalities include short stature, idiopathic premature puberty and renal dysplasia. We now describe a family with two daughters (P1 and P2) with a severe Seckel syndrome phenotype including severe microcephaly (P1: OFC at birth 25,5 cm, 38th week; P2: OFC at birth 24,5 cm, 37th week), severe brain malformation and short stature (P1 at 8y8m: weight 10 kg, length 1m; P2 at 5y8m: weight 7 kg, length 86 cm). Both girls have severe intellectual disability, P1 learned to walk with support at 3,5 years and can say a few words, P2 can neither walk nor talk. Extensive cytogenetic and molecular genetic work-up included karyotyping, analysis of chromosome condensation, array CGH (Agilent 244K), genome-wide linkage analysis on an Affymetrix SNP array and sequencing of the following genes: *MCPH1, CEP152, CENPJ, RCC2*, with the only possibly pathological finding being a novel heterozygous missense change, c.2378C>A, in the *MCPH1* gene, in P1, P2 and their father. Subsequent Whole Exome Sequencing (WES) revealed compound heterozygosity for novel truncating *ASPM* mutations: c.T1674A>T (p.Y558X) and c.9324delT (p.L3108fsX) in both affected daughters and heterozygosity for a splice mutation, c.688-2A>C in *CEP164* in P1. Analysis of the ATM- and ATR-dependent G2-M checkpoint responses in EBV-transformed lymphocyte cell lines from P1 and her father, together with the absence of premature chromatin condensation, made MCPH1 an unlikely contributing candidate for the disorder. Functional cellular analysis confirmed ASPM pathogenicity in lymphocyte cell lines from the patients.

3014W

Mutation in the *SYNJ1* gene associated with autosomal recessive, early-onset parkinsonism. *S. Olgiati[1], M. Fang[2], M. Picillo[3], M. Quadri[1], G.J. Breedveld[1], J. Graafland[1], B. Wu[2], F. Xu[2], R. Erro[3], M. Amboni[4,5], S. Pappata[6], M. Quarantelli[6], H.F. Chien[7], E.R. Barbosa[7], B.A. Oostra[1], P. Barone[5], J. Wang[2,8,9,10], V. Bonifati[1].* 1) Dept. of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 2) BGI-Shenzhen, Shenzhen, China; 3) Dept. of Neurological Sciences, University of Naples "Federico II", Naples, Italy; 4) IDC Hermitage-Capodimonte Institute, Naples, Italy; 5) Dept. of Medicine and Surgery, CEMAND, University of Salerno, Italy; 6) Biostructure and Bioimaging Institute, National Research Council, Naples, Italy; 7) Dept. of Neurology, University of Sao Paulo, Brazil; 8) Dept. of Biology, University of Copenhagen, Copenhagen, Denmark; 9) King Abdulaziz University, Jeddah, Saudi Arabia; 10) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark.

Autosomal recessive, early-onset parkinsonism is clinically and genetically heterogeneous. Here, we report the identification, by homozygosity mapping and exome sequencing, of a *SYNJ1* homozygous mutation (p.Arg258Gln) segregating with disease in an Italian consanguineous family with parkinsonism, dystonia, and cognitive deterioration. Response to levodopa was poor, and limited by side effects. Neuroimaging revealed brain atrophy, nigrostriatal dopaminergic defects, and cerebral hypometabolism. *SYNJ1* encodes synaptojanin 1, a phosphoinositide phosphatase protein with essential roles in the post-endocytic recycling of synaptic vesicles. The mutation is absent in human variation databases, is damaging according to all prediction programs, and replaces an amino acid that is extremely conserved in the synaptojanin 1 homologues and in SAC1-like domains of other proteins. Sequencing the *SYNJ1* ORF in unrelated patients revealed another heterozygous mutation (p.Ser1422Arg), predicted as damaging, in a patient who also carries a heterozygous *PINK1* truncating mutation. The *SYNJ1* gene is a compelling candidate for parkinsonism; mutations in the functionally linked protein auxilin cause a similar early-onset phenotype, and other findings implicate endosomal disturbances in the pathogenesis. Our data delineate a novel form of human Mendelian parkinsonism, and provide further evidence for abnormal synaptic vesicle recycling as a central theme in the pathogenesis.

Copy Number Variants and deletion classes as modifier elements of phenotype in Angelman deleted patients. *S. Russo[1], V. Giorgini[1], E. Mainini[1], G. Randazzo[2], P. Bonanni[2], M. Viri[3], A. Vignoli[4], M. Elia[5], M.T. Bonati[1], L. Larizza[1,6].* 1) Molecular Biology, Institute Auxologico Italiano, Milano, Italy; 2) Epilepsy and Clinical Neurophysiology Unit, Institute Eugeneo Medea, Conegliano Veneto, Italy; 3) Epileptology Center, Hospital Fatebenefratelli, Milano; 4) Epileptology Center, Hospital San Paolo, Milano; 5) IRCCS L'Oasi, Troina (EN), Italy; 6) Medical Genetics, San Paolo School of Medicine, University of Milan, Italy.

Angelman syndrome is a very rare (1:15000) neurodevelopment disease defined by the co-occurrence of major clinical signs, reported in all patients as psychomotor delay, speech absence, peculiar behavior and ataxia. Frequently other features are present: epilepsia occurring in 80% of AS cases, with a very heterogeneous presentation varying for seizure control and age of onset, and associated to a typical EGG profile, microcephaly and sleep disturbance. Molecular bases of disease consist in genetic and epigenetic defects within 15q11-12 region, which affect the expression of UBE3A gene (MIM 601623) coding for an ubiquitinE3 ligase involved in protein degradation through the ubiquitin-proteasome. Clinical presentation appears heterogeneous, both in the severity of the major features and in the kind and number of less frequent signs. This heterogeneity may only partially be accounted by different genetic defects and by mosaicism occurrence. The most common defect (60-70%) is a deletion originating de novo on the maternally inherited chromosome, with different extension in size. Other mechanisms are 15 paternal uniparental disomy, imprinting defects and point mutations of UBE3A gene. Aiming at disclosing the role of modifier factors, we selected a cohort of 50 AS deleted cases. They have been characterized for the deletion size and for harboring rare CNVs by microsatellite segregation and SNP array (Human660W-Quad e Omni 1 Quad). In agreement with the literature most cases grouped in the two main deletion classes, BP1-BP3 and BP2-BP3, while a fraction higher than that reported (17% vs 10%) carried atypical deletions mediated by novel breakpoints. However cases within a specific deletion class displayed a fairly heterogeneous clinical presentation. SNPs array results highlighted several variants yet unreported in databases: although no rearrangement was shared among our AS cohort , a number of interrupted, deleted and duplicated genes were disclosed. Most of the affected genes were reported as susceptibility factors for epilepsy, schizophrenia and autism and code for channels implicated in Na/Ca exchange, receptors and protein involved in cellular trafficking or oxidative stress. Validation of the most interesting modifier genes and the resulting genotype-phenotype correlations is ongoing.

3016F

A Charcot-Marie-Tooth type 2 family with two neuropathy gene variants identified through next generation sequencing using a targeted panel. *F.H. Sansbury[1], T. Antoniadi[2], C. Buxton[2], R. Whittington[2], N.J. Gutowski[3], P.D. Turnpenny[1].* 1) Peninsula Clinical Genetics Service, Royal Devon & Exeter NHS Foundation Trust, Royal Devon & Exeter Hospital (Heavitree), Gladstone Road, Exeter, Devon EX1 2ED, United Kingdom; 2) Bristol Genetics Laboratory, North Bristol NHS Trust, Southmead Hospital, Bristol BS10 5NB, United Kingdom; 3) Department of Neurology, Royal Devon & Exeter NHS Foundation Trust, Royal Devon & Exeter Hospital (Wonford), Barrack Road, Exeter, Devon EX2 5DW, United Kingdom.

We present a 3-generation family with Charcot-Marie-Tooth type 2. Sequencing two affected family members against a targeted panel of neuropathy genes identified a novel *MFN2* c.321G>A p.Asn107Lys variant present in both, plus a previously reported *SCN9A* c.2215G>A p.Ile739Val variant present only in 1 patient. Sanger sequencing of the variants showed the *MFN2* variant was present in 6 of 7 affected family members. The *SCN9A* variant was present in 3 affected family members (including the individual who tested negative for the *MFN2* variant), but also in 1 unaffected family member. Functional studies of the *SCN9A* variant suggest an effect on autonomic function (Han et al, 2012), but its presence in normal controls led the authors to suggest it is a risk factor for small fibre neuropathy in combination with other factors. Interestingly, neuropathic pain is a symptom in the affected family member who does not have the *MFN2* variant. We discuss the possibility of more than one genetic basis for CMT2 in this family and how a neuropathy gene panel approach may identify multiple possible variants.

A Japanese girl with severe form of vanishing white matter disease resembling Cree leukoencephalopathy. *K. Takano[1], T. Wada[1], H. Osaka[1], Y. Tsurusaki[2], H. Saitsu[2], N. Matsumoto[2].* 1) Division of Neurology, Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 2) Human Genetics, Yokohama City University, Yokohama, Kanagawa, Japan.

Vanishing white matter disease (VWM)/ childhood ataxia with central hypomyelination (CACH) is an autosomal recessive brain disorder caused by mutations in each of the 5 genes (*EIF2B1-5*), encoding the 5 subunits of eukaryotic translation initiation factor 2B (eIF2B). Brain magnetic resonance imaging (MRI) shows progressive rarefaction and cystic degeneration of the white matter and its replacement by cerebrospinal fluid. The classical phenotype is characterized by early childhood onset and chronic progressive neurological deterioration with cerebellar ataxia, spasticity, optic atrophy and epilepsy. Recently, it has become apparent that the onset of disease varies from antenatal period to adulthood. There is some genotype-phenotype correlation in VWM patients. Cree leukoencephalopathy is a severe variant of VWM and caused by homozygous mutation (p.R195H) of the *EIF2B5* gene. Our patient is a daughter of healthy, unrelated Japanese parents. She developed lethargy, vomiting and seizure shortly after an oral poliovirus vaccination at the age of 4 month. She presented rapid neurological deterioration, loss of head control, axial hypotonia and pyramidal tract sign within a month of onset. Brain MRI showed abnormal white matter intensity. Exome sequencing identified two mutations at the heterozygous state in the *EIF2B5* gene, a known mutation identified in Cree leukoencephalopathy c.584G>A (p.R195H) and a novel mutation c.1223T>C (p.I408T) in the patient. Ile408 is highly conserved and located within I-patch domain which is important in the interactions between eIF2B subunits. Our patient has a severe phenotype with early onset and progressive disease course resembling Cree leukoencephalopathy. Our patient's genotype may correlate with a severe phenotype.

Proteolipid protein 1 and gap junction α12 gene mutations in 72 Chinese patients with Pelizaeus-Merzbacher disease/ Pelizaeus-Merzbacher like disease and prenatal diagnosis of 15 fetuses in twelve Chinese families with PMD probands. *J. Wang[1], D. Li[1], Y. Wu[1], J. Xiao[2], Q. Gu[1], H. Zhao[1,3], J. Shang[1,4], Y. Yang[1], X. Bao[1], H. Xiong[1], Y. Zhang[1], T. Ji[1], M. Li[1], Y. Meng[5], F. Fang[6], Z. Niu[3], J. Qin[1], H. Shi.[5], F. Zhang[7], X. Wu[1], Y. Jiang[1].* 1) Peking University First Hospital, Beijing, China; 2) Department of Image, Peking University First Hospital, Beijing 100034, China; 3) Department of Neurology, First Hospital of Shanxi Medical University, Taiyuan 030001, China; 4) Department of Neurology, Shanxi Dayi Hospital Affiliated to Shanxi Medical University, Taiyuan 030001, China; 5) Department of Pediatrics, Peking Union Medical College Hospital, Beijing 100730, China; 6) Department of Neurology, Beijing Children's Hospital Affiliated to Capital Medical University, Beijing 100045, China; 7) State Key Laboratory, School of Life Science, Fudan University, Shanghai 200433, China.

Purpose The object of this study was to identify proteolipid protein 1(PLP1) and gap junction α12 mutations in 72 Chinese patients (P1-72) with Pelizaeus-Merzbacher disease (PMD) /PMLD and prenatal diagnosis of fifteen fetuses in twelve Chinese families with PMD probands. Methods Genomic DNA was extracted from peripheral bloods samples. At 19 or 20 weeks gestation, amniotic fluid/chorionic villus sampling (AFS/CVS) was performed. Gene dosage was determined by Multiplex Ligation-dependent Probe Amplification (MLPA). All 7 exons and exon-intron boundaries of PLP1 gene were amplified and analyzed by direct DNA sequencing. Results Of these 72 patients, there were 18 transitional, 45 classical, and 9 congenital PMD according to the clinical and radiological presentation. PLP1 duplications were identified in patients 1-52 with PMD, account for 72.2% (52/72). Their mothers were PLP1 duplications carriers except P52'mother was wildtype. 15 hemizygous missense mutations including eight novel mutations and one reported splicing mutation (IVS5-1G>A) were found in 17 Patients (P53-69) with PMD(23.6%), 12 out of 17 for their mother were showed to be a heterozygote of those mutation, and the remains 5 patients demonstrated de novo. For three patients without PLP1 mutation, we then tested GJC2 mutations with c.925_938del(p.A309Pfs342X), c.201C>G(p.C67T), c.689delG (p.G230Afs), c.735C>A(p.C245X), and c.1199C>A (p.A400E). For the results of prenatal diagnosis(male 9 and female 6), 9 fetuses were PLP1 wildtype, 1 was with PLP1 duplication carrier, and 5 found PLP1 duplication and 1 with c.623G>T(G208V). Conclusions We identified 52 genomic duplications and fifteen missense/splicing mutation of PLP1 gene in 69 Chinese patients with PMD and five missense/framshift mutations in three patients with PMLD. Prenatal diagnoses for fifteen fetuses in twelve PMD proband families were performed, which is useful and helpful for those families. This would be the first report about PLP1 mutations and prenatal diagnosis in PMD patients in mainland of China. Comprehensive Mutation Analysis of 421 Cases with Charcot-Marie-Tooth Disease using Microarray and Exome Sequencing. *A. Yoshimura[1], A. Hashiguchi[1], Y. Higuchi[1], J. Yuan[1], Y. Okamoto[1], T. Nakamura[1], J. Mitsui[2], H. Ishiura[2], Y. Takahashi[2], J. Yoshimura[2], K. Doi[2], S. Morishita[2], S. Tsuji[2], H. Takashima[1].* 1) Kagoshima University, 8-35-1 Sakuragaoka, Kagoshima City, Japan; 2) University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan.

[Objective] Charcot-Marie-Tooth (CMT) disease comprises a group of clinically and genetically heterogeneous inherited peripheral neuropathies. In our study, to identify causative genes and new molecular mechanisms of CMT, DNA microarray and exome sequencing were successively applied. [Methods] From April 2005 to December 2011, after excluding the PMP22 duplication mutation using fluorescence in situ hybridization, 421 cases with suspected inherited peripheral neuropathies were enrolled from Japan. Mutation screening was initially performed on a custom DNA microarray (Affymetrix) containing all 28 known CMT disease-related genes. The negative cases subsequently proceeded to exome sequencing with Illumina HiSeq2000. Using Sanger's method, we confirmed the suspected variants, and a segregation study was performed if the variants were novel. [Result] In 421 cases of suspected CMT, causative mutations were discovered in 56 cases (13.3%) using DNA microarray. Exome sequencing then revealed another 28 reported mutations in the known CMT disease-related genes. Correspondingly, the positive rate of mutation detection was increased in demyelinating CMT (from 15.0% to 23.9%), and axonal CMT (from 12.2% to 22.4%) as well. The total positive rate of mutation detection was improved from 13% to 20%. [Conclusion] We compared the ability of DNA microarray analysis and exome sequencing to detect known pathogenic mutations in CMT, and exome sequencing proved to be more effective. Next-generation sequencing is a trustworthy method in high-thoughput genetic analysis. However, no pathogenic mutation was found in approximately 80% of cases with suspected CMT. In future, we can expect that a large number of novel disease-related genes will be discovered.

ABNORMAL COPY NUMBER VARIANTS ARE FREQUENT IN PATIENTS WITH MALFORMATIONS OF CORTICAL DEVELOPMENT ASSOCIATED WITH EPILEPSY. *F.R. Torres[1], D.A. Souza[1], M.M. Guerreiro[2], M.A. Montenegro[2], A.C. dos Santos[3], V.C. Terra[3], A.C. Sakamoto[3], F. Cendes[2], I. Lopes-Cendes[2].* 1) Department of Medical Genetics, UNICAMP, Campinas, Sao Paulo, Brazil; 2) Department of Neurology, UNICAMP, Campinas, Sao Paulo, Brazil; 3) Department of Neurosciences, USP, Ribeirao Preto, Sao Paulo, Brazil.

Patients with malformations of cortical development (MCD) often suffer from seizures which are frequently refractory to treatment with antiepileptic drugs. Advances in molecular genetics have led to a better understanding of the mechanisms underlying several types of MCDs. However, mutation events remain unidentified in the majority of patients. Recent studies have implicated large, rare copy number variants(CNVs) in a range of neurodevelopmental disorders. Therefore, the aim of this study was to investigate whether CNVs could be involved in different types of MCDs. We used a high resolution SNP-array, CytoScan® HD, to investigate CNVs in a cohort of 33 patients with MCDs, including lissencephaly spectrum, periventricular nodular heterotopia and schizencephaly. To assess the clinical significance of our insertions/deletions findings, we searched all CNVs found in the Database of Genomic Variants (DGV) and The International Standards for Cytogenomic Arrays Consortium (ISCA). Genes located within rare CNVs were subsequently subjected to specific Gene Ontology Terms (Go) search. We detected at least one rare CNV in 13 patients (40%), with a total of 19 rare CNVs identified. The average size of CNVs found was 223kb, ranging from 113kb to 456kb. Each CNV contained approximately two genes. Potentially pathogenic CNVs, according to DGV and ISCA databases, contained genes involved in cell division (*NCAPG2*, *HAUS7*), vesicle mediated transport (*TSNARE1*), actin cytoskeleton organization (*DAAM1*, *ACTR6*) and axon guidance or neuronal migration (*PLXNA1*, *KIRREL3*, *ARX*, *DCX*). Several genes located in regions spanned by rare and potentially pathogenic CNVs described in this work are related to molecular pathways previously shown to be involved in MCDs. In addition, deleterious mutations in genes controlling mitosis, vesicle mediated transport, cytoskeleton organization and neuronal migration, have been previously reported in patients with MCDs. In conclusion, we have shown that SNP-array study is a powerful tool for identifying deleterious variants in patients with MCDs as well as to indicate new candidate genes potentially involved in normal and abnormal cortical development.

Sensorineural hearing loss in OPA1-linked disorders. *D. Bonneau[1], S. Leruez[2], E. Colin[1], D. Milea[2], S. Defoort-Dhellemmes[3], M. Crochet[3], C. Verny[10], M. Ferré[1], J. Lamblin[4], V. Drouin[5], C. Vincent-Delorme[6], G. Lenaers[7], C. Blanchet[8], G. Juul[9], M. Larsen[9], V. Procaccio[1], P. Reynier[1], P. Amati-Bonneau[1].* 1) Département de Biochimie et Génétique, CHU Angers, CNRS UMR6214, INSERM UMR1083 France; 2) Département d'Ophtalmologie CHU Angers, France; 3) Département d'Ophtalmologie CHU Lille, France; 4) Département d'Oto-Rhino-Laryngologie, CHU Lille, France; 5) Département de Biochimie et Génétique, CHU Rouen, France; 6) Service de Génétique Médicale, Centre Hospitalier Arras, France; 7) INSERM U1051, Montpellier, France; 8) Département d'Oto-Rhino-Laryngologie, CHU Montpellier; 9) National Eye Clinic, Kennedy Center and University of Copenhagen, Denmark; 10) Département de Neurologie, CHU Angers, France.

Heterozygous mutations of OPA1 (Optic Atrophy 1), that encodes for a dynamin-related GTPase involved in mitochondrial DNA maintenance, are linked to autosomal dominant optic atrophy (DOA). Optic neuropathy usually occurs insidiously in the first decade of life, about 20% of patients later developing extra-ocular symptoms (DOA+) in particular deafness. We retrospectively reviewed the files of 1380 DOA patients referred to our laboratory from 2003 to 2011. OPA1 mutation was identified in 327 patients (24%) of whom 21 patients (6.4%) had hearing impairment. In 10 patients deafness was detected under age 20 (~48%), in 3 patients over age 20 (~14%) and in 8 patients the age of onset was unknown (38%). Molecular screening of OPA1 identified three mutations, p.Arg445His, p.Gly401Asp and p.Leu243 previously reported associated to optic atrophy and hearing loss; two mutations, p.Val291_Phe328del and p.Ile463_Phe464dup reported in isolated optic atrophy and two novel mutations, p.Arg437Glu and p.Ala357Leufs*4, implicated for the first time in DOA and hearing loss. Optic atrophy and deafness are the only signs in 13/21 patients (62%) additional neurological signs are present in 8/21 patients (38%). In 54% of patients hearing loss started prior to visual abnormalities. A particularly careful should be performed in patients carrying an OPA1 missense mutation because there is a 2-4 fold increased risk of developing 'DOA plus' with missense mutations affecting the GTPase domain or the dynamin domain. In conclusion, deafness linked to OPA1 is probably underestimated since audiological investigations are performed in only a minority of OPA1 mutation carriers.

3022F

Targeted re-sequencing of the human X chromosome exome expands the phenotypic spectrum of ATP7A mutations. *S. MOUTTON[1], A. DELAHODDE[2], M. LANGOUET[1], C. BOLE-FEYSOT[3], K. SIQUIER-PERNET[1], P. NITSCHKE[4], C. VASNIER[2], S. HADJ-RABIA[1], L. YI[5], A. DRECOURT[1], K. PATEL[5], N. BODDAERT[6], A. MUNNICH[1], J.P. BONNEFONT[1], S.G. KALER[5], J. AMIEL[1], L. COLLEAUX[1].* 1) INSERM U781, Université Paris Descartes, Sorbonne Paris Cité, Institut IMAGINE, PARIS, France; 2) Université Paris-Sud, CNRS, UMR 8621, Institut de Génétique et Microbiologie, Orsay, F-91405, France; 3) Plateforme de Génomique, Institut IMAGINE, 75015 Paris, France; 4) Plateforme de Bioinformatique, Université Paris Descartes, Sorbonne Paris Cité, Institut IMAGINE, 75015 Paris, France; 5) Unit on Human Copper Metabolism, Molecular Medicine Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, USA; 6) Department of Paediatric Radiology, Hôpital Necker Enfants Malades, APHP, Paris, France.

We investigated a large pedigree consistent with X-linked inheritance by a combination of linkage analysis and X-exome sequencing using RainDance Technologies®. All 6 affected males exhibited epileptic encephalopathy. Epilepsy onset ranged from 2 to 22 months and consisted of myoclonic seizures, febrile seizures and Lennox-Gastaut syndrome. A single variant perfectly segregating with the disease was identified. This variant (c.3670G>A; p.Gly1224Ser) is located in the gene encoding the P-type copper-transporter ATPase (*ATP7A*). Yeast complementation assays using the *S. cerevisiae* copper transport mutant ccc2Δ demonstrated its pathogenicity since the p.Gly1224Ser mutant *ATP7A* cDNA was unable to restore normal growth on nutritionally restricted media. Mutations in *ATP7A* yield three distinct X-linked conditions. Menkes disease (MD) presents in the first monthes of life with failure to thrive, developmental delay, and seizures. The diagnosis of MD is usually confirmed by decreased serum copper and ceruloplasmin levels and intracellular copper retention. Occipital horn syndrome features more subtle developmental delay, dysautonomia, and connective tissue anomalies beginning in early childhood. Finally, ATP7A-related distal motor neuropathy is characterized by a late-onset neurological phenotype that resembles Charcot-Marie-Tooth disease, type 2.

Because none of these diagnoses had been suggested in our family we undertook detailed re-evaluation of the patients. Brain MRI showed normal cerebral blood vessels morphology but metal overload in basal ganglia. Despite normal hair texture, optic microscopy revealed rare pili torti. Biochemical analysis showed not only normal ceruloplasmin and mildly increased serum copper levels but, surprisingly, low intracellular copper level in patient's fibroblasts compared to controls (15.5 ng/mg of protein). Finally, immunohistochemical analyses performed in patient's fibroblasts showed normal localization to the trans-Golgi network (TGN) of the mutant protein and normal trafficking from the TGN to the plasma membrane in response to increased copper concentration. Our report further expands the phenotypic spectrum associated with ATP7A mutations. Additional experiments are now underway to elucidate the pathophysiological mechanism underlying this condition which is likely different from known MD/OHS-causing mutations.

3023W

Phenotypic and transcriptomic characterization of the RPE affected by mutations that cause RNA splicing factor retinitis pigmentosa. *M.H. Farkas[1], E.F. Nandrot[2], E.D. Au[1], D. Lew[2], K. Bujakowska[1], M.E. Sousa[1], D.G. Taub[1], S.S. Bhattacharya[2], E.A. Pierce[1].* 1) Ocular Genomics Institute, Berman-Gund Laboratory, Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA; 2) Institut de la Vision, Paris, France.

Mutations in the Pre-mRNA Processing Factors 3, 8, and 31 (PRPF3, 8, and 31) cause non-syndromic retinitis pigmentosa (RP) in humans, an inherited retinal dystrophy (IRD). It is currently unclear what mechanisms, or which tissues, are affected when mutations are present in these ubiquitously expressed proteins. Mice with the human mutations in these genes show limited vision loss, accompanied by late-onset morphological changes in the retinal pigment epithelium (RPE), specifically a loss of basal infoldings, vacuole formation, and basal deposits. Since the RPE is critically important for the overall health and maintenance of the retina, we set out to determine if the observed morphological changes are preceded by abnormal function. Specifically, we investigate, in detail, the phagocytic mechanism of the RPE in Prpf3, Prpf8, and Prpf31-mutant mice. Phagocytosis deficiencies of up to 50% are observed in primary RPE cultures, along with a nearly 60% decrease in RPE adhesion. The RPE diurnal rhythm is also affected in all 3 models. In addition, RNA-Seq data show alterations in gene expression in RPE and retina, as well as in brain and muscle. The greatest number of transcripts found to be differentially expressed (DE) are associated with the RPE of the Prpf3-mutant mice, with over 2000 identified. In comparison, all other tissues/models had a few hundred DE transcripts. Categorization of DE transcripts in the RPE of all 3 models revealed an over abundance of transcription factors, IRD genes and extracellular matrix components. Interestingly, there is no overlap of DE transcripts among all 3 models. All 3 mutant models also display an increase in unique novel splicing events, and we find differential expression of novel genes between the mutant and control mice. The RPE appears to be the primary site of pathogenesis for the RNA splicing factor forms of RP. While degenerative changes appear in 2-year old mice, consistent with the late disease onset observed in humans, our characterization suggests the RPE is dysfunctional soon after birth. RNA-Seq analyses, to date, suggest that aberrant splicing occurs globally, yet only affects retinal tissue. The divergent altered transcripts among the 3 models suggest different mechanisms of pathogenesis, even though all 3 Prpf proteins are found in the same core component of the spliceosome. These results provide the greatest insight into the pathogenesis and mechanism of RNA splicing factor RP to date.

3024T

THE RECRIUTMENT OF RNA POLYMERASE II IS IMPAIRED IN CORNELIA DE LANGE SYNDROME. *A. Musio[1], S. Bilodeau[2], C. Amato[1], V. Quarantotti[1], F. Cucco[1,3], I. Krantz[4], L. Mannini[1].* 1) Istituto di Ricerca Genetica e Biomedica, CNR, Pisa, Italy; 2) Centre de recherche en cancérologie de l'Université Laval and Centre de recherche du CHU de Québec (Hôtel-Dieu de Québec), Département de biologie moléculaire, biochimie médicale et pathologie, Faculté de Médecine, Université Laval, Québec, Canada; 3) Dipartimento di Biologia, Università di Pisa; 4) Division of Human Genetics, The Children's Hospital of Philadelphia and the Perelman School of Medicine at the University of Pennsylvania.

Cohesin ensures correct chromosome segregation by holding sister chromatids together from the S phase until their separation in anaphase. Mutations in cohesin and regulatory cohesin genes, NIPBL, SMC1A, HDAC8 and SMC3 are causative of Cornelia de Lange syndrome (CdLS), a rare human development disorder. Since CdLS cell lines show no clear defects in sister chromatid cohesion, the molecular basis underlying CdLS remains elusive. Beyond its structural function in maintaining sister chromatid cohesion, cohesin plays a key role in transcription regulation. It has been suggested that cohesin regulates higher order chromatin organization by the formation of chromatin loops. Recently it has been shown that gene expression profiling of NIPBL- and SMC1A-mutated cell lines exhibit a down-regulation of many genes providing a mechanism for CdLS. However, the molecular mechanisms by which cohesin mutations affect gene expression are not well understood. We hypothesized that the gene transcriptional machinery was somehow affected by mutations in SMC1A found in cell lines derived from CdLS patients. To investigate this we used chromatin immunoprecipitation coupled with massively parallel DNA sequencing (ChIP-seq) to identify genomic regions co-occupied by cohesin, NIPBL and RNA pol II in normal human lymphoblastoid cells. Regions occupied by cohesin, NIPBL and RNA pol II were assigned to genes and compared to available gene expression data from CdLS cell lines. We selected 6 genes for our mechanistic studies, including cell-type specific and housekeeping genes that were differentially expressed between normal and SMC1A mutant cells. We found that the recruitment of RNA pol II to the regulatory regions is strongly decreased in CdLS cell lines irrespective of SMC1A mutations. These findings highlight the pivotal role of cohesin in transcription regulation, and the deficiency of RNA pol II may explain the typical gene dysregulation occurring in CdLS cell lines. This work was supported by a grant from Tuscany Region to A.M.

Characterization of Novel mutations found in Classical and Infertile CF males of Indian population: A molecular approach to establish genotype and phenotype correlation. *R. Prasad[1], H. Sharma[1], F. Becq[2].* 1) Department of Biochemistry, PGIMER, Chandigarh, India; 2) Institute of Physiology and Cell Biology, University of Poitiers, France.

Cystic Fibrosis an autosomal recessive disorder is usually considered as rare disease for Indian population hence much less is known about this disease in context with Indian sub continent. Recently we have established a spectrum of mutations in CFTR gene from classical Cystic Fibrosis as well as from infertile male patients with CBAVD/CUAVD in Indian populations. Among them S549N, L69H in classical CF and G126S, Y852F in CBAVD males were among the rare missense mutations (Sharma et al ., 2009). In this study we have attempted to conduct in vitro gene expression analysis to establish genotype and phenotype correlation and to characterize these four rare missense mutations according to the mechanism that disrupt CFTR protein function. All four mutations from Indian population were characterized by expressing pEGFP-CFTR constructs in BHK-21 cells via 3 step technique viz; CFTR cellular localization was determined by confocal microscopy, where as Western blot analysis and automated iodide efflux assays was used to determine CFTR maturation processes and its channel activity respectively. In Western blot analysis only b-band is obtained for L69H substitution as for F508del whereas in the case of other mutants both b and c bands were found, indicating L69H mutation impair CFTR maturation process, the finding was again confirmed by confocal imaging. Iodide Efflux assay reveled significant decrease in channel activity for L69H and S549N mutants CFTR expressing cells in comparison to WT, although this decrease in channel activity was rescued when cells were incubated at 27 °C. When the effect of CFTR correctors was checked on different mutants, it was found that VX809 significantly ameliorate the defect caused by L69H mutation. Y852F and G126S have no impact on CFTR maturation and function. In conclusion L69H mutation is a class II CF mutation causing impaired maturation leading to protein degradation and Chloride ions impermeability like F508del mutation. This defect is rescued by the corrector VX 809. Whereas S549N mutation can be categorized into a class II/III mutation causing impaired maturation and reduced channel activity.

3026W

Distinct prevalence of homozygous p.V37I variant of GJB2 in Chinese Hans with severe-to-profound, mild-to-moderate or normal hearing phenotype. *Y. Chai[1,2], Y. Tao[1,2], H. Wu[1,2].* 1) Ear Institute, Shanghai Jiaotong University School of medicine, shanghai, China; 2) Department of Otolaryngology-Head and Neck Surgery, Xinhua Hospital, Shanghai Jiaotong University School of medicine, Shanghai, China.

The p.V37I variant of *GJB2* is highly prevalent in East Asians, with a carrier frequency of 6.2% in Chinese Hans. It has been shown that homozygous p.V37I may lead to mild-to-moderate hearing impairment and is a genetic risk for postnatal childhood hearing impairment. On the other side, the complete spectrum of hearing phenotypes associated with the p.V37I variant remains elusive. In this study, we recruited 858 and 88 Chinese Han probands with severe-to-profound and mild-to-moderate childhood hearing impairment, respectively, as well as 1000 Chinese Han adults with normal hearing. Direct sequencing of all subjects for *GJB2* showed that a significant percentage (12.5%, 11/88) of probands with mild-to-moderate hearing impairment was homozygous for p.V37I, in contrast to 0.1% (1/1000) in adults with normal hearing ($P<0.001$). Homozygous p.V37I was also moderately over-represented in probands with severe-to-profound hearing impairment (1.63%;, 14/858, $P<0.01$). Targeted next-generation sequencing of 79 known deafness genes in those 11 probands, however, identified one proband with homozygous p.Y1995X mutation in *CDH23* in addition to the homozygous p.V37I variant in *GJB2*. Our results suggested that the highly prevalent p.V37I variant is associated with a broad spectrum of hearing phenotypes. Though present most frequently in patients with milder degree of hearing impairment, it may also exhibit much severer or completely normal hearing phenotypes. Cautions should be taken when interpret the pathogenic causes for patients carrying the homozygous p.V37I variant though, as some may have separate pathogenic causes in addition to a non-penetrant homozygous p.V37I.

3027T

Mosaic Missense Mutations in the RNase IIIb Domain of DICER1 Cause JANUS, a Novel Overgrowth Syndrome. *S. Klein[1,8], H. Lee[1,6,8], S. Ghahremani[2,8], P. Kempert[3,8], M. Ischander[4,8], M.A. Teitell[6,7,8], S.F. Nelson[1,6,8], J.A. Martinez-Agosto[1,5,7,8].* 1) Department of Human Genetics; 2) Department of Radiology; 3) Division of Hematology-Oncology, Department of Pediatrics; 4) Division of Pulmonary Medicine, Department of Pediatrics; 5) Division of Medical Genetics, Department of Pediatrics,; 6) Department of Pathology and Laboratory Medicine; 7) Jonsson Cancer Center; 8) David Geffen School of Medicine at UCLA, Los Angeles, CA.

Specific genetic conditions that predispose to overgrowth and tumor development have been linked to alterations in tumor suppressor genes. Here we report a distinct syndrome of macrocephaly, developmental delay, bilateral Wilms tumor and bilateral neonatal lung cysts. We name this syndrome JANUS an acronym for the core phenotypic findings, which include a Juxtaposition of Abnormal Head Size, Neonatal Pulmonary Cysts, Urologic Tumors, and Somatic Overgrowth. Although there is phenotypic overlap with previously described overgrowth syndromes, this phenotypic association is novel and its genetic etiology unknown. We performed whole exome sequencing on an affected proband and parental blood samples and identified a de novo missense mutation in the RNase IIIb domain of DICER1. We confirmed an additional missense mutation in the same domain of another unrelated patient by Sanger sequencing. These missense mutations in the RNase IIIb domain of DICER1 affect the metal binding located within this domain. Similar mutations have been previously identified in specific tumor types, including Wilms tumor. Pyrosequencing was used to determine the relative abundance of mutant alleles in various tissue types. The relative mutation abundance is highest in Wilms tumor and kidney samples when compared to blood, confirming that the mutation is mosaic. We have performed bioinformatics analysis of microRNAs affected by these specific mutations and have identified target genes that are over-represented in MTOR, MAPK, and TGF- β signaling pathways. We propose that mutations affecting the metal binding sites of the DICER1 RNase IIIb domain alter the balance of 3p and 5p microRNAs leading to deregulation of these three growth signaling pathways, causing JANUS syndrome. We conclude that mutations in the catalytic RNase domain of DICER1 cause deregulation of specific microRNAs (miRNAs) leading to alterations in central growth pathways, namely MTOR, MAPK, and TGF-β. Similar to mutations in the RAS/MAPK pathway, in which germline mutations result in syndromic presentation or 'rasopathies' while somatic mutations result in neoplasm, somatic mutations in the essential RNase IIIb domain of DICER1 are associated with a number of tumors while mosaic mutations in the same domain cause a novel human overgrowth syndrome.

3028F

Gain and loss of function mutations in *PDE4D* result in two different developmental disorders with mirrored phenotypes. *A. Lindstrand[1], G. Grigelioniene[1], D. Nilsson[1], M. Pettersson[1], BM. Anderlid[1,2], P. Gustavsson[1], H. Valta[5], S. Geiberger[3], K. Lagerstedt[1], F. Taylan[1], J. Wincent[1], T. Laurell[4], M. Pekkinen[6], M. Nordenskjöld[1], O. Mäkitie[1,5,6], A. Nordgren[1].* 1) Department of Molecular Medicine and Surgery and Center of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Women's and Children's Health Karolinska Institutet, Stockholm, Sweden; 3) Department of Pediatric Radiology, Karolinska University Hospital Solna, Stockholm, Sweden; 4) Department of Clinical Science and Education, Södersjukhuset, Karolinska Institutet, Stockholm, Sweden; 5) Children's Hospital, Helsinki University Central Hospital and University of Helsinki, Helsinki, Finland; 6) Folkhälsan Institute of Genetics, Helsinki, Finland.

Point mutations in *PDE4D* have recently been linked to acrodysostosis, an autosomal dominant disorder characterized by facial dysostosis, severe brachydactyly, nasal hypoplasia, short stature, intellectual disability and hormone resistance. We found *PDE4D* mutations in five unrelated patients with acrodysostosis. In addition, two patients with large heterozygous deletions encompassing the entire *PDE4D* locus were identified. These patients do not have acrodysostosis but suffer from a novel intellectual disability syndrome with severe anorexia and characteristic facial features including a long nose and a small chin. Careful clinical comparisons between these patients raised the possibility that different types of *PDE4D* mutations result in opposite phenotype in humans. To further explore the function and pathogenicity of the identified alleles we used zebrafish embryos. We found that zebrafish *pde4d* was expressed in the brain of the developing embryo. Embryos injected with two different morpholinos showed a consistent phenotype (short body length, large head, small jaw), as did embryos injected with mRNA harboring acrodysostosis point mutations (curved body, small head, large jaw). Interestingly, the jaw of embryos injected with mRNA was severely enlarged while in embryos where *pde4d* was suppressed the jaw size decreased, hence capturing the mirror phenotype seen in humans. In addition, results from co-injections of mutated mRNA and wild-type mRNA showed a more severe phenotype compared to embryos injected with the mutated mRNA alone when the mutations were located in the upstream conserved regions of the PDE4D protein, while this effect could not be observed when the mutations were located further down, in the catalytic domain of the protein. In summary, haploinsufficiency of the *PDE4D* gene results in a previously undescribed syndrome with several characteristic traits that represent the extreme opposite of what we see in patients with acrodysostosis. By comparing overexpression of human mutated transcripts to *pde4d* knockdown in zebrafish embryos we could successfully replicate this mirror phenotype. Our data also suggest that the genetic mechanism of the dominant mutations causing acrodysostosis might be different depending on where in the protein they are situated.

3029W

Loss of function mutations in Carbonic Anhydrase XII result in hyponatremic dehydration and elevated sweat chloride concentration. *B. Vecchio-Pagán[1], M. Lee[1], N. Sharma[1], A. Waheed[2], D. Belchis[3], J. Hertecant[4], W. Sly[2], G.R. Cutting[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Medicine, Baltimore, MD; 2) Department of Biochemistry, St. Louis University School of Medicine, St. Louis, MD; 3) Pathology, Johns Hopkins School of Medicine, Baltimore, MD; 4) Tawan Hospital, UAE National University, Al Ain United Arab Emirates.

Functional analysis can provide key evidence that a gene linked to a rare disease by exome sequencing is causative; however, the appropriate physiological context needs to be considered when testing the functional effect of mutations. We provide an illustrative example that demonstrates a new role for for CA XII mediated bicarbonate metabolism in determining the ionic composition of sweat. Exome sequencing revealed a novel homozygous mutation (H121Q) in carbonic anhydrase XII (CA XII) in 2 siblings exhibiting hyponatremic dehydration, salt craving, and elevated sweat chloride (Cl^-) levels in a consanguineous Omani pedigree with three normal siblings. CA XII maintains proper physiological pH through the reversible dehydration of HCO_3^- to CO_2 and H_2O at its extracellular catalytic site. To assess the functional effect of H121Q, we measured the rate of CO_2 hydration. In this assay, H121Q displayed reduced activity (15.4±3.6 %WT activity, n=11). Prior publications have described a different point mutation in CA XII, E143K, in an Israeli Bedouin tribe which segregated with an autosomal recessive phenotype similar to that of the Omani family (OMIM #143860). However, the reported functional assays revealed that the E143K mutation only reduced CA XII function to ~70% WT activity, which we confirmed (75.5±4.9 %WT, n=11). To reconcile the apparent dramatic difference in function between these two mutations, we sought to determine whether either led to altered cellular localization of CA XII. Confocal microscopy using a Protein Tech anti-CA XII antibody was performed upon polarized MDCK cells expressing WT and both CAXII mutants. Wild-type, H121Q and E143K CA XII showed similar localization, primarily at the basolateral cell membrane, suggesting that the catalytic sites of these mutants retain an extracellular orientation. As the E143K mutant had previously been reported to have altered anion sensitivity, we assayed both mutants under Cl^- concentrations which more accurately reflect the extracellular environment of CA XII's catalytic site (100mM Cl^-). In this context, the activity of the E143K mutant was dramatically reduced (3.3±1.3 %WT; n=8) to a level similar to that of H121Q (0.9±0.6 %WT; n=8). Thus, by measuring CA XII in the proper physiological context, we show that the disease causing mutations in both autosomal recessive pedigrees produce severe loss-of-function in CA XII activity.

3030T

A novel splicing silencer generated by dystrophin exon 45 deletion could explain exon 44 skipping that modifies dystrophinopathy. *M. Matsuo[2], EM. Dwianingsih[1], RG. Malueka[1], A. Nishida[1], T. Lee[2], M. Yagi[2], K. Iijima[2], Y. Takeshima[2].* 1) Dept Medical Rehabilitation, Fac Rehabilitation, Kobegakuin Univ, Kobe, Japan; 2) Dept Pediatrics, Graduate School of Medicine,Kobe University, Kobe, Japan.

Background. Duchenne muscular dystrophy (DMD), a progressive muscle-wasting disease, is mostly caused by exon deletion mutations in the dystrophin gene. The reading frame rule explains that out-of-frame deletions lead to muscle dystrophin deficiency in DMD. In outliers to this rule, deletion junction sequences have never previously been explored as splicing modulators. Methods. In a Japanese case, we analyzed the dystrophin gene and mRNA by PCR and real-time reverse transcription (RT)-PCR amplification, respectively, and examined dystrophin expression immunohistochemically. We examined the splicing regulatory activity of the cloned junction sequence in an in vitro splicing system using a chimeric doublesex gene pre-mRNA. Results. We identified a single exon 45 deletion in the patient's genome, indicating out-of-frame mutation. However, his muscle showed weak dystrophin signals. RT-PCR amplification of dystrophin exons 42 to 47 revealed a major normally spliced product with exon 45 deletion and an additional product with deletion of both exons 44 and 45, an in-frame transcript, accounting for approximately 6% of the total mRNA. We considered the latter to underlie the observed dystrophin expression. Remarkably, the junction sequence cloned by PCR walking abolished the splicing enhancer activity of the upstream intron in a chimeric doublesex pre-RNA. Furthermore, antisense oligonucleotides directed against the junction site counteracted this effect. This indicated that the junction sequence was a splicing silencer. Conclusions. This is the first evidence that a novel deletion junction sequence is a splicing silencer. It was strongly suggested that creation of splicing regulator is a modifier of dystrophinopathy.

Skin-specific Kallikrein-5 transgenic mice recapitulate the main features of Netherton syndrome and provide a viable model for therapeutic approaches. *L. Furio[1,2], S. de Veer[1,2], C. Deraison[1,2], A. Briot[1,2], C. Bonnart[1,2], A. Robin[1,2], A. Hovnanian[1,2,3].* 1) University Paris Descartes Sorbonne Cite, Paris, France; 2) INSERM U781 and Imagine Institute of Genetic Diseases, Paris, France; 3) Department of Genetics, Necker hospital, Paris, France.

Netherton syndrome (NS) is a severe genetic skin disease caused by mutations in *SPINK5* encoding the lymphoepithelial Kazal-type-related serine protease inhibitor (LEKTI). Of the proteases which show overactivity in NS (kallikrein-related peptidase (KLK) 5, KLK7 and elastase 2), KLK5 is a potential key initiator of the proteolytic cascade. To address the role of KLK5 in the disease, we have generated a transgenic murine model overexpressing human KLK5 in the skin (Tg*KLK5*). The transgene was highly expressed in the granular layer of Tg*KLK5* epidermis and was associated with increased proteolytic activity. *In situ* zymography showed enhanced KLK5 activity, as well as elevated KLK7 and elastase 2 activities, two proteases which have been proposed to be activated by KLK5. Tg*KLK5* mice show low weight at birth with a growth delay. They show a skin barrier defect with increased transepidermal water loss. The *stratum corneum* is detached from the underlying epidermis as a result of desmosomal cleavage. Whiskers and hairs are abnormal and reduced. Additionally, Tg*KLK5* mice displayed hallmarks of cutaneous inflammation and allergy including high expression of IL-1β, TNF-α and the pro-Th2 cytokine TSLP with mast cells and eosinophils infiltration. Overtime, persistent scratching leads to alopecic, erosive and crusty skin lesions with lymph nodes hyperplasia. Inflammation was also detected at the systemic level, with high serum IgE and TSLP levels. CD4 T cells from lymph nodes showed increased secretion of Th2 and Th17 cytokines. These results help deciphering the role of KLK5 in the NS phenotype and provide a useful model for the development of new therapeutic strategies.

3032W

Unravelling the molecular mechanisms of pathogenesis of Incontinentia pigmenti Mendelian disorder. *F. Fusco[1], MI. Conte[1], A. Pescatore[1], E. Esposito[1], M. Paciolla[1], MG. Miano[1], MB. Lioi[2], JP. Bonnefont[3], S. Hadj-Rabia[3], C. Bodemer[3], G. Royer[3], A. Smahi[3], J. Steffann[3], M.V. Ursini[1].* 1) Dept Human Molecular Genetics, IGB-ABT-CNR, Naples, Italy; 2) University of Basilicata, Potenza, Italy; 3) Hôpital Necker-Enfants Malades, Paris, France.

Incontinentia Pigmenti (IP, OMIM308300) is a X-linked dominant neuroectodermal disease associated with skin defects and with extracutaneous manifestations at variable frequency. IP is caused by mutations in NEMO/IKBKG gene, that partially overlaps the G6PD gene and partially maps in LowCopyRepeat(LCR1). The duplicated copy (LCR2),located in Xq28 in opposite direction to LCR1,contains the nonfunctional copy of NEMO, pseudoNEMO. We will present a review of past and present findings on the NEMO mutations by exploring with high accuracy both genomic context in which the mutations occur and the functional effects on the mutated proteins. Our task is to understand mechanisms of mutagenesis and of pathogenesis that chacterize the IP disease in order to apply these knowledges in diagnosis of disease and eventually, in its therapeutic correction. To these ends, we have compiled a collection of published and novel NEMO mutations. Data catalogued show that 45% are single base-pair substitutions, 42% indels,12% deletions, and 1%complex rearrangements. Moreover, most altered nucleotide sequences result in a premature stop-codon and 10% generate missense mutations. Then, we produced key discoveries on the affected NEMO functions, analysing missense mutations in further detail. NEMO encodes the regulatory subunit of the IKK complex responsible of the activation of NF-kB transcription factor in multiple signalling pathways controlling immunity, cell survival, differentiation and proliferation. Inflammatory cytokines (TNFalfa, IL1 etc) probably function through conformational change in the kinase complex resulting from either ubiquitination of NEMO or NEMO binding to ubiquitin. One of the E3 ligase responsible for non-degradative polyubiquitination of NEMO is TRAF6, which participates in several signalling pathways controlling immunity, osteoclastogenesis, skin development, and brain functions. We studied the IP-associated E57K NEMO mutant found in a mild form of IP, showing an impaired IL-1 signaling, and we established that a fragment encompassing 57-69aa of NEMO is responsible for its binding to the CC domain of TRAF6, required for NF-kB activation. This site appears to work in concert with NUB domain, mapped trough the analysis of the A323P-IP mutant, which binds to the polyubiquitinated chains of TRAF6. These evidences suggest a dual mode of TRAF6 recognition that may allow the design of new inhibitors of NF-kB activation, restricted to TRAF6-dependent stimuli.

3033T

Clinical whole exome sequencing identifies mutations in UPK3A in individuals with renal adysplasia. *M.R. Bekheirnia[1,3], Z. Niu[1], D.A. Scott[1], L. Potocki[1], P. Lurix[1], J.W. Belmont[1], D.J. Lamb[1,2,3], Y. Yang[1], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Center for Reproductive Medicine, Baylor College of Medicine, Houston, TX; 3) Scott Department of Urology, Baylor College of Medicine, Houston, TX.

Congenital Anomalies of Kidney and Urinary Tract (CAKUT) are the most important causes of pediatrics renal failure. While missense mutations in UPK3A gene are rare cause of renal adysplasia, nonsense mutations were not previously reported to be associated with the renal phenotype. Clinical whole exome sequencing is performed in the Medical Genetics Laboratory at Baylor College of Medicine as a clinical test. This study reports our observation of UPK3A mutations during the clinical sign-out of the requested cases. ACMG standards are used for classification of the genetic variants. We have identified a heterozygous (c.545G>A, p.W182X) nonsense mutations in UPK3A in 3 patients with a clinical diagnosis of either unilateral renal agenesis (2 patients) or renal dysplasia (1 patient). Both patients with unilateral renal agenesis inherited the p.W182X variant from an apparently unaffected mother. A parental sample was not available for analysis of the third patient who had renal dysplasia. All 3 patients had other organ involvement. We also identified the p.W182X variant in 4 more individuals who apparently did not have any kidney phenotype. Twelve missense, 2 splice site (c.571+1G>A) and one indel variants were also detected. Among the 12 patients with missense variants, one had echogenic kidneys together with prematurity, dysmorphic features and developmental delay. Of the 2 patients with a splice site variant (c.571+1G>A), 1 had echogenic kidneys and gonadal agenesis on pelvic ultrasound. While there were 2 earlier reports of missense mutations in UPK3A found in association with renal adysplasia, this is the first report of other types of mutations, such as nonsense variants, that are likely to be related to the renal adysplasia phenotype. Thus, a possible loss of function mechanism resulting from a mutation in UPK3A may cause renal adysplasia. Although the nonsense variants display a higher penetrance than the missense variants, in 2/3 of affected cases the variants were inherited from apparently unaffected parents. The role of the uroplakin gene mutations in CAKUT phenotype clearly requires further investigation. Acknowledgement: Supported in part by K12 DK0083014, the Multidisciplinary K12 Urologic Research (KURe) Career Development Program to DJL (MRB is a KURe Scholar).

Molecular Etiology of the Mayer-Rokitansky-Küster-Hauser (MRKH) Syndrome. *A. Ekici[1], C. Büttner[1], P. Strissel[2], P. Oppelt[2], S. Renner[2], M. Beckmann[2], R. Strick[2].* 1) Institute of Human Genetics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany; 2) Department of Gynecology and Obstetrics, Laboratory for Molecular Medicine, University-Clinic Erlangen, Germany.

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome describes women with congenital aplasia of the uterus, cervix and the upper two-thirds of the vagina due to absent paramesonephric (Müllerian) ducts. Women with MRKH have a normal female karyotype (46, XX), normal female external development, internal normally regressed mesonephric (Wolffian) ducts and have correctly timed pubarche and thelarche. The incidence of the MRKH syndrome is one in 4,500 female newborns. MRKH patients represent the second most frequent cause of primary amenorrhea after Turner syndrome and commonly have associated malformations, like skeletal and renal abnormalities. The MRKH syndrome occurs isolated as a genital malformation (type 1), but also with associated malformations (especially malformations of the kidneys and urinary tract (type 2) and MURCS association (Müllerian renal and cervicothoracic somite abnormalities; partial or complete absence of the spinal column, ribs, or arms; asymmetric or improperly developed ribs or arms). To date the genetic or molecular etiology of the MRKH syndrome is completely unknown. In the present project we describe an integrative analysis of three high-throughput analysis data sets from two pairs of discordant monozygotic twins and their family members. First we performed copy number variation analysis with high density SNP microarrays. Second we performed exome sequencing of these sample set, which have not yet been performed according to the literature. In addition, we sequenced the whole methylome of all samples to round out the picture. Even though we did not find any distinct differential variants between affected and non-affected subjects if we analyzed the single data category, we could identify differential methylation pattern in seven loci with candidate genes if we applied a combined genetic-epigenetic disease model for the data analysis. We believe that the methods in the present application will help to unravel the genetic or molecular causes of MRKH and be of clinical relevance in order to help clinicians for an accurate molecular diagnosis and council patients and their families in order to understand the syndrome.

3035W

Variable phenotype in individuals with a *MUC1* mutation causing medullary cystic kidney disease type1. *S. Kmoch[1], A.J. Bleyer[2], K. Kidd[2], K. Hodanova[1], M. Zivna[1], P. Vyletal[1], H. Hartmannova[1], V. Stranecky[1].* 1) Inst Inherited Metabolic Dis, Charles Univ 1st Faculty, Prague 2, Czech Republic; 2) Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC 27157.

A cytosine insertion in the VNTR of the *MUC1* gene was recently identified as the most common cause of medullary cystic kidney disease type 1. The phenotypic expression of *MUC1* mutations have not been well characterized. Methods: Genotyping and evaluation of clinical characteristics were performed on families with a history of autosomal dominant interstitial kidney disease. Results: Twenty-five families were identified with *MUC1* mutation. Of 179 family members undergoing mutational analysis, a mutation was identified in 95 individuals, and 84 individuals did not have a mutation. There were 110 individuals identified as historically affected. Individuals with a *MUC1* mutation suffered from chronic kidney failure with a widely variable age of onset of end-stage kidney disease, ranging from 16 years to greater than 80 years.

Age Range	<20	20 to <40	40 to <60	60 to <80	>=80
Percent starting dialysis	1	40	38	20	1

There appeared to be two types of affected families. In 13 families, the median age of kidney failure was approximately 30, and family members started dialysis between 18 and 49. In the other 12 families, median age of onset ranged from 41 to 68, with age of kidney failure ranging from 22 to 81. Ultrasounds of 38 individuals showed no medullary cysts. While *MUC1* is expressed in many tissues, there were no clinical manifestations of the *MUC1* mutation detected in the breasts, skin, respiratory or gastrointestinal tract. Conclusions: Individuals *MUC1* mutations have highly variable expression, with some individuals proceeding to dialysis in their teenage years, while others remain dialysis-free at greater than 80 years. While *MUC1* is expressed in many tissues, it only results in clinical abnormalities in the kidney. Gene-gene or gene-environment interactions likely contribute to phenotypic variability.

3036T

Unbiased Next Generation Sequencing analysis confirms the existence of autosomal dominant Alport syndrome. *C. Fallerini[1], L. Dosa[1, 2], D. Giachino[3], R. Tita[1], M. Baldassarri[1], D. The story of the mode of transmission of Alport syndrome (ATS) was very troubled. In 1927, the disease was hypothesized as autosomal dominant condition with male segregation distortion. In 1990, the discovery of mutations in COL4A5 gene on the X chromosome completely changed this orientation and by that time ATS was considered an X-linked semidominant condition. Later on, an autosomal recessive form due to either COL4A3 or COL4A4 mutations was identified and it was calculated to account for about 10% of cases. A dominant form was testified more recently by the description of some large pedigrees but the real existence of this form is still questioned by many and its exact prevalence is unknown. The introduction of Next Generation Sequencing allowed us to perform an unbiased simultaneous analysis of the 3 genes(454 GS Junior, Roche) in a large cohort of Italian families (90) with clinical suspicion of ATS. In 48 of them a mutation was identified (53%). The subsequent segregation analysis in 161 family members allowed to clarify that the prevalent form was indeed the X-linked one (65%) and the rarer form the recessive one (4%). Most interestingly, in a relevant percentage of cases corresponding to 31% (15 families) the mode of transmission was autosomal dominant. In these cases either a COL4A3 or a COL4A4 heterozygous mutation segregating with the disease in each generation was found. The autosomal dominant form must therefore be seriously taken into account in all pedigrees in which patients are present in subsequent generations. The use of an unbiased one step approach was crucial for the rapid diagnosis in 20 cases where clinical data and family history would not have been sufficient to split patients into a precise mode of inheritance and select the specific gene. Moreover, in one case classified as likely X-linked, we found two COL4A3 mutations in compound heterozygosity. The autosomal recessive form is less represented in this cohort and this may be due to the low inbreeding rate of the population studied. In conclusion, this study illustrates how NGS can assist clinicians in making the correct diagnosis with significant reduction of turnaround time and positive consequences on patient management. The availability of a rapid and cost effective test encourages the molecular diagnosis also in oligosymptomatic children and helps their treatment delaying renal failure and improving life expectancy in a time-dependent manner.

3037F

A novel truncating mutation in SOX18 dramatically impairs renal function in the hypotrichosis-lymphedema-telangiectasia syndrome. *S. Moalem[1], P. Brouillard[2], D. Kuypers[3], E. Legius[4], E. Harvey[5], M. Francois[6], M. Vikkula[7], C. Chitayat[1,8].* 1) Department of Pediatrics, Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Laboratory of Human Molecular Genetics, de Duve Institute Université catholique de Louvain, Brussels, Belgium; 3) Department of Nephrology and Renal Transplantation, University Hospital Gasthuisberg, Leuven, Belgium; 4) Department of Pediatrics, University Hospital Gasthuisberg, Leuven, Belgium; 5) Department of Pediatrics, Division of Nephrology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 6) Institute for Molecular Bioscience, The University of Queensland, Brisbane, Australia; 7) Walloon Excellence in Life Sciences and Biotechnology (WELBIO), Belgium; 8) Department of Obstetrics and Gynecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

SOX18 mutations in humans have been previously associated with both recessive and dominant Hypotrichosis-Lymphedema-Telangiectasia Syndrome (HLTS) and have been identified in the HMG domain. We report two unrelated families with affected individuals carrying the same *SOX18* mutation: a living child and his stillborn brother from Canada, as well as a living Belgian boy. The two living index cases were diagnosed with HLTS and DNA analysis for the *SOX18* gene showed the same heterozygous C-to-A mutation, resulting in a premature truncation of the protein. In both families, parental DNA showed no detectable mutation. At young ages, the boy of the first family presented with renal failure and severe hypertension, while that of the second family was diagnosed with membranoproliferative glomerulonephritis and hypertension. With time, both boys had a slow progressive deterioration in their renal function, culminating in the need for kidney transplantation. The *SOX18* gene is well known to play a role in the formation of blood and lymphatic vessels, but those with homozygous mutations in this gene do not develop renal failure. Here, we report for the first time two independent cases of renal failure associated with the identical heterozygous mutation in *SOX18*, and thus propose that this disorder be named Hypotrichosis-Lymphedema-Telangiectasia-Renal Syndrome or HLTRS.

3038W

Exome sequencing for diagnosis of disorders of sex development. *E. Vilain[1], V.A. Arboleda[1], H. Lee[2], A. Eskin[1], S.F. Nelson[1,2], R.M. Baxter[1].* 1) Human Genetics, UCLA School of Medicine, Los Angeles, CA; 2) Pathology and Laboratory Medicine, UCLA School of Medicine, Los Angeles, CA.

Disorders of sex development (DSD) are congenital conditions with discrepancies between the chromosomal, gonadal and phenotypic sex of the individual. DSDs have historically been difficult to diagnose and cause great stress to the patients and their families. Development of high throughput genomic technologies are expanding our knowledge of the underlying mechanism of DSDs and opening new avenues for clinical diagnosis. Exome sequencing is poised to become the most effective method to screen all the known genes involved in DSD. We used exome sequencing to analyze 25 intractable cases of 46, XY DSD where all available clinical testing had been unable to generate a definitive genetic diagnosis. Data were analyzed using a gene list containing all genes with well-documented involvement in human DSD, and genes with less strong association with human sexual development (eg OMIM description contains the word 'sex'), or where data exists in animal models. This gene list approach identified a potential genetic diagnosis in 10 cases for a diagnostic yield of 40%. In five cases we identified a known variant or a type of variant considered highly likely to be damaging to the protein. Two individuals were found to have a known variant in *MAP3K1*, and one patient had a missense variant in *NR5A1* that had been associated only with hypospadias while our patient had a more severe phenotype. We also identified a homozygous premature stop codon in *LHCGR*, and a homozygous splice site variant in *STAR* that both fit well with the patients' phenotypes. In a further five cases we identified likely causative, novel, missense variants in known DSD genes. These variants had not been reported in databases of asymptomatic individuals, e.g. the Exome Variant Server, and were predicted to be damaging by in silico prediction algorithms (SIFT, PolyPhen and Condel). We found likely causative variants in *MAP3K1* (in addition to the two cases with a known variant), *WT1* (2 cases with different variants), *CHD7*, and *DHH* that have not previously been reported in human DSD cases. These data contribute further to our understanding of disease causing variants, expand genotype/phenotype correlations, and could be useful for future clinical surveillance. As the list of genes involved in sex determination and differentiation continues to expand we propose that clinical exome sequencing is the best first line diagnostic genetic test for individuals with a DSD.

3039T

RNA-seq gene expression profiling identifies MEK1/2 and SHP2 as positive regulators of chondrocyte terminal differentiation. *ME. Bowen[1], UM. Ayturk[1], W. Yang[2], ML. Warman[1].* 1) Orthopaedic Research Laboratories, Children's Hospital Boston, Boston, MA 02115; 2) Department of Orthopaedics, Brown University, Providence, RI 02903.

The genetic disorder, Metachondromatosis (MC), is caused by heterozygous loss-of-function mutations in *PTPN11*, which encodes the phosphatase SHP2. MC patients develop benign cartilage tumors, resembling exostoses and enchondromas, that likely arise following somatic 'second hit' mutations in *PTPN11*. In a normal growth plate, chondrocytes first proliferate, then undergo hypertrophy, and are subsequently replaced by bone. Since the enchondroma-like lesions in MC patients occur near the growth plate, they may arise from a cluster of growth plate chondrocytes that failed to undergo terminal differentiation and be replaced by bone. Thus, we chose to investigate the role of *PTPN11* in chondrocyte terminal differentiation. We used RNA-seq to identify genes differentially expressed after genetic inactivation of *Ptpn11* in primary murine chondrocytes induced to undergo terminal differentiation in pellet cultures. Furthermore, since SHP2 has been shown to positively regulate the RAF/MEK/ERK pathway in other cell types, we treated chondrocyte pellets with U0126, an inhibitor of MEK1/2, to determine the role of this pathway in chondrocyte terminal differentiation. We found that U0126-treated pellets had increased levels of transcripts associated with proliferative, pre-hypertrophic and early-hypertrophic chondrocytes, but had decreased levels of transcripts associated with late-hypertrophic chondrocytes, including multiple genes encoding proteases that degrade cartilage matrix components. Similar, but less substantial, changes in gene expression were observed after deletion of *Ptpn11*. We were also able to identify a set of MEK1/2-dependent or SHP2-dependent genes whose expression increased over time during the maturation of wild-type chondrocytes in pellet cultures. Many of these genes had not previously been associated with chondrocyte maturation, and thus represent potential novel regulators of terminal differentiation. In summary, our results suggest that SHP2 and the RAF/MEK/ERK pathway may negatively regulate the onset of hypertrophy, but positively regulate transition from early-hypertrophic chondrocytes to terminally differentiated chondrocytes. These data are consistent with the hypothesis that enchondroma-like lesions in MC patients arise due to a failure of chondrocyte terminal differentiation.

3040F

Absence of CyPB directly affects collagen folding and glycosylation, and indirectly affects helical hydroxylation by LH1, altering bone cross-link patterns. *W.A. Cabral[1], I. Perdivara[2], M.A. Weis[3], M. Terajima[4], A.R. Blissett[1], W. Chang[1], E.N. Makareeva[5], E.L. Mertz[5], S. Leikin[5], K.B. Tomer[2], D.R. Eyre[3], M. Yamauchi[4], J.C. Marini[1].* 1) Bone & Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD; 2) Laboratory of Structural Biology, NIEHS, NIH, Research Triangle Park, NC; 3) Orthopaedic Research Laboratories, University of Washington, Seattle, WA; 4) North Carolina Oral Health Institute, University of North Carolina, Chapel Hill, NC; 5) Section on Physical Biochemistry, NICHD, NIH, Bethesda, MD.

Cyclophilin B (CyPB), encoded by Ppib, is an ER-resident peptidyl-prolyl cis-trans isomerase (PPIase) that occurs both independently and as a component of the collagen prolyl 3-hydroxylation complex. CyPB is proposed to be the major PPIase catalyzing the rate-limiting step in collagen folding. Mutations in Ppib cause recessively inherited osteogenesis imperfecta type IX, a moderately severe to lethal bone dysplasia. To investigate the role of CyPB in collagen folding and modification, we generated Ppib-/- mice that recapitulate the OI phenotype. KO mice are small, with reduced femoral aBMD, BV/TV, and MOI. Ppib transcripts are absent in skin, fibroblasts, femora and calvarial osteoblasts, and CyPB is absent from KO OB and FB on western analysis. Only residual (2-11%) collagen 3-hydroxylation is detectable in KO cells and tissues. Collagen folds more slowly in the absence of CyPB, supporting its rate-limiting role in folding. However, total lysyl hydroxylation in Ppib-/- FB and OB collagen is normal, while increased diglycosylation accounts for collagen overmodification and delayed electrophoretic migration. Detailed analysis of bone and OB type I collagen by mass spectrometry revealed site-specific alterations of lysine hydroxylation by LH1. Most importantly, hydroxylation of crosslink residue K87 is reduced by 15-20% in OB collagen. In KO bone, there is dramatic underhydroxylation of helical crosslink residue K87 in both the α1(I) and α2(I) chains, decreased by 40% and 30% compared to WT, respectively. The altered lysine modification causes striking changes in the type and quantity of collagen crosslinks in KO bone. Unhydroxylated forms of divalent (HLNL) and trivalent (LP) crosslinks are increased 3- to 5-fold, leading to increased total crosslinks and decreased DHLNL/HLNL and HP/LP ratios. Altered crosslink patterns contribute to decreased collagen deposition into matrix by 70-80% and directly undermine bone strength. Finally, these findings suggest a novel role for CyPB in supporting the activity of specific collagen lysyl hydroxylase(s), especially LH1, by an unknown mechanism. Thus, CyPB not only facilitates collagen folding directly but also indirectly regulates collagen hydroxylation, glycosylation, crosslinking and fibrillogenesis.

Use of whole exome sequence analysis to identify TLE4 as a causal variant in a family with congenital kyphoscoliosis and prolonged patency of the anterior fontanelle. *P. Giampietro[1], A. Stoddard[2], D. Sweetser[3], C. Raggio[4], R. Blank[2], M. Stephan[5], K. Rasmussen[6], K. Gill[1], S. Sund[1], R. Lorier[2], A. Turner[2], U. Broeckel[2].* 1) University of Wisconsin-Madison, Madison, WI; 2) Medical College of Wisconsin, Milwaukee, WI; 3) Massachusetts General Hospital, Boston, MA; 4) Hospital for Special Surgery, New York, NY; 5) Madigan Healthcare System, Tacoma, WA; 6) Marshfield Clinic, Marshfield, WI.

Congenital vertebral malformations (CVM) represent defects in formation and segmentation of somites and have an estimated incidence of 0.13-0.50 per 1000 live births. Extreme genetic heterogeneity and the rarity of large families with CVM limit the ability to identify mutations in patterning genes associated with CVM by traditional genetic study designs. We therefore used whole exome sequencing (WES) to study a kindred in which a man and his two daughters suffered from kyphoscoliosis, vertebral body hypoplasia, short lumbar spinal pedicles, sacral and coccygeal hypoplasia and prolonged anterior fontanelle patency. WES was performed using Agilent SureSelect hybridization-based exome capture methodology. Results were filtered to excude all except heterozygous nonsynonymous coding variants with minor allele frequency < 1%. This strategy yielded 21 candidates, with *TLE4* harboring a c.A1318G:p.T440A variant. The functional significance of the *TLE4* variant was demonstrated by a mouse knockout of Tle4, the murine homolog. Tle-/- mice displayed a profound impairment of bone formation, while Tle+/- mice displayed a similar phenotype to the affected humans, including shortened vertebral pedicles and delayed mineralization of the skull. *TLE4* encodes a transcription factor in a gene family that participates in the determination of hematological cell fate in response to Notch signaling, a critical signaling pathway in somitogenesis.The Gro/TLE gene family was not known to involved in skeletal development before the identification of *TLE4* as a strong candidate gene in this family and the simultaneous characterization of Tle4 knockout mice. The *Gro/TLE* gene family serves as downstream effectors of Notch signaling, as well as inhibitors of Wntβ-catenin signaling. Disruption of these pathways is seen in certain families with CVMs. In addition, the *Gro/TLE* gene family is also known to interact with *RUNX* family members, with RUNX2 being required for calcification. These findings highlight the potential of whole exome sequence analysis, particularly when coupled with functional studies in appropriate models, to identify novel genetic determinants of uncommon disorders. While further work remains to be done to fully define the mechanisms by which *TLE4* mutations produce the observed phenotypes, these data nevertheless demonstrate the ability of a deep sequencing strategy to discover previously unknown skeletal genes.

Opsismodysplasia (OPS) is a severe autosomal-recessive chondrodysplasia, belonging to the spondylodysplastic dysplasia group. The main clinical and radiological features are y pre- and postnatal micromelia, extremely short hands and feet, severe platyspondyly, squared metacarpals, delayed skeletal ossification, and metaphyseal cupping. In order to identify mutations causing OPS, a total of 19 cases from 12 unrelated families were included in this study. We performed exome sequencing in three cases from three unrelated families and only one gene was found to harbor mutations in all three cases, namely INPPL1 (inositol polyphosphate phosphatase like 1). Screening INPPL1 in the remaining cases identified a total of 16 distinct mutations. Among the 19 cases, prenatal findings led to early termination of pregnancies (especially in recurrent sibs) in 10/19 cases and hygroma, short long bones, short extremities and narrow thorax were consistently observed. Four children died early (stillborn 30 WG- 15 months of age). The five remaining cases (3 to 19 years old), had normal cognitive development, severe short stature (below- 4 SDS), lower limb deformity and severe scoliosis with atlanto-axial instability. Most mutations (8/16) resulted in premature stop codons, located in the catalytic domain, 5-phosphatase. INPPL1 belongs to the inositol-1,4,5-trisphosphate 5-phosphatase family, that govern a plethora of cellular functions by regulating the levels of specific phosphoinositides. The role of INPLPL1 in bone and cartilage is yet unknown. However, histological studies of the femoral growth plate performed in the prenatal cases from 2 families, show similar disorganization of the growth plate with, absence of columnar arrangement of proliferative cells and a reduced hypertrophic zone with a small number of hypertrophic chondrocytes. Our finding supports a key and specific role of INPPL1 in endochondral ossification.

3043F

Novel mutations in the LRP5 gene in patients with osteoporosis-pseudoglioma syndrome.
M. Pekkinen[1], G. Grigelioniene[2], L. Akin[3], K. Shah[4], K. Karaer[5], S. Kurtoglu[3], A.V. Ekbote[4], E. Sagsak[6], J. Söderholm[1], S. Vallius[1], S. Danda[4], E. Åström[2], O. Mäkitie[1]. 1) Folkhälsan Inst Genetics, Folkhälsan Inst Genetics, Univ Helsink, Helsinki, University of Helsinki, Finland; 2) Karolinska Institutet and Karolinska University Hospital, Stockholm, Sweden; 3) Erciyes University, Faculty of Medicine, Department of Pediatric Endocrinology, Turkey; 4) Department of Clinical Genetics, Christian Medical College and Hospital Vellore, India; 5) Intergen, Genetic Diagnosis Research and Application Center, Ankara, Turkey; 6) Dr.Sami Ulus Children's Hospital, Department of Pediatric Endocrinology, Ankara,Turkey.

Background: Osteoporosis-pseudoglioma syndrome (OPPG) is a rare autosomal recessive disorder with congenital or early-onset blindness and severe osteoporosis. OPPG is caused by biallelic mutations in the low-density lipoprotein receptor-related protein 5 (LRP5) gene. We present six novel LRP5 mutations and the resulting phenotypes in four consanguineous Indian and Turkish families. Methods: Peripheral blood samples were obtained from the affected probands and their parents. DNA was extracted using standard procedures. The LRP5 gene was analyzed by direct sequencing after PCR amplification. The observed sequence changes were compared with reference database and 200 control samples. Results: Altogether seven patients from three Turkish and one Indian families were included in the study; in all families the parents were related. All patients had severe osteoporosis with peripheral and vertebral fractures, and congenital or early-onset blindness. In addition, three patients had delayed mental development. DNA sequencing demonstrated in each of the four probands homozygous LRP5 mutations. All mutations were novel and located in exons 1, 2, 3 and 12 of the LRP5 gene; they were regarded deleterious based on prediction programs. In one family the affected child had homozygous sequence variations A3A, A4A, P5L and a deletion of the rs72555376 microsatellite; the healthy parents had none of these changes. In three families with altogether six affected children we found homozygous missense mutations D116N, P197R and I882N; the parents were heterozygous for the changes. Mutations P197R in exon 3 and I882N in exon 12 were associated with mental retardation. Conclusions: We report six novel LRP5 mutations in Turkish and Indian patients with OPPG. All mutations regardless of the location resulted in similar ocular and skeletal phenotype. Mutations in exons 3 and 12 resulted also in developmental delay. The deletion of rs72555376, which causes shortening of a poly-leucine stretch in exon 1, has previously been described in heterozygous state by Chung et al. 2008; the disease mechanism and origin of the homozygous deletion together with 3 other sequence changes in our patient remains to be elucidated in further studies.

3044W

Altered Osteoblast Function underlies phenotype of type V Osteogenesis Imperfecta. *A. Reich[1], A.S. Bae[1], A.M. Barnes[1], W.A. Cabral[1], D. Chitayat[2], S.C. Hill[3], J.C. Marini[1].* 1) Bone and Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD; 2) 2The Hospital for Sick Children, and the Department of Obstetrics and Gynecology, the Prenatal Diagnosis and Medical Genetics Program, Toronto, Ontario, Canada; 3) 3Diagnostic Radiology Department, Clinical Center, NIH, Bethesda, MD.

Osteogenesis imperfecta (OI) is a genetically heterogeneous disorder characterized by bone fragility. Type V OI is the only OI type with dominant inheritance not caused by mutations in type I collagen; furthermore, steady-state collagen from type V osteoblasts has normal gel mobility. Affected individuals have characteristic skeletal findings, including hypertrophic callus and ossification of the interosseus membrane, as well as mesh-like lamellation on bone histology. Type V OI is caused by a unique heterozygous mutation in IFITM5 (c.-14C>T), which encodes Bril, a transmembrane protein expressed in osteoblasts. The mutation generates a start codon, adding five residues to the Bril N-terminus. However, the mechanism of type V OI and its relationship with type I collagen is unknown. We identified 8 patients with the IFITM5 (c.-14C>T) mutation, with variable phenotypic expression. Osteoblasts from type V OI patients were differentiated with osteogenic media in culture over 21 days. Sequencing of cDNA from these cells verified expression of mutant IFITM5 transcripts, consistent with a dominant mechanism. In both control and type V OI differentiated osteoblasts, Bril expression increases substantially and comparably with BMP2 stimulation. Bril protein is moderately decreased in treated mutant cells. Osteocalcin (BGLAP2) expression, a marker of late osteoblast differentiation, was increased in type V osteoblasts vs control during days 10-15 of differentiation, and relatively augmented by addition of BMP2 to cultures. Mineralization, assayed by alizarin red deposition, was also increased in type V osteoblasts during differentiation, vs control. In contrast, type V OI osteoblasts had less than half the COL1A1 expression of control during differentiation. Matrix deposited by proband osteoblasts in long-term culture displayed normal amounts of collagen when examined by confocal microscopy, but with a more sheet-like organization than in control. Finally, comparison of osteoblasts transcripts from two type V patients and control on osteogenic arrays revealed common sets of significantly altered transcripts for mineralization and growth factors, collagens and BMPs. Thus, our data support a proposed role for regulation of Bril by BMP2. The increased mineralization and collagen-related defect demonstrated in type V OI osteoblasts during differentiation may underlie the overactive tissue calcification and hypertrophic callus formation seen in patients.

3045T

Whole Exome Sequencing and functional follow up in 114 cases of non-motile ciliopathies (Jeune-Asphyxiating Thoracic Dysplasia (JATD), Short-Rib-Polydactyly-Syndrome (SRPS), Bardet-Biedl-Syndrome (BBS), Joubert Syndrome (JS) and others). *M. Background: Ciliopathies are complex develop-mental disorders resulting from mutations in genes encoding ciliary proteins. Although individually rare, together they represent a significant disease burden. Phenotypic as well as genetic overlap, together with extensive genetic heterogeneity, has hampered genetic diagnosis in the past but develop-ment of next generation sequencing techniques such as whole exome sequencing (WES) offers new dia-gnostic tools.**Methods:** We investigated 114 ciliopathy cases (61 JATD and SRPS, 37 BBS, 7 JS and 9 other ciliopathy cases) by WES. **Results:** We identified the disease-causing gene in 2/3 of all cases, with 50% of JATD and Joubert cases and up to 90% of BBS cases found to be caused by mutations in known disease causing genes. Copy number variations were detcted in approximately 10% of solved cases from the WES data.WES results also led to revision of the initial clinical diagnosis in 10% of the cases and new phenotype-genotype associations came to light. However, the proportion of cases given a genetic diagnosis was much lower in the more ambiguous phenotypic groups. In contrast to BBS cases, in whom we frequently identified two loss-of-function alleles per proband, all JATD cases carried at least one missense allele, consistent with the hypothesis that JATD patients are hypomorphic for the disease while BBS represents a true 'null' phenotype. 25% of the BBS cases carried >2 mutations, but the third mutation was always a missense allele except in one case. We were able to identify several new genes causing JATD, including 2 genes encoding WD40-repeat containing proteins (new intra-flagellar transport (IFT) dynein components previously undescribed in mammals) in addition to mutations in genes encoding other better understood IFT-subcomplex B components. Functional follow-up studies of these new genes using zebrafish and cell culture model systems are currently under way. **Summary:** Our findings in this large non-motile ciliopathy cohort demonstrate that WES is highly efficient for the genetic diagnosis of heterogeneous recessive disorders and that this diagnosis is facilitated by deep pheno-typing. A surprisingly large number of cases are caused by mutations in known genes, but we also identified several new ciliopathy genes. Compared to NGS gene panel sequencing, WES offers additional opportunities to identify new genes previously not associated with the condition investigated.

3046F

Haplotype Analysis Supports a "Founder" for the Balkan OPG Mutation Causing Juvenile Paget's Disease. *S. Mumm[1,2], K. Geczi[1], M. Huskey[1], D. Naot[3], S. Polyzos[4], T. Cundy[3], W. Van Hul[5], P. Singhellakis[6], M.P. Whyte[1,2].* 1) Washington University School of Medicine, St. Louis, MO, USA; 2) Shriners Hospital for Children, St. Louis, MO, USA; 3) University of Auckland, New Zealand; 4) Aristotle University of Thessaliniki, Greece; 5) University of Antwerp, Belgium; 6) Athens University, Greece.

Juvenile Paget's disease (JPD), a rare autosomal recessive disorder, features extremely rapid bone turnover causing skeletal pain, fracture, and deformity in early childhood. Deafness and retinopathy leading to blindness can follow. Most JPD is due to homozygous loss-of-function mutations in the TNFRSF11B gene encoding osteoprotegerin (OPG) -- the decoy receptor that prevents RANKL binding to its cognate receptor RANK, a major stimulus element for osteoclastogenesis. A variety of mutations in TNFRSF11B, typically transmitted by apparent 'founders' in various geographic locations worldwide, cause JPD. The severity of 'OPG deficiency JPD' seems to vary depending on mutation type and how much of the OPG coding region is disrupted. In two Greek men and another Croatian man who are seemingly unrelated and manifest the mildest form of JPD, a unique homozygous deletion/insertion mutation (966_969delTGACinsCTT) has been reported. This frame-shift deletes 79 carboxy terminal amino acids from the OPG monomer, including a cysteine necessary for homodimerization. When recently referred 2 additional unrelated Greek JPD patients homozygous for this 'Balkan mutation', we studied the likelihood that all of these patients are in fact related by a distant 'founder' in whom the mutation arose many generations ago. To test this hypothesis, we performed haplotype analysis of the 5 Balkan JPD patients and 2 control JPD patients from other geographic regions using SNPs within and surrounding TNFRSF11B. We developed primer sets for 13 informative SNPs, and then PCR-amplified and sequenced these SNPs using leukocyte-derived genomic DNA from each patient. All 5 individuals shared a homozygous common core haplotype of 4 SNPs, whereas each of the 'control' JPD patients had a unique haplotype. Two of the four Greek patients shared a common haplotype of 10 homozygous SNPs, indicating closest kinship. A different Greek patient shared only 5 of these SNPs suggesting more distant relationship. The Croatian JPD patient shared only 4 common markers suggesting he is the most remotely related and consistent with his geographic distance. Hence, all Balkan JPD patients share the common OPG mutation (966_969delTGACinsCTT) and common haplotypes indicating relationship to a genetic founder. Further analysis can determine how many generations ago this founder mutation arose.

3047W

Exome analysis on tubular aggregate myopathy. *Y. Endo[1,2], K. Motomura[1], Y.K. Hayashi[1,2], S. Noguchi[2], I. Nonaka[2], M. Mori-Yoshimura[3], Y. Oya[3], I. Nishino[1,2].* 1) Department of Clinical Development, Translational Medical Center, National Center of Neurology and Psychiatry (NCNP), Kodaira, Japan; 2) Department of Neuromuscular Research, National Institute of Neuroscience, NCNP; 3) Department of Neurology, National Center Hospital, NCNP.

Tubular aggregates (TAs) are a unique structure in muscle fibers, which is derived from sarcoplasmic reticulum, and are seen in certain types of muscle diseases including periodic paralysis, congenital myasthenic syndromes (CMS) and tubular aggregate myopathy (TAM). TAM is defined as unclassified hereditary myopathy, pathologically characterized by the presence of TAs, although causative relationship has not been well established. The objective of this study is to identify pathogenic mutations of TAM and to clarify the clinical phenotypes. We performed whole-exome sequencing in 13 individuals with TAM but with no known genetic defects, and identified pathogenic mutations in *GFPT1* in two individuals. Both individuals had novel homozygous missense mutations, c.41G>A (p.Arg14Gln) and c.723_724insG (p.G241fs), respectively. *GFPT1* was recently reported as a causative gene for limb-girdle CMS (LG-CMS). However, the clinical presentations of the two affected individuals were slightly different from LG-CMS. Individual 1 exhibited slowly progressive limb-girdle muscle weakness with no fluctuation therefore the clinical diagnosis was limb-girdle muscle dystrophy. Individual 2 exhibited limb-girdle and facial muscle weakness from infancy. Therefore, the clinical diagnosis was congenital myopathy. Muscle biopsy showed myopathic change with TAs although the first biopsy of individual 2 performed at age 8 years showed only minimal change without TA. Repetitive stimulation performed in individual 1 after genetic analysis demonstrated the decremental responses diagnostic of myasthenia. Acetylcholine-esterase inhibitor therapy was dramatically effective, improving his status from wheelchair-bound to ambulant without support. *GFPT1*-associated LG-CMS should be considered when affected individuals have limb-girdle muscle weakness and TAs.

Novel *COL11A1* mutations in Stickler syndrome detected by next-generation sequencing. *F. Acke[1,2], F. Malfait[2], O. Vanakker[2], W. Steyaert[2], K. De Leeneer[2], I. Dhooge[1], A. De Paepe[2], E. De Leenheer[1], P. Coucke[2].* 1) Department of Otorhinolaryngology, Ghent University Hospital, Ghent, Belgium; 2) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Stickler syndrome is a connective tissue disorder with considerable phenotypic and genotypic variability, characterized by distinctive facial abnormalities, ocular problems, hearing loss, and joint problems. Up to now, mutations in 5 different collagen genes have been associated with the disease. Mutations in the *COL11A1* gene may result in Stickler syndrome type 2, which can be differentiated clinically by a 'beaded' vitreous and a more severe hearing loss compared to the more prevalent type 1, caused by mutations in *COL2A1*. In literature, only a few dozen *COL11A1* mutations have been reported. We selected 33 unrelated *COL2A1* mutation-negative patients, based on their clinical features, for molecular *COL11A1* analysis, by means of next-generation sequencing technology (MiSeq, Illumina). The bioinformatic pipeline included the CLC bio Workbench 6.0 followed by an in-house developed software package for variant interpretation. Assays lacking sufficient coverage as well as the mutations identified were verified by Sanger sequencing. Out of the 33 selected probands, disease-causing mutations could be identified in 14 independent patients. Half of these mutations are novel, of which most are missense mutations (including 2 glycine substitutions). The other half are previously reported mutations, mostly splice-site alterations. Moreover, additional SNPs were identified. All molecularly confirmed patients had a clinical presentation compatible with Stickler syndrome type 2. In conclusion, *COL11A1* screening in selected Stickler syndrome patients, based on meticulous clinical evaluation, is rewarding. For large genes such as *COL11A1*, next-generation sequencing proves to be an efficient and cost-effective molecular tool.

Mutation analysis of COL1A1 and COL1A2 genes in Indian patients with Osteogenesis Imperfecta. *J. Stephen[1], A. Shukla[1], A. Dalal[2], G. Katta[3], N. Gupta[4], M. Kabra[4], P. Dabadghao[5], S. Phadke[1].* 1) Medical Genetics, Sanjay Gandhi Post Graduate Institute of Medical Science, Lucknow, India; 2) Centre for DNA Fingerprinting and Diagnostics, Hyderabad, India; 3) Department of Medical Genetics, Kasturba Medical college, Manipal, India; 4) All India Institute of Medical Science, New Delhi, India; 5) Endocrinology, Sanjay Gandhi Post Graduate Institute of Medical Science, Lucknow, India.

Osteogenesis Imperfecta (OI) is a condition of decreased bone density of heterogeneous etiology. Most of the cases are inherited in autosomal dominant fashion and are caused by mutations in COL1A1 or COL1A2 genes. These two genes are very large so they have been rarely analyzed systematically in Indian patients with OI. We have selected 35 Indian patients who were clinically diagnosed for OI and sequenced all exons of both the genes. Mutations in COL1A1 gene were identified in 14 cases (six novel) and mutations in COL1A2 were identified in eleven cases (seven novel). Total 55 polymorphisms have been identified in both the genes; out of them eight were novel in the coding region and twelve were novel in the non coding region. No mutation has been detected in ten patients; out of them six were from consanguineous families with one or two similarly affected siblings suggesting autosomal recessive genes. Excluding consanguineous families, mutation has been identified in 25 out of 29 families which accounts for about 86 percent of mutation detection rate in these genes in Indian patients with OI from non consanguineous families. Out of identified mutations, 56 percent were in COL1A1 and 44 percent were in COL1A2 which is similar to the reported rate worldwide.

This report identifies human skeletal diseases associated with mutations in *WNT1*. In ten family members with dominantly inherited early-onset osteoporosis, a heterozygous missense variation c.652T>G (p.Cys218Gly) in *WNT1* segregated with the disease, and a homozygous nonsense mutation (c.884C>A, p.Ser295*) was identified in two siblings with recessive osteogenesis imperfecta. *In vitro*, aberrant forms of WNT1 protein showed impaired capacity to induce canonical WNT signaling, their target genes, and mineralization. *Wnt1* was clearly expressed in bone marrow, especially in B cell lineage and hematopoietic progenitors; lineage tracing identified expression in a subset of osteocytes, suggesting altered cross-talk of WNT signaling between hematopoietic and osteoblastic lineage cells in these diseases.

Identification of novel _SHOX_ target genes in the developing limb using a transgenic mouse model. *G.A. Rappold[1], A. Glaser[1], K. Kleinschmidt[2], I. Scholl[1], R. Röth[1], L. Li[3], N. Gretz[4], G. Mechtersheimer[5], M. Karperien[6], A. Marchini[1,7], W. Richter[2], K.U. Beiser[1]*. 1) Department of Human Molecular Genetics, Institute of Human Genetics, Heidelberg University Hospital, Heidelberg, Germany; 2) Division of Experimental Orthopaedics, Orthopaedic University Hospital, Heidelberg, Germany; 3) Institute of Pathology, University of Göttingen, Göttingen, Germany; 4) Medical Research Center (ZMF), Medical Faculty Mannheim at Heidelberg University, Mannheim, Germany; 5) Institute of Pathology, Heidelberg University Hospital, Heidelberg, Germany; 6) Department of Developmental Bioengineering, University of Twente, Enschede, The Netherlands; 7) German Cancer Research Center (DKFZ), Heidelberg, Germany.

Deficiency of the human short stature homeobox-containing gene (*SHOX*) has been identified in several disorders characterized by reduced height and skeletal anomalies such as Turner, Léri-Weill and Langer syndrome as well as idiopathic short stature. SHOX acts as a transcription factor during limb development and is expressed mainly in prehypertrophic and hypertrophic chondrocytes of the growth plates. Although highly conserved in vertebrates, rodents lack a *SHOX* orthologue. This offers the unique opportunity to analyze the effects of human *SHOX* expression in transgenic mice. We have generated a mouse expressing the human *SHOXa* cDNA under the control of a murine *Col2a1* promoter and enhancer. *SHOX* and marker gene expression as well as skeletal phenotypes were characterized in two transgenic lines. No significant skeletal anomalies were found in transgenic compared to wildtype mice. Quantitative and *in situ* hybridization analyses revealed that the *Col2a1-SHOX* transgene, however, affected extracellular matrix gene expression during early limb development, suggesting a role for *SHOX* in growth plate assembly and extracellular matrix composition during long bone development. For instance, we could show that the connective tissue growth factor gene *Ctgf*, a gene involved in chondrogenic and angiogenic differentiation, among other genes is transcriptionally regulated by SHOX in transgenic mice. This finding was confirmed in human NHDF and U2OS cells and chicken micromass culture, demonstrating the value of the *SHOX*-transgenic mouse for the characterization of SHOX-dependent genes and pathways in early limb development.

3052F

HIBCH deficiency in a patient with phenotypic characteristics of mitochondrial disorders. *M.S. Reuter[1], J.O. Sass[2], A.B. Ekici[1], I. Schanze[3], T. Leis[4], S. Uebe[1], R. Abou Jamra[1], A. Reis[1]*. 1) Institute of Human Genetics, Erlangen, Germany; 2) Clinical Chemistry and Biochemistry, University Children's Clinic Zurich, Switzerland; 3) Institute of Human Genetics, Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany; 4) Department of Pediatrics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany.

The catabolic pathway of the amino acid valine is dependent on a specific 3-hydroxyisobutyryl-CoA hydrolase (HIBCH), a nuclear-encoded mitochondrial protein. Only two patients with HIBCH deficiency and biallelic mutations in the HIBCH gene have been reported in the literature. Both of them demonstrated delayed motor development, muscular hypotonia, and early-onset deterioration of neurological functions. One of the patients additionally manifested various congenital malformations. The phenotype was attributed to an accumulation of methacrylyl-CoA, a highly reactive compound, which readily undergoes reactions with free sulfhydryl groups. We report a third patient, first child of healthy consanguineous parents, with a homozygous one-base pair insertion resulting in a premature stop codon (c.1129_1130insT, p.K377_S378delinsX) in the HIBCH gene (NM_014362). The mutation was detected by homozygosity mapping and whole-exome sequencing on a SOLID 5500xl platform. The patient displays a variety of symptoms reminiscent of mitochondrial dysfunction; like severe muscular hypotonia, intellectual disability, Leigh-like hyperintensities of the basal ganglia in MRI, progressive brain atrophy, repeatedly elevated blood lactate, optic nerve atrophy, seizures, and respiratory chain complex 1 deficiency with borderline depletion of mitochondrial DNA in native muscle tissue. There were no organ or brain malformations. Metabolic screening for aminoacidopathies and organic acidurias yielded normal results. The phenotype of the patient further elucidates the clinical spectrum of HIBCH deficiency. Physical malformations do not appear to be a consistent feature. Instead, the clinical features described here suggest that mitochondrial dysfunction, presumably caused by an accumulation of toxic valine metabolites, contributes to the clinical phenotype. We suggest that HIBCH deficiency should be considered as a differential diagnosis in patients with suspected mitochondrial disorders, particularly with regard to the potential treatability of amino acid metabolism disturbances.

3053W

Discovery of a novel genetic disorder and increased diagnostic rate using Next Generation Sequencing in heterogeneous Ataxias. *A.H. Németh[1,2,3], A.C. Kwasniewska[1,3], S. Lise[3], R. Ataxias are highly heterogeneous disorders caused by mutations in many genes. The diagnostic process is often long and many patients undergo multiple investigations without ever reaching a conclusive molecular diagnosis. The advent of massively parallel, Next Generation Sequencing (NGS) promises to revolutionise genetic testing and shorten the diagnostic process for some patients. We performed a pilot study using heterogeneous ataxias as a model neurogenetic disorder to assess the introduction of NGS into clinical practice. 58 known human ataxia genes were captured followed by NGS in 50 patients who had been extensively investigated and were refractory to diagnosis. All cases had been tested for Spinocerebellar ataxia 1-3,6,7, FRDA and had multiple other biochemical, genetic and invasive tests. Pathogenicity was assessed using a bioinformatics pipeline and novel variants were validated using functional experiments. The overall detection rate in our heterogeneous cohort was 18% and varied from 8.3% in those with an adult onset progressive disorder to 40% in those with a childhood or adolescent onset progressive disorder. The highest detection rate was in those with an adolescent onset and a family history (75%). The majority of cases with detectable mutations had a childhood onset but most are now adults, reflecting the long delay in diagnosis. The delays were caused by the lack of available clinical testing, presence of atypical phenotypes, use of indirect testing and presence of unknown genetic disorders. In the cases in whom we made an eventual diagnosis, the delay was 3-35 years (mean 18.1 years). Alignment and coverage metrics indicated that the capture and sequencing was highly efficient. Our pathogenicity interpretation pathway predicted 13 different mutations in 8 different genes: *PRKCG*, *TTBK2*, *SETX*, *SPTBN2*, *SACS*, *MRE11*, *KCNC3* and *DARS2* of which 9 were novel including one causing a newly described recessive ataxia syndrome, Spectrin-Associated autosomal recessive cerebellar ataxia type 1 (SPARCA1), which is allelic to SCA5. Targeted capture followed by NGS was efficient, cost-effective, and enabled a molecular diagnosis in many refractory cases. A specific challenge of NGS data is pathogenicity interpretation, but functional analysis confirmed the pathogenicity of novel variants showing that our pipeline was robust. Our results have broad implications for clinical neurology practice and the approach to diagnostic testing.

3054T

Shouting won't help: a combined strategy (Next Generation Sequencing and Linkage analysis) to identify Hereditary Hearing Loss (HHL) genes in affected families. *D. Vozzi, G. Girotto, F. Faletra, E. Rubinato, A. Morgan, D. Vuckovic, S. Lenarduzzi, M. Morgutti, P. Gasparini.* 1Med Genet, IRCCS-Burlo Garofolo Children Hospital, Via dell'Istria 65/1, Trieste, Italy.

Nonsyndromic HHL is a common disorder accounting for at least 60% of prelingual deafness. Despite the presence of some common HHL genes (GJB2, GJB6 and MTRNR1) still there is a need to 1) search for new causative mutations/genes and 2) develop new diagnostic approaches to overcome the problem of genetic heterogeneity. As regards to the first point a combined strategy based on linkage analysis (LA) followed by whole-exome sequencing (WES) was developed. Data analysis pipeline is based on data quality evaluation, hg19 reference reads mapping by BWA, variants calling and quality filtering by GATK. 'In silico' analysis of variants was done using a series of tools (PolyPhen-2, MutationTester, etc.). Using this approach we analyzed 6 Italian and 5 Qatari families affected by sensorineural, moderate to severe HHL. In a consanguineous family from Qatar, LA identified a region of 40 Mb on chromosome 5q13 (LOD score 3.8). WES data reported a causative mutation (c.7873 t>g leading to p.*2625Gluext*11) in BDP1 gene. The mutation disrupts the termination codon of the transcript resulting in an elongation of 11 residues of the protein. Immunohistochemistry in the mouse inner ear showed a clear expression of Bdp1 gene. In an Italian dominant family, LA showed a LOD of 3.3 on chromosome 12q24, where WES data analysis identified a new missense mutation (c.1057G>C; pG353R) in P2X2 gene, A 3D model of this protein suggests that the substitution of the hydrophobic Gly, with a charged residue as the Arg, it is expected to destabilize the protein folding. Finally, an Italian pedigree resembling a Y-linked form of HHL was analysed by WES identifying a missense mutation (c.A206T:p.D69V) in a gene (YYY). In silico prediction analysis reported this mutation as disease causing. YYY, a homolog of a HHL gene, is expressed in multiple cochlea cell types. Functional studies are now in progress to confirm the pathogenetic effect of the variation identified. As regards the second point, a Targeted Re-Sequencing (TRS) protocol has been developed based on Ion Torrent™ technology. It analyzes 96 HHL related genes ensuring 92% coverage of the target region (a total of 411.420 bp). The protocol has been tested and validated in many cases and is currently used in our diagnostic service. These findings definitely increase our knowledge of new HHL genes and may suggest new targets for hearing impairment treatment and prevention.

3055F

Genetic etiology study of the non-syndromic deafness in Chinese Hans by targeted next-generation sequencing. *T. Yang[1, 2], H. Wu[1, 2], Y. Chai[1, 2].* 1) Dept of Otolaryngology - Head And Neck Surgery, Shanghai Jiaotong University School of Medicine, Xinhua Hospital, Shanghai, China; 2) Ear Institute, Shanghai Jiaotong University School of Medicine, Shanghai, China.

Although over 60 non-syndromic deafness genes have been identified to date, the etiologic contribution of most deafness genes remained elusive. In this study, we addressed this issue by targeted next-generation sequencing of a large cohort of non-syndromic deaf probands. Probands with mutations in commonly screened deafness genes *GJB2*, *SLC26A4* and *MT-RNR1* were pre-excluded by Sanger sequencing. The remaining 125 deaf probands proceeded through targeted exon capturing of 79 known deafness genes and Illumina HiSeq2000 sequencing. Bi-allelic mutations in 15 less commonly screened deafness genes were identified in 28 deaf probands, with mutations in *MYO15A*, *GPR98*, *TMC1*, *USH2A* and *PCDH15* being relatively more frequent (≥3 probands each). Dominant mutations in *MYO6*, *TECTA*, *POU4F3* and *COCH* were identified in 4 deaf families. A mitochondrial *MTTS1* mutation was identified in one maternally inherited deaf family. No pathogenic mutations were identified in three dominant deaf families and two consanguineous families. We concluded that mutations in the less commonly screened deafness genes were heterogeneous and contributed to a significant percentage (17.4%) of causes for non-syndromic deafness. Targeted next-generation sequencing provided a comprehensive and efficient diagnosis for known deafness genes. Complementary to linkage analysis or whole-exome sequencing of deaf families, pre-exclusion of known deafness genes by this strategy may facilitate the discovery of novel deafness genes.

3056W

Exome sequencing identifies NFS1 deficiency in a novel Fe-S cluster disease, infantile mitochondrial complex II/III deficiency. *S.M.K. Farhan[1,2], J. Wang[1], J.F. Robinson[1], P. Lahiry[1], V.M. Siu[5,6], C. Prasad[5,6], J.B. Kronick[4], D.A. Ramsay[3], C.A. Rupar[5,6], R.A. Hegele[1].* 1) Department of Biochemistry, Western University, London, Ontario, Canada; 2) Robarts Research Institute, Western University, London, Ontario, Canada; 3) Department of Pathology, London Health Sciences Centre, Western University, London, Ontario; 4) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Department of Pediatrics, University of Toronto, Toronto, Ontario; 5) Medical Genetics Program, Department of Pediatrics, London Health Sciences Centre, London, Ontario; 6) Children's Health Research Institute, London Ontario.

Iron-sulfur (Fe-S) clusters are a class of highly conserved and ubiquitous prosthetic groups with unique chemical properties that allow the proteins that contain them, Fe-S proteins, to assist in various key biochemical pathways. Mutations in Fe-S proteins often disrupt Fe-S cluster assembly leading to a spectrum of severe disorders such as Friedreich's ataxia or ISCU myopathy. Herein, we describe infantile mitochondrial complex II/III deficiency, a novel autosomal recessive mitochondrial disease characterized by lactic acidemia, hypotonia, respiratory chain complex II and III deficiency, multisystem organ failure and abnormal mitochondria. We applied autozygosity mapping to identify a homozygous region on chromosome 20 containing 453 genes. Next through whole-exome sequencing, we identified a novel variant within the autozygous region: c.215G>A, p.Arg72Gln in NFS1, a highly conserved cysteine desulfurase involved in the Fe-S cluster assembly machinery and is essential for the maturation of other Fe-S proteins such as ISCU, ISD11 and FXN. NFS1 p.Arg72Gln co-segregates with disease status in the family and was consistently predicted to be damaging by multiple in silico analyses. The exceptionally low minor allele frequency from the community of origin, from geographically and ethnically matched healthy control subjects coupled with reduced NFS1 expression in patient fibroblast cells as demonstrated by independent transfections, allowed us to converge on NFS1 p.Arg72Gln as the likely causative mutation in the affected kindred. We thus describe the first disease in man likely caused by deficiency in NFS1. Our results further demonstrate the importance of NFS1 expression in human physiology.

3057T

Reducing the cost of whole-exome sequencing of parent-affected offspring trios by joint Bayesian variant calling. *B. Hilbush[1], J. Blue-Smith[1], S. Lombardi[1], R. Littin[2], L. Trigg[2], A. Jackson[2], D. Ware[2], J.G. Cleary[2], F.M. De La Vega[1].* 1) Real Time Genomics, Inc., San Bruno, CA; 2) Real Time Genomics, Inc., Hamilton, NZ.

Whole-exome sequencing (WES) has been a successful and cost-effective strategy to identify disease-causing mutations of Mendelian highly penetrant diseases in research and clinical settings. The power to identify disease mutations is much higher by sequencing parent-affected offspring trios rather than the proband alone as genotypes of the parents remove irrelevant variants, aids in the removal of false positives shown as Mendelian inheritance errors (MIEs), and permits identifying recessive patterns. However, the cost of trio-based sequencing has limited its adoption in both clinical and research settings resulting in unsolvable cases. To circumvent this barrier, here we demonstrate a novel informatics approach to substantially reduce the cost of WES of trios leveraging the shared pedigree data allowing for full coverage sequencing of the proband and half coverage of the parents while maintaining high sensitivity and accuracy. Key to our results is the use of a Bayesian caller that simultaneously looks-up the alignment data of all family members when examining a site, scoring genotypes with priors based on Mendelian segregation patterns. To validate the approach, we obtained sequence data for a CEPH trio (Illumina 100bp paired-end, Agilent SureSelect v4+UTR) at a sequencing depth of ~60X coverage for NA12878 and at both 60X coverage and 30X coverage for the parents. We called variants on the full and half parental coverage trios and analyzed sensitivity and call set metrics for each of the individuals. We found that even with reduced parental coverage, we maintained 97.6% sensitivity to detect in NA12878 sites present in the 1000 genomes project OMNI array data across the targeted regions, and could call 98.6% of the offspring variant sites in both parents. Genotype concordance between full and half coverage for the child was 99.79% while both parents were above 99.4%. We also detected 78 de novo candidates and a MIE rate of 0.09%, a rate that is approximately 100X lower than that obtained with a singleton caller for NA12878. Our results show that our approach allows for a rational allocation of sequencing capacity in pedigree studies, resulting in cost savings with little deterioration of call quality. In the case of parent affected-offspring trios, this saving effectively result in sequencing three exomes for the cost of two, greatly empowering disease and clinical studies.

3058F

Systematic identification of causal mutations in Mendelian disorders using exome sequence data. *B. Thomas[1,2], M. Lek[1,2], N. Clarke[3], L. Waddell[3], M.A. Depristo[2], M.J. Daly[1,2], J. Laporte[4], J.J. Dowling[5], C.G. Bonnemann[6], K.N. North[3], D.G. MacArthur[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 2) Broad Institute of Harvard and MIT, Boston, MA, USA; 3) Institute for Neuroscience and Muscle Research, Sydney, NSW, Australia; 4) Department of Translational Medicine, Institut de Génétique et de Biologie Moléculaire et Cellulaire (IGBMC), INSERM U964, CNRS UMR7104, Université de Strasbourg, Collège de France, 67404 Illkirch, France; 5) Department of Paediatrics, University of Michigan Medical Centre, Ann Arbor, MI 48109-2200, USA; 6) Neuromuscular and Neurogenetic Disorders of Childhood Section, NINDS, National Institutes of Health, Bethesda, MD, USA.

Exome sequencing has proven to be a powerful and cost-effective approach for the identification of causal mutations in many patients suffering from rare, severe Mendelian diseases. However, exome analysis unambiguously identifies a causal mutation in only 30-50% of sequenced families, indicating much work remains to be done to increase the yield of causal variants from sequencing-based approaches. Causal mutations can be missed by current exome sequencing approaches for a variety of reasons. Conversely, there may be multiple gene candidates that require further information to prioritize for functional studies. We describe the development of an integrated pipeline for the identification of causal variants from exome data and its application to a cohort of severe, undiagnosed muscle disease patients. Our online application called xBrowse enables the intuitive analysis of family-based exome data, permitting researchers and clinicians to rapidly explore the effects of altering inheritance modes and function/quality filters on the identification of potential causal mutations. Through xBrowse, our collaborators have early access to gene-based RNA expression data across various human tissues, a disease gene-centric protein interaction networks and a large reference panel of over 50,000 exomes. We have applied this integrated approach to exome data over 250 individuals consisting of families and probands affected by a range of neuromuscular diseases. We describe the detection of novel sequence variants with strong evidence for causality in these patients, and provide case studies indicating the value of tissue expression data, protein interaction networks, large reference panels for the prioritization of disease-associated mutations.

3059W

Mutations in PDGFRB and NOTCH3 as Causes of Autosomal Dominant Infantile Myofibromatosis. *L. Tian[1], J. Martignetti[2], L. Dong[1], M. Ramirez[2], O. Camacho[2], C. Camacho-Vanegas[2], Y. Infantile myofibromatosis (IM) is a disorder of mesenchymal proliferation characterized by the development of non-metastasizing tumors in the skin, muscle, bone, and viscera. Occurrence within families across multiple generations is suggestive of an autosomal dominant (AD) inheritance pattern, but recessive (AR) modes of inheritance have also been proposed. In a recent publication, we reported results from a whole-exome sequencing (WES) study in members of 9 unrelated families clinically diagnosed with AD IM to identify the genetic origin of the disorder. We have shown that In eight of the families we identified one of two disease-causing mutations, c.1978C>A (p.Pro660Thr) and c.1681C>T (p.Arg561Cys), in PDGFRB. one family did not have either of these PDGFRB mutations but all affecteds had a c.4556T>C (p.Leu1519Pro) mutation in NOTCH3. In this study, we carried out protein structural homology modeling of PDGFRB and functional studies of NOTCH3 to understand how the mutations in PDGFRB cause IM. We applied novel structural modeling tools to the construction of protein and protein-complex models designed to help elucidate biological mechanisms. We performed bioinformatics network analysis and results have shown the crosstalk between PDGFRB and NOTCH pathways, which may offer new opportunities to identify mutations in other genes which result in IM and is a necessary first step toward understanding the mechanisms of both tumor growth and regression and its targeted treatment.

Mild case of Unverricht-Lundborg disease presenting as juvenile myoclonic epilepsy. *E. Andermann[1,3,4,5,7], D. Amrom[1,3,4,7], F. Andermann[2,3,4,6,7], A.-L. Lehesjoki[8].* 1) Neurogenetics Unit; 2) Epilepsy Service and Seizure Clinic; 3) Montreal Neurological Hospital and Institute, Montreal, Quebec, Canada; 4) Department of Neurology & Neurosurgery; 5) Department of Human Genetics; 6) Department of Pediatrics; 7) McGill University, Montreal, Quebec, Canada; 8) Folhalsan Institute of Genetics and Neuroscience Centre, University of Helsinki.

Unverricht-Lundborg disease (ULD) (EPM1) is a progressive myoclonus epilepsy with variable severity and course, and variable degrees of cognitive deterioration. The onset is usually between 6 and 15 years of age with myoclonus and generalized tonic-clonic seizures. With good antiepileptic management, the patients can now survive into their 50's and 60's. The gene for this disorder was identified in 1996 as cystatin B (CSTB), a cysteine protease inhibitor. The most common mutation is a dodecamer repeat, although rare point mutations have also been described. A 30-year-old female patient had one generalized tonic-clonic seizure during sleep at the age of 11 years, and onset of myoclonic jerks on awakening at around the same time, which are well-controlled with valproic acid. She carries a clinical diagnosis of juvenile myoclonic epilepsy (JME). The patient was born prematurely at 25 weeks'gestation weighing 750 grams. Her developmental milestones were normal and she works as a highschool teacher for behaviourally challenged children. The parents were not known to be consanguineous, although they originated from two small towns 35 kms apart. Four siblings of the maternal grandmother were diagnosed clinically with ULD and were known to us; three sisters died in their 20's and 30's, and one brother died at age 65. A third degree cousin of the mother had epilepsy and died at 18 years of age. A paternal uncle had a single generalized tonic-clonic seizure at the age of 7 years. A distant cousin of the paternal great grandmother was also said to have progressive myoclonic epilepsy. The patient and her partner presented for preconceptional genetic counseling. Carrier screening for the CSTB gene was carried out for both the patient and her partner, employing PCR for the dodecamer repeat, and sequencing of the CSTB gene to rule out point mutations. CSTB testing in the patient surprisingly revealed that she was a compound heterozygote for two mutations: an expansion of the dodecamer repeat and a splice site c.67-1G>C mutation in intron 1, predicting a deletion of the downstream exon 2 with in-frame deletion of 34 aminoacids (p.delV23_K56). This is the second most common mutation underlying EPM1. The husband has no potential EPM1-causing sequence alterations. Although ULD is often confused with JME in the early stages of the disease, it is rare to find patients with ULD at age 30 who are as well controlled and high-functioning as this patient.

3061F

Whole exome sequencing combined with homozygosity mapping in a family with mental retardation, muscle weakness, and abnormal movement. *E. Jaberi[1], B. Farham[2], G.A. Shahidi[3], M. Rohani[3], I. Safari[1], B. Klotzle[4], E. Elahi[1,5].* 1) School of Biology, College of Science, University of Tehran, Tehran, Iran; 2) Iran University of Science and Technology, Tehran, Iran; 3) Dept. of Neurology, Tehran University of Medical Sciences, Tehran, Iran; 4) Illumina, San Diego, California, USA; 5) Dept. of Biotechnology, College of Science, University of Tehran, Tehran, Iran.

We performed whole genome homozygosity mapping in a consanguineous Iranian family with three affected and five unaffected individuals with mental retardation, muscle weakness, and abnormal movement using high density SNP chips. The pattern of inheritance was autosomal recessive. Their symptoms started from childhood with learning difficulty and evaluate as moderate mentally retarded. In addition to mental retardation and muscle weakness, they had severe kyphscoliosis and underwent spinal surgery. All patients had normal sensory and cerebellar examination. Brain MRIs revealed mild cerebral, cerebellar and brainstem atrophy without any significant structural abnormality. Electromyography and nerve conduction studies showed normal sensory and motor action potentials but neurogenic MUAPs in distal upper and lower extremity muscles. Disease status in the family linked to a homozygous region of 13 Mb on chromosome 6. We captured exomes of one affected individual from the family and performed sequencing analysis by a second-generation sequencer with a mean coverage of 30× and sufficient depth to call variants at ~97% of each targeted exome. The genetic variants in the homozygous region were filtered against the 1000 Genomes Project, HapMap, and the dbSNP131 database. After annotation and functional expectation, one gene with a novel splice site disruption mutation was found to be candidates for the disease segregated in the family. The candidate gene has not been reported for any disease before. The observed variation segregated with disease status in the pedigree, and the mutation had not seen in 400 control individuals. According to the sequences of cDNAs of the 3 affected individuals compared to controls, the mutation causes early stop codon which results in synthesis of a truncated protein. Further functional studies are being performed to validate the relation of the candidate gene with the disease phenotype in the family.

3062W

Next Generation Sequencing Defines New Gene(s) Involved in the Enlarged Vestibular Aqueducts and Pendred Syndrome. *F. Alasti, M. Hildebrand, T. Yang, RJH. Smith.* Molecular Otolaryngology and Renal Research Laboratories, Department of Otolaryngology, University of Iowa, Iowa City, 52252 IA. USA.

In patients with sensorineural hearing loss (SNHL), enlarged vestibular aqueduct (EVA), cochlear hypoplasia and Mondini (both EVA and cochlear hypoplasia) have been considered as the most common radiological finding. Pendred Syndrome (PS) is characterized by SNHL, temporal bone anomalies, and thyroid goiter. It is believed that non-syndromic DFNB4 SNHL, EVA, Mondini dysplasia and PS are parts of the same disease spectrum. Biallelic mutations in SLC26A4, is the main cause of the PS-Mondini-EVA-DFNB4 disease spectrum. Pendrin, the anion exchanger encoded by SLC26A4, likely helps maintaining the fluid level and ionic composition of endolymph, which is highly important during development of the shape of the bony structures of inner ear. However, mutations in cis- and trans-regulatory elements of SLC26A4 (transcriptional regulator FOXI1) as well as the potassium channel KCNJ10 have also been reported in carriers of SLC26A4 mutations. Our goal is to study more about the possible physiological mechanisms of ionic homeostasis of the endolymph. We believe that identification of new gene(s) involved in this disease can open new insights into the pathophysiological mechanisms of SLC26A4-related SNHL. We hypothesized that using targeted-sequence capture followed by massively parallel sequencing on our cohort of PS-Mondini-EVA-DFNB4 patients carrying 0 or 1 mutation in SLC26A4; we can likely identify additional gene(s) associated with this phenotype. To address this issue, we designed RNA baits and developed a platform (called EVASeq) by targeting the coding exons of the best candidate genes extracted from our previous murine microarray expression data. Our strategy was screening our samples for the EVASeq platform, as well as for the OtoSCOPE (a platform targetting all the known HL-causing genes) panel. Then, the pedigrees with multiple affected individuals, in which all the genes in both EVASeq and OtoSCOPE panels were excluded, were considered for Whole Exome Sequencing (WES). Sequencing the candidate gene(s) we found through WES in a large cohort of patients with the same clincal data (in order to find a second family), was a strong confirmation. Planning for the relevant functional assays for the gene(s) we found within our WES families is our current approach. The result of this study most likely will provide the first comprehensive insight into the identification of new genetic components involved in this PS-Mondini-EVA-DFNB4 disease spectrum.

3063T

Haploinsufficiency of *GJB5* identified via exome sequencing causes a novel form of cutis laxa. *M. Dasouki[1,2], J. Roberts[3], K. Gonzalez[4], W. Zeng[4], M. Butler[3], A. Belousov[5], I. Saadi[5].* 1) Dept. of Neurology, Univ Kansas Med Ctr, Kansas City, KS; 2) Dept. of Genetics, King Faisal Specialists Hospital & Research Center, Riyadh, Saudi Arabia; 3) Dept of Psychiatry, Univ Kansas Med Ctr, Kansas City, KS; 4) Ambry Genetics, Aliso Viejo, CA, KS; 5) Dept. of Anatomy & Cell Biology, Univ Kansas Med Ctr, Kansas City, KS.

Cutis laxa is a clinically and molecularly heterogeneous genodermatosis. Mutations in five connexin genes (*GJA1*, *GJB2*, *GJB3*, *GJB4*, and *GJB6*) have been associated with a range of heritable skin disorders. Human *GJB5*, *GJB4* and *GJA4* gene cluster maps within a 55 kb genomic region at chr.1p34.3. GJB5 is a novel gene, which is highly expressed in skin and placenta. *Gjb5* null mice have reduced viability. So far, two large microdeletions encompassing GJB5 had been reported. A 4.8 Mb deletion was found in a patient with hypothyroidism, low birth weight, short neck, microtia, micrognathia, strabismus and speech delay while a 2.1 Mb microdeletion was reported in an unrelated child with mental retardation. We ascertained a 36 year old Caucasian female who originally presented with chronic arthralgia, osteopenia, cutis laxa and heart palpitations. Routine clinical evaluations showed persistent large joint hypermobility, significant cutis laxa and left ventricular dysfunction. She had several unsuccessful surgical corrections of her lax skin. Magnetic resonance angiography of her chest was normal. She was treated with beta blockade and intravenous bisphosphonate. Exome sequencing of her gDNA revealed a deleterious frame shift mutation [c.37delG; p.V13fsx26] in *GJB5*. Two unrelated additional variants [c.3193G>A, p.V10645I; c.96818G>A, p.R32273H] were identified in *TTN* gene, which is known to be associated with cardiomyopathies. These *TTN* variants provide a plausible explanation for the ventricular dysfunction in our patient. However, this is the first report of an apparently deleterious mutation in *GJB5* causing cutis laxa. Functional studies using Hela cell scratch assays and patch clamp analyses are underway to characterize the *GJB5* mutation.

3064F

Identification of mutations causing congenital anomalies of the kidney and urinary tract through targeted sequencing. *N. Nicolaou[1], I.J. Nijman[1], A.M. van Eerde[1], G. Monroe[1], E.M. Bongers[2], E. Cuppen[1], K.Y. Renkema[1], N.V. Knoers[1].* 1) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 2) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Congenital anomalies of the kidney and urinary tract (CAKUT) are developmental disorders that involve a spectrum of renal structural malformations. They occur in 1 out of 500 live-births and comprise the major cause of end-stage renal failure in childhood. There are 15 genes reported in the Human Gene Mutation Database with mutations responsible for CAKUT. These genes are very important for renal development as they play a role in kidney cell differentiation. However, a large proportion of cases remain unexplained. Our aim is to identify novel genetic defects involved in the etiology of CAKUT. We hypothesize that CAKUT arise from molecular defects during kidney development, and suggest that the unknown CAKUT candidate genes are also renal developmental genes. Therefore, rare mutations in any of these genes could underline the genetic heterogeneity of CAKUT. We employ a targeted next generation sequencing approach in 500 Dutch CAKUT patients. Enrichment methods allow us to capture and analyze the protein-coding regions of 208 candidate genes and 36 miRNAs, collectively referred to as the CAKUTome, in parallel. All genes selected were previously shown to have experimental evidence for their role in human isolated or syndromic CAKUT or were shown to be involved in disrupted nephrogenesis from previous studies in transgenic animals and cell models. For data analysis we used our in-house mapping and variant calling methodology. Sequencing results from the first 60 patients with severe kidney dysplasia showed that the average read depth is 210X. Approximately 200 variants were called per individual. Further variant prioritization, based on variant frequency data from dbSNP and Genome of the Netherlands, evolutionary conservation, and in-silico predictions, resulted in a list of potentially pathogenic mutations that were further validated by Sanger sequencing. Here we show that our targeted sequencing approach and variant prioritization method is efficient in identifying gene mutations in a large cohort of sporadic CAKUT cases. Previously reported causal mutations in known CAKUT genes were successfully identified in our cohort. Interestingly, the majority of the novel and promising pathogenic variants that we identified were unique for each patient. Hence, CAKUT might be even more heterogeneous in their etiology than expected. Functional studies to test the impact of novel mutations on protein function and kidney development are currently on-going.

3065W

***De novo* germline mutations in *MYL3* and *DYNC1H1* genes discovered by exome sequencing in an infant with congential joint contractures.** *D.W. Sant[1], R.L. Margraf[1], J. Durtschi[1], T.M. Newcomb[3], J.M. Opitz[2,4,5,6], J.C. Carey[5,6], H. Zhou[2], B.E. Katz[7], K.V. Voelkerding[1,2], K.J. Swoboda[3,6].* 1) ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) Department of Neurology, University of Utah, Salt Lake City, UT; 4) Department of Human Genetics, University of Utah, Salt Lake City, UT; 5) Department of Obstetrics and Gynecology, University of Utah, Salt Lake City, UT; 6) Department of Pediatrics (Division of Medical Genetics), University of Utah, Salt Lake City, UT; 7) Private Practice of Pediatrics and Pediatric Neurology (retired), Twin Falls, ID.

This report presents a family with one daughter affected by a previously unclassified disease, characterized by congenital joint contractures. Parents and four siblings are unaffected. To identify the potential causal variants, exome sequencing was performed on the proband, one sister, and both parents. A heuristic filtering approach identified several rare mutations, yielding the *de novo* mutations in the genes *MYL3* and *DYNC1H1* that were potentially correlated with the disorder and predicted inheritance. Sanger sequencing showed that the mutations were both present in the affected daughter, but not in either of the parents or siblings, showing that both mutations arose *de novo*. The *de novo* mutation in *MYL3* is a heterozygous, single base change from A to T on at position chr3:46899880. This variant causes a single-base amino acid change from tyrosine to asparagine (p.Y185N). This base is highly conserved between humans and mice to zebrafish and fruitfly. *MYL3* encodes the myosin light chain 3, an alkali light chain that is necessary for contraction of cardiac muscle and slow skeletal muscle. Mutations in *MYL3* can cause autosomal dominant disorders and have been associated with hypertrophic cardiomyopathy, Duchenne muscular dystrophy, and familial hypertrophic cardiomyopathy-8. The *de novo* mutation in *DYNC1H1* is a heterozygous, single base change from G to A at position chr14:102446717. This variant causes a single-base amino acid change from arginine to glutamine (p.R264Q). This base is highly conserved from humans to fungi. *DYNC1H1* codes for a cytoplasmic dynein protein that is important for cell movement and ATPase activity. Mutations in *DYNC1H1* have been associated with autosomal dominant lower extremity spinal muscular atrophy. In conclusion, we discovered two *de novo* heterozygous mutations in two genes with known heterogeneous and dominant phenotypes. Future work will determine which of these two mutations is likely causative or if both are contributing to cause this novel disorder.

3066T

ZNF259 IS A CANDIDATE GENE FOR ALOPECIA-PRIMORDIAL DWARFISM-RENAL SYNDROME. *A.C Smith[1], C.L Clericuzio[2], A. Ahmed[1], S.L Sawyer[1], D.E Bulman[1], K.M Boycott[1] FORGE Canada Consortium.* 1) Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) University of New Mexico Health Science Center, Albuquerque, NM.

Alopecia-primordial dwarfism-renal syndrome (APDRS) is a distinctive pattern of malformation characterized by congenital alopecia, pre- and postnatal dwarfism and hypoplastic kidneys. This syndrome was observed in 5 Hispanic New Mexican children from four families. All had symmetric intrauterine growth restriction (~ 3 SD below the mean) and progressively severe postnatal growth restriction (~8 SD below the mean). Skin color is very pale with a porcelain-like appearance. The craniofacial appearance is distinctive with prominent forehead, deep-set and up-sloping eyes, small nose, downturned corners of the mouth and full cheeks. One child had cleft palate, two had shunted hydrocephalus and both males had genital hypoplasia. All had severe global delays and sensorineural hearing loss. Four children died at ages 10, 12, 20 and 31 months, from uremia and/or sepsis. The surviving patient is a 16 yo girl with renal failure, an unusual central fat distribution and type1 diabetes. Whole exome sequencing performed on the surviving patient and her unaffected parents yielded a homozygous missense mutation in the patient at a highly conserved locus of the ZNF259 gene, both her parents were carriers. Sanger sequencing of unaffected parents and siblings of a deceased patient demonstrated that these parents and one sibling were also heterozygous carriers of the mutation, although no patient DNA is available. ZNF259 encodes a zinc finger protein with diverse cellular localization and functions. It binds to the inactive form of the EGF receptor in quiescent cells and is then released upon activation. It has been demonstrated to bind to eukaryotic translation elongation factor 1A in proliferating cells, form a multiprotein complex with SMN protein and accumulate in subnuclear structures. Reduction of ZNF259 expression in mammalian cells by siRNA knockdown causes widespread phenotypes, including defects in transcription, prevention of DNA synthesis and accumulation of cells in the G1 and G2 phases of cell cycle. It has been hypothesized the profound inhibition of transcription and cell cycle arrest is due to a defect in pre-mRNA splicing, since cells lacking ZNF259 have been shown to have a deficiency in subcellular localization of snRNP's. Functional ZNF259 assays on patient fibroblast cells, as well as validating the mutation in other patients presenting with clinical features of APDRS are needed to confirm the role of ZNF259 in the pathogenesis of the disorder.

3067F

Novel MSX1 Mutations in Japanese Tooth Agenesis Patients. *S. Yamaguchi[1,2], J. Machida[2,3], M. Kamamoto[2,4], M. Kimura[2,5], A. Shibata[2,5], T. Tatematsu[2,5], H. Miyachi[2], Y. Higashi[5], P. Jezewski[6], A. Nakayama[7], K. Shimozato[2], Y. Tokita[2,5].* 1) Department of Dentistry and Oral Surgery, Aichi Children's Health and Medical Center, Obu, Aichi, Japan; 2) Department of Maxillofacial Surgery, School of Dentistry, Aichi-Gakuin University, Nagoya, Japan; 3) Department of Oral and Maxillofacial Surgery, Toyota Memorial Hospital, Toyota, Japan; 4) Department of Oral and Maxillofacial Surgery, Japanese Red Cross Society Himeji Hospital, Himeji, Japan; 5) Department of Perinatology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan; 6) Department of Periodontology, University of Alabama at Birmingham School of Dentistry, Institute of Oral Health Research, Birmingham, USA; 7) Department of Embryology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan.

Since *MSX1* and *PAX9* are linked to the pathogenesis of non syndromic oligodontia and hypodontia, we performed a detailed mutation analysis of the *MSX1* and *PAX9* genes sampled from Japanese tooth agenesis cases. We identified two novel *MSX1* missense mutations with an amino acid substitution in homeodomain, Thr174Ile(T174I) from a sporadic hypodontia case and Leu205Arg (L205R) from a familial oligodontia case. Both Thr174 and Leu205 in MSX1 are highly conserved amino acids with in homeodomain among wide range of species. To define a possible role of these variants in the pathogenesis, we performed several functional analyses; Western blotting, immunocytochemistry, luciferase reporter assay and electrophoretic mobility shift assay (EMSA). Although the gene products are stable and capable of normal nuclear localization in transfected cells, these variants lose suppression activity on *myoD*-promoter in cells with differentiated condition. As the result of EMSA, we clarified that the DNA binding ability of both mutants was abolished by the mutations. Our findings argue in favor of a causative role of the T174I and L205R in the *MSX1* gene in tooth agenesis and suggest that these amino acid substitutions at the homeodomain of MSX1 may influence cell proliferation and differentiation resulting in lesser tooth germ formation *in vivo*.

3068W

Whole exome sequencing identifies variants causing different monogenic diseases in one nuclear family. *Y. Li[1], E. Lausch[2], K.O. Schwab[2], N. van der Werf-Grohmann[2], T. Velten[2], D. Lütjohann[3], P.V. Lorini[2], U. Matysiak-Scholze[2], B. Zabel[2], A. Köttgen[1,4].* 1) Department of Internal Medicine IV, University Hospital Freiburg, 79110 Freiburg, Germany; 2) Paediatric Genetics Division, Centre for Paediatrics and Adolescent Medicine, University Hospital Freiburg, 79106 Freiburg, Germany; 3) Institute of Clinical Chemistry and Clinical Pharmacology, University Clinics of Bonn, 53127 Bonn, Germany; 4) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Purpose: Whole exome sequencing has greatly facilitated the identification of mutations causing single-gene disorders, and has the potential to implicate genes previously not known to cause monogenic diseases. The purpose of this study was to search for causal mutations in two children from a consanguineous marriage. Both children are affected by hypomagnesemia and congenital hypothyroidism; one sibling also displayed hyperlipidemia. Methods: Whole exome sequencing was carried out using the Agilent SureSelect Exome Enrichment kit and the 5500 SOLiD system. Lifescope software was used for alignment and variant calling. Variants were tested for reproducibility using GATK. Quality metrics such as coverage, number of variants, percentage of known variants and the Ti/Tv ratio were evaluated. Results: Across individuals, mean coverage of the target region ranged from 40x to 63x, and target coverage at >20x ranged from 83% to 91%. After variant filtering (<1% population frequency; stop, splice, frameshift or missense variants; autosomal recessive mode of inheritance; and region of homozygosity obtained homozygosity mapping), 19 candidate variants were identified. One of these is the c.2667+1G>A mutation in TRPM6, which encodes a magnesium transporter expressed in intestine and kidney. This splice variant leads to skipping of exon 19 and is a known cause of autosomal recessive hypomagnesemia with secondary hypocalcemia (MIM #602014). In the child with hyperlipidemia, we identified a homozygous c.C1336T mutation in ABCG5, a sterol transporter. This known mutation introduces a premature stop codon and causes autosomal recessive sitosterolemia (MIM #210250). The other family members are heterozygous for this mutation. Biochemical analyses confirmed the diagnosis of sitosterolemia with elevated serum plant sterols. Mutations in both TRPM6 and ABCG5 were confirmed by Sanger sequencing. We are currently following up additional variants that fulfilled the filtering criteria as candidates for the thyroid phenotype. Both children are treated with thyroxine since shortly after birth and develop normally. Conclusion: Different mutations causing single-gene disorders cluster in offspring from consanguineous marriages, and can give rise to complex clinical pictures. Treatments for all three single-gene disorders are available; the lipid-lowering treatment can be adapted for the specific diagnosis.

3069T

Isolated X-linked Hypertrophic Cardiomyopathy with Restrictive Physiology Caused by a Novel Mutation of the Four-and-a-Half LIM Domain 1 Gene. *H. Hartmannova[1], M. Kubanek[2], M. Sramko[2], L. Piherova[1], L. Noskova[1], K. Hodanova[1], V. Stranecky[1], A. Pristoupilova[1], J. Sovova[1], T. Marek[2], J. Maluskova[3], P. Ridzon[4], J. Kautzner[2], H. Hulkova[1], S. Kmoch[1].* 1) Institute of Inherited Metabolic Disorders, Charles University, 1.st Medical Faculty, Prague 2, Czech Republic; 2) Department of Cardiology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic,; 3) Department of Pathology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; 4) Department of Neurology, Thomayer's Hospital, Prague, Czech Republic.

Hypertrophic cardiomyopathy (HCM) with restrictive hemodynamic pattern has been associated with mutations of myofilament genes, severe exercise intolerance and poor prognosis. However, molecular etiology of this disease remains unexplained in a large proportion of cases. We performed exome sequencing in a Czech family with three males affected by non-obstructive HCM with restrictive phenotype. A novel frameshift mutation c.599_600insT of the four-and-a-half LIM Domain 1 (FHL1) gene was identified in these individuals. In accordance with expected X-linked recessive inheritance the mutation co-segregated in heterozygous females with abnormal electrocardiogram and in one case also with apical HCM. FHL1 is transcribed into three alternatively spliced mRNA isoforms FHL1A, FHL1B and FHL1C, encoding FHL1A, FHL1B and FHL1C proteins, respectively. The insertion does not affect translation of FHL1C but encodes for a frameshifts in translation of FHL1A and FHL1B, that are in both cases followed soon thereafter by a novel stop codon predicting proteosynthesis of one sequentially identical truncated form of the FHL1A containing a neo-peptide composed of 32 aminoacids (200 HRCGGPVLLRGLLQELCGQEVC WMQEPHHWVW-232) on the C-terminal end, (p.F200fs32X). The mutation does not affect transcription, splicing and stability of FHL1A mRNA and results into production of a truncated FHL1 protein, which is contrary to heart tissue homogenates not detectable in frozen tissue sections of myocardial biopsy of affected males. This suggests that p.F200fs32X mutation results in proteosynthesis of truncated neo-protein, which has, either due to loss of LIM 3 and LIM4 domains and/or presence of the neo-peptide on its C-terminal end, altered structural properties limiting function and immunodetection of the mutant protein in the native state. Although skeletal muscle involvement is a common finding in FHL1-related diseases, we could exclude myopathy in all mutation carriers. Our findings thus support the view, that mutations leading to reduced amounts of FHL1 are less deleterious (or even benign, as in our case) for skeletal muscle than missense mutations exerting their pathogenic effects through misfolding, self-aggregation and co-aggregation of FHL1-binding partners.

SHORT syndrome is a rare, multisystem disease characterized by short stature, anterior chamber eye anomalies, characteristic facial features, lipodystrophy, hernias, hyperextensibility and delayed dentition. As part of the FORGE Canada Consortium we studied individuals with clinical features of SHORT syndrome to identify the genetic etiology of this rare disease. Whole exome sequencing in an affected child-unaffected parents trio identified a de novo frameshift insertion in exon 14 of PIK3R1, c.1906_1907insC, p.Asn636Thrfs*18. Heterozygous mutations in exon 14 of PIK3R1were subsequently identified by Sanger sequencing in three additional affected individuals and two affected family members. One of these mutations, c.1945C>T, p.Arg649Trp, was confirmed to be a de novo mutation in one affected individual and was also identified and shown to segregate with the phenotype in an unrelated family. The other mutation was a de novo truncating mutation, c.1971T>G, p.Tyr657*, identified in another affected individual. PIK3R1 is involved in the PI-3K signaling cascade and, as such, plays an important role in cell growth, proliferation and cell survival. Functional studies on the fibroblasts cells with the PIK3R1, c.1906_1907insC mutation showed decreased phosphorylation of downstream S6 target of the PI-3K-AKT-mTOR pathway. Our findings show that PIK3R1 mutations are the major cause of SHORT syndrome and suggest the molecular mechanism of disease may involve down-regulation the PI-3K-AKT-mTOR pathway.

Whole Exome Sequencing of Permanent Neonatal Diabetes Patients. *H.M. Highland[1], H. Ye[2], J.E. Below[1], V.P. Paz[2], D. Muzny[3], R.A. Gibbs[3], E. Boerwinkle[1,3], C.L. Hanis[1], G.I. Bell[2], L.H. Philipson[2], S.A.W. Greeley[2].* 1) Human Genetics Center, The University of Texas Health Science Center at Houston, P.O. Box 20186, Houston, TX 77225; 2) Section of Adult and Pediatric Endocrinology, Diabetes, & Metabolism, The University of Chicago, 5841 South Maryland Avenue, MC 1027, Chicago, IL 60637; 3) Human Genome Sequencing Center, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030.

Introduction: Permanent Neonatal Diabetes Mellitus (PNDM) is characterized by hyperglycemia onset within the first six months of life that does not resolve. While most PNDM patients were historically treated with insulin therapy, those with mutations in *KCNJ11* or *ABCC8* usually have an excellent response to oral sulfonylurea treatment, highlighting the critical importance of a genetic diagnosis to guide personalized treatment. PNDM is a monogenic disease with marked genetic heterogeneity in a case series. It is most commonly caused by mutations in *KCNJ11*, *INS*, *ABCC8*, *EIF2AK3*, *FOXP3*, *GATA6*, *GCK*, *PDX1*, *RFX6*, *PTF1A*, *NEUROD1*, *NEUROG3*, *GLIS3*, and other very rare causes. Mutations in many of these genes result in numerous syndromic features in addition to PNDM. **Methods:** We undertook deep whole exome sequencing of 18 singleton patients with PNDM, four parent-offspring trios with unaffected parents, and one multiplex family. With the exception of one positive control, these patients had been screened for mutations in PNDM genes consistent with their clinical presentation. Three patients also have trisomy 21. We have investigated three hypotheses of the relationship between PNDM and trisomy 21. 1) PNDM and trisomy 21 are unrelated conditions. 2) A disomic homozygous variant on chromosome 21 is sufficient to cause recessive disease. 3) Increased dosage of a gene on chromosome 21, such as a micro RNA, interacts with an uncommon variant elsewhere in the genome to cause permanent neonatal diabetes. **Results:** Of the 22 independent cases, we have identified mutations likely to be the basis of PNDM in 11 of the patients. These mutations have been found in known PNDM genes (*FOXP3*, *INS*, *KCNJ11*, *EIF2AK3*, and *IER3IP1*). The patients with mutations in *FOXP3* presented without all the characteristics typical of mutations in that gene. For the trisomy 21 patients, viable candidates have emerged under each model that require further biological validation. **Conclusions:** We've found broader phenotypic variation in patients with mutations in known PNDM genes than has previously been established. Our ability to find variants under each proposed relationship between trisomy 21 and PNDM points out both the promises and challenges of next generations sequencing for Mendelian diseases.

Pseudoxanthoma elasticum in a United States Veteran. *S. Konda, W. Chen, J. Toro.* Dermatology Department, Veterans Affairs Medical Center, Washington, DC.

Pseudoxanthoma elasticum (PXE) is an autosomal recessive disorder with ectopic mineralization of the elastic fibers of the reticular dermis of the skin, Bruch's membrane of the eye, and the cardiovascular system. The prevalence is estimated to be around one in 50,000 with a carrier frequency of ~1:150-300. Inactivating mutations in the ABCC6 gene, which encodes MRP6, an ABC-cassette efflux transporter protein in hepatocytes and renal cells that has been implicated in the pathogenesis of PXE. Over 300 distinct mutations in the ABCC6 gene have been described. A 67-year-old Caucasian man with a history of Hodgkin's disease, hypercholesterolemia, basal cell carcinomas, and actinic keratoses presented with a lifelong history of yellow cobblestone lesions and lax skin localized to his neck, axillary vaults, and antecubital and popliteal fossae. He had a history of angioid streaks with retinal hemorrhages and associated decreased visual acuity for which he is followed at the NIH. He denied any history of myocardial infarctions, mitral valve prolapse, gastrointestinal bleeding, elastosis serpiginosa perforans, oral penicillamine therapy, or family history of similar lesions. Dermatologic exam showed numerous yellow papules and reticulated yellow plaques with a cobblestone appearance and redundant skin localized to his neck and axillary vaults with subtle involvement of his antecubital and popliteal fossae. A skin biopsy obtained from a plaque localized to his left axillary vault demonstrated clumped fragmented elastosis in the reticular dermis consistent with PXE. The fragmented elastic fibers stained strongly with Verhoeff-Van Gieson and Von Kossa stains. His skin lesions are asymptomatic. Genetic genetic testing for mutations in ABCC6 showed the patient is heterozygous for two mutations: IVS21±1 G>T and R1141X. He is currently undergoing treatment for his angioid streaks with bevacizumab, a humanized monoclonal antibody that inhibits vascular endothelial growth factor A (VGEF-A). Some studies advocate patients may benefit from limiting dietary calcium and phosphorous. He is enrolled in a clinical trial to evaluate if dietary magnesium supplementation can modulate the course of his disease.

3073F

A *de novo* mutation in *TLE3*, encoding the transducin-like enhancer protein 3, is associated with a rare subtype of frontonasal dysplasia.
Y. Xi[1], C.L. Beaulieu[1], A.C. Smith[1], J. Schwartzentruber[2], F.P. Favaro[3], D.B. Bulman[1], M.A. Guion-Almeida[3], A. Richieri-Costa[3], A.M. Innes[4], K.M. Boycott[1] FORGE Canada Consortium. 1) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montréal, Quebec, Canada; 3) Department of Clinical Genetics, Hospital of Rehabilitation of Craniofacial Anomalies, University of Sao Paulo (HRAC-USP), Bauru, SP, Brazil; 4) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada.

Frontonasal dysplasia is the hallmark of several syndromes involving the frontonasal process. One of the syndromes within this spectrum is characterized by midline facial clefting, agenesis of the corpus callosum, basal encephalocele, pituitary and ocular abnormalities. These features are very close to Sakoda syndrome (OMIM # 610871). All cases reported to date have been sporadic. Here employing whole-exome sequencing on a patient and his parents, we identified a *de novo* mutation in the *TLE3* gene (NM_ 005078:exon15:c.A1517G:p.K506R), encoding the transducin-like enhancer protein 3. Analysis of a further three patients with a similar clinical presentation did not identify any mutations in this gene and suggests this may be a genetically heterogeneous developmental syndrome. TLE3 belongs to the Gro/TLE protein family, members in which are broadly expressed during development and have essential functions in many developmental pathways including Notch and Wnt signalling (Jennings *et al* Genome Biol 2008). TLE family proteins perform their transcriptional repression functions by interacting with a diverse profile of transcription factors (including Hes, Runx and Pax) rather than binding DNA directly. The C-terminal WD repeat domain in TLE proteins is highly conserved and responsible for their interactions with transcription factors (Carvalho *et al* Mol Endocrinol 2010). In our study, the mutation in TLE3 (p.K506R) lies in the first WD repeat and this mutation could change its binding efficiency to various transcription factors during frontonasal development. Recently, TLE proteins were also shown to biochemically interact with EphrinB1, mutations in which cause craniofrontonasal dysplasia; the WD domain plays important role in regulation of this interaction (Kamata *et al* BMB Reports 2011). Thus *TLE3* is a novel candidate gene for this subtype of frontonasal dysplasia. Future experiments such as immunoprecipitation and Western blotting will be performed to dissect the binding capacities of wt and mutant TLE3 with different transcription factors and EphrinB1. Morpholino knockdown on zebrafish *tle3a* and *tle3b* (*TLE3* homologs in zebrafish) will also be performed to characterize their functions during craniofrontonasal development.

Minimal evidence for oligogenic inheritance in Joubert syndrome based on the first 20 genes.
R. Bachmann-Gagescu[1], I. Phelps[2], B. O'Roak[3], C. Isabella[2], D. O'Day[2], M. Kircher[3], J. Dempsey[2], I. Glass[2], D. Witten[4], G. Cooper[5], J. Shendure[3], D. Doherty[2]. 1) Institue for Molecular Life Sciences, University of Zurich, Zurich, Switzerland; 2) 2Dept of Pediatrics, University of Washington, Seattle, USA; 3) Dept of Genome Sciences, University of Washington, Seattle, USA; 4) 4Dept of Biostatistics, University of Washington, Seattle, USA; 5) HudsonAlpha Institute for Biotechnology, Huntsville, Alabama.

Joubert syndrome (JS) is a ciliopathy characterized by a distinctive hindbrain malformation, ataxia and cognitive dysfunction. It is typically inherited in an autosomal recessive manner with biallelic mutations in one of 20 genes shown to be associated with this disorder. Despite the rapid progress in gene identification and the large number of genes already identified, the underlying cause remains undetermined in almost 50% of subjects with JS, because they lack biallelic mutations in any of the 20 known JS genes. However, heterozygous variants in two or more JS-associated genes have been reported in multiple patients, raising the possibility that JS could be caused by oligogenic inheritance in some patients. If oligogenic inheritance were a common mechanism for JS, we hypothesize that patients without biallelic mutations in a single causal gene will carry heterozygous rare, deleterious variants (RDVs) in multiple genes. To test this hypothesis, we used a novel, highly efficient, molecular inversion probe-based capture technology to sequence the 20 known JS-associated genes in 362 patients with JS. Using a recessive model where biallelic RDVs in any of the 20 known JS-associated genes were considered causal, we were able to determine the cause in less than two-thirds of our subjects. The total number of RDVs across all JS-associated genes was lower in subjects without an identified cause compared to those with an identified cause. Moreover, the proportion of subjects that carried ≥2 heterozygous RDVs was not significantly different between the groups with and without biallelic RDVs in a causal gene. Our data provide no support for the hypothesis that a significant proportion of JS cases are due to oligogenicity (i.e. heterozygous RDVs in multiple genes). The etiology underlying JS in the group still lacking an identified cause will most likely be due to a second unidentified RDV in a known JS-gene with an already identified heterozygous RDV, or to variants in genes yet to be implicated in JS. True oligogenic inheritance may still occur in JS; however, it would have to be quite rare or involve unidentified RDVs in the currently known JS-genes, RDVs in as yet undiscovered JS-genes, or common variants in either group of genes. Future work will focus on identifying the remaining genetic causes of JS and determining the role of additional heterozygous RDVs as modifier variants in expression of the phenotype.

Primary ciliary dyskinesia (PCD) is a genetically heterogeneous, autosomal recessive disorder, characterized by oto-sino-pulmonary disease and situs abnormalities. PCD-causing mutations have been identified in 19 genes, but collectively they account for only ~65% of all PCD. To identify mutations in additional genes that cause PCD, we performed exome sequencing on 3 unrelated probands with ciliary outer and inner dynein arm (ODA+IDA) defects. Mutations in *SPAG1* were identified in one family with three affected siblings. Further screening of *SPAG1* in 98 unrelated affected individuals (62 with ODA+IDA defects; 35 with ODA defects; one without available ciliary ultrastructure) revealed biallelic loss-of-function mutations in 11 additional individuals (including one sib-pair). All 14 affected individuals with *SPAG1* mutations had a characteristic PCD phenotype, including 9 with situs abnormalities. Additionally, all individuals with mutations who had defined ciliary ultrastructure had ODA+IDA defects. SPAG1 was present in human airway epithelial cell lysates, but was not present with isolated axonemes, indicating that it likely plays a role in the cytoplasmic assembly/trafficking of the axonemal dynein arms. Together, these results demonstrate that mutations in *SPAG1* cause PCD with ciliary ODA+IDA defects, and that exome sequencing is useful to identify genetic causes of heterogeneous recessive disorders. This abstract was funded by 5U54HL096458-06 (NIH/ORDR/NHLBI), 5R01HL071798 (NIH/NHLBI), 5R01HL094976 (NIH/NHLBI), RC2 HL-102923 (NIH/NHLBI), 5R21HG004749 (NIH/NHGRI), UL1 TR000083 (NIH/NCATS), UL1 TR000154 (NIH/NCATS), DFG Om6/4, IZKF Om2/009/12, BESTCILIA (EU), SYSCILIA (EU) and Howard Hughes Medical Institute.

3076F

A Genetic Snapshot of Risk Alleles in the Jewish Population. *D. Zielinski, Y. Erlich.* Whitehead Institute for Biomedical Research, Cambridge, MA.

Carrier screening has been instrumental in preventing rare genetic disorders. As a result of various bottlenecks and isolation, risk alleles for certain disorders are found at a higher frequency in the Jewish population, which has particularly benefited from prenatal screening. Despite great success, including the prevention of fatal disorders in some communities, carrier screening does not cover the entire allele spectrum, resulting in false negatives and thus residual risk. Current methods to ascertain new risk alleles rely on sequencing affected children. We are taking a proactive approach to uncover risk alleles through complete sequencing of the entire coding regions of more than 150 genes documented by the Israeli Ministry of Health that are associated with genetic disorders in Jews of various ethnic backgrounds. The aims of this study are to uncover novel alleles in known disease-associated genes and generate more data on disease burden, including carrier frequencies of known founder mutations as well as minor mutations.

Studying rare variations is a needle in a haystack problem, as large cohorts have to be sequenced in order to trap the variations and gain statistical power. However, sample preparation techniques have not kept pace with the exponential growth in high throughput sequencing technology and rely on tedious, individual barcoding. We have developed a scalable solution, called DNA Sudoku, to reduce sample preparation time and costs and increase throughput. After several successful pilot studies, we have employed the pipeline to take a genetic snapshot of risk alleles for genetic disorders in the Jewish population, focusing our efforts on a relatively small cohort of healthy, ethnically matched individuals, in order to create a comprehensive risk catalog and further improve carrier screening.

3077W

Exome sequencing identifies *de novo* and post-zygotic mutations in *GATA6* associated with congenital diaphragmatic hernia. *J. Bennett[1], L. Yu[2], J. Wynn[2], Y.H. Cheung[2], Y. Shen[3], G.B. Mychaliska[4], T.M. Crombleholme[5], K.S. Azarow[6], F.Y. Lim[7], D.H. Chung[8], D. Potoka[9], B.W. Warner[10], B. Bucher[10], C. Stolar[11], G. Aspelund[11], M.S. Arkovitz[12], H. Mefford[1], W.K. Chung[2], The University of Washington Center for Mendelian Genomics.* 1) Division of Genetic Medicine, University of Washington, Seattle, WA; 2) Division of Molecular Genetics, Department of Pediatrics, Columbia University Medical Center, New York, NY; 3) Department of Biomedical Informatics, Columbia University Medical Center, New York, NY; 4) Department of Surgery, University of Michigan Health System, Ann Arbor, MI; 5) Colorado Fetal Care Center, Division of Pediatric General, Thoracic, and Fetal Surgery, Children's Hospital Colorado and the University of Colorado School of Medicine, Aurora, CO; 6) Department of Pediatric Surgery, University of Nebraska College of Medicine, Omaha, NE; 7) Division of Pediatric General, Thoracic, and Fetal Surgery, Center for Molecular Fetal Therapy, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 8) Department of Pediatric Surgery, Vanderbilt University Medical Center, Vanderbilt Children's Hospital, Nashville, TN; 9) Department of Pediatric Surgery, University of Pittsburgh School of Medicine, Pittsburgh, PA; 10) Division of Pediatric Surgery, Washington University School of Medicine, St. Louis, MO; 11) Division of Pediatric Surgery, Department of Surgery, Columbia University Medical Center, New York, NY; 12) Division of Pediatric Surgery, Tel Hashomer Medical Center, Tel Hashomer, Israel.

Congenital diaphragmatic hernia (CDH) is a relatively common and severe birth defect that affects 1 in 3,000 births. It is characterized by herniation of abdominal viscera into the chest cavity through the incomplete formation of diaphragm. Lung hypoplasia is frequently associated with CDH and contributes significantly to its morbidity and mortality. Although chromosomal anomalies and mutations in several genes have been implicated in the etiology of CDH, the cause for most patients is unknown. We used whole exome sequencing (WES) in two families with CDH and congenital heart disease, and identified mutations in *GATA6* in both. In the first family, we identified a *de novo* missense mutation (c.1366C>T; p.R456C) in a sporadic CDH patient with tetralogy of Fallot. In the second, a nonsense mutation (c.712G>T; p.G238X) was identified in two siblings with CDH and a large ventriculoseptal defect. The G238X mutation was inherited from their mother, who was clinically affected with congenital absence of the pericardium, patent ductus arteriosus, and gastrointestinal malrotation, but without clinical manifestations of CDH. Deep sequencing of blood and saliva derived DNA suggested somatic mosaicism as an explanation for her milder phenotype, with only approximately 15% mutant alleles. To determine the frequency of *GATA6* mutations in CDH, we used targeted capture and sequencing to screen a cohort of 357 patients with CDH, with and without congenital heart disease. We identified one additional *de novo* mutation (c.1071delG, p.V358Cfs34X) in a patient with CDH and atrioseptal defect. Mutations in *GATA6* have been previously associated with pancreatic agenesis and congenital heart disease, and mutations in its paralogue, *GATA4*, have recently been implicated in CDH as well. We conclude that, in addition to the heart and the pancreas, *GATA6* is involved in development of two additional organs, the diaphragm and the pericardium, which share a common embryonic origin. In addition we have shown that both *de novo* and post-zygotic mutations can contribute to the development of common birth defects. Our data suggests that WES provides an unbiased powerful tool to identify genes causing CDH.

3078T

Whole-Exome Sequencing identified a homozygous *FNBP4* mutation in a family with a condition similar to Microphthalmia with Limb Anomalies. *Y. Kondo[1], E. Koshimizu[1], A. Megarbane[2], H. Hamanoue[3], I. Okada[1], K. Nishiyama[1], H. Kodera[1], S. Miyatake[1], Y. Tsurusaki[1], M. Nakashima[1], H. Doi[1], N. Miyake[1], H. Saitsu[1], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Medical Genetics Unit, St. Joseph University, Beirut, Lebanon; 3) Department of Obstetrics and Gynecology, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Microphthalmia with limb anomalies (MLA), also known as Waardenburg anophthalmia syndrome or ophthalmoacromelic syndrome, is a rare autosomal recessive disorder. Recently, we and others successfully identified *SMOC1* as the causative gene for MLA. However, there are several MLA families without *SMOC1* abnormality, suggesting locus heterogeneity in MLA. We aimed to identify a pathogenic mutation in one Lebanese family having an MLA-like condition without *SMOC1* mutation by whole-exome sequencing (WES) combined with homozygosity mapping. A c.683C>T (p.Thr228Met) in *FNBP4* was found as a primary candidate, drawing the attention that FNBP4 and SMOC1 may potentially modulate BMP signaling.

3079F

Depletion of exome sequencing reads reveals a 14kb homozygous deletion in a patient with PHARC syndrome. *T. Harel[1], C. Gonzaga-Jauregui[1], T.O. Crawford[2], M. Koenig[3], R.A. Gibbs[1,4], J.R. Lupski[1,5,6], Baylor-Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Departments of Neurology and Pediatrics, Johns Hopkins University, Baltimore, Maryland; 3) Institut de Genetique et de Biologie Moleculaire et Cellulaire (IGBMC), CNRS-INSERM-Universite de Strasbourg, 67404 Illkirch, France; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, 77030; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, 77030; 6) Texas Children's Hospital, Houston, TX, 77030.

Whole-exome sequencing (WES) has proved extremely useful in identifying simple nucleotide variation (SNV), i.e., single base pair mutations and small indels, responsible for highly penetrant Mendelian phenotypes. However, assessment of copy number variation (CNV), small deletions and duplications, responsible or contributing to Mendelian phenotypes from WES data is still a task in progress as bioinformatic algorithms are being developed and improved. We performed exome sequencing in a patient from a Qatari consanguineous family that presented with polyneuropathy, hearing loss, ataxia, retinitis pigmentosa, and cataract (PHARC). Analysis of the WES data reads and mapping in the vicinity of the ABHD12 gene, encoding abhydrolase domain-containing protein 12 and associated with PHARC syndrome, showed complete absence of sequencing reads in a 14kb region on chromosome 20, encompassing exon 1 of ABHD12. Additionally, there was absence of heterozygosity (AOH) surrounding the proposed deletion region. Subsequent confirmation by PCR of the deletion breakpoint confirmed autosomal recessive segregation of the deletion with the phenotype in the family. Moreover, Sanger sequencing of the breakpoint revealed this deletion to be identical to one reported previously by Fiskerstrand et al. (2010) in a family from the United Arab Emirates. This finding suggests that this deletion might have occurred as a single event in a common ancestor's haplotype and that it might currently be segregating in the population of this region. The deletion breakpoint maps within a region of microhomology and high identity between a pair of flanking Alu elements. Interestingly, WES also identified a homozygous rare and predicted deleterious GDAP1 variant (p.A336S) in the proband. GDAP1 is a known and well characterized neuropathy-associated gene. Segregation of this variant was confirmed in two of the three affected siblings of the Qatari family but was not present in the third, nor in the Emirati patient. The contribution of this mutation to the neuropathy phenotype in these patients need be considered. In summary, we show the importance of considering CNV and SNV contribution and interplay in Mendelian phenotypes. Meticulous analysis of WES data can reveal copy number variation of direct clinical relevance, providing additional utility of exome sequencing in identifying the genetic basis of rare genetic disorders.

3080W

From monogenic to oligogenic: strategies to uncover oligogenic modes of inheritance in individuals with intellectual disability. *W.D. Jones[1], M. Van Kogelenberg[1], D. King[1], T. Fitzgerald[1], H.V. Firth[1,2], M.E. Hurles[1], J.C. Barrett[1], Deciphering Developmental Disorders Study.* 1) Human Genetics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Cambridge University Department of Medical Genetics, Addenbrooke's Hospital, Cambridge CB2 2QQ.

Phenotypes that segregate in a Mendelian manner have long been thought to result from alterations in a single gene or unique loci. However there is recent evidence to suggest that oligogenic modes of inheritance may underlie intellectual disability in some individuals. The Deciphering Developmental Disorders (DDD) Project is a study of individuals with developmental disorders with recruitment from 24 Regional Genetics Services across the UK and Republic of Ireland. Individuals first undergo detailed clinical phenotyping at their local Genetics centre. This is followed by exome-array Comparative Genomic Hybridisation (CGH) of the proband and exome sequencing of the proband and both parents. The combining of data from array CGH analysis and trio exome sequencing affords a powerful platform to look for evidence of oligogenic modes of inheritance in individuals with intellectual disability. A control data set known as the 'imaginary siblings' will be generated to carry out this analysis, consisting of variants present in the parents not inherited by the proband. The computational and statistical methods employed in the analysis for oligogenic models will be presented alongside preliminary results.

3081T

Integrative genomics reveals that distal cis-regulatory mutations cause isolated pancreatic agenesis. *M.N. Weedon[1], I. Cebola[2,3], A. Patch[1], S.E. Flanagan[1], E. De Franco[1], R. Caswell[1], S.A. Rodríguez-Seguí[2,3,4], C. Shaw-Smith[1], C. Cho[5], H. Lango Allen[1], J.A.L Houghton[1], C.L. Roth[6], R. Chen[7], K. Hussain[8,9], P. Marsh[10], L. Vallier[5], A. Murray[1], S. Ellard[1], J. Ferrer[2,3,11], A.T. Hattersley[1].* 1) University of Exeter Medical School, UK; 2) Institut d'Investigacions Biomèdiques August Pi I Sunyer, Spain; 3) CIBER de Diabetes y Enfermedades Metabólicas, Spain; 4) Ciudad Universitaria, Argentina; 5) Wellcome Trust-Medical Research Council Cambridge Stem Cell Institute, Cambridge, UK; 6) Seattle Children's Hospital Research Institute, USA; 7) School of Biomedical Science, King's College London, UK; 8) London Centre for Paediatric Endocrinology and Metabolism, London, UK; 9) University College London, London, UK; 10) School of Medicine, King's College London, London, UK; 11) Imperial College, London, UK.

The contribution of cis-regulatory mutations to human disease remains poorly understood. Whole genome sequencing can identify all non-coding variants, yet discrimination of causal regulatory mutations represents a formidable challenge.

We performed homozygosity mapping and whole genome sequencing on probands from two consanguineous families with non-syndromic pancreatic agenesis. We first looked for recessive coding mutations in the exomes of these patients, but no causal mutations were identified.

To search for non-coding disease-causing mutations, we annotated the 6,024 rare (<1% frequency in the 1000 genomes project) or novel homozygous variants from these patients using epigenome maps from human pancreatic progenitor cells. Only one variant, a novel SNV, occurred in a functionally annotated region and was shared by both unrelated patients. This variant occurs several tens of kb from PTF1A in a short (~400bp) region of conservation. Follow-up sequencing identified four different recessive point mutations and an 8kb deletion spanning the functional element in 9 of 12 non-syndromic pancreatic agenesis cases.

Experiments including 3C and reporter assays clearly demonstrate that this previously uncharacterised non-coding element acts as a developmental enhancer of PTF1A in human pancreatic progenitor cells. The 6 mutations prevent enhancer activity by abolishing transcription factor binding or deleting the enhancer sequence.

Integrating genome sequencing and epigenomics in a disease-relevant cell type can uncover novel non-coding elements underlying human development and disease.

Clinical Exome Sequencing identifies de novo mutations in the *MLL* gene causing Atypical Wiedemann-Steiner Syndrome in two unrelated Individuals. *F. Quintero-rivera[1], S.P. Strom[1], J. Mann[4], R. Lozano[5], H. Lee[1], N. Dorrani[3], O. O'Lague[4], N. Mans[5], J.I. Deignan[1], E. Vilain[2,3], S.F. Nelson[1,2,3], W.W. Grody[1,2,3].* 1) Deparment of Pathology and Laboratory Medicine, UCLA School of Medicine, Los Angeles, CA; 2) Deparment of Human Genetics, UCLA School of Medicine, Los Angeles, CA; 3) Deparment of Pediatrics, UCLA School of Medicine, Los Angeles, CA; 4) Kaiser Permanente, Fresno Medical Center; 5) Deparment of Pediatrics, University Of California Davis Medical Center, Sacramento, CA.

Wiedemann-Steiner Syndrome (WSS) is characterized by mild to moderate developmental delay, dysmorphic facial features, and hypertrichosis cubiti (excessive hair on the elbows) [MIM#: 605130]. Here we report two unrelated patients for whom Exome sequencing of parent-proband trios was performed clinically at the UCLA Molecular Diagnostics Laboratories. For patient 1, clinical features at 9 years of age, include developmental delay, craniofacial and multiple minor anomalies: down-slanting palpebral fissures, thick eyebrows and hair, premature dental eruption, fifth finger clinodactyly, tapered fingers, and astigmatism. Patient 2 presented at 1 year of age with intrauterine growth retardation, developmental delay, significant central hypotonia, Rt. microphthalmia and small palpebral fissure, prominent nasal bridge, micrognathia, Lt. hand 3-4 syndactyly, mild pectus excavatum, and small sacral hair tuft. In patient 1, a de novo missense (p.Cys1448Arg) variant was identified in the *MLL* gene (RefSeq transcript ID: NM_001197104.1). In patient 2, a de novo splice site mutation (c.4086+1G>A) was identified in the same gene. *MLL* - Myeloid/Lymphoid Or Mixed Lineage Leukemia Gene - encodes a broadly expressed DNA-binding protein that methylates histone H3K4 and positively regulates expression of target genes, including genes in the HOX and WNT pathways. It is frequently translocated in hematological malignancies, including ALL, AML, and MLL. Mice carrying a hemizygous knockout allele of *MLL* are small at birth and have reduced growth, indicating that dosage of the gene is critical to development. However, the molecular mechanism of *MLL*-related WSS has not been established. Based on clinical and molecular genomic findings, both patients may have novel presentations of WSS. As the hallmark hypertrichosis cubiti was not initially appreciated in either case, this syndrome was not suspected clinically. This report expands the phenotypic spectrum of clinical phenotypes and de novo mutations of the *MLL* gene associated with WSS.

3083W

Follow-up of diagnostic exome sequencing in persons with severe intellectual disability; Re-analysis of data, recurrency screening, CNV detection and genome sequencing. *L. Vissers[1], H. IJntema[1], J. Hehir-Kwa[1], C. Gilissen[1], J. de Ligt[1], R. Leach[2], R. Tearle[2], W. Nillesen[1], B. van Bon[1], M. Willemsen[1], H. Scheffer[1], H. Brunner[1], B. de Vries[1], T. Kleefstra[1], J. Veltman[1].* 1) Dept Human Gen 855, UMC Nijmegen, Nijmegen, Netherlands; 2) Complete Genomics, Inc. 2071 Stierlin Court Mountain View, CA 94043.

In 2012 we described the use of exome sequencing in the diagnostic workup of patients with unexplained severe intellectual disability (ID). In this initial study we detected 16 pathogenic mutations in 100 patients, mostly involving de novo germline point mutations and insertion-deletion events. Here we describe our ongoing genetic studies in this cohort. One of the follow-up studies is aimed at identifying recurrent de novo germline mutations in 21 candidate genes by using various approaches, including targeted next generations sequencing in a large ID cohort. So far these efforts have revealed additional mutations in 7 of our candidate ID genes. Detailed clinical analysis of the patients with mutations showed phenotypic overlap, confirming that these genes cause ID when mutated. A second follow-up study involves the re-analysis of the existing exome data of these patients and their parents using a new software program, Lifescope, which is more sensitive in detecting variants than the program originally used. This analysis provided a positive molecular diagnosis in 5 patients by the identification of de novo mutations in known ID genes. A third follow-up study, which is currently ongoing, is aimed at the identification of CNVs based on read-depth information of exome data using CoNIFER, a software tool that we recently validated in a series of patients with pathogenic CNVs. Finally, we performed whole genome sequencing in 50 of the unexplained ID patients and their parents. Preliminary results of 22 trios confirm the presence of 2 de novo exonic mutations detected only by re-analysis of the original exome sequencing data. In addition whole genome sequencing in these trios revealed 5 de novo exonic mutations in novel candidate ID genes as well as one de novo mutation in the UTR of a known ID gene. While much of this work is still ongoing, it does already demonstrate that the initial diagnostic yield of 16% by exome sequencing is an underestimation; at this moment the number is already at 26%. This yield can be substantially higher by further improving variant detection on exome sequencing data and by follow-up of the many candidate genes in larger clinical cohorts. In addition, whole genome sequencing may not only give a more complete picture of variation present in the exome but will also provide us insight into possible causative mutations in the non-coding part of the genome.

3084T

Mutation analysis of the RBPJ gene in Adams-Oliver syndrome patients. *W. Wuyts, F. de Vogel, E. Van Hul.* Dept Med Gen, Univ Antwerp, Antwerp, Belgium.

Introduction Adams-Oliver syndrome (AOS)is a rare genetic disorder characterized by aplasia cutis congenita (ACC) and terminal transverse limb defects. Mutations in the RBPJ and ARHGAP31 genes have been described as a cause of autosomal dominant AOS, while mutations in the DOCK6 and EOGT genes were shown to be responsible for the autosomal recessive form. We performed mutation analysis of the RBPJ gene in a cohort of AOS patients to determine the relative contribution of RBPJ to AOS. **Materials and Methods** A cohort of 58 patients with clinical characteristics of AOS were included in the study, including familial and sporadic cases. Mutation analysis of the RBPJ gene was performed by sequence analysis of all coding exons. **Results and discussion** In three families an RBPJ missense variant was detected, including one previously reported pathogenic RBPJ mutation (p.Thr441Thr, p.Lys169Glu,p.Phe66Val). Three other intronic variants need further evaluation in a larger control population. In conclusion, mutations in the RBPJ gene seem only present in a limted number of AOS patients.

Application of targeted next-generation sequencing in the diagnosis of pediatric neurological disorders. *N. Okamoto[1], F. Miya[2], T. Tsunoda[2], M. Kato[3], S. Saitoh[4], M. Yamasaki[5], Y. Kanemura[6,7], K. Kosaki[8].* 1) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 2) Laboratory for Medical Science Mathematics, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 3) Department of Pediatrics, Yamagata University Faculty of Medicine, Yamagata, Japan; 4) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 5) Department of Pediatric Neurosurgery, Takatsuki General Hospital, Osaka, Japan; 6) Division of Regenerative Medicine, Institute for Clinical Research, Osaka National Hospital, National Hospital Organization, Osaka, Japan; 7) Department of Neurosurgery, Osaka National Hospital, National Hospital Organization, Osaka, Japan; 8) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan.

[Introduction] We have developed a next generation sequencing (NGS)-based mutation screening strategy. This system enabled us to screen 284 genes associated with pediatric neurological disorders. [Materials and Methods]Fifty patients with neurological disorders were included in the study. They are from one institution (Osaka Medical Center). Under the approval by our institutional ethics committee, patients were analyzed by the targeted exome sequence. To capture the target exonic DNAs, we used SureSelectXT Custom capture library (Agilent) for 1.6 Mb exons of neuronal genes capture. The sequence library was constructed using SureSelect XT Target Enrichment System for Illumina Paired-End Sequencing Library kit (Agilent). We performed sequencing the DNA with 101-bp paired-end by 24-multiplex per lane using Illumina HiSeq 2000 sequencer and obtained 1.90 + 0.32 (mean + s.d.) Gb sequence data. To extract disease causal mutation, we excluded known variants found in dbSNP, 1000 Genomes Project, ESP6500 and our control samples , and narrowed the candidates to nonsynonymous and nonsense SNVs. [Results] Several pathogenic mutations were identified. An early termination codon in the *DYRK1A* gene was found in a patient with severe intellectual disability (ID), absent speech, motor disturbance and visual disturbance (Patient 1). Heterozygous mutations in the *CASK* gene were found in two females with mental retardation and microcephaly with pontine and cerebellar hypoplasia (Patient 2,3). A patient with microcephaly and severe ID and showing similar conditions with Kleefstra syndrome had a mutation in the *MBD5* gene(Patient 4). A patient with cutis laxa had an *ALDH18A1* mutation (Patient 5). A female patient with Angelman syndrome like features had mutation in the *GABRD* gene (Patient 6). A patient with ID, ptosis and pachygyria of the frontal lobe had a mutation in the *ACTB* gene. He was compatible with Baraitser-Winter syndrome (patient7). [Discussion] Our NGS-based mutation screening strategy is sensitive and specific in detecting sequence variants in some neurological disorders. We propose that this NGS-based targeted sequencing method would be an alternative to current technologies for identifying the multiple genetic causes of neurological disorders.

Disruption of the Rac GTPase activator DOCK7 in epileptic enecephalopathy. *F.F. Hamdan[1], J.M. Capo-Chichi[1], B. Maranda[2], G.A. Rouleau[3], J.L. Michaud[1].* 1) Sainte Justine Hospital Research Center, Montreal, Quebec, Canada; 2) Division of Genetics, Centre Hospitalier Universitaire de Sherbrooke, Sherbrooke, Quebec, Canada; 3) Montreal Neurological Institute, McGill University, Montreal, Qc, Canada.

The genetic basis of intellectual disability remains unexplained in the majority of cases. Here we used exome sequencing to study two sisters (aged 7 and 9 yrs) with severe intellectual disability and intractable epilepsy from a non-consanguineous French Canadian family. We found 186 rare amino acid-altering or splicing variants that were shared between the exomes of the 2 affected siblings. None of these was homozygous. *DOCK7* is the only gene containing compound heterozygous mutations (c.C3709T:p.R1237X and c.2510delA:p.D837fs; NM_001271999) shared by the sisters. Both mutations, which truncate DOCK7 upstream of its GEF domain, were absent from all public SNP databases (1000 Genomes, Exome Variant Server (EVS), dbSNP138), and from our in-house exome dataset (>1000) which includes at least 200 French Canadian individuals. Inspection of *DOCK7* for truncating or splicing variants in the exome variant server data set, revealed only 2 heterozygous truncating variants, in 2 different individuals, out of approximately 13000 sequenced alleles. This indicates that, despite its large size (2129 amino acid), *DOCK7* does not accumulate truncating mutations and, therefore, maybe essential in humans. DOCK7 encodes a guanine exchange factor (GEF) belonging to the DOCK180 super family whose members activate Rho GTPases. DOCK7 is enriched in the brain and has been shown to activate Rac and promote axon formation, axon myelination, and cortical neurogenesis. Based on the importance of DOCK7 in brain function and the severity and rarity of the identified mutations, our data suggests that disruption of *DOCK7* may be responsible for the epileptic encephalopathy observed in this family. Interestingly, DOCK7 is known to physically interact with the TSC1-TSC2 protein complex whose dysfunction causes Tuberous Sclerosis Complex, a multisystemic disorder with high incidence of ID and epilepsy. Identification of additional similarly affected families with *DOCK7* recessive deleterious mutations will be necessary to establish *DOCK7* as a neurodevelopmental disease gene. Collaborations towards this effort are welcome.

Whole genome sequencing, clinical interpretation, and deep brain stimulation in a severely mentally ill person. *G.J. Lyon[1,2,3], J. O'Rawe[1,2], R. Robison[3], E. Kiruluta[4], G. Higgins[5], M. Reese[4].* 1) Stanley Institute for Cognitive Genomics, One Bungtown Road, Cold Spring Harbor Laboratory, NY, USA, 11724; 2) Stony Brook University, 100 Nicolls Rd, Stony Brook, NY, USA, 11794; 3) Utah Foundation for Biomedical Research, E 3300 S, Salt Lake City, Salt Lake City, UT, USA, 84106; 4) Omicia Inc., 2200 Powell St., Emeryville, CA, USA, 94608; 5) AssureRx Health, Inc., 6030 S. Mason-Montgomery Road, Mason, Ohio 45040.

We report here the detailed phenotypic characterization, clinical-grade whole genome sequencing (WGS), and two year outcome of one man with severe obsessive compulsive disorder treated with deep brain stimulation (DBS) targeting the anterior limb of the internal capsule (ALIC). Since implantation, this man has reported steady improvement, highlighted by a drop in his Yale-Brown Obsessive Compulsive Scale score from ~35 to a score of ~25. A rechargeable Activa RC neurostimulator battery has been of major benefit in terms of facilitating a degree of stability and control over the stimulation. His psychiatric symptoms reliably worsen within hours of the battery becoming depleted, thus providing confirmatory evidence for the efficacy of DBS for OCD in this person. Whole genome sequencing in the CLIA-certified Illumina WGS lab revealed that he is a heterozygote for the p.Val66Met variant in BDNF, encoding a protein that is a member of the nerve growth factor family, and which has been found to predispose carriers to various psychiatric illnesses. He carries the p.Glu429Ala allele in methylenetetrahydrofolate reductase (MTHFR) and the p.Asp7Asn allele in ChAT, encoding choline O-acetyltransferase, which synthesizes the neurotransmitter acetylcholine, with both alleles having been shown to confer an elevated susceptibility to psychoses. We have discovered many other variants in his genome, including pharmacogenetic variants, and have archived and offered the clinical sequencing data to him, so that he and others can re-analyze his genome for years to come. To our knowledge, this is the first N=1 human study in the clinical neurosciences including 1) clinical-grade WGS with management of genetic results for a person with severe mental illness and 2) detailed neuropsychiatric phenotyping and individualized treatment with deep brain stimulation for his OCD. His WGS results and positive outcome with DBS for OCD is one example of individualized medicine in neuropsychiatry, including genomics-guided preventive efforts and brain-implantable devices.

Genes Make Sense: Seeking Causative Genes for Human Congenital General Anosmia. *A. Alkelai[1], T. Olender[1], P. Tatarskyy[1], V. Boyko[1], D. Oz-Levi[1], I. Keydar[1], R. Milgrom[1], E. Feldmesser[1], E. Ben-Asher[1], E.K. Ruzzo[2], D.B. Goldstein[2], E. Pras[3,4], D. Lancet[1].* 1) Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel; 2) Center for Human Genome Variation, Duke University School of Medicine, Durham, North Carolina 27708, USA; 3) The Danek Gertner Institute of Human Genetics, Sheba Medical Center, Ramat Gan, Israel; 4) The Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

The neuronal and cell-biological mechanisms underlying vertebrate olfaction have been studied in considerable detail, but there is a gap in our understanding of the genetic and molecular basis of chemosensory variability and related monogenic disorders. Congenital general anosmia (CGA) affects <0.1% of general population, and appears in isolated or syndromic forms. While for an appreciable number of syndromic CGA types a causative gene has been identified, knowledge about the genetic basis of the isolated CGA instances has been scarce. Our laboratory has samples from a large CGA cohort, including 66 families of Jewish origin (Feldmesser et al, Chem Senses 32:21-30, 2007). We performed whole-exome capture (SureSelect Human All Exon kit - Agilent Technologies, Santa Clara, CA) and next-generation sequencing (Hiseq 2000 sequencing system, Illumina, Inc. San Diego, CA) in 22 selected individuals from 7 of these families multiply affected with anosmia. Now we report results of the Affymetrix human SNP 6.0 array genotyping, linkage analysis, homozygosity mapping, CNV analysis and whole-exome sequencing in one of these families with X-linked/recessive/dominant with incomplete penetrance mode of inheritance. By using variety of methods we identified number of candidate regions harboring possible CGA pathogenic variants. The best candidate variants are located in such genes as *SPATA5L1* (compound heterozygous mutation), *CALML6* (heterozygous mutation) and *SEMA3A* (heterozygous mutation) and now are being further validated. All the implicated genes appear in our recently constructed general olfactory sensitivity database (GOSdb) (Keydar et al, Hum Mutat, 34: 32-41, 2013). The identification of specific pathogenic functional CGA variants will help to elucidate the molecular basis of general olfactory sensitivity.

Arthrogryposis multiplex congenita (AMC) is characterized by congenital contractures of at least two distinct joints of the body. The overall incidence is 1 in 3000 live births. Non-syndromic AMC is the direct consequence of fetal hypo/akinesia sequence which may lead, in addition to AMC, to pterygia, lung hypoplasia, diaphragmatic defect, or cleft palate. Non-syndromic AMCs include a large spectrum of diseases of motor neurons, neuromuscular junction, or skeletal muscle. The difficulty in establishing the genetic diagnosis in AMC patients is likely caused by the high locus heterogeneity and/or non-identified disease genes and the lack of suitable screening methods. In order to gain insight into the underlying cause of these diseases, whole genome scanning using SNP microarrays alone or combined with whole exome sequencing (WES) were performed in a cohort of 32 multiplex and/or consanguineous families with undiagnosed non-syndromic AMC. In these families, extensive clinical and genetic evaluation had not led to established diagnosis. We identified mutations in genes already known to be responsible for AMC or neuromuscular disorders (NMD) in 20 out of 32 (62%) families. The primary targets were skeletal muscle in 12 families, neuromuscular junctions in 4 families, axoglial in 3 families or other target in 1 family. Among known AMC or NMD genes, our study confirmed that mutations of SYNE-1 are responsible for AMC and revealed two AMC families carrying mutations of the TTN gene extending the clinical spectrum of TTN gene mutations. Pathogenic mutations of 4 new genes were identified. The mutations of these genes may be classified as causative (2 genes), highly candidate (1 gene) or possibly causative (1 gene). This is based on gene mutation type, RNA and morphological analysis of the neuromuscular system (including transmission electron microscopy) in patient tissue samples and the availability of mouse models or the generation and characterization of a zebrafish model. NGS technologies may be therefore regarded as the most promising approach to unravel undiagnosed AMC leading to a diagnosis in ~80% of cases as shown in the present study. This will be particularly useful during pregnancy when ultrasound examination reveals AMC or reduced fetal mobility but also when single joint contracture is associated with additional symptoms such as the ones described above. Establishing early diagnosis should provide accurate information on the prognosis.

Scientific advances from removing the financial barrier- results of the NGS pilot program at Boston Children's Hospital. *C.A. Brownstein[1,2,3], W.A. Wolf[1,3], T.W. Yu[1,3], L.M. Kunkel[1,3], C.A. Walsh[1,3], A.H. Beggs[1,2,3], D.M. Margulies[1,2,3].* 1) Genomics- Research Connection, Boston Children's Hospital, Boston, MA; 2) Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

Lack of access to new technologies inhibits discoveries. In an effort to equalize access to next generation sequencing (NGS) for its researchers and clinicians, Boston Children's Hospital (BCH) awarded a number of pilot grants to provide whole genome and exome sequencing for patients and human research subjects. Emphasis was on assessing the impact of NGS on analysis of a mix of patients with phenotypes ranging from severely affected individuals with diagnostic dilemmas and for whom testing would have a likelihood of clinical impact, to subjects or cohorts of subjects with phenotypes that were likely to yield important new insights into the biology and treatment of disease. Awards were determined by multidisciplinary, cross-departmental committees, and sequencing was performed by the BCH Genetic Diagnostics Laboratory and LabCorp. Datasets were used to develop an in-house BCH NGS analysis pipeline optimized for human disease gene discovery from pedigrees and cohorts. In addition to providing sequencing data to clinicians and investigators, the project provided a single standard of oversight for the hospital, and evaluated the entire process from selecting patients for sequencing, obtaining their informed consent, generating and analyzing sequencing data, interpreting and reporting clinical results, integrating results into the medical record, seeking reimbursement from payors, and complying with governmental regulations. As of May 2013, the pilot has awarded over 600 exomes and genomes for 42 investigators at BCH (averaging 30 exomes per award), leading to gene discoveries, grants, and publications. A post-sequencing inventory has been performed for 3 researchers awarded grants. From the first award, pathogenic mutations of known genes were identified in 29 patients and 3 novel disease genes have been discovered with one paper published, and two more papers in preparation. From the second award, one paper has been submitted, 3 patients now have diagnoses, and two have had treatment changes as the result of their new diagnoses. From the third award, one grant has been written, and two papers are in preparation. In less than 18 months, results of this program have served to better understand disease, improve diagnosis, develop a robust and institutionally viable NGS pipeline, and ultimately improve treatment of our patients. Sequencing will now be offered to BCH researchers and clinicians at a reduced cost to maintain this pace of discovery.

Alu Yb8 insertion near SMN1 exon 7 as a rare cause of SMA. *S.M. Kirwin[1], K.M.B. Vinette[1], I.L. Gonzalez[1], S.L. Dugan[2], K.J. Swoboda[3], T.M. Newcomb[3], V.L. Funanage[1].* 1) Molecular Diagnostics Laboratory, Nemours/duPont Hospital for Children, Wilmington, DE; 2) Division of Medical Genetics, Children's Hospitals and Clinics of Minnesota, Minneapolis, MN; 3) Pediatric Motor Disorders Research Program, Department of Neurology, University of Utah School of Medicine, SLC, UT.

Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder primarily affecting young children. Approximately 95% of cases of SMA are caused by homozygous deletion of exon 7 of the SMN1 gene, although up to 5% of cases can arise by heterozygous deletion of a single SMN1 copy paired with a subtle mutation elsewhere within the gene. We report a novel SMN1 gene mutation that involves insertion of an Alu element at an L1 endonuclease recognition site, coinciding with the intron 6 branch point. The proband originally presented with severe muscular atrophy, tongue fasciculations, and ventilator dependency, with no family history of SMA. MLPA testing at another lab had reported a single functional copy of SMN, and gene sequencing was requested at our molecular diagnostic laboratory. Mutations at the branch point of intron 6 have been reported to affect inclusion of exon 7 in the SMN product; however, the position of the insertion precludes detection by the MLPA assay used, as the primers are 3' to the inserted Alu. Our SMN quantitative assay uses primers within intron 6 and intron 7, and detected zero copies of SMN1, 1 copy of SMN2, and a product of an unusual size that did not appear to digest with DraI. This product was purified, sequenced, and revealed the presence of a normal SMN1 exon 7 preceded by a complete Alu element of the Yb8 family. Members of the Yb8 family of Alu elements are described as currently active in retroposition, and there are reports of de novo Alu Yb8 insertions causing disease. The 'A' tail found on the Alu in our patient's SMN1 gene was 40 bp in length. Recently inserted Alus are characterized by A-tails between 40 and 97bp. Parental testing revealed that the father carries one copy of SMN1, whereas the mother carries two copies of SMN1, one containing the inserted Alu. Since the first submission of the proband's sample for testing, an additional affected sibling was born, and was shown to carry only the same mutated SMN1 allele, thus confirming the pathogenicity of the Alu insertion in this family. Unique neuroimaging features present in both brothers and not typically seen in 5q SMA include generalized cortical atrophy, hypoplastic appearing optic nerves and possible CNS myelination abnormalities. The severe infantile phenotype in association with congenital weakness and clearly evident central nervous system involvement expand the phenotype previously associated with infantile onset 5q SMA.

Identification of a novel *GATA3* mutation in a Taiwanese family with idiopathic sensorineural hearing impairment by massively parallel sequencing. *Y.H. Lin[1,2], C.C. Wu[1,3], T.Y. Hsu[4], W.Y. Chiu[5], C.J. Hsu[1], P.L. Chen[2,3,5,6]*. 1) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 2) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 3) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 4) Department of Otolaryngology, E-DA Hospital, I-Shou University, Kaohsiung, Taiwan; 5) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 6) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan.

Hearing impairment is a genetically heterogeneous condition with > 100 deafness genes identified thus far. Recent studies have confirmed the utility of massively parallel sequencing (MPS) in addressing the genetically heterogeneous hereditary hearing impairment. In our previous study, we used Illumina HiSeq2000 to sequence 80 genes in 12 multiplex families, and identified 2 known mutations and 2 novel mutations as the causative mutations in 4 families. Recently, we further upgraded the screening panel to include 131 deafness genes, and applied the panel to another 12 unrelated multiplex families with idiopathic sensorineural hearing impairment. Criteria for data filtering included: allele frequencies <5%, both PolyPhen2 and SIFT scores >0.95, Sanger sequencing, segregation pattern, and evolutionary conservation of amino acid residues. In the proband of an autosomal dominant family with 9 affected members, we found a novel single nucleotide deletion mutation, c.149delT, in exon 2 of *GATA3*. If translated, c.149delT should result in a frameshift with a premature stop codon after a new amino acid sequence of 144 residues (p.Leu50fsX144). Heterozygosity for c.149delT was identified in all the 9 affected family members and 1 family member with normal hearing; the absence of hearing phenotypes in the latter might be attributed to his young age. *GATA3* haploinsufficiency is thought to be associated with HDR syndrome which is characterized by hypoparathyroidism, deafness, and renal anomalies. We examined the clinical features in 7 affected members in the family. All the 7 subjects revealed mild to moderate sensorineural hearing impairment. By contrast, except for 1 subject with bilateral parenchymal renal disease, the other 6 presented no signs of hypoparathyroidism or renal anomalies, indicating relatively mild phenotypes in this family. To our knowledge, the present study represents the first report to achieve genetic diagnosis before the clinical diagnosis of HDR syndrome is made. Compared to hearing impairment which is the most penetrant feature of HDR syndrome and usually develops at an earlier age, symptoms/signs of hypoparathyroidism and renal anomalies may remain clinically undetected at the time of assessment. Accordingly, genetic screening for multiple deafness genes with MPS might be helpful in identifying certain types of syndromic hearing loss such as HDR syndrome, contributing to earlier diagnosis and earlier treatment in the affected individuals.

3093T

DNM2 - related centronuclear myopathy found with the use of exome sequencing in a patient with clinical diagnosis of peripheral neuropathy. *D. Safka Brozkova[1], J. Haberlova[1], M. Gonzales[2], S. Zuchner[2], P. Seeman[1]*. 1) Charles University 2nd Medical School and University Hospital Motol, Prague, Czech Republic; 2) University of Miami Miller School of Medicine, Miami, Florida.

Centronuclear myopathy is a slowly progressive muscular disease, where autosomal dominant form is caused by mutations in DNM2 gene. Peripheral neuropathy is a neurological disease that is very heterogeneous and can be caused by mutations in more than 40 genes, therefore to find the right cause of the neuropathy can be difficult. A patient with healthy parents and 3 healthy siblings was affected with muscle weakness on upper and lower limbs and reduced facial expression. The electrophysiology examination showed the neurological lesion. First genetical examination was focused on deletion of the exon 7 and 8 in SMN1 gene and did not reveal any deletion. Subsequent Sanger sequencing of peripheral neuropathy associated genes - HSP22, SH3TC2, HSP27, MFN2, BSCL2, GDAP1 did not reveal any pathological variant. Since the Sanger sequencing of all neuropathy associated genes would be much expensive, we decided to perform the exome sequencing of the affected patient. According to a pedigree we were looking for the recessive or de novo variant. The filtering criteria for candidate variants were as follows: non synonymous coding or splice-site variant, not present in NHLBI EVS, GERP score >3 or PhastCons score > 0.6. No recessive variant was found. 43 variants were revealed with de novo mode of inheritance. After the detailed research, only one variant p.E368K, in DNM2 gene was already reported as the cause of centronuclear myopathy. Sanger sequencing confirmed the variant in affected patient, variant was missing in parents. The phenotype of the p.E368K mutation is in between the myopathy and neuropathy. The exome sequencing helped to refine the clinical diagnosis. Thanks to the already published variant, the exome seqencing of the parents was not needed. Support- IGA MHCZ NT 14348.

3094F

Comprehensive molecular diagnosis of 179 Leber congenital amaurosis and juvenile retinitis pigmentosa patients by targeted next-generation sequencing. *X. Wang[1,2], H. Wang[1,2], V. Sun[5], H. Tuan[1], V. Keser[5], K. Wang[2], H. Ren[5], I. Lopez[5], J.E. Zaneveld[1,2], S. Siddiqui[5], S. Bowles[1], A. Khan[5], J. Salvo[1,4], S.G. Jacobson[6], A. Iannaccone[7], F. Wang[1,2], D. Birch[8], J.R. Heckenlively[9], G.A. Fishman[10], E.I. Traboulsi[11], Y. Li[1,2], D. Wheaton[8], R.K. Koenekoop[5], R. Chen[1,2,3,4]*. 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, USA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA; 3) Program in Developmental Biology, Baylor College of Medicine, Houston, USA; 4) Structural and Computational Biology & Molecular Biophysics Graduate Program, Baylor College of Medicine, Houston, USA; 5) McGill Ocular Genetics Laboratory (MOGL), Montreal Children's Hospital, Departments of Paediatric Surgery, Human Genetics and Ophthalmology, McGill University Health Center, Montreal, Quebec, Canada; 6) Scheie Eye Institute, Department of Ophthalmology, University of Pennsylvania, Philadelphia, USA; 7) Hamilton Eye Institute, University of Tennessee Health Science Center, Memphis, USA; 8) Retina Foundation of the Southwest and Dept. of Ophthalmology, University of Texas Southwestern Medical School, Dallas, USA; 9) Center for Retinal and Macular Degeneration, University of Michigan, Ann Arbor, USA; 10) The Chicago Lighthouse for the Blind and Visually Impaired, Chicago, USA; 11) Ophthalmology, Cleveland Clinic, Cleveland, USA.

Background: Leber congenital amaurosis (LCA) and juvenile retinitis pigmentosa (RP) are inherited retinal diseases that cause early-onset severe visual impairment. An accurate molecular diagnosis can refine the clinical diagnosis and allow gene-specific treatments. Methods: We developed a capture panel that enriches the exonic DNA of 163 known retinal disease genes. Using this panel, we performed targeted next-generation sequencing (NGS) for a large cohort of 179 unrelated and prescreened patients with the clinical diagnosis of LCA or juvenile RP. Systematic NGS data analysis, Sanger sequencing validation, and segregation analysis were utilized to identify the pathogenic mutations. Patients were re-visited to examine the potential phenotypic ambiguity at the time of initial diagnosis. Results: Pathogenic mutations for 72 patients (40 percent) were identified, including 45 novel mutations. Of these 72 patients, 58 carried mutations in known LCA or juvenile RP genes and exhibited corresponding phenotypes, while 14 carried mutations in retinal disease genes that were not consistent with their initial clinical diagnosis. We re-visited patients in the latter case and found that homozygous mutations in PRPH2 can cause LCA/juvenile RP. Guided by the molecular diagnosis, we re-classified the clinical diagnosis in 2 patients. Conclusions: We have identified a novel gene and a large number of novel mutations that are associated with LCA/juvenile RP. Our results highlight the importance of molecular diagnosis as an integral part of clinical diagnosis.

3095W

A Founder Mutation in *COL4A3* Causes Autosomal Recessive Alport Syndrome in the Ashkenazi Jewish Population. *B.D. Webb[1], T. Brandt[1], L. Liu[1], J. Liao[1], C. Jalas[2], A. Fedick[3], M.D. Linderman[4], G.A. Diaz[1], R. Kornreich[1], H. Trachtman[5], L. Mehta[1], L. Edelmann[1]*. 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Bonei Olam, Center for Rare Jewish Genetic Disorders, Brooklyn, NY; 3) Microbiology and Molecular Genetics, UMDNJ- Robert Wood Johnson Medical School, Piscataway, NJ; 4) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Pediatrics, New York University School of Medicine, New York, NY.

Alport syndrome is a genetically heterogeneous inherited progressive nephropathy that arises from mutations in the type IV collagen genes, *COL4A3*, *COL4A4*, and *COL4A5*. Symptoms may also include sensorineural hearing loss and ocular lesions. Here we determined the molecular basis of Alport syndrome in a non-consanguineous Ashkenazi Jewish family with multiple affected females by performing linkage analysis followed by targeted next generation sequencing. We identified a homozygous *COL4A3* mutation, c.40_63del, in affected individuals. Interestingly, we observed that the mutant alleles in the affected children were inherited from each parent on partially conserved haplotypes. Large-scale population screening of 2,017 Ashkenazi Jewish samples was next completed and we determined the carrier frequency of this mutation to be 1 in 183. These findings suggest that the *COL4A3* c.40_63del is a founder mutation and that this mutation may be a common cause of autosomal recessive Alport syndrome in the Ashkenazi Jewish population. Additionally, we have determined that heterozygous carriers of the *COL4A3* c.40_63del mutation in this family do not meet criteria for a diagnosis of Thin Basement Membrane Nephropathy, and we conclude after reviewing the literature that most patients heterozygous for this mutation will not develop benign familial hematuria.

3096T

De novo frameshift mutation in ASXL3 in a patient with global developmental delay, microcephaly, and craniofacial anomalies. *D.L. Dinwiddie[1,2,3,4,5,6], S.E. Soden[3,4,6], C.J. Saunders[3,4,5,6], N.A. Miller[3,4], E.G. Farrow[3,4,6], L.D. Smith[3,4,6], S.F. Kingsmore[3,4,5,6].* 1) Department of Pediatrics, University of New Mexico Health Sciences Center, Albuquerque, NM; 2) Clinical Translational Science Center, University of New Mexico Health Sciences Center, Albuquerque, New Mexico; 3) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, Missouri; 4) Department of Pediatrics, Children's Mercy Hospital, Kansas City, Missouri; 5) Department of Pathology, Children's Mercy Hospital, Kansas City, Missouri; 6) School of Medicine, University of Missouri-Kansas City, Kansas City, Missouri.

Currently, diagnosis of affected individuals with rare genetic disorders can be lengthy and costly, resulting in a diagnostic odyssey and in many patients a definitive molecular diagnosis is never achieved despite extensive clinical investigation. The recent advent and use of genomic medicine has resulted in a paradigm shift in the clinical molecular genetics of rare diseases and has provided insight into the causes of numerous rare genetic conditions. In particular, whole exome and genome sequencing of families has been particularly useful in discovering *de novo* germline mutations as the cause of both rare diseases and complex disorders. We present a six year old, African American female with microcephaly, autism, global developmental delay, and metopic craniosynostosis, who is nonverbal, and suffered intrauterine growth restriction. Exome sequencing of the patient and her two parents revealed a heterozygous two base pair *de novo* deletion, c.1897_1898delCA, p.Gln633ValfsX13 in the ASXL3 gene, predicted to result in a frameshift at codon 633 with substitution of a valine for a glutamine and introduction of a premature stop codon. To better understand the rare, nonsynonymous variant burden and impact of mutations in the ASXL3 gene, we examined the variants of a frequency of less than 1% in the ASXL3 gene in an internal variant database that contains clinical phenotype and variant information from more than 1,300 exomes. 29 variants of with a frequency of less than 1 percent were discovered. Characterization of these 29 rare variants revealed 19 that were predicted to deleterious by SIFT and 11 predicted to be probably or possibly damaging by PolyPhen2. Phenotypic evaluation of the samples with these rare, non-synonymous variants revealed zero patients with developmental delay, microcephaly, or other craniofacial anomalies, suggesting that these variants are unlikely to be pathogenic in a heterozygous state. In conclusion, we provide additional evidence that, indeed truncating and frameshifting mutations in the ASXL3 gene are the cause of a newly recognized disorder characterized by severe global developmental delay, small birth size, and craniofacial anomalies. Furthermore, we expand the knowledge about disease causing mutations and the genotype-phenotype relationships in the ASXL3 gene and provide evidence that rare, nonsynonymous, damaging mutations are not associated with developmental delay or microcephaly.

3097F

Unraveling disease genes causing autosomal recessive disorders in Qatari population by whole exome sequencing. *S. Fahiminiya[1], M. Almuriekhi[2], Z. Nawaz[3], KH. Abu Khadija[3], J. Majewski[1], T. Ben-Omran[2].* 1) Department of Human Genetics, Faculty of medicine, McGill University and Genome Quebec Innovation Center, Montreal, Quebec, Canada; 2) Section of Clinical and Metabolic Genetics, Department of Pediatrics, Hamad Medical Corporation, Doha, Qatar; 3) Section of Cytogenetic, Department of Pathology and Laboratory Medicine, Hamad Medical Corporation, Doha, Qatar.

Background: Whole Exome Sequencing (WES) was applied as a molecular diagnostic tool to identify disease-causing mutations in autosomal recessive disorders (ARD) in Qatari population where alternative molecular diagnostic tools had failed to detect pathogenic variants in causal genes. ARD are usually severe and rare, resulting from the transmission of one defective allele by each parent, which occurs with higher rate in consanguineous families. The prevalence of consanguineous marriage is high in Qatar (47%) that results in a higher incidence of several ARD. To reduce the overall socio-economic burden of such diseases, the development of diagnostic tools and prevention strategies is a priority for our population. To achieve these goals, the genes causing human genetic diseases should be first discovered. Methods: Whole exome capturing, sequencing and bioinformatics analyses were performed using our standard protocols at Genome Quebec Innovation Center, Canada. Results: WES was performed on 26 consanguineous Qatari families. The mode of inheritance was assumed to be AR because of unaffected status of parents, consanguinity and having equally affected male and female children. In families with one or only male affected child, de novo and X-linked inheritance were also considered. This led to the identification of definitive causal mutations in 12 families: Hypophosphatemic rickets; Hurler syndrome; Glycogen storage disease; Noonan-Like syndrome; Seckel syndrome; Geleophysic dysplasia; Limb-girdle muscular dystrophy; Multiple Fractures; Metachromatic Leukodystrophy; Immunodeficiency and Juvenile onset cataract. For 6 other families, we identified several candidate (1-26) genes in which the validation or functional studies are in progress: mental retardation; CNS anomaly; eye anomalies; peripheral neuropathy; axonal peripheral neuropathy and Oro-facio-digital syndrome. The 8 remaining families are still inconclusive, but further bioinformatics analysis and comparisons with future samples may yet reveal pathogenic cause. Conclusion: Our study highlights that WES is a powerful molecular approach for discovery pathogenic gene mutations- especially when traditional molecular genetic screening has failed. Furthermore, with decreasing sequencing costs and improving analysis pipelines, we expect WES to be in widespread clinical use in the near future that will help us to decrease time and cost of diagnosis and to focus on appropriate treatment and supportive care.

3098W

Exome sequencing unveils novel disease-causing variation in a Charcot-Marie-Tooth disease cohort. *C. Gonzaga-Jauregui[1], T. Harel[1], D. Pehlivan[1], Y. Okamoto[1], W. Wiszniewski[1], D. Muzny[2], R.A. Gibbs[1, 2], J.R. Lupski[1, 2, 3], Centers for Mendelian Genomics.* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Charcot-Marie-Tooth (CMT) disease is the most common hereditary neuropathy affecting approximately 1/2500 individuals. CMT is a clinically heterogeneous distal symmetric polyneuopathy (DSP) with two major groups distinguished electrophysiologically: demyelinating CMT1 and axonal CMT2. Although the major cause of CMT, the 1.4 Mb duplication CNV of 17p11.2 that is responsible for ~70 percent of the CMT1 cases, is used extensively in clinical diagnosis and part of the evidenced based practice guidelines in the United States for evaluation of DSP, CMT shows extensive underlying genetic heterogeneity with about 50 loci identified or linked to date to the different subtypes of the disease. Furthermore, homozygous CMT1A duplication CNV and triplication CNV can portend a more severe clinical course while each conveys distinct genetic recurrence risk. Exome sequencing allows assessing all the coding variation in the 2 percent of the human diploid genome that we can interpret through our knowledge of the genetic code; however, personal exomes contain ~10,000 - 12,000 nonsynonymous variants and many of these are novel. Further, even in genetic conditions with known responsible genes, interpretation can be complicated by the presence of novel variants in more than one causative gene. We have performed exome sequencing at high coverage (> 100X) of a cohort of 39 patients with different clinical presentations of CMT, in whom the genetic cause had not previously been identified using a multitude of clinically available and research molecular genetic analyses. We have found the apparent causative mutations in several individuals, and potentially disease causing mutations in novel genes in additional subjects. We also show that affected individuals can have known or novel rare variants in multiple CMT genes, possibly contributing to the mutational load and phenotypic variation in the disease. These findings are consistent with the recently proposed Clan Genomics hypothesis [Cell (2011);147(1):32-43] which posits that new mutations (in both CNV and SNV) in patients or those that arose in recent ancestors in the family or clan, and novel combinations from the proband's parents, but NOT common/ancient alleles studied in populations by Genome-Wide Association Studies (GWAS), account for many medically actionable variants.

3099T

A Novel Missense Mutation in EDAR Underlies the Autosomal Recessive Hypohidrotic Ectodermal Dysplasia with Bilateral Amastia and Palmoplantar Hyperkeratosis. *H. Haghighi-Kakhki[1], A. Haghighi[2,3], P. Nikuei[4], N. Saleh-Gohari[5], S. baghestani[6], P. Krawitz[7], J. Hecht[8], S. Mundlos[8].* 1) Masshad Azad University, Mashhad, Iran; 2) Wellcome Trust Centre for Human Genetics, Nuffield Department of Clinical Medicine, University of Oxford, Oxford, UK; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Hormozgan Fertility and Infertility Research Center, Hormozgan University of Medical Sciences, Bandarabbas, Iran; 5) Genetic Department, Kerman University of Medical Sciences, Kerman, Iran; 6) Department of Dermatology, Hormozgan University of Medical Sciences, Bandar Abbas, Iran; 7) Institut für Medizinische Genetik und Humangenetik, Charité Universitätsmedizin Berlin, Berlin, Germany; 8) Max-Planck-Institut für molekulare Genetik, Ihnestr. 63-73, 14195 Berlin, Germany.

Ectodermal dysplasias (EDs) are a large group of heritable complex conditions with more than 200 members and common clinical characteristics of anomalies of the hair, teeth, nails, and sweat glands with or without involvement of other organs. Anhidrotic ectodermal dysplasia is a rare inherited disorder characterized by a congenital dysplasia of ectodermal structures and their accessory appendages manifested primarily by hypohidrosis, hypotrichosis and hypodontia. Autosomal recessive ectodermal dysplasia is caused by mutations in EDAR gene. Using whole exome sequencing, we identified novel compound homozygous missense mutations in EDAR, c.338G>A (p.C113Y) and c.1037C>T (p.T346M), causing the disease in an extended consanguineous kindred. The proband presented with sparse hair, absent sweating, hypodontia, and conical teeth. The unusual features of absence of breasts and palmoplantar keratoderma were also noted. The findings of our study expand the knowledge on genotype-phenotype correlations in EDAR and will have important implications for genetic screening and diagnosis. This is the first genetic study of anhidrotic ectodermal dysplasia in Persian population.

3100F

Whole-exome sequencing and genome-wide homozygosity mapping analysis of fetal autopsy tissue reveals a putative pathogenic frameshift mutation in *OBSL1*, consistent with a diagnosis of 3-M Syndrome. *A.C. Lionel[1,2], R.F. Wintle[1], S. Farrell[3], D. Cushing[3], T. Paton[1], T.L. Stockley[4], D.J. Stavropoulos[4], P.N. Ray[4], M. Szego[1,2,5], L. Lau[1], S.L. Pereira[1], C.R. Marshall[1,2], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) McLaughlin Centre and Department of Molecular Genetics, the University of Toronto, Ontario, Canada; 3) Genetics Department, Credit Valley Hospital, Mississauga, Ontario, Canada; 4) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Centre for Clinical Ethics, the University of Toronto, Ontario, Canada.

We report here a consanguineous couple who have experienced three consecutive pregnancy losses following the fetal ultrasound finding of short limbs caused by retardation of long bone growth. Post-termination autopsies revealed some proximal limb shortening in two fetuses, and a spectrum of mildly dysmorphic features. Radiographs showed no evidence of skeletal dysplasia and karyotype was normal. High resolution microarray genotyping using the Illumina Infinium HumanOmni2.5-quad BeadChip was performed for the three fetuses and the parents using DNA from autopsy material and whole blood respectively. Copy number variation (CNV) analysis did not reveal any potentially pathogenic CNVs that were present in all three fetuses. Homozygosity mapping revealed two regions present in all three affected fetuses that reached genome-wide significance: one of 9.7 Mb at chromosome 2q34-q35, and another of 35.7 Mb at chromosome 8q13.2-q22.3. These regions were both heterozygous in the parents. Paired-end whole exome sequencing was performed on two of the affected fetuses on a Life Technologies SOLiD 5500xl platform with target enrichment using the Agilent SureSelect 50 Mb human all exon capture kit. We prioritized novel, nonsynonymous variants that were in the regions of shared homozygosity. The most plausible candidate was an insertion variant in the gene *OBSL1* on chromosome 2 (c.1273insA), resulting in a frameshift and premature stop (p.T425nfsX40). This variant was validated by Sanger sequencing, and showed segregation consistent with an autosomal recessive model of disease inheritance (i.e., heterozygous in both parents, homozygous in all three fetuses). This frameshift variant in *OBSL1* has been previously observed in patients with 3-M syndrome, an autosomal recessive disorder characterized by severe pre- and postnatal growth retardation. Prenatal diagnosis of 3-M syndrome based on ultrasound is findings is unreliable, given that intrauterine growth retardation has many causes and is not specific for this syndrome. Additionally, although growth retardation of long bones in utero has been reported, this finding is not always seen in children with 3-M syndrome. Exome- or whole-genome sequencing of additional 3-M syndrome families will help identify mutations in *OBSL1* and other genes. Our study provides novel insight into the early clinical manifestations of 3-M syndrome, and demonstrates the utility of exome sequencing as a tool for prenatal diagnosis.

3101W
Functional Evaluation of candidate mutations identified in whole exome sequneces of patients with undiagnosed diseases. *Y. Lu[1], P. Xie[1], E. Ruzzo[1], A. Need[1], V. Shashi[2], Y. Jiang[2], X. Zhu[1], D. Goldstein[1].* 1) Center for Human Genome Variation, Duke University School of Medicine, Durham, North Carolina, USA; 2) Department of Pediatrics, Duke University School of Medicine, Durham, North Carolina, USA.

A number of recent studies suggest that whole exome sequencing of both patients and parents (trio sequencing) can resolve up to 50 % of undiagnosed childhood diseases (Need et al. 2012). We have recently sequenced 15 such trios and evaluated functional consequences of candidate mutations. Here we report functional consequences of three mutations of particular interest. A proband with severe osteopetrosis, autism, and developmental delay, carries a homozygous nonsynonymous mutation, R95H, in sorting nexin 10 (SNX10). SNX10 is essential for osteoclast formation and resorption, which the malfunction will result in osteopetrosis. Our data from in vitro analysis suggests that this mutation leads to loss of function of SNX10. Another hemizygous nonsynonymous mutation (rs148886271; P670S) in BCL6 corepressor (BCOR) was found to down-regulate protein expression in a well-characterized 1721 amino acid (a.a.) isoform, but induced a greater than 50-fold up-regulation in another abundant 1703 a.a. isoform whose function is uncharacterized. The evidence together suggests a complicated influence on normal BCOR function as a transcriptional factor co-regulator and possibly leads to altered downstream transcriptional activation that may cause global developmental delay observed in this patient. Several other genes which are of great interests but still lack functional evidence include ANK3, which has been implicated as a candidate gene in epilepsy and autism. Compound heterozygous mutations in ANK3 were found in one patient with severe intractable seizures in our cohort. We are planning to proceed functional evaluation of ANK3 through mouse hippocampus primary culture. Further studies, including confirming molecular results by patients RNA and protein samples are still required to fully understand the influence of these variants in vivo. Overall, our work illustrates the central role of functional evaluation in the interpretation of personal genomes, since many of the most interesting mutations have not been characterized before. Our work also illustrates that patients with undiagnosed diseases may carry mutations that can inform about human biology more generally, such as the mutations in SNX10 and their potential relevance to bone related disorders.

3102T
Whole exome sequencing identifies novel mutations in three families with GAPO syndrome. *D. Pehlivan[1], E. Karaca[1], T. Gambin[1], S.N. .Jhangiani[2], G. G. Gonzaga-Jauregui[1], Y. Bayram[1], W. Wiszniewski[1], A.H. Cebi[1], D. Muzny[2], M.M. Atik[1], R.A. Gibbs[2], M. Selman Yildirim[3], A. Zamani[3], D. Gul[4], N.H. Elcioglu[5], B. Bozkurt[6], J.R. Lupski[1,7,8].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 3) Necmettin Erbakan University, Meram Medical Faculty, Department of Genetics, Konya, Turkey; 4) Department of Medical Genetics, Gülhane Military Medical Academy, Ankara, Turkey; 5) Department of Pediatric Genetics, Marmara University Medical Faculty, Istanbul, Turkey; 6) Selcuk University Medical Faculty, Department of Ophthalmology, Konya, Turkey; 7) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 8) Texas Children's Hospital, Houston, TX, USA.

GAPO syndrome (MIM# 230740) is the acronym for Growth retardation, Alopecia, Pseudoanodontia, and Optic atrophy. So far about 30 cases have been reported worldwide, making it one of the rarest recessive conditions. Distinctive craniofacial features including alopecia, rarefaction of eyebrows and eyelashes, frontal bossing, high forehead, midfacial hypoplasia, hypertelorism, and thickened eyelids and lips make it a readily recognizable phenotype. However there are additional clinical findings in each reported case. Mutations in ANTXR1 has recently been found to be causative for GAPO syndrome. ANTXR1 plays a role in the regulation of extracellular matrix.In this study we applied whole exome sequencing in three GAPO syndrome families with six affected individuals. Exome sequencing analysis revealed two novel mutations, one frameshift, one splice site, and previously described mutation in the ANTXR1 gene. We here present clinical findings of patients with GAPO syndrome. Our patients contribute to make a better genotype-phenotype correlation in this rare condition and are important to understand the role of ANTXR1 in the function/dysfunction of the extracellular matrix.

3103F
A genome-wide catalogue of genetic variants for nephrotic syndrome via whole genome sequencing. *M.G. Sampson[1,4], A. Tan[2,4], C.A. Gadegbeku[3,5], J. Sedor[3,6], M. Kretzler[3,4], H.M. Kang[2,4], Nephrotic Syndrome Study Network (NEPTUNE), The Michigan O'Brien Renal Center (CPROBE).* 1) Pediatrics and Communicable Disease; 2) Public Health-Biostatistics; 3) Internal Medicine-Nephrology; 4) University of Michigan, Ann Arbor, MI; 5) Temple University, Philadelphia, PA; 6) Case Western Reserve University, Cleveland, OH.

Nephrotic syndrome (NS) is a rare glomerular condition with more than 20 known Mendelian genes and few common risk variants. Yet, these explain a minority of the population prevalence across the lifespan, particularly in adults. To identify known and novel variants associated with NS molecular, histologic, and clinical phenotypes, we are performing low-pass whole genome sequencing (WGS) and exome chip genotyping on 550 affected subjects recruited into observational NS cohorts from North American medical centers. Here we present initial data on the first 256 patients. Subjects were either recruited at time of initial indicated biopsy for suspected primary NS or had an existing diagnosis of focal segmental glomerulosclerosis (FSGS) or membranous nephropathy (MN). All underwent Illumina Exome Chip genotyping and Illumina HiSeq WGS. WGS data underwent GotCloud pipeline with linkage disequilbrium refinement, and comparison to Exome Chip genotypes. The variant frequencies were compared to the latest release of 1000 Genomes and Exome Sequencing Projects, stratified by ancestry. Diagnoses were 52% minimal change disease/FSGS, 25% MN, and 24% other glomerulopathy. Subject ancestry was 49% European (EUR), 29% African (AFR), 15% Admixed American (AMR), and 7% Asian (ASN). Mean sequencing depth was 4.2x. 20.9M SNPs were identified, with transition to transversion ratio (Ts/Tv) 2.16. 330K (16%) SNPs were novel to dbSNP Build 135. Comparing with exome chip data, low-pass WGS was estimated to have 89% power to detect shared variants in 256 cases and 30% power to detect singleton variants. We identified novel loss-of-function and essential splice-site variants shared among our cases in 55 and 64 genes, respectively. In AFR FSGS cases, the minor allele frequency (MAF) of the known FSGS risk haplotype, G1, in APOL1 was 31% (OR=1.6). In EUR MN cases, the allele frequencies of the known MN risk SNPs, rs2187668 and rs4664308, were 33% (OR=4.4) and 83% (OR=3.5), respectively. At the time of abstract submission, we are systematically performing genome-wide association analysis and testing the enrichment of associated variants in regulatory elements. We plan to integrate this genetic data with kidney biopsy-derived RNA-Seq, histologic, and outcome data from the same patients. This should clarify existing, and define new, associations between genetic variation and both endophenotypes and clinical outcomes.

3104W
Personalized functional genomics approach elucidates novel Mendelian disease genes and provides proof of pathogenicity for variants of uncertain significance. *P. Bonnen[1,2], A. Besse[1,2], S. Lalani[2], W. Craigen[2], F. Scaglia[2], R. McFarland[3], C. Bacino[2], R. Taylor[3], K. Scott[2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Wellcome Trust Centre for Mitochondrial Research, The Medical School, Newcastle University, Newcastle upon Tyne, NE2 4HH, UK.

Genome-wide sequencing is now at the forefront of our efforts to identify genetic underpinnings of disease. Bioinformatic analyses of sequence data alone can only predict the impact of variants in known disease genes. For discovery of novel disease genes and to provide proof of pathogenicity of specific alleles, we combine genome-wide sequencing efforts with robust pipelines that allow functional characterization of gene variants in patient cells. This scalable infrastructure is intended to accelerate validation of mutations driving single gene disorders with the ultimate goal of translating annotated variants into clinical diagnostics and therapeutics. Combining the resolution of genome-wide sequencing with functional profiling of variants in patient cells enables the personalized identification of bona fide pathogenic mutations. Our approach combines whole exome sequencing with (1) consistent, systematic and thorough functional profiling on every study patient regardless of variation in clinical presentation, (2) bioinformatic analyses to prioritize pathogenic variants, (3) delivery of the wild-type copy of suspected pathogenic genes to rescue cellular dysfunction and (4) delivery of patient mutations with simultaneous knockdown of the endogenous gene of interest into healthy cells to recapitulate cellular disease phenotypes. Our approach has already revealed several novel disease genes, and importantly, has enabled validation of the pathogenicity of alleles reported as variants of uncertain significance (VUS) in the diagnostic setting. Our current study cohort consists of children with pediatric onset diseases with clinical and diagnostic assessment that present with mitochondrial, neuromuscular, neurological, cardiomyopathy, bone, and rapid aging diseases. Our personalized functional genomics approach has discovered novel disease genes and validated pathogenic mutations in greater than 60% of this cohort. This approach serves as a model for validation of sequence-based genetic findings, and our results provide new insights into the mechanisms underlying the pathology of these single gene disorders and delivers genes and pathways for further study of the pathogenetic mechanisms underlying diseases with more complex etiology.

Genotype-phenotype correlation in a national mutation study of Danish patients with HHT. *P.M. Torring[1,2], K. Brusgaard[1], L.B. Ousager[1], P.E. Andersen[3], A.D. Kjeldsen[2], HHT centre, Odense University Hospital.* 1) Dept. of Clinical Genetics, Odense University Hospital, Odense, Denmark; 2) Dept. of Otorhinolaryngology, Odense University Hospital, Odense, Denmark; 3) Interventional Radiology, Odense University Hospital, Odense, Denmark.

Purpose: Hereditary Haemorrhagic Telangiectasia (HHT) is an autosomal dominantly inherited vascular disease characterized by the presence of mucocutaneous telangiectasia and visceral arteriovenous malformations (AVM). About 85% of HHT patients carry mutations in the ENG, ACVRL1 or SMAD4 genes. Here, we report on the genetic heterogeneity in the Danish national HHT population and address the prevalence of pulmonary AVM (PAVM). Methods: Probands of 107 apparently unrelated families received genetic testing, including sequencing and multiplex ligation-dependent probe amplification (MLPA) analyses of ENG, ACVRL1 and SMAD4. Results: In 89% of the probands (n=95), a mutation was identified in one of the three genes. We identified 64 unique mutations, primarily in ENG and ACVRL1, of which 27 (41%) were novel. Large deletions were identified in both ENG and ACVRL1. The prevalence of PAVM was 52.3% in patients with an ENG mutation and 12.9% in the ACVRL1 mutation carriers. We diagnosed 80% of the patients clinically, fulfilling the Curaçao criteria, and those remaining were diagnosed by genetic testing. Conclusions: Proper genetic testing requires analysis for both mutations and large rearrangements of all three genes. Inclusion of a pathogenic mutation as a diagnostic criterion is discussed.

Exome sequencing of subjects with Congenital Insensitivity to Pain and their family members to reveal novel pain genes. *B. Zhang[1], W. He[1], J. Stephens[1], B. Sidders[2], S. Scollen[2], S. Paciga[1], L. Wood[1], M. Sudworth[3], G. Johnson[3], S. John[1], N. Danziger[4], C. Vangjeli[2].* 1) Pfizer Inc, Eastern Point Road, Groton, CT 06340, USA; 2) Pfizer Neusentis, Granta Park, Great Abington, CB21 6GS, UK; 3) Pfizer Ltd, Ramsgate Rd, Sandwich, CT13 9NJ, UK; 4) Department of Clinical Neurophysiology and Pain Center, Groupe Hospitalier Pitié-Salpêtrière, Paris, France.

Congenital insensitivity to pain (CIP) is a rare heterogenous condition comprised of an absence of sensation to noxious stimuli and can be accompanied by a range of other clinical abnormalities, including anosmia, anhydrosis, and mental retardation. Three genes have consistently been shown to harbour mutations in patients with CIP - SCN9A, NTRK1, and NGF - but some studies that have sequenced these genes failed to identify mutations segregating in families with the disorder. It is therefore likely that there are mutations in other genes responsible for CIP, which may represent novel therapeutic targets for pain. We sequenced the exome of 30 subjects - 15 with CIP and 15 unaffected family members - using the Agilent SureSelect v4 all exon 51Mb kit for exome capture and the Illumina HiSeq 2000 for sequencing. Sequences were aligned using BWA and variants called using GATK. Depending on the mode of inheritance and the levels of relatedness within the families, different mutation filtering strategies were employed.Mutations were filtered using frequency cutoffs in public databases including 1000 genomes, dbSNP and the exome variant server, as well as from 400 in-house exome sequenced samples. Autozygosity mapping was used to identify genomic regions of particular interest. Of the 10 families, 2 of them have potentially functional mutations that segregate in known genes - one family has a novel nonsense mutation in SCN9A and another has a 27bp deletion in the NTRK1 gene. For the other 8 families, we have identified lists of segregating mutations, but of these, the causative mutations remains to be elucidated. Future steps include sequencing coding regions that had poor coverage as well as putative regulatory regions of the 3 known CIP genes, as well as GWAS chip genotyping of all samples to more accurately define runs of homozygosity and/or regions identical by descent. It is likely that the CIP in several of the families will not be the result of known CIP genes, and thus these future steps are likely to reveal novel genes responsible for CIP.

3107W

Whole exome sequencing of a dominant retinitis pigmentosa family with female-specific expressivity identifies a novel deletion in PRPF31. *E.E. Davis[1], A. Villanueva[2], J.R. Willer[1], E.T. Dermitzakis[3], N. Katsanis[1].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 2) Virtual Eye Care MD, Merida, Yucatan, Mexico; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland.

Photoreceptor dysfunction is the most common cause of visual impairment and affects ~1 in 3,000 humans. Underscored by an excess of 180 primary disease gene loci, inherited retinal disorders are hallmarked by vast genetic heterogeneity, thereby posing significant molecular diagnostic challenges. However, the extensive clinical variability observed within and among pedigrees with causal mutations at the same locus offers the unique opportunity to dissect cis and trans modulating effects. Here, we report the genetic dissection of a large Mexican family with non-syndromic retinitis pigmentosa (RP) and apparent female-enriched expressivity and age of onset in the first two decades of life. We ascertained all available members of a large, multigenerational pedigree using fundus photography, dark adaptation studies and electroretinography. Next, we performed whole-exome sequencing on two affected first cousins, an obligate carrier, and a married-in, unrelated spouse. Additional Sanger sequencing of candidate pathogenic variants was performed in the entire pedigree, and we identified a novel 14 bp deletion in exon 9 of PRPF31 (p.Arg289Profs*30), a gene implicated previously in adult-onset dominant RP. The mutation segregated with the phenotype of all ten exclusively female affecteds, but was also present in six family members with no fundus changes, two females and four males, a distribution found to represent a significant female bias in expressivity. Subsequent studies in lymphocyte cells showed that the penetrance/expressivity of the PRPF31 deletion allele was concordant with the expression levels of wild-type message. However, neither the known modulators of PRPF31 expression nor cis-eQTLs within 100 kb of the locus could account for the variance in expression of the message or the clinical phenotype. Although non-penetrance and variable expressivity have been reported previously for this locus, primarily for pedigrees of European descent, these data suggest the existence of a novel modulating mechanism of PRPF31 expression in addition to a hitherto unreported gender bias of expressivity.

3108T

A new palmoplantar keratoderma with severe erythermalgia allelic to Olmsted syndrome. *S. Duchatelet[1,2], S. Pruvost[2,3], S. De Veer[1,2], S. Fraitag[4], P. Nitschké[2,5], C. Bole-Feysot[2,3], C. Bodemer[2,6], A. Hovnanian[1,2,6,7].* 1) INSERM, U781, Paris, France; 2) Université Paris Descartes - Sorbonne Paris Cité, Institut Imagine, Paris, France; 3) Genomics Plateform, IMAGINE Foundation, Paris, France; 4) Department of Pathology, Necker-Enfants Malades hospital, APHP, Paris, France; 5) Bioinformatics Plateform, Paris Descartes University, Paris, France; 6) Department of Dermatology, Necker-Enfants Malades hospital, APHP, Paris, France; 7) Department of Genetics, Necker-Enfants Malades hospital, APHP, Paris, France.

We describe a new severe genetic skin disease in a seven-year-old girl from healthy and non consanguineous French parents. The patient presented with progressive and severe palmoplantar keratoderma (PPK) associated with intense erythermalgia manifesting by acute flares of inflammation, itching, burning pain, vasodilatation and redness of the extremities (hands, feet and ears), triggered by heat. Skin biopsy showed hyperplastic epidermis with hyperkeratosis, parakeratosis, hypergranulosis and papillomatosis, together with dilated capillaries in the upper dermis. Finger and toe nails were thin and brittle. Her hair was fine, dry, curly and unmanageable. Microscopic hair examination shows superficial irregularities without specific abnormalities under polarizing microscopy. Whole exome sequencing identified a *de novo* heterozygous p.Leu673Phe mutation within *TRPV3* (transient receptor potential cation channel, subfamily V, member 3) encoding a nonselective cation channel involved in a variety of processes, including temperature sensation and vasoregulation. Recently, distinct missense *TRPV3* mutations were identified in Olmsted syndrome (OS), a rare keratinizing disorder with periorificial hyperkeratosis and mutilating PPK, all features which were absent in our patient. In addition, the association of severe erythermalgia clearly distinguishes our patient from previously described cases of PPK. The p.Leu673Phe missense mutation involves a highly conserved amino acid residue across species and is predicted to be damaging by *in silico* analysis. This mutation introduces a significant change in size at a critical position of the molecule. Using a TRPV3 homology model, we show that Leu673 is located immediately above the predicted activation gate residue Met677 on the preceding S6 transmembrane helical turn. We suggest that this mutation impairs channel activity and causes the unique and severe skin condition seen in our patient. The clinical features in our patient expand the phenotype of palmoplantar keratoderma associated with *TRPV3* mutations. The molecular mechanisms through which *TRPV3* mutations lead to OS or other palmoplantar keratoderma phenotype are yet to be explored.

3109F

A mutation in A-band titin is associated with hereditary myopathy with early respiratory failure in a Japanese family.
R. Izumi[1,2], T. Niihori[1], Y. Aoki[1], N. Suzuki[2], M. Kato[2], H. Warita[2], T. Takahashi[3], M. Tateyama[2], T. Nagashima[4], R. Funayama[4], K. Abe[5], K. Nakayama[4], M. Aoki[4], Y. Matsubara[1]. 1) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 2) Department of Neurology, Tohoku University School of Medicine, Sendai, Japan; 3) Department of Neurology and Division of Clinical Research, National Hospital Organization Nishitaga National Hospital, Sendai, Japan; 4) Division of Cell Proliferation, United Centers for Advanced Research and Translational Medicine, Tohoku University Graduate School of Medicine, Sendai, Japan; 5) Department of Neurology, Okayama University Medical School, Okayama, Japan.

Hereditary myopathy with early respiratory failure (HMERF, MIM #603689) was originally described as an autosomal dominant disease characterized by adult onset proximal or distal myopathy with early respiratory failure and overlapping pathologic findings with myofibrillar myopathy. HMERF had been considered an extremely rare disease, caused by a rare TTN gene mutation (c.97348C>T of the kinase domain) among North European population. In 1993, our group reported a Japanese family with dominantly inherited cytoplasmic body myopathy, which is now included in myofibrillar myopathy. Currently, this family includes 20 patients in five successive generations who show almost homogeneous clinical features characterized by chronic progressive distal muscle weakness and early respiratory failure. However, the underlying genetic etiology in this family was unknown. In this study, we performed linkage analysis and whole exome sequencing to identify the responsible genetic mutation of the family, clinically and pathologically compatible with HMERF and identified a novel c.90263G>T mutation in the TTN gene. Recently, additional seven TTN mutations have been revealed in 29 families with HMERF by massively parallel sequencing in other groups. All the eight mutation, including ours, were clustered in the fibronection type 3 domain (A150 domain) of the A-band TTN. This finding suggested that the A150 domain plays critical roles in the pathogenesis of HMERF as well as the kinase domain, although detailed mechanisms of pathogenesis remain unknown. HMERF is a more frequent disease than previously expected and identified in different ethnic groups. Further studies will be needed to estimate the frequency of TTN mutations in HMERF and to understand the molecular function of titin.

Offit[1,2]. 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Cancer Genome Computational Analysis, Broad Institute, Boston, MA; 5) Weill Cornell Medical College, New York, NY; 6) Genomics Platform, Broad Institute, Boston, MA; 7) Lymphoma Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 8) Massachusetts General Hospital Cancer Center, Boston, MA; 9) Medical & Population Genetics, Broad Institute, Boston, MA; 10) Departments of Genetics and Medicine, Harvard Medical School, Boston, MA.

Hodgkin's disease (HD) is a cancer of the immune system characterized by the presence of Reed-Sternberg cells. Concordance for HD seen in identical twins and increased familial aggregation suggests that there are genetic susceptibility factors involved in its predisposition. Genome-wide association studies have shown that there are multiple loci associated with HD at chromosome 6p21 HLA locus and several other loci near genes such as REL, PVT1 and GATA3. A germline mutation in NPAT in a family was described in a Finnish family.

We have performed exome capture and sequencing of 33 individuals with HD (including 10 affected sib-pair) and where available an unaffected sibling and the unaffected parents (n=18) from multiple kindreds with only Hodgkin's lymphoma. The family structure of majority of these HD sib-pairs reflects a plausible recessive mode of inheritance. Targeted exome capture was achieved using Agilent SureSelect 30MB and sequencing was performed using Illumina HiSeq chemistry. Mapping and variant calling were performed using BWA and GATK either at Broad Institute or at MSKCC. QC was performed using standard criteria and variants annotated using SNPEff. Variants were filtered based on public control data such as ESP6500, 1000genomes, prediction algorithms such as SIFT and Polyphen2 and on conservation scores such as GERP and Phylop. Analyses were performed in both recessive and dominant mode where applicable. Recurrence of variant analyses was also performed

We did not observe truncating NPAT mutations in any family. We also did not observe any segregating high quality, high impact mutations in REL, PVT1 or GATA3. No such mutations were observed in the HLA gene cluster. Ongoing efforts are geared to the discovery of segregating rare variants in the germline (including genes reportedly mutated in somatic tissue) in this type of lymphoma. To understand the population risk and the prevalence, the frequency of these genic-variants need to be estimated in a larger cohort of familial lymphomas. Future plans include a targeted capture of prioritized genes in 1000 sporadic HD cases ascertained at MSKCC.

Anhidrosis, defined as the absence of perspiration in the presence of an appropriate stimulus such as heat or exercise, is a rare condition that may be acquired or congenital. The reasons for anhidrosis, or reduced sweating (hypohidrosis), are heterogeneous and may be caused by defects of sweat gland innervation in disorders of the autonomous nervous system or by a reduced number of functional sweat glands in different ectodermal syndromes. Reports on Familial generalized anhidrosis with normal sweat glands (GANSG) (MIM 106190) are very few.

We have identified a consanguineous Pakistani kindred segregating autosomal recessive GANSG in five affected family members. Using gene mapping and targeted re-sequencing we identified a novel homozygous missense mutation (c.7492G>A; p.G2498S) in the *ITPR2* gene associated with anhidrosis. The *ITPR2* gene encodes for the Inositol 1,4,5-trisphosphate receptor type 2 (InsP3R2), a member of the InsP3R protein family of intracellular Ca^{2+} channels. Functional studies showed that the mutation affects the selective filter for Ca^{2+}-ions with a resulting loss of function of InsP3R2. Furthermore, the *Itpr2*$^{-/-}$ mice show a markedly reduced sweat gland response upon pilocarpine stimulation when compared to wild-type littermates. Taken together, our findings indicate that the *ITPR2* mutation p.G2498S underlies anhidrosis in the patients investigated. Furthermore, we have identified InsP3R2 mediated Ca^{2+} release as a critical mechanism for eccrine sweat gland function, perspiration and thermal cooling.

Mitochondria are small organelles and serve as the powerhouse of the living cells because they generate vital energy in their respiratory chain system consisting of protein complexes I to V. Mitochondrial respiratory chain disorder (MRCD) is an intractable disease that develops in childhood. It is a highly frequent inborn error of metabolism that occurs in at least one out of every 7,000 births. Prominent symptoms develop in such organs as the brain, heart, liver and muscles, where a great deal of energy is required. In most cases, effective treatment has not been established yet. It is known that various gene abnormalities cause defects of the protein complexes of the respiratory chain, which results in mitochondrial dysfunction. However, identification of the causative gene and the understanding of pathogenic mechanism of MRCD remain largely unsolved. In this study, We applied SNP array and exome sequencing in combination with stepwise filtering of gene variants. Exome sequencing data were filtered using three different criteria: (i) the presence of mutations in known disease causing genes; (ii) mutations in genes that code for mitochondrial proteins; (iii) unbiased genome-wide approach with strict filtering strategy. For this study, 103 unrelated individuals were chosen who display juvenile-onset mitochondrial disorders. In 18/103 cases, we identified mutations in known disease-causing genes (AARS2, ACAD9, BOLA3, COX10, GFM1, MPV17, NDUFA1, NDUFA10, NDUFAF6, PC, RARS2, SUCLA2, SURF1 and TUFM). Currently we prioritize rare variants in mitochondria-related genes. In addition, unbiased genome-wide analysis allows the identification of new disease genes thereby extending our understanding of the underlying pathomechanisms. The progress of our precisely controlled strategy will be presented at the meeting.

Mutation in ATP6AP2, an essential accessary subunit of vacuolar ATPase, causes X-linked Parkinson Disease with Spasticity (XPDS). *E. Korvatska[1], T. Strovas[2], D.-H. Chen[3], J.B. Leverenz[2,3,4,5], K. Kiianitsa[6], I.F. Mata[2,3], D.A. Nickerson[7], C.P. Zabetian[2,3,5], B.C. Kraemer[2,9], T.D. Bird[2,3,8], W.H. Raskind[1,4,8].* 1) Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 2) Geriatric Research, Education, and Clinical Center, VA Puget Sound Health Care System, Seattle; 3) Department of Neurology, University of Washington, Seattle; 4) VISN-20 Mental Illness Research, Education, and Clinical Center, Department of Veteran Affairs, Seattle; 5) Parkinson's Disease Research, Education, and Clinical Center, VA Puget Sound Health Care System, Seattle; 6) 6Department of Immunology, University of Washington, Seattle; 7) Department of Genome Sciences, University of Washington, Seattle; 8) Department of Medicine (Medical Genetics), University of Washington, Seattle; 9) Department of Medicine (Gerontology Division), University of Washington, Seattle.

We report a novel gene for a parkinsonian disorder. X-linked Parkinson Disease with Spasticity (XPDS) presents either as typical adult onset Parkinson's disease or earlier onset spasticity followed by parkinsonism. We previously mapped the XPDS gene to a 28 Mb region on Xp11.2-X13.3. Exome sequencing of one affected individual identified five rare variants in this region, of which none was missense, nonsense or frame shift. Using patient-derived cells we tested the effect of these variants on expression/splicing of the relevant genes. A synonymous variant in ATP6P2, c.345C>T (p.S115S), markedly increased exon 4 skipping resulting in overexpression of a minor splice isoform that produces a protein with internal deletion of 32 aa in up to 50% of the total pool, with concomitant reduction of isoforms containing exon 4. ATP6P2 is an essential accessory component of the vacuolar ATPase required for lysosomal degradative functions and autophagy, a pathway frequently affected in Parkinson's disease. Reduction of the full-size ATP6AP2 transcript in XPDS cells and decreased level of ATP6AP2 protein in XPDS brain may compromise V-ATPase function, as seen with siRNA knockdown in HEK293 cells, and may ultimately be responsible for the pathology.

3114T

Identification of genetic defects in cone and cone-rod dystrophy by whole exome sequencing. *C. Lazar[1,2], L. Zelinger[3], M. Mutsuddi[1,4], L. Mizrahi-Meissonnier[3], A. Boleda[1], R.R. Priya[1], E. Banin[3], D. Sharon[3], A. Swaroop[1].* 1) Neurobiology-Neurodegeneration & Repair Laboratory (N-NRL), National Eye Institute, National Institutes of Health, Bethesda, MD, 20892; 2) Institute for Doctoral Studies, Babes-Bolyai University, Mihail Kogalniceanu 1, Cluj-Napoca, Romania, 400084; 3) Department of Ophthalmology, Hadassah - Hebrew University Medical Center, Jerusalem, Israel 81120; 4) Department of Molecular and Human Genetics, Varanasi, India 221005.

Cone dystrophy (CD) and cone-rod dystrophy (CRD) are clinically and genetically heterogeneous retinal disorders displaying autosomal dominant (AD), autosomal recessive (AR) and X-linked inheritance patterns. Several genetic loci have been implicated, and causative mutations have been identified in over twenty genes. The goal of this study is to identify the cause of disease in AD and AR families with cone-dominated retinal phenotypes using whole exome sequencing. Finding causal variants in retinal dystrophies is difficult using traditional methods because of the high degree of genetic heterogeneity. Whole exome sequencing (WES) has been successfully applied for molecular characterization of cohorts affected with a heterogeneous condition as well as identification of novel variants. In this study, WES was performed on 13 individuals from four unrelated Israeli families. Three of the families were clinically diagnosed with CRD and one with CD. To capture the target regions from genomic libraries, we used the Agilent Sure Select Human All Exon V4 capture kit. Sequencing was carried out on an Illumina Genome Analyzer IIx. The sequencing reads that passed the initial quality control achieved an average coverage of 60X. Initial data analysis was performed using Genomatix software. Potential candidate variants are being filtered against an existing Israeli cohort dataset. Additional analysis using other publicly available analysis tools and databases are being used for further filtering and to identify rare variants. We are evaluating the expression of the putative candidates in fetal and adult retina in our global expression databases and will be validating significant causal variants using Sanger sequencing. Initial analysis of three families has led to the identification of rare variants in CDHR1, C8orf37 and GUCY2D genes. CDHR1 and C8orf37 were previously reported to cause AR form of CRD and GUCY2D was previously implicated in the cause of AD CRD. In CDHR1 we have identified a new non-sense mutation predicted to result in a truncated protein with loss of several important domains. Further experiments will be carried out to understand the biological effect of the novel variants in causing the disease pathology. Our studies should help us in better understanding the molecular basis of cone and cone-rod dystrophy, thereby improving clinical management and development of new therapeutic strategies.

A novel germline *PIGA* mutation in Ferro-Cerebro-Cutaneous Syndrome: A neurodegenerative X-linked encephalopathy with epilepsy and systemic iron-overload.
R.L. Margraf[1], E.M. Coonrod[1], J. Durtschi[1], K. Mallempati[1], A. Kumanovics[1,2], T.M. Newcomb[3], J.M. Opitz[2,4,5,6], J.C. Carey[5,6], H. Zhou[2], B.E. Katz[7], K.V. Voelkerding[1,2], K.J. Swoboda[3,6]. 1) ARUP Institute for Clinical and Experimental Pathology®, ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology ,University of Utah, School of Medicine, Salt Lake City, Utah; 3) Department of Neurology ,University of Utah, School of Medicine, Salt Lake City, Utah; 4) Department of Human Genetics ,University of Utah, School of Medicine, Salt Lake City, Utah; 5) Department of Obstetrics and Gynecology ,University of Utah, School of Medicine, Salt Lake City, Utah; 6) Department of Pediatrics (Division of Medical Genetics) University of Utah, School of Medicine, Salt Lake City, Utah; 7) Private Practice of Pediatrics and Pediatric Neurology (retired), Twin Falls, Idaho, 83303, USA.

This report presents a family with three males affected by Ferro-Cerebro-Cutaneous Syndrome, a novel X-linked syndrome of neurodegeneration, cutaneous abnormalities, and systemic iron overload. Linkage studies demonstrated a shared haplotype at Xp21.3-Xp22.2, a region spanning 18 megabases and containing more than 100 candidate genes. When candidate gene sequencing proved unsuccessful, exome sequencing was used to determine the causal variant. A heuristic filtering approach identified several rare mutations in the linkage region, but only the PIGA mutation segregated with disease in the family. The *PIGA* gene contains a germline three base pair in frame deletion (deleted positions chrX:15342943-15342945, p.110delLeu). The leucine residue that is deleted in the affected males is highly conserved from humans to zebrafish. The unaffected great-grandfather had the same X allele as all the affected males, but without the *PIGA* mutation. This indicates that the *PIGA* mutation arose *de novo* on the X allele from the great-grandfather to the grandmother who then passed the *PIGA* mutation on to several children, including an affected male. *PIGA* encodes an enzyme in the GPI anchor biosynthesis pathway. Clonal expansion of cells with somatic *PIGA* mutations causes paroxysmal nocturnal hemoglobinuria (PNH). In PNH, blood cells including erythrocytes are deficient in GPI anchor proteins, reducing expression of critical cell surface proteins and predisposing cells to complement-mediated lysis. Recently, a family with a germline *PIGA* mutation was reported where affected males had multiple congenital anomalies and severe neurologic impairment resulting in infantile lethality. In contrast, affected boys in this report were born without anomalies and were apparently neurologically normal prior to onset of seizures after 6 months of age, with 2 surviving to the second decade. An affected individual was tested for the presence of GPI anchor proteins in granulocytes, monocytes, and erythrocytes; and only granulocytes were found to be deficient in GPI anchored proteins. This could explain the milder phenotype seen in our patients compared to *PIGA* mutations that lead to erythrocyte lysis or early lethality. The novel *PIGA* mutation in this family likely caused a reduction in GPI-anchor protein cell surface expression in various cell types, resulting in the observed novel and complex phenotype involving the central nervous system, skin and iron metabolism.

Deciphering the genetic background of PEHO-like syndrome.
M. Muona[1,2,3], A. Laari[3,4,5], A.-K. Anttonen[3,4,5,6], M. Somer[7], A. Palotie[1,8,9], A.-E. Lehesjoki[3,4,5]. 1) Institute for Molecular Medicine Finland, Helsinki, Finland; 2) Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 3) Folkhälsan Institute of Genetics, University of Helsinki, Helsinki, Finland; 4) Haartman Institute, Department of Medical Genetics and Research Program's Unit, Molecular Medicine, University of Helsinki, Helsinki, Finland; 5) Neuroscience Center, University of Helsinki, Helsinki, Finland; 6) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 7) Norio Centre, Rinnekoti Foundation, Helsinki, Finland; 8) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton CB10 1SA, UK; 9) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

PEHO syndrome (progressive encephalopathy with edema, hypsarrhythmia, and optic atrophy) is an infantile onset neurodegenerative disorder. The clinical presentation in Finnish patients, homozygous for a founder mutation (unpublished), is relatively uniform and includes hypotonia, infantile spasms with hypsarrhythmia, profound psychomotor retardation, optic atrophy, and progressive brain atrophy originating in cerebellum. A significant number of patients manifest many of these features in the absence of the typical neuroradiological findings, or with no sign of progression. These patients remain without proper diagnosis but are often classified as PEHO-like. We aim to decipher the genetic basis of PEHO-like syndrome by using exome sequencing. We have selected 29 Finnish, mostly sporadic, PEHO-like patients, who have been excluded for the PEHO founder mutation. Exome sequencing was performed using Illumina HiSeq 2000 platform. We carried out variant filtering using strategies assuming two different patterns of inheritance: recessive and de novo. In the former we selected potentially deleterious variants - either homozygous or compound heterozygous - of essential splice site, nonsense, frameshift, and missense types with a 1000 genomes minor allele frequency below 1%. In the '*de novo*' analysis we included only heterozygous, potentially damaging variants absent from the control databases. Analysis of the first 21 exomes revealed likely pathogenic hemizygous mutations in *CDKL5*, a known infantile epileptic encephalopathy gene, in two male patients. Capillary sequencing of the patients' parents showed that the mutations occurred *de novo*. In an affected sibpair we identified likely pathogenic compound heterozygous mutations in *ABAT*, previously linked to epileptic encephalopathies in a few cases. One patient had a three-amino-acid duplication previously reported as pathogenic in *SPTAN1*. Finally, we have also identified potentially pathogenic mutations in genes without a previous connection to encephalopathies. We are currently analysing the exomes of the remaining eight patients. To facilitate identification of heterozygous de novo variants we have also sequenced the exomes of parents of seven patients. Our findings imply that PEHO-like syndrome is genetically highly heterogeneous. A subset of patients had mutations in previously established disease genes, indicating the utility of exome sequencing as a diagnostic tool.

3117T

Aicardi Goutieres Syndrome (AGS) - phenotypic variability and diagnosis in a series of cases using whole-exome sequencing. *V. Narayanan[1,2], S. Szelinger[1,3,4], J.J Corneveaux[1,3], I. Schrauwen[1,3,5], A.L. Siniard[1,3], A.A. Kurdoglu[1,3], I. Malenica[1,3], K.M. Ramsey[1,3], D.W. Craig[1,3], M.J. Huentelman[1,3].* 1) Center for Rare Childhood Disorders, Translational Genomics Research Institute, Phoenix, AZ; 2) Pediatric Neurogenetics Center, Barrow Neurological Institute, Phoenix AZ; 3) Neurogenomics Division, Translational Genomics Research Institute, Phoenix AZ; 4) Molecular and Cellular Biology Interdisciplinary Graduate Program, School of Life Sciences, Arizona State University, Tempe AZ; 5) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

AGS is an autosomal recessive heterogeneous disorder, with causal mutations reported in 6 genes (TREX1, RNAseH2A, RNAseH2B, RNAseH2C, SAMHD1, ADAR) to date. Markers of AGS include elevated CSF interferon-alpha, elevated CSF neopterin and tetrahydrobiopterin, and basal ganglia or cerebellar calcification, are not universal in all cases. Due to a wide range of clinical symptoms that do not completely follow the known genetic risk models many suspected AGS cases remain undiagnosed and possible new causal genes remain unidentified. Here we describe 3 families with affected children in whom AGS was suspected and causal variations identified by family based whole-exome sequencing. Each study participant was pooled into multiplexed libraries of 6 total samples by TruSeq Exome Enrichment v2 chemistry and sequenced on two lanes of a HiSeq2000 flowcell to a mean target depth of 97±70X. In Family 1, with a single affected male and parental consanguinity, initial clinical diagnosis of leukodystrophy was made but biochemical and genetic testing was negative. Exome sequencing uncovered a single homozygous variant in exon 3 of RNASEH2B that is highly conserved, deleterious and never before seen in any public SNP databases. Both parents were identified as carriers, fitting autosomal recessive inheritance, which was validated by Sanger sequencing. In Family 2, a single affected female with normal development until 13 months of age but progressive encephalopathy after immunization was observed. Exome sequencing uncovered compound heterozygous variants in Exons 2 and 9 of (ADAR1). Both variants were highly conserved and deleterious as defined by in-silico prediction algorithms and one of the two causal variants is a previously described risk allele for AGS cases. In Family 3, with two affected boys, the initial clinical diagnosis was acute disseminated encephalomyelitis (ADEM), but questioned after the younger sibling developed a subacute encephalopathy. Exome sequencing uncovered deleterious compound heterozygous variants in Exon 2 and 8 of RNASEH2A. One of the variants was never before seen, while the other had no reported frequency in target population. In conclusion AGS may be more prevalent than previously thought and should be considered in cases of acute encephalopathy with features of white matter disease, following infection or immunization. Whole exome sequencing may be an efficient approach to diagnosis, and discovery of new genes linked to AGS.

3118F

Exome sequencing identifies mutations in a novel gene in patients with Noonan syndrome. *T. Niihori[1], Y. Aoki[1], T. Banjo[2], N. Okamoto[3], S. Mizuno[4], K. Kurosawa[5], T. Ogata[6], F. RAS GTPases mediate a wide variety of cellular functions, including proliferation, cell survival and differentiation. Recent studies have revealed that germline mutations and genetic mosaicism of classical RAS, including HRAS, KRAS and NRAS, show a wide spectrum of genetic disorders: Noonan syndrome and related disorders (RAS/mitogen-activated protein kinase (MAPK) pathway syndromes or RASopathies), nevus sebaceous and Schimmelpenning syndrome. In the present study, we identified a total of nine missense, nonsynonymous mutations in a gene encoding a member of the RAS family, in 17 of 180 individuals (9%) with Noonan syndrome and related conditions without mutations in known genes. Clinical manifestations in the mutation-positive individuals are consistent with those of Noonan syndrome, which are characterized by distinctive facial appearance, short stature and congenital heart defects. Seventy percent of mutation-positive individuals had hypertrophic cardiomyopathy, a high frequency compared with the 20% incidence in individuals with Noonan syndrome overall. Luciferase assays in NIH3T3 cells showed that five mutants identified in children with Noonan syndrome enhanced ELK1 transactivation. The introduction of mutant mRNAs of this gene into one cell-stage zebrafish embryos was found to result in a significant increase of embryos with craniofacial abnormalities, incomplete looping and a hypoplastic chamber in the heart and an elongated yolk sac. These results demonstrated that gain-of-function mutations in this gene cause Noonan syndrome, showing a similar biological effect to mutations in other RASopathy genes. Note: The name of the gene will be disclosed at the meeting.

3119W

Identification of pathogenic variants in Idiopathic Scoliosis. *S. Patten[1,2], E. Alix[3,4], A. Labalme[3,4], S. Girard[5], B. Biot[6], C. Poizat[3,4], D. Sanlaville[3,4], J. Berard[7], G. Idiopathic scoliosis (IS) is a spine deformity affecting up to 3% of adolescents. Despite strong evidences of genetic contributions to the etiology of IS, the causative genes remain unidentified. We previously identified a new disease gene location (3q12.1 or 5q13.3) in a large extended family with apparent monogenic inheritance (Edery P et al, Eur J Hum Genet 2011). In the present study, we performed SNP genotyping to further refine these loci. Whole exome sequencing was performed in 7 affected individuals from the large family and 4,564 single nucleotide variants (SNVs) were identified in our targeted chromosomal regions. These SNVs were subsequently filtered and the pathogenic nature of candidate SNVs was assessed by functional studies in zebrafish. We identified one rare missense SNV (MAF<1%) in a gene, within the 5q13.3 IS interval, that segregated with IS in the family and resulted in spinal deformities similar to that observed in IS patients when overexpressed in zebrafish. Sanger sequencing of this gene was subsequently performed in 40 additional multiplex families, and in 150 unrelated IS cases. Co-transmission of that same SNV and the disease was also observed in 3/40 additional families and it was identified in 3/150 unrelated IS cases. We also identified a missense mutation in this gene in 1/40 family, and another rare missense variant in the gene in 5/150 IS patients. None of these three nucleotide variants were found in 206 control chromosomes of individuals in the same geographical area. Functional analyses of these mutations in zebrafish also resulted in spine deformities similar to that observed in IS patients. These results indicate that these variants cause IS and, to our knowledge, we report on the first ever causative gene in idiopathic scoliosis.

3120T

Exome sequencing is the preferred approach for identifying the genetic cause in consanguinous and non-consanguinous recessive disease. *H. Smeets[1], J. Vanoevelen[1], M. Gerards[1], R. Kamps[1], T. Theunissen[1], B. De Koning[1], I. Boesten[1], M. van Geel[1], P. Lindsey[1], C. Stumpel[1], M. Nguyen[1], M. Gerrits[1], S. Ghesquiere[1], S. Stevens[1], C. de Die[1], B. van den Bosch[1], I. De Coo[2].* 1) Dept Clin Genet, Maastricht UMC, Maastricht, Netherlands; 2) Dept Neurology, Erasmus UMC, Rotterdam, Netherlands.

Exome sequencing is becoming the primary approach in genetic testing, particularly suited to solve *de novo* cases and patients with recessive disease. We performed exome sequencing in 27 families with predominantly recessive neurological syndromes and, if available, a metabolic cellular phenotype. In most families more than one child was affected. Counseling information and SNP-array data was used to classify the parents as consanguinous or non-consanguinous. Exome sequencing was done on a single patient per family, using an Illumina HiSeq2000 system. Quality criteria were >90 million reads per sample, >90% coverage per base at 10X, more than 65% coverage per base at 20X, <50% duplicate reads, >80X mean corrected coverage and a specificity of >65%. Data analysis was performed using an in-house optimized pipeline. Filtering of the variants was based on frequency (<1%), functional impact, function of the gene, the genetic model (homozygous or compound heterozygous), genetic localization and segregation in the family. If the number of remaining variants was too high or the the data did not match the quality criteria (<10%) an additional patient was sequenced. A total of seven patients were homozygous or compound heterozygous for mutations in the genes LPIN1, SCL19A3 (2 times), AARS2, DHODH, SERAC1, MMP14, five of which could be directly linked to the phenotype and two were confirmed after *in vitro* validation. In 16 patients possibly pathogenic variants were identified in genes, which could be connected to the phenotype. If possible, these variants are functionally validated or confirmed in additional patients, but providing the definite evidence can be cumbersome. Still, we expect to solve the majority of the families studied. In the consanguinous families, the phenotypes are often not caused by a single gene defect and more genes are mutated, each explaining different parts of the clinical spectrum. As the parents involved have a risks of offspring with different pathologies, it is advisable in those families to screen both parents completely for shared recessive mutations to determine recurrence risks and prenatal options.

3121F

Next-Generation Sequencing Identities PXDN Mutations in Patients with Complex Microphthalmia and Anterior Segment Eye Disease. *A. Slavotinek[1], A. Choi[1], R. Lao[2], P. Ling-Fung Tang[2], W. Mayer[1], E. Wan[2], T. Bardakjian[3], P.Y. Kwok[2], A. Schneider[3].* 1) Dept Pediatrics, Division of Genetics, Univ California, San Francisco, San Francisco, CA; 2) Cardiovascular Research Institute, UCSF, San Francisco, CA; 3) Division of Medical Genetics, Einstein Medical Center, Philadelphia, PA.

Anophthalmia and microphthalmia (A/M) are common and significant because of visual loss. Mutations in SOX2 and other genes can cause A/M, but more than half of affected individuals do not receive a molecular diagnosis. A/M can be isolated ('simplex A/M') or accompanied by additional ocular defects ('complex A/M'). We used exome sequencing to study children with simplex A/M (n=14), complex A/M (n= 5) and other eye defects including anterior segment dysgenesis (ASD) and retinal dysplasia (n=3). Samples were initially analyzed for known genes associated with A/M and if negative, further analysis was undertaken. We present two families who had PXDN mutations as a cause of their eye defects. The first family had an affected sib pair with complex A/M and ASD, sclerocornea, microphthalmia, developmental delays and hypotonia. The older male sibling had glaucoma. Both sibs had two PXDN mutations: c.1021C>T, predicting p.Arg341* and a frameshift mutation, c.2375_2397del, predicting p.Tyr791Serfs*65 and premature protein truncation. The second family was a single affected male with bilateral ASD who had healthy parents. There was no known consanguinity. This child had a paternally inherited, missense mutation, p.Gln316Pro, and a maternally inherited frameshift mutation, p.Tyr398Thrfs*40. Mutations in PXDN have been described in 3 families with congenital cataracts, microcornea, sclerocornea and glaucoma, but extraocular anomalies were not noted (Khan et al., 2011). Peroxidasin is usually located in the endoplasmic reticulum and can be secreted into the extracellular space. The protein contains a peroxidase domain and motifs that are typical for extracellular proteins, including an amino-terminal secretory signal sequence and ligand binding domains, with leucine-rich repeat regions, C2-type immunoglobulin-like motifs and a von Willebrand factor type C domain (Khan et al., 2011). The peroxidasins are involved in hydrogen peroxidase metabolism, although the substrates for this reaction in the eye have not been characterized. It is unclear if PXDN provides adhesive support for the corneal and lens epithelium, or if the reduced antioxidant capacity that results from lack of this enzyme leads to increased reactive oxygen intermediates and insoluble aggregates that result in cataracts and corneal clouding. We conclude that PXDN mutations should be considered in complex microphthalmia and anterior segment dysgenesis.

3122W

Diagnostic exome sequencing to elucidate the genetic basis of likely recessive disorders in consanguineous families. *P. Makrythanasis[1], M. Nelis[1,2], F.A. Santoni[1], M. Guipponi[3], A. Consanguinity is a risk factor for autosomal recessive (AR) disorders. Although many of the clinical phenotypes presenting in the offspring of consanguineous couples are of unknown etiology, advances in sequencing the protein-coding portion of the human genome (exome) provide an opportunity to arrive at a molecular diagnosis in at least a proportion of unresolved phenotypes, thereby identifying novel candidate genes responsible for AR phenotypes. Samples were collected from 41 consanguineous families characterized by a wide spectrum of clinical phenotypes suggestive of AR inheritance. DNA was taken from the patient(s), all unaffected siblings and the parents. All samples were genotyped with a 720K SNP array to define the identical-by-descent chromosomal regions likely to contain the responsible pathogenic variants. Exome sequencing was performed on one affected individual per family. Variants within the identified target areas were called and filtered using bioinformatic tools. The putative pathogenic variant was found in known disease-causing genes (VLDLR, DMP1, FKTN, SEPSECS, GUCY2D, BBS4, SYNE1 and POMGNT1, TACO1) in 9 families. In 4 families evidence for a simultaneous presence of two monogenic disorders was identified. In 21 families, variants of likely pathogenicity were found. In 7 families, no plausible candidates were identified. Consanguineous families provide a unique opportunity to identify pathogenic variants in both known and candidate genes responsible for recessive. We identified a putative causative variant in 9/41 families tested and in further 4/41 evidence for affection from two monogenic disorders. High-throughput sequencing represents a substantial improvement in our ability to diagnose recessively inherited disorders and identify novel candidate genes.

3123T

Exome sequencing identifies loss of function mutations in *UBE3B* in a family with intellectual and developmental delay, hypotonia, distal digital hypoplasia, and hearing loss. *Y.R. Li[1,2], S.A. Shalev[5], J. Liang[3], Y. Guo[2], J. Zhang[3], B.J. Keating[2,4,10], Y. Chen[3], L. Tian[2], S.S. Vergano[6], X. Xu[3], H. Hakonarson[2,4,10], J. Wang[3,7,8,9], M.A. Deardorff[4,11].* 1) Medical Scientist Training Program; Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania 19104; 3) BGI-Shenzhen, Shenzhen 518083, China; 4) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania; 5) Genetic Institute, Emek Medical Center, Afula, Israel; 6) Division of Medical Genetics and Metabolism, Children's Hospital of the King's Daughters, Norfolk, Virginia; 7) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 8) King Abdulaziz University, Jeddah, Saudi Arabia; 9) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Denmark; 10) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 11) Department of Pediatrics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania 19104.

Recessive, loss of function, mutations in the *UBE3B* gene have recently been reported in the Blepharomphimosis-Ptosis-Intellectual Disability (BPIDS) and Kaufman oculocerebrofacial syndromes (KOS). Here we present an additional family with clinical features caused by recessive mutations in *UBE3B*, identified using of autozygosity mapping and exome sequencing. The family presented with known consanguinity, including multiple affected siblings as well as an affected paternal cousin with severe growth and global intellectual developmental delays, hypotonia, severe sensorineural hearing loss, genitourinary (GU) anomalies, bilateral aplasia of the distal phalanges, micrognathia, microcephaly, and hypoplasia of the distal phalanges of one or more toes. The proband and brother both died of unknown causes at ages 9 and 2, respectively; metabolic testing of all three affected individuals revealed no abnormalities. Given the complex presentation and lack of a clear definitive diagnosis, we performed exome sequencing of the affected proband, two unaffected siblings, and unaffected parents to identify a Mendelian mutation that would be causative for this disorder. Given the pattern of inheritance, we expected to identify a homozygous mutation in the proband that was present in a heterozygous state in the parents, and either absent or heterozygous in the unaffected siblings. We identified a deleterious homozygous (A>G) splice acceptor site mutation in intron 13 of *UBE3B* (c.1451-2A>G) predicted to result in skipping of exon 14. The *UBE3B* gene resides in a 591kb region of shared autozygosity on chromosome 12q24.11, identified by SNP array in the affected siblings and affected paternal cousin. We confirmed the mutation to be homozygous in the three affected children and heterozygous in both the parents and two unaffected siblings. The features in this family, while distinct, demonstrate significant clinical overlap with those identified in BPIDS and KOS. Our findings suggest that there is a broader clinical spectrum of features caused by mutations in *UBE3B*, underscoring the evolving genetic landscape of phenotypically overlapping disorders in the neurocognitive syndromic developmental axis.

3124F

Affected Sib Analysis of Human X-Exome Data to Identify Novel X-linked Intellectual Disability Genes. *T. Niranjan[1,2], C. Skinner[3], T. Turner[1,2], M. May[3], L. Holloway[3], A. Chakravarti[1], C. Schwartz[3], T. Wang[1,4].* 1) The McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Predoctoral Training Program in Human Genetics, Johns Hopkins University, Baltimore, MD; 3) Greenwood Genetics Center, Greenwood, SC; 4) Department of Pediatrics, Johns Hopkins University, Baltimore, MD.

X-linked Intellectual Disability (XLID) is a group of genetically highly heterogeneous disorders caused by mutations in genes on the X chromosome. More than 90 XLID genes have been found, which account for ~50% of XLID disorders. To systematically identify responsible genes for the remaining XLID, we sequenced the X-exome of 55 XLID families (a single affected male from 27 families and two affected males from 28 families) using an Agilent SureSelect system and the HiSeq2000 platform. An average of 1,844 ± 246 variants were identified in each X-exome with a mean coverage of 49x. To enrich disease-causing mutations, we initially tried to use variant datasets from dbSNP and the male portion of 1000 Genomes as filters. However, these databases present several challenges for an efficient enrichment of disease-causing mutations. dbSNP contains potentially unannotated pathological mutations and available male data from 1000 Genomes contain an excess of ambiguous variants for the X chromosome. To solve these problems, we tested and optimized a novel strategy by sequencing affected sibs in proband families to enrich for shared variants and by eliminating neutral variants using a small cohort of unrelated males. This approach achieved a substantial (98.1%) reduction in the number of variants for follow-up studies and significantly enriched for known XLID genes, including *ATRX*, *HUWE1*, *MECP2*, *MED12*, *MAOA*, and *PHF8* ($p < 0.005$, hypergeometric test). Novel candidate XLID genes including *ZC4H2* are also identified. We conclude that the affected sib-based approach can be used to effectively enrich for disease-causing mutations in genetically heterogeneous X-linked disorders and that publicly available human reference databases including dbSNP and 1000 Genomes should be used with caution as automatic filters to enrich for disease-causing mutations in X-linked disorders.

3125W

Novel C10orf2 mutations cause Perrault syndrome. *H. Kawakami, H. Morino, R. Miyamoto, H. Maruyama.* Dept Epidemiology, Hiroshima Univ RIRBM, Hiroshima, Japan.

Purpose: Perrault syndrome, first reported in 1951, is characterized by sensorineural hearing loss in both genders and gonadal dysfunction in females, and genetically and clinically heterogeneous autosomal recessive disorder. **HSD17B4**, **HARS2**, **CLPP** and **LARS2** were reported as responsible genes for Perrault syndrome so far. By exome sequencing, we searched further mutations of the syndrome.

Methods: Patients are 38-year-old and 32-year-old sisters. There is no genetic relationship between their parents. The parents and brother have no similar symptoms. We performed exome-sequencing. We used BWA for alignment/mapping, Samtools and Picard for SAM/BAM handling, GATK and Samtools for variant call, and Annovar for annotation. Functional predictions due to amino acid changes were estimated by PolyPhen2 , SIFT and Mutation Taster.

Results: Total reads of two affected patients are 9,003,317,959 and 10,599,079,582 bp, and mean coverages are 84.87 and 99.92. Total variant numbers are 116,627 and 120,840 and 100 common variants which were not found in open variant database, dbSNP135, 1000 genomes and ESP, nor in in-house variant database were filtered. Among these variants, we detected only one gene, C10orf2 which contained multiple variants, c.1172G>A (p.R391H) and c.1754A>G (p.N585S). These variants are predicted to be damaging by all the three algorithms. C10orf2:c.1172G>A was paternal and c.1754A>G was maternal allele. Affected two women had both variant alleles, but unaffected brother had only paternal one.

Conclution: We found novel compound heterozygous mutations in C10orf2, encoding Twinkle which cause Perrault syndrome. C10orf2 was also known as the causative gene of PEOA4 and IOSCA. However, the phenotype of this family is different from these diseases. Twinkle is a DNA helicase which unwinds short stretches of double-stranded DNA and, along with mitochondrial single-stranded DNA biding protein and mtDNA polymerase gamma, is thought to play a key role in mtDNA replication. Since **HARS2**, **CLPP** and **LARS2** which were known as responsible genes for Perrault syndrome are associated with mitochondrial function, the mutations of C10orf2 are reasonable as the cause of the syndrome.

3126T

Novel clinical presentations associated with mutations in nuclear genes of the mitochondrial translation apparatus. *M. RIO[1,2], Z. ASSOULINE[1], A.S. LEBRE[1], N. BODDAERT[2], I. DESGUERRE[2], A. MUNNICH[1,2,3], A. ROTIG[3].* 1) SERVICE DE GENETIQUE, HOPITAL NECKER-ENFANTS MALADES, PARIS, France; 2) DEPARTEMENT DE PEDIATRIE, HOPITAL NECKER-ENFANTS MALADES, PARIS, France; 3) INSTITUT IMAGINE, INSERM U781, HOPITAL NECKER-ENFANTS MALADES, PARIS, France.

The mitochondrial protein synthesis apparatus allows the synthesis of the 13 respiratory chain (RC) subunits encoded by mitochondrial DNA. The deficiency of mitochondrial protein synthesis can be caused by mutations in any component of the translation apparatus including tRNA, rRNA and proteins. We report here 4 patients from 3 independent families with mutations in 3 nuclear genes encoding proteins of the mitochondrial translation apparatus. All patients presented a multiple RC deficiency in muscle, liver or fibroblasts and an abnormal pattern assembly of RC complexes in fibroblasts. Interestingly the clinical presentations of the patients differ for the previously reported patients with mutations in these genes. Patients 1-2 are two brothers born to non consanguineous parents. They presented hypoglycemia, trunk hypotonia and lactic acidosis at 2 days of age. They died at 6 and 5 days of age. Exome sequencing detected two heterozygous mutations of MTO1 encoding the mitochondrial translation optimization 1. MTO1 mutations have been identified in two families with hypertrophic cardiomyopathy and lactic acidosis. Patient 3 is a girl born to consanguineous parents of Turkish origin. She has sideroblastic anemia, psychomotor retardation, microcephaly, exocrine pancreatic dysfunction, short stature, and mild mental retardation. She has a homozygous PUS1 mutation. PUS1 encodes the pseudouridylate synthase 1 that converts uridine to pseudouridine once it has been incorporated into an RNA molecule. PUS1 mutations were previously reported in patients with multiple RC deficiency and myopathy, lactic acidosis, and sideroblastic anemia (MLASA). Patient 4 is a girl born to non consanguineous parents. She presented trunk hypotonia in the first months of life. She developed tonic spasms without hypsarrhythmia on EEG between 6 and 18 months of age. At 2.5 years, she had delayed development, growth retardation, hypotrophia, microcephaly and spastic diplegia. She had permanent hyperlactatemia. Brain MRI detected bilateral anomalies of thalamus. Exome sequencing identified two heterozygous mutations in GFM1 encoding the mitochondrial elongation factor G1. Until now GFM1 mutations were associated with either severe encephalopathy or liver insufficiency. These results give support to the clinical and genetic heterogeneity of mitochondrial disorders and highlight how difficult genotype-phenotype correlations are in OXPHOS deficiency.

3127F

Targeted sequencing of mitochondrial exome in pediatric patients with mitochondrial diseases. *M. Tesarova[1], T. Honzik[1], H. Kratochvilova[1], A. Vondrackova[1], V. Stranecky[2], M. Rodinova[1], H. Hansikova[1], J. Zeman[1].* 1) Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague 2, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague 2, Czech Republic.

Mitochondrial diseases (MD) represent both clinically and genetically heterogeneous group of disorders. More than 130 nuclear genes have been described so far whose mutations lead to MD. Accurate targeting of the genetic analysis based on clinical symptoms or laboratory tests is possible for only a few types of MD (e.g. MNGIE syndrome, mitochondrial encephalocardiomyopathy - *TMEM70*, Leigh syndrome due to *SURF1* mutations). For most of MDs, even specialized enzymatic and protein analyses do not allow unambiguously to narrow a group of candidate genes. Next generation sequencing is a significant milestone in discovery of genetic bases of inherited diseases and it already transforms genetic diagnostics. In last two years, more than 25 MD-genes were identified by exome sequencing. In a group of 26 patients with mitochondrial disease we performed targeted sequencing of mitochondrial exome (>1100 nuclear genes mostly based on MitoCarta Inventory; http://www.broadinstitute.org/pubs/MitoCarta/index.html). In 6 patients, mutations in known MD-genes *TSFM*, *COX10*, *AIFM1*, *TK2*, and *MGME1* were found. In 3 patients no gene was prioritized. In the other patients candidate variants in genes with previously unknown association with MD were selected and are further evaluated to support their pathogenicity. *Supported by research projects UNCE 204011, RVO-VFN64165/2012 and grants IGA NT13114/4, IGA NT14156/3..*

Whole Genome Sequencing for Rapid Identification of Sequence Variants Associated with Recessive Canine Disease Models. *G.S. Johnson[1], D.P. O'Brien[2], R. Zeng[1], D. Gilliam[1], T. Mhlanga-Mutangadura[1], J.R. Coates[2], M.L. Katz[3], J.F. Taylor[4], R.D. Schnabel[4].* 1) Department of Veterinary Pathobiology, University of Missouri, Columbia, MO, USA; 2) Department of Veterinary Medicine and Surgery, University of Missouri, Columbia, MO, USA; 3) Mason Eye Institute, University of Missouri, Columbia, MO, USA; 4) Division of Animal Sciences, University of Missouri, Columbia, MO, USA.

Over the past 25 years we have accumulated over 100,000 canine DNA samples, many from dogs with a variety of inherited diseases. One area of focus is the identification of the causal mutations underlying these diseases with two objectives: (1) to facilitate the breeding of healthy dogs, and (2) to identify canine models for heritable human diseases. In 2010, we began sequencing the genomes of dogs believed to bear distinct recessive diseases. To date, we have generated genome sequence data from 28 dogs. Collaborators at UCLA and T-GEN have provided an additional 34 genome sequences from domestic dogs and closely related wild canids. Ongoing sequencing efforts and collaborations are expected to produce in excess of 100 genome sequences by the end of 2013. Our model for the identification of causal variants uses 1 case and N-1 controls as a starting point, where the case is assumed to be homozygous for a variant that is not present in any of the N-1 control animals. Additional models under development will accommodate more complex genetic etiologies such as compound heterozygosity and incomplete penetrance. Currently, our efforts have resulted in the identification of five variants that are apparently causal for their respective diseases. We shall describe an *SAG* mutation associated with progressive retinal atrophy as an example. Furthermore, these sequenced genomes have provided us with an opportunity to explore reverse genetics which involves predicting recessive phenotypes from heterozygous sequence variants, identifying homozygous individuals by screening our archived DNA samples, and finally, verifying the predicted phenotype.

3129T

Whole Exome Sequencing on two fetuses with Centronuclear Myopathy of consanguineous parents from Sudan shows two possible candidates. *N. Dohrn[1], V.G. Le[2], A. Petersen[3], P. Skovbo[4], I.S. Pedersen[2], A. Ernst[2], H. Krarup[2], M.B. Petersen[1].* 1) Department of Clinical Genetics, Aalborg University Hospital, Denmark; 2) Section of Molecular Diagnostics at Department of Clinical Biochemistry, Aalborg University Hospital, Denmark; 3) Institute of Pathology, Aalborg University Hospital, Denmark; 4) Department of Obstetrics and Gynaecology, Aalborg University Hospital, Denmark.

Arthrogryposis multiplexa congenita (**AMC**) is a rare congenital disorder characterized by multiple joint contractures. There are several possible underlying conditions but the common pathway is the lack of fetal movement. Usually termination of pregnancy is performed due to the known severity of the disorder. Exact diagnosis is identified at autopsy subsequently. We present a consanguineous healthy couple from Wadi Halfa, Sudan, with two separate pregnancies with female fetuses showing AMC. The mother's great grandfather was the grandfather of the father. Ultra sound (**US**) in the 13th week showed AMC, leading to termination of the first pregnancy. The second pregnancy showed the same malformation on US in the 13th week, also leading to termination. Array-CGH, karyotype (46,XX) and investigation for Congenital Myotonic Dystrophy were all normal. A full autopsy including CNS and muscle histopathological examination of the two foetuses were performed. The muscle examination included immunohistochemistry and electron microscopy. A diagnosis of Centronuclear Myopathy with autosomal recessive inheritance (**AR-CNM**) was proposed as there was a greater amount of centrally located nuclei and a greater variation in the muscle fibre diameter than expected for the gestational age and as no other specific myopathies were found.

CNM is seen with either X-linked, autosomal dominant or recessive inheritance. The autosomal recessive form of CNM is currently only reported to be caused by mutations in either the *BIN1* or *RYR1* genes, and many patients are without any genetic clarification. Some cases were detected during fetal life, but none of them were severe enough to result in termination of pregnancy, in contrast to our case. Blood samples and cell cultures from the parents and foetuses, respectively, were analyzed with Whole Exome Sequencing (WES). The WES result showed no mutations in the two previously known genes, *RYR1* and *BIN1*. This is in agreement with results from sanger sequencing previously carried out on *BIN1*. The WES suggested two possible candidates for a novel gene responsible for AR-CNM. They were identified by using multiple filtration parameters to filter from the starting collections of twelve thousands variants for each of the four exomes. Both genes are without any previous connection to a neuromuscular disease. We are in the process of carrying out confirmation on our WES results concerning the two candidates.

Leber congenital amaurosis (LCA) is a severe form of retinal dystrophy and children present with nystagmus and poor vision in the first year of life. There are at least 21 known disease genes and few distinguishing clinical features to focus candidate gene sequencing. Allele-specific assays testing for known variants and Sanger sequencing of specific gene regions provide answers for some patients. We applied whole exome sequencing in a family with LCA, where previous targeted assay and sequencing approaches had been unsuccessful in disease gene identification. We implemented two independent bioinformatic pipelines, BWA-GATK and SOAP, to interrogate the sequence data and maximize our capacity for valid variant identification. Our first pipeline resulted in 16 prioritized variants, while the second led to 8 prioritized variants. Four variants overlapped between the two groups of prioritized variants, one of which was the top candidate predicted from both pipelines, a novel homozygous nonsense mutation in *TULP1*. **TULP1** is a member of the tubby gene family and has roles in rhodopsin movement, synapse formation and survival of the photoreceptors, and causes approximately 1% to 2% of cases with LCA. The disease-causing variant was confirmed on Sanger sequencing and segregated appropriately in the family. This study highlights the value of a whole exome sequencing approach as a rapid means for known and novel variant identification in disease genes in the genetically heterogeneous retinal disease of LCA.

The oral-facial-digital syndrome type VI (OFD VI) or Varadi-Papp syndrome has recently been caracterised by the following diagnostic criteria: molar tooth sign (MTS) and one or more of the following: 1) tongue hamartoma and/or additional frenula and/or upper lip notch; 2) mesoaxial polydactyly of one or more hands or feet and 3) hypothalamic hamartoma. Because of the MTS, OFD VI belongs to the 'Joubert Syndrome Related Disorders' (JSRD). Its genetic etiology remains largely unknown although mutations in the TMEM216 gene, responsible for Joubert (JBS2) and Meckel-Gruber (MKS2) syndromes, have been reported in only two patients. Few mutations in the X-linked OFD1 gene have also been reported in male JBS patients with oral defects or female patients with OFD syndrome and mild MTS. Combined exome and Sanger sequencing identified compound heterozygous or homozygous causal mutations in the C5orf42 gene in 8/9 families including a severe fetus with microphthalmia, cerebellar vermis hypoplasia, corpus callosum agenesis, bilateral hand and feet preaxial and postaxial polydactyly, unilateral hand mesoaxial polydactyly with Y-shaped metacarpal phalange, and severe skeletal dysplasia but absent oral manifestations. Altogether, we identified 12 novel C5orf42 mutations in 11 cases from 8 families. All patients presented distal anomalies with constant feet preaxial polydactyly (11/11 cases) and frequent mesoaxial polydactyly (7/11 cases) in at least one distal extremity with Y-shaped metacarpal abnormality (6/8 cases). Mutations of this gene have already been reported in Joubert but classical additional features usually reported in JSRD appeared absent, such as polycystic disease and retinal disease. In contrast to highly heterogeneous JSRD with 20 causative genes identified to date, OFD VI seemed genetically highly homogeneous. In conclusion, we report that C5orf42 is the major gene responsible for OFD VI syndrome and confirm that OFD VI and JBS syndromes are allelic disorders, enhancing the complex, highly heterogeneous group of ciliopathies.

3132T

Independent origin of multifocal skin tumors and high frequency of mosaicism in patients with Tuberous Sclerosis Complex (TSC). *M.E. Tyburczy[1], J. Wang[2], S. Li[2], R. Thangapazham[2], Y. Chekaluk[1], J. Moss[3], D. Kwiatkowski[1], T. Darling[2]*. 1) Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Uniformed Services University of the Health Sciences, Bethesda, MD; 3) Cardiovascular and Pulmonary Branch, NHLBI, National Institutes of Health, Bethesda, MD.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder caused by mutations in TSC1 or TSC2. It is characterized by formation of tumors that are thought to arise through a two-hit gene inactivation model. Two-thirds of TSC cases are sporadic, and mosaicism is known to occur at low frequency in TSC. We sought to examine several questions on the pathogenesis of TSC skin lesions through analysis of a set of TSC patients enriched for those with adult presentation and diagnosis (PMID 21690595). Fibroblast-like cells were grown from 33 skin tumor samples obtained from 23 TSC patients and 23 parallel samples of normal-appearing skin. Long range PCR was used to amplify all coding regions and most nearby intronic sequence from each of TSC1 and TSC2, followed by library preparation for next generation sequencing. Over 3000x read depth was achieved, and sequencing data was analyzed using BWA, Picard, GATK, Python, and Matlab to identify all sequence variants present at an allele frequency ≥1%. We identified TSC2 mutations in 27 of 33 cultures, with allele frequencies ranging from 1% to 56%, and a single TSC1 mutation in one culture. Five cultures, 4 from patients with adult presentation of TSC, had no mutations in either TSC1 or TSC2. Sixteen cultures had two different mutations in TSC2, including one case of loss of heterozygosity (LOH). Twelve had only a single mutation identified. Seven (39%) of 18 patients showed mosaicism. Blood DNA analysis of one patient showed no evidence of the mosaic mutation seen in the cultured cells. In four patients, multiple tumors showed distinct second hit mutations in TSC2. Strikingly, 7 of the 14 second hit point mutations were CC>TT dinucleotide mutations, likely due to UV-induced damage. Such CC>TT mutations have never been identified as germline mutations in TSC1 or TSC2. In summary, there are multiple novel observations: 1) Skin tumors in TSC develop through two-hit inactivation of TSC2. 2) Different TSC skin lesions have distinct second hit events, indicating that they must arise independently. 3) Genomic loss or classic LOH is rare in TSC skin lesions. 4) UV-induced mutation is likely a contributing genetic event to development of skin lesions in TSC. 5) Mosaicism is common in TSC patients with adult presentation. 6) Lack of mutation identification in some TSC patients with adult presentation is consistent with extreme mosaicism as a potential cause.

3133F

REPS1 is a novel gene of Neurodegeneration with Brain Iron Accumulation. *A. DRECOURT[1], N. BODDAERT[2], I. DESGUERRE[2], D. CHRETIEN[1], A. MUNNICH[1,2], A. ROTIG[1]*. 1) INSTITUT IMAGINE, INSERM U781, PARIS, France; 2) DEPARTEMENT DE PEDIATRIE, HOPITAL NECKER-ENFANTS MALADES, PARIS, FRANCE.

Neurodegeneration with brain iron accumulation (NBIA) encompasses a group of rare neurogenerative disorders transmitted with an autosomal recessive inheritance. This heterogeneous group of disorders can be differentiated by clinical, brain MRI and molecular features. The hallmark features of NBIA include progressive extrapyramidal dysfunction (dystonia, rigidity, choreoathetosis) and iron accumulation in the brain, primarily in the basal ganglia. To date, mutations in PANK2, PLA2G6, FA2H, ATP13A2, C2orf37, CP, FTL and WDR45 have been associated with NBIA. The largest subgroup (50%) of NBIA observed so far is PKAN (pantothenate kinase associated neurodegeneration), caused by PANK2 mutations. The remaining individuals are said to have 'idiopathic NBIA', meaning that the underlying cause is not yet known. Consequently, the disease causing genes are still to be identified in several patients with idiopathic NBIA. We have performed exome sequencing in two sisters with NBIA and identified two heterozygous mutations in REPS1 gene encoding RALBP1 associated Eps domain containing 1. Reps1 is involved in endocytosis and the two mutations (p.Ala113Glu and p.Val78Leu) are located in its EH1 domain that interacts with Rab11-FIP2. The function of Reps1 in iron metabolism is currently unknown but it has been well demonstrated that its protein interacting partner, RabB11-FIP2, functions in transferrin recycling. Western Blot analysis detected a low Reps1 protein level in patient fibroblasts indicating a probable misfolding and degradation of the protein due to the missense mutations, as REPS1 transcript was found in normal amount. We investigated the iron metabolism and oxidative stress in patient's fibroblasts. Colorimetric ferrozine-based assay allowed us to detect a dramatic increase of iron levels in patient fibroblasts. We also observed an increase of ferritin and iron responsive protein (IRP1) amounts suggesting iron accumulation in those cells. In keeping with that, SOD2 and IRP1 protein amounts were highly increased whereas aconitase activity was decreased. All these result indicate that Reps1 mutation induce deregulation of iron metabolism and oxidative stress. In conclusion we report REPS as a novel gene for NBIA. Improvement in our understanding of the biochemistry and pathophysiology of this form of NBIA will help for novel therapeutics of this neurological condition.

3134W

Challenging diagnostic cases resolved by whole exome sequencing.
S.F. Suchy[1], J.E. Abdenur[2], T. Ben-Omran[3], W.K. Chung[4], K. Leydiker[2], S.J. Bale[1], A. Daly[1], E.V. Haverfield[1]. 1) GeneDx, Gaithersburg, MD; 2) Division of Metabolic Disorders, CHOC Children's, Orange CA; 3) Section of Clinical and Metabolic Genetics, Department of Pediatrics, Hamad Medical Corporation, Weill Cornell Medical College, Doha, Qatar; 4) Columbia University Medical Center, New York, NY.

Accurate diagnosis is essential to the appropriate management of genetic disorders, particularly inborn errors of metabolism (IEM). We present three challenging cases in which the molecular cause was identified by whole exome sequencing (WES). Case 1: A one year-old child presented with hypotonia, developmental delay, encephalopathy, seizures, intermittent strabismus and dystonia. There were two similarly affected siblings. Extensive work-up of blood and urine, and imaging studies were non-revealing. CSF studies were declined by the parents. WES was performed (Agilent SureSelect XT2 All Exon V4 kit and an Illumina HiSeq2000), on the proband and parents. A homozygous p.Phe375Leu mutation in the tyrosine hydroxylase gene (TH) was identified. Both parents were carriers of the mutation. Case 2: A two year-old male presented with congenital ichthyosis, developmental delay, white matter changes, mild hip dysplasia and constipation. Studies included: a normal metabolic work-up (organic acids, very long chain fatty acids, amino acids, acylcarnitine profile) and a normal chromosome microarray. WES revealed two mutations in trans in the ALDH3A2 gene. One was a frameshift (p.Asn255IlefsX11) and the second was a deletion of exons 1-3. Case 3: A 3 1/2 year-old male was referred from neurology to the metabolic genetics clinic due to distal muscle weakness, motor delay, an unbalanced gait and speech delay. He had no calf hypertrophy or scoliosis. The metabolic work-up and MRI of the head and spine were normal. WES revealed a novel p.Arg844Cys mutation in the ATP7A gene. There are three main phenotypes associated with ATP7A mutations: Menkes disease, occipital horn syndrome and X-linked distal motor neuropathy. Patients with identical mutations who had different phenotypes have been described (Kennerson et al., AJHG, 86, 2010). This proband's phenotype and the location and the type of mutation are consistent with reported cases of X-linked distal motor neuropathy. A different mutation, p.Arg844His, affecting this same codon has been reported previously in association with Menkes disease, and this missense change was observed to result in a mis-localized protein (Moller et al., Hum Mut 26, 2005). The diagnosis of many genetic disorders remains a challenge. Disorders characterized by a broad phenotypic spectrum or occurring in a patient with an atypical presentation can further confound the diagnosis. WES offers another option for these diagnostic dilemmas.

3135T

Exome Sequencing Utility for Implication of Genes in Mendelian Disorders.
S. Jhangiani[1], M. Bainbridge[1], C. Gonzaga-Jauregui[2], W. Wiszniewski[2], T. Gambin[2], J. Lu[1], H. Doddapaneni[1], M. Wang[1], C. Buhay[1], H. Dinh[1], Y. Han[1], C. Kovar[1], J. Santibanez[1], J. Reid[1], D. Valle[3], E. Boerwinkle[1], D. Muzny[1], J. Lupski[2], R. Gibbs[1], Centers for Mendelian Genomics. 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, Maryland,.

Whole exome sequencing has proven to be the most successful way to elucidate the molecular basis of Mendelian disorders. The Human Genome Sequencing Center at Baylor College of Medicine has generated over 25 Tb of data for more than 250 phenotypes. Our high-throughput multiplexed exome pipeline, producing 2K capture libraries per month, is automated from library construction through annotated VCF generation in part using the Mercury pipeline. Since 2012, we joined the Centers for Mendelian Genomics with the Baylor-Johns Hopkins Center for Mendelian Genomics and have collected samples from 20 countries and initiated collaborations with over 86 institutions. The collection encompasses over 200 phenotypes and has generated 20 Tb of whole exome Illumina data.

Coverage of the genome's most understood regions is far greater with exome sequencing and still the most cost efficient method for gene association to disease. Whole genome shotgun sequencing generated from a patient with Charcot Marie Tooth syndrome was compared against whole exome data from the same individual. Not only were the majority of disease associated mutations found in the exome data, including the causative CMT locus in the patient, but an additional mutation was found in *SH3TC2* because of increased target coverage using this application.

Gene-disease association is still highly debated; however, discovery of a candidate mutation in several unrelated individuals with similar phenotypes gives power to disease implication. A candidate mutation was discovered in one family with a novel phenotype, sharing characteristics to Bohring-Opitz syndrome. The proband showed a *de novo* truncating mutation in *ASXL3*. Additional patients were found searching for other patients with the same *de novo* nonsense mutation in the identical gene - fostering the idea that molecular diagnostics is the future of the field. Whole exome data in conjunction with the molecular diagnostics will play an integral role in disease associations to genes.

3136F

Autosomal Dominant FSGS without extra-renal symptoms due to mutations in LMX1B gene.

Inherited forms of Focal segmental glomerular sclerosis (FSGS) are genetically heterogeneous and mutations in six genes (WT1, LMX1B, ACTN4, TRPC6, INF2 and ARHGAP24) have been reported in about 20% of families with autosomal dominant (AD) forms of the disease. In some AD cases various types of extra-renal involvement have been observed. For example LMX1B mutations are found in nail-patella syndrome (NPS, OMIM #161200) in which some cases exhibit FSGS with specific type III collagen lesions in the glomerular basement membrane (GBM). In one family out of a worldwide cohort of 74 with AD inheritance and no identified mutation, whole exome sequencing identified a mutation in LMX1B that segregated with FSGS in 5 affected individuals, all of whom lack the extra-renal features of NPS, including the GBM ultrastructural changes. Screening of the 73 other families in this cohort identified mutations in the same codon (R246) in two further families. Protein structure modeling suggests that R246 is a critical residue for interaction of LMX1B with the homeodomain of target genes. The results indicate that isolated FSGS can arise due to mutations in LMX1B, a gene normally associated with a broader syndromic phenotype. Other genes that underlie syndromes of which FSGS is a part of the phenotype should be considered in screening families in which no underlying cause of their familial FSGS has been identified.

3137W

Niemann-Pick Disease Type C Caused by Maternal Uniparental Isodisomy of Chromosome 18.
M. Fietz[1], S. Stark[1], A. Leo[1], G. Jenkins[2], B. Bennetts[2,3,4], J. Christodoulou[3,4,5]. 1) Dept Biochemical Genetics, SA Pathology (at WCH), North Adelaide, SA, Australia; 2) Dept Molecular Genetics, Western Sydney Genetics Program, Children's Hospital at Westmead, Sydney, NSW, Australia; 3) Discipline of Paediatrics and Child Health, Sydney Medical School, University of Sydney, Sydney, NSW, Australia; 4) Discipline of Genetic Medicine, Sydney Medical School, University of Sydney, Sydney, NSW, Australia; 5) Genetic Metabolic Disorders Service, Western Sydney Genetics Program, Children's Hospital at Westmead, Sydney, NSW, Australia.

Background: Niemann-Pick disease type C (NP-C) is an autosomal recessive lysosomal storage disorder with an estimated Australian incidence of 1:140,000. It has a broad clinical spectrum, ranging from neonatal lethal presentation through to adult-onset neurodegenerative disease. NP-C is caused by mutations in either the *NPC1* (18q11.2, ~95% of cases) or *NPC2* (14q24.3) genes. Mutations in these genes lead to abnormal intracellular cholesterol trafficking, detectable by analysis of cholesterol accumulation and esterification in cultured cells. Case Study: Patient ES was a term baby born to non-consanguineous parents, presenting at 2-months of age with conjugated hyperbilirubinaemia and hepatosplenomegaly. Cultured fibroblast studies revealed that he was affected by NP-C. He was commenced on oral miglustat therapy at 5-months of age on a compassionate basis. When reviewed at 15-months of age he had motor and growth delay, but cognitive development was progressing well. Purpose of Study: The aim of the study was to determine the causative mutation(s) for NP-C in patient ES, to enable future prenatal testing for this family. Results: Sequence analysis of *NPC1* revealed homozygosity for a previously unreported single nucleotide deletion in exon 15 (c.2336delT). However, analysis of parental DNA revealed that the mutation was carried by his mother but not his father. Subsequent microsatellite analysis of chromosome 18 demonstrated maternal uniparental isodisomy (UPD) over the length of chromosome 18, revealing the cause of the homozygous mutation in ES. Further, these results strongly suggest a post-zygotic error as the cause of the UPD. Conclusion: We believe this is the first report of NP-C being caused by UPD for chromosome 18, and this case highlights the importance of parental carrier testing for confirmation of the genetic basis of Mendelian disorders.

3138T

Leber congenital amaurosis with early-onset severe macular atrophy and optic atrophy is likely pathognomonic of NMNAT1 mutations. *I. Perrault[1], M. Nicouleau[1], S. Hanein[1], N. Delphin[1], B. Introduction: The nuclear nicotinamide mononucleotide adenyltransferase 1 (NMNAT1) encodes a homohexameric NAD- synthesizing enzyme as well as a chaperone that protects against neuronal activity-induced degeneration. Recently, NMNAT1 mutations have been reported to cause a highly specific Leber congenital amaurosis phenotype characterized by severe neonatal neurodegeneration of the central retina with early-onset optic atrophy. The purpose of the present study was to search for second NMNAT1 disease alleles in single heterozygote patients harboring the NMNAT1 phenotype. Methods: Nine sporadic cases and two sibs harboring single heterozygote NMNAT1 mutations were screened for copy number variations (CNV) using array comparative genomic hydridization (CGH, CytoScanHD) and mutations affecting regulatory elements or the splicing using Sanger sequencing of genomic DNA and/or lymphoblastoid cDNA. NMNAT1 haplotypes were constructed using SNP and microsatellite segregation analysis to search for shared ancestral alleles. Results: cDNA sequencing allowed identifying a one-exon duplication in the two sibs and 1/9 sporadic case sharing a same NMNAT1 haplotype. Array CGH analysis is ongoing to characterize the mutation at the genomic level. In 4/9 apparently unrelated sporadic cases, genomic DNA sequencing identified a same deep intronic change that affects a predicted regulatory element. All four cases were born to a parent originating from a French Indian Ocean island: La Réunion, suggesting that the change occurred on an ancestral allele. Haplotype analysis was consistent with this hypothesis. cDNA sequencing in 1/4 individual evidenced lack of amplification of the mRNA encoded by the allele harboring the deep intronic change. This suggests that the change, or a variant in linkage disequilibrium, is responsible for down regulation or instability of the mRNA. Conclusion: Here, we report that at least 6/10 LCA patients with single heterozygote NMNAT1 mutations carry a second disease allele undetected by exome sequencing. This result suggests that severe neonatal neurodegeneration of the central retina with early-onset optic atrophy is pathognomonic of NMNAT1 mutations. In-depth molecular analysis of the gene and surrounding regulatory elements should be considered in all patients harboring this highly specific LCA phenotype.

3139F

Lujan-Fryns Syndrome - conglomeration of different genetic entities? *K. Hackmann[1], S. Maas[2], N. Di Donato[1], E. Schrock[1], V.M. Kalscheuer[2], A. Rump[1].* 1) Institut fuer Klinische Genetik, TU Dresden, Dresden, Germany; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany.

Lujan-Fryns Syndrome (LFS) has been described as X-linked intellectual disability (XLID) with a marfanoid habitus. Previous analyses identified mutations in three different genes on the X chromosome, namely MED12, UPF3B, and ZDHCC9. We investigate these genes for mutations in 30 patients clinically diagnosed with LFS. No mutation was detected in any of the three genes. Molecular karyotyping revealed one case of Phelan-McDermid syndrome and one case of microduplication 16p11.2. In a third case we found a previously undescribed de novo duplication on chromosome 12p13, which we consider as potentially pathogenic. In several other cases we identified familial variants of unknown pathogenicity. Five individuals without noticeable deletions or duplications were analyzed by X-exome sequencing. After filtering against entries in publicly available databases two missense mutations in two genes currently not connected with disease remained. These might account for the phenotypic appearance but additional studies have to be carried out. The mutations were found in NKAP and LAS1L, respectively. It seems that there are cases that resemble LFS at least on a clinical level and do not necessarily have to have an X-linked cause. Exome sequencing should be the next step in order to identify the genetic causes in these patients. The clinical diagnosis LFS implies an XLID and might therefore lead to a misguided diagnostic procedure. We assume that one essential criterion for the clinical diagnosis of LFS is an X-linked segregation of the disorder. If this is not the case there is probably no higher incident of aberrations on the X chromosome to be expected in LFS cases than in any other form of intellectual disability of unknown cause. It remains to be corroborated by studying additional cases, if LFS is a single clinical entity or if there is a phenotypic overlap between several disease entities.

Expression of mouse acidic mammalian chitinase in periplasmic space of Escherichia coli. *K. Okawa, A. Kashimura, K. Ishikawa, Y. Kida, K. Iwabuchi, Y. Matsushima, M. Sakaguchi, Y. Sugahara, F. Oyama.* Biotechnology Laboratory, Department of Applied Chemistry, Faculty of Engineering, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan.

Acidic mammalian chitinase (AMCase) have been shown to be closely associated with asthma in mouse model, allergic inflammation and food processing. Biochemical characterization of AMCase requires large quantities of purified protein. Currently, efforts to characterize these proteins structurally and biochemically rely on mammalian, insect cell expression systems and E. coli. We describe herein an E. coli-expression system allowing periplasmic production of active AMCase in E. coli. The mouse AMCase cDNA was cloned into the E. coli expression vector for extracellular expression in E. coli. Most of the expressed AMCase was present in the periplasmic space with chitinolytic activity measured using the chromogenic substrate, p-nitrophenyl β-D-N, N'-diacetylchitobiose (PNP-diacetylchitobioside). This recombinant protein can be used to elucidate detailed biomedical functions of the mouse AMCase.

3141T

Familial generalized seizures due to LGI1 mutation: importance of family history for genetic testing. *D.R.M. Amrom[1,3,4,7], F. Andermann[2,3,5,7], E. Andermann[1,3,4,6,7].* 1) Neurogenetics Unit; 2) Epilepsy Service and Seizure Clinic; 3) Montreal Neurological Hospital & Institute, Montreal, Quebec, Canada; 4) Department of Neurology & Neurosurgery; 5) Department of Pediatrics; 6) Department Human Genetics; 7) McGill University, Montreal, Quebec, Canada.

It is well known that patients with temporal lobe epilepsy may present with generalized seizures, and the temporal localization depends on further investigation. We present a family with 5 individuals in 3 generations where the clinical pattern consisted largely of generalized seizures, but who were then shown to have epilepsy due to an LGI1 mutation. The proband is a 46-year-old female who had four nocturnal seizures, all occurred around 5-6 am, the first one at age 19 years. She has been seizure free since adequate compliance with treatment. Her first EEG performed at 19 years showed an excess of slow waves at 2-4 Hz over both posterior regions without epileptic activity. Her second EEG at 22 years showed spikes and slow spike waves alternating over both temporal regions, mostly during drowsiness, and increased during hyperventilation. During intermittent photic stimulation, a photomyoclonic response appeared. Her 40-year-old sister had her first tonic-clonic seizure at 12 years which was generalized from the onset. All but one of her subsequent attacks occurred during sleep. Before the only seizure that occurred while awake, she felt diffuse numbness and heard a whooshing sound suggestive of neocortical temporal lobe involvement. The third sister is 52 years old; she had her first generalized seizure at 19 years. A year prior to this, she had transient symptoms of a tingling sensation associated with a wooshing noise. She later had other generalized attacks preceded by this aura. A diagnosis of neocortical or lateral temporal, possibly autosomal dominant partial epilepsy with auditory features (ADPEAF), was suggested. Although the proband only had nocturnal generalized seizures, LGI1 sequencing was performed on the basis of the family history. A c.611delC mutation leading to a frameshift and premature termination of the protein was identified. Generalized nocturnal and diurnal seizures associated with interictal generalized spike-wave activity occurring in a family with ADPEAF is unusual. They may represent secondarily generalized seizures or primary generalized seizures or both. In addition, photosensitivity in the proband is unusual as well. This family illustrates that patients with ADPEAF may present with generalized seizures and generalized spike and wave epileptic discharges. Intensive monitoring and attention to aura with auditory features should lead to accurate diagnosis of this genetically determined epileptic syndrome.

3142F

Type V Osteogenesis Imperfecta: don't miss the subtleties. *E.M. Carter[1], C.L. Raggio[1,], J.G. Davis[1,2].* 1) Center for Skeletal Dysplasias, Hospital for Special Surgery, New York, NY; 2) NY-Presbyterian Hospital, Weill Cornell Medical College, New York, NY.

Osteogenesis Imperfecta (OI) is a group of heritable connective tissue disorders characterized by predisposition to fracture. Diagnosis is made by clinical and radiographic criteria, family history, and increasingly through molecular genetic testing. Type V OI (OI5) accounts for ~4-5% of all dominant OI. It is a clinically heterogeneous group caused by dominant mutation of *IFITM5* (c.-14C>T). Distinguishing features can include hyperplastic callus formation after fracture/surgery, calcification of the radioulnar interosseous membrane, and/or radial head dislocation. Here we present two cases. Case 1: A now 12 yr old girl referred by her pediatrician at 5 yrs because of multiple fractures since the age of 9 mos. Family history: no consanguinity, no one else with fractures, skeletal dysplasia, or metabolic bone disease. X-rays: calcification of the radioulnar interosseous membrane, hyperplastic callus formation at the distal fibulas, mild scoliosis, mild bell-shaped thorax, gracile ribs, and osteopenia. Physical exam: ligamentous laxity, limited forearm supination/pronation, white sclerae, no dentinogenesis imperfecta (DI), and no contractures. No mutation detected in *col1α1/col1α2*. Findings were consistent with OI5. Molecular confirmation through *IFITM5* sequencing is pending. Case 2: A now 2 yr old boy of mixed Hispanic ancestry referred by his orthopaedic surgeon at 1 yr because of multiple fractures since the age of 3 mos. Family history: no consanguinity, no one else with fractures, skeletal dysplasia, or metabolic bone disease. After a radius/ulna fracture at 10 mos a skeletal survey showed multiple healed fractures. No mutation was detected in *col1α1/col1α2*. X-rays: gracile ribs, hypertrophic chondrocostal junctions, bilateral bowing of the radius and ulna, vertebral compression fractures, hypertrophic tibia callus, osteopenia, and moderate metaphyseal sclerosis. Physical exam: ligamentous laxity, white sclerae, and no DI. Findings were consistent with OI5, confirmed through mutation analysis of *IFITM5* (c.-14C>T). With accurate clinical diagnosis, >90% of individuals with OI have a *col1α1/col1α2* mutation. For individuals with no col1α1/col1α2 mutation, a skeletal survey should be performed to look for distinguishing features of OI5. Although clinical variability is wide, genetic testing is sensitive: 100% have the c.-14C>T *IFITM5* mutation. Accurate diagnosis is important in evaluation of non-accidental injury and for genetic counseling.

Mesenteric Cyst A Case Report and a Review of the Genetic Implications of this Rare Disease. *J. Davalos.* Area of Health # 1, Quito, Pichincha, Ecuador.

Case Report A 44 -year- old woman, using by 13 years a IUD, asymptomatic, the IUD was removed and we finded a 18 centimeters pelvic mass and a red spotty skin pigmentation in the left arm.The ultrasound scan reported a pelvic cyst containing 1,7 liters and a 3,1 cm right ovarian cyst. A computerized tomographic scan revealed a mesenteric cyst, the mass measured 14.1 × 10.8 cm and contained approximately one liter of serous fluid and also reported a small hepatic cyst. Discussion Mesenteric cysts are one of the most rare intra-abdominal tumors.1 The reported incidence ranges from 1/20,000 to 1/250,000 admissions to hospital.2 As proposed by Gross, mesenteric and omental cysts are thought to represent benign proliferations of ectopic lymphatics that lack communication with the normal lymphatic system.3 Other etiologic theories include (1) failure of the embryonic lymph channels to join the venous system, (2) failure of the leaves of the mesentery to fuse, (3) trauma, (4) neoplasia, and (5) degeneration of lymph nodes.4 Genetic Considerations Carney complex (CNC) is a familial multiple neoplasia syndrome transmitted as an autosomal dominant trait. CNC was initially described as the association of myxomas, spotty skin pigmentation, and endocrine overactivity. A variety of endocrine and nonendocrine tumors occur in patients with CNC.Primary pigmented nodular adrenocortical disease (PPNAD), a rare cause of ACTH-independent Cushing syndrome. PPNAD is observed in one-fourth of patients with CNC. Approximately half of the cases of CNC are familial. Putative genetic loci have been identified by linkage analysis at chromosome 2p16 and 17q22-24. Recently, the responsible gene on 17q22-24, PRKAR1A, was identified. Mutations in the PRKAR1A tumour suppressor gene were recently found in CNC1 mapping kindreds, while the CNC2 and perhaps other genes remain unidentified. Additional mutations in this gene were described later in other kindreds).Overall, inactivating mutations of this gene have been observed in ~41% of CNC kindreds.5,6Polycystic liver disease (PCLD) is characterized by the growth of fluid-filled cysts of biliary epithelial origin in the liver. PCLD is most often associated with autosomal dominant polycystic kidney disease (ADPKD).A causative gene, PCLD, was mapped to chromosome 19p13.2-13.1, with a maximum LOD score of 10.3. Haplotype analysis refined the PCLD interval to 12.5 cM flanked by D19S586/D19S583 and D19S593/D19S579.7.

3144T

The Role of Molecular Genetic Analysis in the Diagnosis of Primary Ciliary Dyskinesia. *R.H. Kim[1], D.A. Hall[2], E. Cutz[3], M.R. Knowles[4], K. Nelligan[5], K. Nykamp[6], M.A. Zariwala[7], S.D. Dell[8].* 1) Clinical Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Respirology, St Michael's Hospital, University of Toronto, Toronto, ON, Canada; 3) Division of Pathology, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 4) Department of Medicine, University of North Carolina School of Medicine, Chapel Hill, North Carolina USA; 5) Division of Respiratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 6) Prevention Genetics, Marshfield, Wisconsin, USA; 7) Department of Pathology and Laboratory Medicine, University of North Carolina School of Medicine, Chapel Hill, North Carolina USA; 8) Division of Respiratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada; Department of Pediatrics and Institute of Health Policy, Managment and Education, University of Toronto, Toronto, ON, Canada.

Rationale: Primary Ciliary Dyskinesia (PCD) is an autosomal recessive genetic disorder of motile cilia. The diagnosis of PCD has previously relied on ciliary analysis with transmission electron microscopy or video microscopy. However, patients with PCD may have normal ultrastructural appearance and ciliary analysis has limited accessibility. Alternatively, PCD can be diagnosed by demonstrating biallelic mutations in known PCD genes. Genetic testing is emerging as a diagnostic tool to complement ciliary analysis where interpretation and access may delay diagnosis. **Objectives:** To determine the clinical utility of genetic testing of patients with a confirmed or suspected diagnosis of PCD in a multi-ethnic urban centre. **Methods:** 28 individuals with confirmed PCD on transmission electron microscopy of ciliary ultrastructure and 24 individuals with a probable diagnosis of PCD based on a classical PCD phenotype and low nasal nitric oxide had molecular analysis of 12 genes associated with PCD. **Results:** 28/49 (57%) who underwent ciliary biopsy were diagnosed with PCD through an ultrastructural defect. Of the 52 individuals who underwent molecular genetic analysis, 22 (42%) individuals had two mutations in known PCD genes. 24 previously unreported mutations in known PCD genes were observed. Molecular findings also aided in the interpretation of inconclusive biopsy results. Combining both diagnostic modalities of biopsy and molecular genetics, the diagnostic yield increased to 69% compared to 57% based on biopsy alone. **Conclusions:** The diagnosis of PCD is challenging and has traditionally relied on ciliary biopsy which is unreliable as the sole criteria for a definitive diagnosis. Molecular genetic analysis can be used as a complementary test to increase the diagnostic yield and facilitate carrier testing and genetic counseling.

3145F

Genotype-Phenotype Correlation in Bardet- Biedl syndrome. *O. MHAMDI[1], H. CHAABOUNI[1,2].* 1) Department of Human Genetics, Faculty of Medicine, Tunis, Tunisia; 2) Department of Hereditary disorders, Charles Nicolle Hospital. Boulevard 9 Avril 1006 Tunis.

Bardet-Biedl syndrome (BBS) is an autosomal recessive disease characterized by retinal dystrophy, obesity, postaxial polydactyly, learning disabilities, renal involvment, and male hypogenitalism. BBS is a genetically heterogeneous with 17 genes (BBS1-BBS17), mutations in BBS genes accounting for approximately 70-80% of cases. Triallelic inheritance has been suggested in about 5% of cases. The genotype-phenotype correlation in BBS was unclear and can be explained by genetic locus heterogeneity, triallelism and modifier genes such as CCDC28B.In order to analyze more clearly, we evaluated a world wide cohort of 371 patients from 330 families with Bardet-Biedl syndrome in whom disease-causing genes were identified. The phenotype spectrum of studied BBS patients was ranged between mild to severe. Thus, our studies have important implication for molecular diagnosis and genetic counselling in BBS patients.

3146W

Fragile X triplet repeat instability is influenced by both the presence and position of AGG interruptions in intermediate and premutation alleles. *S. Nolin[1], R. Cao[2], J. Taylor[2], A. Glicksman[1], N. Ersalesi[1], W.T. Brown[1], J. Coppinger[2], G. Latham[2], A. Hadd[2].* 1) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) Asuragen, Inc., Austin, TX.

Fragile X syndrome is a common cause of inherited intellectual disability that results from the expansion of a CGG repeat in the 5' untranslated region of the FMR1 gene to >200 copies. We examined FMR1 repeat instability in 762 transmissions of fragile X intermediate (45-54 repeats) and small premutation (55-90 repeats) alleles. Novel PCR assays were used to identify the number and position of the AGGs that occur within the CGG repeat region. Twenty-eight percent of the transmissions contained no AGGs, 44% had one AGG and 27% had two AGGs. Consistent with prior studies, the absence of AGG interruptions within the repeat was associated with an increased risk for instability on transmission as well as an increased risk for expansion to a full mutation in larger alleles. Alleles with two AGGs were least likely to exhibit instability or expansion to a full mutation on transmission. Alleles with one AGG had moderate risks for instability or expansion to full mutation. Surprisingly, the position of the single AGG interruption in these alleles was correlated with instability. Most of the one-AGG alleles had an interruption at position 10 while a minority had one at position 11. Analysis of one-AGG alleles with 45-59 repeats revealed an increased risk of instability for alleles with an AGG at position 10 compared to those with an AGG at position 11. Similarly, analysis of one-AGG alleles with 70-90 repeats revealed an increased risk for full mutation expansion for alleles with an AGG at position 10 compared to those with the AGG at position 11. These results and the fact that AGGs in expanded alleles occur more frequently at position 10 than position 11, suggest that AGGs at position 11 have a greater influence in stabilizing the FMR1 repeat region on transmission.

3147T

Identification of a novel nonsense mutation and a missense substitution in the AGPAT2 gene causing congenital generalized lipodystrophy type 1. *A. Haghighi[1], M. Razzaghy-Azar[2], A. Talea[2], M. Sadeghian[3], S. Ellard[4], A. Haghighi[5].* 1) University of Toronto, Toronto, Ontario, Canada; 2) Endocrinology and Metabolism Research Center, Tehran University of Medical Sciences, Tehran, Iran; 3) Pediatric Gastroenterology Department, H. Aliasghar Hospital, Tehran University of Medical Sciences, Tehran, Iran; 4) Institute of Biomedical and Clinical Science, Peninsula College of Medicine and Dentistry, University of Exeter, Exeter, UK; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Headington, Oxford OX3 7PS, UK.

Congenital generalized lipodystrophy (CGL) is an autosomal recessive disease characterized by the generalized scant of adipose tissue. CGL type 1 is caused by mutations in gene encoding 1-acylglycerol-3-phosphate O-acyltransferase-2 (AGPAT2). A clinical and molecular genetic investigation was performed in affected and unaffected members of two families with CGL type 1. The AGPAT2 coding region was sequenced in index cases of the two families. The presence of the identified mutations in relevant parents was tested. We identified a novel nonsense mutation (c.685G>T, p.Glu229*) and a missense substitution (c.514G>A, p.Glu172Lys). The unaffected parents in both families were heterozygous carrier of the relevant mutation. The results expand genotype-phenotype spectrum in CGL1 and will have applications in prenatal and early diagnosis of the disease. This is the first report of Persian families identified with AGPAT2 mutations.

3148F

Phenotype - genotype correlation in a Colombian Oculocutaneous Albinism (OCA) cohort. *C. Lattig[1], D. Sanabria[1], A. Fernandez[2], O. Urtatiz[1], Fundacion Contraste - Albinos por Colombia.* 1) Laboratorio de Genética Humana, Departamento de Ciencias Biológicas, Universidad de los Andes, Bogota, Colombia; 2) Hospital Militar, Bogotá, Colombia.

Oculocutaneous albinism (OCA) is a genetic condition of melanin synthesis characterized by a complete lack or generalized reduction in pigmentation of hair, skin and eyes. OCA1, one of the four types of OCA is the most frequent worldwide and is caused by mutations in TYR gene. The TYR gene consists of 5 exons spanning about 65 kb of genomic DNA and encoding a protein of 529 amino acids. In the present study, we have 20 unrelated cases of albinism with complete ophthalmological evaluation. Sequencing of the TYR gene in these individuals revealed three novel mutations, one nonsense mutation, c.551C>G (S184X) and two missense mutation, c.739T>C (C246R) and c.163 T>G (p.C55G), all of them in exon 1. We also found the p.R402Q temperature-sensitive mutation in three individuals. In three cases we were not able to detect any mutations in any of the five exons of the TYR gene. Individuals 07 and 08 are siblings and both present the novel mutation p.C246R in heterozygous state; in addition individual 08 has the variant R402Q in heterozygous state and has a more severe albino phenotype than individual 07. We present the first report of a phenotype - genotype correlation in a Colombian OCA cohort.

Support to the International Rare Diseases Research Consortium: a new service to the research community. *P. Lasko[1,2,3], B. Cagniard[4], S. Höhn[4], R. Favresse[4], D. Désir-Parseille[4], S. Peixoto[4], M. Bellanger[4], N. Lévy[4], S. Aymé[4].* 1) International Rare Diseases Research Consortium, Montreal (IRDiRC), Quebec, Canada; 2) CIHR Institute of Genetics, Montreal, Quebec, Canada; 3) Department of Biology, McGill University, Montreal, Quebec, Canada; 4) SUPPORT IRDiRC, Paris, France.

The International Rare Diseases Research Consortium (IRDiRC) brings together members that share common goals and principles and have agreed to work in a coordinated and collaborative manner within a multinational consortium to advance research in this critical area. The IRDiRC scientific secretariat has been established at the Rare Diseases Platform in Paris. IRDiRC's two main objectives are to deliver 200 new therapies for rare diseases and means to diagnose most rare diseases by the year 2020. Its members are over 30 public and private research funding organizations that have each dedicated over 10 million US$ to research into rare diseases. A number of challenges will be addressed through collaborative actions: establishing and providing access to harmonised data and samples, performing the molecular and clinical characterisation of rare diseases, boosting translational, preclinical and clinical research, and streamlining ethical and regulatory procedures. The consortium has established three Scientific Committees. The Diagnostics committee advises on research related to the diagnoses of rare disease, including sequencing and characterization of these diseases. The Interdisciplinary committee provides expertise on cross-cutting aspects of rare diseases research including issues related to ontologies, natural history, biobanking, and registries. The therapies committee gives guidance for the pre-clinical and clinical research aiming to deliver new therapies for rare diseases. The guiding principles of IRDiRC, its plan for action and its achievements so far will be presented, as well as ways for the genetic research community to get engaged in this global effort.

3150T

Role of CFTR in regulating spermatogenesis and Implications in male infertility. *H. Sharma[1], R. Prasad[1], S.K. Singh[2], R. Mohan[2].* 1) Department of Biochemistry, PGIMER, Chandigarh, India; 2) Department of Urology, PGIMER, Chandigarh, India.

The cystic fibrosis transmembrane conductance regulator (CFTR) is a cAMP - activated Chloride and HCO3 conducting channel, mutations of which are known to be associated with male infertility. CFTR mutations have been identified in patients presented with spectrum of genital phenotypes ranging from impaired spermatogenesis to CAVD and obstruction in reproductive tract other then vas-deferens or epididymis, although some contradictory reports are also available. Moreover spectrum of mutation identified in Indian patients with classical CF and infertile CBAVD male is heterogeneous and is completely different from that of Caucasians population, therefore the Present study was undertaken to establish the spectrum and frequency of CFTR mutation in Indian infertile male population and to understand the possible involvement of CFTR gene in the etiology of male infertility other than CAVD. Blood samples from infertile males with, obstructive azospermia (n=25) with palpable vas deferens and oligospermia (n=100) were used for genomic DNA isolation and screening mutations in seven exons (2,3,4,7,8,10) hot spots of CFTR gene. Delta F-508, N1303K, R553X, G551D, G542X, 621+1G>T and W1282X were the other known most common mutation screened in Indian infertile males through allele specific ARMS PCR analysis. IVS8-Poly T allele polymorphism was also determined in all infertile male patients. Out of 25 cases with obstructive azospermia 17(68%) were found to have mutation in single CFTR allele where as among 100 oligospermic males only 17% males were also found to have mutation in CFTR gene. Delta F-508 (9.5%) and IVS8 (5T) allele (22%) were the most common mutations identified in Indian infertile male population. Two novel mutations in exon 10 of CFTR were also indentified in patients with obstructive azospermia. The increased frequency of CF mutations in males with reduce sperm quality and quantity and in males with azospermia without CBAVD suggest CFTR protein may be involved in the process of spermatogenesis or sperm maturation apart from playing critical role in the development of epididymal gland and vas-deferens. Moreover exon 10 in NBD1 region of CFTR playing important role in etiology male infertility,therefore Indian infertile male presented with obstructive azospermia or spermatogenetic defect and opting for assisted reproductive technology (ART) should be advised for screening of exon 10 of CFTR.

3151F

Milder course in Duchenne patients with nonsense mutations and no muscle dystrophin. *M. Zatz, R.C.M. Pavanello, M. Lazar, N.C.V. Lourenço, A. Cerqueira, L. Nogueira, M. Vainzof.* Human Genome and stem cell research center, Biosciences Institute, Universidade de Sao Paulo, Sao Paulo, SP, São Paulo, Brazil.

Duchenne muscular dystrophy (DMD) is a lethal X-linked condition caused by mutations in the dystrophin gene which results in the absence of muscle dystrophin. The course is usually severe and very similar in affected patients. Without careful management, loss of ambulation occurs between 10-12 years of age. On the other hand, in Becker muscular dystrophy (BMD) there is a wide variability in the severity of the phenotype which has been mainly associated with the site of the deletion and to the amount of muscle dystrophin. Therefore, the quantity/quality of muscle dystrophin has been strongly associated with appropriate muscle function. Animal models with null mutations and no muscle dystrophin are of great interest. The mdx mice are almost asymptomatic, while the GRMD (golden retriever muscular dystrophy) dogs are usually severely affected representing the best model for DMD. Such clinical difference might be related to the size of the dystrophic muscle. We have previously identified two exceptional GRMD dogs with a very mild phenotype and no muscle dystrophin. A DMD patient with a milder course despite the absence of muscle dystrophin was also reported (Dubowitz, 2006). Here we report two additional very rare DMD patients with nonsense mutations in the DMD gene and no muscle dystrophin. Case 1, currently age 14, is only mildly affected, with discrete calves' hypertrophy, some difficulties for running and climbing stairs but with normal ability to walk. His youngest brother shows a severe course, being confined to a wheelchair at age 9. Both carry an out of frame duplication in exon 2. Case 2, is an isolated DMD patient who, at age 15, is able to walk without difficulties and climb stairs with the aid of the bannister. He carries an out-of-frame deletion encompassing exons 51 to 54. Dystrophin IF and WB with three antibodies against the N-terminal, rod domain and C-terminal, showed a typical DMD pattern, in both of them. Merosin was positive, and sarcoglycans were faint, as observed in most DMD dystrophin deficient patients. Therapeutic trials aiming the amelioration of muscle function have been targeting the production of muscle dystrophin in affected DMD patients. Importantly, our observations indicate that it is possible to have a functional large muscle even without dystrophin. Finding the underlying protective mechanisms is of utmost importance and may lead to new avenues for treatment.

MEFV Gene Mutation Detection In Arabic Patients. *R. Taha[1], S. Ayesh[2], M. Kambouris[1,3], H. El-Shanti[1,4].* 1) Molecular Genetics, Shafallah Medical Genetics Center, Doha, Qatar; 2) Gene Medical Labs, Gaza, Palestinian Territory; 3) Yale University School of Medicine, Genetics, New Haven CT, USA; 4) University of Iowa, Pediatrics, Iowa City, IA, USA.

Autoinflammatory diseases are characterized by inflammation in the absence of high-titer autoantibodies or antigen-specific T cells. Familial Mediterranean fever (FMF) is the archetypal hereditary autosomal recessive periodic fever syndrome & auto-inflammatory disease characterized by recurrent self-limiting episodes of fever & painful polyserositis. It is found in families of Mediterranean ancestry, especially non-Ashkenazi Jews, Armenians, Turks, and Arabs. The offending MEFV gene localizes at Hsa 16p, encodes the pyrin (marenostrin) protein, it is highly polymorphic with multiple disease causing mutations and normal polymorphisms. In Arabic FMF patients the spectrum and distribution of MEFV mutations are distinctive and the portion of unidentified mutations [50%] is the highest amongst the groups affected by FMF. The MEFV genomic region in 100 Palestinian patients with clear FMF symptomatology consistent with the clinical diagnostic criteria and with only one identified pathogenic mutation was screened to identify the second pathogenic mutation as well as coding and non-coding variations, large duplications or deletions and intronic variations. Mutation analyses involved sequencing of exons and splice sites, sequencing putative regulatory regions by using Long range PCR, Multiplex Ligation-dependent Probe Amplification (MLPA) to detect large deletions or duplications & sequencing of the entire genomic region of MEFV. No second pathogenic mutation was identified in any of the samples by sequencing MEFV exons, splice sites, as well as putative regulatory regions. MLPA did not detect any large MEFV genomic deletions or duplications. Twenty rare intronic variants were identified (each in 1-3 patients) and were not present in ≈700 ethnically matched control chromosomes. The biological significance of these variations could not be determined. There are strong evidences of preferential amplification of one allele over the other due to extensive polymorphism within the genomic sequence that would account for the lack of detection of the second pathogenic mutation. Alternatively, the effects of modifier genes or other loci that influence the clinical picture of FMF in Arabic populations can not be excluded. The comprehensive identification of MEFV mutant alleles among FMF patients is essential for the efficient examination of specific genotype-phenotype correlation patterns and for development of molecular tools to support the clinical diagnosis.

PhenomeCentral: An Integrated Portal for Sharing and Searching Patient Phenotype Data for Rare Genetic Disorders. *M. Brudno[1], M. Girdea[1], S. Dumitriu[1], S. Köhler[2], P.N. Robinson[2], A.J. Brookes[3], K. Boycott[4], C.F. Boerkoel[5], W.A. Gahl[5], Canadian CARE for RARE Consortium (FORGE) and NIH Undiagnosed Diseases Program.* 1) Centre for Computational Medicine, Hospital for Sick Children & University of Toronto, Toronto, ON, Canada; 2) Charite Hospital, Berlin, Germany; 3) Department of Genetics, University of Leicester, Leicester, United Kingdom; 4) Children's Hospital of Eastern Ontario, Ottawa, ON Canada; 5) National Institutes of Health Undiagnosed Diseases Program.

The availability of low-cost genome sequencing has allowed for the identification of the molecular cause of hundreds of rare genetic disorders. Solved disorders, however, only represent the 'tip of the iceberg'. Because the discovery of disease-causing variants typically requires confirmation of the mutation or gene in multiple unrelated individuals, an even larger number of genetic disorders remain unsolved due to difficulty identifying second families. With many groups now tackling these remaining undiagnosed disorders, which may be present in only a handful of individuals seen at different hospitals and sequenced by different centers, it is critical to establish effective and secure data-sharing techniques that allow clinicians and scientists to identify additional families via phenotype and genotype searches.

To address this need, we have developed PhenomeCentral (http://phenomecentral.org), a repository for secure data sharing targeted to the rare disorder community. Each patient record within PhenomeCentral consists of a thorough phenotypic description capturing observed abnormalities as well as relevant absent manifestations, expressed using Human Phenotype Ontology terms. Furthermore, each record can be labeled by the creator as: *private* hidden from everyone except the contributor; *public* viewable and searchable by all registered users; or *matchable* the record cannot be directly viewed or searched, but is reachable via an automated phenotype matching system (following Cafe Variome principles) which informs contributors of the existence of profiles similar to their cases. The phenotypic features shared among these records are presented without revealing additional patient information or the contributors, enabling direct communication for any subsequent data sharing.

PhenomeCentral currently incorporates phenotype data for >400 patients with rare genetic disorders without a molecular diagnosis, including: 200 from the Canadian CARE for RARE project and 150 from the NIH Undiagnosed Diseases Program (UDP). Clinical geneticists and scientists studying rare disorders can request accounts, and new patients can be added either using the PhenoTips User Interface, built into PhenomeCentral, or uploaded in bulk. An interface allowing for the deposition and analysis of genomic data (whole-exome VCF files and CNVs) is under development.

Ocular phenotypes in aneurysm syndromes collected from GenTAC (National Registry of Genetically Triggered Thoracic Aortic Aneurysms and Cardiovascular Conditions) Registry. *G. Oswald[1], KW. Holmes[1,4], S. LeMaire[2], W. Ravekes[1], NB. McDonnell[3], C. Maslen[4], RV. Shohet[5], RE. Pyeritz[6], R. Devereux[7], DM. Milewicz[8], EM. Reynolds[9], JP. Habashi[1], GenTAC Registry Consortium.* 1) Johns Hopkins University, Baltimore, MD; 2) Baylor College of Medicine, Houston, TX; 3) NIA at Harbor Hospital, Baltimore, MD; 4) Oregon Health & Science University, Portland OR; 5) Queen's Medical Center, Honolulu, HI; 6) The University of Pennsylvania, Philadelphia, PA; 7) Weill Cornell Medical College of Cornell University, New York, NY; 8) University of Texas Medical School at Houston, Houston, TX; 9) University of Maryland, Baltimore, MD.

The National Registry of Genetically Triggered Thoracic Aortic Aneurysms and Cardiovascular Conditions (GenTAC) has enrolled over 3400 patients with aortic aneurysm syndromes, including Marfan (MFS), Loeys-Dietz (LDS), vascular Ehlers-Danlos (vEDS), Bicuspid Aortic Valve with enlargement (BAVe) and Familial Thoracic Aortic Aneurysm Disease (FTAAD). The GenTAC Registry was queried for prevalence of ocular features, showing its utility to investigators studying non-cardiac features of these disorders. Ectopia lentis (ECL) was reported in 53% of patients with MFS, with equal distribution between age and gender, consistent with previously published data. ECL was not observed in LDS or vEDS, and rarely reported in other aneurysm conditions (<1%). Retinal detachment (RD) was observed in 8.7% of MFS and rarely in other aneurysm syndromes (<1%). ECL and RD were concomitant in 51 of 61 MFS patients. Glaucoma and cataracts were reported in 4% and 8.3% of MFS patients, respectively. Myopia was most commonly reported in MFS, but not significantly different than that observed in the general population. LDS showed the highest prevalence of strabismus/amblyopia of 12.3% as compared to MFS (8.3%) and other syndromes. Patients with MFS are commonly counseled to avoid LASIK correction of refractive error due to speculation that surgery's mechanical forces may increase RD risk. Analysis of the operative data available in a subset of patients found that 3.1% of enrolled patients with a confirmed diagnosis of MFS reported having undergone LASIK. Of the 12 MFS patients who had LASIK, 7 had ECL (58.3%) and 2 had RD (16.7%). 2/12 patients who had lens extraction (16.7%) and 5/22 with lens implants (23%) had RD. Direct causation cannot be inferred because the timing of LASIK in relation to the RD was not available. This review of ocular data within the GenTAC registry identifies a >50% prevalence of lens dislocation in MFS and a notable absence of lens dislocation in LDS as previously reported; therefore, presence or absence of lens dislocation is a useful diagnostic tool in differentiating patients. Furthermore, this data supports the theoretical risk that LASIK correction may increase the risk of retinal detachment in patients with connective tissue disorders however more detailed studies investigating the temporal relationship need to be done.

3155W

Budd-Chiari syndrome as the presenting symptom of familial thrombotic thrombocytopenic purpura caused by a novel frameshift mutation of ADAMTS13. *R. Parvari[1,3], M. Arafat[1], K. Akel[2], B. Yerushalmi[2], M. Aviram[2], D. Landau[2].* 1) Shraga Segal Dept of microbiology, immunology and Genetics, Ben Gurion Univ of the Negev, Beer Sheva, Israel; 2) Department of Pediatrics, Soroka Medical Center, Beer Sheva, Israel; 3) National Institute of Biotechnology, Ben Gurion Univ of the Negev, Beer Sheva, Israel.

Both Budd Chiari syndrome (BCS) and thrombotic thrombocytopenic purpura (TTP) are rare pediatric diagnoses. Thrombotic microangiopathy, the pathological hallmark of TTP, may be due to acquired or congenital defects in the protease ADAMTS13, which cleaves the vWF multimers and prevents uncontrolled thrombosis. We have been treating an extended Bedouin family of 5 patients with different TTP manifestations. The index case, a 10 years old boy previously healthy was admitted because of headache, jaundice, epistaxis and macro hematuria of 3 days duration. He was further diagnosed with BCS caused by occlusion of the hepatic veins. The child has been since treated with fresh frozen plasma infusions and enoxaparin. He experienced several TTP relapses. Liver biopsy shows evidence of BCS, without cirrhosis. The child has experienced an early (hematologic) good response to plasma treatment but no venous recanalization could be obtained, leading to signs of severe portal hypertension Four other affected members in the extended family experienced TTP-like episodes during childhood or pregnancy. Three patients were found to have very low (< 5%) ADAMTS13 levels. Sequencing ADAMTS13 has revealed a novel frameshift mutation that will result in the absence of 82 amino acids the carboxy terminus deleting the CUB2 domain. This is the first description of familial TTP presenting with BCS, a major vessel thrombosis.

3156T

In silico and molecular analyses of mutations that alter mRNA splicing of COL1A1. *J. Schleit, S. Bailey, T. Tran, D. Chen, P.H. Byers.* Pathology, University of Washington, Seattle, WA.

Approximately 10-20% of inherited pathogenic mutations alter mRNA splicing. Phenotypes of affected individuals are often dependent on the stability of the mRNA produced by the mutant allele. Currently, the downstream effects of mutations on mRNA splicing are often difficult to predict, complicating diagnoses based on DNA sequence alone. As the use of molecular diagnostics moves increasingly to DNA sequencing, the need to understand the effects of splice site mutations will increase further. We sought to identify factors that determine the mRNA splice products in the heritable disorder osteogenesis imperfecta (OI). To better understand the relationship between genotype and mRNA splicing outcomes, we examined clinical and molecular data from 219 OI patients with 122 unique mutations within the introns COL1A1, which encodes the proa1(1) chain of type I collagen. We examined mutations representing OI types I-IV with approximately 73% of patients diagnosed with OI Type I, 11% with OI Type IV, 6% with OI Type III, and 10% with OI Type II. 106 of the 219 (48%) of patients had mutations in the canonical GT-AG splice donor or acceptor site. All patients with OI Type I, for which cDNA was examined, produced unstable mRNAs with premature termination codons due to translational frameshifts. 34 individuals with G to A transitions in the final nucleotide of COL1A1 introns (IVS(X)-1G>A) had OI type I phenotypes, due to shift of the splice acceptor site one nucleotide downstream when the first nucleotide of the exon was guanine. In contrast, 72 individuals with IVS(X)+1G>A mutations had highly variable OI phenotypes (Types I-II) and the splice outcomes yielded diverse and often multiple mRNA products. In patients with OI Types II-IV we detected abnormal, stable mRNAs resulting from in-frame splice outcomes. For splice donor site mutations there was no correlation between outcome and intron size or the predicted strength of native and alternative splice sites in these individuals. To examine additional factors which may impact splice outcome, we treated wild-type human fibroblasts with the transcriptional inhibitor Actinomycin D. Using intron specific primers, we measured the speed and order of intron splicing of COL1A1 using quantitative PCR and capillary electrophoresis. mRNA splice outcomes were independent of the speed at which COL1A1 introns were spliced, however the order in which introns are normally removed appears to play a role in determining splice outcome .

3157F

Characterization of Escherichia coli-expressed acidic mammalian chitinase. *A. Kashimura, K. Okawa, K. Ishikawa, Y. Kida, K. Iwabuchi, Y. Matsushima, M. Sakaguchi, Y. Sugahara, F. Oyama.* Biotechnology Laboratory, Department of Applied Chemistry, Faculty of Engineering, Kogakuin University, 2665-1 Nakano, Hachioji, Tokyo 192-0015, Japan.

Chitinase hydrolyze chitin, a polymer of N-acetyl-D-glucosamine, which is present in a wide range of organisms, including fungi, insects, and parasites. Although mammals do not have chitin synthase, chitinase genes were found in both human and mouse genomes. It has been known that chitinase activity is significantly increased in plasma from patients with Gaucher disease, an autosomal recessive lysosomal storage disorder. Recent researches have shown that elevated expression of chitinases is closely associated with progression of allergy and asthma. The pathophysiological role for the mammalian chitinases remains unproven. To understand how these chitinases interact with chitin and degrades it, we expressed and purified acidic mammalian chitinase in Escherichia coli as a fusion protein. The recombinant protein showed a robust peak of activity with maximum was observed at pH 2.0, where the optimal temperature was 54 °C. This protein also shows a heat-stable until 56 °C at both pH 2.0 or 56 °C at pH 7.0 for 30 min. The chitinolytic activity of the recombinant AMCase against PNP-diacetylchitobioside was comparable to CHO-expressed one. Furthermore, the recombinant AMCase bound to chitin beads and cleaved colloidal chitin and released mainly chitobioside fragments. Thus, E. coli-expressed AMCase possesses chitinase functions comparable to CHO-expressed one.

3158W

Total uniparental isodisomy of all 23 paternal chromosomes with whole genome homozygozity in blood but not in skin in a Czech girl with deafness. *P. Seeman[1], M. Malíková[2], J. Neupauerová[1], M. Trková[3], M. Putzová[3].* 1) Child Neurology, DNA Laboratory, 2nd Medical Faculty, Charles University and University Hospital Motol Prague, Praha 5, Czech Republic; 2) Institute of Biology and Medical Genetics, 2nd Medical Faculty, Charles University and University Hospital Motol Prague, Praha 5, Czech Republic; 3) Gennet Prague, Genetics and Reproduction Medicine Center, Praha 7, Czech Republic.

We report an extremely unusual and probably not yet reported case of uniparental isodisomy of all 23 chromosomes . A Czech patient, 12 year of age was originally tested for non-syndromic deafness. A novel mutation p.V234I in the ESRRB gene was detected in homozygous state. Subsequent testing in parents and brother revealed this mutation only in the father in heterozygous state, but not in the mother. Therefore parentity was tested by a set of microsatellite markers form chromosome 17 and X, but only paternal alleles were detected in homozygous state and maternal alleles were absent. Initially we thought on a deletion deletion, but MLPA from the CMT1A regions showed no copy number variation. Extensive testing using 36 microsatellite markers spread over the entire genome showed homozygozity in all markers from all chromosomes 23 with always only paternal allele present . SNP array confirmed the whole genome homozygozity without copy number change. DNA isolated from blood was used for all this initial testing. Since we could not believe such status could be possible in all tissues without major problems we repeated all the above testing with DNA isolated from cultivated skin fibroblasts and buccal cells. In skin and buccal DNA alleles from both parents were present - no isodisomy and no loss of heterozygozity was present. Finally we tested DNA from blood sampled from the patient 3 years after the first blood sampling and the results were identical. So we concluded this patient has a mosacism for blood cells with parental isodisomy of all chromosomes. Except the prelingual sensorineural deafness the phenotype of this girl was without abnormalities and with normal mental and motor development and status. Consequences for the health status of this girl in the future is hardly predictable, but there may be increased risk for blood malignancy. Supported by IGA MH NT 14348 and NT 11521-4.

3159T

Genotype and Family Analysis of 68 Thai families with Duchenne Muscular Dystrophy. *L. Choubtum[1], K. Taweechue[2], W. Khunin[3], S. Nujarean[3], C. Limwongse[2,4], D. Wattanasirichaigoon[3].* 1) Research Center, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 2) Department of Research and Development, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand; 3) Division of Medical Genetics, Department of Pediatrics, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 4) Department of Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Background: Duchenne muscular dystrophy (DMD; OMIM#300377) is a severe X-linked devastating disorder, resulted from mutation in the dystrophin gene which encodes the dystrophin protein. The DMD gene is located on Xp21.2-p21.1. It contains 79 coding exons and encodes a 3,685 amino acid residues-containing peptide. The aim of this study is to describe genotypic defects and family structure including positive family history, carrier status of the mother, and number of affected individuals of the families. Methods: Patients with the diagnosis of DMD based on clinical manifestation, family history and elevated levels of creatine kinase were enrolled in the study through genetics/neuromuscular clinics and network for prevention of reoccurrence for DMD as part of the Development Potentials of the Thai People Project, Faculty of Medicine Ramathibodi Hospital. Multiplex PCR and/or multiple ligation-dependent probe amplification (MLPA) were employed as the first tier genetic analysis of the DMD gene. If the result of multiplex PCR/MLPA came out negative, then it was followed by PCR-direct sequencing for all 79 coding exons and brain/muscle promoter region of the gene. Results and Conclusion: A total of 68 unrelated DMD families were enrolled in the study. Multiplex PCR/MLPA revealed 72% of the probands harboring exon(s) deletion (41) or duplication (8). Nineteen probands had sequencing analysis, 10 of whom the result are available which show family-specific including nonsense and frameshift mutations. There were positive family history in 17 (28%) families, and family data was incomplete in 8 families. There were a total of 115 affected (deceased and living) cases with the maximum affected case of 8 in one family. Thirty-one mothers of the 43 probands with negative family history were tested for carrier status, and 39% (12 out of 31) were shown to be carrier. The results of this study support the previous observation that large deletion/duplication of the DMD gene are accounting for two-thirds ad the genetic pathology of DMD. In this study, there was a lower rate of positive family history and maternal carrier for sporadic cases compared to those previously described in the literature.

3160F

Novel mutations in *EDA* gene in hypodontia and curly hair. *J.-W. Kim*[1,2], *K.-E. Lee*[1], *J. Ko*[1]. 1) Pediatric Dentistry, Seoul National University School of Dentistry, Seoul, South Korea; 2) Molecular Genetics, Seoul National University School of Dentistry, Seoul, South Korea.

Hypodontia (tooth agenesis) is the developmental absence of at least one tooth except third molar. Familial hypodontia can occur as an isolated form or as part of a genetic syndrome. Mutations in *MSX1*, *PAX9* and *AXIN2* genes has been identified in familial non-syndromic hypodontia. Ectodermal dysplasia is a group of syndromes affecting ectodermal origin tissues and comprises more than 150 different forms. Mutations in the ectodysplasin-A (*EDA*) gene have been associated with X-linked hypohidrotic ectodermal dysplasia and partial disruption of the EDA signaling pathway has been shown to cause isolated form of hypodontia. We have identified two X-linked hypodontia families, and performed mutational analysis of *EDA* gene. Mutational analysis revealed two novel *EDA* mutations: c.866G>T, p.Arg289Leu; c.1135T>G, p.Phe379Val (reference sequence NM_001399.4). These mutations were perfectly segregated with hypodontia and curly hair within each family and were not found in 150 control X-chromosomes with same ethnic background and 1000 genome project. This study broadens the mutational spectrum of *EDA* gene and understanding of X-linked recessive hypodontia with curly hair. This work was supported by grant (02-2013-0002) from the SNUDH Research Fund and by grants from the Bio & Medical Technology Development Program (2011-0027790), the Science Research Center grant to Bone Metabolism Research Center (2012-0000487) by the Korea Research Foundation Grant.

3161W

Defects in *Nek8* result in abnormal specification of developmental patterning, polycystic kidney disease, and impaired response to replication stress. *D.R. Beier[1, 2], D.K. Manning[2], M. Sergeev[3,4], S. Houghtaling[1], P. Czarnecki[3,4], M. Garnass[2], H.J.C. Choi[5], W. Goessling[2], K.A. Cimprich[5], J.V. Shah[3,4]*. 1) Center for Developmental Biology and Regenerative Medicine, Seattle Children's Research Institute, Seattle, WA; 2) Brigham and Women's Hospital, Division of Genetics, Boston MA; 3) Harvard Medical School, Systems Biology, Boston MA; 4) Brigham and Women's Hospital, Renal Division, Boston MA; 5) Stanford University School of Medicine, Department of Chemical and Systems Biology, Stanford, CA.

The serine threonine kinase *Nek8* is emerging as a multifunctional protein with roles in disparate cellular functions. We discovered *Nek8* in an analysis of the juvenile cystic kidneys *(jck)* mouse model of PKD; affected mice carry a missense mutation in its presumptive regulatory domain. Missense mutations in this domain of *Nek8* have also been identified in patients with the renal cystic disease nephronophthisis (NPHP9) and in the Lewis PKD rat. We generated a *Nek8*-null allele; homozygous mutant mice die at birth and exhibit randomization of left-right asymmetry, cardiac anomalies, and glomerular kidney cysts. Ciliogenesis is intact in *Nek8*-deficient embryos and cells, but nodal ciliary signaling is perturbed as left-sided marker genes are misexpressed . We have also made *jck/Nek8-* compound heterozygotes; these mutants develop less severe cystic disease than *jck* homozygotes and suggest that the *jck* missense allele may encode a gain-of-function protein. Notably, *Nek8-/-* and *Pkd2-/-* embryonic phenotypes are strikingly similar. PC2 is expressed properly in *Nek8*-deficient embryos and cells; however, similar to cells lacking PC2, *Nek8*-depleted IMCD cells exhibit diminished calcium influx in response to fluid shear stress, which suggests *Nek8* may play a role in mediating PC2-dependent signaling. Mass spectrometry revealed *Nek8* binds *Anks6*, the gene mutated in the *cy/+* PKD rat. Morpholino mediated disruption of *Anks6* in zebrafish results in the formation of pronephric cysts. However, unlike loss of function mutations in *Nek8, Invs* and *Nphp3*, defects in L/R asymmetry were not seen. More recently, *Nek8* has been identified as a key effector of the ATR (ATM and Rad3-related) mediated replication stress response. Cells lacking *Nek8* form spontaneous DNA double-strand breaks, and *Nek8* protein physically interacts with ATR and travels with the replication fork. Of note, elevated DNA damage signaling is evident in *jck* homozygous kidneys at 3 weeks of age, well prior to when they exhibit extensive cystic disease. Thus, in addition to the well-established specific localization of *Nek8* to the Inversin compartment of the ciliary axoneme, it is also present in the nucleus and binds to chromatin. Functionally, it plays a role in mediating embryonic nodal signaling, maintenance of renal tubular integrity, and DNA damage response. It will be of interest to assess whether these activities reflect multiple independent *Nek8* activities, or are mechanistically related.

3162W

Mutation in the mouse homolog of *C5ORF42* disrupts ciliogenesis and causes cerebellar defects and other Joubert Syndrome phenotypes associated with the disruption of SHH signaling. *R. Damerla[1], C. Cui[1], G. Gabriel[1], X. Liu[1], B. Gibbs[1], R. Francis[1], Y. Li[1], B. Chatterjee[1], M. Srour[2], JL. Michaud[2], GJ. Pazour[3], CW. Lo[1].* 1) Developmental Biology, University of Pittsburgh, Pittsburgh, PA; 2) Centre of Excellence in Neurosciences of Université de Montréal and Sainte-Justine Hospital Research Center, Montreal, Quebec, Canada H3T 1C5; 3) Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, Massachusetts, USA.

Mutations in cilia related genes are observed to cause a host of rapidly expanding genetic disorders known as ciliopathies. Two recent studies of patients in Canada and Saudi Arabia linked mutations in an uncharacterized gene *C5ORF42* with Joubert syndrome (JBTS). We report for the first time a mouse model for Joubert syndrome with a missense mutation in *2410089E03Rik*, the mouse homolog of *C5ORF42*. This mutant, named Heart Under Glass (Hug) was recovered from a forward genetic screen with ENU mutagenesis using fetal ultrasound imaging to identify congenital heart defects. Genome scanning to map the mutation followed by exome sequencing analysis identified the mutation in Hug as *2410089E03Rik* (c.T757C:pS235P). Hug mutants exhibited a host of defects characteristic of JBTS patients, including polydactyly, craniofacial anomalies, cystic kidneys, and congenital heart defects comprising of outflow tract malalignment associated with pulmonary atresia. These developmental anomalies are also reminiscent of other ciliopathies, suggesting they may arise from a ciliogenesis defect and the disruption of cilia dependent planar cell polarity pathways (PCP) and Shh signaling. Immunocytochemistry in fibroblasts derived from both the Hug mutant mice and from a JBTS patient with a *C5ORF42* mutation showed defects in ciliogenesis. This was associated with perturbation of the cilia transition zone. Shh signaling was observed to be disrupted in Hug mutant fibroblasts, but stereocilia patterning was not perturbed, suggesting cochlear PCP regulation is not affected. Detailed analysis of the brain showed abnormal cerebellar development associated with a significant reduction in vermis foliation, defects that are clinically relevant for assessing JBTS prognosis. Together, these studies showed the novel Hug mutant mouse model will be invaluable for further interrogating the role of cilia biology in the pathophysiology of JBTS.

NIH Study `Clinical and Molecular Investigations into Ciliopathies': Findings on Joubert Syndrome and Related Disorders (JSRD). *J.K. de Dios[1], D. Doherty[2], I.G. Phelps[2], T. Vilboux[1], A. Cullinane[1], D. Yildirimli[1], J. Shendure[3], B. O'Roak[3], J. Bryant[1], W. Zein[4], B. Brooks[4], R. Fischer[1], K. Daryanani[5], B. Turkbey[6], P. Choyke[6], J. Snow[7], T. Heller[8], M. Parisi[9], M. Huizing[1], W.A. Gahl[1], M. Gunay-Aygun[1]*. 1) NHGRI, NIH, Bethesda, MD; 2) Division of Developmental Medicine and Genetic Medicine, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA; 4) NEI, NIH; 5) NIH Clinical Center; 6) NCI, NIH; 7) NIMH, NIH; 8) NIDDK, NIH; 9) NICHD, NIH.

Human diseases caused by defects of the primary cilium/basal body/centrosome are a group of distinct disorders with overlapping features including hepatorenal fibrocystic disease, obesity, retinal degeneration and other functional and structural defects of the eyes and the brain, skeletal dysplasia, polydactyly, and situs inversus. JSRD is a clinically and genetically heterogenous group of ciliopathies defined based on the distinctive constellation of midbrain and hindbrain malformations that result in the `molar tooth sign' on brain imaging. Most JSRD patients display hypotonia, developmental delay, abnormal eye movements, and an abnormal respiratory pattern in infancy. Variable features include fibrocystic kidney disease, congenital hepatic fibrosis, retinal degeneration, retinal colobomas, and polydactyly. 21 genes identified to date account for approximately 50% of JSRD. The exact frequency and nature of kidney, liver, retina, brain and other organ system involvement in JSRD is not well defined. Under our ciliopathy study (www.clinicaltrials.gov, trial NCT00068224), ongoing since 2003, we have evaluated a total of 275 patients including 101 JSRD patients at the NIH Clinical Center. Enrollment criterion for JSRD was `molar tooth sign' on brain MRI. Evaluation included abdominal magnetic resonance imaging and high resolution ultrasonography, echocardiogram, comprehensive kidney and liver function tests, hormone levels, cognitive evaluations and DNA sequencing. Our cohort of 101 JSRD patients included 87 families; 10 families had 2 and 2 had 3 affected siblings. 46 families (53 %) had mutations in known JSRD genes including mutations in TMEM67 (15 patients, 12 families), C5orf42 (13, 10), CC2D2A (7, 6), AHI1 (5), CEP290 (4), NPHP1 (3, 2), TMEM216 (2), OFD1 (2), MKS1 (2) and KIF7 (1). Ages ranged from 0.6 to 36 years (9.2 + 7.6); there were 42 females and 14 adults. Kidney disease was diagnosed in 34% (34/101) and liver disease was present in 30% (30/101). Retinal degeneration was present in 34% (34/101) and 30% (30/101) had uveal colobomas. Neurocognitive functioning in JSRD ranged from average to severely impaired; the distribution suggested that genotyping may explain the variability. Identification of the underlying genetic causes of the remaining JSRD patients and further description of the full clinical spectrum of the related phenotypes will provide the groundwork for more focused studies and future therapeutic interventions.

3164W

Nephronophthisis type 3 with bone marrow fibrosis caused by NPHP3 gene mutations; expanding the clinical phenotype of a ciliopathy. *E. Leon[1], T. Biagi[1], K. Mistry[2].* 1) Genetics, Children's National Medical Center, Washington, DC; 2) Nephrology, Children's National Medical Center, Washington, DC.

Nephronophthisis (NPHP) is a recessive cystic kidney disease phenotypically related to Joubert syndrome, Meckel syndrome, and Senior-Loken syndrome. These associated conditions are thought to be united by the dysfunction of the primary cilium/basal body complex. NPHP is the most frequent genetic cause of end-stage kidney disease in children and young adults and can be caused by mutations in nine different genes encoding nephrocystins (NPHP1-8 and ALMS1). Disease recurrence has never been reported in kidneys transplanted into patients with NPHP. Mutations in the NPHP3 gene can cause two phenotypes: NPHP type 3 characterized by kidney and hepatic fibrosis and Renal-Hepatic-Pancreatic dysplasia that presents with oligohydramnios, hepatic and pancreatic cysts and fibrosis along with cardiac and brain anomalies resembling Meckel syndrome. We present a 4-year-old boy born at term to an unrelated Caucasian young couple via induced vaginal delivery due to oligohydramnios and enlarged left kidney. He was initially diagnosed with polycystic kidney disease, developed renal failure at 4 months and had a left nephrectomy that showed kidney fibrosis. He was initially treated with peritoneal dialysis followed by chronic hemodialysis. He developed pancytopenia and a bone marrow biopsy showed fibrosis. He was found to have delayed gastric emptying and severe oropharyngeal dysphagia. He developed failure to thrive and a G-tube was placed. He was found to have hepatosplenomegaly at age 2. Secondary hypertension and hypogammaglobulinemia were also noted. He had kidney and liver transplants at 3.5 years of age. His kidney transplant failed without signs of rejection or acute tubular injury. An echocardiogram showed a bicuspid aortic valve with associated dilation of the ascending aorta. A brain MRI showed normal structure. NPHP3 gene sequencing showed two previously reported pathogenic mutations c.2570+1G>T and c.406delA. He is now anuric, hemodialysis-dependent with generalized decreased muscle bulk and unable to walk. His cognition and speech are intact. This case presentation expands the clinical phenotype produced by NPHP3 gene mutations. The new unreported clinical findings are bone marrow fibrosis, persistent splenomegaly, and delayed gastric emptying. The reason of the failed renal transplant in this case continues to be unknown. The multiorgan compromise seen in this ciliopathy needs to be considered in any patient with the clinical diagnosis of NPHP.

Investigating the clinical features and genetics of idiopathic generalized epilepsy starting in mothers of babies with epilepsy. *S. Ghavimi[1], H. Azimi[2,3].* 1) Mofid Hospital, Shahid Beheshti Medical University, Tehran, Iran; 2) All Saints University School of Medicine, Dominica; 3) PsychoGenome, Ottawa, Ontario, Canada.

Objective: To investigate the clinical features and genetics of idiopathic generalized epilepsy starting in mothers of babies with epilepsy. Methods: Patients with general spike, defined as generalized seizures with spike or polyspike and wave on EEG, were studied in the setting of a first seizure clinic where an early postictal EEG record is part of the protocol. This outpatient study was conducted on 200 mothers who came to the clinic of Mofid's Hospital. Results: Of 200 mothers with an electro-clinical diagnosis of IGE, 56 (28%) were diagnosed as adult onset IGE. The seizure patterns in these 30 cases were tonic-clonic seizures + absences (8), tonic-clonic seizures + myoclonus (16), and tonic-clonic seizures alone (45). Tonic-clonic seizures were often precipitated by alcohol or sleep deprivation. The proportion of affected first and second degree relatives did not differ between the classical and adult onset IGE groups. Twenty adult onset cases were treated with sodium valproate, four with other antiepileptic drugs, and 50 were untreated. Conclusions: Babies born to mothers who are epileptic can gave an increase in chance of being epileptic themselves. Although it is still not clear how or when the epilepsy will start, it is clear that these children, just like their mothers carry the genes, or mutation required to have idiopathic generalized epilepsy . Adult onset IGE is a relatively frequent and benign disorder. Seizures are usually provoked and are easy to control. Patients in this age group may often be misdiagnosed as having non-lesional partial epilepsy. Early postictal EEG and sleep deprivation studies may improve the detection of these patients. Pedigree analysis suggests that adult onset IGE, like classical IGE, has a genetic etiology.

The role of fibrillin-1 in human mesenchyme stem cell adipogenesis. *M.R. Davis[1], C. Duffy[2], P. DeSousa[2], V. MacRae[1], K.M Summers[1].* 1) Genetics and Genomics, The Roslin Institute, The University of Edinburgh, Roslin, Midlothian , United Kingdom ,EH25 9RG; 2) MRC Centre for Regenerative Medicine, SCRM Building, The University of Edinburgh, Edinburgh bioQuarter, 5 Little France Drive, Edinburgh, EH16 4UU.

The extracellular matrix is important in maintaining the structure of connective tissues, including bone, skin, blood vessels and adipose. Fibrillin-1 is a leading component of 10 nm microfibrils, which provide strength and elasticity to connective tissues. Mutations in the fibrillin-1 gene lead to the connective tissue disorder Marfan syndrome (MFS), which affects the cardiac, ocular and musculoskeletal systems. Many patients suffering from MFS present with depletion in adipose tissue throughout their bodies, which has also been demonstrated in mouse models. Therefore it is important to further investigate the significance of fibrillin-associated microfibrils in adipose formation. This study used mesenchymal stem cells (MSCs), which are capable of differentiating into multiple connective tissue lineages, to investigate the role of fibrillin-1 in formation of adipocytes. Fibrillin expression at the mRNA and protein level was examined using fluorescent immunocytochemistry, quantitative PCR (qPCR) and bioinformatics validation utilizing various online databases. The study demonstrated the presence of fibrillin-1 microfibrils and RNA expression early in primary human MSC differentiation to the adipose lineage. Fibrillin-1 was degraded and mRNA levels decreased as differentiation proceeded. Since many MFS patients lack appropriate formation of adipose tissue, we suggest that a fibrillin matrix is necessary for the early stage of differentiation into this connective tissue lineage but not required to develop the specific differentiated state.

Reappraising the child and adult findings from Eastern Quebec kindreds: A protective-compensatory model may reconcile the genetic and the developmental findings in schizophrenia. *M. Maziade[1,2], T. Paccalet[1], M. Battaglia[1,2].* 1) Centre de recherche Institut universitaire en santé mentale de Québec, Québec, Canada; 2) Laval university, Faculty of Medicine, Québec, Canada.

Background: The neurodevelopmental, the multifactorial-oligogenic and the gene-environment diathesis models have provoked advances in schizophrenia research, yet the exact pathophysiology remains indefinable. We broadened our analysis of 20 years of findings in adults and children descending from densely affected families in the Québec population with a founder effect. The goal was to inspect the link between these family-genetic and developmental findings.

Method: 48 multigenerational families affected by schizophrenia or bipolar disorder represented a quasi-total sample of affected kindreds in the Eastern-Quebec catchment area. Among the 1274 adult family members with lifetime best-estimate diagnoses, 341 had DSM-IV schizophrenia or bipolar disorder. Young offspring of an affected parent were studied with the same clinical, physiological and cognitive measures as the adults.

Results: First, in clinical, neuropsychological and molecular genetic terms, the reported findings in these strongly familial schizophrenia patients and relatives bore a striking resemblance to those reported in sporadic samples. Second, we observed a considerable degree of heterogeneity despite the origin from a founder-effect population in the pedigrees. Third, cognitive deficits in some non-affected adult relatives were as severe as those in patients. Finally, children/adolescents descending from the kindreds displayed neurodevelopmental endophenotypic anomalies comparable to those of adult patients.

Discussion: These four observations could be reconciled under the hypothesis that highly familial and sporadic cases share mechanisms based on defective protective genes, a model to an extent similar to cancer and cardiovascular and metabolic findings. These defective protective genes running in families would longitudinally disturb the compensatory mechanisms in children inheriting them and might be at the core of the schizophrenia process.

3168W

Heritability of obesogenic growth trajectories during development in a model system. *C. Schmitt[1], S. Service[1], R. Cantor[2], A. Jasinska[1], M. Jorgensen[3], J. Kaplan[3], N. Freimer[1].* 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles, CA; 3) Department of Pathology, Section on Comparative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Obesity is increasingly prevalent worldwide, and has severe negative impacts on public health. Obesity arises from a complex interaction of genetic predisposition and environment that can accumulate throughout life. Although increasing evidence points to the importance of early development in the manifestations of adult disease, few studies have been undertaken of developmental measures that might be associated with adult obesity risk. The search for obesogenic markers during development in humans is complicated by the ubiquity of diets high in fat and simple carbohydrates, and the difficulty in assessing the actual diets of study subjects. This research investigates the genetic underpinnings of obesogenic growth trajectories from birth to adulthood in a genetically well-characterized model system under a controlled diet and environment: the African green monkey (*Chlorocebus aethiops sabaeus*) in the Vervet Research Colony at Wake Forest School of Medicine.

We used growth curve analysis on measures taken thrice yearly on body size and composition - body weight (BW), BMI and waist circumference (WC) - in a population of 641 monkeys measured from 2000 through 2012. 33 individuals, 6 M and 27 F, presented with signs of chronic abdominal obesity - defined as having an adult WC above 40.5 cm for at least three successive measurements. Individuals measured < 6 times were excluded from analysis (max = 30, mean = 12.6 ± 6.12). Growth was modeled using three-parameter logistic growth curves in nonlinear mixed effects models, with parameters modeled as fixed effects and subject within sex and obesity status modeled as random effects. As expected, we found a strong effect of sex and obesity status on all parameters of growth. We assessed heritability of individual growth parameters using maximum likelihood variance components analysis in SOLAR. Growth parameters were highly and significantly heritable, with sex as a significant covariate (e.g., BW: ϑ_1, asymptote of growth, $h^2 = 0.54$, $p < 0.0001$; ϑ_2, midpoint of growth, $h^2 = 0.27$, $p < 0.0001$; ϑ_3, rate of growth, $h^2 = 0.34$, $p < 0.0001$). This study suggests that adult obesity is a developmental process driven in part by heritable obesogenic trajectories resulting in faster and longer growth to larger adult size. A more detailed examination of growth trajectories may be used to assess early obesity risks and promote the discovery of novel biomedical interventions.

Functional assessment of type 2 diabetes associated loci in pancreatic β-cell specification. *E.A. Robb, N.A. Zaghloul.* University of Maryland School of Medicine, Baltimore, MD.

An estimated 24 million people in the United States are affected by the multifactorial disease, Type 2 Diabetes (T2D). Efforts to pinpoint the causative genes successfully identified 66 loci and at least as many genes contributing to T2D susceptibility using genetic association studies. However, nearly two decades later, little is still known about the precise role each identified variant plays in the disease. A key characteristic of T2D patients is the inability to maintain a functional population of pancreatic β-cells accompanied by a failure to produce and secrete sufficient insulin. In order to assess the extent to which these T2D-associated genes contribute to the generation and maintenance of β-cells, we have designed a semi-high throughput assay using the zebrafish model. Antisense oligonucleotide morpholinos, designed to individually target each T2D gene, were injected into double-transgenic embryos at the 1-2 cell stage. Expression of fluorescent mCherry (under the control of the *insulin* promoter) was utilized to specifically assess developing β-cells while overall pancreatic development was evaluated using green fluorescent protein (under the control of the *ptf1a* promoter). For each injected morpholino, we quantified the area (mass) and intensity of mCherry expression while also assessing potential effects of the morpholino on general pancreatic development by examining GFP-expressing exocrine progenitor cells. Examination of 61 T2D-associated genes (note that 7 T2D-associated genes did not have orthologs in the zebrafish), 22 genes are necessary for β-cell generation as they produce a reduction in mass and intensity; of these, 9 were previously known to affect β-cells. Four additional genes result in decreased insulin expression in β-cells. Thus, novel roles in β-cell development have been identified for several of these genes. Glucose regulation (insulin secretion and glucose level) assays were carried out for each of the 22 T2D-associated genes found to contribute to the development of the pancreatic β-cell. These genes were also investigated using whole-mount *in situ* hybridization (ISH) to identify the developmental stage of pancreatic disruption and mechanism of beta cell specification. Taken together, these data not only suggest the importance of β-cell production in genetic susceptibility to T2D, but also corroborate previous findings, supporting the use of the zebrafish model to investigate the role of T2D genes of unknown function.

Recapitulation of Metatropic Dysplasia Phenotypes in Mice Expressing Mutant TRPV4. *M.M. Weinstein[1, 2], S.W. Tompson[1], Y. Chen[3], B. Lee[3], D.H. Cohn[1, 2].* 1) Molecular, Cell, and Developmental Biology, University of California, Los Angeles; 2) Department of Orthopaedic Surgery and Orthopaedic Hospital Research Center, University of California, Los Angeles; 3) Howard Hughes Medical Institute and Department of Molecular and Human Genetics, Baylor College of Medicine, Huston, TX.

Mutations that activate the calcium channel TRPV4 have been shown to cause a spectrum of skeletal dysplasias including autosomal dominant brachyolmia, spondylometaphyseal dysplasia - Kozlowski type, and both lethal and non-lethal metatropic dysplasia. The mechanism by which these activating mutations cause growth plate dysfunction is not currently understood. In order to better understand the pathology caused by *TRPV4* activating mutations in the skeleton, we created transgenic mice overexpressing either wild-type or mutant TRPV4 in cartilage.

Mice transgenic for wild-type TRPV4 showed no morphological changes during the embryonic stage, but did have a slight delay in skeletal mineralization. Mice transgenic for the R594H TRPV4 mutant allele recapitulated defects seen in the skeletons of humans with lethal metatropic dysplasia including abnormalities of the ribcage, autopod, and vertebrae as well as displaying dumbbell-shaped long bones and perinatal death. The differences between expression of normal versus mutant TRPV4 indicate that increasing the quantity of normal TRPV4 at the cell surface is not sufficient to cause a severe skeletal dysplasia, and that a defect in the regulation of channel function, as seen in the mutant mice, is necessary for producing the abnormalities that characterize the TRPV4 skeletal dysplasias.

In addition to modeling the *TRPV4* disorders in mice, we were also able to better understand some key features of the skeletal pathology caused by TRPV4 defects. In both moderately and severely affected mutant TRPV4 transgenic mice, growth plates had enlarged reserve zones with reduced numbers of poorly organized proliferating and hypertrophic chondrocytes. In the most severely affected mutants, there were only a few hypertrophic cells with no distinct hypertrophic zone and there was a complete lack of endochondral ossification. Despite these abnormalities, the overall pattern of expression of the cartilage collagens within the growth plate was appropriate, indicating that the primary mechanism by which *TRPV4* mutations exert their effect is by inhibiting growth plate chondrocyte differentiation.

Mandibular *Prdm16* expression is critical to normal secondary palate formation in the mouse. *B.C. Bjork, L.N. Furlan, B.T. Nelson, L. Pitstick.* Dept Biochemistry, Midwestern Univ, Downers Grove, IL.

Non-syndromic orofacial clefting is one of the most common human birth defects with both multigenic and environmental influences that contribute to its etiology. Pierre Robin sequence (PRS)-type clefting is a `palate-extrinsic' mechanism of cleft secondary palate that results as an indirect consequence of an abnormally small mandible and a posteriorly-displaced tongue. Autosomal recessive ENU-induced and gene trap null loss-of-function mutant alleles of *Prdm16* model PRS, in that the mutant phenotype includes cleft palate, mandibular hypoplasia and a posteriorly-displaced tongue.

PRDM16 is a zinc finger transcription factor and known regulator of TGFβ superfamily signaling. We previously showed that TGFβ signaling is perturbed in *Prdm16 loss-of-function* mutants. *Prdm16* is critical in determining brown adipose cell fate and in the maintenance of hematopoeitic and neuronal stem cell populations. Our research aims to identify genes whose expression is altered as a consequence of *Prdm16* loss to gain a more complete understanding of the genetic, molecular and developmental mechanisms involving *Prdm16* during mouse and human palate and mandible development. To this end, we performed a qualitative assessment of the molecular consequences of *Prdm16 loss-of-function* by whole-mount *in situ* hybridization using a subset of probes specific to genes critical during normal mandible and palate development. In particular, *Goosecoid (Gsc)* exhibited reduced expression levels in the mandible and nasal prominences, and as a target of TGFβ/SMAD signaling, *Gsc* presents a strong candidate for examination as a direct transcriptional target of PRDM16.

Finally, we used the $Prdm16^{cGT}$ conditional gene trap null mutant mouse model to investigate the mechanism by which *Prdm16* loss results in clefting. We employed the *Hand2::cre* and *Osr2::cre* mouse strains to ablate *Prdm16* expression specifically in the mandible and palate shelf mesenchyme, respectively. We determined that *Prdm16* expression in the mandible, but not the palate, is required for normal palate development. These findings further demonstrate the critical role that *Prdm16* plays during mandible patterning and palate formation and validate the exploration of *PRDM16* as a candidate gene with contributions to the etiology of at least some PRS-type clefting cases.

Mouse models reveal an essential role for RERE in eye development. *B. Kim[1], O. Shchelochkov[2], M. Justice[1], B. Lee[1], D. Scott[1].* 1) Molecular & Human Genetics, Baylor College Med, Houston, TX; 2) Department of Pediatrics, University of Iowa, Iowa IA.

Microphthalmia occurs in approximately 1 out of 10,000 individuals and can be caused by alterations in genes involved in the early development of the eye. In an effort to identify novel genes involved in the development of microphthalmia, we carried out an autosomal recessive ENU screen. We found a novel mouse stain (*eyes3*) with microphthalmia. The mutation responsible for the eyes3 phenotype was mapped by linkage analysis to a region of mouse chromosome 4 that is synthetic to human chromosome 1p36.31-p36. *Rere* (arginine-glutamic acid dipeptide repeats) maps to this region and was selected as a positional candidate based on its role as a nuclear receptor co-regulator. Sequencing revealed a homozygous c.578T>C change in *Rere*, which produces a single amino acid change in a highly conserved BAH domain of RERE (p.Val193Ala). To confirm that the microphthalmia seen in the *eyes3* strain was due to a defect in *Rere*, these mice were crossed with mice carrying an RERE null allele (*om*). Homozygous *om* embryos (*Rere*$^{om/om}$) die around E9.5, but a portion *Rere*$^{om/eyes3}$ mice lived into adulthood but have microphthalmia and optic nerve atrophy. We examined the expression pattern of RERE in the developing mouse eye. At E13.5, RERE expressing cells were primarily located in the lens epithelial cells and the optic cup margin. RERE was detected in the ganglion cell layer and the lens at birth. At postnatal day 14 (P14), RERE was expressed in the outer nuclear layer (ONL), inner nuclear layer (INL), and ganglion cell layer (GCL). Histological examination revealed that the lens was not formed in *Rere*$^{om/eyes3}$ embryos at E15.5. In wild type embryos, invagination of the lens placode results in formation of the optic cup and the lens vesicle around E10.5. In *Rere*$^{om/eyes3}$ embryos, the lens vesicle is not developed due to failure of invagination of the lens placode which, consequently, leads to shallow lens pit and abnormal development of the optic cup. This is consistent with RERE's role in retinoic acid signaling which is required for reciprocal interactions between the optic vesicle and invaginating lens placode. We conclude that RERE is required for lens induction in mice. It is likely that RERE performs a similar role in humans and may contribute to the development of ocular phenotypes through its effects on retinoic acid signaling in the developing eye.

3173W

Functional and mutational analysis of long-range enhancers of ZIC3 in patients with congenital heart defects and laterality in zebrafish models. *J. Marino[1,2], S. Hook[2], P. Hu[2], R. Hart[2], E. Rossler[2], J.A. Towbin[3], J.W. Belmont[3], L. Ribeiro-Bicudo[1], M. Muenke[2].* 1) Genetics, Hospital for Rehabilitation of Craniofacial Anomaly Rua Sílvio Marchione, 3-20 Vila Universitária 17012-900 - Bauru, SP - Brasil - Caixa-postal: 1501; 2) National Institute of Health, Bethesda, MD, USA National Institutes of Health 35 Convent Drive, Bldg 35, Room 1B202 Bethesda, MD 20892-3717; 3) Baylor College of Medicine, Houston, TX, USA.

Mutations in ZIC3 frequently result in X-linked heterotaxy in humans, a syndrome consisting of left-right patterning defects, midline abnormalities, and cardiac malformations. Studies in mouse models of Zic3 dysfunction also result in heterotaxy, indicating conserved mammalian function of this developmental transcription factor. Deletion of the entire ZIC3 locus in humans, or gene dysfunction in the classical mouse mutant bent tail model, results in heterotaxy, indicating that loss-of-function is the most common pathogenic mechanism. Here we use comparative genomic alignments of non-coding elements near ZIC3 to identify and test for conserved function of potential human regulatory elements in the zebrafish model. We set out to examine the ZIC3 genomic locus by testing all of the potential enhancers and promoter elements identified by the ECR browser tool (http://ecrbase.dcode.org/). Functional elements were then subjected to Sanger sequencing in 380 control samples compared with 366 patients with congenital heart defects and/or laterality. We now describe two mutations in the ECR1 within a 521bp fragment, a C-G transition and G-C transition (both in affected males). Similarly, ECR2 showed a male specific C-A transition mutation in a 433bp functional enhancer fragment. These findings are in addition to several other mutation positive regulatory elements at the ZIC3 locus. Here we describe both the functional and mutational landscape of the laterality gene ZIC3 and provide evidence that non-coding elements will likely prove to be important in our understanding of disease pathogenesis and in future genetic testing.

3174W

Functional characterization of Gli2 in normal breast development and in breast cancer. *C. Zhao, PA. Beachy.* Institute for Stem Cell Biology and Regenerative Medicine, Stanford University, CA, 94305.

The highly conserved Hedgehog (Hh) signaling pathway plays critical roles in embryogenesis and adult tissue homeostasis. Gli2, an essential transcriptional factor of the Hh pathway, is required for embryonic development and postnatal growth of various tissues. Germline mutations in Gli2 often lead to developmental disorders, such as holoprosencephaly or hypopituitarism; whereas somatic mutations or gene amplifications of Gli2 have been found in a growing list of malignancies, including breast cancer. Despite progress in identifying germline or somatic Gli2 mutations in ectoderm-derived tissues, such as in the skin, little is known about function of Gli2 in mammary gland development and in mammary tumors. We find that Gli2 is expressed in mammary stromal cells and its expression is differentially regulated via secreted factors from mammary epithelial cells during a mammary regenerative cycle. Importantly, genetic ablation of Gli2 function in mammary stromal cells results in a distended mammary gland with disrupted terminal end buds (TEB). Intriguingly, a subset of Gli2 mutations in human breast cancer when expressed in FACS-isolated mammary stromal cells causes elevated Hh pathway activity. We propose a paracrine model that involves epithelial-secreted factors to regulate stromal-specific Gli2 expression in normal mammary development and deregulation of this epithelial-stromal interaction contributes to mammary malignancies.

3175W

Modeling *Foxf1* deficiency and overexpression in mice. *A.V. Dharmadhikari[1, 2], B. Carofino[1,2], M.G. Hill[1], X. Ren[3], T.V. Kalin[3], J. Zabielska[4], W-Y. Wan[5], T. Majewski[6], H.B. Brown[1], A. Gambin[4], P. Szafranski[1], V.V. Kalinichenko[3], M.J. Justice[1,2], P. Stankiewicz[1,2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Program in Translational Biology & Molecular Medicine, Baylor College of Medicine, Houston, TX; 3) Division of Pulmonary Biology, Cincinnati Children's Hospital Research Foundation, Cincinnati, OH; 4) Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland; 5) Dept of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 6) Dept of Pathology, University of Texas MD Anderson Cancer Center, Houston, TX.

Alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV) is a rare neonatally-lethal diffuse developmental disorder of the lungs caused by haploinsufficiency of *FOXF1*. All affected newborns die in the first month of life due to severe respiratory distress and pulmonary hypertension. *Foxf1* null mice die by midgestation as a result of defects in mesodermal differentiation and cell adhesion. *Foxf1* heterozygous mice exhibit up to 90% neonatal mortality, depending on genetic background. For the current study, *Foxf1* heterozygous mice with a deletion of the forkhead binding domain were generated and are congenic on the C57BL/6J background. In contrast to recent reports that *FOXF1* is incompletely paternally imprinted in the human lungs, early postnatal mortality was observed regardless of parental transmission of the deleted allele; no differences were seen in *Foxf1* expression in embryonic and postnatal lung tissues from reciprocal crosses. Analysis of RNA from postnatal day 0.5 *Foxf1*$^{+/-}$ and wildtype lungs using Illumina mouse WG-6 v2.0 expression bead chip microarray revealed statistically significant deregulation ($p<0.05$, $fdr<0.05$) of several genes, including those involved in pulmonary vascular development (*Sema3C*, *Dll4*, and *Ednrb*), lung branching morphogenesis (*Fgf10* and *Lama1*), and the blood pressure regulating renin-angiotensin system (*Ren1*, *Cma1*, and *Cpa3*). To study the effects of *Foxf1* overexpression, we knocked a Cre-inducible *Foxf1* allele into the *ROSA26 locus*. These mice have been mated to *CMV*-cre and Tie2-cre mice to obtain whole body and vascular endothelial cell specific overexpression of *Foxf1*, respectively. We are currently mating *ROSA26Foxf1*; *Tie2*-cre mice to *Foxf1*$^{+/-}$ mice, which we hypothesize will rescue early postnatal mortality. This could inform future gene therapy studies in patients with ACDMPV.

3176W

Transgenic zebrafish expressing mutant skeletal muscle actin *acta1a* genes model human nemaline myopathy. *O. Ceyhan, A.H. Beggs.* Division of Genetics and Program in Genomics, The Manton Center for Orphan Disease Research, Boston Children's Hospital and Harvard Medical School, Boston MA, USA.

The nemaline myopathies (NMs) are a group of rare genetic neuromuscular disorders that tend to present at birth or infancy with moderate to severe muscle weakness and defined by an accumulation of rod-like structures (nemaline bodies) in myofibers. Heterozygous (dominant) mutations in the skeletal muscle α-actin gene (*ACTA1*) account for ~25% of all NM cases and ~50% of the severe presentations. Despite our current understanding of normal actin function, the mechanisms that lead to defects in muscle development and function in patients with *ACTA1* mutations remain unclear and there are no curative therapies available for treatment. In order to elucidate the molecular defects underlying the muscle pathology in *ACTA1*-related NM, we are generating a panel of transgenic zebrafish lines that express a series of disease-linked dominant *ACTA1* mutations on the zebrafish acta1a transcript, the predominant actin expressed in the majority of zebrafish skeletal muscle. We initially tested whether three of these variants, *acta1a H42Y*, *M134V*, and *V165M*, would lead to a muscle phenotype by injecting the mutant mRNAs into zebrafish embryos. Fish overexpressing mutant actins displayed myopathic phenotypes characterized by delayed hatching from the chorion and curved bodies to variable degrees that correspond with the severity of disease in patients with these mutations. We next generated an *acta1a V165M* transgenic line that stably expresses mutant actin in all fast myofibers, and characterized its neuromuscular phenotypes by morphological and histological analysis at different time points. The *acta1a V165M* fish display muscle weakness as evidenced by their thin bodies and curved tails at 2 days-post-fertilization (dpf) and reduced motility in touch-evoked escape response assay at 5 dpf. Whole-mount phalloidin staining at 2 dpf revealed actin aggregates in the affected fish muscle, while electron microscopy demonstrated Z-line thickening and severe myofibrillar disorganization. These results provide proof of concept that zebrafish models of actin mutations recapitulate the human disease and have robust myopathic phenotypes that may be amenable for high-throughput chemical screening.

3177W

Zebrafish *ptk7* loss-of-function mutants reveal useful genetic models for human congenital and idiopathic scoliosis. *M. Hayes[1, 2], B. Ciruna[1, 2].* 1) Program in Developmental & Stem Cell Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Ontario, Canada.

Scoliosis refers to three-dimensional curvatures of the spine and is typically broken-down into two sub-categories: congenital scoliosis (CS) that presents with vertebral anomalies associated with developmental defects, and idiopathic scoliosis (IS) diagnosed by curvature with no underlying abnormality. IS typically develops postnatally, most commonly in adolescents. Despite decades of research into the causes of scoliosis, the lack of appropriate animal models has made the investigation of possible pathological mechanisms difficult. We have generated loss-of-function *ptk7* mutant zebrafish and have observed a highly penetrant spinal curvature phenotype. Maternal-zygotic (MZ) *ptk7* mutant embryos, which represent a complete loss-of-function model, display non-canonical Wnt/PCP and canonical Wnt/β-catenin signaling defects. *Ptk7* expression in the tail bud and defects in Wnt/β-catenin-dependent mesodermal specification in MZ*ptk7* suggest a role for *ptk7* in vertebral patterning *in vivo.* Indeed, we observe vertebral malformations in MZ*ptk7* larvae that closely mimic human CS phenotypes. We suggest a role for early *ptk7* expression and Wnt/β-catenin signaling in axial development and CS pathology. Interestingly, zygotic loss of *ptk7* does not affect vertebral patterning and we do not observe vertebral malformations in mutant larvae. However, *ptk7* mutant juveniles develop severe axial curvatures that progress up until sexual maturity. We suggest that with no underlying vertebral abnormalities, *ptk7* mutant zebrafish represent a model of adolescent idiopathic scoliosis (AIS) and we are currently using these zebrafish to test possible signaling mechanisms involved in pathogenesis. Our evidence suggests that depending on the timing of loss-of-function, similar gene pathways may be associated with both CS and IS. Common pathological mechanisms may be associated with both types of abnormalities and we are using loss of *ptk7* as a model to test possible contributing factors to the human disease.

FGF Ligands Regulate Chondrocyte Differentiation in the Proximal Limb. *I.H. Hung[1,2], D.M. Ornitz[3], G.C. Schoenwolf[4], M. Lewandoski[2].* 1) Pediatrics/Medical Genetics, University of Utah, Salt Lake City, UT; 2) Cancer and Developmental Biology Lab, National Cancer Institute, Frederick, MD; 3) Dept. of Developmental Biology, Washington University School of Medicine, St. Louis, MO; 4) Dept. of Neurobiology and Anatomy, University of Utah, Salt Lake City, UT.

Activating mutations in fibroblast growth factor (FGF) receptors result in chondrodysplasia and craniosynostosis syndromes, highlighting the critical role for FGF signaling in skeletal development. Although the roles of the FGFRs in bone development have been relatively well-characterized, only two FGF ligands, FGF9 and FGF18, have been shown to regulate embryonic skeletogenesis. Our previous analyses of FGF9 and FGF18 single knockout mice suggested that these FGF ligands may be functionally redundant. To test this hypothesis and to further elucidate their roles, we have generated and analyzed the limb phenotypes of an Fgf allelic series. Here we demonstrate novel roles of these FGF ligands in chondrogenesis of the proximal limb.

The maternal polymorphism rs2236131 in ITPK1 gene is associated with neural tube defects in a high-risk Chinese population. *z. Guan, JH. Wang, J. Guo, F. Wang, XW. Wang, GN. Li, Q. Xie, X. Han, B. Niu, T. Zhang, Wang JH.* Department of biotechnology, Capital Institute of Pediatrics, beijing, Beijing, China.

Neural tube defects (NTDs) are common and severe malformations that are multifactorial, involving the combined action of both genetic and environmental factors. Inositol as maternal nutritional facts and its related genes are suggested to be implicated in Neural tube defects (NTDs), but the mechanisms are not clear. Inositol, 1,3,4-trisphosphate 5/6-kinase (ITPK1) is a key enzyme in inositol metabolism, and has been studied for gene mutation in the mouse but not single nucleotide polymorphism (SNP) in NTD-affected pregnancies. A case-control study of women with NTD-affected pregnancies (n=200) and controls (n=320) from a high-risk area for NTDs in China was carried out to investigate the association of the polymorphisms in ITPK1 gene with NTDs. The 13 tag SNPs of ITPK1 chosen based on the minor allele frequency (MAF) >20% were genotyped by the Sequenom MassArray system, and we found that 4 tag SNPs were statistically associated with NTDs ($p<0.05$). After stratifying participants by NTD phenotypes, the significant association only existed in cases with spina bifida. We predicted the binding capacity of transcription factors in the 4 tag SNPs using the bioinformatics method. Only the rs2236131 is located in the sequence transcription factors (SP-1). EMSA (electrophoretic mobility shift assay) was applied to verify the binding activity between wild and mutated oligonucleotides probes for the positive SNP (rs2236131), and showed a different allelic binding capacity of specificity protein-1 in the intron region of the ITPK1, which is affected by an G→A exchange. The RT-PCR showed that the expression decreased significantly in mutant type with rs2236131 compared with wild type in the health pregnancy ($P<0.05$). These results suggested that the maternal polymorphism rs2236131 of ITPK1 was a potential risk factor for NTDs in a high-risk area of China and the allele A of rs2236131 in ITPK1 might affect the ITPK1 gene expression level. These can supply one of the worthwhile predictor of NTDs. Foundation: National Natural Science Foundation (81070491).

SPECC1L deficiency causes neural crest cell delamination and migration defects in orofacial clefting. *I. Saadi[1], N.R. Wilson[1], A.J. Olm-Shipman[1], E. Kosa[1], D.S. Acevedo[1], K.M. Stumpff[1], G. Smith[1], L. Pitstick[2], B.C. Bjork[2], A. Czirok[1].* 1) Dept. of Anatomy & Cell Biology, University of Kansas Medical Center, Kansas City, KS; 2) Dept. of Biochemistry, Midwestern University, Downers Grove, IL.

Orofacial clefts are among the most frequent birth defects, affecting 1/800 births, in the U.S. alone. While a number of contributory genes have been identified, there is continued need to understand underlying pathogenetic mechanisms. Previously, we identified *SPECC1L* as the first gene mutated in a severe cleft that extends from the oral cavity to the eye, termed Oblique Facial Cleft (ObFC). Although less common, insights into cellular and molecular mechanisms underlying ObFC directly impact our understanding of more common facial malformations, including cleft lip. We have now created a mouse model of Specc1l deficiency using two independent genetrap alleles. Homozygous *Specc1l* mutants are embryonic lethal with defects in delamination and migration of neural crest cells (NCCs). Cranial NCCs delaminate from early embryonic neural folds and migrate to the first and second branchial arches, which give rise to majority of craniofacial structures. Specc1l is expressed in the neural folds at E8.5 (site of premigratory NCC delamination) and in the branchial arches at E10.5 (destination of migratory NCCs). In rare cases, heterozygous *Specc1l* mutant embryos show regressed facial prominences late in development, consistent with the human phenotype. *In vitro* and *in vivo* cellular analyses indicate increased actin filaments and decreased AKT signaling upon SPECC1L deficiency. SPECC1L protein is stabilized at cell-cell boundaries upon confluence and interacts with both β-catenin and E-cadherin, two canonical components of adherens junctions (AJs). Indeed, upon confluence, SPECC1L-kd cells show drastic alteration in β-catenin and E-cadherin staining that suggests *stronger* AJs. *In vitro* live-imaging analyses of wound-repair assays confirm that *SPECC1L*-kd cells move normally prior to AJ change (confluence), but significantly slower than control cells after AJ change (confluence). Lastly, AKT is proposed to directly inhibit E-cadherin levels. Thus, reduced AKT upon SPECC1L deficiency is also consistent with *stronger* AJs in kd cells. Modulation of cell-cell contacts is important not only for NCC delamination from the neural folds, but also for collective migration of NCCs to their defined destinations. We have confirmed altered β-catenin staining in epithelial and mesenchymal tissue *in vivo*. Thus, SPECC1L is an entirely novel modulator of AJ strength - the first to actually weaken AJs normally - and of AKT signaling affecting NCC function in facial morphogenesis.

3181W

Mutations in MAP3K1 tilt the balance from SOX9/FGF9 to WNT/β-catenin signaling. *J.C. Loke, A. Pearlman, H. Ostrer.* Pathology, Albert Einstein College of Medicine, Bronx, NY.

In-frame mis-sense and splicing mutations (resulting in a 2 amino acid insertion or a 34 amino acid deletion) dispersed through the MAP3K1 gene tilt the balance from the male to female sex-determining pathway, resulting in 46,XY disorder of sex development (DSD). These MAP3K1 mutations affect the balance by enhancing WNT/β-catenin/FOXL2 expression and β-catenin activity and by reducing SOX9/FGF9/FGFR2 expression. These effects are mediated at multiple levels involving MAP3K1 interaction with protein co-factors and phosphorylation of downstream targets. In primary lymphoblastoid cells and NT2/D1 cells transfected with wild type or mutant MAP3K1 cDNAs under control of the constitutive CMV promoter, these mutations increased binding of RHOA, MAP3K4, FRAT1 and AXIN1 and increased phosphorylation of p38 and ERK1/2. Overexpressing RHOA or reducing expression of MAP3K4 in NT2/D1 cells produced phenocopies of the MAP3K1 mutations. Reducing expression of RHOA or overexpressing MAP3K4 in NT2/D1 cells produced anti-phenocopies. Furthermore, the effects of the MAP3K1 mutations were rescued by co-transfection with wild type MAP3K4. Although MAP3K1 is not usually required for testis-determination, mutations in this gene can disrupt normal development through the gains of function demonstrated in this study.

Losartan increases bone mass by direct inhibition of osteoclasts. *S. Chen[1], T. Sibai[2], N. Rianon[3], T. Yang[4], J. Black[5], E. Munivez[1], T. Bertin[1], B. Dawson[1], Y. Chen[1], B. Lee[1,6].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Boston University School of Medicine Orthopaedic Surgery, Boston University, Boston, MA, USA; 3) Department of Internal Medicine, University of Texas Medical School at Houston, TX, USA; 4) Laboratory of Skeletal Biology, Center for Skeletal Disease and Tumor Metastasis, Van Andel Research Institute, Grand Rapids, MI, USA; 5) Department of Pathology, Microbiology and Immunology, Vanderbilt University, Nashville, TN, USA; 6) Howard Hughes Medical Institute, Houston, TX, USA.

Osteoporosis and hypertension are two major chronic diseases of advanced age. Although traditionally these diseases are viewed as separate entities, increasing evidence suggests an overlapping etiology. One important determinant for both hypertension and osteoporosis is renin-angiotensin signaling. Inhibition of this signaling pathway lowers blood pressure and has demonstrated potential for bone loss prevention. We investigated the molecular mechanism underlying the regulation of bone mass by the renin-angiotensin pathway through animal studies and observational human data. Wild type mice were treated with Losartan, an antihypertensive drug that inhibits the angiotensin type 1 receptor, from birth until 6-weeks of age, after which bones were collected for microCT and histomorphometric analyses. Elderly hypertensive women treated with Losartan were examined by Dual-energy X-ray absorptiometry and bone turnover markers at 6 and 12 months after the onset of treatment. Losartan increased trabecular bone volume vs. tissue volume (a 98% increase) and cortical thickness (a 9% increase) in 6-week old wild type mice. The bone changes were attributed to decreased osteoclastogenesis as demonstrated by reduced osteoclast number per bone surface in vivo and suppressed osteoclast differentiation in vitro. At the molecular level, RANKL-induced ERK1/2 phosphorylation was attenuated by Losartan, suggesting a convergence of RANKL and angiotensin signaling at the level of ERK1/2 regulation. This also suggests that Losartan acts on ERK1/2, the essential mediator of RANKL signaling, and influences osteoclast differentiation. Two women (Age 81 and 74) were prospectively treated for idiopathic hypertension with Losartan. Interestingly, both showed evidence of decreased bone resorption as measured by the urinary N-telopeptide. Altogether, inhibition of the angiotensin pathway by Losartan has beneficial effects on bone beyond reducing blood pressure. Our study adds evidence to support the relationship between angiotensin receptor blockers (Losartan) and age-related bone loss that increases the risk of fractures in the elderly.

3183W

The role of the ELOVL gene family in neurodevelopmental disorders. *J. Gerard[1], A. Moreno-De-Luca[1,2], D.W. Evans[1,2].* 1) Neuroscience Department, Bucknell University, 701 Moore Avenue, Lewisburg, PA 17837; 2) Geisinger-Bucknell Autism and Developmental Medicine Center, 120 Hamm Drive, Lewisburg, PA 17837.

Very long-chain fatty acids (VLCFAs) are essential for basic cell structure and multiple cellular functions including intercellular signaling. Fatty acid elongases, encoded by the elongation of very long-chain fatty acids (ELOVL) gene family, catalyze the first and rate-limiting step in VLCFA synthesis, condensing acyl-CoA and manoyl-CoA to produce 3-ketoacyl-CoA. Mammals have seven elongases (ELOVL1-7), each of which exhibits a characteristic pattern of expression and substrate specificity. Previous research suggests that abnormalities in the ELOVL genes may cause a wide range of disorders. Heterozygous mutations in ELOVL4 result in autosomal dominant Stargardt macular dystrophy 3, whereas homozygous mutations cause a severe neurodevelopmental disorder characterized by ichthyosis, spastic quadriplegia, and intellectual disability. Elovl3-null mice display a tousled and sparse hair coat, irritated eczematous-like skin, and increased transepidermal water loss. Elovl6 -/- mice present with obesity, hepatic steatosis, and insulin resistance. ELOVL7 overexpression is thought to play a role in prostate cancer growth. By searching through the International Standards for Cytogenomic Arrays (ISCA) Consortium database, a repository of whole genome chromosomal micro array (CMA) data from patients with clinically diagnosed neurodevelopmental disorders, we identified two individuals with overlapping deletions in chromosome 5q12.1 with a smallest region of overlap including a single gene, ELOVL7. Case 1 was referred for autism and developmental delay and found to have a 135 kb deletion including only ELOVL7. Case 2 presented with oromotor apraxia and developmental delay and has a 275 kb deletion spanning ELOVL7, DEPDC1B (DEP domain containing 1B), and ERCC8 (excision repair cross-complementing rodent repair deficiency, complementation group 8). These findings highlight the importance of the ELOVL family of genes and their potential to cause disease if disrupted. We propose that haploinsufficiency of the ELOVL7 gene increases the risk for neurodevelopmental disorders including autism.

3184W

AKT1 gene mutation levels are correlated with the type of dermatologic lesions in patients with Proteus syndrome. *M.J. Lindhurst[1], J. Wang[2], H. Bloomhardt[1], A.M. Witkowski[1], L.N. Singh[1], D.P. Bick[3], M.J. Gambello[4], C.M. Powell[5], C.R. Lee[6], T.N. Darling[2], L.G. Biesecker[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Department of Dermatology, Uniformed Services University of the Health Sciences, Bethesda, MD, USA; 3) Department of Pediatrics and Obstetrics & Gynecology, Medical College of Wisconsin, Milwaukee, WI, USA; 4) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 5) Departments of Pediatrics and Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 6) Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, MD.

Proteus syndrome (PS) is characterized by progressive, mosaic, segmental overgrowth and occurs sporadically. PS is caused by a post-zygotic somatic activating mutation c.49G>A, p.Glu17Lys in *AKT1*. To date, all patients who meet the clinical diagnostic criteria for PS and have been tested in our laboratory have this mutation. Skeletal overgrowth and dermatologic lesions are the most common manifestations of PS. Cerebriform connective tissue nevi (CCTN) are a highly specific and common lesion in patients with PS and are characterized by a massively expanded dermis filled with thick collagen bundles. Epidermal nevi (EN) can occur sporadically or as part of several syndromes including PS. They have a rough surface, are dark in color, usually follow the lines of Blaschko, and exhibit hyperkeratosis, papillomatosis and acanthosis. It is unknown which cells determine the formation of these lesions. Based on the histology, we hypothesized that CCTN were generated by mutation positive cells in the dermis and that EN were generated by mutation positive cells in the epidermis. To test this hypothesis, we isolated fibroblasts and keratinocytes from CCTN, EN and apparently normal skin samples and measured the level of the mutant allele in each cell type. The mutation level in the fibroblasts isolated from seven CCTN biopsies from the feet of three patients ranged from 9-32%. The mutant allele was not found in any of the keratinocyte cultures from these samples. In four biopsies from apparently unaffected skin in two patients, the mutation level in the fibroblasts was 6-27% and there was no evidence of the mutant allele in the keratinocytes. The mutation level in fibroblast cultures isolated from nine EN samples from seven patients ranged from 0-38%, whereas in keratinocytes isolated from these EN, the mutation level was 0-44%. We conclude that the *AKT1* p.Glu17Lys activating mutation in keratinocytes is a key determinant of EN formation. The inability to detect the mutation in two of the EN keratinocyte cultures could be due to a sampling artifact or could indicate that there are multiple mechanisms that lead to EN formation. That mutant cells were found in dermal fibroblasts of both CCTN and normal-appearing skin, suggests that the presence of mutant cells in the dermis is necessary, but not sufficient, to drive the formation of CCTN.

3185W

Function of miR-199a-5p in Stage-specific Osteogenesis of Human Mesenchymal Stem Cells. *S. Gu[1], X. Chen[2], B.F. Chen[1], G. Li[1], H.W. Ouyang[2], C. Wan[1], T.L. Lee[1], W.Y. Chan[1].* 1) Rm623,LKS Integrated Biomedical Sciences Building, The Chinese University of Hong Kong, HKSAR, Hong Kong; 2) Zhejiang Provincial Key Laboratory of Tissue Engineering and Regenerative Medicine, Zhejiang University, Hangzhou, Zhejiang Province, China.

Elucidating the regulating mechanisms of osteogenesis of human mesenchymal stem cell (hMSC) is important for the development of cell therapies for bone loss and regeneration. MSC differentiation involves complex pathways that are regulated at both transcriptional and posttranscriptional levels. However, the key regulator(s) of MSC differentiation has not been identified. microRNAs (miRNAs) have been shown to regulate almost every biological process, including stem cell differentiation. Here, we show that miR-199a-5p modulates osteogenic differentiation of hMSCs. miR-199a expression detected by qPCR revealed its up-regulation during osteogenesis of hMSCs. Over-expression of miR-199a-5p but not -3p enhanced differentiation of hMSCs both *in vitro* and *in vivo*, whereas inhibition of miR-199a-5p by miR-199a-5p siRNA reduced osteogenesis of hMSCs. In order to study the underlying mechanisms of miR-199a-5p function during osteogenesis, a cyclic pathway, Twist1-miR-199a-HIF1α, was identified to have dual functions in osteogenesis both *in vitro* and *in vivo*. At early stage of differentiation, HIF1α-Twist1 pathway enhanced osteogenesis by up-regulating miR-199a-5p, while at late stage of differentiation, miR-199a-5p enhanced osteogenesis maturation by inhibiting HIF1α-Twist1 pathway. In conclusion, our findings demonstrated for the first time that Twist1-miR-199a-5p-HIF1α cyclic pathway could regulate MSC osteogenesis at different stages, which could represent a therapeutic strategy for enhancing bone formation.

3186W

DFLAT: Functional Annotation for Human Development. *H.C. Wick[1], D.P. Hill[2], H. Drabkin[2], H. Ngu[1], M. Sackman[1], C. Fournier[1,3], J. Haggett[1], J.A. Blake[2], D.W. Bianchi[4], D.K. Slonim[1,3].* 1) Department of Computer Science, Tufts University, Medford, MA; 2) Bioinformatics and Computational Biology, The Jackson Laboratory, Bar Harbor, ME; 3) Tufts University School of Medicine, Boston, MA; 4) Mother Infant Research Institute, Tufts Medical Center, Boston, MA.

Recent technological advances have led to a notable increase in genomic studies of the developing human fetus and neonate. Interpreting these studies requires widespread characterization of the functional roles of genes in different organs at appropriate developmental stages. The Gene Ontology (GO), a valuable and widely-used resource for characterizing gene function, offers perhaps the most suitable functional annotation system for this purpose. However, due in part to the difficulty of studying molecular genetic effects in humans, even the current collection of comprehensive GO annotations for human genes and gene products is often inadequate for scientists wishing to study gene function during human fetal development.

The Developmental FunctionaL Annotation at Tufts (DFLAT) project aims to improve the quality of analyses of fetal gene expression and regulation by curating human fetal gene functions using both manual and semi-automated GO procedures. Eligible annotations are then contributed to the GO database and included in GO releases of human data. In addition to augmenting GO directly, DFLAT has produced a considerable body of functional annotation that, although too preliminary for incorporation in GO, may provide valuable information about developmental genomics. This includes developmentally relevant annotations transferred from mouse orthologs to human genes. A collection of gene sets combining existing GO annotations with the 13,344 new DFLAT annotations is available for use in novel analyses. Gene set analyses of expression data on several data sets, including amniotic fluid RNA from fetuses with trisomies 21 and 18, umbilical cord blood, and newborns with bronchopulmonary dysplasia, were conducted both with and without DFLAT annotation.

The results demonstrate widespread changes with DFLAT and an increase in the number of implicated gene sets. Blinded literature review supports the validity of newly significant findings obtained with the DFLAT annotations. Newly implicated significant gene sets suggest specific hypotheses for future research. Overall, the DFLAT project contributes new functional annotation and gene sets likely to enhance our ability to interpret genomic studies of human fetal and neonatal development.

3187W

Transcriptome and pathway analysis of fetal and adult human retina, RPE, and choroid. *A.S. Boleda, M. Brooks, A. Maminishkis, S. Miller, A. Swaroop.* National Eye Institute, National Institutes of Health, Bethesda, MD.

Current knowledge of the human retina, retinal pigment epithelium (RPE), and choroid is derived from a variety of in vitro and in vivo models. Thus, functional differentiation of human tissue transcriptomes was carried out using RNA-Seq in fetal and adult tissues. By determining the expression profile of different ocular tissue types in adult and developing retina we build a foundation of knowledge for disease investigation. In this study, RNA-Seq was performed for human fetal samples (18-19th week post-conception) of three ocular tissue types (retina, RPE, and choroid) as well as for 3 adult foveal and peripheral retinal tissues (86, 87, and 92-year-old healthy eyes). Directional RNA-seq libraries (27 fetal and 6 adult) were prepared following a modified version of the standard Illumina TruSeq RNA protocol. Illumina GAIIx technology was employed for single-end sequencing to 76 nucleotides. Parallel alignments and analyses of sequencing output were performed using Genomatix software and the Tuxedo Suite. The JMP 10 package was implemented for computing principal components (PCA), creating hierarchical clusters and filtering lists of differentially expressed genes. Further pathway and network analysis was performed using GOrilla. Approximately 32 million reads per sample mapped uniquely to the Hg19 reference genome. About 28,000 transcripts were expressed at an RPKM value greater than 1.0 in any tissue, and of these between 10-15,000 transcripts showed differential expression between tissue types. PCA demonstrated that samples cluster by tissue type, and initial pathway analysis was in concordance with our predictions. Three sets of differential analysis comparisons were made. The first compared the fetal tissue types, the second compared the adult and fetal retinas, and finally we compared the adult tissue types. Genes up-regulated specifically in the fetal retina are involved in neuron differentiation, synaptic transmission and visual perception pathways. Those up-regulated in the fetal RPE are important to pigment biosynthetic processes, vitamin A metabolic processes, and light detection. Finally, up-regulated genes in fetal choroid were found to be involved in pathways for anatomical and structural morphogenesis, cellular developmental processes, response to stimuli, and multiple pathways important to immune response.

3188T

RING CHROMOSOMES ABERRATIONS AT A PEDIATRIC MEXICAN HOSPITAL. TWO CASES WITH MOSAISISM OF CHROMOSOME 13, 46XY / 46, XY, r (13) AND CHROMOSOME 18, 46, XY / 46, XY, r (18).
M. Hurtado-Hernadez[1], J.M. Aparicio-Rodriguez[2,4], M. Barrientos-Perez[3], S. Chatelain-Mercado[5]. 1) Cytogenetics; 2) Genetics; 3) Endrocrinology, Hospital para el Nino Poblano, Puebla, Puebla; 4) Estomatology, Benemerita Universidad de Puebla; 5) Biothecnology, Universidad Autónoma Metropolitana, Mexico.

The autosomic alteration due to a ring formation is a rare aberration of either chromosome 13 and 18 which is in relation with phenotipic malformations, neurologic problems and genital abnormalities. Two clinical polymalformed cases with skull treboliform dismorfies with early seizures and malformed genitals with micropenis is presented from four of the total patients found in this study. Among chromosomic alterations, the ring of autosomic chromosome 13 and 18 are not frequent, the main phenotipical alterations in this study are in relation to neurological, genital and craniofacial malformations. Taking in consideration that mutations or chromosome aberrations are alterations in the chromosome number or structure. They are mainly considered due to gametogenesis inborn error (meiosis) or during the zygote first cellular divisions. All these alterations might be observed during metaphase from the cellular cycle, where DNA loses are seen due to DNA repair processes deficiency o total absence, among others. 4617 chromosomal studies were performed at Hospital Para El Nino Poblano (Pediatric Hospital) in Mexico (from 1992 to 2011) were 34.6% (1596 patients) showed different chromosomal alterations and only two patients showed ring chromosome aberrations. These chromosome changes are classified as structural alterations. Both pediatric patients with these genetic diseases are described in this study analyzing their clinical characteristics, medical or surgical treatments according to the phenotypic alterations.

Inverted Duplication with Terminal Deletions: Variations on a Theme.
N. Christacos[1], S. Schonberg[1], C. Lau[2], J. Kelly[1], P. Mowrey[1]. 1) Dept Cytogenetics, Quest Diagnostics, Chantilly, VA; 2) Genetics Branch, Center for Cancer Research, National Cancer Institute, Bethesda, MD.

Chromosomal rearrangements resulting in an interstitial inverted duplication with associated terminal deletion, first described in 1976, have become well-established as recurrent underlying causes of genomic imbalance in man, and have been described in association with multiple chromosome regions. The application of newer molecular cytogenetic methods, in particular microarray, has allowed for a significantly higher level of resolution for detecting and characterizing these and other chromosomal abnormalities. Three mechanisms are commonly proposed to explain the origin of inverted duplications with terminal deletions, all involving formation of a dicentric chromosome intermediate that subsequently breaks during meiosis to form a monocentric duplicated and deleted chromosome. Reported cases in the literature nearly all follow a pattern of a relatively distal deletion breakpoint with end stabilization at breakpoint associated repeat sequences, likely due to ascertainment bias as others would typically result in fetal lethality. Here we report the cytogenetic results of three cases that do not follow this typical pattern and may not be completely explained by previously proposed mechanisms. Case 1 involves a derivative chromosome 14 with a proximal 14q breakpoint secondary to inverted duplication with terminal deletion and capture of the deleted region of chromosome 14 by the 7p telomeric region. Inverted duplication of chromosome 14 (14q11.2q13.1) was confirmed with FISH using the T-cell receptor LSI TRA/D probe (Abbott Molecular). As the entire deleted region was captured intact, a dicentric intermediate may not fully explain this result. Case 2 involves a derivative chromosome 15, also with a proximal long arm breakpoint secondary to inverted duplication with terminal deletion and fetal rescue by chromosome 15 nondisjunction. Case 3 has the commonly encountered inverted duplication of 8p (8p11.2p23.1) in which the inv dup (8p) chromosome was stabilized at its breakpoint by telomere capture of distal 4p resulting in duplication bands 4p15.2 to the 4p terminus. These cases illustrate how the use of newer molecular cytogenetic technologies are crucial to identifying these uncommon variations of interstitial duplication with associated terminal deletion and present a cautionary note that many such rearrangements may not follow the most common pattern described in the literature.

3190T

Infertility related to a rearrangement of the Y chromosome.
P.A. Delgado[1], S. Iyer[2], A. Jarrin[1], N. Rao[1], C.A. Tirado[1]. 1) UCLA Dept. of Pathology and Laboratory Medicine, Los Angeles, CA; 2) UT Southwestern Medical Center Dallas, Texas.

Structural abnormalities of the Y chromosome are the most frequent chromosomal aberrations in infertile male. Herein, we present a 30 year-old male with a history of infertility. A physical examination reveals no characteristics no characteristics associated with any gonosomal aneuploidy. Further studies also showed oligopermia. Chromosome analysis of peripheral blood shows what seems to be a deletion of the Y chromosome first described as 46, X, del(Y)(q11.23). C-banding was negative for the heterochromatic region normally found on the distal long arm (q) of the Y chromosome. It couldn't be determined by this analysis if part of the euchromatic band q11.23 has been deleted. FISH analysis using the SRY probe showed two signals for the **SRY** gene. Molecular genetic studies showed that there was no deletion of the AZ regions. This patient had a derivative (der) Y chromosome which results in partial monosomy of the long (q) arm and partial disomy for the short (p) arm. The ISCN was modified as: 46,X,der(Y)(-pter->q11.23::p11.2- >pter).ish der(Y)(DYZ3+,SRY++). Most of these cases are mosaic. Structural rearrangements of the Y chromosome are very common. Their influence on gonadal and somatic development is extremely variable depending on the genomic sequences duplicated or deleted and the variable degrees of mosaicism. However, rearrangements of the Y chromosome will often show a clinical picture of azoospermia or oligospermia. Further molecular genetic testing for microdeletions of the long arm of the Y chromosome was recommended. Genetic evaluation of the patient was also suggested.

3191F

A Further Case of de novo Isochromosome 18q with additional skeletal system abnormalities.
E. Karaca, T.R. Ozdemir, A. Durmaz, F. Ozkinay, O. Cogulu. Ege University Faculty of Medicine, Department of Medical Genetics, Izmir, Turkey.

Isochromosome 18q is a rare chromosomal disorder presenting a variety of phenotype ranging from mild facial dysmorphism to severe malformations. Findings in isochromosome 18q overlap with isochromosome 18p and trisomy 18, and the clinical picture has been reported from foetuses. Because very few cases have been described in the literature, the phenotypical features have not been fully well-defined because of the rarity of those cases. Main features can be summarized as holoprosencephaly, heart defects, defects of the gastrointestinal and genitourinary systems and extremity anomalies. Here, we present a new case of isochromosome 18q. The proband is a 16 months old female who was born to nonconsanguineous parents. She was first admitted to the hospital at 15 days old because of pulmonary insufficiency and has been hospitalized twice because of pulmonary infections and developmental delay. On admission her weight was 4880 g (3p), height: 53 cm (<3p), and her head circumference was 38 cm (25p). Her physical examination showed short stature, exophthalmos, right eye ptosis, blue sclera, low-set ears, long philtrum, high palate, micrognathia, pectus excavatum, short extremities, fusiform fingers, pes equinovalgus, hallux valgus and club foot. Immunological and biochemical laboratory analysis were normal. Echocardiography revealed ventricular septal defect. Visual electrophysiology showed bilateral partial conduction defects. Abdominal and cranial USG were normal. She had sensorineural hearing loss (right ear 60dB, left ear 75dB). Cranial MRI showed corpus callosum hypoplasia and dilated anterior subarachnoid space. Bone survey revealed distinctive skeletal system abnormalities such as small jaw, pectus excavatum, coxa valga, delayed ossification of hip and bilateral pes equinovalgus. Her karyotype was 46,XX, i(18)(q10). Her parents' karyotypes were normal. Skeletal system abnormalities such as pectus excavatum and coxa valga were described in trisomy 18 but not in isochromosome 18q syndrome. In conclusion our case contributes to the literature in two ways; first additional skeletal anomalies, and second reporting a further case of a very rare chromosomal disorder.

3192T

Tetrasomy 13q32.2qter Due to an Apparent Inverted Duplicated Neocentric Marker Chromosome in an Infant With Hemangiomas, Failure to Thrive, Laryngomalacia, and Tethered Cord. *J. Liu[1], M. Del Vecchio[2], D. Pezanowski[1], H. Punnett[1], J.P. de Chadarévian[1].* 1) Dept Path & Lab Med., St Chris Hosp for Children, Drexel University College of Medicine, Philadelphia, PA 19134; 2) Department of Pediatrics, Temple University School of Medicine, Philadelphia, PA 19140.

Fewer than 100 small supernumerary marker chromosomes (sSMCs) with a non-α-satellite neocentromere structure have been reported in the literature. The major morphology of a neocentric sSMC is an inverted duplication of a distal chromosome end, while ring chromosomes and centric minutes represent a small percentage. Fourteen percent were derived from segments on 13q with four breakpoints (13q14, 13q21, 13q31, 13q32) described. To date, only 5 neocentric sSMCs containing inverted duplicated segment 13q32qter have been reported, and three of the 5 cases were deceased when the manuscripts were published. Here we report a 9 week old African American male who was admitted with laryngomalacia and failure to thrive. He had multiple hemagiomas on the tip of the nose, the mid-forehead, the scalp, and the sacrum. Other abnormalities observed included micrognathia, posterior rotation of the ears, sacral dimples, tag, and cleft, tethered cord, mild splenomegaly, elevated hemoglobin/hematocrit and thrombocytopenia. He was a 34-week preemie with a normal newborn screen and hearing test. Family history was negative, consanguinity was denied. A month after the hospital visit, the proband was found dead in his crib. Chromosomal Microarray Analysis (CMA) with Affymetrix's CytoScan™ HD SNP array revealed a terminal triplication on the long arm of chromosome 13 from 13q32.2 to 13qter (tetrasomy 13q32.2qter), spanning approximately 15.6 Mb in size and encompassing 16,495 markers/probes. Reflex chromosome analysis demonstrated a small supernumerary marker chromosome (sSMC) in 95 of 100 metaphases examined that was consistent with a high percentage (95%) mosaicism karyogram. The morphology of the identified sSMC was suggestive of an inverted duplication (inv dup) of a chromosomal segment and, based on CMA findings, most likely comprises two extra copies of the segment 13q32.2qter. Reflex FISH study was consistent with the structure of an inverted duplication with a neocentromere. Genotype pattern of the involved SNPs by CMA suggests a 'U' type exchange at meiosis I. Parental cytogenetic studies were negative. We have described in this report the sixth case of an apparent neocentric sSMC containing an inverted duplicated chromosomal fragment 13q32qter characterized by genome wide SNP array, conventional cytogenetic and FISH studies. The documented clinical details will assist the medical genetics community to better understand this rare chromosomal disorder.

3193F

Prenatal diagnosis of a complex 9 break rearrangement requires karyotype, microarray and whole-genome sequencing. *M.J. Macera[1], A. Sobrino[1], B. Levy[2], V. Jobanputra[2], V. Aggarwal[2], A. Mills[1], C. Esteves[2], C-Y. Yu[3], C. Hanscom[4], V. Pillalamarri[4], M. Talkowski[4], D. Warburton[3].* 1) Department of Genetics, New York-Presbyterian Hospital, Columbia University Medical Center, New York, NY; 2) Department of Pathology and; 3) Genetics and Development and Pediatrics, Columbia University, New York, NY; 4) Center for Human Genetic Research, Massachusetts General Hospital, Department of Neurology, Harvard Medical School, Boston, MA.

Complex chromosomal translocations, defined as apparently balanced constitutional structural rearrangements involving three or more chromosomes or more than two breakpoints, are rarely detected in prenatal testing. Only 0.03% from a survey of 269371 prenatal studies were determined to be de novo (Giardino et. Al. 2009). We report a case with 5 chromosomes involved in a four way translocation and a separate two way translocation; both arms of the same chromosome 18 were involved in separate translocations. A 28 year old primi-gravida woman presented for amniocentesis sampling at 21 weeks gestation. Ultrasound and MRI revealed bilateral ventriculomegaly (13mm and 15mm) and colpocephaly, with partial agenesis of the corpus callosum. Her prior family history was unremarkable with no unusual environmental exposure. Cytogenetic and FISH analysis with telomere probes on amniocytes revealed a 46,XX,t(3;18;5;7)(p25;p11.2;q13.3;q32), t(9;18)(p22;q21) karyotype in all cells examined. SNP oligonucletide microarray analysis (SOMA) on fetal DNA showed no loss or gain of chromosomal material at any breakpoints. The pregnancy was terminated because of ultrasound findings. The unusual complex karyotype was confirmed in fetal kidney cells. Both parents had normal chromosomes. Next generation sequencing of fetal genomic DNA using large-insert jumping libraries, followed by PCR and Sanger validation identified minimal chromosomal losses and or gains. However 7 OMIM annotated genes were disrupted at the breakpoints. CNTN6 and TBC1D5 are interrupted on chromosome 3, CNTNAP2 on chromosome 7, PTPRD on chromosome 9 and L3MBTL4, LOC100130480 and WDR7 on chromosome 18. The chromosome 5 breakpoint did not involve any gene disruption. Sequencing revealed even more complexity. It was determined that small portions of chromosomes 3 and 7 were inserted into the chromosome 5 breakpoint and the p arm of chromosome 18 has a 184.5 kb inversion at the chr3/chr18 junction. This brings the total number of breaks in this chromosome complement to 9. The characterization of this extremely complex abnormality illustrates the necessity of both cytogenetic and molecular testing. G-banding coupled with telomere and painting probes detected the initial rearrangements. While microarray analysis showed no pathogenic gain or loss of material at the breakpoints of the translocations, sequencing found 7 genes disrupted by this rearrangement, as well as an even more complex chromosomal rearrangement.

3194T

Familial translocation t(4p;8p) associated with a phenotype of combined hyperlipidemia. *N. Quaresemin[1], M.L.M. Castro[1], C.H.P. Grangeiro[1], J.A. Josahkian[1], C.M. Lourenço[4], L.A.F. Laureano[2], J. Huber[1,3], E.S. Ramos[1,3], L. Martelli[1,2,3].* 1) Serviço de Genética Médica, Hospital das Clínicas da Faculdade de Medicina de Ribeirão Preto- USP, Ribeirão Preto, São Paulo, Brazil; 2) Laboratório de Citogenética - Hospital Das Clínicas da Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 3) Departamento de Genética - Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil; 4) Departamento de Neurociências e Ciências do Comportamento - Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto - SP, Brasil.

Combined hyperlipidemia affects around 2% of individuals and its etiology remains unknown. Lipoprotein lipase gene is located on short arm of chromosome 8 to 8p21.3interval which is considered a candidate genomic region for combined hyperlipidemia. We report four members of a family with rearrangements between chromosomes 4 and 8, two apparently balanced translocations and two derivatives of chromosome 4. The first patient (P1) was referred to Medical Genetics Division due to seizures and microcephaly. Chromosomal analysis by GTG banding showed a karyotype 46,XX, der(4)t(-4;8)(p16;p23.1)pat. The paternal karyotype was 46, XY, t(4;8)(p16;p23.1) and maternal karyotype was normal. Her lipidogram revealed hypercholesterolemia and hypertriglyceridemia. Even with a specific corrected diet, inadequate control of dyslipidemia persisted. The serum copper values were also elevated and she presented with persistent proteinuria. The 2nd patient is her half brother who presented with hypotonia at birth, failure to thrive and seizures. Interestingly, evaluation of lipids did not detect dyslipidemia or proteinuria, but showed elevated serum copper values. His karyotype was 46, XY, der(4)t(4;8)(p16;p23.1)pat. Cytogenetic investigation was performed on the extended family. Cholesterol and triglycerides levels were elevated in their father (P3), who was the carrier of the translocation. Another daughter (P4) carried the same 4;8 translocation and her lipidogram confirmed combined hyperlipidemia. The paternal grandparents both had normal karyotypes. Metabolic tests suggested an incomplete oxidation of long-chain fatty acids for P1. It has also been hypothesized defect in beta oxidation of lipids in P2. Our results indicate the need for cholesterol levels investigation in patients with aberrations involving this region of chromosome 8. In this family, overexpression of the candidate gene, 1-acylglycerol-3-phosphate-O-acyltransferase 5(AGPAT5), that maps to 8p23.1 may be correlated to the hyperlipidemia phenotype. Genomic investigation including aCGH, expression analysis and NGS are necessary for establishing a precise karyotype/phenotype/genotype correlation between this region of chromosome 8 and combined hyperlipidemia.

3195F

Mosaicism of a supernumerary marker ring chromosome six in a patient with Turner phenotype. *J. Rojas Martínez, Y.P. Guatibonza, J.C. Prieto, O.M. Moreno.* Pontificia Universidad Javeriana, Bogota, Bogota D.C, Colombia Carrera 7 No. 40 - 62.

Supernumerary marker chromosomes (SMCs) are abnormal chromosomes present in about 0.05% of the human population and in approximately 30% of carriers, an abnormal phenotype is observed. Supernumerary marker chromosomes derived from the chromosome 6(SMC 6)are rare, this anomaly has been reported in less than 1% of the cases with SMCs, associated with a phenotype highly variable related to their content of euchromatin, often involving the regions 6p21.2 to 6q11.2. We report the case of a female patient of 17 years old, with short stature, and polycystic ovary syndrome. Product from the third maternal pregnancy, non-consanguineous parents, with a history of low birth weight. On physical examination were found some minor anomalies as high nasal root, anteverted nares, flat philtrum, left palpebral ptosis, facial hirsutism, short and wide neck, low hairline in the posterior line, cubitus valgus, clinodactyly of the fifth finger in hands, hypogonadism with oligomenorrhea, along with a lack of development of secondary sexual characteristics. Renal gammagraphy shows a horseshoe kidney and the neuropsychology valuation reports a mild cognitive deficiency. Suspecting chromosomopathy, is performed a high resolution banding G Karyotype (BG) which reports: mos 47, XX, + r [61] / 48, XX, + r1 + r2 [30] / 46, XX [9], with occurrence of a mosaic with cell lines with presence of one and two small supernumerary marker ring chromosomes of unknown origin and a cell line with normal female karyotype. The array-CGH analysis revealed a gain in the 6p12.2-q12 region, with a size of 15,082 Mb, was performed high-resolution BG karyotype and FISH in the mother, which were normal, the father was not available for analysis. The partial trisomy 6p by supernumerary marker chromosomes are rare and have been reported with different phenotypes including psychomotor retardation, low birth weight and genital anomalies as in the case of this patient, as well as craniofacial, brain and limbs abnormalities, microcephaly and cardiac abnormalities. It is proposed that the phenotypic abnormalities associated with an SMC 6 are due to the presence of dosage sensitive genes in the trisomic region. Our case also presents excess genetic material in q12 region, (this region contains uncharacterized genes with respect to the phenotype) apparent in a mosaic karyotype, adding other variables in the expression of SMC 6, that could explain the Turner phenotype in this patient not previously reported.

3196T

Clinical and molecular characterization of a subtelomeric deletion of 19p13.3 including *STK11* with Peutz-Jeghers syndrome. *S. Ishimaru[1], T. Kudo[2], T. Murakoshi[2], R. Fukuzawa[3], T. Kuchikata[4], H. Yoshihashi[4].* 1) Division of Hematology and Oncology, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan; 2) Division of Gastroenterology, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan; 3) Division of Pathology, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan; 4) Division of Medical Genetics, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

The subjects with a deletion of 19p have been infrequently reported. Additionally, there have been only a few studies describing full clinical features of subjects with a subtelomeric deletion of 19p on the basis of molecularly defined breakpoints. Peutz-Jeghers syndrome (PJS;MIM175200) is an autosomal dominant disorder characterized by pigmented macules on the lips and oral mucosa and multiple gastrointestinal hamartomatous polyps. The majority of cases with a clinical diagnosis of PJS are the result of disease-causing sequence variants in *STK11* (serine-threonine kinase 11) located on 19p13.3, however some are due to exons and whole-gene deletions. Here, we present the clinical manifestations on the subject with a pure subtelomeric deletion of 19p13.3 including *STK11* with PJS phenotype and review the current literatures looking for genotype-phenotype correlations. Case: The propositus was a 19-year-old female. She was delivered at term without any critical problems during the perinatal period. In childhood, she required treatment and education for congenital heart defect (ASD), seizure, repetitive middle ear disease, hearing impairment, mental retardation. At 17 years, her features included a distinctive facial appearance with relative macrocephaly, scoliosis, joint laxity, and moderate intellectual disability. The spotty pigmentation of lips and buccal mucous membrane were noted. The karyotyping was normal. The subtelomeric FISH analysis identified a cryptic deletion of 19p13.3. The oligo-array CGH (ISCA 180K manufactured by Agilent) was performed to determine the size of deletion and the precise breakpoints, which was found to be 1.1Mb(chr19: 259395-1406597 from pterminus). The deleted region encompassed at least 49 genes, including *SKT11*. Esophagogastroduodenoscopy showed multiple flat stomach polyps of varying size in the stomach. Conclusions: To our knowledge, there are a few studies reported on the subject with a pure subtelomeric deletion of 19p[Archer *et al.*(2005), Souza *et al*. (2011), Scollom *et al*. (2012)], delineating clinical features and breakpoints. Some clinical findings (distinctive facial appearance, congenital heart disease, seizures, intellectual disability) in our subject shared common manifestations with those previously reported with 19p13.3 deletion. The clinical findings and cytogenetic results found in this study support that a pure subtelomeric deletion of 19p13.3 causes the emerging contiguous gene deletion syndrome.

3197F

Association between abnormal phenotype and chromosome heteromorphisms. *J.D. Grzesiuk[1], C.S. Pereira[1], F.G.O. Gennaro[1], L.A.F. Laureano[2], S.A. Santos[1], J. Huber[2], L. Martelli[1,2].* 1) Dept of Genetics, University of São Paulo, Ribeirão Preto, SP, Brazil; 2) Clinical Hospital, School of Medicine, Ribeirão Preto, SP, Brazil.

Heteromorphisms are variations among individuals in heterochromatin regions such as inversions, duplications and deletions and they are considered benign changes. However, literature suggests its association with several disorders as infertility, cancer, mental retardation, schizophrenia and Walker-Warburg syndrome. This study aimed to describe the frequency of different chromosome heteromorphisms in patients referred for diagnostic investigation and the phenotype of the carriers. We have reviewed GTG banding karyotypes of 2,892 patients referred to the Medical Genetics Division at the Clinical Hospital (HCRP) between 2006 and 2013. Among them, 92 patients (3.18%) presented heteromorphic chromosomes, similar to the frequency of 2-5% observed by Gardner and Sutherland (2004) in the general population. This finding corroborates with the literature suggesting that heteromorphisms are not involved with phenotypic changes. However, among the heteromorphic patients, other phenotypic findings, as mental retardation and facial dysmorphisms, were described in 61 patients (66,30%), four times more frequent than the reproductive disorders phenotype diagnosed in 16 patients (17,39%). Increase in length of the heterochromatin on the long arm of chromosomes 1, 9, 16 and Y represented 29,35% of the heteromorphisms, while the satellites and stalks on the short arm of chromosomes 14,15, 21 and 22 were detected in 16,30% and chromosome 9 inversions were seen in 34,78%. We have also noticed a high rate of co-occurrence of heteromorphisms, 18 of the 92 heteromorphic patients (19,57%) presented two heteromorphisms or one heteromorphism concomitant to other type of chromosome abnormality, that reinforces the hypothesis of heteromorphism interchromosomic effect. The most frequent variants were located on chromosome 9 and the pericentric inversion of chromosome 9 was the main finding associated with positive phenotypes. The differences in size of the segments, the occurrence of two chromosomal breaks and the complexity of the inversion mechanisms could be directly related to small losses or gains of critical genetic material and consequent more severe phenotypes. Genomic studies and gene expression analysis should be used for characterization of the heteromorphisms and better understanding about its phenotypic effects.

3198T

Ring chromosome 11: Familial case with normal development.and short stature. Further delineation of this rare cytogenetic abnormality.
A. Singer[1], R. Berger[2], R. Segal[3], C. Vinkler[4]. 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Tel Aviv, Israel; 2) Cytogenetic Lab. Maccabi Health Services Rehovot Israel; 3) Institute of Medical Genetics, Shaare Zedek Medical Center Jerusalem Israel; 4) Institute of Medical Genetics,Wolfson Medical Center, Holon. Israel.

Autosomal ring chromosomes are uncommon cytogenetic aberrations identified in prenatal and postnatal diagnosis. It is estimated to occur in less than 1:30,000. Rings have been reported for all chromosomes, although those involving autosomes 13 and 18 are among the most common. The classic mechanism of ring formation is breakage in both arms of a chromosome followed by fusion of the two broken arms and loss of the distal segments. Therefore, phenotypic abnormalities associated with partial deletions, can be found among patients with ring chromosomes. Only a few examples of parental transmission are known and it has been estimated that about 99% of all ring chromosomes arise sporadically. Ring chromosome 11 is rarely observed and only a few cases have been reported, almost all have growth failure, variable phenotypes and some degree of intellectual disability. We present a case of a mother and daughter with ring chromosome 11. The girl is 8 years old and was referred to our clinic for evaluation because of short stature. Her parents are healthy and nonconsanguineous. The father's height is normal and mother's height is 153 cm (3rd centile). The girl's height is 112 cm (-2.5 SD), she has three hypopigmented skin lesions, myopia, no significant dysmorphic features and normal development. Cardiac echo was normal. GTG-banded chromosome analysis on peripheral blood of the proband showed a karyotype 46, XX, r(11)(q15;p25) in all metaphases examined. Paternal chromosomes were normal and maternal chromosomes showed equal mosaic of 45XX-11/46,XX,r(11)(q15;p25). This is the first description of familial ring chromosome 11 with short stature and normal development lacking any other phenotypic abnormality. The phenotypic differences in previously reported cases are most likely due to the differences in the size of the terminal deletion(s) at one or both arms or the result of mitotic instability. Further evaluation is being done with SNP array in order to define the deleted area addressing the mild phenotype in our family. Detailed molecular characterization and documentation of chromosomal imbalances and their clinical presentation is important for accurate genotype phenotype correlations and appropriate genetic counseling.

3199F

Mosaic Turner Syndrome with unilateral absence of digital phalanges and renal agenesis.
h. ulucan, a. koparir, g. guven, a. celebi, e. koparir, m. seven, m. ozen. department of medical genetics, istanbul university cerrahpasa medical school, istanbul , Turkey.

Turner's syndrome (TS) is a sex chromosome disorder occurring in 1 in 2,500 female newborns and in approximately 50 in 100,000 adult females and is due to partial or total loss of the second sex chromosome. There is great variability in cytogenetic findings, including the 45,X karyotype, mosaics without structural abnor¬malities (as mos 45,X/46,XX and mos 45,X/ 46,XY) and structural abnormalities with or without mosaicism (as isochromosomes and marker chromosomes). The 45,X/46,XX chromosomal pattern is the most frequent mosaic type of this disease (36%). TS is characterized by retarded growth, gonadal dysgenesis and infertility. Renal and/or collecting system malformations have been found in 30-40% of cases; including horseshoe kidney, renal malrotation and collecting system malformations. Skeletal anomalies are frequent but severe hand anomalies were not reported. Here, we report five-year-old female with unilateral absence of digital phalanges and unilateral renal agenesis whose choromosomal analysis showed 45X, 46XX. TS is known to cause multisystemic disorders. Here we present a case with unilateral renal kidney which is reported as a rare anomaly. Skeletal anomalies are frequent with TS but severe hand anomalies were rare. Our patient had also absence of fingers of hand which has not been reported up to now. We discuss here; the absence of fingers in TS may be a new clinical finding or it is a sequelae of amniotic band.

3200T

A *de novo* case of 5q33.3-q34 interstitial triplication together with uniparental isodisomy of 5q34-qter.
A. Fujita[1], H. Suzumura[2], N. Harada[3], N. Matsumoto[1], N. Miyake[1]. 1) Department of Human Genetics, Yokohama City Graduate School of Medicine, Yokohama, Kanagawa, Japan; 2) Department of Pediatrics, Dokkyo Medical University, Tochigi, Japan; 3) Cytogenetic Testing Group, Molecular genetic Research and Analysis Department, Clinical Development Service Center, Mitsubishi Chemical Medience Corporation, Tokyo, Japan.

De novo triplication together with uniparental disomy (UPD) is a rare genomic rearrangement, except for those that occur on chromosome 15q11-q13. To our knowledge, co-occurrence of these two events has previously only been reported in two individuals with *de novo* intrachromosomal triplication at 11q23.3-q24.1. Here, we report the first report of a patient with *de novo* triplication together with uniparental isodisomy of chromosome 5q who with suspected karyotype of 46,XX,del(5)(q33.1q33.3),dup(5)(q31.3q33.3) or (q33.1q35.1). Our cytogenetic analysis with high resolution SNP array and FISH analysis revealed tetrasomy of 5q33.3-q34 (6.5-Mb) caused by *de novo* middle inverted triplication and uniparental isodisomy of 5q34-qter (18-Mb). Furthermore, haplotype analysis showed two informative microsatellite markers *D5S412* and *D5S2118* within the tetrasomic region indicated biparental inheritance, whereas the other two informative microsatellite markers *D5S400* and *D5S2034* within the UPD region originated from unipaternal allele inheritance. Majority of her clinical features were observed in previously reported cases of duplication overlapping with 5q33.3-q34, except the presence of hearing loss in the proband. The *FOXI1* gene, which causes autosomal recessive deafness (OMIM 600791, DFNB4) when mutated, was contained within the uniparental isodisomy region (5q34-qter). However, no mutations were identified following Sanger sequencing of *FOXI1*. As segmental isodisomy is a post-fertilization error, it is thought to have occurred during mitosis just after fertilization via a U-type exchange, while inverted duplication could have occurred during meiosis or mitosis. The final karyotype was interpreted as 46,XX,trp(pter→q34::q34→q33.3::q33.3→qter), arr 5q33.3q34(156,244,462-162,761,495)×4,5q34qter(162,761,596-180,592,321)×2 hmz. The paternal UPD was first noticed as the LOH detected by the SNP array. Thus, following only a single experiment, the SNP array can be used for genotyping as well as the detection of copy number alterations. This study reaffirms that the SNP array is a powerful tool to screen for UPD in a single experiment, especially in cases of isodisomy.

3201F

Xq28 duplication including MECP2 in 11 French affected females: what can we learn for diagnosis and genetic counselling? *S. El Chehadeh[1], R. Touraine[2], F. Prieur[2], M. Doco-Fenzy[3], T. Duplication of chromosome Xq28 including the MECP2 gene has been described primarily in male patients with severe developmental delay, spasticity, epilepsy, stereotyped hand movements and recurrent infections. Females carriers are most of the time asymptomatic and display an extreme or complete skewing of chromosome X-inactivation. Symptomatic females have been reported in 15 cases in the literature, the majority with a milder phenotype. The duplications resulted from a X-autosome translocation resulting in functional Xq disomy or were de novo or inherited intrachromosomal Xq duplications associated with a random X inactivation. The duplications were maternally inherited in only 3 cases, the others were de novo. We carried out in 2012 a national study that permitted to identify in France 11 affected females, including 2 twins, aged 4.5 to 40 years, among the 100 patients carrying a MECP2 duplication. Five were intrachromosomal duplications of Xq, 3 resulted from an unbalanced X-autosome translocation, and 2 were small size intragenic MECP2 duplications, which causality determination is on going. The size of the duplications ranged from 5.5 Kb to 11.7 Mb. The duplications were de novo in all 7 patients with available parents. Together with the literature, we showed that females with X-autosome translocations display the most severe phenotype, similar to males, while others display an unspecific phenotype. In our study 22% of affected female patients presented with spasticity, 33% with epilepsy, 66% with stereotyped hand movements, and 56% with recurrent infections. These results are of importance for genetic counselling since an abnormal phenotype in females born from carrier mothers is very rare.

3202T

Clinical features in a pediatric population due to chromosome deletions at a third level pediatric Mexican hospital in 19 years period of time: Five case reports. *S. Chatelain[1], J.M. Aparicio-Rodriguez[2,6], M.L. Hurtado-Hernandez[3], M. Barrientos-Perez[4], R. Zamudio-Meneses[5], M. Palma-Guzmán[6], H. Chavez-Ozeki[6].* 1) Biotechnology, Universidad Autónoma Metropolitana. , Mexico City; 2) Genetics,; 3) Cytogenetics; 4) Endocrinology; 5) Cardiology, Hospital Para El Niño Poblano Bolv Del Nino Poblano; 6) Estomatology, Benemérita Universidad Autónoma de Puebla, Mexico.

Chromosome aberrations are considered as alterations in the chromosome number or structure. They are mainly due to gametogenesis inborn error (meiosis) or occur during the zygote first cellular divisions where DNA repair processes are deficient. Two Wolf Syndrome patients and two criduchat patients or patients with deletion of the short arm of chromosome 4 and 5, respectively, and deletion of chromosome 9 in one patient, were observed among 4617 karyotype studies performed from 1992 to 2011, at the Hospital Para El Niño Poblano (Pediatric Hospital) in Mexico. These chromosome structural alterations or deletions at chromosomes 4, 5 and 9, observed among five patients from three different families were chosen to analyze their clinical characteristics, medical or surgical treatments and their medical evolution according to the genetic disease.

3203F

Syndromic intellectual disability in a patient with 3.5 Mb deletion at 1p13.3. *H. Cho, K. Ha, L.C. Layman, H. Kim.* OB/GYN, Georgia Regents University, Augusta, GA., United States.

1p13.3 deletion syndrome is characterized by psychomotor retardation, hearing loss, short stature, and abnormalities of the digits. Here we report on a 35-year-old Asian woman with intellectual disability, bilateral hearing loss, short stature, high arched feet, sandal gap toes, hyperactivity, seizure, low-set ears, astigmatism, ptosis, hypotonia, kyphosis, lordosis, high arched palate, and constipation. A 244K Agilent comparative genomic hybridization (CGH) revealed a deletion of at least 3.5 Mb (chr1:107,682,629-111,177,029: GRCh37/hg19) at 1p13.3 in this patient. At least 30 genes are deleted in this region and 14 genes are overlapping with one unreported case. Some genes deleted or disrupted by a balanced translocation in this region have been reported (Borg et al. 2005; Kuilenburg et al. 2009). The Netrin G1 (NTNG1) gene providing axon guidance cues, G protein signaling modulator 2 (GPSM2) regulating neuroblast self-renewal as well as four potassium channel genes -KCNA2, KCNA3, KCNA4, KCNA10- might have contributed to the psychomotor phenotype and seizure in this patient. VAV3 reported to regulate osteoclast function and bone mass might be involved in short stature and the bone phenotype of this patient. Phenotypes such as low-set ears, kyphosis, lordosis, and high arched palate have not been previously reported in the 1p13.3 deletion syndrome region, suggesting the presence of causative gene(s) in the new genomic region deleted in this patient. The candidate genes within deleted region have been described and the phenotype /genotype relationship has been discussed.

3204T

Molecular cytogenetic analysis of 8p23.1: about two Tunisian patients. *H. Ben Khelifa[1], M. Kammoun[1], I. Ben Haj Hmida[1], H. Hannechi[1], N. Soyah[2], H. Elghezal[1], A. Saad[1], S. Mougou-Zrelli[1].* 1) Laboratory of Human Cytogenetics, Molecular Biology and Biology of Reproduction, CHU Farhat Hached - Sousse-Tunisia; 2) Department of Pedriatrics, CHU Farhat Hached -Sousse- Tunisia.

To date more than 50 cases of interstitial or terminal 8p23.1 deletions have been reported. This aberration is especially prone to various genomic rearrangements mainly because of the existence of the two olfactory receptor gene clusters (REPD and REPP) which is associated with a spectrum of anomalies including especially congenital heart malformations microcephaly and mental retardation. We report on two Tunisian patients, with different clinical features but they have in common mental retardation, similar dysmorphic features, microcephaly otherwise without heart malformation. The conventional karyotype on R banded chromosomes at a resolution of 450-550 bands, revealed a terminal deletion of the short arm of chromosome 8 in only one patient. Using CGH array on a 75 Kb resolution average, we characterized this 8p deletion of 8,883,636 bp: arr 8p23.3- 8p23.1 (191,530-9,075,165) X1. The second patient carried a smaller cryptic interstitial deletion of 1,181,530 pb at 8p23.1: arr 8p23.1 (8,229,404 - 9,410,934) X1. Fluorescence in situ hybridization (FISH) analysis confirmed the deletions and the parental analysis returned normal. Taken together, these data allowed us to define a critical deletion region of 845 Kb for the major features of a deletion 8p. Indeed, the absence of cardiac malformations in these cases, often associated with the 8p deletions, could be explained by the retention of SOX7 and GATA4 genes, implicated in heart development, in both patents. Also, we suggest that loci for the microcephaly and mental retardation are within the subregion of the commonly deleted region. Indeed, the different sizes of the reported deletions could otherwise explain the non-similarity of the clinical features observed in our patients. Even though, further studies are needed to establish more clearly the role of the discussed candidate genes in carriers of 8p23.1 deletions.

Silver and Titanium dioxide Nanoparticles role in Genotoxicity. *A. Ganapathi[1], L. Koude[1], V. Mariganti[1], P. Upendram[2], Q. Hasan[2], B. Priyanka[1], R. Rohit[3], R. Devaki[1].* 1) Biochemistry, Kamineni Institute of Medical Sceinces, Hyderabad, Andhra Pradhesh, India; 2) Departments of Genetics, Kamineni Institute of Medical Sciences, Sreepuram, Nalgonda, Hyderabad, Andhra Pradhesh, India; 3) Indian Institute of Chemical Technology, Hyderabad, Andhra Pradhesh, India.

Objectives We investigated the genotoxic effects of 10-20 nm silver (Ag) and Titanium dioxide (TiO2) nanoparticles (NPs) by evaluating chromosome aberrations, polyploidy status, Apoptosis and micronucleus (MN) assay. Methods Before testing, we confirmed that the Ag-NPs were completely dispersed in the ex-perimental medium by sonication (three times in 1 minute) and filtration (0.2 µm pore size filter), and then we measured their size in a zeta potential analyzer. After that the geno-toxicity was measured. Results After incubation with the defined concentration and size of the Silver and TiO2 nanoparticles, 100 metaphases were analyzed under microscope, 9%, 12% structural aberrations and 3%, 2% numerical aberrations were observed respectively. There was no aberration found in the control sample. After incubation with the defined concentration and size of the Ag & TiO2 nanoparticles, 1000 bi-nucleated cells were analyzed under microscope, 3% and 1% of these cells were observed with micronuclei respectively. However both nanoparticles did not show any apoptosis. Conclusions All of our findings indicate that Ag-and TiO2 NPs show genotoxic effects in mammalian cell system. In addition, present study sug¬gests that the genotoxicity effect of Ag and TiO2 nanoparticles is concentration and size dependent. Keywords Chromosomal aberrations, Polyploidy status, Genotoxicity, Micronucleus assay, Nanoparticles, Apoptosis.

Mosaicism involving a normal cell line and an unbalanced structural rearrangement. *B.M. Shaw[1], S. Elrefai[1], B. Wolf[1], L. Whiteley[2], M. Strecker[3], K. Hovanes[3], M. Cankovic[2], S. Michalowski[1].* 1) Medical Genetics, Henry Ford Health System, Detroit, MI; 2) Pathology, Henry Ford Health System, Detroit, MI; 3) CombiMatrix Diagnostics, Irvine, CA.

Mosaicism for a normal cell line and a cell line with an unbalanced structural arrangement is a rare occurrence. We report a small-for-gestational age, female infant with cleft palate, low-set ears, ventriculomegaly and joint contractures born to a 28-year-old G2P2 mother. The parents are from Yemen and are reportedly non-consanguineous. The infant was intubated at birth for respiratory distress and eventually expired at 25 days of life due to respiratory complications. Chromosome analysis on cultured lymphocytes revealed a 46,XX,der(1)t(1;1)(p36.3;q25.2)[6]/46,XX[15] karyotype. Microarray analysis using a custom Illumina SNP array showed a female with a mosaic 1q25.3-q44 duplication and a 1p36.33-p36.31 deletion. These results were confirmed by both metaphase and interphase FISH analysis. These findings may be explained by one of four potential mechanisms: 1) chimerism; 2) an unbalanced zygote, loses the abnormal chromosome 1 and undergoes monosomy rescue, resulting in isodisomy for the normal chromosome 1 in a subpopulation of cells; 3) a zygote with two normal chromosome 1s and a derivative chromosome 1 is formed via 3:1 segregation from parent carrying a balanced inversion, and as a result of the abnormal cell line's instability, secondary loss of the normal chromosome 1 and the derivative chromosome 1 occurs, resulting in two different cell lines; 4) a translocation occurs between chromatids during embryogenesis, resulting in either two unbalanced cell lines (one of which was non-viable), or a normal and a balanced cell line. Variable number tandem repeat (VNTR) analysis was performed and ruled out chimerism in this patient. Monosomy rescue is considered unlikely given that no stretches of homozygosity suggestive of isodisomy were detected by SNP array and the mother has a normal karyotype. Although possible, A 3:1 segregation of chromosome 1 seems unlikely, since trisomy 1 has only once been reported in an eight-cell pre-embryo, and this configuration would also result in tetrasomy of a large portion of 1q. Based on these results, we speculate that the chromatid translocation during embryogenesis is the most likely mechanism.

High resolution copy number analysis of genes involved in gonadal differentiation in patients with disorder of sexual development. *S.A Yatsenko[1,2], F.X. Schneck[3,4], J. Fox[3], S. Madan-Khetarpal[4,5], S.F Witchel[4,6], U. Surti[1,2,7], A. Rajkovic[1,2,7].* 1) OB/GYN & Reproductive Sci, Univ Pittsburgh, Magee-Womens Hosp., Pittsburgh, PA; 2) Department of Pathology, Univ Pittsburgh, School of Medicine, Pittsburgh, PA; 3) Department of Urology; Univ Pittsburgh; 4) Children's Hospital of Pittsburgh of UPMC, PA; 5) Department of Pediatrics and Department of Medical Genetics; Univ Pittsburgh; 6) Division of Pediatric Endocrinology; Univ Pittsburgh; 7) Department of Human Genetics, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Cytogenetic and molecular genetic analyses are essential elements in clinical diagnosis and gender assignment in children with disorders of sexual development (DSD). In patients with multiple congenital anomalies the whole genome array comparative hybridization (aCGH) has become the first tier test in the clinical diagnosis. A significant number of genes have been recognized to play a role in male and female sex development, however small deletions and duplications involving an individual gene have remained beyond the detection resolution by routine aCGH. To detect copy number variations (CNVs) with the resolution of 0.5-1 kb we have constructed a custom CGH microarray with oligonucleotide probes covering 397 clinically relevant and candidate genes associated with gonadal differentiation and genitourinary tract development. We studied 37 patients diagnosed with sex-reversal or genitourinary tract abnormalities including seven XX males, seven XY females, and 23 individuals with 46,XY chromosome complement and partial testicular differentiation, ambiguous external genitalia, cryptorchidism, or hypospadias. Pathogenic CNVs involving a single gene were detected in 4 patients (~10%) with nonsyndromic abnormalities. These include heterozygous and hemizygous imbalances within the *CYP11B1*, *DAX1*, *POU3F*, and *FGF13* genes, ranging from 1 to 160 kb in size. The application of high-resolution custom DSD microarray in patients with DSD conditions provides substantial advantages in the detection of small genomic and intragenic aberrations that are beyond the resolution of currently available aCGH analysis and other molecular techniques such as FISH analysis and sequencing of the gene of interest. As the number of genes implicated in sex development continues to grow, high resolution genome-wide approaches provide valuable information for the clinical diagnosis and management of patients with nonsyndromic DSD.

3208T

22q11.2 deletion in patients with syndromic cleft lip and palate. *S. Carpeta[1], I. Zarante[2], M.C Martinez[3], O.M Moreno[2].* 1) Biological science student Master. Institute of Genetics, Pontifical Javeriana University, Bogota, Colombia; 2) Teacher Institute of Genetics, Pontifical Javeriana University, Bogota, Colombia; 3) Teacher Empowered Dentistry, Pontifical Javeriana University, Bogota, Colombia.

Craniofacial abnormalities are one of the most common features of all birth defects, orofacial disorders being the most frequent. Cleft lip and palate are congenital malformations that affect 1 of every 700 live births and arise from variable deficiencies in tissues that form the palate and upper lip during the first weeks of gestation. In 30% of cases, genetic factors are found. Craniofacial abnormalities are described in 22q11.2 microdeletion syndrome as part of the 180 clinical signs known to contribute to the phenotypic spectrum. The aim of this study was to determine the presence of chromosomal abnormalities and 22q11.2 deletions in patients with cleft lip and palate and clinical suspicion of 22q11.2 deletion syndrome in patients from ECLAMC program and various hospitals in Bogotá. The patients analyzed had cleft lip, cleft palate and cleft lip accompanied by other clinical features associated with 22q11.2 deletion syndrome, such as congenital heart disease, dysmorphic features, inmunologic abnormalities or behavioral and learning disorders. We performed high-resolution G-banding karyotype and molecular analysis of the 22q11.2 region by MLPA (SALSA MLPA KIT P250-B1 DiGeorge). We evaluated 33 patients, 18 men and 15 women. 15 patients had palate clefts, 14 had cleft lip and palate and 3 had cleft lip. None of the patients had abnormal karyotype, 5 patients had the 22q11.2 deletion detected by MLPA, 4 of them had a deletion within the typically deleted region of ~ 3 Mb, and one had a atypical distal deletion expanding between LCR D and LCR F (~ 1.8 Mb). Patients with the confirmed deletion presented in addition to the cleft lip / palate, mainly cardiac abnormalities, immune abnormalitites and abnormal facies. The patient with the atypical deletion presented with hypothyroidism, anxiety, inguinal hernia and herpes zoster. These results suggest the importance of evaluating patients with cleft lip / palate in a genetics service and applying molecular tools as MLPA for analysing the 22q11.2 region in order to establish the genetic etiology in this group of abnormalities and provide appropriate genetic counseling.

3209F

Co-occurrence of 22q11 Deletion Syndrome and HDR Syndrome. *R. Fukai[1,2], N. Ochi[3], N. Matsumoto[1], N. Miyake[1].* 1) Department of Human Genetics, Yokohama City Graduate School of Medicine, Yokohama, Kanagawa, Japan; 2) Department of Neurology and Stroke Medicine, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 3) Department of Pediatrics, Aichi Prefectural Hospital and Rehabilitation Center for Disabled Children, Dai-ni Aoitori Gakuen, Okazaki, Japan.

22q11 deletion syndrome [MIM 188400] is one of the most common chromosomal deletion syndromes and is usually caused by a 1.5-3.0 Mb deletion at chromosome 22q11.2. It is characterized by hypocalcemia resulting from hypoplasia of the parathyroid glands, hypoplasia of the thymus, and defects of the cardiac outflow tract. We encountered a Japanese boy presenting with an unusually severe phenotype of 22q11 deletion syndrome, including progressive renal failure and severe intellectual disabilities. Diagnostic testing using fluorescent in situ hybridization revealed deletion of the 22q11 region, but this did not explain the additional complications. To seek the additional genetic causing, we performed copy number analysis using whole genome single nucleotide polymorphism (SNP) assay was performed. The detection threshold of the copy number alterations was set as follows: a confidence value of 90%, 20 contiguous probes, and larger than 100 kb for duplications; and a confidence value of 89%, 20 contiguous markers, and larger than 10 kb for deletions. As a result, the *de novo* pathological deletions at 10p14 (7.4 Mb-8.9 Mb) were newly identified in the proband in addition to the *de novo* deletion at 22q11.2 (19.0 Mb-21.5 Mb). The deleted 10p14 region is the locus for hypoparathyroidism, deafness, and renal dysplasia (HDR) syndrome [MIM 146255] caused by haploinsufficiency of *GATA3*. Conclusively, these two syndromes sufficiently explain the patient's phenotype. As far as we know, this is the first report of the co-occurrence of 22q11 deletion syndrome and HDR syndrome. As the two syndromes overlap clinically, this study indicates the importance of carrying out careful clinical and genetic assessment of patients with atypical clinical phenotypes or unique complications. Unbiased genetic analysis using whole genome copy number SNP arrays is especially useful for detecting such rare double mutations.

3210T

Generation of a Custom Array for Copy Number Variation in Congenital Diaphragmatic Hernia. *M. Russell[1,2], K. Darvishi[2,3], M. Longoni[1,2], CH. Hsieh[2,3], F. High[1], A. Kashani Pour[1], A. Tracy[1], C. Coletti[1], C. Zhang[2,3], B. Pober[1,2], K. Lage[1,2], C. Lee[2,3], P. Donahoe[1,2].* 1) Dept Pediatric Surgery, Massachusetts General Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Department of Pathology, Brigham and Women's Hospital, Boston, MA.

Congenital Diaphragmatic Hernia (CDH) is a common birth defect (1/3,000 live births in the United States), characterized by a diaphragm defect often with severe lung hypoplasia. CDH is genetically heterogeneous, usually occurring in isolation, and on occasion as part of a syndrome. Recurring chromosomal imbalances or point mutations have been implicated in CDH; however, the etiology remains unknown for the majority of cases. We have used array-based comparative genomic hybridization (aCGH) to detect congenital diaphragmatic hernia (CDH) candidate loci, hypothesizing that they contain CDH-causative genes. We analyzed aCGH data on 57 CDH patients from our cohort with either isolated or complex CDH using two different platforms, Agilent 244k and Agilent 1M arrays. A total of 32 rare CNVs (defined as <5% frequency reported in the Database of Genomic Variants) were selected for follow up. We also combined our CNV findings with an additional 48 CDH-associated CNV regions reported in the literature, as well the chromosomal regions of known CDH associated or CDH candidate genes identified via different techniques in our laboratory. With these data a custom CNV 'morbid map' was created using statistical/bioinformatic integration. This 'morbid map' of CDH-associated CNVs and gene regions will be validated by designing custom arrays on 350+ CDH patients within our cohort and 1,000+ controls, to identify CNVs that are significantly associated with CDH risk. In a collaborative effort with other CDH investigators, we will replicate our findings in a second large cohort of cases and controls. Using aCGH data, we have developed a morbid map and a custom array to test statistically valid associations between rare CNVs and CDH.

3211F

Multiplex Ligation-dependent Probe Amplification (MLPA) for detection of copy number variation in early-onset glaucoma patients from the US. *K. Allen, M. Janessian, K. Linkroum, W. Abdrabou, E. DelBono, J.L. Wiggs.* Massachusetts Eye and Ear Infirmary, MA.

Early-onset glaucoma can be caused by mutations in CYP1B1, FOXC1, and PITX2. We have previously identified mutations in these genes in approximately 25% of patients from the United States using Sanger sequencing methods. The purpose of this study is to determine the frequency of copy number variations in CYP1B1, FOXC1, and PITX2 in this US clinic-based population using Multiplex Ligation-dependent Probe amplification (MLPA). MLPA testing was performed using genomic DNA samples from 50 early onset glaucoma patients using the MRC Holland SALSA MLPA probemix kits for CYP1B1 (P128-B2 Cytochrome P-450) and FOXC1 and PITX2 (P054-B1 FOXL2-TWIST1).

MLPA raw data analysis was analyzed using the MRC Holland protocol for internal quality controls. Intra-sample normalization was calculated by comparing the relative florescence intensity of each peak within a sample. Inter-sample normalization was calculated by dividing the relative peak area of each experimental sample to that of reference samples included within the same experiment. In this study, a normal dosage quotient was 0.85-1.15. A dosage quotient of 0.35-0.65 was considered a heterozygous deletion.

MLPA analysis for this study revealed heterozygous deletions in CYP1B1 (1 patient), FOXC1 (3 patients) and PITX2 (1 patient). The heterozygous CYP1B1 deletion found in this study spanned the entire coding region for this gene. Insertions or homozygous copy number variants were not identified. The results of this study show that deletions in CYP1B1, FOXC1, and PITX2 are relatively frequent mutations in this patient population and should be included as part of the genetic diagnostic evaluation.

3212T

Autoimmune Disorders as Late Onset Feature of 16p11.2 Duplications. *C. Lowther[1,9], DJ. Stavropoulos[2,3], S. Dyack[4,5], AL. Lionel[6], CR. Marshall[6], SW. Scherer[6,7], AS. Bassett[8,9].* 1) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 2) Cytogenetics Laboratory, Department of Pediatric Laboratory Medicine, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Laboratory Medicine and Pathology, University of Toronto, Ontario, Canada; 4) Department of Pediatrics, Dalhousie University, Halifax, Nova Scotia, Canada; 5) Izaak Walton Killam Centre, Division of Medical Genetics, Halifax, Nova Scotia, Canada; 6) The Centre for Applied Genomics and Program in Genomics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 8) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 9) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

The use of genome-wide microarrays to detect pathogenic copy number variations (CNVs) is now routine in many postnatal settings, and there is growing interest in the aplication to prenatal diagnosis. This has placed additional pressure on the medical genetics community to delineate the variable expressivity of CNVs such as recurrent 600 kb 16p11.2 duplications to inform genetic counselling and anticipatory care. Notably, there is limited information as yet on the adult phenotype apart from the known enrichment of 16p11.2 duplications in schizophrenia (SZ). We assessed multiple relatives of probands previously identified to carry the 16p11.2 duplication from two cohorts comprised of adults diagnosed with SZ or tetralogy of Fallot. Each individual, regardless of duplication status, underwent phenotyping including comprehensive medical, psychiatric and physical assessment to identify major lifetime features and illnesses. We report on the first 19 adults from five families, 12 of whom had the 16p11.2 duplication (median age 58, range 32-88). Eight (66.6%) of these 12 had some form of neuropsychiatric illness: three with major depression and one with intellectual disability, in addition to the four ascertained with SZ. None of the seven individuals without the 16p11.2 duplication had a neuropsychiatric phenotype. With respect to the physical phenotype of the 16p11.2 duplication, two individuals had spinal abnormailities: spina bifida occulta and spinal stenosis. There were also five with autoimmune disorders including rare conditions: lichen sclerosus and Addison's disease. One individual had developed severe blepharospasm, a rare form of dystonia, in middle age. To our knowledge this is the first study to report that late onset autoimmune and movement disorders may be features of the extended adult 16p11.2 duplication phenotye. Of the ~25 genes in the 16p11.2 region, candidates for autoimmune disorders include SPN, a sialoglycoprotein found on the surface of T lymphocytes, and CORO1A, an actin regulatory gene previously associated with a reported case of severe combined immunodeficiency. Variants of PRRT2, a potential candidate gene for dystonia, have been associated with paroxysmal kinesigenic dyskinesia. Later onset features associated with pathogenic CNVs can only be observed in well phenotyped adults. Further study of genetic modifiers within and outside of the 16p11.2 region may shed light on the variable phenotypic expression.

3213F

Evaluation of newborns with multiple congenital anomalies by array-CGH: the experience of a public hospital from Southern Brazil. *M. Riegel[1,2,3], L. Dorfman[1], R. Mergener[2], K. de Souza[1], JC. Leite[3].* 1) Post Graduate Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil; 2) Molecular Cytogenetics Laboratory, Gene Therapy Center, Hospital de Clínicas de Porto Alegre, Porto Alegre-RS, Brazil; 3) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre-RS, Brazil.

Aim and methods: We analyzed DNA samples isolated from individuals with multiple congenital abnormalities born in a public hospital from Southern of Brazil to identify copy number variants involving critical chromosome regions using array comparative genomic hybridization (array-CGH). Results: In a series of samples from 32 newborns with Multiple Congenital Anomalies (MCA) we identified six deletions and four duplications. We identified one subject with a previously unknown 12 Mb deletion at 4p16.3-p15.33 associated with the Wolf-Hirschhorn syndrome region and one subject with a complete trisomy of chromosome 13. Thirty of the syndromic cases had MCA without a specific clinical diagnosis. The deletions were pathogenic and associated with the phenotypes in two cases and the duplications were classified as pathogenic and associated with the phenotypes of two subjects. In two further cases, an observed genomic imbalance was classified as variation of unknown significance (VOUS) as there was insufficient evidence to conclude if the CNV was either pathogenic or benign. In general, gain involving CNVs was more common than loss, accounting for ~70% of the imbalances. Conclusion: We have shown that array-CGH analysis of DNA samples obtained from newborns with MCA of unknown etiology is an efficient method to identify candidate chromosomal loci and/or genes, complementing the genetic evaluation of newborns with MCA. Cytogenetic testing is expected to use mostly array-CGH based technology in the near future. However, the high cost associated with the cytogenetic molecular methods and the present lack of technical skills and professional experience needed for its application are major challenges for public hospitals in developing countries such as Brazil. Financial support: FIPE/HCPA 10-560; CNPq 214906/2012-4; CNPq 402012/2010-0.

3214T

Germline DNA Copy Number Variation investigation in individuals with Argyrophilic Grain Disease reveals CTNS as a plausible candidate gene. *C. Rosenberg[1], L. Kimura[1], D. Schlesinger[2], A. Gonçalves[1], P.L. Pearson[1], C.K. Suemoto[4], C. Pasqualucci[5], A.C. Krepischi[3], L.T. Grinberg[6], D. Vilella[1].* 1) Genetics Evolutionary Biology, Universidade de Sao Paulo, sao paulo, sao paulo, Brazil; 2) Israel Institute for Teaching and Research Albert Einstein,, São Paulo, Brazil; 3) National Institute of Science and Technology in Oncogenomics, AC Camargo Hospital, São Paulo, Brazil; 4) Discipline of Geriatrics, Department of Internal Medicine, University of São Paulo Medical School,São Paulo, Brazil; 5) Department of Pathology, University of São Paulo Medical School, São Paulo, Brazil; 6) Brazilian Aging Brain Study Group - LIM22, Department of Pathology, University of São Paulo Medical School, São Paulo, Brazil.

Argyrophilic grain disease (AgD) is a late-onset dementia morphologically characterized by the presence of argyrophilic grains (ArG) in neuronal processes and coiled bodies in oligodendrocytes. Several studies have confirmed that the main protein constituent of ArG is the abnormally and hyperphosphorylated tau protein and that the grains are found in both cortical and subcortical structures. It also became apparent from recent clinicopathological studies that AgD shows a significant correlation with advancing age and it might account for approximately 5% of all dementia cases. However, the cause of AgD is not known. The disease seems to be sporadic but genetic studies have failed to discover a link of AgD with a particular gene locus. An important and recent advance in human genetics was the recognition that our genome presents copy number variations (CNVs) that involve gain or losses of genomic DNA among phenotypically normal individuals. Indeed, it has become well established in the literature that CNVs represents a significant proportion of the total genetic variability in the human population. Since the discovery of the existence of CNVs it has increased the number of studies that demonstrate its critical role in the phenotypes of complex diseases. However, there are no reports of specifics CNVs related to AgD. Therefore, the aim of this work was to identify CNVs, using the array-CGH, that possibly contributes to the development of AgD. The samples were obtained from the Brain Bank of the Brazilian Aging Brain Study Group. The array-CGH analysis revealed a 315 Kb genomic imbalance in the 17p13.2 region that includes a gene involved in age- related memory deficit, the CTNS. There is a study showing that a knockout mice Ctns -/- presents a severe age-related memory deficit, which makes CTNS a good candidate gene for susceptibility to AgD.

3215F

DUF1220 Domain Copy Number Associated with Extreme Brain Size in Individuals with 1q21 Copy Number Variations. *V.B. Searles[1,2,3], J. Davis[1], S.W. Cheung[4], S.C.S Nagamani[4], J. Sikela[1,3].* 1) Biochemistry and Molecular Genetics, University of Colorado School of Medicine, Denver, CO; 2) Medical Scientist Training Program, University of Colorado School of Medicine, Denver, CO; 3) Human Medical Genetics and Genomics Program, University of Colorado School of Medicine, Denver, CO; 4) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background: Copy number variations (CNVs) in chromosome 1q21 are associated with recurrent neurodevelopmental disorders. DUF1220, a protein domain on 1q21, is hyper-amplified specifically in the human lineage and has been associated with an evolutionary increase in human brain size. Previous work has suggested DUF1220 copy number reduction is associated with microcephaly in individuals with 1q21 CNVs, but obtaining accurate DUF1220 copy number measurements has been limited by technological methods. The present study was designed to confirm the association between DUF1220 copy number and brain size in an expanded number of individuals with 1q21 CNVs using a novel method for accurately measuring copy number of highly duplicated sequences. Methods: DNA and clinical data from 47 pediatric individuals with 1q21 CNVs was used for genotype-phenotype analysis. 41 of these individuals had previously been analyzed by arrayCGH. We estimated brain size using fronto-occipital head circumference Z-scores (FOCZ), a standard measure used in pediatric studies. We analyzed DUF1220 copy number for two DUF1220 clades, conserved clade 1 (CON1) and human-lineage specific clade 1 (HLS1). Copy number was determined using digital-droplet PCR (ddPCR), a novel PCR-based technique. This method entails digesting genomic DNA then dispersing the digested DNA into over 12,000 oil droplets. DNA within each droplet is amplified with DUF1220-specific primers and the presence or absence of the target sequence is read via fluorescence measurements on a droplet reader. Results: Copy number of DUF1220 clades CON1 and HLS1 was associated with brain size in this pediatric population with 1q21 CNVs (CON1: $R2=0.41$, $p<0.00001$; HLS1: $R2=0.20$, $p<0.01$; total DUF1220: $p<0.0001$). This confirms previous results using arrayCGH data in a slightly larger sample size. ddPCR copy number estimates correlated with previous high-density 1q21 arrayCGH signal intensities from the same samples (HLS1: $R2=0.98$, $p=3.3e-42$; CON1: $R2=0.75$, $p=3.56e-15$). Conclusions: We confirmed previous results showing that DUF1220 copy number is associated with brain size in a pediatric population with 1q21 CNVs, and extended this association to a larger population. We also demonstrate that ddPCR is an effective technique for determining copy number of highly duplicated sequences such as DUF1220 and may be used for similar studies in future research where arrayCGH analysis or qPCR do not meet accuracy needs.

3216T

Delineation of the genomic structure in the human 2q13 region. *B. Yuan[1], P. Liu[1], K. Potamousis[2], D. Schwartz[2], J.R. Lupski[1,3,4].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 2) Laboratory for Molecular and Computational Genomics, University of Wisconsin-Madison, Madison, WI 53706, USA; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030, USA; 4) Texas Children's Hospital, University of Texas Health Science Center at Houston, Houston, TX 77030-1501, USA.

Familial juvenile nephronophthisis is an autosomal recessive kidney disorder, which is the most frequent inherited cause of chronic renal failure in children. Loss of function of the gene *NPHP1* is responsible for approximately 85% of the nephronophthisis cases. About 80% of these patients carry a large homozygous deletion including *NPHP1*. *NPHP1* maps to 2q13, a region with extremely enriched low copy repeats (LCRs). Previous studies have demonstrated that deletion of the *NPHP1* can be mediated by nonallelic homologous recombination (NAHR) between two 45kb flanking repeats. One non-pathologic inversion haplotype involving *NPHP1* region flanked by two 358kb large inverted repeats has also been reported. Moreover, extensive evidence suggest that the human 2q13 region is structurally highly polymorphic. Therefore, we hypothesize that different historical genomic rearrangements occurred within the 2q13 region and generated various structural haplotypes observed in the human population today. Individual susceptibility to the *NPHP1* deletion can be affected by the haplotypes they carry in their personal genomes. By exploring the different haplotypes from various individuals, we may glean a more detailed understanding of the correlation between disease susceptibility and structural variation mediated by LCRs. We aim to find evidence to support the various predicted structural haplotypes. By mining the data from the literature, we observe the polymorphic copy number variation of the 45kb repeats in the 2q13 region in different populations. Optical Mapping analysis of one HapMap individual reveals the inversion haplotype of *NPHP1* region as well as the deletion of one 45kb repeat. In this study, we will also use fosmid clones constructed in the Human Genome Structural Variation (HGSV) project to infer potential haplotypes. The discordant fosmid clones whose mapping cannot be explained by the 2q13 genomic structure in the reference genome imply alternative haplotypes. In total, 226 discordant fosmids in the 2q13 region are called from 17 HapMap individuals involved in HGSV project. By examining all the available discordant fosmids, we may be able to identify novel haplotypes. The various predicted haplotypes identified by this study will promote our understanding of the complex structure in the 2q13 region and other regions with similar high-level LCRs.

Designing Custom Oligo FISH Probes for the Detection of Chromosomal Rearrangements in FFPE Tissues. *A. Bergstrom Lucas[1], M. Ruvolo[1], V. Kulkarni[1], S. Chen[1], B. Mullinax[2], J. Venneri[2], J. Barboza[3], S. Happe[3], S. Fulmer-Smentek[1], M. Srinivasan[1].* 1) Genomics R&D, Agilent Technologies, Santa Clara, CA; 2) Genomics R&D, Agilent Technologies, La Jolla, CA; 3) Genomics R&D, Agilent Technologies, Cedar Creek, TX.

Cancer cells frequently contain chromosomal rearrangements that result in oncogene activation, and the genes involved in these rearrangements are increasingly being identified using molecular technologies. We have developed a new generation of fluorescently labeled *in situ* hybridization (SureFISH) probes for the detection of these rearrangements. SureFISH probes are comprised of thousands of unique long oligonucleotides that are tiled across the targeted chromosomal region avoiding non-unique portions of the genome. The oligonucleotides are synthesized using Agilent's Oligonucleotide Library Synthesis (OLS) technology. Using knowledge of translocation breakpoints, SureFISH probes are designed to detect the translocated sequences using both break-apart and dual fusion strategies. The *in silico* design methodology and *de novo* synthesis of the SureFISH probes enables the optimization of design characteristics so that each probe provides balanced signals, facilitating the detection of chromosomal rearrangements. The flexibility afforded by the SureFISH design pipeline also enables rapid probe customization. Custom designs can be generated that target almost any genomic region, allowing for the production of probes that are not possible using other methods. We demonstrate the performance of both catalog/routine and custom probes on cytological samples and tissues that have been preserved in formalin and embedded in paraffin (FFPE).

3218T

Rearrangement of MLL gene (11q23) in pediatric patients with Acute Leukemia at Hospital Civil de Guadalajara `Dr. Juan I. Menchaca'. *H.J. PIMENTEL-GUTIÉRREZ[1, 2], L. BOBADILLA-MORALES[1, 2], S. GALLEGOS-CASTORENA[1], B. GONZÁLEZ-QUEZADA[2], F. SÁNCHEZ-ZUBIETA[1], F. GÁLVEZ-GÁLVEZ[1], A. CORONA-RIVERA[1, 2].* 1) Unidad de Citogenética, Serv. Hematol. Oncol. Pediát., Div. Pediatría, Hosp. Civil "Dr. Juan I. Menchaca";; 2) Laboratorio de Citogenética, Genotoxicidad y Biomonitoreo, Inst. Genét Hum 'Dr.ECR', CUCS, Universidad de Guadalajara.

Introduction: The Mixed-Lineage Leukemia gene (MLL, 11q23) is essential for normal hematopoiesis in acute leukemias. Although MLL disruption is generally related to unfavorable patient prognosis, more than 73 different chromosomic translocations that generate fused genes involving MLL have been reported, posing a point at issue on clinical prognosis classifications. Statement of Purpose: To present cytogenetic findings that involve MLL/11q23 in pediatric patients with acute leukemia and to correlate them with treatment response. Methods Used: Unstimulated bone marrow samples of pediatric acute leukemias were cultured 24 hours. After culture chromosome harvest was done for slide preparation and Wright staining. Fluorescence in situ hybridization was done using MLL break apart probe supplied by Abbott Molecular. Summary of Results: 11 cases were studied: 2 cases of acute myelogenous leukemia (AML) M4, 5 cases of AML M5 and 3 cases of acute lymphoblastic leukemia (ALL). Rearrangements found: 5 cases with t(9;11), 2 with t(4;11), 1 with t(6;11) and 1 with del(11q23). The patients where 5 male and 6 female (one of which was an infant with t(4;11)). Central nervous system infiltration was found in 3/11 cases, while visceromegaly on 4/11. Treatment was chemotherapy-based according to leukemia type. Survival in 18% of the patients (2/11), from which 2 received bone marrow transplant. Conclusions: The t(11q23;variable) are found on 10% of ALL (70% of infants) and 3% of AML as Slany and cols. demonstrated. Five different rearrangements where found, from which t(9;11) was the most common. Poor response to treatment was found in the majority of cases. The patient with t(1;11) had good outcomes, which has been reported previously.

3219F

A derivative chromosome involving the q arms of chromosome 1 and 15 is associated with myeloproliferative neoplasm. *P. Hord, C. McCoin, C. Curtis, S. Singh.* Cytogenetics, CSI Laboratories, Alpharetta, GA.

A derivative chromosome, der(1;15), is rare however, it is recognized as a recurrent finding in myeloid disorders. To date, only 10 case studies have been reported in *Atlas of Genetics and Cytogenetics in Oncology and Haematology*, affecting patients with a median age of 47 years. The aim of this study is to report the cytogenetic profile of three new cases referred to our laboratory with clinical histories of a myeloproliferative neoplasm. Bone marrow specimens received from the patients were cultured and harvested using standard procedures. Twenty GTW-banded cells were analyzed using CytoVision (Genetix) system and the karyotypes were written according to the International System of Human Cytogenetic Nomenclature (ISCN) 2009 Standards. All of these patients were cytogenetically identified to have a derivative chromosome, possibly dicentric, consisting of the q arms of chromosomes 1 and 15, in place of one normal chromosome 15, resulting in a net gain of 1q (trisomy 1q). In each of these cases, the der(1;15) was accompanied by additional chromosomal abnormalities, indicative of clonal evolution and/or disease progression. We conclude that our cases are very similar to those reported previously and demonstrate a clear association of the der(1;15) with myeloproliferative neoplasms. The mechanisms that result in leukemogenesis or its progression are not clear. However, several factors such as rearrangements which silence genes at the chromosomal breakpoints, partial trisomy resulting in a gene dosage effect, the development of acquired uniparental disomy, and juxtapositioning of both centromeric regions may play a role. Additionally, chromosome 1 may harbor oncogenes or tumor suppressor genes that are pathogenetically relevant to both chronic and advanced phases of MPN. It is therefore important to generate a database of these less frequently seen abnormalities that may be potential markers for disease progression or targets for newer generation drugs.

3220T

Effect of methamidophos on bone marrow cells of mice in vivo: Micronucleus assay. *I. Aranha.* Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

The use of pesticides is still the main strategy to fight plagues in agriculture. Methamidophos is an organophosphorous pesticide largely used in the world crop due to its efficiency. The purpose of the present work was to study the effect of methamidophos on chromosomes of mice bone marrow cells in vivo, using the micronucleus assay. Animals (ICR mice) were separated into four groups. In the first group, 6 animals received methamidophos intraperitoneally during five consecutive days in a concentration equivalent to 25% of the LD50. In the 6th day, animals were sacrificed, their femurs removed, the bone marrows collected and smears were made for slides preparation. After 24h cells were stained with Giemsa Gurr (2%) and analyzed under optical microscope. As positive control, 6 animals received cyclophosphamide (50mg/mL), once and 6 animals not exposed to any drug served as negative control for the experiment. In the test group, 13353 cells were observed and 183 showed micronuclei. In the positive control group, 12037 cells were observed and 238 had micronuclei and in the negative control group, of 12156 cells observed, none had micronucleus. The chi-square test for independence showed that our results were extremely significant (P<0.0001). They suggest that methamidophos is responsible for the micronuclei observed.

3221F

Mood disorders associate with a gene-disrupting chromosomal translocation spanning three-generations. *C. Ernst[1,2], F. Jollant[2], C. Hanscom[3], M. Stone[3], I. Blumenthal[3], G. Turecki[1,2], C. Cruceanu[1], M. Talkowski[3,4].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Department of Psychiatry, McGill University, Montreal, Quebec, Canada; 3) Center for Human Genetic Research, Harvard Medical School, Boston, MA, USA; 4) Medical and Population Genetics program, the Broad Institute, Cambridge, MA, USA.

We identified a family that carried a translocation across three generations [46,XX,t(11;14)(p11.2;p12)]. Due to a profound history of mood and anxiety disorders associated with the anomaly, we sequenced the translocation to basepair resolution using a mate-pair library preparation followed by massively parallel sequencing. The translocation breakpoints were localized to an unmapped contig, chrUn_gl000220, which we can now locate to Chr 14p12, and to intron 3 of LRRC4C. LRRC4C is a binding partner for Netrin G1, an axon guidance molecule important in neurodevelopment. To understand if LRRC4C is important in mood disorders, we analyzed exome sequencing data from a large bipolar family study and identified additional subjects with very rare amino-acid altering mutations in this gene, suggesting that LRRC4C mutations might have a role depressed mood and anxiety. These data demonstrate the benefits of using whole-genome sequencing to detect structural variation for psychiatric disorders and for localizing unmapped contigs to the human genome.

Effectiveness of comprehensive cytogenetic investigations in the diagnosis and genetic counseling of 8,131 patients. *L. Martelli[1,2], J. Huber[2], S.A. Santos[1], L.A.F. Laureano[2], A.C. Laus[1], J.A. Squire[3], E.S. Ramos[1,2].* 1) Dept Genetics, University of Sao Paulo, Ribeirao Preto, SP, Brazil; 2) Clinical Hospital, School of Medicine, Ribeirao Preto, SP, Brazil; 3) Dept Pathology and Molecular Medicine, Queen's University, Kingston, ON, Canada.

Aberrations involving gain or loss of chromosomal segments are particularly important in clinical cytogenetics. Classical karyotyping systematically supported by companion molecular cytogenetics has been a powerful tool for genome scanning, detecting aberrations involving gains and losses of chromosomal regions, as well as intra and inter-chromosomal rearrangements. The main objective of this study was to demonstrate the importance of comprehensive chromosomal and molecular cytogenetic analysis for clinical diagnosis over the last 15 years at the Department of Medical Genetics (HCFMRP). Initially, we evaluated 8,131 karyotypes from patients, of these 7,469 were informative, corresponding to 91.85% of the samples. Chromosomal aneuploidies were detected in 1,363 karyotypes (18.25%), structural aberrations in 405 karyotypes (5.42%) and 483 karyotypes (6.47%) had normal karyotypes with variants of normality. Among the translocations, 26 were inherited and these findings were used to determine the risk of recurrence. A subset of 17 patients required extensive molecular cytogenetic analysis including SKY and FISH techniques, to evaluate supernumerary marker chromosomes. The definitive diagnosis was established for 71% of these patients. Seven markers were originated from acrocentric chromosomes - five derivatives of chromosome 15 and two from 22 -, two from chromosome 9, and one from each pair 2, 4, 10 and 18. For four cases the origin was inherited. For two cases mBand analysis provided additional characterization of the chromosomal rearrangements. In one case of reciprocal translocation (1q;11p), small deletions were excluded in 1q31 and 11p13 cytobands. In the second case, the karyotype with homozygous inversion in chromosome 12 was characterized as 46, XY, der (12) inv (12) (p11.2p12.3) inv (12) (q21.1q24.1) x2. This patient was also investigated by aCGH technique which showed genomic gains within cytoband 12p12.3 that seemed to be related to the clinical phenotype. In conclusion, our results combining classical/molecular/cytogenomics methods have established the diagnosis of chromosomal disorders in 24% of the patients with a positive phenotype and were essential to define the etiologic diagnosis of 1,768 patients, determining the genetic counseling for their families.

3223F

Characterizing the cytogenetic dose-response relationship at very low doses of gamma radiation using structural chromosomal aberrations. *I. Seth[1], M.C Joiner[2], J.D Tucker[1].* 1) Biological Sciences, Wayne State University, Detroit, MI; 2) Department of Radiation Oncology, Wayne State University, Detroit, MI.

The shape of the dose-response curve at very low doses of radiation has long been a topic of debate in the field of radiation biology. The linear-no-threshold (LNT) model is widely used to assess risks associated with low dose exposures. According to the LNT model, the risks of genetic damage increase linearly with dose without any threshold. However, lack of knowledge of the shape of the dose-response curve at low doses, where most exposures occur, is a major problem because if low dose risks are not understood, then risk estimation and establishing scientifically valid dose limits for radiation protection are not possible. The low-dose hypersensitivity (LDH) phenomenon, in which cells are especially sensitive to low doses but then show increased radio-resistance at higher doses, provides evidence of non-linearity in the low dose region. LDH is more prominent in the G2 phase of the cell cycle than the G0/G1 or S phases and others have shown that G2 phase cells with sub-threshold DNA damage enter mitosis due to failure of the ATM-dependent G2 arrest. We hypothesized that the cytogenetic dose-response relationship at very low doses is also non-linear, and hence, should not be extrapolated from the effect at high doses. To test our hypothesis, experiments were performed in which human peripheral blood lymphocytes from one normal healthy blood donor were acutely exposed to cobalt-60 gamma rays at doses 0-4 Gy, with dose groups below 1 Gy spaced at intervals of 0.1 Gy. Damage was assessed using structural chromosomal aberrations. Preliminary results indicate that the effect per unit dose is up to 6-fold higher between 0 and 0.3 Gy than between 0.4 and 1.5 Gy. These data provide the first cytogenetic evidence for the existence of LDH in human peripheral blood lymphocytes and suggest that the LNT model is not optimal for making radiation risk assessments in the low-dose region.

3224T

Double Robertsonian translocation in pregnancy loss. *S. Wenger.* Dept Pathology, West Virginia Univ, Morgantown, WV.

The incidence of balanced Robertsonian translocation is 1/1,000 with rob(13;14) being the most common at 76%, followed by rob(14;21) at 10%. Data from our laboratory during the past 26 years identified 64 cases, two of which were acquired in leukemia and one which was mosaic with a normal karyotype. The most common Robertsonian translocation was 13;14 (52%) followed by 14;21 (16%). Absent from our records were 14;22, 21;22 and 22;22. Fourteen families were identified in which eleven demonstrated maternal inheritance, two were paternal and one case had a noted family history of trisomy 14 with no further detail. It was not possible to determine the de novo rate since not all parents were evaluated for all of the Robertsonian translocations. Adverse outcomes involving trisomies related to the Robertsonian translocation included 13, 14, and 21, although one case had an additional three way reciprocal translocation and another case had a single X chromosome. Within these fourteen families, not all pregnancy losses were karyotyped, however one pregnancy loss had both trisomy 13 and 15 as the result of two copies of rob(13;15)mat. Only one other case has been reported in the literature with a duplicated Robertsonian translocation; a karyotype of 44,XX,rob(14;21)(q10;q10)matx2 in a 17 year old woman with primary amenorrhea (Kopakka et al., Int J Gynecol Obstet 2012;116:253-257). The most likely explanation for two copies of an inherited Robertsonian translocation is nondisjunction of the Robertsonian translocation in meiosis II or first mitotic division of the zygote.

3225F

Detection of Interstitial 9q34.2-q34.3 Deletion Including the COL5A1 Gene by Array-CGH in a Patient With Classical Ehlers-Danlos Syndrome and Developmental Delay. *E.C. Beltran[1,2,3], D.W. Stockton[1,2,3], M. Hicks[1,2,3], M. Hankerd[4,5], D. Schloff[4,5], M. Kristofice[4,5], S. Ebrahim[4,5].* 1) Children's Hospital of Michigan-Specialty Center, Detroit, MI; 2) Division of Genetic and Metabolic Disorders, Detroit, MI; 3) Department of Pediatrics, Wayne State University School of Medicine, Detroit, MI; 4) Department of Pathology, Wayne State University School of Medicine, Detroit, MI; 5) Detroit Medical Center University Laboratories, Cytogenetics Laboratory, Detroit, MI.

Ehlers-Danlos syndromes (EDS) are a heterogeneous group of heritable connective tissue disorders. The classic type is characterized by hyperextensible skin, atrophic cutaneous scars due to tissue fragility and joint hyperlaxity. Mutations within the COL5A1 (9q34) or COL5A2 (2q31) genes have been found in about half of patients with Classical Type EDS. We report a 13 year old female who was referred for a genetic consultation because of EDS, developmental delay with mild cognitive impairment and partial complex seizures. She was diagnosed with EDS at 8 years by a skin biopsy. Genetic workup for a unifying diagnosis identified an interstitial 9q34.2-q34.3 deletion encompassing the COL5A1 gene. Array comparative genomic hybridization (CGH) testing detected a 1.95 Mb interstitial deletion involving chromosome 9 long arm region: arr[hg18] 9q34.2q34.3 (136,405,205-138,358,850)x1. The deleted segment harbors 35 genes including COL5A1 gene implicated in Ehlers-Danlos syndrome. However, the deleted region does not include the EHMT1 gene suggested to be associated with 9q subtelormeric deletion also known as Kleefstra syndrome. Partial deletions of chromosome 9 long arm are rare, and are associated with a wide range of phenotypes depending on the size of the deleted region. A MEDLINE search for reports of chromosome 9q34.2-q34.3 deletions encompassing the COL5A1 gene did not reveal similar cases. However, there are a few reported cases with deletions that overlap this region described in individuals with variable degrees of developmental delay, cognitive impairments, facial dysmorphisms, and other congenital malformations. Deletion of chromosome 9q encompassing the COL5A1 gene in our patient is likely satisfactory explanation for her classic EDS presentation plus her neurological symptoms. The specific contribution of the other genes in the region to her neurologic symptoms is not clear. She has some phenotypic similarities to the 9q subtelomeric deletion syndrome despite excluding the EHMT1 gene.

3226T

Use of cytogenetic tools to detect oxidative damage markers in diabetes mellitus and cardiomyopathy patients. *R. Saraswathy[1], C.R.A. Moses[2], K.T. Babu[3].* 1) Biomolecules and Genetics, VIT University, Vellore, India; 2) Madras Medical College, Chennai; 3) Heartline Medical and Research centre, Vellore.

Oxidative DNA damage is known to be strongly correlated with age related diseases and cancers. Various in vitro and in vivo cytogenetic methods have been developed to assess the DNA damages in human and animals. In this study a correlation between the DNA damages in diabetes mellitus and cardiomyopathy patients due to oxidative stress developed during pathogenesis was determined. The cytogenetic tools such as chromosomal aberration analysis and cytokinesis block micronucleus cytome assays were utilized. The results revealed a significantly higher frequency of DNA damage in the patients than in the controls. The interaction between the defect in the patient's genome and various environmental contaminants they are exposed to may lead to DNA damage and genomic instability. This study will not only lead to the use of cytogenetic tools to assess the oxidative damage markers in other human diseases but develop interventional strategies for prevention.

3227F

Partial Trisomy 21 in a Patient without the Down Syndrome Phenotype. *A. Umrigar[1], T.J. Chen[2], F. Tsien[1].* 1) Department of Genetics, LSU Health Sciences Center, New Orleans, LA; 2) Hayward Genetics Center, Tulane School of Medicine, New Orleans, LA.

We present a 24-year old female who was found to have trisomy 21 by routine karyotype, but did not present with the typical Down Syndrome phenotype. The patient had short stature, strabismus, and mental deficiency, but with none of the common dysmorphic features of Down syndrome. Previous results indicated that the patient had three copies of chromosome 21, one of which appeared smaller in size. Subsequent fluorescence *in situ* hybridization (FISH) using the Down Syndrome Critical Region (DSCR) probe showed a deletion of the 21q22.11-22.2 region on the third copy of the 21 chromosomes. Microarray comparative genomic hybridization (aCGH) revealed a deletion of approximately 13.721 Mb at 21q22. Thus, it is concluded that the patient's lack of the Down Syndrome phenotype is due to this deletion. This occurrence is extremely rare, requiring both the deletion of the DSCR and a meiotic non-disjunction event of the normal chromosome. Additionally, the proband later miscarried a fetus with Potter syndrome, but we were unable to perform cytogenetic and molecular analyses of the products of conception (POC). Our case demonstrates the importance of molecular confirmation in atypical patients previously diagnosed by karyotype.

3228T

Age-related decrease of meiotic cohesins in human oocytes. *M. Tsutsumi[1], R. Fujiwara[1], H. Nishizawa[1], H. Kogo[2], H. Inagaki[1], T. Ohye[1], T. Kato[1], H. Kurahashi[1].* 1) Fujita Health University, Toyoake, Japan; 2) Gunma University, Maebashi, Japan.

Chromosomal segregation error, e.g. nondisjunction or predivision, during meiotic cell division produces aneuploid gametes. Aneuploidy of fetal chromosomes causes miscarriage or newborns with congenital birth defects such as Down syndrome (DS). It is well known that the majority of the extra chromosome of trisomy 21 in DS originates from segregation error of maternal meiosis I, and the risk of DS increases with maternal age. Also, age-related aneuploidy causes elevated risk of miscarriage in older women. However, the etiology of maternal age-related increase of segregation error remains unclear.

Meiotic cohesins have a key role in correct segregation of chromosomes in meiosis. In mammalian oocytes, the cohesion between sister chromatids is established by the cohesin complex at fetal stage, and then the oocytes become arrested at prophase I for a prolonged period until they are ovulated after the sexual maturation. However, it has been shown that the meiotic cohesin does not undergo turnover after birth in female mice. It is possible that this might cause the gradual decrease of cohesins, and then results in increased risk of age-related segregation error.

To verify this hypothesis, we examined the amount of meiotic cohesins in oocytes by quantification of immunofluorescence signal intensity on ovarian tissue sections. Oocytes were obtained from ovaries surgically resected from eight women having ovarian cancers (age range: 19-49 years) as well as those from normal C57BL/6N female mice. It was demonstrated that the immunofluorescence levels of meiosis-specific cohesin subunits, REC8 and SMC1B, decreased in women in their 40s compared to around 20 years old. Age-related decrease of meiotic cohesins was also shown in mice. In contrast, the signal levels of subunits shared by mitotic and meiotic cells, SMC3 and RAD21, did not change. These results suggest that the decrease of the meiotic cohesin subunits impairs the cohesion between sister chromatids with age to induce segregation error. To elucidate the mechanism of decrease of meiotic cohesins will contribute to develop a novel strategy to prevent age-related increase of aneuploidy.

3229F

Microcephaly and chromosomal abnormalities: review of four years study. *M. Kammoun[1], S. Dimassi[1], H. Hannachi[1], I. Bel hadj Hmida[1], N. Soyah[2], H. El Ghzel[1], A. Saad[1], M. Soumaya[1].* 1) department of cytogenetic and reproductive biology, Farhat hached, university teatching Hospital, Sousse, Tunisia; 2) Department of pediatrics, Farhat hached, university teatching Hospital, Sousse, Tunisia.

Microcephaly is clinically a heterogeneous disorder caused by several conditions including genetic defects. We analyzed cytogenetic profiles of 135 children referred for microcephaly during the period from January 2009 to December 2012. Standard karyotyping was abnormal in 14% of cases. Conventional and molecular Cytogenetic analysis using Fluorescent In Situ Hybridization and Comparative Genomic Hybridization array showed us that microcephaly is mostly related to Angelman syndrome(42%) , chromosome 18 rearrangements(26%) and Wolf Hirschorn syndrome (WHS) secondary to 4p16.3 deletion(21%). Down syndrome, Williams and Turner syndrome, 8p23.1 and 5p21 deletion, 17q23 duplication, trisomy X and Xq28 duplication were also associated to microcephaly. Microcephaly is commonly induced by autosomal recessive mutations. Nevertheless, it is associated to the majority of chromosomal rearrangements. UBE3A gene, which is involved in AS, is proved to contribute to cellular proliferation and its invalidation was shown to be significantly associated to increased cerebellar apoptosis. Microcephaly is probably related to DOK6 haploinsufficiency located at 18q 22 and shown to be involved in cortex neurite outgrowth and in neural precursor cell differentiation during cortical development. Otherwise, Xq28 duplication is an emerging syndrome that involves MECP2 gene, a transcriptional regulatory factor strongly involved in the central nervous system development. Microcephaly is frequently associated to chromosomal rearrangement. CGH array is of great importance to detect cryptic anomalies and to narrow critical regions of microcephaly and so identifying new candidate microcephaly genes.

3230T

Constitutional 560.49 kb chromosome 2p24.3 duplication including the MYCN gene identified by oligonucleotide and SNP chromosome microarray analysis in a child with multiple congenital anomalies and bilateral Wilms tumor. *M.A. Micale[1,3], B. Embrey IV[1], J.K. Macknis[1,3], C.E. Harper[2], D.J. Aughton[2,3].* 1) Dept Pathology and Laboratory Medicine, Beaumont Health System, Royal Oak, MI; 2) Beaumont Children's Hospital, Royal Oak, MI; 3) Oakland University William Beaumont School of Medicine, Rochester, MI.

Less than 100 patients with partial chromosome 2p trisomy have been reported.Clinical features are variable and depend on the size of the duplicated segment, but generally include psychomotor delay, facial anomalies, congenital heart defect, and other abnormalities. A subset of patients has also developed neuroblastoma. We report a 560.49 kb duplication of chromosome 2p in a 13 month-old male with hydrocephaly, ventricular septal defect, suspected partial agenesis of the corpus callosum, and bilateral Wilms' tumor. He underwent neoadjuvant chemotherapy followed by right radical nephrectomy that revealed triphasic Wilms' tumor with favorable histology and skeletal muscle differentiation. A needle core biopsy on one of two lesions on the left kidney revealed Wilms' tumor. A partial left nephrectomy revealed focally positive margins that necessitated left flank radiotherapy. The tumor karyotype was 46,XY,t(7;8)(q36;p11)[8]/46,XY[12]. DNA sequencing of the WT1 gene revealed no mutation. His constitutional karyotype was 46,XY, suggesting that the t(7;8)(q36;p11) was associated with the malignancy. Cytogenomic evaluation of peripheral blood utilizing a 135K NimbleGen oligonucleotide array revealed a 539.57 kb chromosome 2p24.3 duplication involving four OMIM genes: NBAS, DDX1, MYCNOS, and MYCN. SNP array analysis of the tumor utilizing the CytoScan HD array identified a 560.49 kb chromosome 2p24.3 duplication with no other pathogenic genomic abnormalities. This is, to our knowledge, the first reported partial trisomy 2p case with constitutional MYCN duplication in a child with bilateral Wilms' tumor. As of May 2013, the 2-year-old boy continues to do well without clinical or radiographic evidence of recurrent disease. This case is also instructive because the child's health insurer initially denied authorization for CMA on the basis that 'there is insufficient evidence in the peer-reviewed literature to demonstrate the clinical/therapeutic utility' of CMA, and it was more than one year before such authorization was granted. That initial decision to deny coverage could have had untoward health implications for this child, as the identification of constitutional MYCN duplication necessitated surveillance for neuroblastoma. While the child did not develop neuroblastoma during the time it took to get insurance authorization for CMA, it is obvious how such a delay could have precluded early detection of a second malignancy for which this child is at high risk.

3231F

Incorporation of flanking probes reduces truncation losses for fluorescence in situ hybridization analysis of recurrent genomic deletions in tumor sections. *M. Yoshimoto[1,2], O. Ludkovski[3], J. Good[1], R.J. Gooding[4], A. Boag[1], A. Evans[3], M.S. Tsao[3], P. Nuin[1], J. McGowan-Jordan[2,5], J.A. Squire[1].* 1) Department of Pathology and Molecular Medicine, Queen's University, Kingston, Canada; 2) Cytogenetics Laboratory, Children's Hospital of Eastern Ontario, ON, Canada; 3) University Health Network, Princess Margaret Hospital, Division of Applied Oncology, Toronto, ON, Canada; 4) Department of Physics, Engineering Physics and Astronomy, Queen's University, Kingston, ON, Canada; 5) Department of Pediatrics, University of Ottawa, Ottawa, ON, Canada.

The establishment of quality control standards in clinical laboratories using routine fluorescence in situ hybridization (FISH) analysis of formalin-fixed paraffin-embedded (FFPE) sections is crucial as more genomic biomarkers are used for predictive and prognostic oncology. For gene fusions, break-apart and gene amplifications there are guidelines for both analysis and reporting, but at the present time there are no comparable guidelines for the application and analysis of genomic deletions using FFPE sections. The use of FISH on archival FFPE samples is technically demanding and becomes more challenging when applied to paraffin-embedded tissue microarrays. In this study we report a generalizable four-color deletion FISH approach to assist interpretation problems arising when evaluating FISH signals. The guidelines will help address interpretative dilemmas associated with overlapping and truncated nuclei in FFPE prostate cancer sections. The four-color FISH approach was developed using the PTEN gene deletion model in prostate cancer. The PTEN assay was based on a robust bioinformatics analysis of 311 published human genome array datasets and comprises a centromeric 'chromosome enumeration' probe, a specific PTEN gene probe, and flanking probes either side of the target probe. The sensitivity and specificity parameters of the four-color PTEN probe set were further characterized using a large number of well-characterized tumors and stringent scoring criteria. The incorporation of flanking probes allowed the analysts to determine if the chromosomal region was subject to truncation loss. A minimum threshold for apparent deletion frequency was set to address the heterogeneous and homogeneous nature of tumor histology. In addition the approach facilitated analysis of genotypic heterogeneity and varying clonality within different foci of tumor in the prostate. Overall the approach provided robust and highly reproducible results that minimized inter- and intra-assay variability. The four-color FISH deletion assay reduced the frequency of misinterpretation and improved both the quality and throughput of FISH analyses using clinical samples. Moreover the use of established controls and conservative cut-offs for assigning deletions will facilitate more coherent approach to developing reporting standards for deletion assays as more tumor suppressor genes of clinical importance are discovered by next generation sequencing methods.

High resolution genome profiling in Li-Fraumeni patients without germline mutations in TP53 gene. *T.R. Basso[1], R.A.R. Villacis[1], M. Pinheiro[2], M.I.W. Achatz[1,3], S.R. Rogatto[1,4].* 1) CIPE, AC Camargo Cancer Center, São Paulo, SP., Brazil; 2) Bioscience Institute, UNESP, Botucatu, SP., Brasil; 3) Oncogenetics Department, AC Camargo Cancer Center, São Paulo, SP., Brazil; 4) Department of Urology, Faculty of Medcine UNESP, Botucatu, SP., Brazil.

Li-Fraumeni (LFS) and Li-Fraumeni like (LFL) syndromes predisposes a variety of different tumors occurring over a wide age range and are associated with germline mutations in TP53. Around 80% of LFS and 40% of LFL are predictive to carry germline TP53 mutations. The aim of this study was to assess germline copy number variations (CNVs) in a cohort of 18 patients with tumors typical of LFS/LFL, history of multiple primary tumors and without pathogenic mutations in the TP53 gene. Peripheral blood samples were obtained from patients at least one year after finished the chemotherapy and or radiotherapy. Genomic alterations were evaluated using the Affymetrix high-density microarray platform (CytoScan™HD). The data were analyzed by Affymetrix Chromosome Analysis Suite (ChAS) software. The CNVs detected were confirmed using the single nucleotide polymorphic (SNPs) probes present in the same platform. It was found 21 CNVs: Genomic gains on 1p31.3, 11q25 and 21q21.1 were detected in one case each. Nine cases presented 18 genomic losses mapped on chromosomes 1, 2, 4, 6, 7, 8, 9, 13 and 14. One female patient, who developed three malignant neoplasms (melanoma at age 40, breast at age 43 and bladder carcinoma at age 47), presented five genomic losses. Interestingly, one patient with history of three tumors (breast at age 58, non-Hodgkin lymphoma at age 61 and lip carcinoma at age 65) exhibited a large deletion (43 Mb) on 7q22.1-34. One patient was diagnosed as Turner Syndrome. In overall these findings reveal putative candidates associated with multiple primary cancer predisposition in these families.

3233F

A patient with Angelman-like features due to deletion of chromosome 15q26.1q26.2 encompassing *CHD2* and *RGMA*. *S. Kantarci[1], J.A. Martinez[2]*. 1) Deparment of Pathology and Laboratory Medicine, UCLA; 2) Depatment of Human Genetics, UCLA, Los Angeles, CA.

Angelman syndrome (AS) is a neurodevelopmental disorder caused by a variety of genetic abnormalities involving chromosome 15q11-13 region that is subject to regulation by genomic imprinting. Characteristic clinical features include severe developmental delay, speech impairment, gait ataxia, seizure, inappropriate laughter, microcephaly, strabismus, subtle dysmorphic facial features, and hyperactive lower limb deep-tendon reflexes. About 10% of patients with a presumptive clinical of Angelman syndrome (AS) have an unknown etiology. Here, we report a 4.5-year-old female patient with a history of global developmental delay. The patient was born to a 39-year-old G4 P3 mother with an ectopic pregnancy at 40 weeks' gestation. Prenatal chromosome testing was normal. At birth, the weight was 6 pounds and the length was 19 inches. She developed strabismus at 4 months of age and wears eyeglasses. By the age of 2 years, she presented speech delay, hypotonia, and increased tone on the left lower extremity. She walked at 14 months old, but toilet trained at 2.5-year-old. Although she had previously some ambulatory issues, her walking improved immediately after bilateral eye repair but she has some spasticity of the left lower extremity. She had her first words at the age of 2.5 years and sentences by 3.5-year-old. She has short stature, microcephaly, dysmorphic features (facial hypotonia with a flat midface, posteriorly rotated ears, micrognathia, and down turned corners of the mouth), and bilateral 5th finger clinodactyly. The patient was recently found to have absence seizures by EEG and they remain uncontrolled. Her parents and two siblings are healthy. Chromosomal microarray analysis (CMA) using Affymetrix CytoHD SNP array revealed a 2.7 Mb deletion of chromosome 15q26.1q26.2 ranging from genomic position 93,510,242 to 96,199,396 (GRCh37/hg19). This deletion interval includes 5 RefSeq genes: *CHD2* (exons 17-39), *RGMA*, *MCTP2*, *LOC400456*, and *LOC145820*. Parental CMA studies were not available. Chromosome 15q26.1q26.2 deletions (>5Mb) including *CHD2*, *RGMA*, and additional genes have been previously reported in patients with congenital diaphragmatic hernia. Recently, a de novo ~500Kb deletion of 15q26.1 encompassing only *CHD2* and *RGMA* in a female patient with Angelman syndrome-like phenotype without diaphragmatic hernia was described. Our report supports the significance of chromosome 15q26.1 deletion encompassing *CHD2* and *RGMA* in Angelman syndrome-like phenotype.

3234T

De novo complex unbalanced chromosome rearrangement, a case of ``constitutionalchromothripsis''. *M. Haddadin[1], M. ElNaggar[1], T. Sahoo[1], R. Owen[1], LM. Bird[2], L. Ross[1], S. Wang[1], L. Hinman[1], F. Boyar[1]*. 1) Deptartment of Genetics, Quest Diagnostics, Nichols Institute, San Juan Capistrano, CA; 2) Department of Pediatrics, Division of Genetics/Dysmorphology, Rady Children's Hospital San Diego.

The term complex chromosome rearrangement (CCRs) is used when 3 or more breaks involving two or more chromosomes are present. Chromothripsis was first coined by Stephens PJ, et al. (2011) to describe massive clustered chromosomal rearrangements (breakage and illegitimate repair) in cancer cells. Subsequently a similar phenomenon leading to CCRs in the germline of patients with congenital disorders was described (Kloosterman WP et al., 2011). The wide utilization of Oligo-SNP array for the study of congenital disorders and developmental abnormalities has allowed for the discovery of a wide range of genomic micro-rearrangements that were not detectable by conventional chromosome studies. Here we report a case of a newborn child with ventricular septal defect, Dandy Walker malformation, craniosynostosis, solitary right kidney and cryptorchidism. Chromosome analysis revealed an unbalanced rearrangement involving chromosomes 2 and 4. Oligo SNP-array study combined with FISH studies targeting the involved regions revealed a CCR involving chromosomes 1, 2 and 4, with duplicated segments of distal 1q, fragmented into five segments and inserted randomly into 2p and 4p. A pericentric inversion of chromosome 2; a reciprocal translocation between 2p and 4p and a microdeletion on 7q were also observed: (46,XY,der(2)ins(2;1)(p23;q41q32.1)inv(2)(p23q14.2)t(2;4)(p23;p16),der(4) ins(4;1)(p15.3;q41q42.1)t(2;4)(p23;p16,arr1q32.1q41(203,434,243-222,304,374)x3,1q42.11q42.12(224,577,514-225,253,174)x3, 1q42.12q42.2(226,610,463-231,048,716)x3,7q36.1(150,301,556-15 1,452,199) x1). Parental chromosome analysis and Oligo-SNP array analysis were normal. Since partial trisomy of chromosome 1 is very rare, segmental duplication of distal 1q may be the upper limit of what an embryo can tolerate and still survive. Although the other chromosome breaks and possible disruption of critical genes may contribute to the phenotype of this patient, the cardinal anomalies of skull deformation, CNS, cardiovascular and genitourinary anomalies in this patient may be attributed mainly to partial 1q duplications. A minimum of 17 break and reunion events involving 3 chromosomes having multiple translocations, duplications and an inversion characterize this CCR. Until recently, the finding of a de novo CCR of a child was attributed to germline mosaicism for one or more rearrangement in a parent. Germline chromothripsis may be involved in this case.

3235F

Telomerase gene copy number is increased in IBD and PSC. *A. Amiel[1,2], Y. Sulayev[1,2], H. Katz[1,2], A. Stein[3], M. Liberman[1], F. Konikof[3], I. Laish[3]*. 1) Genetic Institute, Kfar-Saba, Israel; 2) Bar-Ilan University, Ramat-Gan; 3) Gastroenterology and Liver Institute,.

Background: Telomerase is an enzyme complex that lengthens telomeres. It is composed of the catalytic subunit of human telomerase reverse transcriptase (hTERT) and the telomerase RNA component (TERC) encoded by TERC gene. Gene amplifications involving the TERC gene (3q26) are frequent in human tumors. Telomere capture (TC) is an alternative process by which broken chromosomes can aquire new telomeres. Primary sclerosing cholangitis (PSC) and inflammatory bowel disease (IBD) are pre-malignant conditions. The aim of this study was to evaluate the TERC gene copy number and TC status in peripheral lymphocytes of patients with PSC and IBD, as a possible surrogate marker for increased tendency for malignancy. Methods: By applying fluorescence in situ hybridization (FISH) to leukocytes of 14 PSC patients, 13 IBD patients (8 with Crohn's disease, 5 with ulcerative colitis) and 12 healthy controls, we estimated gene dosage of the TERC gene at 3q26.3. We used the SNRPN and 13q14.3 genes (red) and the 13qter and 15qter (in green) to evaluate the TC phenomenon. Results: The percentage of cells with more than two copies of the TERC gene was significantly higher in PSC patients (mean (3 x red signals) 44.7) than in IBD patients (mean 29.6) and controls (mean 3.9; p-value < 0.0001). The TERC gene copy number was also higher in PSC patients with concomitant colitis (64%) despite significantly lower disease activity indices. Significantly more cells were observed with TC with both genes in IBD lymphocytes than in control cells. Conclusion: TERC gene copy number is increased in IBD and even more in PSC lymphocytes, while TC is higher in IBD lymphocytes. These findings may be related to the different tendencies and predispositions of these conditions to become malignant. In addition, TC is another mechanism for telomere elongation and is probably higher when the telomerase gene copy number is lower.

3236T

Structural anomalies of the Y chromosome versus sexual ambiguity or infertility. *I. Ben Hadj Hmida[1], S. Dimassi[1], M. Kammoun[1], H. Kairi[2], H. Marmouche[3], A. Saad[1], S. Mougou-Zrelli[1]*. 1) Laboratory of Cytogenetics and Reproductive Biology and Human Genetics, Farhat Hached University Teaching Hospital, Sousse, Tunisia; 2) Department of Gynecology, Farhat Hached University Teaching Hospital, Sousse, Tunisia; 3) Department of Endocrinology, University Hospital Fattouma Bourguiba, Monastir, Tunisia.

Human Y chromosome evolution has progressively been directed towards a role in sex determination and reproduction. Among the structural anomalies of chromosomes, Robertsonian translocations between acrocentric chromosomes and reciprocal translocations are found with a frequency of 8 to 10 times higher in infertile men. Given the rather random chromosomal breakpoints encountered in reciprocal translocations, it is unlikely that achieving gametogenesis is due to the systematic breaking of a major gene in spermatogenesis. Genetic disorders of chromosomal origin could give rise to abnormal karyotypes or germinal mosaic figure. They could involve gene abnormalities affecting numerous genes localized on several chromosomes, in particular the Y chromosome. The physiopathologic identification of male infertility is interesting because of the risk of the genetic factors involved being transmitted to the offspring The isochromosome Y of either can be detected in female subjects with a classic Turner syndrome, or in subjects with gonadal dysgenesis with ambiguous genitalia or infertile male subjects. We identified, in the laboratory of Human Cytogenetics and Reproductive Biology, during January 2010 to January 2012, two patients with karyotype 46, XisoYp/45, X in one woman with a hypogonadotropic hypogonadism with Karyotype 46,XisoYp[5]/45, X[7] and in a man having azoospermia and sexual ambiguity with Karyotype 46,XisoYp[12]/45, X[6]. A fluorescent in situ hybridization was performed for these two cases in search of the SRY gene was present showing the form isochromosomique. The relationship between chromosomal abnormalities and infertility are not yet clear, since subjects with alterations may be highly variable in their spermatogenesis. Chromosomal rearrangements observed could either delete one or more genes involved in spermatogenesis or prevent proper chromosome pairing and initiate a shutdown of meiosis. Therefore individuals carrying isochromosomes Y, are described with variable phenotypes of infertility. Clinical manifestations range from a kind female phenotype Turner, a male phenotype with azoospermia and sexual ambiguity. Azoospermia may be accompanied by a deletion of the region Azoospermia factor (AZF).

3237F

Molecular Diagnosis of Deletions and Duplications Associated with Intellectual Disability and Obesity. *C.S. D'Angelo[1], M.F.M. Santos[1], C.A Kim[2], C.M. Lourenço[3], C.P. Koiffmann[1].* 1) Human Genome and Stem Cell Center, Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of Sao Paulo, Sao Paulo, Brazil; 2) Genetics Unit, Department of Pediatrics, Children Institute, School of Medicine, University of Sao Paulo, Sao Paulo, Brazil; 3) Neurogenetics Unit, Department of Medical Genetics, School of Medicine, University of Sao Paulo, Ribeirao Preto, Brazil.

Some rare genetic syndromes lead to obesity, often associated with intellectual disability (ID), abnormal development, dysmorphic features and congenital malformations. Prader-Willi syndrome (PWS) is the most common syndromic form of obesity. It is caused more specially by deletions of the SNORD116 (H/MBII-85) gene cluster in the paternally derived PWS/ Angelman syndrome (AS) region of chromosome 15. Other genomic disorders associated with copy number variants (CNVs), such as chromosomal deletions of 1p36, 2q37, 6q16, 9q34, 11p13 and 17p11.2, have an increased prevalence of obesity. In most cases, haploinsufficiency of one gene in the deleted region explains the majority of phenotypes of the disorders (e.g. HDAC4 [2q37], EHMT1 [9q34], RAI1 [17p11.2]), whereas in other syndromes haploinsufficiency of one gene in the deleted region explains only some specific feature(s); haploinsufficiency of SIM1 and BDNF explains the obesity in PWS-like patients with interstitial 6q deletions and WAGR patients with larger 11p13 deletions, respectively. The recent implementation of chromosomal microarray analysis (CMA) into the field of clinical genetics has revealed an increasing number of CNVs that are factors, or causes of obesity co-morbid with ID, e.g. deletions at 1p21.3, 2p25.3, and 16p11.2. Nearly 300 patients with obesity in the context of an ID syndrome were evaluated for chromosomal imbalances by MLPA after DNA methylation analysis ruled out PWS. Half of these patients were further investigated with different array platforms. We identified syndromic genomic disorders, such as deletions of 1p36 (7 cases), 2q37 (HDAC4; 5 cases), 6q16 (SIM1; 2 cases), 9p24 (3 cases), 9q34 (EHMT1; 1 case), and 17p11.2 (RAI1; 5 cases), as well as specific CNVs already linked to obesity, such as 1p21.3 and 2p25.3 deletions and an unbalanced translocation der(8)t(8;12) . Additionally, we identified 22q11.2 deletions causing DiGeorge syndrome (6 cases), 22q11.2 duplication syndrome (1 case), and 22q11.2 distal deletion syndrome (2 cases). Known genomic disorders with incomplete penetrance and variable expressivity included 15q11.2 deletion of NIPA1 (2 cases), 16p11.2 deletion of SH2B1 (1 case), 16p11.2 duplication of TBX6 (1 case), 16p13 deletion of MYH11 (1 case), 17q11.2 duplication of NF1 (1 case), and 17q21.31 duplication of MAPT (1 case). Clinical variability in well-known syndromes may facilitate the identification of disease genes.Financial Support: CEPID-FAPESP, CNPq.

Mechanisms of concurrent deletions and duplications at 1p36. *M. Gajecka[1,2], J.A. Karolak[1,2], J. Shen[3], K. Wakui[4], C. Glotzbach[5], L.G. Shaffer[6].* 1) Institute of Human Genetics, PAS, Poznan, Poland; 2) Department of Genetics and Pharmaceutical Microbiology, Poznan University of Medical Sciences, Poland; 3) Children's Hospital Central California, Madera, CA, USA; 4) Department of Medical Genetics, Shinshu University School of Medicine, Nagano, Japan; 5) Signature Genomic Laboratories, PerkinElmer, Inc., Spokane, WA, USA; 6) Paw Print Genetics, Genetic Veterinary Sciences, Spokane, WA, USA.

In Monosomy 1p36, four classes of rearrangements are identified: pure terminal deletions, interstitial deletions, unbalanced translocations and complex rearrangements. Here we present seven cases of complex rearrangements involving terminal or interstitial deletions and duplications. To characterize the aberrations and identify mechanisms of concurrent deletion and duplication formation, rearrangements were analyzed using array CGH, SNP arrays and other molecular cytogenetics and molecular biology methods. For each individual, deletion and duplication sizes and parental origin of the rearrangements were determined. Fiber FISH analysis demonstrated either tandem or direct duplications. Rearrangement breakpoints were determined and characterized and we found that deletion and duplication sizes as well the breakpoints locations were different in each patient. We were not able to identify all junctions in the rearrangements. In four cases, apparently simple junctions were found to be more complex at the sequence level. Both duplications and deletions were interrupted with insertions of material from 1p or other chromosomal regions. Our results show higher than accepted complexity of the studied rearrangements and indicate involvement of multiple mechanisms in the DNA breakage and repair process during rearrangement formation. Scenarios of the rearrangement formation based on the DNA sequence level examination and computational analyses will be presented. Support: Polish Ministry of Science and Higher Education, Grant NN301238836.

Unexpected 10.6 Mb 19q13.33q13.43 duplication due to a de novo translocation: Contribution for phenotype-genotype correlation. *F.T. Lima, G.M.G. Carvalheira, S.S. Takeno, M.M. Oliveira, V.F.A. Meloni, M.I. Melaragno.* Disciplina de Genética, EPM-UNIFESP, Sao Paulo, SP, Brazil.

The current use of high-resolution techniques, such as genomic arrays, has revealed an unprecedented number of different cytogenomic unbalances. One of them, partial trisomy 19q, a rare aneusomy, had only a few cases reported in literature, with different breakpoints and an inconsistent clinical delineation. We report on a female patient with mild phenotypic findings and an important cognitive alteration, the only child of a non-consanguineous couple. At eight years old, she presents some facial dysmorphisms, astigmatism, short stature, long fingers, Raynaud's phenomenon, skeletal alterations, neuropsychomotor developmental delay and intellectual disability. She had recurrent infections, urolithiasis and seizures beginning at age four years old. Karyotype using G-banding at 550 band-resolution was normal. Subsequent studies with the MLPA (Multiplex Ligation-dependent Probe Amplification) technique, using SALSA MLPA kit P070 Human Telomere-5 containing probes for subtelomeric regions, revealed three copies of 19q. Genomic array using the Affymetric Genome-Wide Human SNP Array 6.0 showed a 10.6 Mb duplication of the long arm of chromosome 19 resulting in: arr19q13.33q13.43(48,463,121-59,097,842)×3. FISH with a BAC probe for 19q13.43 (RP-11-359B7), used to determine the genomic duplication position, revealed that the duplicated region was attached to the short arm of chromosome 21. The distal region of the chromosome19 corresponds to a genomic segment with a very high transcriptional activity, with more than 600 known genes encompassed by the duplicated region, 30 of them associated with known diseases, including epilepsy, intellectual disability and speech delay, as presented by the patient described. This rearrangement is unprecedented in literature, and its size is unexpected in view of the phenotype observed. The phenotypic consequences of duplications are complex to be studied because the chromatin context can modify the transcriptional status of trisomic segments, especially when attached near DNA repetitive regions. Therefore, localization and orientation of the extra copy may interfere in its expression levels and, consequently, in the clinical features. This report adds important data for the genotype-phenotype correlation of this region and emphasizes the importance of a cytogenomic assessment in the presence of a normal karyotype. Financial support: FAPESP, CNPq, Brazil.

Small supernumerary marker chromosome 17: molecular characterisation of a new case and review of the literature. *J.M. Turbitt[1], J. Murphy[1], R. McGowan[2], P. Batstone[1].* 1) Cytogenetics department, North of Scotland Regional Genetics Service, Aberdeen; 2) Clinical Genetics Unit, Aberdeen Royal Infirmary, Aberdeen.

Small supernumerary marker chromosomes (sSMC) are structurally abnormal chromosomes that cannot be thoroughly characterised by conventional G-banding analysis and are present in 0.288% of patients with developmental delay. The unstable, gene-rich 17p11.2-p12 chromosome region is associated with various structural anomalies including SMCs. To date there are relatively few cases of chromosome 17-derived sSMCs reported in the literature. Those that are recorded are of variable size, tissue distribution and level of mosaicism. Here we report a 30-year-old male with a de novo mosaic SMC(17). Our patient presented with learning difficulties, anxiety and tremors and is a known carrier of a paternally inherited balanced translocation between chromosomes 1 and 11, which is thought not to contribute to his phenotype. Conventional cytogenetic analysis revealed the presence of two cell lines. One cell line had 46 chromosomes and the t(1;11) and the second had 47 chromosomes with the t(1;11) and an additional sSMC. FISH and array-CGH studies revealed that the sSMC was comprised of the centromere and proximal short arm of chromosome 17. The sSMC appeared to be present in approximately 70% of cells. Parental chromosome analysis and array-CGH indicate that the sSMC appears to have arisen de novo. Phenotypically patients with the sSMC(17) have been described with mental retardation/developmental delay, hypotonia and dysphasia; features which are often found in Potocki-Lupski syndrome (PLS). Whilst this patient's duplication overlaps the PLS region it does not include the FLII/RAI1 gene region that has been implicated in the syndrome. To our knowledge, only a few cases of SMC(17) that do not include this region have been described to date. Our patient's SMC(17) will be compared to other reported cases in the literature.

3241F

Wolf Hirschhorn Syndrome with epibulbar dermoids in a patient with deletion 4p associated to Xp duplication. *S. Bragagnolo, M. Colovati, R.S. Guilherme, M.I. Melaragno, A.B. Perez.* Centro de Genética Médica, UNIFESP - EPM, São Paulo, São Paulo, Brazil.

Wolf-Hirschhorn syndrome (WHS) is a multiple malformation genomic syndrome that results from a deletion of the critical region (WHSCR) at 4p16.3 region. About 50%-60% of individual have a de novo deletion of 4p16 and about 40%-45% have an unbalanced translocation de novo or inherited from a parent with a balanced rearrangement. WHS is characterized by typical craniofacial features consisting of broad bridge of the nose continuing to the forehead, microcephaly, high forehead with prominent glabella, ocular hypertelorism, epicanthus, highly arched eyebrows, short philtrum, downturned mouth, micrognathia, and poorly formed ears with pits/tags. All affected individuals have pre- and postnatal growth deficiency and retardation, hypotonia with muscle underdevelopment and developmental delay/intellectual disability. The ocular abnormalities include strabismus, refractive errors, downslanting palpebral fissures, microphthalmos, microcornea, iris coloboma, optic nerve coloboma, ocular cyst, ptosis, glaucoma, and nystagmus. The epibulbar dermoid, hemifacial microsomia, ear malformation and vertebral anomalies are observed in patients with oculoauriculovertebral spectrum (OAVS). It has been recently suggested, based on the molecular analysis of a balanced translocation t(4;8)(p15.3;q24.1) in an OAVS patient, that abnormal expression of BAPX1, located in 4p15.3, might be involved with the etiology of OAVS. We described a six month-old female, with cleft palate, pulmonary stenosis, atrial septal defect and gastroesophageal reflux. Presented with growth deficiency, developmental delay, apparent facial asymmetry, high forehead, ears tags and left microtia, cleft palate, pectus carinatum and pre-sacral pit. The ophthalmological evaluation revealed epibulbar dermoids in the right eye. Her mother, maternal aunt, grandmother and great-grandmother have ears pits and hearing impairment. The patient' s conventional G-banded karyotype was normal at 550 band resolution but genomic array (Genome-Wide Human SNP Array 6.0,Affymetrix) revealed a ~13 Mb deletion in chromosome 4 and a ~9 Mb duplication in chromosome X (.arr 4p16.3p15.33(68,345-13,569,183)×1,Xp22.33p22.31(168,551-8,907,556)×3, GRCh37/hg19), including the BAPX1 gene in 4p15.3, a possible candidate involved in OAVs pathogenesis. This is the first patient with WHS with epibulbar dermoids, hemifacial microsomia, and other phenotypic changes common to OAVS.

3242T

Goldenhar syndrome and oculoauriculovertebral spectrum (GS/OAVS): Clinical and cytogenomic study. *M.ES. Colovati, S. Bragagnolo, R.S. Guilherme, A.G. Dantas, A.B. Perez, M.I. Melaragno.* Genetics Division, Department of Morphology and Genetics, Universidade de São Paulo, São Paulo, Brazil.

Goldenhar syndrome (GS) has been characterized as having an association with external ear deformities, facial asymmetry, epibulbar dermoid, and vertebral changes. Its etiology is multifactorial, familial cases have been described with autosomal recessive or dominant. Some authors characterizes microtia, hemifacial microsomia and Goldenhar syndrome phenotypes a oculoauriculovertebral spectrum (OAVS). In contrast, Goldenhar syndrome is part of the OAVS, but there is changes in other organs or systems, the most common being cardiovascular (50%), central nervous system or mental impairment (5 to 10%) and renal / respiratory (5%). The accuracy of a clinical diagnosis is a challenge for clinical geneticists, since there is a heterogeneous phenotype and etiology. To date, several chromosomal abnormalities have been associated with the syndrome involving most frequently 22q and 5p. In literature, five 22q11.2 microdeletions have been described involving the same region, suggesting a possible OAVS candidate gene. In this study we analyzed 30 patients with GS/OAVS by G-banding and we found three patients with positive cytogenetic results with two apparent chromosome heteromorphisms and one inversion: 14ps+, 15ps+ and inv(12)(q15q24.1). These three patients were evaluated by genomic array (Genome-Wide Human SNP Array 6.0,Affymetrix) and Multiplex Ligation-Dependent Probe Amplification (MLPA kit SALSA P250). In one patient these metodologies revealed a ~581 kb deletion in chromosome 22 (.arr 22q11.21(20,716,923-21,297,749)×1, GRCh37/hg19). The regions deleted includes 21 genes and it is flanked by the low copy repeats LCR-B and LCR-C, not including the 1.5 Mb DiGeorge critical region (LCR-A to LCR-B). This patient presents hemifacial microsomia, retrognathia, agenesis of external auditory canal and ossicular chain with right moderate hearing loss, soft palate cleft, and thoracic hemivertebrae. His neuro-psycho-motor development is normal. We present the sixth patient with OAVS and 22q11.2 microdeletion reported in literature. This study supports the previous reports indicating that patients with GS/OAVS should be screened for 22q11.2 microdeletion and other chromosomal abnormalities in order to identify genomic loci that are potentially involved in this disease pathogenesis and also to understand the phenotypic and genetic heterogeneity in this syndrome. Financial support: FAPESP, Brazil.

3243F

CGH-array characterization of an interstitial 7p deletion in two patients exhibiting features of GCPS, RSS and SCS syndromes. *H. Hannachi[1], M. Kammoun[1], S. Dimassi[1], A. Labalme[2], D. Sanlaville[2], M. Gribaa[1], S. Mougou-ZERELLI[1], A. Saad[1].* 1) Human Cytogenetics, Molecular Genetics and Reproductive Biology Departements CHU Farhat Hached, Sousse, Tunisia; 2) Laboratoire de cytogénétique constitutionnelle Centre de Biologie et Pathologie Est CHU de Lyon-GH Est - Hospices Civils de Lyon 59 Boulevard Pinel 69677 BRON CEDEX FRANCE.

Given the richness of the short arm of chromosome 7 in genes regulating development, as GLI3, TWIST and HoxA cluster, 7p interstitial deletions are well documented. We report here, two additional patients sharing common clinical features involving severe craniofacial dysmorphism, syndactyly, severe psychomotor retardation and failure to thrive. Deletions, detected in standard karyotype, benefited of a CGH-array exploration revealing losses of genomic material of 11Mb and 13Mb. Molecular investigations performed to characterize the parental origin of rearrangements showed that the small deletion is carried by the paternal chromosome; the other is carried by the maternal one. Association of haploinsufficiency of the segment 7(p12p14) in the first patient with the triad of symptoms: frontal bossing, limb abnormalities, mental retardation evoked Greig syndrome (GCPS). Alteration of GLI3 gene is detected in 75% of patients carrying this syndrome. Haploinsufficiency of this gene in our patient resulted in several phenotypic features compatible with the mild form of GCPS. However, they differ in the occurrence of microcephaly and severe failure to thrive. The deleterious region encompasses the maternally imprinted segment 7(p12p13). Uniparental maternal disomy (UPDmat) of this interval was reported in 10% of Silver-Russell syndrome (RSS) patients. This syndrome is mainly characterized by a severe failure to thrive. Then, we hypothesize that the nullosomy for the paternal copy of 7(p12p13) gave rise to the symptoms of RSS, in this patient. On the other hand interstitial deletion of the segment 7(p21.3p15.3) in the second patient alters the candidate gene TWIST, which is known to be involved in 71% of cases of Saethre-Chotzen syndrome (SCS). Hemizygosity of this gene seems to be the main cause of SCS phenotypic manifestations in this patient. The particular severity of the phenotype and the development of an umbilical hernia may be related to the loss of a large number of genes mapping on this segment. Our findings support that the clinical features of patients with del(7p) are relatively consistent and specific to the region of deletion. Using CGH-array for diagnosis purposes may refine the characterization of additional cases allowing better genotype-phenotype correlation.

Compound Heterozygous Microdeletion of Chromosome 15q13.2q13.3 Region in a Child with Hypotonia and Global Developmental Delay. *P. PRASUN[1], L. SIVASWAMY[3], L. SCUSSEL[3], M. HANKERD[4], M. KRISTOFICE[4], S. EBRAHIM[2]*. 1) Division of Genetics and Metabolism, Children's Hospital of Michigan, Detroit, MI; 2) Department of Pathology, Wayne State University School of medicine, Detroit, MI; 3) Division of Pediatric Neurology, Children's Hospital of Michigan, Detroit, MI; 4) Detroit Medical Center University Laboratories, Cytogenetics Laboratory, Detroit, MI.

Heterozygous deletion of the 15q13.3 BP4-BP5 region (OMIM #612001) is characterized by a highly variable clinical phenotype ranging from mental retardation, epilepsy, neuropsychiatric disorders, and facial dysmorphism to a complete absence of symptoms. Homozygous and compound heterozygous micrdeletions of the same region are extremely rare with only a few cases having been reported in the literature to date. We report on the molecular detection of compound heterozygous 15q13.2q13.3 deletions in a 23 month old Caucasian female with global developmental delay, generalized muscular hypotonia, and visual dysfunction. The patient was first evaluated by pediatric neurologist at the age of 3 month and found to have generalized hypotonia, no head control, no face regard or visual fixation. MRI of the brain and routine karyotype were obtained both of which were normal. There was concern of cortical visual failure and a detailed evaluation by pediatric ophthalmologist was done. Ophthalmologic examination and evaluation consisting of visual evoked potential (VEP) and electroretinogram (ERG) were normal. Patient has a 6 year old brother with global developmental delay, hypotonia, and seizure disorder. He was found to have mosaicism for ring chromosome 20 by G-banding karyotype. Chromosomal microarray detected a 1.28 Mb deletion on one chromosome 15q13.2q13.3 region, and a smaller sized deletion estimated to be 410 Kb in size on the second chromosome 15q13.3 homologue resulting in nullisomy for at least the smaller deletion within the15q13 region. The larger deletion contained 7 genes: MTMR15, TRPM1, MIR211, KLF13, OTUD7A, CHRNA7, and MTMR10. The smaller deletion contained CHRNA7 and part of OTUD7A genes. The deletions were confirmed by FISH. Thus this patient is a compound heterozygous for the 1.28 Mb deletion on one chromosome 15q13.2q13.3 and a smaller size deletion on the other chromosome 15q13.3 region. Compound heterozygous 15q13.3 microdeletion is extremely rare and to our best of knowledge only two such patients have been reported in literature thus far. The findings in our patient suggests that pathogenesis of visual dysfunction which is a consistent finding in homozygous/compound heterozygous 15q13.3 microdeletion depends upon the size of microdeletion. Homozygous loss of CHRNA7 leads to cortical visual dysfunction while homozygous loss of TRPM1 further contributes to visual failure by retinal dysfunction.

3245F

Deletion 12q12 - 12q13.11: Case Report with unusual neurologic manifestations. *A.M. Zarante[1], G. Giraldo[1], J.C Prieto[1,2]*. 1) Instituto de Genetica Humana, Universidad Javeriana, Bogota, Colombia; 2) Hospital La Victoria, Secretaria Distrital de Salud, Bogota, Colombia.

Interstitial deletions involving the long arm of chromosome 12 are rare events and few case had been reported in the literature , this deletions are characterized by : developmental delay, growth retardation, macrocephaly, facial dysmorphism, prominent forehead, hypertelorism, downslanting palpebral fissures, upturned nose, Low-set ears, pterygium colli, cardiac anomaly, 2-3 toe syndactyly, single palmar creases, genitourinary malformations, anomalies , pyloric stenosis, Ectodermal anomaly, asthma/reactive airway, ocular abnormalities and normal MRI. We present a case of a Colombian girl of 8 years old. She was born at term after a normal pregnancy, non-consanguineous parents and family history was unremarkable. The patient presented a global developmental delay. MRI showed cerebellar vermix hypoplasia. The findings found on the physical examination were: microcephaly, narrow forehead, front and back low implantation hair, bilateral palpebral ptosis, downslanting palpebral fissures, high nasal root, hypoplastic nasal wings, anteverted nares, flat philtrum, thin lips, dental crowding, with winged ears, helix folding, in the limb presents shortening and clinodactyly fifth finger, 2-3 toe syndactyly and joint hypermobility. The band R karyotype reported: 46, XX, the Comparative Genomic Hybridization (CGH) analysis showed deletion of 12q12-12q13.11 (2,695 MB). The parents were negative for deletion of 12q12-12q13.11, Then it is a novo deletion. We describe a patient with a cytogenetically 12q deletion is about 2695 MB detected by Array CGH this deletion has been associated with developmental delay, growth retardation, facial dysmorphism. The striking thing about this case is the cerebellar vermix hypoplasia and microcephaly.

3246T

Molecular cytogenetic techniques in investigation of suspected microdeletion syndromes: an experience with 330 cases. *A. Halder, M. Jain, I. Chaudhary, V. Mohan, P. Kumar*. Reproductive Biology, All India Institute of Medical Sciences, New Delhi, Delhi, India.

Background: Microdeletion syndrome is characterized by small (< 5Mb) chromosomal deletion in which one or more genes are involved. They are frequently associated with multiple congenital anomalies. The phenotype is the result of haploinsufficiency of genes in the critical interval. FISH, MLPA, QFPCR and aCGH techniques are commonly used for the diagnosis. Here this study will assess role of FISH and aCGH in the diagnosis and research on suspected microdeletion syndrome. Method: This study was comprised of 330 cases of suspected microdeletion syndromes. There were 184 cases of 22q11.2 microdeletion, 52 cases of William, 47 cases of Prader Willi/ Angelman, 18 cases of Miller Dieker, 14 cases of Retinoblastoma, 5 cases of Trichorhinophalangeal (TRP) and 10 cases of other microdeletion syndromes. FISH was carried out in all using non-commercial probes. Subsequently, aCGH was performed in 55 cases (40 cases of 22q11.2 and 15 cases of other microdeletion). In another 36 (mostly 22q11.2 microdeletion) aCGH experiment is in progress. Result: FISH was confirmatory in 29 cases (8.8%; 20 cases of 22q11.2 microdeletion, 5 cases of Prader Willi, 3 cases of William and 1 cases of TRP syndrome). There were 10 cases with mosaicism and 19 cases with pure deletion. Microarray was picked up CNV with or without LOH in 72.5% of cases, mostly involving several chromosomal loci. However, aCGH was failed to pick up mosaic cases (even 45% deleted cell lines). Clinically suspected specific deletion was detectable only in 27.3% cases by aCGH. Variation in deletion size, break point difference as well as other CNVs was observed. Conclusion: We conclude FISH should not be the first method of choice for clinically suspected microdeletion syndrome as cost, labor & time versus benefit is unjust. We think aCGH should be first line of investigation and FISH may be used for confirmation, detecting mosaicism, screening family members and prenatal diagnosis. However, microarray is likely to miss mosaic cases, if deleted cell concentration is less than 50%. Furthermore, microdeletion syndrome best fitted with genomic disorder as several chromosomal loci are involved in CNV with or without LOH and alteration in deletion size or breakpoint. We did not find identical deletion profile in any case, thus explaining reason for phenotypic variability between cases.

3247F

Array CGH in pediatrics diagnosis versus karyotype. Experience with 189 cases. *M. Pérez Sánchez[1], A. Mora.[1], J.L. Barrionuevo.[2], S. Roldán.[2], A.R. González.[3]*. 1) Análisis Clínicos, Hospital Virgen de las Nieves, Granada, Granada, Spain; 2) Pediatria. Hospital Virgen de las Nieves. Granada. Spain; 3) FIBAO. Hospital San cecilio. Granada.

Microarray-based comparative genomic hybridation (array CGH) has provide a relatively quick method to scan the genome for gains and loses of chromosomal material with significantly higher resolution and greater clinical yield than was previously possible. This new methodologies have led to identification of novel genomic disorder (microduplications and microdelections) in patients with developmental delay/mental retardation and/or multiple congenital anomalies (DD/MR/MCA), with a significant increase in diagnostic yield . In this study we present the result of array CGH obtained in 189 children with normal karyotype but DD/MR/MCA . The NimbleGen CGX Cytogenetic Microarrays platform was performed. The results has shown that in 41 patients (21,7 %) was detected a chromosomal delection or duplication previously described like pathogenic copy number variants (CNVs),. In 18 cases (9,5 %) was necesary the analysis of parental simples,showing that 7 anomalies (49 %) had ocurred de novo and was clasificated as pathogenic and in 11 cases (61 %) appeared to be inhereted from an unaffected parent. In a total of 48 patients (25,4 %) was posible to detect a pathogenic CNVs . In contrast, only in less than 2 % of cases chromosomal alterations can be detected when karyotyping studies are performed. Several recent studies suggest that when aCGH is performed with a finding of an apparently normal karyotype, the diagnostic yield increases by an additional 8-17 %, in our study, we have obtained a 25,4 % of children with pathogenic CNVs that is higher than the results obtained by other authors. This increase at the detection rate probably is due to the array type utilized or for different methods in patients selecction. As a conclusison, array CGH is the most advanced method yet for assessing genomic imbalances associated with genetic disease. It has greatly enhanced the diagnostic capabilities of the clinical cytogenetics laboratory and has led to the continued discovery of novel genetic síndromes. These technology is being implemented routinely in our laboratory when a phenotype of DD/MR/MCA autism and apparently balanced translocations are presents.

3248T

Linear Measurement of the 2p telomere in μm may be associated with dementia status of people with Down syndrome. *E.C. Jenkins[1], L. Ye[1], S.J. Krinsky-McHale[1], W.B. Zigman[1], N. Schupf[1,2], W.P. Silverman[3].* 1) Dept Hum Genetics, NYS Inst Basic Res Dev Disab, Staten Island, NY; 2) Taub Institute for Research in Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 3) The Kennedy Krieger Institute and The Johns Hopkins University School of Medicine, Baltimore, MD.

We have recently reported that 11 people with Down syndrome (DS) and mild cognitive impairment (MCI) exhibited shorter telomeres in short-term T lymphocyte cultures versus 11 age- and sex-matched controls with DS without MCI (Jenkins et al., 2012). Multiple methods were used to compare telomere (tel) lengths of individuals with and without MCI using an FITC-labeled PNA tel probe (DAKO). Regardless of the method used, we found a consistently strong relationship between tel length and cognitive status [i.e., MCI (shorter tel) vs. no MCI (longer tel)]. We were able to develop classification criteria for tel 'length' that corresponded to clinical status (MCI/no MCI) with either perfect or near perfect sensitivity and specificity. In fact, one method based on 'direct' linear measurement of chromosome 1 tel length referenced against the remainder of chromosome 1, showed a 4 SD separation between the highest ratio from a case with MCI versus the lowest ratio from a case with 'normal aging.' This led us to hypothesize that this method will be validated as either a biomarker of clinical status or as a predictor of individual risk. Recently, we developed a less labor-intensive method that might have equally impressive power, by testing the same digitized material with the short arm of chromosome 2, reducing measurement time by almost half. We chose chromosome 2 because: 1) it provided us with a new measurement (distinct from our original measures), 2) we had a centromere 2 probe (provided as a gift from DAKO) that allowed rapid identification of chromosome 2, and 3) the cen [2] probe facilitated measurement of the chromosome 2 short arm. Eleven people with DS and MCI have now been compared to 11 age-sex-matched DS controls thus far. Consistent with our previous findings, tel length in the two groups did not overlap. In fact, the largest ratio for an individual with MCI was 2.45 SDs smaller than the smallest ratio for a control case. This substantial separation in scores between groups was associated with a highly significant difference in group means, $t(10) = 9.64$, $p < .0001$. We now plan to extend these findings to establish a method likely to have perfect specificity and sensitivity but requiring significantly less time and effort compared to the previous procedure which we found to show the greatest separation between groups. Supported in part by NYS OPWDD, Alz. Assoc. IIRG-96-077, IIRG-07-60558; NIH PO1-HD035897, RO1-HD037425, RO1-AG014673, and P30-HD024061.

Copy Number Variations in patients with Agenesis of Corpus Callosum. *C.P. Oliveira[1,2], C.T.N. Medina[2], R.S. Heredia[2], R.O.A. Benício[2], M.T.O. Cardoso[2], S.F. Oliveira[3], A. Pic-Taylor[3], J.F. Mazzeu[1,4].* 1) Laboratory of Clinical Genetics, Faculty of Medicine and Health (FS), University of Brasilia (UnB), Federal District, Brazil; 2) Genetics Nucleus (NUGEN), Hospital de Apoio (HAB), Secretary of State for Health, Federal District, Brazil; 3) Department of Genetics and Morphology, Institute of Biologic Sciences, University of Brasilia (UnB), Federal District, Brazil; 4) Post-graduation program in Genomic Sciences and Biotechnology Catholic University of Brasilia (UCB), Federal District, Brazil.

Agenesis of corpus callosum (AgCC) is a common brain malformation that can be found isolated or in association with other systemic malformations. Individuals with brain malformations have a high rate of de novo copy number variations (CNV), including microduplications and microdeletions, which may play an important causative role. This study aimed to search for copy number variations in patients with AgCC in order to identify possible causative genes for this condition. We assessed 19 patients with partial or complete AgCC by a comprehensive radiological and clinical review. Genome cytogenetic analysis was performed using Affymetrix 750k SNP array. At least 25 consecutive probes were considered in order to call for an abnormality. From a total of 19 AgCC patients, we identified six that showed pathogenic CNVs. Two individuals presented large chromosomal rearrangements also confirmed by G-banding: a tetrasomy 9p and an unbalanced translocation t(5;15). In one patient, array data disclosed a 3p duplication (~22 Mb) and a deletion 13q (~30Mb) suggesting a possible translocation, further confirmed by re-examination of patient karyotype: t(3;13)(q26.3;q31.1). In three patients we identified small rearrangements: a 657 kb duplicated segment on chromosome 16q (chr16:77,972,993 - 78,540,503 - hg19), a 261 kb duplicated segment on 4q (chr4:73,833,080-74,094,428) and a 760 kb deleted segment in Xp (chrX:1,979,232-2,742,089). These segments were not described previously as common CNVs and genes mapped in these regions are correlated with various neurological and morphological disorders and clinical features, like intellectual disability and brain malformations. These results confirm that chromosome rearrangements are an important cause of AgCC and that chromosome microarray analysis is an useful diagnostic tool for the etiology of this condition. Sex Chromosomal Mosaicism In The Gonads Of Patients With Disorders Of Sex Development (DSD). *AKader. SA[1], Kamel. AK[1], AGhany. HM[2], Desouky. N[3], Mekkawy. MK[1], Hennawy. A[4], Makhluf. M[2], Mazen. I[5].* 1) Human Cytogenetics, National Research Center, Cairo, Egypt; 2) Cytogenetics,Specialized Children's Hospital,Cairo University, Cairo, Egypt; 3) Pediatric Surgical Division, Specialized Children's Hospital, Cairo University, Cairo,Egypt; 4) Pathology,Cairo University, Cairo,Egypt; 5) Clinical Genetics,National Research Center,Cairo, Egypt.

The phenotypic variability observed in DSD patients with sex chromosomal abnormalities depends on many factors including the presence of SRY gene, the complexity of the structural rearrangement and the presence of chromosomal mosaicism, especially 45,X cell line,which can affect the threshold of SRY gene expression. The phenotypic sex strongly depends on the percentage of Y chromosome and 45,X cells in the developing gonads. This can explain differences observed between gonadal phenotype and the karyotype. We report on ten patients with variable presentations of disorders of sex development (DSD) including ambiguous genitalia, primary amenorrhea and short stature. Conventional cytogenetics studies and flourescence insitu hybridization(FISH) technique on peripheral blood showed a non mosaic chromosomal constitution in five patients. The other five patients exhibited mosaic cell pattern associated with different types of sex chromosomal abnormalities including 45,X, isodicentric Y chromosome, X;Y translocation and ring X chromosome. FISH analysis on paraffin embedded or fresh cultured gonadal tissue specimens was done for all patients and showed mosaicism in eight of them and a single cell line in two patients. Our study demonstrates the importance of studying sex chromosome mosaicism in the gonadal tissue of patients showing a discrepancy between their karyotype and gonadal phenotype. Using FISH technique on paraffin embedded or fresh cultured gonadal tissue specimens is recommmended in those patients for better understanding of the phenotype/ karyotype correlation.

Directional genomic hybridization: An improved biomarker for radiation exposure. *F. Ray[1,2], E. Robinson[2], M. Cornforth[2,3], J. Bedford[1,2], E. Goodwin[2], S. Bailey[1,2].* 1) Environmental Radiological Health Sciences, Colorado State Univ, Fort Collins, CO; 2) KromaTiD Inc, 320 East Vine Drive, Fort Collins, CO; 3) University of Texas Medical Branch, Galveston Texas.

Cytogenetic biomarkers have been a preferred choice for retrospective estimation of radiation exposure because they are sensitive, quantifiable, and relevant to biological effects of concern. The most commonly used involve the measurement of dicentrics and symmetrical translocations. Both have shortcomings that become increasingly problematic for assays carried out at long times after radiation exposure. Dicentrics in samples from peripheral blood lymphocytes decrease with time after exposure (t1/2 1-2 years), and in the case of more stable symmetrical translocations, background levels are 10-fold higher and increase with age. Another aberration type, inversions, result from exchanges within a chromosome that reverse the orientation of the broken segment. We have developed an approach based on directional genomic hybridization (DGH) that facilitates detection of inversions with a greater than 10 fold improvement in resolution over existing techniques, allowing the detection of 1Mb or smaller inversions. Bioinformatics guided design of sequence- and strand-specific probe sets, which when coupled with single-stranded hybridization, produced chromatid - rather than chromosome - paints. Inversions register simply as a signal switch from one sister chromatid to the other in the inverted region. Importantly, like chromosome paints, chromatid paints also reveal translocations and dicentrics. Modeling suggested that inversions should be more common than translocations after densely vs. sparsely ionizing radiation exposures. We irradiated human cells with high LET heavy ions or low LET gamma rays and, using chromatid painting, compared the dose-response yields for induction of inversions, translocations and dicentrics. As predicted, the slope of the dose-response curve following heavy ion irradiations was steeper, and the yields per unit dose for inversions were higher than for either translocations or dicentrics. In another application, chromatid painting of orangutan cells revealed an inversion that presumably occurred during karyotype evolution of mammals. Together, our results demonstrate that inversion detection is useful for a variety of applications and can be further developed for use as a sensitive tool to measure past exposure to ionizing radiation and/or other clastogens. Funding for this work was provided by NASA (NNX09CE42P; NNX10CB05C) and NIAID (R01AI080486-02).

A novel approach to detecting miRNA in living cells. *D. Weldon, A. Ko, G. Johnston, V. Koong.* EMD Millipore, Temecula, CA.

The regulatory role that microRNA's play in gene expression has made them a target of interest in many areas of research. Unfortunately, detecting miRNA has been limited to fixed or lysed cells, which presents the problem of looking at only a single time point while utilizing duplicate samples to mimick more dynamic study's of changes in expression levels which can be observed only in live cells. The ability to monitor miRNA levels within live cells without altering gene expression or affecting cell health allows for a more biologically relevant understanding of miRNA biology. However, monitoring RNA within intact cells can prove to be challenging with current techniques due to complex or harmful sample preparation techniques or transfection reagents. Further, amplification methods can create false positives or erroneously inflate differences. Here we describe the ability to detect miRNA levels in live intact cells without the need for transfection reagents. We compare the expression level of miR-21, miR-210, and miR-155 in live cells to that of levels seen by RT-PCR. RT-PCR data is limited to a population of cells where the live cell data is captured at the single cell level. Our technique utilizes gold nano-particles conjugated to duplexed oligonucleotides. In the presence of target RNA a fluorescent reporter is released from the proximity of the gold and fluorescence can be detected. In contrast to traditional RNA detection methods our technique allows for the detection within live cells allowing us to sort them based on their miRNA expression and subsequently re-use those cells for follow up experiments. This illustrates the advantage of profiling the RNA expression in live cells with the ability to further study those cells in downstream applications. It also allows for the ability to understand the expression levels of a given miRNA target across a population of cells at the single cell level using flow cytometry as the detection platform. Detecting RNA expression levels in live cancer cells with the ability to utilize the same cells in downstream testing gives researchers the ability to perform experiments which were previously thought to be impossible.

Mosaic Maternal UPD15 in a Newborn with Complex Heart Defect. *D. Pickering[1], W.G. Sanger[1,2], R.E. Lutz[2], J. Carstens[1], M. Wiggins[1], B.J. Dave[1].* 1) Human Genetics Laboratories, Munroe-Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE; 2) Genetics Medicine Department, Munroe-Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE.

Prader Willi syndrome (PWS) results from lack of the paternal copy of chromosome 15q11.2-13.2, most often due to either deletion 15q11.2-q13.2 or maternal uniparental disomy (UPD) of chromosome 15. Microarray analysis using high-density genome-wide SNP arrays detects UPD events as well as copy number changes. Based on copy-neutral segmental or whole chromosome isodisomy detected by SNP array, subsequent methylation studies for paternal and maternal allele are typically performed to confirm the diagnosis. We report here a newborn male referred for microarray with clinical findings of complex congenital heart defect (CHD) involving unbalanced AV canal with hypoplastic arch and dysmorphic facies, small rib cage, and undescended testes. The pregnancy was complicated by intrauterine growth retardation and heart defect detected by ultrasound. Prenatal karyotype and aneuploidy FISH studies were normal. High-density SNP array detected a 49,000,000 base-pair segment of copy-neutral loss of heterozygosity (LOH) at chromosome 15q14-q25. Large interstitial segments of LOH without deletion and restricted to one chromosome typically indicate uniparental heterodisomy. Confirmatory chromosome 15 methylation studies using primer sets covering SNPRN revealed the presence of the methylated maternal band and a significantly diminished unmethylated paternal band suggestive of mosaicism. Concurrent high-resolution chromosome analysis on 20 cells was normal. Subsequent FISH studies analyzing 500 interphase nuclei using SNPRN and 15q telomere probes to rule out possible concomitant low-level mosaicism of trisomy 15 in peripheral blood were also normal. There was no evidence of mosaic trisomy 15 by SNP array copy number analysis. Although fibroblast cells were unavailable, based on the faint paternal band observed in methylation studies, the 49Mb interstitial 15q segmental LOH noted by SNP microarray and the patient's CHD, it is reasonable to assume that a second cell line containing a paternal copy does exist. Additional studies on buccal mucosa tissue are pending. This case highlights the ability of SNP array to identify UPD, even uniparental heterodisomy, nevertheless, ensuing confirmatory studies may be challenging. Understanding the underlying mechanisms of UPD is essential for accurate interpretation, diagnosis, and appropriate recommendations.

Segments of Homozygosity and Uniparental Disomy Identified by Oligonucleotide SNP Array: Experience from a Reference Laboratory. *J. Wang, L. Ross, L. Mahon, R. Owen, M. Hemmat, B. Wang, M. El Naggar, A. Anguiano, F. Boyar, M. Haddadin, T. Sahoo.* Cytogenetics Laboratory, Nichols Institute, Quest Diagnostics, San Juan Capistrano, CA.

Copy neutral segments with allelic homozygosity (SOH) are frequently identified in cases interrogated by oligonucleotide-SNP microarrays. SOH may be due to parental relatedness, chromosomal recombination or rearrangements. Depending on the genomic context, it may indicate ancestral homozygosity, uniparental isodisomy (UPD), or parental consanguinity. We collected cases from consecutive specimens sent to our clinical laboratory over the past two years. The cases were reported based on the presence of SOH >10 Mb in a single region or >5 Mb in at least two regions. The percentage of the genome encompassed by SOH regions was calculated based on the total coverage of Affymetrix CytoScan™ HD array, which is about 2,700 Mb. Classification of the cases for the degree of parental relatedness was based on the 95% confident interval value recently published (Sund et al., 2013). Of 14,575 cases analyzed by SNP arrays, 67% had a normal result, 23% had results of unclear clinical significance, and 10% had clinically significant copy number variations (CNVs). For each category, about 5-6% of cases had one or more reportable SOH. Of the 872 (6% of 14,575) cases with SOH, 659 (76%) cases were interpreted as arising due to identity by descent (IBD), and 213 (24%) cases were suspected or confirmed as resulting from UPD. For the cases with IBD, an estimate of the inbreeding percentage was estimated, and 5% were suspected to have first degree or closer parental relatedness, 9% second, 19% third, 16% fourth, and 51% fifth. Suspected or confirmed UPD cases were identified involving every single chromosome. Of the 16 cases with SOH from chromosome 15 alone, six cases had isoUPD15 (4 confirmed by methylation studies), another six were confirmed to have mixed iso- and hetero-UPD15. One case had copy number neutral mosaic maternal UPD15 with modified Prader-Willi phenotype. At least ten cases with SOH were confirmed to contribute to autosomal recessive disorders, such as homozygous deletions in the MCPH1 gene (microcephaly), homozygous nonsense mutation in the growth hormone receptor gene (Laron syndrome, pituitary dwarfism), and homozygous nonsense mutation in the RFXAP gene (immune deficiency, Bare lymphocyte syndrome type III). This study demonstrates that the identification of SOH, in addition to CNVs, is much more frequent than previously recognized and often reflects close parental relatedness or unravels UPD in many cases.

The first case of mos 46,XX,+21,der(21;21)(q10;q10)[16]/ 45,X [14] with clinical evolution and parental karyotypes: 46,XY [20] and 46,XX [20]. *M. Carvalho[1], E. Carvalho[2], M. Montenegro[2], K. Carvalho[3].* 1) Medical Genetics, Universidade Estadual do Ceará-UECE/APAE-CE/UniChristus, Fortaleza, Ceará, Brazil; 2) ICrHCFMUSP; 3) Medical Genetics, Universidade Estadual do Ceará.

Double aneuploidy involving both autosomal and sex chromosomes is very rare. Down's/Turner's mosaic, occurs in about 1 in 2 000 000. We report the first case of Down's/Turner's mosaic with robertsonian translocation. The patient was the first child of non consanguineous parents. It was a female whom born a term, by uneventful cesarean section, weighting 2,220g and with length of 46 cm, without neonatal complications. At birth, the pediatrician made the diagnosis of Down syndrome. At 3 months, in consultation with routine pediatric a heart murmur was heard, so the patient was referred to a cardiologist. Echocardiography was performed and diagnosed congenital heart disease (patent ductus arteriosus). There were performed two surgeries to repair the heart defect, one with 6 months of life and another with 2 years. She also had mild developmental delay. At 3 years old she was examined at our outpatient Genetic unit. The patient showed more clinical findings of Down syndrome than Turner syndrome: low weight and height for age, microcephaly, flat facial profile, upslanting palpebral fissures, epicanthal folds, short nose with depressed nasal bridge, hypotonia with tendency to keep month open and protrude the tongue, short neck, single palmar creases, and prominent ears. Abdominal ultrasound and thyroid function were normal. Cytogenetic analysis of peripheral blood preparations by using G-banding revealed mosaicism with 2 cell lines (mos 46,XX,+21,der(21;21)(q10;q10)[16]/ 45,X [14]). Additional genetic studies (karyotypes) are required to define the cause which probably originated this double aneuploidy with this translocation or isochromosome. So we present the first case related of Down-Turner mosaicism with robertsonian translocation or isochromosome and we review the previous reports of Down-Turner syndrome.

3256T

Characterization of Expression Profile of the CER1 Gene and Two Regulatory Elements in Human Mesenchymal Progenitor and Neural Stem Cells. *X. Hauge, J. Sloan.* Dept Biol & Physics, Kennesaw State Univ, Kennesaw, GA.

Terminal deletions of the short arm of human chromosome 9 (9p-) cause mental retardation, cardiac abnormalities, abnormal genitalia, trigonocephaly and other craniofacial abnormalities. The gene that is of most interest for understanding this syndrome is the cerberus 1 gene (CER1) which plays a role in establishing the anterior-posterior axis in vertebrates. The ortholog of CER1 in mouse binds directly to bone morphogenic proteins (BMPs) and prevent BMPs from binding to their cognate receptors, acting as a BMP inhibitor. The inhibition may slow the ossification of sutures, allowing normal brain growth and development. A deletion of the CER1 gene or of its regulatory elements could cause a premature closure of sutures, leading to trigonocephaly. Little is known regarding the CER1 expression profile during embryonic development in humans due to legal and ethic issues. We seek to investigate the expression profile of the CER1 gene during early embryonic bone development using pluripotent human mesenchymal progenitor cells. We cultured mesenchymal progenitor cells in the osteogenic differentiating medium for various time periods, and then isolated RNA from these cells. To quantify the gene activities of the CER1 and several important osteogenic markers, such as RUNX2 and BSP, quantitative polymerase chain reactions were performed. We also examined the CER1 expression profile in human neural stem cells. Finally, we examined the regulatory functions of an enhancer and a repressor in mesenchymal progenitor cells using a dual luciferase assay. These regulatory elements were cloned from the critical region of 9p- syndrome previously by us. Enhancer clone 5008 demonstrated higher activity in the human mesenchymal progenitor cells than in adult human cell lines.

3257F

Four new patients with maternal UPD20: a phenotype of isolated growth retardation and feeding difficulties. *E.J. Bhoj[1], S. Mulchandani[2], B. Thiel[2], E. Zackai[1], I. Krantz[1], N. Spinner[2,3], L. Conlin[2,3].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology & Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology & Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

We present four new patients with maternal uniparental disomy (UPD) for chromosome 20 and propose that maternal UPD20 is associated with a consistent phenotype characterized by prenatal onset growth retardation and feeding difficulties in the absence of dysmorphic features. Uniparental disomy of chromosome 20 is a rare diagnosis. Previously eleven patients with paternal UPD20 have been reported, which were associated with pseudohypoparathyroidism. There are additionally four reports of patients with maternal UPD, all with prenatal and or postnatal growth retardation. However, in three of these patients the phenotype was complicated by mosaic or full trisomy 20, and in those patients psychomotor retardation was also recorded. In previously reported patients, the phenotype of individuals with UPD20 and mosaic trisomy 20 was hypothesized to be a result of the mosaic trisomic cells. This report expands on the description of isolated UPD20 with four new patients identified using genome-wide SNP arrays. All four patients were referred with isolated prenatal-onset growth retardation and feeding difficulties requiring direct gastric feeds. Two of these individuals had a significant increase in length upon growth hormone supplementation. Two of the four patients had complete isodisomy suggestive of monosomy rescue or post-zygotic trisomy rescue and two had iso-hetero disomy consistent with a trisomy rescue mechanism. Chromosome 20 harbors many known and predicted imprinted genes. The phenotype related to maternal UPD20 can be a consequence of known disease-associated imprinted loci (including GNAS) or from other imprinted genes on chromosome 20. All of these patients are undergoing extensive clinical testing to further delineate the physiologic mechanisms affected by UPD20 leading to their phenotype. Given the similarity between our patients and those previously reported, we propose that the growth retardation and feeding difficulties result from matUPD20 rather than mosaic trisomy 20, while the trisomic cells may be the main contributor to psychomotor retardation. This study doubles the number of previously-reported patients with UPD20, allowing for improved description of the phenotype and more accurate prognostication of the course of the disease with and without interventions such as growth hormone supplementation.

Targetted Amplicon Sequencing of Tongue cancer Genome: Indian Experience. *R. Rawal, S. Bagtharia, K.C. Kothari, S.N. Shukla, A.K. Saxena.* Cancer Biology, Gujarat Cancer & Research Institute, Ahmedabad, India.

Cancer of tongue is one of the most common malignant cancers of the oral cavity predominantly found in India and its subcontinents. The major cause of morbidity and mortality in these patients is due to the high local invasiveness & recurrence, with lymph node and distant metastasis. Lack of predictive and prognostic biomarkers leading to over- or under-treatment of patients poses significant personal and socioeconomic impact. Present study was undertaken to unravel the molecular signatures in patients with tongue cancer with and without habit of tobacco consumption. Study included two patients with cancer of oral tongue (One with habit of tobacco and one without habit of tobacco). The Genomic DNA was extracted from fresh frozen tumour tissue and peripheral blood derived Mono nuclear cell fraction in both cases. The Genomic DNA samples were segregated in to 3 pools (Pool1: Tumour genomic DNA from Patient without habit; Pool2: Tumour genomic DNA from Patient with habit and Pool3: Pooled Genomic DNA from PBMNC of both the patients). Targeted amplicon sequencing was carried out on ION-TORRENT PGM following manufacturer's instruction using 409 gene Ampliseq cancer panel 318 chip. The output data was uploaded by Torrent Variant Caller plugin and analyzed using ION REPORTER and INGENUITY independently. Sequences were compared against hg19 human genome sequence as control. Pool1 and Pool2 results were further compared with constitutional genome (Pool3). Data were filtered using frequency (35%-100%) and coverage (20X-100X) for the exonic region. The other variables used for filtering the data were zygosity, missense mutations etc. Results were plotted Chromosome wise and Venn diagrams were plotted to identify common and unique variants (genes) showing non-synonymous mutations in exonic region. There were 47 unique variants (23genes) in Pool1 and 21 variants (13 genes) in pool2 with 6 common variants (13 genes). The unique allelic variants in tobacco habitues and non habitues suggestive of a tobacco independent mechanism of malignant transformation in tongue tissue.

3259T

The relationship between breast cancer and Tetraspanin8 (TSPAN8) gene polymorphism. *M. Acar[1], T. Yilmaz[1], M. Oznur[1], Z. Unal[1], E. Gunduz[1], M. Gunduz[1,2].* 1) Medical Genetic, Turgut Ozal University Medical Faculty, Ankara, Turkey; 2) Departments of Otolaryngology Head and Neck Surgery, Ankara, Turkey.

Drugs have been improved for breast cancer but there is still a need safe and more effective treatments. Variations in BRCA1, BRCA2, CDH1, PTEN, STK11 and TP53 genes increase the risk of breast cancer. Unfortunately most risk factors of breast cancer in women are not known. TSPAN8 gene (tetraspanin8) is a member of the transmembrane 4 super family. It's cytogenetic localization is at 12q21.1. Most of the coded proteins are surface proteins. These proteins mediate signal transduction in cell development, activation, growth and motility. This gene is expressed in different carcinomas and has been proved to have a relation with ovarian cancer, gastric carcinoma, colorectal cancer, polycystic ovary syndrome, esophageal cancer and diabetes. It is also seen in cell migration and invasion. With up regulation the gene occupies surrounding tissues. It causes metastasis of the lungs and also shortens the life span of rats. Our project's aim is to find a connection between breast cancer and the polymorphism of TSPAN8 rs7961581 C>T. Proving that the polymorphism of TSPAN8 rs7951581 has a role in breast cancer's etiopathogenesis could lead to a means for early diagnosis of this cancer, use of the gene as a biomarker and development of a more effective treatment. For the experimental group, 50 patients diagnosed with breast cancer in 2008-2012 were selected. The DNA was isolated from the tumor tissue. DNA was isolated from blood collecte from the control group of 50 indivudals with no diagnosise of breast cancer. For the TSPAN gene specific primers were designed and the gene was amplified using polymerase chain reaction(PCR). After checking the quality of the amplified products using agarose gel electrophoresis, the gene was cut with Hpy166II restriction enzyme which recognizes the rs7961581 polymorphism. We identified the genotype, confirmed the PCR-RFLP(Restriction Frangment Lenght Polymorphism) results with DNA chain analysis and entered our data into SPSS16.0 and evaluated the relationship between the data using the chi-square test. 23(46%) individuals from the experimental group have the genotype TT,25(50%) CT and 2(4%) CC.14(28%) individuals from the control group have TT,25(50%) CT and 11(22%) CC. There is a recognizable statistical relation between breast cancer and TSPAN8 rs7961581 polymorphism (pearson chi-square=0.015). However a broader investigation must be done to confirm the significance of these findings.

3260F

PPM1D Mutations in Circulating White Blood Cells and the Risk of Ovarian Cancer. *M.R. Akbari[1,2], P. Lepage[3], B. Rosen[4], J. McLaughlin[2,5], H. Risch[6], M. Minden[7], S.A. Narod[1,2].* 1) Women's College Research Institute, Univ Toronto, Toronto, ON, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 3) Genome Quebec Innovation Centre, McGill University, Montreal, Canada; 4) Department of Gynecology-Oncology, Princess Margaret Hospital, Toronto, Canada; 5) Samuel Lunenfeld Research Institute, University of Toronto, Toronto, Canada; 6) Department of Epidemiology and Public Health, School of Public Health, School of Medicine, Yale University, New Haven, USA; 7) Department of Medical Oncology, Princess Margaret Hospital, Toronto, Canada.

One fifth of ovarian cancer cases are estimated to be hereditary and the genes responsible for these are being found continuously and PPM1D was the last one in this series with some unique features. We used deep amplicon sequencing of the PPM1D mutation hot spot (exon 6) in white blood cells' (WBC) DNA of a case-control group and found 20 carriers of truncating mutations among 1,295 ovarian cancer cases and one in 834 controls (OR = 13.1, 95%CI : 1.7 - 97.5, p = 0.0005). All these mutations were mosaic in WBCs and the lifetime risk of ovarian cancer among the female first-degree relatives of PPM1D mutation carriers was similar to the risk among the female first-degree relatives of non-carrier ovarian cancer patients (HR = 1.32; p = 0.78) that suggest PPM1D mutations are probably not inherited. Also the 12-year survival of the PPM1D-positive cases was lower than PPM1D-negative cases (HR = 2.0, 95%CI : 1.21 - 3.39, P < 0.007). The high odds ratio for PPM1D carriers justifies preventive oophorectomy and approximately one percent of all ovarian cancers might be prevented through screening for PPM1D mutations in healthy women regardless of their family history.

3261W

Juvenile myelomonocytic leukemia in six months old boy with breast cancer and leukemia in his Family history. *M. Akouchekian.* Medical Genetics , Tehran University of Medical Science, Tehran, Iran.

Juvenile myelomonocytic leukemia (JMML) classified as a rare childhood cancer and it usually occurs in children younger than 2 years old. It is known that certain medical conditions such as neurofibromatosis type 1 can make a child more likely to develop it. We investigate the chromosomal abnormality of six months old boy diagnosed JMML patient that his grandfather died from breast cancer in age of 57 and the grandfather's father died from leukemia in age of 60. Deletion 7(q) is diagnosed in this boy. Cluster of breakpoints in 7q11 to 7q36, is with two common minimal morphological zones in q22 and in q32-34. Using loss of heterozygocity (LOH) studies and YAC libraries, a 2 to 3 Mb segment in 7q22 has been designated as proximal common deleted area; the q33-34 zone is the consensual area for the distal deletion; LOH studies suggest that a specific mechanism, such as mitotic recombination in bone marrow stem cell leading to homozygosity in both granulocytes and lymphocytes, may be implicated. We also plan to run a whole genome study in this family to investigate the relationship between cancer family histories with this rare childhood cancer. The contribution between NF1 mutation and 7q deletion in JMML disease will also investigate.

3262T

Analyses of genome-wide linkage scan data among families with aggregation of breast and prostate cancer reveals evidence for linkage at 16q21-23. *J. Beebe-Dimmer[1,2], E. Lange[3], K. Zuhlke[4], K. Cooney[4].* 1) Karmanos Cancer Inst, Detroit, MI; 2) Wayne State University, Detroit, MI; 3) University of North Carolina, Chapel Hill, NC; 4) University of Michigan, Ann Arbor, MI.

Purpose: Epidemiologic studies have shown a co-clustering of breast and prostate cancer suggesting that there are germline variants that increase the risk of both hormonally-driven neoplasms. Mutations in BRCA1 and BRCA2 genes may explain a small portion of the observed occurrence of both breast and prostate cancer within families. The current investigation focuses on the delineation of chromosomal regions which may harbor new genes that play a role in the aggregation of breast and prostate cancer among first degree family members. Methods: A genome-wide linkage scan was conducted on 50 families participating in the University of Michigan Prostate Cancer Genetics Project. All families had at least 2 first-degree relatives diagnosed with prostate cancer and at least one female relative diagnosed with breast cancer in a first-degree relationship with one of the participating prostate cancer cases. Genome-wide multipoint nonparametric linkage analyses for the combined phenotype of prostate and breast cancer were performed using the software Merlin. Results: The strongest evidence for linkage was detected at 16q22 (LOD=3.07 at rs722579), a region previously reported to be in linked to prostate cancer. This region contains several interesting candidate genes including known prostate cancer tumor suppressor genes WWOX and ATBF1, as well as BCAR1, a gene involved in a number of critical carcinogenic processes including cell migration, growth, and differentiation. Conclusions: Next generation sequencing of the genes in this region in our linked families are in progress to identify new mutations that explain clustering of prostate and breast cancer in these families and provide us new information on shared genetic pathways between these two common cancers.

3263F

Diversity of inherited damaging mutations in all breast cancer genes in three series of breast cancer patients: young onset, triple-negative and those unselected for family history, age at diagnosis or hormone receptor status. *G. Bernier[1], J. Mandell[1], T. Walsh[1], S. Casadei[1], M. Lee[1], E. Swisher[2], M.C. King[1].* 1) University of Washington, Division of Medical Genetics, Seattle, WA; 2) University of Washington, Department of Obstetrics and Gynecology, Seattle, WA.

In addition to *BRCA1* and *BRCA2*, inherited mutations in multiple other genes predispose to breast cancer. Many of these genes are in the BRCA-Fanconi Anemia complex. We used BROCA, a targeted genomic capture and massively parallel sequencing approach, to identify all classes of mutations in all known breast cancer genes. Only truncations, complete gene deletions, splice mutations known to lead to a mutant message, and missenses demonstrated functionally to be damaging were counted. Study participants were three series of breast cancer patients: those sequentially enrolled from two local cancer centers and not selected for age at diagnosis, family history or hormone receptor status (SBC; n=253); those with invasive breast cancer diagnosed at age 40 or younger (YBC; n=533); and those with triple negative (i.e. estrogen receptor, progesterone receptor, and HER2 negative) breast cancers (TNBC; n=344). SBC patients had not been commercially tested for *BRCA1* and *BRCA2* at time of enrollment so all genes were included in their analysis. YBC and TNBC patients with positive commercial test results for *BRCA1* or *BRCA2* were not recruited, so only genes other than *BRCA1* and *BRCA2* were included in the YBC and TNBC analyses. Of the SBC patients, 7.1% (18/253) carried damaging mutations in any targeted gene: 3 in *BRCA1*, 4 in *BRCA2*, 4 in *CHEK2*, 2 in *PALB2*; and 1 each in *TP53*, *ATM*, *BARD1*, *BAP1*, and *NBN*. Of the YBC patients, 7.7% (41/533) carried damaging mutations in genes other than *BRCA1* or *BRCA2*: 21 in *CHEK2*, 4 in *PALB2*; 3 each in *ATM*, *BARD1*, *BRIP1*, *RAD51D*; and 1 each in *TP53*, *NBN*, *STK11*, and *MRE11A*. Of the TNBC patients, 7.6% (26/344) carried mutations in genes other than *BRCA1* and *BRCA2*: 8 in *PALB2*, 7 in *BARD1*, 3 each in *CHEK2* and *RAD51D*, 2 each in *BRIP1* and *RAD51C*, and 1 in *Abraxas*. The mutational spectrum of these patients was highly heterogeneous, with 53 different mutations in 13 different genes. Across all series, the most common alleles were *CHEK2* c.1100delC (8 patients, including one homozygote) and *PALB2* p.Y1183X (4 patients), consistent with the large contribution of northern European ancestry to the Pacific Northwest population. TNBC patients included surprisingly large numbers with *PALB2* or *BARD1* mutations. Carriers of mutations in all genes met NCCN criteria for *BRCA1*/*BRCA2* testing. We recommend adapting the current genetic testing guidelines for breast cancer patients to include multi-gene evaluations, such as BROCA, for those that meet testing criteria.

Germline Copy Number Variants as Genetic Risk Factors for Familial Colorectal Cancer Type X. *D.D. Buchanan[1], M. Clendenning[1], C. Rosty[1,2,3], M.D. Walsh[1,4], S. Parry[5,6], A.K. Win[7], J.L. Hopper[7], M.A. Jenkins[7], Colon Cancer Family Registry.* 1) Cancer & Population Studies Group, QIMR, Brisbane, Queensland, Australia; 2) School of Medicine, University of Queensland, Brisbane, Queensland, Australia; 3) Envoi Pathology, Brisbane, Queensland, Australia; 4) Sullivan and Nicolaides Pathology, Brisbane, Queensland, Australia; 5) New Zealand Familial Gastrointestinal Cancer Service, Auckland Hospital, Auckland, New Zealand; 6) Department of Gastroenterology, Middlemore Hospital, Auckland, New Zealand; 7) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, Parkville, Victoria, Australia.

Background: Only one-third of the familial risk of colorectal cancer (CRC) is explained by variants in known CRC susceptiblity genes. Multiple-case CRC families that fulfil the Amsterdam-I criteria for Lynch syndrome but do not carry mismatch repair (MMR) gene mutations and demonstrate no evidence of MMR-deficiency in their tumors are referred to as meeting the Familial Colorectal Cancer Type X (FCCTX) criteria. Copy number variants (CNVs; deletions or duplications of DNA segments), have been detected in and around cancer predisposing genes such as the MMR genes, BRCA1 and BRCA2; however, the role of germline CNVs in CRC susceptibility remains poorly understood. The aim of this study was to identify rare or novel germline CNVs that predispose to CRC in families that meet the FCCTX criteria. Methods: Blood-derived DNA from CRC- and polyp-affected and unaffected relatives from 15 multiple-case CRC families fulfilling the FCCTX criteria and from 16 unrelated controls from the Australasian Colorectal Cancer Family Registry were genotyped using the Illumina HumanOmni2.5-8 SNP array. CNVs were identified using Partek GS v6.6 from LogR ratios. Candidate CNVs were identified that encompassed genes, segregated with CRC, were absent in unaffected relatives and unrelated controls, and either not previously reported in the Database of Genomic Variants (DGV) or were reported as rare. Results: Forty CRC-affected (mean age at diagnosis =56.7 years ± standard deviation (SD)= 11.7 years) , 33 early-onset polyp-affected (mean =45.6 years ± SD= 11.3 years) and 15 unaffected family members of 15 FCCTX families (minimum 2 CRC-affected and 1 unaffected relative/family) were genotyped. The number of CNVs that were present in all CRC-affected individuals in a family but not detected in the controls or seen in the DGV ranged from 5 to 13 deletions per family and 14 to 30 duplications per family. Candidate CNVs included a duplication that lies 5' to the PTPRJ gene (previously reported as a likely CRC-susceptibility gene) and a deletion encompassing the CTNNA3 gene on 10q21.3. Conclusion: We have identified several rare or novel germline CNVs that segregate with CRC-affected members in families that meet the FCCTX criteria. Future studies will extend the study to genotype additional FCCTX families, test a large series of CRC cases and controls for variants in these genes and further characterise the effects of these candidate CNVs on gene expression.

3265T

HLA-DPB1 polymorphisms and cervical squamous cell carcinoma risk. *T. Chang[1], Y. Yang[2,3], Y. Lee[1,4,5], T. Chen[2], W. Lin[1], S. Chang[1].* 1) Med Res Dept, Mackay Memorial Hosp, New Taipei, Taiwan; 2) Department of Gynecology and Obstetrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Gynecology and Obstetrics, Taipei Medical University, Taipei, Taiwan; 4) Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 5) Pediatrics, Taipei Medical University, Taipei, Taiwan.

Cervical cancer is a multifactorial disease and infection by oncogenic human papillomaviruses (HPVs) represents the major environmental risk factor. However, the mere presence of HPVs is not enough for cervical cancer development and host immunogenetic background may play an important role. Variations in human major histocompatibility genes may alter the efficiency of immune response to HPV antigens and have been implicated in the risk for cervical cancer. The aim of this study is to examine the role of the human leukocyte antigen (HLA)-DPB1 gene in cervical cancer susceptibility. We used high-resolution methods to genotype HLA-DPB1 in 344 women with cervical squamous cell carcinoma (CSCC) and 250 age/sex matched healthy controls. The presence and genotypes of HPV in CSCC patients were determined by PCR. We found the HLA-DPB1*13:01 was associated with an increased risk of both CSCC (OR = 1.68, 95% CI 1.17-2.43) and HPV-16 positive CSCC (OR = 1.94, 95% CI 1.26-2.98). However, the significance remained only in HPV-16 positive CSCC patients after Bonferroni correction (*Italic Text*$P_{\text{Subscript Text}}c$ = 0.02). In conclusion, our results suggest that HLA-DPB1*13:01 is involved in the genetic susceptibility to HPV-16 positive CSCC in the Taiwanese population. Further studies with larger cohort are required to confirm the role of DPB1*13:01 in the development of CSCC.

Replication of cervical cancer susceptibility loci identified in genome-wide association study in a northern Swedish population.
D. Chen[1], J. Hammer[1], D. Lindquist[2], U. Gyllensten[1]. 1) Department of Immunology, Genetics and Pathology, Uppsala University, Sweden, Uppsala, Sweden; 2) Department of Radiation Science, Umeå University, Sweden.

In a genome-wide association study (GWAS) we have previously identified and performed the initial replication of three novel susceptibility loci for cervical cancer: rs9272143 upstream of *HLA-DRB1*, rs2516448 adjacent to MHC class I polypeptide-related sequence A gene (*MICA*) and rs3117027 at *HLA-DPB2*. The risk allele T of rs2516448 is in perfect linkage disequilibrium with a frameshift mutation (A5.1) in *MICA* exon 5, which results in a truncated protein. To validate these associations in an independent study and evaluate effect modification by age of onset and tumor stage, we genotyped the single-nucleotide polymorphisms at rs2516448, rs9272143, rs3117027 and the *MICA* exon 5 microsatellite in 961 cervical cancer patients and 1725 cancer-free control subjects from northern Sweden. Association between each variant and cervical cancer risk was estimated by logistic regression analysis. The C allele of rs9272143 conferred protection against cervical cancer (odds ratio [OR]=0.73, 95% CI=0.65-0.82; $P=1.8\times10^{-7}$), whereas the T allele of rs2516448 increased the susceptibility to cervical cancer (OR=1.36, 95% CI=1.21-1.52; $P=1.8\times10^{-7}$), with the same association shown with *MICA-A5.1*. We also identified protective effects of the *MICA-A4* (OR=0.79, 95% CI=0.67-0.93; $P=4.1\times10^{-3}$) and *MICA-A5* (OR=0.60; 95% CI=0.50-0.72, $P=5.2\times10^{-8}$) alleles. The direction and the magnitude of these associations were consistent with our previous findings. None of the variants studied showed heterogeneity by age. No association was observed between rs3117027 and risk of cervical cancer (OR=0.99, 95%CI=0.87-1.11 for allele A; P=0.80). Our results support the role of *HLA-DRB1* and *MICA* in the pathogenesis of cervical cancer.

Gene Expression Profiling of a Single Laser Capture Microdissected (LCM) Cell.
S. Chu, M. Gauthier, K. Schmidt, S. Patel. Life Technologies, South San Francisco, CA.

Laser Capture Microdissection (LCM) is a technique providing a rapid and reliable method to procure purified cell populations, either as multiple single cells or a group of cells, from a heterogeneous tissue sample allowing a targeted approach to genomic profiling. When analyzing gene expression profiles from a group of cells, the average profile may not be a true representation of the many different profiles that could exist even in a pure cell population (e.g., in different states of growth, differentiation, or activation). As a result, the transcriptional variability of individual cells and any insight into the relationship between specific genes in single cells are lost. To fully understand the complexity of tissue and cellular heterogeneity, it is necessary to measure molecular signatures at the single cell resolution. Here we developed a workflow for gene expression profiling of a single LCM cell that can also be applied to small number of LCM cells. The ArcturusXT™ LCM system was used to harvest single cells from frozen human tumor tissue samples which were then processed and analyzed with a quantitative RT-PCR assay platform.

Loss in the function and homeostasis of the PDE family might inflict on the cAMP and cGMP signaling and lead to the development of prostate cancer.
R.B. de Alexandre[1,2], A. Horvath[1], A.D. Manning[1], N. Hatipoglu[1], F. Kardauke[2], D. Carraro[3], F. Soares[3], M. Nesterova[1], C. Stratakis[1], F.R. Faucz[1,2]. 1) Section on Endocrinology & Genetics, PDEGEN, NICHD, NIH, Bethesda, MD, USA; 2) Laboratory of Molecular Genetics, NIMA, PPGCS, Pontificia Universidade Catolica do Parana, Curitiba, Brazil; 3) Laboratory of Genomics and Molecular Biology - A.C. Camargo Hospital, São Paulo, Brazil.

The phosphodiesterases (PDEs) are a family of 11 intracellular isozymes coded by 21 different genes. They are responsible for hydrolyzing cAMP and cGMP to their respective 5'-nucleoside monophosphate. Some PDEs are specific for the hydrolysis of cAMP or cGMP, while others have mixed specificity. Each PDEs has a different ability to control each of these messengers concentration in different tissues, provoking different cellular responses and functions. Cyclic AMP and cGMP intracellular levels depend on the balance between their synthesis and degradation. Variants in PDEs have been associated with different disorders. The first PDE to be implicated in the predisposition of prostate cancer (PCa) was the PDE11A, whose inactivating mutations have been reported to be frequent in its patients. Further, higher levels of cAMP have been measured in prostate cancer compared to the normal tissue. In addition, cAMP and cGMP signaling is involved in PCa cell growth and modifies androgen receptor effects. We sequenced 16 different PCa tumor DNAs on SOLiD4 platform, after targeted enrichment for the coding parts of 196 genes, including the family of the phosphodiesterases, adenylate and guanylate synthases, all genes involved in cAMP and cGMP pathways and other genes related to endocrine tumors. After alignment and variation calling, Sanger sequencing confirmation and biostatistics analysis (through comparison patients with controls of the 1000 Genome Project), we were able to select 22 different SNPs associated with the disease. These significant SNPs where found to be located in the PDE1C, PDE2A, PDE4B, PDE5A, PDE6A, PDE6B, PDE6C, PDE8A, PDE8B and PDE11A genes. Moreover, it was found two novel mutations confirmed by Sanger located in the PDE1A and PDE7B genes. Furthermore, th previously-ere are still seven novel mutations with large chances to be real positives spread through the PDEs awaiting to be confirmed by Sanger sequencing. These results demonstrate that there might be a set of disarrangement in the intracellular levels of cyclic AMP and cGMP altering its balance. This data also establish a link between the PDEs and PCa, suggesting that, not as what was report previously with only the PDE11A, but that the whole family might be involved with a higher susceptibility to PCa. However, further investigations at protein level, trying to identify what exactly each alteration might influence in the final phenotype, are needed to be accomplished previously publication.

3269F

Genetic variants in miR-499a, miR-938 and miR-1206 are associated with gastric cancer in Europeans from the EPIC-EURGAST study. *Y. Espinosa-Parrilla[1, 2], X. Muñoz[3, 4], I. Torruella-Loran[1], C. Bonet[5], N. Garcia[4, 5], E. Riboli[6], C.A. Gonzalez[5], N. Sala[4, 5].* 1) Ciencies Experimentals i de la Salut (CEXS-UPF), Institut de Biologia Evolutiva (UPF-CSIC), Barcelona, Barcelona, Spain; 2) Programa de Genética Humana, ICBM, Facultad de Medicina, Universidad de Chile, Santiago de Chile; Chile; 3) Hereditary Cancer Program; Catalan Institute of Oncology (ICO-IDIBELL), Barcelona, Spain; 4) Molecular Epidemiology Group, Translational Research Laboratory, Catalan Institute of Oncology (ICO-IDIBELL), Barcelona, Spain; 5) Unit of Nutrition, Environment and Cancer, Cancer Epidemiology Research Program, ICO-IDIBELL, Barcelona, Spain; 6) Department of Epidemiology and Public Health, Imperial College London, London, United Kingdom.

MicroRNAs (miRNAs) are post-transcriptional gene regulators that participate in diverse biological pathways and may act as either tumor suppressors or oncogenes. Single nucleotide polymorphisms (SNPs) in miRNAs may contribute to cancer development causing changes in either miRNA expression or function. To look for a possible contribution of miRNA genetic variants to gastric cancer (GC) susceptibility we selected 40 SNPs potentially functional because of their location in the seed (4), mature (5) or precursor (31) sequence of 40 miRNAs and genotyped them in 1284 controls matched to 365 incident GC cases with different histological and tumor location phenotypes (European Prospective Investigation into Cancer and Nutrition (EPIC) cohort). Logistic regression analysis under the log-additive model showed that rs2114358T/C, located in the precursor sequence of miR-1206, was associated with the non-cardias localization of the adenocarcinoma (p value= 0.0093, OR (95% CI)= 0.73 (0.58-0.93)); this SNP could affect the dosage of the corresponding miRNA by altering its biogenesis or stability. Furthermore, two out of the four SNPs located in miRNA seed regions were associated with GC: rs12416605C/T in miR-938 associated with the diffuse phenotype (p value= 0.0281, OR (95% CI)= 0.70 (0.51-0.97)) and rs3746444T/C in miR-499a-3p associated with the cardias CG subtype (p value= 0.0308, 0.64 (0.42-0.98)). To investigate if differential gene regulation could be underlying the genetic association of GC with these SNPs in miR-938 and miR-499a we predicted target genes for the different miRNA alleles of both variants using TargetScan. We found a very low overlapping of predicted genes for the different alleles (three common target genes for the two alleles of rs12416605 and no common target genes for the two alleles of rs3746444) as well as a significant decrease in the number of genes predicted to be regulated by the minor alleles of rs12416605 (115 and 75 predicted target genes for the C and T alleles, respectively) and rs3746444 (259 and 9 predicted target genes for the T and C alleles, respectively). These results indicate that specific miRNA allele variants are associated with GC susceptibility in European populations probably influencing either miRNA dosage or the number and spectrum of target genes regulated by these miRNAs.

3270W

Bladder cancer susceptibility variants within CCNE1 are associated with mRNA expression of an alternative splicing form. *Y.P. Fu[1], I. Kohaar[1], W. Tang[1], P. Porter-Gill[1], J.D. Figueroa[2], M. BACKGROUND: SNP rs8102137 located 6 Kb upstream of the cyclin E1 gene (CCNE1) on chromosome 19q12 is associated with bladder cancer in a genome-wide association study (GWAS). CCNE1 regulates cell cycle and thus is a strong candidate gene for cancer susceptibility. METHODS: Based on the bladder GWAS and the 1000 Genomes Project reference panel (phase 1 version 3, 2012 March revised), we imputed 4,650 SNPs within +/- 200 Kb of CCNE1 region (GRCh37, chr19: 30,102,901-30,515,215) among 3,532 bladder cancer cases and 5,120 controls of European ancestry. CCNE1 mRNA expression was evaluated by RNA-Sequencing in 6 pairs of tumor-normal bladder tissue samples and with custom-designed TaqMan assays in 42 muscle-invasive bladder tumor and 42 adjacent normal tissue samples. Logistic regression and multivariable linear models were used to test for the association between SNPs and bladder cancer risk, and between SNPs and mRNA expression. All models were assumed the log-additive SNP effects and adjusted for study sites, age, gender, and smoking habits when applicable. RESULTS: A total of 700 well-imputed and 76 GWAS-genotyped SNPs in the CCNE1 region were used for analyses. We identified an imputed SNP rs7257694, a coding synonymous variant (Ser390Ser) in CCNE1 gene, was in strong linkage disequilibrium (LD) with the GWAS marker rs8102137 (r^2=0.763, D'=0.995). With validation through actual genotyping, rs7257694 showed a per-allele odds ratio (OR) of 1.10 (95%CI=1.03-1.17) for bladder cancer risk, which was comparable to rs8102137 (OR=1.12, 95%CI=1.05-1.20) in the same samples. In addition to the main CCNE1 transcript, RNA-sequencing revealed 2 splicing forms of CCNE1 with deletion of exons 5 or 7. TaqMan assays showed significantly higher mRNA expression in bladder tumors than in adjacent normal bladder tissues of total CCNE1 (p=3.97E-12) and of a transcript without exon 5 (p= 6.15E-10). The mRNA expression of CCNE1 transcript without exon 7 was significantly associated with both rs8102137 and rs7257694 in normal and tumor bladder tissues (all $p<0.05$). CONCLUSION: In addition to the GWAS variant rs8102137, we identified a CCNE1 coding synonymous SNP rs7257694 as a variant associated with bladder cancer risk and with mRNA expression of the CCNE1 transcript without exon 7. Future studies are warranted to validate our findings in additional samples and investigate the possible functional mechanisms of this genetic association in bladder cancer.

Few mutations in known high-risk gastric cancer susceptibility genes in Chinese gastric cancer kindreds. *A.M. Goldstein[1], N. Hu[1], L.-J. He[2], X.-Y. Han[3], J. He[1,4], M. Rotunno[1], M. Malasky[1,4], H. Su[1], L. Wang[1], C. Wang[1], L. Burdett[1,4], B. Hicks[1,4], K. Jones[1,4], J. Boland[1,4], A. Hutchinson[1,4], M. Yeager[1,4], T. Ding[3], C. Giffen[5], M.A. Tucker[1], S.J. Chanock[1], M. Lee[6], P.R. Taylor[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, Maryland, USA; 2) YangCheng Cancer Hospital, YangCheng, Shanxi, PR China; 3) Shanxi Cancer Hospital, Taiyuan, Shanxi, PR China; 4) Cancer Genetics Research Laboratory, SAIC-Frederick, Inc., Frederick National Laboratory for Cancer Research, Frederick, Maryland, USA; 5) Information Management Services, Inc., Silver Spring, MD, USA; 6) Center for Cancer Research, National Cancer Institute, NIH, Bethesda, Maryland, USA.

Gastric cancer (GC) causes more than 700,000 deaths each year. Familial GC results from the complex interplay of genetic and environmental factors. Several high-risk susceptibility genes for familial GC and related disorders have been identified, but most of these genes have not been examined in families from high-incidence regions such as the Taihang Mountains of North-Central China, a region with some of the highest rates reported for GC and esophageal cancer (EC). We searched the Human Gene Mutation Database (HGMD) and COSMIC to select germline disease-causing genes in familial GC. To allow for related phenotypes, we also included susceptibility genes for gastrointestinal polyps and colorectal cancer. Fourteen genes (*CDH1, MET, MUTYH, TP53, MLH1, MSH2, MSH6, PMS1, PMS2, APC, CTNNA1, SMAD4, BMPR1A, MADH4*) were selected. Families with 3 or more GC and/or EC cases (including ≥2 GC patients) from an ongoing family study were eligible for this study. Twelve eligible families were selected for exome sequencing; 8 families had at least 3 GC cases. The goal of our study was to determine whether high-risk GC-related susceptibility genes are important in GC families from the Taihang Mountains. Twenty-six patients with available DNA were exome sequenced. We interrogated the exome sequencing data for rare co-segregating mutations in the 14 GC-related susceptibility genes. Rare co-segregating variants were found in only 3 (*CDH1, MSH2, MUTYH*) of the 14 genes in two GC families. An *MSH2* substitution (rs63750716) was found in 2 patients (1 GC; 1 EC) with available DNA from a 4 case family (2 GC; 2 EC); it was seen at 0.3% frequency in Asian 1000 Genomes subjects and predicted to be neutral (MutationAssessor). Variants in *CDH1* and *MUTYH* were seen in a single family with 3 GC patients, but, each variant was seen in only 2/3 GC cases. The *CDH1* substitution was novel; the *MUTYH* substitution was reported in 0.5% of Asian subjects in 1000 Genomes; both variants were predicted to have medium functional impact (MutationAssessor). Further study is needed to determine whether these rare variants increase risk for GC in these two families. Overall, examination of 14 GC-related susceptibility genes revealed rare co-segregating variants in two GC kindreds from a high-risk region of China. No co-segregating mutations were observed in the remaining 10 familial GC kindreds suggesting that other genes and/or non-genetic factors are involved in familial GC risk in this region.

Transcriptome analysis reveals novel gene coding variants and fusion transcripts in infant acute lymphoblastic leukemia. *A.M. Gout[1,2], R.S. Kotecha[1,3,4], J. Ford[1], R.W. Francis[2], A.H. Beesley[1], M.N. Cruickshank[1], U.R. Kees[1].* 1) Division of Children's Leukaemia and Cancer Research, Telethon Institute for Child Health Research, University of Western Australia Centre for Child Health Research, Perth, Australia; 2) Division of Bioinformatics and Biostatistics, Telethon Institute for Child Health Research, University of Western Australia Centre for Child Health Research, Perth, Australia; 3) Department of Hematology and Oncology, Princess Margaret Hospital for Children, Perth, Australia; 4) School of Pediatrics and Child Health, University of Western Australia, Perth, WA, Australia.

Acute lymphoblastic leukemia (ALL) occurring in the first year of life is rare, accounting for 2-5% of pediatric ALL cases. Infant ALL is distinguished by unique clinical and biological characteristics, with an aggressive course following a short latency period. The mixed lineage leukemia (MLL) gene, located on chromosome 11q23, is involved in 80% of cases. Currently, 79 different MLL-fusion partner genes have been molecularly characterized with t(4;11), t(9;11) and t(11;19) the most frequent translocations in infant ALL. In this study we focused on MLL-rearranged infant ALL where diagnosis occurred at < 92 days. At present, the outcome for these infants remains poor with 26% five-year survival. Given the advent of next generation sequencing, further insight into the biology of the disease may identify potential targets for novel therapies and ultimately improve outcome. We performed RNA-sequencing (Illumina, 100bp paired end) on six primary patient infant ALL samples: three patients had the t(4;11) translocation, one patient had a t(11;19) translocation and a pair of monozygotic twins with a rare MLL-translocation partner gene, t(1;11). Upon alignment of sequence reads to reference sequences (including genome, splice junction and transcriptome sequences), a pipeline utilizing Genome Analysis ToolKit (GATK) functions, Annovar, SIFT, Polyphen2, dbSNP and COSMIC was used to process the sequence alignments and annotate single nucleotide variants (SNVs). Ingenuity Pathway Analysis was performed on gene lists associated with predicted damaging SNVs. This revealed an over-representation of cancer-associated genes harboring damaging SNVs that were shared among all six infant ALL patient samples. This gene set involves multiple genes previously reported to be involved with hematological neoplasia that may represent novel therapeutic targets for treatment. We also sought gene fusions in these datasets using FusionFinder that led to the identification of a number of novel putative gene fusions involving known oncogenes. Further studies are required to determine the role of these SNVs and gene fusions in infant leukemogenesis.

Chemotherapy-Induced Peripheral Neuropathy and Cognitive Dysfunction: Role of Genetic Variation. *K. Holohan[1,2], Y. Wang[3], B.C. McDonald[3,4], S.K. Conroy[2,3], D.J. Smith[3], J.D. West[3], K. Nho[3], S. Kim[3], A.J. Saykin[1,3,4].* 1) Medical and Molecular Genetics, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 2) Training in Research for Behavioral Oncology and Cancer Control Program, Indiana University School of Nursing, Indianapolis, Indiana; 3) Center for Neuroimaging, Department of Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, Indiana; 4) Indiana University Melvin and Bren Simon Cancer Center, Indiana University School of Medicine, Indianapolis, Indiana.

Although the cerebral effects of pain have been studied via neuroimaging in many disease models, this topic has not yet been investigated with chemotherapy-associated peripheral neuropathy and cognitive dysfunction. Previous studies have reported cognitive dysfunction measured by decreased neuropsychological test performance, increased cognitive complaints, and alterations in neuroimaging measures, and treatment with paclitaxel and docetaxel has been strongly associated with increased incidence and severity of peripheral neuropathy symptoms (PNS). Significant genetic modifiers have been identified for both of these adverse events, but possible correlations between them have not been explored. We hypothesized that chemotherapy-induced peripheral neuropathy and cognitive dysfunction may be associated, and that these measures may be modified by genes *EPHA5*, *FGD4*, or *FZD3*, which have been previously associated with chemotherapy-induced peripheral neuropathy. We examined this hypothesis in a prospective cohort of breast cancer patients treated with (Ctx+, n=27) and without (Ctx-, n=26) chemotherapy and healthy controls (HC, n=26) studied at baseline (BL; post-surgery, before chemotherapy) and one month after treatment completion (1M) or yoked intervals. Neuroimaging included pulsed arterial spin labeling MRI to obtain cerebral blood flow (CBF), cognitive complaints were assessed using the Multiple Ability Self-Report Questionnaire (MASQ), PNS were assessed using the 9-item FACT/GOG-Ntx subscale, and all subjects were genotyped using the Illumina OmniExpress BeadChip. Neuroimaging analysis of Ctx+ patients using SPM8 indicated that PNS at 1M covarying for BL were positively associated with CBF change from BL to 1M in the left anterior cingulate region ($p<0.001$ uncorrected), which has been associated with pain processing. This measure of CBF change was set-tested in PLINK for association with *EPHA5*, *FGD4*, and *FZD3*. The *EPHA5* gene set was significantly associated with CBF change, as well as with PNS at 1M covarying for BL ($p<0.03$). Further analysis indicated that one of the most significant SNPs, rs13149946, was also associated with the language subdomain of the MASQ ($p=0.028$), suggesting that this gene may be involved in both pain processing and cognition, and could be a potential target to address both of these issues. Future investigation should test *EPHA5* for association with other measures of cognitive processing and replication in other cohorts.

Occult hepatitis B and carcinogenic markers in chronic hepatitis C infection. *R. issa.* molecular diagnostics, institute of genetic engineering, cairo, Egypt.

The presence of HBV-DNA in the patient's serum without detectable HBV surface antigen (HBsAg.) called occult infection. Detection of occult HBV infection in chronic hepatitis C virus patients was investigated by using qualitative PCR. Co-infection with occult HBV in chronic HCV patients increases the risk for progression to hepatocellular carcinoma (HCC).Detection of CD45-CD90+ as a biomarker in HCC patients by flow cytometry. We searched for serum HBV DNA in 30 patients with histologically verified HCV-related chronic liver disease, in addition to 10 healthy control subjects collected at National Liver Institute in Shebin El-Kom, Monofiya University, Egypt from January, 2010 to October, 2010. Off 40 patients, the sera of 9 (15.0%) were positive for HBV DNA by the different PCR assays, documenting an occult HBV infection. It found that 5 patient samples are positive for HBV DNA (Surface gene) (12.5%) of total 40 patient samples, also 3 patient samples are positive for HBV DNA (X gene) (7.5%) of total 40 patient samples, and only one patient sample was positive HBV DNA (core gene)(2.5 %) of total 40 patient samples. Only two samples from the nine positive samples were positive for both X-gene and Surface gene. In conclusion these data suggest that occult HBV infection may have clinical significance in chronic hepatitis C patients. Keywords: Biomarker, Flowcytometery, Hepatocellular carcinoma, Occult HBV. Introduction Occult hepatitis B infection (OBI) has been recognized for nearly 20 years. However, with the improvements in sensitivity of serological and genomic amplification assays, the frequency and attention given to this nearly silent form of the infection has been growing. Because low or very low viral load is part of the definition of OBI, molecular data are scarce, and, because most patients affected are asymptomatic, little clinical data, in particular histological, is available (Allain J.P. 2005). Hepatocellular carcinoma (HCC) is one of the most common malignant tumors worldwide ranging between 3% and 9% annually Velazquez et al., 2003. In Egypt, HCC reports to account for about 4.7% of chronic liver disease patients. HBV and HCV infections are strongly associated with liver cirrhosis and HCC Rahman et al., 2001. Africa ., 2008).

3275F

Fine mapping of the Finnish hereditary prostate cancer linked loci at 2q37 and 17q12-q22. *V.H. Laitinen[1], T. Rantapero[1], D. Fischer[2], E.M. Vuorinen[1], T.L.J. Tammela[3], T. Wahlfors[1], J. Schleutker[1, 4].* 1) Institute of Biomedical Technology/BioMediTech, University of Tampere and Fimlab Laboratories, Tampere, Finland; 2) School of Health Sciences, University of Tampere, Tampere, Finland; 3) Department of Urology, Tampere University Hospital and Medical School, University of Tampere, Tampere, Finland; 4) Medical Biochemistry and Genetics, Institute of Biomedicine, University of Turku, Turku, Finland.

Linkage studies of Finnish hereditary prostate cancer families have revealed a strong connection between prostate cancer and two chromosomal regions, 2q37 and 17q12-q22. The 17q12-q22 locus is the same previously reported in the US population from Michigan and recently, both of these genomic regions have been detected in multinational GWS analyses. Although the recently identified G84E variant in the *HOXB13* gene at 17q21-q22 has been detected at a high frequency in Finnish prostate cancer patients, this variant alone does not explain the observed linkage to 17q12-q22. Neither is the candidate gene at 2q37 known for the present. To explain the linkage, we therefore screened these two regions of interest by next-generation sequencing (NGS). The NGS produced over 100.000 unique sequence variants which were carefully filtered in a multistep prioritization process, yielding a subset of 58 putative prostate cancer associated variants co-segregating with the disease in the analyzed families. These variants were then validated in 1293 Finnish prostate cancer cases and in 923 controls with Sequenom MassARRAY system. Statistical analyses revealed 13 SNPs in 7 genes that were significantly associated with prostate cancer. Two novel susceptibility alleles were identified in the *ZNF652* gene (17q21.3), one allele in the *HDAC4* gene (2q37.2) and one in the *EFCAB13* gene (17q21.3). As a complementary approach, we investigated the impact of prostate cancer associated sequence variants on the regulation of genes located within the two linked regions. This targeted expression quantitative trait loci (eQTL) analysis was performed by combining the NGS data with transcriptome data obtained from RNA sequencing. In total, five candidate eQTLs were found at 2q37 and 1881 candidates at 17q12-q22 before multiple testing adjustment. The novel prostate cancer associated SNPs identified in this study may be exploited in cancer risk assessment, and they further support the suggested role of *ZNF652* as a prostate cancer candidate gene. Moreover, this is the first targeted resequencing project studying the locus on 2q. The regulatory elements discovered by eQTL mapping provide new insights into the complex genetic events contributing to prostate cancer predisposition.

3276W

Novel *EZR/ERBB4* fusion gene found in follicular variant of papillary thyroid cancer. *S. Lee[1], H.-G. Jee[2], K. Lee[2], J.-S. Seo[1].* 1) Biomedical Sci, Seoul National Univ, Seoul, South Korea; 2) Seoul National University Hospital, Seoul, South Korea.

Thyroid cancer is one of the most prevalent cancers worldwide, and papillary thyroid cancer accounts for ~80% of all thyroid cancers. Here we conducted RNA sequencing for 46 papillary thyroid cancer tissues in Korean patients and explored any fusion mutations found using the TopHat-Fusion program. As a result, we discovered 3 fusion mutations using our stringent criteria and these include *CCDC6/RET* and *PAX8/PPARG* fusions, which have been previously reported for this cancer type. The other *EZR/ERBB4* fusion is a novel fusion mutation found in papillary thyroid cancer, and the sample having this mutation was diagnosed as the follicular variant subtype with abnormal pathological findings. This is an in-frame mutation and the expression pattern verified this fusion at the exon level. Previous reports have shown that *ERBB4* is a driver gene for carcinogenesis in multiple types of cancers. In this study, we suggest the *EZR/ERBB4* fusion as a novel driver mutation in papillary thyroid cancer, showing the atypical follicular patterns of pathology.

3277T

Sequence variants in *BARD1* and breast cancer susceptibility: results from the Breast Cancer Family Registry study. *F. Lesueur[1,2], F. Damiola[1], N. Robinot[1], N. Forey[1], G. Durand[1], C. Voegele[1], M.P. Vallée[1], J.L. Hopper[3], M.C. Southey[4], I.L. Andrulis[5], E.M. John[6], S.V. Tavtigian[7], Breast Cancer Family Registry.* 1) Genetic Cancer Susceptibility group, International Agency for Research on Cancer, Lyon, France; 2) Inserm, U900, Institut Curie, Mines ParisTech, Paris, France; 3) Center for Molecular, Environmental, Genetic and Analytical Epidemiology, School of Population Health, EGA The University of Melbourne, Victoria, Australia; 4) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Victoria, Australia; 5) Department of Molecular Genetics, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON, Canada; 6) Cancer Prevention Institute of California, Fremont, CA, USA and Stanford University School of Medicine and Stanford Cancer Institute, Stanford, CA, USA; 7) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, USA.

The RING-finger mediated BARD1/BRCA1 heterodimer is essential for the tumor suppressor functions of BRCA1, and both BRCA1 and BARD1 possess a pair of tandem BRCT domains that interact in a phosphorylation-dependent manner with target proteins. Since missense mutations in *BRCA1* that disturb the BARD1/BRCA1 interaction lead to breast cancer predisposition, it has been suggested that comparable mutations in *BARD1* may be responsible for a proportion of familial breast cancer. Indeed, likely pathogenic germline variants in this gene have occasionally been described in breast and/or ovarian cancer families. With the aim to investigate the frequency and attributed risk of *BARD1* variants in breast cancer susceptibility and to clarify relevance of mutation screening of this gene to familial cancer clinics and counselors, we sought to estimate the frequencies and nature of rare *BARD1* variants in a sample of women with early onset breast cancer (N=1,311) and frequency matched controls (N=1,111) from three population-based centers of the Breast Cancer Family Registry. High throughput screening of *BARD1* coding and flanking intronic regions in this series identified 30 missense variants, 13 synonymous variants and three variants in intronic regions close to splice junctions. To distinguish functionally neutral variants from those that may contribute to breast cancer risk, we used a combination of phylogenetic information with current knowledge on protein structure. Predictions on functional relevance of detected variants were obtained from different prediction algorithms. Among variants likely to alter the key RING and BRCT domains, we report for the first time a cysteine substitution (c.221G>T; p.Cys74Phe) affecting the BARD1 C3HC4 RING motif. This substitution was found in one case. The only protein-truncating variant identified was the synonymous substitution c.1977 A>G (p.Arg659Arg) leading to aberrant transcript that removes the second BRCT domain of BARD1 (p.Cys53_Trp635delinsfsX12); it was found in 7 cases (0.5%) and 9 controls (0.8%). Overall, the number of variants predicted to be damaging or neutral were evenly represented among cases and controls. Hence, our findings do not confirm in a population-based study setting of women with early onset breast cancer a risk associated with rare truncating or missense variants in BARD1. However we cannot exclude the possibility that mutations in *BARD1* will explain some small proportion of hereditary breast cancer.

3278F

Field synopses of genetic variation in colorectal neoplasia. *J. Little[1], H. Campbel[2], G. Gresham[1], Z. Montazeri[1], S. Sivakumaran[2], E. Theodoratou[2].* 1) Epidemiology & Community Med, Univ Ottawa, Ottawa, ON, Canada; 2) Centre for Population Health Sciences, University of Edinburgh, Edinburgh, UK.

Objectives: We present results from the CRC field synopsis, report on work in progress on colorectal polyps, and comment on differences in the nature of the evidence, such as volume and quality of evidence, and issues including manner of detection of polyps, investigation of initially detected vs. recurrent polyps, and subtype. Methods: We have recently completed a field synopsis for colorectal cancer (CRC) and are in progress of developing one on colorectal polyps. For the CRC synopsis, we reviewed over 10,000 titles, then collated and extracted data from >600 publications reporting on >400 polymorphisms in >100 different genes. We carried out meta-analyses to derive summary effect estimates for >90 polymorphisms in >60 genes, including unpublished data from GWAS. For the polyp synopsis, we collated and extracted data from more than 170 publications reporting on about 200 different genes. Odd ratios are estimated based on meta-analysis for 11 polymorphisms so far. We considered four genetic models (two additives, one dominant, and one recessive). To assess the credibility of associations, we applied the Venice criteria and added consideration of Bayesian False Discovery Probability. Results: Based on meta-analysis for CRC 16 independent variants at 13 loci represent the most highly credible findings and 23 variants at 22 loci have 'less credible' association. We haven't gene associated with polyps at this stage. In addition, we stimulate discussion about (a) updating of field synopses and (b) operationalization of the Venice criteria, for both of which there appear to be differences across field synopses. These issues have relevance in public health beyond the area of genetic susceptibility. Conclusions: Our data should help results of genetic associations studies to be placed in context and interpreted appropriately and should help direct future research effort.

3279W

Genomic analysis of inherited breast cancer among Palestinian women. *S. Lolas-Hamameh[1,2], D. Dweik[1], F. Fostira[4], T. Walsh[3], M.K. Lee[3], S. Casadei[3], MC. King[3], E. Levy-Lahad[2], M. Kanaan[1].* 1) Hereditary Research Laboratory, Bethlehem University, Bethlehem, Palestine; 2) Medical Genetics institute, Shaare Zedek Medical Center, Jerusalem, Israel; 3) Departments of Medicine and Genome Sciences, University of Washington, Seattle, Washington, USA; 4) National Centre for Scientific Research"Demokritos", Athens, Greece.

In the Middle East, breast cancer incidence among Palestinian women has historically been low, but with increased education and later initiation of child bearing among Palestinian young women, is now rapidly increasing. Furthermore, perhaps because of its historically low incidence, breast cancer among Palestinian women is strikingly familial. We explored the genetic bases of this familial risk in the context of providing culturally appropriate genetic counseling services to high-risk women. Participants were 274 Palestinian and Arab-Israeli women with breast cancer, most either with a positive family history of breast or ovarian cancer (116 subjects) or diagnosed at age 40 or younger (130 subjects). Genomic DNA was tested by BROCA, which enables the capture and simultaneous multiplex sequencing of all coding, regulatory, and intronic regions of 30 known breast and ovarian cancer genes. Considering only unambiguously damaging mutations (i.e. truncations, complete deletions, splice mutations leading to a mutant message, and missenses proven experimentally to be damaging), 29 of the 274 subjects (11%) carried a mutation responsible for their breast cancer. These included 22 of the 116 familial subjects (19%), 8 of the 130 young-onset-nonfamilial subjects (6%), and 0 of the 29 subjects not meeting either criterion. The damaging mutations included 7 in BRCA1, 10 in BRCA2, 2 in ATM, 2 in BARD1, and 1 each in TP53, CHEK2, CDH1, PALB2, ATR, BRIP1, and XRCC2. With two exceptions (BRCA2 p.E2229X and BRCA2 c.6462delTC), all mutations were different. Also, two subjects had two mutations each: in CHEK2 and BARD1; and in CHEK2 and ATM. Multiple variants potentially altering splicing and missenses potentially damaging to function are still in process of evaluation and remain good candidates. Based on the historical demography of the region, we anticipated that the spectrum of mutations predisposing to breast cancer in the Palestinian population would be broad, with multiple individually rare, highly localized mutations, rather than a small number of founder alleles; that is, a European pattern rather than an Ashkenazi Jewish pattern. This proved to be true. Breast cancer among Palestinian women is generally diagnosed at late stages, and consequently has poor prognosis. If Palestinian women at genetically high risk were provided the opportunity to undertake special scrutiny, staging and mortality could be substantially improved.

3280T

Prostate cancer risk regions in 8q24 and 17q24 are differentially associated with somatic *TMPRSS2:ERG* fusion status. *C. Maier[1,2], A.E. Rinckleb[1,2], M. Luedeke[1,2], J.L. Stanford[3,4], J. Deep sequencing of prostate cancer (PrCa) genomes has recently pointed at an early role of *ETS* gene fusions in tumorigenesis, and revealed a characteristic landscape of structural rearrangements accompanying the oncogene translocation. Since PrCa in general has been proven partially heritable, we considered fusion positive PrCa as a distinct tumor entity that may be traced back to specific sets of germline risk factors. In a collaborative setting involving 1,221 cases with somatic status of the oncogene *TMPRSS2:ERG* we have investigated 27 common PrCa risk variants, known from previous GWAS studies, for their particular contributions to fusion positive or negative subclasses. Mantel-Haenszel meta-analysis was used to compare frequencies of risk alleles between the two subtypes. In a first set of 552 cases the PrCa risk loci 10q11 (rs10993994: OR = 1.35; p = 0.015), 19q13 (rs2735839: OR = 1.73; p = 0.0035), 17q24 (rs1859962: OR = 1.29; p = 0.038) and 8q24 (rs16901979: OR = 0.53; p = 0.021) appeared associated with fusion status at nominal significance. A replication round comprising a further 669 cases verified a selective involvement of 17q24 in fusion positive PrCa (stage 1 and 2 combined: p = 0.0016), and of 8q24 in fusion negative PrCa (stage 1 and 2 combined: p = 0.0006). Both loci, 17q24 and 8q24, are gene deserts, where the causal process for PrCa susceptibility is not fully understood to date. Noteworthy, one additional locus (rs1447295) in 8q24, which represents a risk region independent from rs16901979, also showed association with fusion status in our study (stage 1 and 2 combined: OR = 0.70; p = 0.0024). The concurrence of both 8q24 variants being associated with fusion negative PrCa is not due to linkage disequilibrium, and indicates a common pathogenic mechanism that is unrelated to *ETS* activity. In contrast, *ETS* pathway involvement at the 17q24 locus is plausible, since long range interactions have previously been described between risk genotypes and the nearby *SOX9* gene, encoding a transcription factor which was observed to be co-expressed with *ERG* in the androgen driven profile of fusion positive tumors. In brief, our study further supports the distinctness of *ETS* positive vs. negative PrCa, and demonstrates in principle, that molecular subtypes could represent different entities also on the germline level. Larger sets of PrCa cases with somatic typing will be required in order to identify patterns of corresponding predisposing factors.

Identification of Susceptibility Loci in Hereditary Prostate Cancer Families Using Copy Number Variation and Linkage Analysis. *D. Mandal[1], E. Ledet[2], J.E. Bailey-Wilson[3], M. Li[4].* 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Tulane Cancer Center, Tulane University School of Medicine, New Orleans, LA; 3) National Human Genome Research Institute/National Institutes of Health, Baltimore, MD; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

In the United States, it is estimated that about 238,590 new cases of prostate cancer will be diagnosed and about 29,720 men will die from this disease in 2013. Family history is the most significant predictor of prostate cancer development and approximately 10% of prostate cancer cases are attributable to inheritable genetic factors. However, disease gene identification for prostate cancer has been extremely challenging due to both disease and genetic heterogeneity. To overcome the effects of ethnic disparity, genetic heterogeneity, incomplete penetrance, and missing heritability, our goal was to identify genetic components of prostate cancer by using a comprehensive approach combining both array comparative genomic hybridization (aCGH) analysis and linkage analysis. Eight prostate cancer cases were studied using aCGH to search for germ-line copy number variants (CNVs) associated with hereditary prostate cancer. The study subjects were from 8 large, high-risk, clinically homogenous families with European ancestry from Southern Louisiana. Three novel regions of CNVs were identified: 16q23, 11q22, and 2q22 in all 8 prostate cancer cases. Both model-based and model-free linkage analyses were performed on 4 of the most informative families (≥5 prostate cancer cases/family) from these 8 prostate cancer cases. Genotyping for linkage analyses was done using Illumina Infinium II SNP HumanLinkage-12 panel. Suggestive evidence of linkage was obtained at 2q14 (HLOD score of 1.94). Using aCGH, a 68 kb duplication was observed in this region in all 8 hereditary prostate cancer cases. These genetic findings, which were identified in multiple large, well-characterized families, provide new insight into hereditary prostate cancer. Future fine mapping of the 2q14 region in a larger cohort of patients, confirmation of novel CNVs in additional subjects and use of next-generation sequencing approaches are needed to provide further evidence of susceptibility loci for prostate cancer.

A systems biology approach reveals novel mechanisms associated with cancer metastasis in EMT-MET cell reprogramming. *R.C. McEachin[1], H. Roca[2].* 1) Computational Medicine and Bioinformatics, Univ Michigan, Ann Arbor, MI; 2) Urology, Univ Michigan, Ann Arbor, MI.

Cancer progression is characterized, in part, by altered or aberrant gene expression. Mesenchymal to Epithelial Transition (MET) is a reversible process (EMT) that is critical to metastasis in cancer progression. In this work, we established 'MET signatures' to characterize changes of gene expression in models of prostate cancer and breast cancer, where we induced MET by over-expression of OVOL1, OVOL2, or both OVOL transcription factors (TFs). We assessed differential expression by RNA-Seq (FDR ≤ 0.05 AND Fold Change ≥ ± 2.0) and established a set of genes representing the MET signature for each model (1,622 in BC and 2,692 in PC). The 740 genes at the intersection of these two sets represent the common MET signature for these two cancer models. We performed ConceptGen enrichment testing for this set and found significant enrichment for annotation consistent with cancer progression (e.g., biological adhesion, blood vessel development). Interestingly, we also found that annotation for regulation of expression by AP-1 TF is significantly enriched in this set (FDR 7.9E-5). Since we initially induced MET by over-expression of OVOL TFs, we hypothesized that AP-1 and OVOL TFs cooperate in regulation of the MET signature. Consistent with this model, using Genomatix Genome Analyzer we found that promoters for the set of MET signature genes are significantly enriched for AP-1 binding sites, OVOL sites, and the combined model including both sites. To help us understand the broader implications of the MET signature, we did two follow-on analyses. We first identified 129 genes showing at least +0.50 correlation with OVOL1 expression in the 178 cancer types from Barretina et al. in Oncomine. Of these 129 genes almost 60% (74 genes) are common to the MET signature, consistent with the MET signature's impact in a broadened range of cancer phenotypes. We then used GeneGo to model the network of interactions among the genes annotated as being AP-1 regulated in the ConceptGen analysis. We prioritized drug/target combinations in this network for follow-on testing, emphasizing the potential clinical/translational relevance of this work. In summary, we find significant evidence consistent with the OVOL TFs having important roles in MET in two modeled cancers. We also find evidence of cooperation between the OVOL TFs and AP-1 in MET, a broadened role of MET signature genes in a range of cancers, and immediate targets for follow-up in the clinic.

Copy number variation of the antimicrobial-gene, defensin beta 4, is associated with susceptibility to cervical cancer. *K. Miura[1], S. Abe[1], A. Kinoshita[2], H. Mishima[2], S. Miura[1], Kl. Yoshiura[2], H. Masuzaki[1].* 1) Dept OB/GYN, Nagasaki Univ Sch Med, Nagasaki, Japan; 2) Dept Human Genetics, Nagasaki Univ Sch Med, Nagasaki, Japan.

Background: Cervical carcinogenesis has two critical transition steps: persistent oncogenic human papillomavirus (HPV) infection and progression to cervical cancer. Oncogenic HPV infection alone is not sufficient to cause cervical cancer. Host genetic factors may also contribute to cervical cancer pathogenesis, but their roles remain to be determined. The defensin beta 4 gene, DEFB4, which has antimicrobial properties, is a candidate host genetic factor for susceptibility to cervical cancer. **Objectives:** The aim of this study was to investigate association between copy number variation of DEFB4 and susceptibility to cervical cancer in a population at high-risk of persistent oncogenic HPV infection. Methods: The study subjects comprised 204 women with cervical cancer, a population having a high-risk of persistent oncogenic HPV infection (cervical cancer group), and 200 healthy women from the general population (control group). Copy number variation of DEFB4 in each test sample was determined by relative quantitation using the comparative CT (ΔΔCT) method. Differences between the two groups were evaluated. **Results:** The median DEFB4 copy number in the cervical cancer group was four and in the control group was five (p=2.77e-4, t-test). The odds ratio of cervical cancer in individuals with 4 DEFB4 copies or less was higher (odds ratio 2.02; 95% confidence interval odds ratio 1.36-3.02), compared with that in individuals with 5 or more copies (odds ratio 0.49; 95% confidence interval odds ratio 0.33-0.74). Therefore, both groups indicated a two-tailed significant difference from an odds ratio of 1.00 at the 5% level; level. **Conclusions:** We found copy number variation of DEFB4 was a host genetic factor conferring susceptibility to cervical cancer. A lower DEFB4 copy number was associated with susceptibility to cervical cancer.

Effects of Waterpipe Smoking on gene expression. *Z. Montazeri, H. El katerji, J. Gomes, J. Little.* Epidemiology and Community Medicine, University of Ottawa, Ottawa, Canada.

Objectives: Recently, a sharp rise in waterpipe smoking has been observed in North America and Europe, especially among young adults. There is a belief that waterpipe is the healthiest way to smoke tobacco. We studied the effects of waterpipe smoking on gene expression among young waterpipe smokers. Methods: Adverse health effects of waterpipe smoking have been reported in different studies, but this evidence has been appraised as of poor quality. There is a gap in the evidence as to the potential health effects of waterpipe smoking. We are investigating the effects of waterpipe smoking on gene expression among young waterpipe smokers in Ottawa, Canada. We asked participants to respond to a questionnaire and to provide a saliva sample. DNA extracted from these samples is being analyzed using PCR arrays. Results: We selected 18 genes to study the potential carcinogenic effects of waterpipe smoking on cancer based on gene expression. They have been selected based on the fact that they are induced by cigarette smoking as well as they are in the pathways of cancer diseases; genes of xenobiotic metabolism are also included. The main inclusion criteria was that the individual was between the age of 18 and 25 and reported that they smoked waterpipe. The fold change between before and after one hour and a half of smoking waterpipe, effect size, ranged between 0.02 and 34.42. Conclusions: Results could be used to predict the health effects of waterpipe smoking. This research will be used in knowledge translation to enable public health professionals and policy makers to make informed decisions about the control of waterpipe smoking, including potential prevention strategies and cessation interventions.

Upregulation of TRF1 and TRF2 (telomere repeat binding factors) protein contributes to telomere shortening in renal cell carcinoma. *D. PAL[1], U. Sharma[1], R. Khajuria[1], S.K Singh[2], N. Kakkar[3], R. Prasad[1].* 1) Biochemistry, PGIMER, Chandigarh, Chandigarh, India; 2) Urology,PGIMER,Chandigarh, India; 3) Histopathology, PGIMER,Chandigarh,India.

Upregulation of TRF1 and TRF2 (telomere repeat binding factors) protein contributes to telomere shortening in renal cell carcinoma D Pal1* , U Sharma1, R Khajuria1, SK Singh2 , N Kakkar3 and R Prasad1. 1. Department of Biochemistry, PGIMER, Chandigarh 2. Department of Urology, PGIMER, Chandigarh 3. Department of Histopathology, PGIMER, Chandigarh *e.mail-: deekshapal64@gmail.com Background : TRF1 and TRF2 are telomere repeat binding proteins that are exclusively found at the telomeres. Both TRF proteins have a Myb-like helix-turn-helix domain in their carboxyterminus and a central conserved domain that includes sequences responsible for the formation of homodimers. The two proteins do not heterodimerize, and they differ substantially at the N terminus which is acidic in TRF1 but basic in TRF2. The protection of human telomeres crucially depends on these factors and it is reasonable to assume that the requirement for TTAGGG repeats at chromosome ends reflects the need for TRF1 and TRF2 binding. Telomere dysfunction is believed to be the significant factor in carcinogenesis. To elucidate the carcinogenesis mechanism, the expression of TRF1, TRF2 and change in telomere length were investigated in renal cell carcinoma (RCC). Materials and Methods: Total 80 cases of RCC treated by surgery under advanced Urology services of Nehru Hospital, at Postgraduate Institute of Medical Education and Research, Chandigarh were included in the present study. For comparison, normal renal cortex samples were taken in each case. Transcriptional expression of TRF1 and TRF2 were estimated by real time PCR. Whereas Protein levels were detected by using immunohistochemical and immunofluorscence method. The mean telomere length was determined by southern blotting followed by hybridization. Results: The expression of TRF1 and TRF2 were significantly higher in the tumor tissue in comparison with normal renal parenchyma. The mean telomere length in RCC tissue was significantly shorter than that in normal renal parenchyma. The mean telomere length in all tissue samples were inversely correlated with the level of TRF1 and TRF2 expression. Conclusion: Our result suggests that the upregulation of TRF 1 and TRF2 may work to reduce the telomere length in RCC and could contribute to the carcinogenesis of renal cell carcinoma.

3286T

Screening of *XRCC2* in breast cancer families. *L.M. Pelttari[1], S. Vilske[1], C. Blomqvist[2], K. Aittomäki[3], H. Nevanlinna[1].* 1) Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 2) Department of Oncology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Clinical Genetics, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland.

XRCC2, one of the five RAD51 paralogs, is involved in the repair of DNA double-strand breaks through homologous recombination. Most of the breast cancer susceptibility genes, including the high risk genes *BRCA1* and *BRCA2*, have an important role in DNA damage repair. Deleterious mutations in the *XRCC2* gene were recently identified in an exome-sequencing study of familial breast cancer patients and a homozygous truncating mutation in the gene was identified in a Fanconi anemia patient. However, the association of *XRCC2* with breast cancer was not confirmed in a larger case-control study. To investigate the role of *XRCC2* mutations in breast cancer predisposition in the Finnish population, we sequenced the coding region, the 5'UTR, and the exon-intron boundaries of the gene in blood DNA samples of 344 familial breast cancer patients. This extensive set of non-BRCA1/2 breast cancer families included 342 families with at least three breast or ovarian cancer patients among first or second degree relatives and 2 families with two affected first degree relatives. We detected four known polymorphisms among the breast cancer families: one downstream, one 5'UTR, one intronic and one missense variant. No novel changes or truncating mutations were identified. None of the polymorphisms were predicted to be pathogenic and the minor allele frequencies were comparable to the population frequencies. Our results indicate that *XRCC2* does not contribute to familial breast cancer predisposition in the Finnish population. Taken together, it is unlikely that *XRCC2* has a significant contribution to breast cancer susceptibility.

3287F

Large-scale resequencing analysis of six melanoma susceptibility genes in the European Prospective Investigation into cancer and nutrition Cohort. *M. Pertesi[1], N. Forey[1], J. Oliver[1], N. Robinot[1], C. Voegele[1], EPIC. skin cancer working group[3], F. Le Calvez-Kelm[1], J. McKay[1], F. Lesueur[1,2].* 1) Genetic Cancer Susceptibility Group, International Agency for Research on Cancer, Lyon, France; 2) Inserm U900, Institut Curie, Mines ParisTech, Paris, France; 3) International Agency for Research on Cancer, Lyon, France.

Cutaneous malignant melanoma (CMM) is an important health problem in fair-skinned populations worldwide, showing a dramatic increase in incidence over the past decades. Established risk factors include sun exposure, nevus propensity, pigmentary traits, and familial history. Inherited DNA sequence variants are involved in the development and prognosis of CMM and three classes of susceptibility genes have been described. Highly-penetrant mutations in the cell cycle related genes *CDKN2A* and *CDK4* account for about 2% of CCM cases across populations, while more moderately penetrant alleles (*MC1R*, *MITF*), and very common, low-penetrance SNPs in genes related to pigmentation, nevus count, immune response, DNA repair, and metabolism explain about 12% of the familial risk in European populations. Given that the genome-wide association studies conducted by International consortia were well powered to detect SNPs with OR>1.5, it seems unlikely that many additional common alleles with moderate effects on melanoma risk exist, indicating that other uncommon-to-rare susceptibility alleles remain to be identified. To test this hypothesis we designed a cost-effective multiplex-targeted resequencing assay specifically testing for 6 melanoma susceptibility genes identified in the pangenomic studies. About 17kB of DNA sequence corresponding to the exons and flanking intronic regions of *MC1R*, *MITF*, *ASIP*, *TYR*, *TYRP1* and *BAP1* genes is being screened in 1061 CMM cases, and 1061 matched controls from the European Prospective Investigation into cancer and nutrition Cohort. Our custom mutation screening workflow involves the creation of a barcoded sample library for each individual including amplified regions of interest and sequencing on the PGM Ion Torrent sequencer. Each step of the process is tracked by a Laboratory Information Management System. To assess the sensitivity and specificity of our custom workflow, we compared PGM data with High-Resolution Melt (HRM) and Sanger sequencing data in a subset of 429 subjects screened for variants in the highly polymorphic *MC1R* gene. We identified 462 and 461 sequence variations, with the two workflows, respectively. These correspond to 27 distinct common and rare variants, including 1 inframe deletion and 1 duplication. Single nucleotide variants were missed in 7 subjects screened by HRM/Sanger and in 8 subjects screened by PGM. Discrepancies concerning homozygous/heterozygous status were found in 12 subjects carrying a common SNP.

3288W

K939Q polymorphism in the XPC gene may not affect the risk of bladder cancer: a case-control study and a meta-analysis. *M. SANKHWAR[1], S.N. SANKHWAR[1], N. GUPTA[2], A. ABHISHEK[1], S. RAJENDER[2].* 1) Urology, King George Medical University, Lucknow, Uttar Pradesh, India; 2) Endocrinology Division, CSIR-CDRI, Lucknow, Uttar Pradesh, India.

Purpose: Lys939Gln (K939Q), an A>C transversion in exon 15 of the XPC gene, has been extensively studied in relation to cancer. Keeping in view its decisive polymorphic effects and collocations with bladder cancer, we have analysed this polymorphism in Indian bladder cancer patients, and conducted a meta-analysis to generate a pooled estimate about the effect of this polymorphism on bladder cancer. Material and methods: The polymorphism was analysed using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) in 234 case and 258 control samples, followed by chi square test for statistical analysis. Meta-analysis included a total of fourteen studies comprising of 5403 cases and 5688 controls. Forest plot and funnel plot were used to interpret statistical significance of association and publication bias, respectively. Egger's test was performed to confirm funnel plot symmetry statistically. Results: We observed no significant association between K939Q polymorphism and bladder cancer. Tobacco chewing was found to be a risk factor for bladder cancer (OR= 1.93; 95%CI=1.32-2.83, P=0.0005). Meta-analysis showed association of CC genotype with marginal significance in homozygous and recessive models (OR=1.28, 95%CI=1.03-1.59, P=0.021, and OR=1.27, 95% CI=1.05-1.54, P=0.014), which turned non-significant upon applying Bonferroni's correction. Meta-analysis on the basis of ethnicity showed no significant association in any of the ethnic groups. Conclusion: K939Q substitution does not affect bladder cancer risk in Indo-European populations of Uttar Pradesh and perhaps also in other populations across the world. .

3289T

COMPLEXO: Identifying the missing heritability of breast cancer via next generation collaboration. *M.C. Southey[1], D.E. Goldgar[2], COMPLEXO.* 1) Dept Pathology, Univ Melbourne, Melbourne, VICTORIA, Australia; 2) Huntsman Cancer Institute, The University of Utah School of Medicine, Salt Lake City, UT 84112, USA.

A proportion of the remaining unexplained genetic susceptibility to breast cancer is likely to be explained by many rare mutations in a large number of genes. Coordinated international collaboration offers great potential to advance the discovery of additional breast cancer susceptibility genes by increasing the likelihood of identifying functionally relevant genetic variants in the same genes in multiple families. A new consortium, COMPLEXO (a name chosen to reflect the complexity of the exome), has been formed to facilitate collaborations between researchers actively applying massively parallel sequencing to understand the genetics of breast and ovarian cancer. The aim of COMPLEXO is to bring to massively parallel sequencing the same power of large sample sets that have proven so successful in examining the role of common variants in cancer populations via the consortium model such as the Breast Cancer Association Consortium (BCAC), the Ovarian Cancer Association Consortium (OCAC) and the Collaborative Oncology Gene-environment Study (COGS). However, sequencing studies provide additional challenges in terms of defining specific modes of collaboration given differences in sequencing and targeted capture platforms, bioinformatics platforms, the need to integrate ongoing studies in many centers and socio-ethical-legal issues that are not as relevant to initiatives that are genotyping common genetic variation. These issues are relevant to research in all complex human diseases. We will describe our working and governance structures, our early experiences and ongoing activities aimed at identifying more of the missing heritability of breast cancer.

3290F

Common genetic polymorphisms in the coagulation factors 5 and 10 genes are associated with risk of breast cancer and correlate with increased coagulation activity. *M. Tinholt[1,2,3], MK. Viken[1], S. Nyberg[4,5], AL. Børresen-Dale[4,5], V. Kristensen[4,5,6], KK. Sahlberg[4,5], R. Kåresen[3,7], E. Schlichting[7], O. Garred[8], G. Skretting[2], AE. Dahm[2], BA. Lie[1], PM. Sandset[2,3], N. Iversen[1].* 1) Dept. of Medical Genetics, Oslo University hospital and University of Oslo; 2) Dept. of Haematology and Research Institute of Internal Medicine, Oslo University Hospital; 3) Institute of Clinical Medicine, University of Oslo; 4) Dept. of Genetics, Institute for Cancer Research, Oslo University Hospital; 5) The K.G. Jebsen Center for Breast Cancer Research, Institute for Clinical Medicine, Faculty of Medicine, University of Oslo; 6) Dept. of Clinical Molecular Biology (EpiGen), Akerhus University Hospital, University of Oslo; 7) Dept. of Breast and Endocrine Surgery, Oslo University Hospital; 8) Dept. of Pathology, Oslo University Hospital.

Tumor cells express coagulation factors, thereby creating a pro-thrombotic state in cancer. Besides increasing the risk of thrombosis, pro-coagulants may promote pro-cancer signaling independent of coagulation. We aimed to gain a better understanding of the molecular mechanisms controlling the interplay between cancer and hemostasis through a Norwegian case-control study of 390 non-treated breast cancer patients and 350 healthy controls. SNP associations in the hemostatic genes *F2, F3, F5, F7, F10* and *TFPI* (n=42 from HapMap) were explored, in addition to the F5 Leiden (rs6025) and the prothrombin (rs1799963) variants. Genotype-phenotype correlations were conducted between the SNPs that were associated with breast cancer and mRNA expression in tumor and plasma levels of twelve hemostatic parameters. Increased levels of the coagulation factors F8, F9 and VWF, and decreased levels of antithrombin were detected in the patients. Global activation of coagulation was demonstrated in an endogenous thrombin generation assay, by increased D-dimer levels, and increased activated protein C resistance (APCR). The genetic risk factors of thrombosis (F5 Leiden and the prothrombin variants) showed no association with breast cancer. Four common SNPs in *F5* and one in *F10* were significantly associated with risk of breast cancer. The minor alleles of *F5* rs12120605 and rs6427202 were more frequent in patients (OR=1.52, [95%CI,1.07-2.17] and OR=1.40, [95%CI,1.02-1.91]). They were associated with increased tissue factor and factor 5 mRNA expression in tumors, respectively. In contrast, the minor alleles of *F5* rs6427199 and rs9332542 were more frequent in controls (OR=0.71, [95%CI,0.52-0.96] and OR=0.65, [95%CI,0.49-0.87]), and they correlated with antithrombin in plasma and factor 5 mRNA levels in tumor, respectively. This implies that these SNPs may be located in trans- and cis-acting DNA elements that contribute to regulate the pro-coagulant expression in plasma and tumors. The *F5* rs6427199 also correlated with lowered APCR, partly explaining the case-control variation in APCR not explained by the F5 Leiden variant. *F10* rs3093261 also associated with breast cancer (OR=1.60, [95%CI, 1.17-2.17]), but with no clear effect on hemostatic phenotypes. In conclusion, this study demonstrates novel associations of common SNPs in hemostatic genes (*F5* and *F10*) influencing the risk of breast cancer, and that the pro-coagulant phenotype verified in patients may be due to genetic effects.

3291W

Estrogen and Progesterone receptor gene polymorphisms as risk factors for Cervix Cancer in South Indian Population. *P. Upendram[1], V. Kiran Kumar[1], S. Poornima[1], A. Shah[2], Q. Hasan[1].* 1) Department of Genetics & Molecular Biology, Kamineni Hospitals, Hyderabad, India; 2) Department of Oncology, Kamineni Hospitals, Hyderabad, India.

Carcinoma of the uterine cervix is the most frequent gynaecological malignancy affecting women in developing countries despite being a potentially preventable disease. Globally, it is the second most frequent cancer affecting women with a steady rise in incidence among younger women. It is evident from current literature that specific polymorphisms in hormone receptor genes may enhance the risk for certain gynaecological malignancies. Altered responses to estrogen and progesterone lead to steroid hormone dependent disorders like endometriosis, endometrial cancer, breast cancer and ovarian cancer. Despite evidence that estrogen may play an important role in the carcinogenesis of cervical cancer, its action and mechanism in cervical cancer invasion is not well defined. To the best of our knowledge there are no studies that have focused on the estrogen and progesterone receptor (ER and PR) gene variants in cervical cancer especially in the Asian Indian population. The aim of this case control study from South India was to establish the association between the T/C SNP of estrogen receptor (ER) alpha gene recognized by PvuII enzyme (rs2234693) and a 306bp Alu insertion in the PGR gene (rs1042838) with cervical cancer. DNA was isolated from a total of 200 women comprising 100 cases with cervical cancer and 100 age-matched healthy controls using the salting out technique. Polymorphisms were evaluated by Polymerase Chain Reaction followed by restriction enzyme digestion / gel electrophoresis. Our results showed a statistically significant association of the C allele of ER gene (OR= 5.8072; 95% CI=3.7671 to 8.9521; p<0.0001) with cervix cancer. The homozygous CC genotype (OR= 26.000; 95% CI=8.8791 to 76.1338; p<0.0001) showed a 26 fold increased risk for this cancer. However, the T2 allele of PR gene did not show any significant association with cervix cancer (OR=1.3700; 95% CI=0.7193 to 2.6093; p= 0.33). Estrogen and its receptors are implicated in the promotion and prevention of various cancers. The uterine cervix is highly responsive to estrogen, however, the role of estrogen receptor polymorphisms in cervical cancer has not been well established. Our results suggest that the ER PvuII polymorphism but not PROGINS polymorphism can be used as a bio-marker to identify women with a high risk of developing cervix cancer. A larger study in different ethnic groups is warranted for establishing the association of cervix cancer with the ER polymorphism.

3292T

Fine-mapping of Genome-wide Association Study-identified Risk Loci for Colorectal Cancer in African Americans. *H. Wang[1], C.A. Haiman[2], T. Burnett[1], B.K. Fortini[2], L.K. Kolonel[1], B.E. Genome-wide association studies of colorectal cancer (CRC) in Europeans and Asians have identified 21 risk susceptibility regions (29 index SNPs). Characterizing these risk regions in diverse racial groups with different LD structure can help localize causal variants. We examined associations between CRC and all 29 index SNPs in 6,597 African Americans (1,894 cases and 4,703 controls). Nine SNPs in 8 regions (5q31.1, 6q26-q27, 8q23.3, 8q24.21, 11q13.4, 15q13.3, 18q21.1, 20p12.3) formally replicated in our data with one-sided p-values < 0.05 and the same risk directions as reported previously. We performed fine-mapping of the 21 risk regions (including 250kb on both sides of the index SNPs) using genotyped and imputed markers at the density of the 1000 Genomes Project to search for additional or more predictive risk markers. Among the SNPs correlated with the index variants, two markers, rs12759486 (or rs7547751, a putative functional variant in perfect LD with it) in 1q41 and rs7252505 in 19q13.1, were more strongly and statistically significantly associated with CRC, after conditioning on the index signals (P<0.0006). The average per allele risk was improved using the replicated index variants and the two new markers (OR = 1.14, P = 6.5×10^{-16}) in African Americans, compared to using all index SNPs (OR = 1.07, P = 3.4×10^{-10}). The contribution of the two new risk SNPs to CRC heritability was estimated to be 1.5%. This study highlights the importance of fine-mapping in diverse populations.

Zinc Transporter Gene Variants and Susceptibility to Urological Cancers. *L. Wu[1], K. Rabe[1], A. Parker[2], G. Petersen[1].* 1) Mayo Clinic, Rochester, MN; 2) Mayo Clinic, Jacksonville, FL.

Introduction: Laboratory studies have demonstrated that zinc and zinc transporters play important roles in the development of urological cancers, including prostate, bladder, and renal cell cancer. To date however, there have been no efforts to evaluate whether germline variation in zinc transporter genes alter the risk of developing these cancers. Motivated by this, we evaluated associations of known variants in zinc transporter genes with risk of prostate, bladder, and renal cell cancer using three NCI Genome Wide Association Study (GWAS) data sets downloaded from dbGaP. Methods: Data consisted of GWAS data from the PLCO Screening Trial (prostate; 1172 cases, 1157 controls); Bladder Cancer study (3527 cases, 5119 controls); and Renal Cancer study (1453 cases, 3531 controls). All genotyped variants in 10 ZNT family genes (ZNT1-ZNT10) and 14 ZIP family genes (ZIP1-ZIP14) in each data set were analyzed by logistic regression models to evaluate the association of each variant with risk of developing prostate, bladder, and renal cancer, respectively. We evaluated these associations in a univariable setting, after adjusting for available covariates, such as age and gender. Correction for multiple comparisons used Max T permutation tests. Results: One variant in ZIP11, rs8081059, was associated with increased risk of renal cancer (OR=1.28, 95% CI= 1.13-1.45; corrected p= 0.049). Another ZIP11 variant, rs11871756, was associated with an increased risk of bladder cancer risk (OR=1.43, 95% CI 1.24-1.63; corrected p=0.0002). We also found three variants in ZIP11 associated with a decreased risk of bladder cancer: rs11077654 (OR=0.76, 95% CI 0.68-0.85; corrected p=0.001), rs9913017 (OR=0.76, 95% CI= 0.68-0.85; corrected p= 0.002), and rs4969054 (OR=0.78, 95% CI 0.69-0.88; corrected p=0.02). Interestingly, these three protective variants are within the same LD block. There were no associations between zinc transporter variants and prostate cancer risk. Conclusion: We report for the first time that specific genetic variants of a zinc transporter gene, ZIP11, are associated with risk of renal and bladder cancer. If validated in larger, more focused studies, further investigations are warranted to explore the functional significance of ZIP11 in these two cancers.

The Prevalence of the *HOXB13* G84E Prostate Cancer Risk Allele in Men Treated with Radical Prostatectomy. *K.A. Zuhlke[1], J. Beebe-Dimmer[2,3], C. Yee[2,3], A.M. Johnson[1], P.C. Walsh[4,5], S.D. Isaacs[4,5], W.B. Isaacs[4,5], K.A. Cooney[1,6].* 1) University of Michigan Medical School, Department of Internal Medicine, Ann Arbor, MI; 2) Wayne State University, Department of Oncology, Detroit, MI; 3) Karmanos Cancer Institute, Detroit, MI; 4) Johns Hopkins University, Baltimore, MD; 5) James Brady Urologic Institute, Baltimore, MD; 6) University of Michigan Medical School, Department of Urology, Ann Arbor, MI.

Purpose: A rare, non-conservative substitution (G84E) in the homeobox transcription factor *HOXB13* gene, located on chromosome 17q21, was recently reported to confer an increased risk of prostate cancer. As a follow-up to this investigation, DNA samples from 9,559 men undergoing radical prostatectomy were genotyped to determine the frequency and clinical correlates of this mutation in men with prostate cancer.

Materials and Methods: DNA samples from men treated with radical prostatectomy at the University of Michigan and John Hopkins University were genotyped for G84E and confirmed by Sanger sequencing. The frequency and distribution of this allele was determined according to specific patient characteristics (family history, age at diagnosis, pathologic Gleason grade and stage).

Results: 128 of 9,559 patients were heterozygous carriers of G84E (1.3%). Patients who possessed the variant were more likely to have a family history of prostate cancer (46.0% vs. 35.4% p=0.006). G84E carriers were also more likely diagnosed at a younger age compared to non-carriers (55.2 years vs. 58.1 years; p<0.0001). However, there was no difference in the proportion of patients diagnosed with high-grade or advanced stage tumors by carrier status.

Conclusions: In our study, carriers of the rare G84E variant in *HOXB13* were both younger at the time of diagnosis and more likely to have a family history of prostate cancer compared to homozygotes for the wild-type allele. No significant differences in allele frequency were detected according to select clinical characteristics of prostate cancer. Further investigation is required to evaluate the role of *HOXB13* in prostate carcinogenesis.

3295T

Prevalence of germline mutation p.R337H in the *TP53* gene in families with multiple cases of cancer. *K.C. Andrade[1,2], K.M. Santiago[1], A. Nobrega[1], F.P. Fortes[1], M.I. Achatz[1].* 1) A.C. Camargo Cancer Center, São Paulo, Brazil; 2) UNESP, São Paulo State University - Biosciences Institute, Botucatu - São Paulo - Brazil.

BACKGROUND: Germline mutations in the *TP53* gene are associated to the Li-Fraumeni Syndrome (LFS) and its variants Li-Fraumeni-Like (LFL). The diseases predispose carriers for early onset tumors, including soft tissue sarcoma, pre-menopausal breast cancer, central nervous system tumors and adrenocortical carcinoma. In Brazil, there is a high frequency of a germline *TP53* mutation in South and Southeastern population, due to a founder effect. It is estimated to be present in 0.3% of the local inhabitants. However, only a few families have been diagnosed with such alteration. Our hypothesis was that the current criteria applied for LFS are not enough to detect them. Therefore, the development of suitable criteria to select them will enable not only the identification of at-risk families, but also provide adequate screening and early detection of associated tumors. OBJECTIVE: To determine the efficacy of wide criteria for detection of p.R337H carriers. METHODS: 31 patients from Oncogenetics Department, A.C. Camargo Cancer Center, SP, were selected and tested for the p.R337H mutation. Criteria for inclusion were: (1) more than three family members with cancer AND (2) at least one of them under age 50 AND (3) two of them being first or second degree relatives. Germline DNA was extracted from peripheral blood and analyzed by Restriction Fragment Length Polymorphism. The confirmation of positive finding was done through direct sequencing of exon 10. RESULTS: One out of 31 patients (3,22%) was found to carry the p.R337H mutation. The patient developed ductal invasive breast cancer at age 47 and invasive adenocarcinoma of the lung at age 48. In addition, an extensive cancer family history was reported. DISCUSSION: These results show that the proposed criteria may detect carriers, but further studies including a larger group of families will be useful to define its effectiveness. Also, in order to improve sensibility, the inclusion of more stringent criteria will be needed. Moreover, one of the tumors manifested in family history is of great interest: the development of an Ewing's Sarcoma (ES) in her second degree relative at age 9. Current data indicate that the annual incidence of ES has had an average of 2.93 cases per million. Overall, 27% of them occur in the first decade of life and lesions in the *TP53* gene are only observed in 10% of this kind of cancer. Therefore, it is one of the few reports of a very early onset childhood ES in a LFS family.

Is *IGSF1* involved in human pituitary tumor formation? *F.R. Faucz[1], A.D. Horvath[2], P. Xekouki[1], E. Szarek[1], G. Evgenia[1], A.D. Manning[1], I. Levy[1], E. Saloustros[1], R.B. de Alexandre[1], M. Nesterova[1], C.A. Stratakis[1].* 1) Section on Endocrinology & Genetics, Program on Developmental Endocrinology & Genetics, Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), National Institutes of Health (NIH), Bethesda, MD; 2) McCormic Genomic and Proteomic Center, Department of Biochemistry and Molecular Biology, The George Washington University, Washington, DC.

IGSF1 is a membrane glycoprotein highly expressed in the anterior pituitary gland. Mice with a deficiency in *Igsf1* show central hypothyroidism and increased body size. Recently, mutations in this gene were found in humans with central hypothyroidism and testicular enlargement [Sun et al, Nat. Genet. 44(12):1375-81, 2012]. We looked for *IGSF1* germline variations in patients with giantism from the NIH data registry and in healthy controls. We also looked for the expression of IGSF1 in growth hormone (GH)-producing adenomas. We sequenced 11 patients with giantism and 92 health individuals (100% White Americans) for *IGSF1* germline mutations. Immunohistochemistry for IGSF1 was performed in sections from three GH-producing adenomas and in normal pituitary. In 1 out of 11 patients we identified the sequence variant p.Asn604Tre (c.1811A>C), which by *in silico* analysis is potentially destructive. The same variation, however, was found in 2 of our controls. We also identified 29 more variations in a total of 18 healthy individuals (16.85%) (3 nonsense, 3 frameshifts and 25 missense), but only 4 of them have been described previously. Immunohistochemistry showed variable IGSF1 staining in the GH-producing tumor from the patient with the *IGSF1* mutation compared to a GH-producing tumor from a patient negative for *IGSF1* mutations and to a normal control. *IGSF1* gene appears quite polymorphic. The mutation identified in one of our patients with giantism was also detected in healthy controls. The increased expression of IGSF1 in patients with an *IGSF1* germline mutation may indicate that *IGSF1* does not have a causative role in pituitary tumor development but may work as a modifier during oncogenesis.

3297W

Mutational Landscape of Candidate Genes in Familial Prostate Cancer. *A. Johnson[1], K. Zuhlke[1], C. Plotts[2], J. Douglas[2], S. Thibodeau[3], K. Cooney[1,4].* 1) Internal Medicine - Hem/Onc, Univ Michigan, Ann Arbor, MI; 2) Human Genetics, Univ Michigan, Ann Arbor, MI; 3) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 4) Urology, Univ Michigan, Ann Arbor, MI.

Family history is a major risk factor for prostate cancer (PCa), suggesting a genetic component to the disease. However, traditional linkage and association studies have failed to fully elucidate the underlying genetic basis of familial PCa. Here we use a candidate gene approach to identify potential PCa susceptibility loci in whole-exome sequencing data from familial PCa cases. 500 candidate genes were identified based on function and/or previous association with prostate or other cancers. SNPs in these candidate genes were identified in whole-exome sequence data from 33 PCa cases from 11 multiplex PCa families. Overall, 3513 candidate gene SNPs were identified, including 805 missense and 9 nonsense variants. Fifty-six missense variants were shared by all 3 family members in each family in which they were observed; 43 of these were observed in all 33 cases and were presumed to be rare variants in the reference sequence and excluded from further analysis. The remaining 13 shared, missense variants as well as the 9 nonsense variants were re-sequenced for verification. Confirmed variants were then tested in all additional family members with available DNA to assess co-segregation with PCa status. All 9 nonsense variants and 12 of 13 shared, missense variants were confirmed. One of the confirmed missense variants was *HOXB13* Gly84Glu which was recently identified as a PCa susceptibility allele. The Gly84Glu minor allele was observed in 1 family where it showed partial co-segregation with disease. Two other missense variants, *BLM* Gln123Arg and *PARP2* Arg283Gln, and 1 nonsense variant, *CYP3A43* Arg441Ter, showed complete co-segregation with PCa status. Mutations in *BLM* are known to cause Bloom Syndrome, a recessive disorder with multiple phenotypic effects including predisposition to various cancers. Additionally, a *BLM* truncating mutation was recently identified as a possible breast cancer susceptibility allele. *PARP2* plays a role in DNA damage repair and has been studied as a therapeutic target in multiple cancers. *CYP3A43* is a member of the cytochrome P450 superfamily which is involved in drug and steroid hormone metabolism, and *CYP3A43* variants have previously been associated with PCa risk and mortality. Four additional variants, *RAD18* Glu453Ter, *IGHMBP2* Val293Ile, *RAD51D* Asn138Ser and *POLE* Ala31Ser, displayed partial co-segregation with PCa. Further research is needed to determine the exact role of these variants in PCa susceptibility.

3298T

Development of a Next Generation Sequencing panel to assess hereditary cancer risk that includes clinical diagnostic analysis of the *BRCA1* and *BRCA2* genes. *B. Roa[1], K. Bowles[1], S. Bhatnagar[2], N. Gutin[1], A. Murray[1], B. Wardell[2], M. Bastian[2], J. Mitchell[2], J. Chen[2], T. Tran[2], D. Williams[2], J. Potter[2], S. Jammulapati[2], M. Perry[2], B. Morris[2], K. Timms[2].* 1) Myriad Genetic Laboratories, Inc., Salt Lake City, UT; 2) Myriad Genetics, Inc., Salt Lake City, UT.

Approximately 7% of breast and 11-15% of ovarian cancers are estimated to be due to germline DNA mutations, the majority of which occur in the *BRCA1* and *BRCA2* genes. However, a comprehensive hereditary breast and ovarian cancer risk assessment should include germline sequencing of the *BRCA1* and *BRCA2* genes, as well as additional genes with a known association in breast/ovarian cancer patients. Sanger DNA sequencing has been the gold standard for molecular genetic analysis. However, it is labor-intensive and costly for the analysis of large gene panels. Next Generation Sequencing (NGS) platforms allow for efficient analysis of larger gene panels, but lack of standardization of sample preparation, NGS platforms, and data analysis presents challenges to diagnostic laboratories. Optimized assay design and validation are critical to maximize the analytical sensitivity and specificity of NGS assays, and to ensure high quality interpretation for clinical decision making. We developed a 25-gene NGS hereditary cancer panel that uses RainDance PCR technology for high-throughput sample preparation, Illumina HiSeq and MiSeq NGS technologies, and commercially available and lab-developed informatic tools. The panel and assays were custom-designed to ensure high-quality, clinically actionable results. Initial assessment of analytical sensitivity and specificity was performed by comparing *BRCA1* and *BRCA2*. NGS was performed on 1864 anonymized patient samples, which had previously undergone Sanger sequencing of *BRCA1* and *BRCA2*. Sanger sequencing identified 15,878 variants, of which 681 were unique and 482 were classified as disease-associated mutations. We identified 15,877 variants at an initial sensitivity of >99.99% for *BRCA1* and *BRCA2*. One polymorphic variant was missed due to a variant under the primer. Sensitivity was subsequently optimized through process improvements. No additional variants were found by NGS, yielding a specificity of 100%. This preliminary analysis facilitated assay optimization, and a comprehensive validation of all 25 genes in the NGS panel. This analysis indicates that a NGS gene panel designed to meet rigorous quality standards can be used to provide clinical sequencing results equivalent to those obtained from Sanger DNA sequencing analysis. Utilization of appropriately designed and implemented NGS technology will allow for analysis of larger gene panels, resulting in greater sensitivity without loss of specificity.

3299F

Development of 3C-based target sequencing technology for candidate gene discovery in prostate cancer.
MJ. Du[1], TZ. Yuan[1], RL. Dittmar[1], XY. Huang[1], SN. Thibodeau[2], L. Wang[1]. 1) Pathology, Medical College of Wisconsin, Milwaukee, WI; 2) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

So far, genomewide association studies have identified over 70 chromosome loci (represented by single nucleotide polymorphisms, SNPs) with an increased risk of prostate cancer. However, the biological roles of these loci in prostate cancer development are unclear. As many of these risk-loci have been found in non-coding regions of the genome, with many residing at some distance from any nearby annotated genes, many of these causal variants are believed to regulate target genes through long range interactions. Although chromosome conformation capture (3C) is used to analyze the long range interactions between different fragments, the traditional 3C assay and its variations are not sufficient to identify unknown genomic regions that interact with multiple risk loci in a cost-efficient manner and in a single enrichment assay. Here, we developed a 3C-based multiple targets enrichment assay and applied this assay to the analysis of 3 prostate cancer risk regions at 8q24. The novelty of this assay is to use short oligos as primers and label target fragments by multiple primers extension. Briefly, a standard approach was used to generate a 3C library by using LnCap cell line, followed by sonication and size selection of 3C DNA into 300-500bp fragments. Nine short oligos (in three risk regions at 8q24) were then hybridized to the fragmented 3C library. Primers extension at high annealing temperature (65°C) was performed with the presence of biotin-labeled dCTP. After strepavidin beads purification, a nano scale library construction method was applied to build a sequencing library. qPCR analysis showed up to 1000 fold target enrichment under our current condition. Finally, a perl-based computer algorithm was written to analyze the long range interactions from large scale sequencing data. The sequencing data showed that the risk regions interacted with multiple chromosome loci. However, interactions with MYC gene, 250kb downstream from nearest prostate cancer risk SNP, was modest. This result indicates that the 8q24 risk regions may physically interact and regulate multiple genes across the whole genome and the new multiple primers extension enrichment assay has great potential to detect the long range genetic interactions. Further development of this multiple targets enrichment 3C method will facilitate candidate genes identification and help to define the biological roles of prostate cancer risk SNPs.

3300W

From GWAS to therapy: Fatty acid synthase in uterine leiomyomata.
Z. Ordulu[1], M. Hayden[1], S. Eggert[2], B.J. Quade[2], C.C. Morton[1,2]. 1) Ob/Gyn, Brigham and Women's Hospital, Boston, MA; 2) Pathology, Brigham and Women's Hospital, Boston, MA.

Uterine leiomyomata (UL) pose a major public health problem given high prevalence (>70%) in women of reproductive age and their indication for >200,000 hysterectomies in the U.S. annually. A genome-wide SNP linkage panel was analyzed in 261 white UL sister pair families from the Finding Genes for Fibroids study (FGFF). Genome-wide association studies performed in two independent cohorts of white women identified a SNP with a p-value that reached genome-wide significance (rs4247357, P = 3.05E-08, odds ratio (OR) = 1.299). The candidate SNP was under a linkage peak and in a block of linkage disequilibrium in 17q25.3 which spans the genes fatty acid synthase (FASN), coiled-coil domain containing 57 (CCDC57) and solute carrier family 16, member 3 (SLC16A3). It has been reported previously that FAS transcripts and/or protein levels are upregulated in various neoplasms and implicated in tumor cell survival. By immunohistochemistry (IHC) we found FAS protein levels are elevated (3-fold) in UL in comparison to matched myometrial tissue. We assessed effects of FAS inhibitor C75 on cell counts in primary cell cultures of matched UL and myometrium by Coulter counting and by cell proliferation assays at 24, 72, and 120 hours after treatment with different concentrations of the inhibitor. Cell counts are reduced in a dose and time dependent manner with a half maximal inhibitory concentration (IC50) of approximately 50 uM. Additional samples are being obtained to stratify the results by rs4247357 genotype and FAS expression status. FASN represents the first potential UL predisposition gene identified in white women and the responsiveness of UL to inhibition of FAS can be a potential model for targeted therapy to mitigate the risks and complications of surgical interventions.

Skibola[6], P.I.W. de Bakker[5], J. Liu[1,13]. 1) Human Genetics, Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore, Singapore; 2) Department of Medicine, Clinical Epidemiology Unit, Karolinska Institutet, Stockholm, Sweden; 3) School of Public Health, Division of Environmental Health Sciences, University of California - Berkeley, Berkeley, CA; 4) Department of Radiology, Oncology and Radiation Sciences, Uppsala University, Uppsala, Sweden; 5) Broad Institute of Harvard and MIT, Cambridge, MA; 6) School of Public Health, Department of Epidemiology, University of Alabama at Birmingham, Birmingham, AL; 7) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 8) University of California, San Francisco, Department of Epidemiology and Biostatistics, San Francisco , CA; 9) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 10) Rheumatology Unit, Department of Medicine, Karolinska Institutet and Karolinska University Hospital Solna, Stockholm, Sweden; 11) State Key Laboratory of Oncology in South China, Sun Yat-sen University Cancer Center, Guangzhou, China; 12) Department of Etiology and Carcinogenesis, Cancer Institute and Hospital, Chinese Academy of Medical Science and Peking Union Medical College, Beijing, China; 13) Saw Swee Hock School of Public Health, National University Health System, National University of Singapore, Singapore, Singapore.

Non-Hodgkin lymphoma represents a diverse group of blood malignancies, of which follicular lymphoma (FL) is a common subtype. Previous genome-wide association studies have identified independent SNPs, in particular rs2647012 and rs10484561, within the HLA class II region significantly associated with FL risk. To determine if coding variants in HLA genes are responsible for these associations, we imputed classical HLA alleles and coding variants in our discovery GWAS samples of 379 FL cases and 791 controls using a phased reference panel consisting of 2,767 unrelated founders of European descent, with genotypes for 2,537 SNPs in the HLA region, 263 classical HLA types determined to 4-digit resolution and 372 variable amino acid positions encoded in the coding regions of the HLA genes for each founder. We conducted global multiallelic tests and/or biallelic trend tests across all the imputed variants and validated the top result in two independent datasets, for a total of 689 cases and 2,446 controls. The strongest association was observed at a single hexa-allelic amino acid 13 position within the HLA-DR peptide binding groove encoded by the HLA-DRB1 gene ($P=2.3\times10^{-15}$). This variant may fully explain the associations observed at this locus, including rs2647012 ($P=4.72 \times 10^{-11}$; after adjustment P= 0.804) and rs10484561 ($P=2.61 \times 10^{-11}$; after adjustment P = 0.356). Conversely, conditioning on genotypes at rs2647012 ($P=1.68\times10^{-7}$), rs10484561 ($P=7.58\times10^{-7}$) or both SNPs (P=0.005) did not fully eliminate the association observed at amino acid 13, suggesting that the genotypes at amino acid 13 are well- but not fully- tagged by these two SNPs. Amino acid 13 is tightly linked to the nearby amino acid 11, and both are previously reported to be associated with rheumatoid arthritis (Raychaudhuri et. al. 2012 Nat Genet 44:291-296). We provide preliminary evidence that the same coding variants may influence FL risk in the Chinese population ($P= 1.70 \times10^{-4}$) and are now expanding our efforts to confirm the association in the Asian population. This coding variant may explain the complex SNP associations identified by GWAS and suggests a common HLA-DR antigen-driven mechanism for the pathogenesis of FL and rheumatoid arthritis. Further trans-ethnic comparisons across European and Asian sample collections is expected to provide further insights into similarities and differences in the genetic factors underlying these complex and heterogeneous malignancies in each population.

Expression-based classification of melanoma cell sensitivity to temozolomide. *T. Zhang[1], M. Xu[1], C. Sereduk[2], D. Chow[2], J. Trent[2], H. Yin[2], K. Brown[1].* 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Cancer and Cell Biology Division, The Translational Genomics Research Institute (TGen), Scottsdale.

While there are multiple promising new immunotherapeutic and targeted approaches for treating melanoma, not all patients are eligible for these therapies and most of those that are ultimately relapse, highlighting a critical need for improved chemotherapeutics. Temozolomide (TMZ) is an orally administered DNA-methylating agent used in the treatment of advanced cancers including melanoma. TMZ has shown some advantage in the clinic in terms of preventing central nervous system relapse and patient quality of life. In order to find novel vulnerabilities that may be exploited to sensitize melanoma cells to TMZ, we utilized pre-existing expression profiling data and known TMZ-sensitivity from 18 melanoma cell lines to develop a classifier of TMZ-sensitivity. We used the support vector machine (SVM) method to build the model, and applied this classifier to predict the TMZ-sensitivity in 25 independent melanoma cell lines. We subsequently validated these predictions by experimentally determining the IC50 of these cell lines to TMZ using a high-throughput cell viability assay. The result showed that more than 80% of melanoma cell lines were accurately predicted. We analyzed the genes differentiating TMZ-sensitive and -resistant melanoma cells using both microarray data, and most recently RNA-sequencing data using Ingenuity Pathways Analysis. We identified two key genes (MITF and EGFR) each known to regulate a large number of the differentially expressed genes. EGFR and a large network of EGFR targets were significantly underexpressed in TMZ resistant lines. At the same time, MITF and a large group of known MITF targets were significantly overexpressed in resistant lines. We also identified E-cadherin (CDH1), which is known to play a key role in invasion and transition from radial to vertical growth in melanoma, as highly upregulated in resistant cell lines. We functionally characterized the role of EGFR in TMZ sensitivity via EGF treatment or overexpression in resistant cell lines, as well as antibody, small molecule, and shRNA inhibition of EGFR in sensitive cell lines. Small-molecule inhibition of EGFR decreases downstream ERK and AKT pathway signaling in both TMZ-sensitive cell lines tested. Our expression profiling data suggest that TMZ sensitivity may be mediated by multiple large gene regulatory networks, and that EGFR may play a role in therapeutic response of melanoma to TMZ.

3303W

Mining of TCGA data links AGR3 dysregulation to surfactant homeostasis in lung cancer. *A. Umesh, J. Delaney, J. Shima, J. Park, R. Wisotzkey, M. Shekar, I. Kupershmidt.* NextBio, Santa Clara, CA.

We previously identified AGR3, a protein disulfide isomerase with unknown physiological function, as an RNA expression marker for triple negative breast cancer based on ESR1/PGR/ERBB2 RNA levels using NextBio (NB) Clinical, a patient-centric analytical platform. Here we investigated AGR3's role in 19 cancers by mining genomic data of 11,000 patients currently integrated into NB Clinical and performed correlations against publically available curated genomic data using NB Research. Analysis of RNA expression data from patients of 19 cancers revealed AGR3 dysregulation in ovarian, kidney, lung, head/neck, breast, uterine, and brain cancers, using a 2-fold cutoff in either direction as compared to normal tissue. These patients were further stratified based on AGR3 over vs underexpression, using a 2-fold cutoff against disease median. Fifty top-ranked dysregulated genes from each cancer totaling 291 genes were identified and imported to NB Research for further insights. The NB Body Atlas application showed our 291 gene signature to most highly correlate with lung amongst all normal tissues, and highest with bronchial and airway epithelial cells amongst cell types. AGR3 itself also had the highest correlation with pulmonary epithelial cells, and was highly correlated with lung cancer when queried with the NB Disease Atlas application. We followed up by assessing the top 50 genes obtained with NB Clinical from lung cancer patients alone. Stratification by AGR3 expression showed concomitant dysregulation of genes involved in pulmonary surfactant homeostasis and secretion, including surfactant proteins (SFTPA-D), surfactant associated-proteins (SFTA1-2), and secretoglobins (SCGB1A1,SCGB3A1-2). Analysis of patient clinical parameters showed decreased AGR3 expression in 66% of current smokers and in 71% of patients with the primitive subtype of lung squamous cell carcinoma (LSCC). AGR3 was increased in 65% of patients with secretory LSCC. Through analysis of individual patients and correlations with public genomic data, we identify dysregulated pulmonary epithelial AGR3 expression as a biomarker in lung cancer with an effect on surfactant homeostasis. This is functionally akin to its paralog, AGR2, which partakes in intestinal mucus production and is reported to be overexpressed and secreted in prostate and pancreatic cancers (Park et al 2008; Zhang et al 2005). These data highlight epithelial secretion-related mechanisms and the AGR genes in cancers.

3304T

Down-regulation of *SIDT1* gene in leukemia. *J. Mazzeu[1], S.G. Magalhães[2], L.H. Sakamoto[2,3,4], R. Camargo[2,3,4], M.B. Daldegan[4,5], B.D. Lima[2].* 1) Ciências genômicas e Biotecnologia, Universidade Católica de Brasilia, Brasilia, DF, Brazil; 2) Departamento de Biologia Celular, Universidade de Brasília, Brasília, DF, Brazil; 3) Hospital da Criança de Brasília José Alencar, Setor de Oncologia e Hematologia Pediátrica Núcleo de Oncologia e Hematologia Pediátrica, Secretaria de Saúde do DF, Brasília, DF, Brazil; 4) Núcleo de Genética, Secretaria de Saúde do DF, Brasília, DF, Brazil; 5) Núcleo de Hematologia e Hemoterapia, Secretaria de Saúde do DF, Brasília, DF, Brazil.

The use of small interfering RNAs (siRNAs) has been a promising therapeutic approach for the treatment of various diseases including leukemias. These small non-coding siRNAs can trigger the sequence-specific degradation of homologous mRNAs. However, cell-specific delivery of small interfering RNA (siRNAs) is the main obstacle to in vivo applications of siRNAs.It has been shown that SID-1 and its human homologue SIDT1 that localize to the plasma membrane facilitate siRNA uptake in human systems.Knowing that leukemic cells are difficult to be transfected and based on the hypothesis that SIDT1 could facilitate siRNAs delivery into these cells to perform post-transcriptional regulation we examined the human *SIDT1* expression levels in myeloid and lymphoid leukemia patients. We have tested 80 samples from patients with ALL, AML and CML, seven leukemic cell lines (697, RS4;11, Nalm-6, Jurkat, REH, HL-60 and K562) and samples of non-leukemic individuals as controls.We investigated *SIDT1* mRNA levels using real-time quantitative PCR (RT-qPCR) . The results of the relative quantification analysis of *SIDT1* gene expression show that the gene was down-regulated in all seven human leukemic cell lines analyzed, particularly for 697, REH and HL-60 cell lineages when compared to the non-leukemic individuals. The K562 cell lineage does not present any expression of *SIDT1* gene, since no mRNA was detected in RT-qPCR ($p<0,05$). Low expression levels of *SIDT1* mRNA were also observed in all samples positive at diagnosis for ALL, AML and CML ($p<0,05$).Several miRNAs (miR-31, miR-155 and miR-564) have been shown to be abnormally down-regulated in CML cell lines and in patients with CML as compared to non-leukemic individuals. Based on this evidence we suggest that down-regulation miRNAs could be result of the absence or lower expression of the gene *SIDT1* that decrease the siRNA transfer between cells. Our results demonstrate that the presence of cellular changes that lead to leukemia causes changes in the expression level of mRNA of a gene that is essential in the activation pathway by interfering RNA transport of exogenous dsRNA. The mechanisms that lead to this decrease are still unknown, as there are only few studies on gene *SIDT1*. However, these studies have great importance for scientific research and for clinical application as *SIDT1* can be exploited as a marker to establish the presence, persistence or reappearance of leukemic hematopoiesis.

3305F

Genetic polymorphisms in the 9p21 region associated with multiple cancers. *W. Li[1], R. Pfeiffer[1], F. Gu[1], Z. Wang[1,2], M. Yeager[1,2], X. Deng[1,2], L. Amundadottir[1], J. Luo[3], S. Chanock[1], N. Chatterjee[1], M. Tucker[1], A. Goldstein[1], X. Yang[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institute of Health, Rockville, MD; 2) Cancer Genomics Research Laboratory, NCI-Frederick, SAIC-Frederick Inc. Frederick, MD; 3) Information Management Services, Inc., Calverton, MD.

Background and aims The chromosome 9p21 region encompasses several tumor suppressor genes and germline genetic polymorphisms in this region have been associated with the risk of several cancers. The goal of this study was to identify common genetic variants in the 9p21 region that were associated with multiple cancers using publicly accessible genome-wide association studies (GWAS) data. **Methods** We analyzed 9p21 SNPs (21,067,104-32,440,834, hg18) from eight GWAS studies with data deposited in the database of Genotype and Phenotype (dbGAP), including esophageal squamous cell carcinoma (ESCC), gastric cancer (GC), pancreatic cancer, renal cell carcinoma (RCC), lung cancer (LC), breast cancer, bladder cancer (BC), and prostate cancer (PC). The number of subjects ranged from 2252 in PC to 7619 in LC. We first performed single SNP analyses for each study separately using logistic regression. For SNPs with $P<0.01$ associated with at least one cancer, we conducted the meta-analyses through a subset-based statistical approach (ASSET) to combine *P* values across studies. We also calculated gene-level *P*-values using a resampling-based adaptive rank truncated product method. Bonferroni correction was used to adjust for the number of SNPs/genes and studies examined. **Results** We identified five SNPs that showed significant associations for LC [rs12686452 (C9orf72), rs12683422 (LINGO2), rs7849984 (LINGO2), rs2492813 (MOB3B), and rs10511838 (intergenic region of LINGO2-ACO1)], two SNPs for ESCC [rs1063192 (CDKN2B), rs2157719 (CDKN2BAS)], two for BC [rs2764736 (intergenic region of ELAV2-TUSC1) and rs1502895 (intergenic region of LINGO2-ACO1)], and one for RCC (rs7033375, intergenic region of C9orf72-LINGO2) (all $P\leq 2.59\times10^{-6}$). In the meta-analysis by ASSET, rs1502895 (C-T) was positively associated with BC and LC ($P=8.16\times10^{-11}$); rs12683422 (C-T) showed positive effect for LC ($P=1.10\times10^{-24}$) but negative for the subset of RCC and BC ($P=1.48\times10^{-4}$); rs10813205 (C-T, intergenic region of LINGO2 and ACO1) was positively associated with the subset of GC, LC, PC and RCC ($P=7.75\times10^{-5}$). At gene level, MOB3B, LINGO2, and C9orf11 were significantly associated with the risk of LC, while CDKN2B, CDKN2A, and CDKN2BAS were associated with the risk of ESCC (all $P\leq 4.70\times10^{-5}$). **Conclusions** Several genetic variants in the 9p21 region were associated with the risk of multiple cancers, suggesting that this region may contribute to a shared susceptibility across different cancer types.

3306W

Cryptic mutations in introns and exons leading to splice alterations in breast cancer genes. *S. Casadei[1], T. Walsh[1], C.H. Spurrel[2], A.M. Thornton[1], J.B. Mandell[1], S.M. Stray[1], M.K. Lee[1], M.C. King[1, 2].* 1) Medical Genetics, University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA.

Despite the widespread availability of genomic sequence, we still know very little about the frequency and spectrum of deeply intronic variants that alter splicing so as to introduce a stop and thereby increase risk of disease. Such mutations could lead either to extension of an exon (a bleeding exon) or to creation of a new exon from intronic sequence (exonification). We are exploring this phenomenon in 594 families with multiple cases of breast and/or ovarian cancer, for whom all affected relatives are wildtype for all known breast cancer genes, based on evaluation by BROCA (see poster by T. Walsh et al.). Our first experiment has been to mine the complete BRCA1 intronic data that was generated by BROCA. The target region was chr17:41,190,000-41,280,000, which includes the 3'UTR, all intronic sequence, 5'UTR, and bidirectional promoter of BRCA1, and the first exon of NBR2, but not the off-target duplicated pseudogene of BRCA1. We identified every variant in this region that was rare (<0.01 carrier frequency among 3000 persons tested by BROCA; and minor allele frequency <0.005 on dbSNP) and familial (present in at least two affected relatives in its host family). This screen yielded 195 variants in BRCA1 introns. We next used NNSPLICE0.9 to predict the activation of cryptic donor (5'ss) or acceptor (3'ss) splice sites at each intronic variant. Of the 195 rare familial variants, 29 (15%) were predicted to lead to altered splicing; 10 by activating a cryptic 5'ss and 19 by activating a cryptic 3'ss. For example, a variant deep in BRCA1 intron 5 was shared by three cousins with breast cancer in CF232. The variant was predicted to activate a cryptic donor splice site (taaagtag > TAAAlgtaa; 5'ss score 0.09 < 0.98), leading either to an extension of 249 additional exonic nucleotides, or to introduction of a pseudoexon by pairing with an acceptor splice site located 63bp upstream (3'ss: 0.85). In either scenario, an early stop is included in the newly exonic sequence. Of the 29 variants predicted to alter splicing, 15 are located near sites of nucleosome occupancy, 12 are embedded in Alu sequences, and 2 are located <300bp from a constitutive exon. We will test the consequence of each of these variants by RT-PCR molecular analysis of patient RNA. It is important to understand how intronic events affect splicing. Bioinformatics tools can predict novel cryptic exons, which can then be tested by molecular analysis.

3307T

***MEIS1* silencing influences the expression of cancer/testis antigen *SSX2* in myeloid leukemia cell line K562.** *J. Torres-Flores[1,2], A. Aguilar-Lemarroy[1], A. Bravo-Cuellar[1], L.F. Jave-Suarez[1].* 1) Division of Immunology; Centro de Investigacion Biomedica de Occidente; Instituto Mexicano del Seguro Social; Guadalajara, Jalisco, 44340, Mexico; 2) Doctoral Program of Human Genetics; University of Guadalajara, Guadalajara, Jalisco, 44340, Mexico.

Introduction: *MEIS1* is a transcription factor involved in proliferation and differentiation of hematopoietic cells. *MEIS1* deregulation is associated with malignancies, including leukemias. Recent studies indicate that the presence of *MEIS1* in leukemic cells promotes their proliferation. *SSX2* is a cancer/testis antigen normally expressed in human germ cells and several solid tumors. Conversely, *SSX2* has low expression in hematopoietic malignancies. SSX2 is a nuclear protein with transcriptional repressor activity due to possible interaction with *Polycomb* group members; these genes play a role in regulating the expression of the *HOX* genes by epigenetics modulation. **Aim:** To show evidence that *SSX2* can be regulated by *MEIS1* gene expression. **Methods:** As part of a larger research, we modified a cell culture of K562 through shRNA for silencing the expression of *MEIS1* mRNA. Three cultures of K562 cells were transformed: one with a shRNA sequence to interfere with the messenger of *MEIS1* by targeting exon 9, other for exon 13, and another with lentiviral vector empty. RT-PCR expression analysis was performed using three housekeeping genes to normalize results: *ACTB*, *RPL32* and *GAPDH*. Computer analysis was performed using Matinspector v8.0 software. **Results:** K562/LVX+E9 and +E13 knockdown-cell lines showed *MEIS1* subexpression by qPCR by comparing with K562-LVX-. Interestingly, *MEIS1* silencing increased *SSX2* expression. *In silico* analysis revealed three target regions with *MEIS1* binding potential located 3' to the transcription start (positions 1218, 2230 and 3402), these possible binding sites are contained in the intronic regions 1, 3 and 4, respectively. Additionally, a possible binding site was also identified 3023 basepairs upstream of *SSX2* initiation site, this binding site is located in the *LOC791098* pseudogene. **Discussion and conclusions:** *MEIS1* is involved in cell proliferation and differentiation. However, its role in cancer development is poorly understood. Our observations indicate that *MEIS1* down-modulation increase expression of *SSX2*, a cancer-testis antigen found in solid tumors but not reported in hematopoietic malignancies and leukemia-derived cell lines. We can speculate that overexpression of *MEIS1* represses *SSX2* gene, which could compromise the repressor activity of the *PolyComb* group complex. Additional studies at the protein level are needed to confirm our findings.

Monoallelic epigenetic silencing of the Apc tumor suppressor gene and parent of origin effects in a rat model of colon cancer. *J. Amos-Landgraf[1], A. Irving[2], M. Ford[2], W. Dove[2].* 1) Veterinary Pathobiology, University of Missouri, Columbia, MO; 2) McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, WI.

We have developed a rat genetic model of Familial Adenomatous Polyposis (FAP) that recapitulates many aspects of the human disease and has certain advantages over existing mouse models of colon cancer. The Polyposis in rat colon (Pirc) rat harbors a nonsense mutation at amino acid 1137 of Apc, a gatekeeper of the Wnt pathway involved in over 80% of human colon cancers. The Pirc rat develops the majority of its tumors in the colon, in contradistinction with existing mouse genetic models where tumors form preferentially in the small intestine. The Pirc rat also exhibits a sex bias with males having an increased susceptibility, as is seen in the human disease. We have shown that tumors initiate through both somatic genetic and epigenetic mechanisms, and that genetic background greatly alters the colonic phenotype. We utilized qRT-PCR, aCGH, Sanger sequencing, and quantitative allele-specific pyrosequencing of DNA and cDNA in heterozygous animals to monitor genetic and epigenetic events in tumors. Remarkably, we found 30% of Pirc rat tumors maintained heterozygosity of Apc in their genomic DNA. We speculate that either additional genetic or epigenetic events occur to initiate these tumors. To score allelic ratios in DNA and cDNA from F1 tumors provides a general assay for allele-specific changes in expression, irrespective of mechanism. Half of the tumors in the Pirc rat that maintained heterozygosity of DNA had a strong bias of expression for the mutant allele in cDNA.

To explore the strong influence of genetic background we created two congenic derivatives of the Pirc strain on the BN and ACI genetic backgrounds. The BN-Pirc line is highly resistant to tumor development (male average of 0.75 tumors), while the ACI-Pirc congenic line shows a dramatic susceptibility with males developing over twice as many tumors as the F344N/Tac co-isogenic line (average 30.3 tumors). The ACI-Pirc congenic line crossed with BN develops an average of 3.7 ± 2.1 tumors per animal at 6 months of age. Interestingly, the parent of origin of the ACI allele has a significant impact on tumor number. When the ACI-Pirc allele is inherited maternally the male offspring develop an average of 2.9 ± 1.5 tumors, in contrast to an average of 4.9 ± 2.3 tumors when the Pirc allele is inherited paternally (Wilcoxon rank sum P=0.01). We hypothesize that genetic variation in imprinted genes in the ACI genetic background influence tumor initiation in the progeny of these crosses.

3309W

Evaluation of a cancer gene sequencing panel in a hereditary risk assessment clinic. *Y. Kobayashi[1], A.W. Kurian[2,3], E. Hare[1], M.A. Mills[2], K.E. Kingham[2], A.S. Whittemore[3], V. McGuire[3], G. Gong[3], U. Ladabaum[2], M. Cargill[1], J.M. Ford[2,4].* 1) InVitae, San Francisco, CA; 2) Department of Medicine, Stanford University, Stanford, CA; 3) Department of Health Research and Policy, Stanford University, Stanford, CA; 4) Department of Genetics, Stanford University, Stanford, CA.

Sequencing panels of multiple cancer-associated genes are entering clinical practice, but little is known about the performance and yield of such testing among relevant patient populations. 199 adult female patients were referred to the Stanford Clinical Cancer Genetics Program for clinical assessment of hereditary breast and ovarian cancer risk; 141 had breast cancer and 57 carried known mutations in *BRCA1* or *BRCA2* (*BRCA1/2*). Germline DNA samples from these patients were sequenced on a custom multigene sequencing panel. This panel covered the entire coding region, exon-intron boundaries (+/- 10bp) and any other known pathogenic variants for 43 genes that have published associations with risk of breast, ovarian and other cancers, and an additional 32 cancer-associated variants elsewhere in the genome. A validation set of 200-300 samples is currently being processed. Analytic results for *BRCA1/2* sequencing and pathogenicity interpretations were concordant with prior clinical testing for all patients. Twenty variants that were designated as pathogenic, either based on published literature or due to a novel truncating or splice donor/acceptor effect, were observed in genes other than *BRCA1/2*, including *ATM*, *BLM*, *CDH1*, *CDKN2A*, *MUTYH*, *MLH1*, *NBN*, *PRSS1* and *SLX4*. Many patients carried more than one variant (including variants of uncertain clinical significance). Thirteen patients had pathogenic variants which warranted a change in cancer screening or preventive interventions based on practice guidelines: these patients were invited for confirmatory clinical testing, genetic counseling and screening recommendations. One 53-year old patient with a personal history of breast and endometrial cancers was found to carry a pathogenic *MLH1* mutation; she underwent risk-reducing salpingo-oophorectomy and colonoscopy, with removal of a tubular adenoma.

Among patients referred for clinical evaluation of hereditary breast and/or ovarian cancer risk, a comprehensive sequencing assay for 43-cancer associated genes and 32 cancer-associated variants identified 20 patients [10.1%, 95% confidence interval (CI) 6.5%-15.1%] with pathogenic mutations in genes other than *BRCA1/2*, of which 13 (6.5%, CI 3.8%-11%) mutations prompted a change in cancer screening or prevention. Disclosure of research testing results to participants who donated specimens several years previously appears feasible and well-tolerated.

3310T

Novel Integrative Genomics Approach to Biomarker Discovery in Prostate Cancer. *C. Hicks[1,2,3], L. Miele[1], T. Koganti[1], J. Sitthi-Amorn[1], S. Vijayakumar[3].* 1) Cancer Institute, University of Mississippi Medical Center, 2500 N. State Street, Jackson, MS 39216; 2) Department of Medicine, University of Mississippi Medical Center, 2500 N. State Street, Jackson, MS 39216; 3) Department of Radiation Oncology, University of Mississippi Medical Center, 2500 N. State Street, Jackson, MS 39216.

Recent advances in high-throughput genotyping and reduction in genotyping costs have made possible identification of common genetic variants associated with increased risk of developing prostate cancer using genome-wide association studies (GWAS). However, despite this remarkable success, several challenges remain in translating GWAS discoveries into clinically actionable biomarkers. First, genetic loci associated with prostate cancer generally explain very little of the disease risk. Second, the trait-SNP associations alone do not necessary lead directly to the identification of causal genes and do not provide insights about the broader biological context in which the identified variants and associated genes operate. Here we report the results of a novel integrative genomics approach that combines GWAS information with gene expression data to elucidate the molecular mechanisms underpinning GWAS findings and to identify gene regulatory networks and biological pathways enriched for genetic variants. Our working hypothesis is that genes containing SNPs associated with increased risk of developing prostate cancer are functionally related and interact with one another and their downstream targets in gene networks and pathways. We tested this hypothesis using publicly available GWAS information on 300 SNPs mapped to 175 genes derived from over 350,000 cases and over 350,000 controls and gene expression data derived from 493 samples (347 samples with prostate cancer, 25 samples with metastatic cancer and 121 control samples). We performed both supervised and unsupervised analysis followed by network and pathway analysis using Ingenuity IPA. Supervised analysis revealed 70 SNP-containing genes associated with prostate cancer and 65 genes associated with metastatic disease. Unsupervised analysis using hierarchical clustering revealed that the SNP-containing genes are co-expressed and have similar patterns of expression profiles. In addition, we identified novel genes which are functionally related with SNP-containing genes. Network and pathway analysis revealed gene regulatory networks and biological pathways enriched for SNPs. Among the identified pathways included the Thrombopoietin, androgen, prolactin and the IGF-1 signaling pathways, all of which have been implicated in prostate cancer. Integration of GWAS information with gene expression data provides insights about the broader context in which genetic variants operate.

Exomic Sequencing to Identify Germline Variants in Familial Melanoma. *H.N. Shabbir[1], M.T Landi[2].* 1) Miami Dade College, Miami, FL; 2) National Cancer Institute, Department of Cancer Epidemiology and Genetics.

Germlines are the source of DNA in all cells. A mutation at the germline level is the first step to developing cancer, and the vast majority of cancer is genetic. Melanoma, the leading cause of skin cancer death, is known to be highly heritable and rare. Using a family model, high risk variants related to melanoma can be identified. The goal of the study is to integrate information from sequencing, epigenetics, and expression to identify functional and regulatory genes that are associated with melanoma. Families with two or more 1st degree relatives with melanoma were considered at high risk and were investigated in this study. Initially, sequencing data of families with 3 or more relatives with the disease were examined and shared DNA variants were selected for further examination. Genetic databases and annotation tools were used to identify genes based on their known gene function and regulation, pathways, and variant conservation. Gene browsers were also used to identify any histone markers, DNA methylation sites, and other epigenetic indicators. Based on our candidate genes, there is a possibility of genetic heterogeneity, in which multiple genes may be responsible for disease susceptibility. Selected candidate genes will undergo fine mapping to further investigate the region and replication in additional families and population studies of melanoma.

Molecular Classification of Myeloproliferative Neoplasms (MPNs) Patients in the State of Qatar According to World Health Organization (WHO) 2008 Criteria. *N. Al-Dewik[1,2], Q. Fernandes[2], YK. Naidu[2], N. Bonnin[3], E. Verger[3], B. Cassinat[3], JJ. Kiladjian[4], H. El Ayoubi[2], M. Yassin[2].* 1) QMGC, HMC, Doha, Qatar; 2) Molecular Genetics of Cancer Research Lab, NCCCR-HMC, Doha, Qatar; 3) Unité de Biologie Cellulaire, France; 4) Centre d'Investigations Cliniques, Hôpital Saint-Louis, Paris, France.

Background:MPNs are clonal haemopoietic disorders that are characterized by excessive proliferation of one or more of blood lineages. MPNs include PV, ET and PMF which are associated by the presence of JAK2 V617F mutation in about 90% of PV and 50% of ET and PMF. The molecular workup of JAK2 & related gene mutations were included in WHO 2008 as one major criterion for the diagnosis of Ph- MPNs. Aims: To genetically characterize MPN patients (pts) in Qatar according to the latest (WHO 2008) criteria using molecular studies for JAK2 V617F mutation, JAK2 exons 12-15 & MPL (S505N & W515 L/K) mutations. Methods: Blood samples were collected from suspected MPN cases & DNA was extracted. Allelic discrimination assays were used to evaluate point mutations causing JAK2 V617F & MPL (W515 L/K) mutations. JAK2 Exon 12 was analyzed using High Resolution Melting Curve (HRM) assay & Sanger Sequencing. In some cases the entire MPL exon 10 & exons 12-15 was studied by RNA extraction followed by cDNA synthesis, amplification & sequencing. Results: 300 patients were classified into PV, ET and PM. Out of 119 PV, 97% of cases were positive for the JAK2 V617F mutation and 3% of cases were negative for other mutations. Out of 165 ET, 48% of cases were positive for JAK2 V617F, one had MPL S505N mutation and 50% of cases were negative for other mutations. Out of 15 PMF, 33% of cases were positive for JAK2 V617F and one unclassified case was characterized by DVT had JAK2 exon 13 mutation (R564L). Conclusion: This study used novel molecular approaches to confirm the diagnosis of MPNs cases in Qatar. The observed patterns of mutations were found to be similar to the international data. In our cohorts of patients, JAK2 V617F mutation was found to be present in almost every patient with PV, nearly 50% of ET patients and less than 50% of PMF patients due to the low number of PMF patients in this study. Our original findings show the presence of MPL S505N mutation in one ET patient which was reported both as an inherited or acquired mutation in very rare cases of ET and R564L mutation in one unclassified MPNs case. An ET patient with MPL S505N progressed to AML. The impact of R564L mutation found in 1 atypical case is still unknown & needs further investigation. We report for the first time the presence of most frequent mutations found in MPNs patients in Qatar. This study is preliminary before further molecular investigations to explore & identify mutations in other candidate genes.

3313T

Novel association between tanning addiction and *PTCHD2* alleles using a whole-exome variant array. *A.E. Bale[1], A.T. Dewan[1], L.M. Ferrucci[1], J. Gelernter[1], D.J. Leffell[1], S.T. Mayne[1], J. Stapleton[2], B. Cartmel[1].* 1) Yale Univ, New Haven, CT; 2) Cancer Institute of New Jersey, New Brunswick, NJ.

Skin cancer is the most common malignancy worldwide; and its rapidly increasing incidence in young adults is related to a preventable exposure, excess ultraviolet (UV) radiation from indoor and outdoor tanning. Several studies have provided evidence for biological dependence on the physiologic effects of UV, analogous to substance dependence. We hypothesized that tanning addiction, like substance addiction, may have a genetic underpinning. European Americans under age 40 in Connecticut who participated in a case-control study of basal cell carcinoma (BCC) were recontacted to complete an online survey (response rate=82%) that included 3 tanning addiction questionnaires to assess lifetime symptoms of tanning dependence. DNA collected as part of the BCC case-control study was genotyped for 319,000 variants~mainly exonic~on the Affymetrix Axiom 319 Array. Of 476 subjects who passed QC, 79 exhibited symptoms of tanning dependence on all 3 scales and 213 were negative for tanning dependence on all scales; individuals with an intermediate phenotype (tanning dependent on one or two scales) were excluded. Including missense, nonsense and splice site changes, there were 157,955 variants across 14,903 genes. A gene-based burden analysis was performed in which each sample was dichotomously scored for each gene as either having one or more minor alleles or no minor alleles. For each gene, differences in these frequencies by tanning dependence underwent a Fisher's exact test. For one gene, *PTCHD2*, we observed significantly more individuals without symptoms of tanning dependence with a minor allele, compared to individuals who exhibited symptoms of tanning dependence (OR = 0.27, $p=2.5\times10^{-6}$, p value for significance with Bonferroni correction=3.36×10^{-6}). To validate this method of analysis, we evaluated Axiom Array data on BCC cases (n=354) and controls (n=363) from the parent study. The top gene in this BCC risk analysis was *MC1R* ($p=1.67\times10^{-6}$; OR=2.07), as expected based on our previous analysis of this same sample in which we directly sequenced *MC1R*. *PTCHD2* is a gene of unknown function whose product is expressed mainly in the brain. While requiring replication, the association between variants in this gene and reduced risk for tanning addiction supports a biological basis for this behavioral trait. Delineating molecular mechanisms that drive tanning dependence may lead to novel medical interventions to stem the epidemic of tanning and skin cancer in young people.

The PROFILE Feasibility Study: Genetic prostate cancer risk stratification for targeted screening. *R. Eeles[1,2], E. Bancroft[1,2], N. Taylor[2], T. Dadaev[1], E. Page[1], D. Keating[1], N. Borley[3], N. Desouza[4], C. Goh[1,2], E. Saunders[1], A. Lee[5], D. Easton[5], A. Antoniou[5], Z. Kote-Jarai[1], E. Castro[1,2].* 1) Oncogenetics Team, Div of Genetics & Epidemiology, Inst Cancer Res, Sutton, Surrey, United Kingdom; 2) Cancer Genetics Unit. The Royal Marsden NHS Foundation Trust, London, UK; 3) Academic Urology Unit. The Royal Marsden NHS Foundation Trust, London, UK; 4) Radiology Department. The Royal Marsden NHS Foundation Trust, London, UK; 5) Center for Cancer Genetic Epidemiology, University of Cambridge, UK.

Background: Prostate cancer (PC) screening is controversial and a better assessment of individualized PC risk is needed. Several single nucleotide polymorphisms (SNPs) conferring a cumulative risk of PC have been identified. We have explored the potential role of genetic markers for targeted screening in a population with increased risk of PC due to family history (FH) of the disease. **Methods:** PROFILE was developed as a pilot study to determine the feasibility of targeted PC screening using prostatic biopsy (PB) and its association with specific genetic profiles in men with FH. We also evaluated the role of PSA and Diffusion Weighted MRI (DW-MRI) as screening tools in this population. 100 men aged 40-69 with FH of PC were enrolled. Cumulative SNP risk scores were calculated by summing 59 risk alleles for each locus using the weighted effect (log-additive model). DW-MRI was performed in 50 patients. Participants were asked to undergo a 10 core PB regardless of baseline PSA. **Results:** 35% of invited men entered the study. Median age 53 yrs (40-69) and median PSA was 1.15. Ninety men accepted to undergo a PB as primary PC screening. Twenty-two tumours were found and 45% of them were clinically significant [Median age 64yrs (47-69), median PSA 5.4 (0.91-9.3)] which compares with 24% in general population screening. The predictive performance of DW-MRI, PSA, genetic model and genetic model plus PSA measured by AUC were: 0.85, 0.73, 0.57 and 0.74, respectively. The genetic model performed best in men with a normal PSA of <3(AUC 0.63). Analyses of a 78 SNP profile from the recent COGS results are underway. **Conclusions:** Our results indicate that PB is acceptable for PC screening in men with FH of PC. The numbers of men undergoing DW-MRI were small but the AUC would warrant a larger study. The SNP risk score was more predictive in men with PSA<3 where PB would not normally be undertaken, therefore an expanded study to investigate the role of genetic profiling in directing PB in PC screening is indicated.

Although the use of genome-wide association studies (GWAS) has resulted in notable successes in identifying common single nucleotide polymorphisms (SNPs) associated with colorectal cancer (CRC), genotyping platforms to date have primarily focused on common alleles with frequencies greater than 5%. The Genetics and Epidemiology of Colorectal Cancer Consortium (GECCO) investigated the spectrum from common to rare genetic variation in the human exome by successfully genotyping 10,105 cases and 10,009 controls of European ancestry on the Illumina Human Exome array with over 240,000 markers targeting rare non-synonymous, splice site, and stop variants. We examined associations between CRC and 61,229 single variants with minor allele frequencies (MAF) $\geq$ 0.1% using logistic regression analysis and a Bonferroni-corrected p-value threshold of $0.05/61{,}229 = 8.2 \times 10^{-7}$. Additionally, we assessed CRC risk in relation to aggregation of variants with MAF < 5% in 14,570 genes using MiST, which combines burden and variance component tests (Bonferroni-corrected p-value threshold of $0.05/14{,}570 = 3.43 \times 10^{-6}$). In addition to statistically significant associations with known GWAS loci for colorectal cancer, we identified potentially novel variants with p-values $< 1 \times 10^{-4}$ for follow up. After conducting a combined meta-analysis with an additional 5,825 cases and 7,814 controls of European descent from the Colorectal Cancer Family Registry (CCFR) study and a Kentucky population-based case-control study with Exome-array data, as well as additional GECCO studies with 1000 Genome Project imputed data, we identified a novel marginally significant association for a low frequency, missense variant (MAF = 0.046) in *HIVEP1* [discovery p-value = 1.54×10^{-5}, OR = 1.23; combined p-value = 5.5×10^{-7}, OR = 1.21]. None of the gene-based tests remained statistically significant after accounting for multiple comparisons. In summary, our study provides support for an association between a novel low-frequency variant in *HIVEP1* and CRC risk, and suggests that even larger sample sizes are needed to identify less frequent and rare variants in the human exome that contribute to the development of CRC.

3316T

Pathway analysis shows different leukemia subtypes are involved with distinct biological mechanisms. *Ll. Hsu[1], FB. Briggs[2], XR. Shao[2], AP. Chokkalingam[1], KM. Walsh[3], C. Metayer[1], LF. Barcellos[2], P. Buffler[1].* 1) School of Public Health, University of California, Berkeley, Berkeley, California, CA, USA; 2) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, CA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, California, USA.

The incidence of acute lymphoblastic leukemia (ALL) has been found to be nearly 20%; higher among Hispanics than non-Hispanic Whites. However, only a few studies have been conducted in the Hispanic population. Genome-wide association studies (GWAS) have showed evidence for association in IZKF1, ARID5B, CEBPE, CDKN2A, and BM1-PIP4K2A. However, these loci account for <10%; of leukemia genetic risk, indicating additional susceptibility loci are yet to be discovered and advanced bioinformatics tools may further guide future directions. We applied pathway-based analyses in Hispanic GWAS data of the California Childhood Leukemia Study (CCLS), testing for biological functions that are significantly enriched in childhood leukemia. Furthermore, we compared whether different biological pathways were overrepresented in major disease subtypes, including B-cell ALL, hyperdiploid B-ALL and TEL-AML1 ALL. The study population is comprised of 323 Hispanic ALL cases and 454 controls from the CCLS, using Illumina OmniExpress v1 genotyping platform. For pathway analyses, we selected genes that had at least one associated significantly SNP (P<0.001), when adjusted for age, gender, and genetic ancestry. Of the 187 genes identified, 185 genes were incorporated for analysis using a hypergeometric test to compare the submitted list to a reference of all human genes using WebGestalt v.2. The top five overrepresented KEGG pathways in ALL include axon guidance (FDR=5.1e-06), protein digestion and absorption (FDR=0.0007), melanogenesis (FDR=0.0014), leukocyte transendothelial migration (FDR=0.0021), and focal adhesion (FDR=0.0021). Interestingly, 90% of the identified pathways are associated with cancer development, such as Wnt signaling and MAPK pathway. Between different disease subtypes, pathway analyses results indicate that hyperdiploidy B-ALL and TEL-AML1 ALL involve distinct biological mechanisms compared to ALL. This is the first study to show distinct biological pathways are overrepresented in different leukemia disease subtypes using pathway-analyses approaches. We further used LASSO and targeted maximum likelihood estimation method to identify causal SNPs within each pathway. The results demonstrate that newly developed bioinformatics tools and causal inference methods can help identify novel loci to further understand leukemia pathogenesis.

3317F

A Genome-Wide Association Study Identifies New Susceptibility Loci for Esophageal Adenocarcinoma and Barrett's Esophagus. *D.M. Levine[1], W.E. Ek[2], R. Fitzgerald[3], S. MacGregor[2], D.C. Whiteman[4], T.L. Vaughan[5].* 1) Department of Biostatistics, University of Washington School of Public Health, Seattle, WA USA; 2) Statistical Genetics, Queensland Institute of Medical Research, Queensland, Australia; 3) MRC Cancer Cell Unit, Hutchison-MRC Research Centre and University of Cambridge, Cambridge, UK; 4) Cancer Control, Queensland Institute of Medical Research, Queensland, Australia; 5) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA USA.

Esophageal adenocarcinoma (EA) is a cancer with rising incidence and poor survival. Most patients survive less than a year, and five-year survival is about 20%. For reasons that are not clear, incidence of EA is substantially higher in men and persons of European ancestry. Most EAs arise in a specialized intestinal metaplastic epithelium, which is diagnostic of EA's precancerous lesion, Barrett's esophagus (BE). We report the results of the first genome-wide association study of EA, and the first to examine EA together with its precancerous lesion BE. We utilized fourteen, largely population-based, epidemiologic studies from the Barrett's and Esophageal Adenocarcinoma Consortium (BEACON) collected over the past two decades. We analyzed 5,564 cases (2,393 EA and 3,175 BE) and 10,120 controls in two phases. For the combined case group we identified three novel genome-wide associations. The first is on 19p13 ($P=3.6\times10^{-10}$) in CRTC1, a putative cancer gene. A second is on 9q22 ($P=1.0\times10^{-9}$) in BARX1, which encodes a transcription factor important in esophageal specification. A third is on 3p14 ($P=5.5\times10^{-9}$) near the transcription factor gene, FOXP1, which regulates esophageal development. Consistent with our previous findings showing extensive polygenic overlap between EA and BE, our most significant results were for EA and BE combined, and, together, suggest that much of the genetic basis for EA lies in the development of BE, rather than progression from BE to EA. Further dissection of these loci is likely to lead to insights into the etiology of this rapidly fatal cancer.

3318W

GENE EXPRESSION NETWORKS FOR NON-SMALL CELL LUNG CANCER MAJOR SUBTYPES. *L. Liang[1, 2], M.B. Freidin[3, 4], E. Lim[3, 4], A.G. Nicholson[5], S. Popat[3, 6], M.F. Moffatt[3], W.O. Cookson[3].* 1) Epidemiology, Harvard Sch Public Health, Boston, MA; 2) Biostatistics, Harvard Sch Public Health, Boston, MA; 3) National Heart and Lung Institute, Imperial College London, London, UK; 4) Department of Thoracic Surgery, Royal Brompton Hospital, London, UK; 5) Department of Histhopathology, Royal Brompton Hospital, London, UK; 6) Lung Unit, Royal Marsden Hospital, London, UK.

Lung cancer (LC) remains the most common cancers worldwide for decades, and causes more than a million deaths annually. LC was in focus of numerous genetic and genomic studies including global transcriptome profiling for the purpose of identification of robust expression signatures for early diagnostics, molecular classification, disease prognosis, and response to treatment regimes. In this study we used systems biology approaches to identify transcription networks as well as individual loci that provide the way to explain transcriptome complexity of LC. Lung tumour and matched normal specimens from 69 patients with squamous cell carcinoma (SQCC, 25 patients) and adenocarcinoma (ADC, 44 patients) were analyzed. We found that gene expression profile can remarkably distinguish between tumour subtypes. Among the 36 co-expression network modules identified, three modules are highly significantly (pvalue<1e-8) associated with both subtypes, one module with ADC only and two modules with SQCC only. These networks contain very interesting patterns of genes. Controlling for false discovery rate < 0.001, we identified 2869 transcripts were differentially expressed between tumour subtypes and 69 transcripts were associated with smoking status. The hub genes of identified network modules that were consensus or specific to tumour subtypes reveal important biological pathway and molecular signature. To the best of our knowledge, this is the first study utilising co-expression network algorithm for the analysis of co-expression networks in non-small cell lung cancer. Our results might reveal new biomarkers to distinguish between ADC and SQCC, and identify new potential therapeutic targets.

3319T

HPV and Cervical Cancer in Guatemala and Venezuela-Low-cost screening with NextGen sequencing. *H. Lou[1], G. Villagran[2], U. Odey[3], J. Sawitzke[4], D. Wells[4], J. Troyer[4], M. Dyba[5], A. Ruch[6], R. Orozco[7], V. Arguata[7], E. Gharzouzi[2], E. Alvirez[3], M. Dean[5].* 1) SAIC Genetics Core, CIP, CCR, NCI, Frederick MD; 2) Instituto Cancerologia, Guatemala City, Guatemala; 3) Hospital Central Universitario 'Dr. Antonio M Pineda', Barquisimeto, Lara State. Venezuela; 4) SAIC-Frederick, Frederick MD; 5) LEI, CCR, NCI, Frederick MD; 6) Toledo Hospital, Toledo, Ohio; 7) Hospital San Juan de Dios, Guatemala City, Guatemala.

High-risk human papillomavirus infections are causally related to cervical cancer development. Cervical cancer represents the most dramatic cancer health disparity of women in the world, with over 200,000 deaths annually, concentrated in poor, rural, and indigenous populations. Guatemala and Venezuela are illustrative of this disparity as cervical cancer is the predominant cause of cancer cases and deaths in women. To determine the HPV viral strains in invasive tumors, we initiated a prospective collection of invasive cervical cancer cases with tissue collected in RNAlater. DNA-based testing has been shown to be useful in identifying persistent carriers at risk for cervical cancer. To determine the prevalence of HPV in women over 30, cervical swabs were collected at the time of a Pap exam and preserved in 3ml of Scope mouthwash. A total of 351 cancer cases with an average age of 53 (22-81 years), and 395 swabs of non-cancer cases over age 30 were obtained. We amplified the HPV L1 gene from DNA purified from cancer tissues and cell lysates from cervical swab samples using BS GP5+ and GP6+ primers and nested PCR was used to confirm the undetermined samples by primer MY09/11 (1st run PCR) and BS GP5+ and GP6+ (2nd) run PCR. DNA sequencing of HPV from tumor tissue revealed detectable in HPV in 96% of samples with HPV16 in 53%, HPV18 in 12%, HPV45 in 10% and HPV 26, 31, 33, 35, 39, 52, 56, 58, 67, 68, 69, and 73 in 0.8-4.9% of samples. The prevalence of HPV infection in women without cancer is approximately 12%. To employ NextGen sequencing for HPV determination we bar-coded the same BS GP5+ and GP6+ primers and sequenced on the Ion Torrent PGM. An average of 8000 reads were obtained for each sample. Highly comparable data was obtained as from the conventional sequencing and mixtures of HPV types as well as polymorphisms within the isolates was observed. From the HPV16 and HPV18 samples, oncoprotein E6 and E7 RNA was quantitated to estimate viral load. In conclusion, vaccination against HPV16 and HPV18 can protect for up to 70% of invasive cervical cancers, but active screening will be required for many years. A sensitive and low cost approach to cervical sampling, including Next-Gen sequencing has been developed that could be employed to reduce the burden of cervical cancer worldwide.

3320F

Individualized prostate cancer risk prediction using a polygenic risk score. *R. Szulkin, T. Whitington, F. Wiklund, PRACTICAL consortium.* Department of Medical Epidemiology and Biostatistics,Karolinska Institutet, Stockholm, Sweden.

Introduction: Multiple common prostate cancer susceptibility single nucleotide polymorphisms (SNPs) have ben established. Their ability to individually discriminate between prostate cancer patients and healthy controls are limited due to small effect sizes; however, combinations of multiple SNPs have shown predictive capacity. The aim of this study was to develop an optimal polygenic risk score that distinguish between prostate cancer cases and controls, as well as between aggressive and non-aggressive disease.

Materials and methods: Utilizing a large international prostate cancer genetics consortium (PRACTICAL) approximately 83,000 SNPs, enriched for prostate cancer association, genotyped in 22,924 cases and 22,889 controls were available for analysis. Prostate cancer cases were classified as having aggressive (Gleason score>7) or non-aggressive (Gleason score <7) disease. To discriminate between cases/controls and aggressive/non-aggressive disease we constructed polygenic SNP risk scores that were assessed in logistic regression models. Increasing number of SNPs were added to the score, ranked according to strength of association with prostate cancer, and evidence of biological function extracted from public resources including the ENCODE project. To select the optimal number of SNPs in the score and to avoid over fitting, a five-fold cross validation procedure was employed in a 'training dataset' (85% of data) and then evaluated in a 'test dataset' (15% of data).

Results and conclusion: Initial analysis show that prostate cancer prediction based on a risk score including 54 established prostate cancer susceptibility SNPs result in an area under the curve (AUC) of 0.66. By adding an additional 80 SNPs into the risk score, selected by high association with prostate cancer, the predictive performance increased notably (AUC=0.70). We anticipate that this result can be further improved by incorporating functional information to rank SNPs. We show that a polygenetic risk score may be a clinically useful tool to identify individuals who would benefit from targeted screening.

3321W

BRCA1 and BRCA2 (BRCA) gene analyses on an economic platform: A global consortium to demonstrate the feasibility of a shared, dedicated workflow for non-optical next generation sequencing (NGS) with a custom BRCA AmpliSeq kit on the Ion Torrent PGM™. *J. Weitzel[1], J. Costa[2], A. Mensenkamp[3], A. Ekici[4], J. Herzog[1], M. Ligtenberg[3], H. Feilotter[5], P. Park[5], A. Hidalgo-Miranda[6], N. Williams[7], R. Ellis[7], J. Carlos-Machado[2].* 1) Clinical Cancer Gen, City of Hope, Duarte, CA; 2) Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal; 3) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Netherlands; 4) Institute of Human Genetics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; 5) Department of Pathology and Molecular Medicine Queen's University, and Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 6) Cancer Genomics Laboratory National Institute of Genomic Medicine, Distrito Federal, Mexico City, Mexico; 7) West of Scotland Genetic Services, Laboratory Medicine, Southern General Hospital, Glasgow, Scotland, UK.

While the 'Jolie effect' has refocused attention on the central role of BRCA gene analyses in the diagnosis and prevention of hereditary breast and ovarian cancer, there is a global disparity in access to affordable testing. The development of bench top NGS technologies holds promise for faster, more comprehensive and cost-effective methodologies than Sanger sequencing. We describe here a global consortium developing and demonstrating the feasibility of a shared, dedicated workflow for clinical grade BRCA gene analyses using Ion AmpliSeq™ multiplex PCR technology combined with Ion PGM™ System. The non-overlapping primers were designed to provide 1) 100% coverage of all coding exons and exon-intron boundaries; 2) overlapping amplicons covering exons; 3) no SNPs in the last five nucleotides of primer; and 4) maximum of three non-validated SNPs per primer. The technical protocol was developed and piloted by centers in the Netherlands and Portugal, and the current phase III testing includes 5 additional centers (California, USA; D.F., Mexico; Glasgow, Scotland; Erlangen, Germany; Ontario, Canada). More than 200 different known germline BRCA mutation positive cases were selected (~30 per center), many representative of a given region, with the aim to assess the ability to detect and call the full spectrum of mutation types, with additional cases in or within close proximity to homopolymer regions. Data analyses include independent and blind evaluation and power estimation of the new methodology. All samples were studied using both Sanger sequencing and the Ion PGM™ System. For data-analysis various software packages were evaluated, with an aim to harmonize the analyses as a custom workflow on Ion Reporter to facilitate use in widely disparate settings. The technical platform has been established in all 7 centers, with excellent performance characteristics: 100% coverage of the targeted regions; >100x coverage across all but 1 amplicon in BRCA2 (>40x), while using barcoding to analyze 8 cases simultaneously on a 316 chip. There was high sensitivity and specificity; technical challenges in the bioinformatic component and emerging copy number variation detection methods will be discussed. This work demonstrates the potential for mutational screening of BRCA1 and BRCA2 using the Ion AmpliSeq™ technology combined with the Ion Torrent PGM, and the feasibility of deploying a common protocol to diverse geographic settings, with a close collaboration among peers.

3322T

Inherited predisposition to cancer in Mexican women. *C.M. Laukaitis[1,2], A. Chaudhury[1], C. Mauss[2], T. Walsh[3], P.A. Thompson[2], A.M. Lopez[1,2], A. Daneri Navarro[4], M-C. King[3].* 1) Department of Medicine, University of Arizona, Tucson, AZ., USA; 2) University of Arizona Cancer Center, Tucson, AZ, USA; 3) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA, USA; 4) Centro Universitario De Ciencias De La Salud Universidad De Guadalajara Sierra Mojada No 950, Edificio P Primer Niviel, Colonia Independencia Guadalajara, Jalisco, Mexico.

With the emergence of comprehensive sequencing approaches for evaluation of breast and ovarian cancer genes, it is our hope to offer risk assessment for these cancers as part of an integrated program of cancer prevention for Latina women in the U.S. Southwest and Mexico. However, our experience suggests that genomic analysis of cancer risk in this population presents special challenges, because Hispanic control populations have been less thoroughly evaluated than others for naturally occurring variation in critical genes. The goal of the present pilot project is to apply BROCA capture and sequencing to identify and characterize inherited damaging mutations of all classes in all known breast and ovarian cancer genes. Participants in the study are 92 women of Mexican ancestry (49 from southern Arizona and 43 from northern Mexico) who were diagnosed with invasive breast cancer and enrolled in the ELLA Binational Breast Cancer Study. Of the participants, 15% (14/92) carry unambiguously damaging mutations (truncations, complete gene deletions, and missense mutations shown experimentally to lead to loss of protein function) in a known breast cancer gene: 5 in BRCA1, 5 in BRCA2, 2 in CHEK2, 1 in PALB2 and 1 in RAD51C. Several of these clearly damaging mutations are population specific.The challenge arises because an additional 9% of participants (8/92) carry other rare, and hence likely population-specific, mutations of unknown functional consequence in the same genes. Four participants carry variants in BRCA1 or BRCA2 at sites predicted by in silico tools to alter splice enhancers. Four other participants carry missense mutations in CHEK2 that are predicted by in silico tools to be damaging to kinase function. None of these variants appear in public databases of the 1000 Genomes Project, in dbSNP, or in the NHLBI exome sequencing project; none are characterized functionally in gene-specific databases. The problem of variants of unknown significance arises in all populations, certainly, but in our experience it is disproportionately frequent in populations with little previous evaluation for naturally occurring benign variation. Both functional and population genetics approaches will be important in resolving the meaning of this variation.

3323F

Association of Genetic variants of Cancer stem cell genes (CSC) in Gallbladder Cancer Susceptibility in North Indian population. *K. Sharma[1], B. Mittal[1], A. Yadav[1], A. Kumar[1], S. Misra[2], V. Kumar[2].* 1) Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences (SGPGIMS), Lucknow, UP, India; 2) Surgical Oncology. King George Medical University, Lucknow,India.

Introduction: Many properties of malignant cells are suggestive of those in normal stem cells. Current evidence suggests that cancer stem cells (CSC) are accountable for cancer progression and recurrence. Germline variants in CSC genes may bring about distorted gene function and activity, thus causing interindividual variations in a patient's chemoresistance and tumor recurrence capability. Still, the associations of genetic variations in these genes with GBC have not yet been done. Methods: The present study included 598 subjects including 398 GBC patients and 200 healthy controls from North India. This study examined association of ALCAM rs1157 G>A, CD44 rs187116 G>A, CD44 rs187115 T>C, ALDH1A1 rs13959 A>G. Genotypes were determined by self designed PCR-RFLP and ARMS-PCR. Statistical analysis was done by SPSSver16. In-silco analysis was performed using Bioinformatics tools (F-SNP, FAST-SNP). Results: Statistical analysis by logistic regression showed marginal association of ALCAM rs1157 G>A polymorphism with GBC risk (p=0.05). However CD44 rs187116 G>A, CD44 rs187116 T>C, ALDH1A1 rs13959 A>G were not associated with GBC risk. CD44 rs187116 G>A, CD44 rs187116 T>C haplotypes did not show significant association with GBC. On stratification based on gender, ALCAM rs1157 [AA] genotype showed increased risk of GBC in females [p=0.017] and CD44 rs187116 [GA] genotype with males [p=0.017]. Subdividing the GBC patients on the basis of gallstone status, ALCAM rs1157 G>A polymorphism imparted higher risk in patients with stones when compared to controls [p=0.04]. In case-only analysis, risk was not modified with tobacco usage and age of onset. Insilico analysis of ALCAM rs1157 G>A and CD44 rs187116 T>C revealed variable change in transcriptional and splicing regulation respectably. Conclusion: This is the first report of association of cancer stem cell genetic variants with GBC susceptibility. The study found important role of ALCAM rs1157 G>A with GBC risk. Grant support: DBT, DST and ICMR Government of India.

Semiconductor-based next-gen sequencing reveals cancer risk-associated genetic variations in Chiba J-MICC cohort study. *J. Katayama[1], Y. Hayashi[1], H. Mikami[2], H. Kageyama[2], M. Ohira[2], S. Yokoi[2], H. Nagase[2].* 1) Life Technologies, Tokyo, Japan; 2) Chiba Cancer Center research Institute, Chiba, Japan.

Ion AmpliSeq technology is a simple, efficient and rapid process for enriching hundreds to thousands of genomic targets for next generation sequencing from 10 ng of FFPE or whole genomic DNA in a single tube. We conducted this next-gen sequencing approach to identify risk-associated genetic variants primarily in cancer risk population in a population-based cohort study following 7,900 of healthy people in a local area of Chiba since 2005. To focus the screening for cancer related gene, we used comprehensive cancer panel with Ion personal genome machine sequencer for this screening. We evaluated sufficient data amount for detection of germ-line SNVs by comprehensive cancer panel on 318chip. A preliminary study using 20 risk for stomach cancer and 8 healthy individuals by 4 barcoded run reveal over 80 percent region covered by X20 coverage. (Mean: 88.03, Range: 81.17-93.46). So, we concluded 4 samples parallel run has sufficient data amount for germ-line SNVs screening. The comparison of germ-line SNVs between risk and healthy control, we identify more frequent unknown variants and non-synonymous germ-line SNVs. These variants need the further evaluation by conventional method to avoid false positive. And also these several common variants in risk group but not in healthy group are further validating in the expanded risk and healthy population. The ability to examine 409 high-profile genes at once empowers that researchers may realize a more complete picture of the genetic variation that associated with cancer risk in a restricted population.

3325T

A support vector machine classifier for estrogen receptor positive and estrogen receptor negative early-onset breast cancer. *R. Upstill-Goddard[1], D. Eccles[1], S. Rafiq[1], W. Tapper[1], J. Fliege[2], A. Collins[1].* 1) Human Genetics and Cancer Sciences, Faculty of Medicine, University of Southampton, Duthie Building (Mailpoint 808), Southampton General Hospital, Tremona Road, Southampton, SO16 6YD, United Kingdom; 2) Centre for Operational Research, Management Science and Information Systems, University of Southampton, Mathematics Building (54), Highfield Campus, Southampton, SO17 2JL, United Kingdom.

A major breast cancer subtype distinction depends upon the expression of receptors for the hormone estrogen on tumour cells. Tumours that express large numbers of estrogen receptors are termed estrogen receptor-positive while cancers expressing few receptors are estrogen receptor-negative. The influence of germline genetic variants on driving the development of either of these cancer subtypes in an individual is poorly understood. A novel approach was used to explore genome-wide single nucleotide polymorphism (SNP) data from breast cancer samples; a machine learning algorithm, called a support vector machine (SVM), was used to build a classification model capable of accurately distinguishing between estrogen receptor-positive and -negative breast cancer cases based on this SNP data. Machine learning methods have seldom been applied to genome-wide data in this way. A sample of 542 breast cancer patients, all of whom were diagnosed before the age of 40, were genotyped for ~500 000 genome-wide SNPs. A subset of 200 SNP variants was selected from the full set of SNPs based on a strong association with the receptor-negative phenotype ($p<0.0005$), determined using a chi-squared association test. Five SVM classification models, each using a different choice of kernel mapping function, were produced from the genotype data for the 200 SNPs in all 542 samples. In all cases classification accuracy exceeded 90%. A set of 139 genes are associated with the subset of 200 SNP variants and are thus implicated in the estrogen receptor phenotype in early-onset breast cancer. Functional classification of these genes identified enrichment for functions of the immune system. This finding is consistent with the role of inflammation in cancer and observations of a particular subtype of estrogen receptor-negative breast cancer that exhibits a good prognosis alongside extensive immune cell infiltration into the tumour site. Further exploration of the influence of SNPs on the estrogen receptor subtype distinction is on going, with particular focus on SNPs in immune system pathways. Understanding the relationship between the underlying patient genome and the process of oncogenesis is critical for the development of appropriate targeted treatment and disease prevention.

3326F

Inversion-mediated gene fusions involving NAB2-STAT6 in malignant meningioma. *C. Ling[1], F. Gao[1], L. Shi[1], G. Zada[1,2], WJ. Mack[1,2], K. Wang[1,3,4].* 1) Zilkha Neurogenetic Institute, Keck School of Medicine,University of Southern California, Los Angeles, USA; 2) Department of Neurosurgery, Keck School of Medicine, University of Southern California, Los Angeles, USA; 3) Department of Psychiatry, Keck School of Medicine, University of Southern California, Los Angeles, USA; 4) Division of Bioinformatics, Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, USA.

Meningiomas are the most common primary intracranial tumors, with ~3% meeting criteria for anaplastic/malignant (WHO grade 3) classification. Despite previous gene expression studies using microarray techniques, gene fusion events in meningiomas have not been reported. In this study, we explored transcriptional gene fusion in three malignant and four benign meningiomas, using the high-throughput RNA sequencing (RNA-Seq) technique. Candidate gene fusions were detected using both TopHat-Fusion and Chimerascan. In one malignant meningioma, we identified an inversion-mediated fusion between two adjacent genes (NAB2 and STAT6) on chromosome 12q13.3, which created two novel in-frame transcripts. Sanger sequencing on both cDNA and genomic DNA was used to validate fusion transcripts and map the exact chromosomal inversion junctions. The fusion of NAB2-STAT6 was localized between the end of exon 6 of NAB2 and the beginning of exon 18 of STAT6, with 98 junction reads identified from RNA-Seq data. The fusion of STAT-NAB2 was supported by 126 junction reads, which connects the last nucleotide of exon17 of STAT6 with the first nucleotide of exon7 of NAB2. Interestingly, the fused exons of STAT6 encoded the transcription activation domain of STAT6, and gene expression of NAB1, NAB2, TGFB1 and CASP9 was up-regulated in the malignant subject compared to other subjects, suggesting a functional role of this gene fusion product in activating transcription of these genes. On the other hand, gene fusion of STAT6-NAB2 is likely to produce a protein product incapable of transcription activation. Expression of the STAT6 downstream target gene BCL2L1 is down-regulated, implying a potential functional effect of STAT6-NAB2 fusion. The NAB2-STAT6 fusion has been recently reported as a recurrent fusion event in solitary fibrous tumors. Thus, the gene fusions detected in our study may play a role in malignant transformation of meningiomas and further investigation with more samples is necessary to understand the cause of genome instability observed.

Copy number gains on chromosome 21 contribute to risk of acute lymphoblastic leukemia in non-Down syndrome children. *A.J. de Smith[1], A.M. Yiorkas[2], R.G. Walters[3], K.M. Walsh[1,4], C. Metayer[5], L.F. Barcellos[5], P.A. Buffler[5], A.I. Blakemore[2], A.P. Chokkalingam[5], J.L. Wiemels[1].* 1) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 2) Section of Investigative Medicine, Imperial College London, London, United Kingdom; 3) Clinical Trial Service Unit and Epidemiological Studies Unit, University of Oxford, Oxford, United Kingdom; 4) Division of Neuroepidemiology, Department of Neurological Surgery, University of California, San Francisco, San Francisco, CA 94143, USA; 5) School of Public Health, University of California Berkeley, Berkeley, CA 94704, USA.

The causes of childhood acute lymphoblastic leukemia (ALL), the most prevalent cancer in children, are largely unknown. Children with Down syndrome have an approximately 20-fold increased risk of developing ALL, suggesting a role for genes on chromosome 21 (Chr21). In this study, we investigated germline copy number variation on Chr21, with the hypothesis that copy number gains in non-Down syndrome individuals may be associated with increased ALL risk. Genome-wide SNP data (Illumina Human OmniExpress array) were available for 305 Hispanic children with ALL and 451 controls matched on age, gender, ethnicity and maternal race, from the California Childhood Leukemia Study (CCLS). Copy number variants (CNVs) were predicted using PennCNV, with default parameters. For quality control, samples with excess log R ratio variance and GC waviness, and CNVs with a PennCNV confidence score <20 were excluded. Cases with Down syndrome were also excluded. Association analysis was carried out in PLINK, with minimum CNV segment length at the default 20kb. We assessed the burden of large copy number gains according to the average number per sample, with a cut-off of 100kb for large and 500kb for very large gains. Case-control association analysis of specific Chr21 copy number gains was also carried out. A total of 1264 copy number gains were detected on Chr21 across all subjects. There was a highly significantly increased rate of large copy number gains (>100kb) in cases (0.744) compared to controls (0.588), with $p = 5.5 \times 10^{-6}$ (Fisher's exact test, one-tailed). The rate of very large copy number gains (>500kb) was also significantly higher in cases (0.049) than controls (0.007) ($p = 2.1 \times 10^{-4}$). A common copy number gain at the *SLC19A1* locus was nominally associated with increased ALL risk, with 75.1% cases carrying this CNV compared to 67.6% controls (odds ratio = 1.44, 95% CI: 1.04-2.00, p = 0.028). *SLC19A1* is involved in regulation of intracellular levels of folate, which is required for DNA repair and methylation, and previous studies suggest folate pathway genes may play a role in childhood ALL susceptibility. Results of this study suggest that large copy number gains on Chr21 contribute to risk of ALL in children without Down syndrome. Identifying Chr21 genes associated with childhood ALL should provide insight into the etiology of this disease, and may help to explain the increased risk of ALL in children with trisomy 21.

3328T

A Case of Hyperdiploidy in CLL/SLL: A Rare Cytogenetic Event Associated with Poor Prognosis. *M. DeNicola, S. Pullakat, S. Yea, P. Delgado, L. Yang, N. Rao, C.A. Tirado.* Pathology & Laboratory Medicine, UCLA, Los Angeles, CA., USA.

Hyperdiploidy has been described in a variety of malignancies including acute lymphoblastic leukemia and plasma cell myeloma, in which the abnormality is associated with a very good prognosis. Herein we describe a 61 year-old female who presented with an eleven month history of enlarging lymph nodes in her neck. A CT scan revealed bulky confluent lymphadenopathy in the left neck involving stations 2-5 with extension into the superior left mediastinum, enlarged lymph nodes in the right neck involving stations 2B and 5, and a large soft tissue density overlying the left occipital bone measuring 9 cm in maximum dimension. She denied fevers, chills, or night sweats, but did endorse mild fatigue. Her WBC count was 4,900/uL with a differential of 55% neutrophils, 33.7% lymphocytes, and 9.2% monocytes. The hemoglobin was 8.5gm/dL, platelets 227,000/mcL, ESR 38, and LDH 212. SPEP showed two IgM kappa monoclonal proteins. A core biopsy of the left neck mass showed infiltration of the lymph node by atypical lymphoid cells with slightly irregular nuclei, condensed chromatin, and medium amounts of cytoplasm. The atypical lymphoid cells expressed CD19, CD20, PAX5, CD5, BCL2, and IgM with a Ki67 of 10%; the cells were negative for CD10, CD23, BCL1, BCL6, and IgD. Flow cytometry revealed a monotypic B cell population with kappa light chain restriction and co-expression of CD20 and CD5. Molecular pathology studies were positive for clonal B-cell gene rearrangement. While consideration was given to nodal marginal zone lymphoma, a final diagnosis of atypical chronic lymphocytic lymphoma (CLL) was made. The initial chromosome analysis showed an abnormal karyotype described as 46-48,XX,add(3)(q12),+16,+mar[cp3]/46,XX[1]. A second karyotype a week later showed a hyperdiploid clone described as : 46,X,-X,-3,-6,+7,+9,-14,-15,+16,+17,+17,+20,-22[1]/46,XX[19]. Concurrent FISH studies using the CLL FISH panel showed with an extra copy of chomosome13 and an extra copy of the short arm of chromosome 17. FISH for t(11;14) was negative. These results suggest the presence of an underlying complex hyperdiploid karyotype. Hyperdiploidy is a rare event in SLL/CLL and it is usually associated with a poor prognosis.

3329F

The cytogenetic landscape and downstream consequences in 16,172 cancer samples. *L. Franke[1], R.S.N. Fehrmann[2], J. Karjalainen[1], L. de Vries[2], M. van Vugt[2], C. Wijmenga[1].* 1) Department of Genetics, University Medical Centre Groningen, University of Groningen, Groningen, Netherlands; 2) Department of Oncology, University Medical Centre Groningen, University of Groningen, Groningen, Netherlands.

With the growing public availability of gene expression data, integration and re-analysis of thousands of samples has the potential to discover new patterns that yield important novel biological insight. We integrated gene expression profiles from 77,840 samples (human, mouse and rat) to identify 2,206 'transcriptional components' (TCs) that explain the major regulators of gene expression. These TCs in combination with a 'guilt-by-association' approach allowed us to predict biological functions of individual genes, identifying and experimentally proving FEN1 as an essential homologous recombination repair gene. Many of these TCs describe metabolic, physiological and cell-type specific differences. Surprisingly, upon correcting expression data of 16,172 primary tumor samples for these TCs, we oberved that the residual expression signals accurately reflected somatic copy number aberrations (SCNAs), thereby revealing the cytogenetic landscape in these tumors. A genome-wide association study at an unprecedented large scale was performed that resulted in a robust genomic signature that associated individual SCNAs to genomic instability. In addition, analysis of this cytogenetic landscape revealed clear commonalities and differences between different types of cancer. Subsequent expression quantitative trait locus (eQTL) analysis enabled us to link SCNAs to their downstream effects on biological pathways. In summary, our method provides a tool to re-analyze and re-interpret the vast amount of expression data currently available to explore cytogenetic alterations in relation to phenotypic data and to discover new biological functions of genes.

3330W

Genomic copy number signatures uncovered genetically distinct group which is different from Adenocarcinoma and Squamous cell carcinoma of the lung cancer. *E. LEE[1], J. Lee[2], H. Kim[1], B. Shin[1], J. Kim[1], A. Kim[1], B. Kim[1].* 1) Korea university Guro hospital, Seoul, South Korea; 2) Korea university College of medicine.

Adenocarcinoma (AC) and squamous cell carcinoma (SCC) consisting of the most of non-small cell lung carcinoma (NSCLC) have different clinical presentation, morphology, treatment and prognosis. Recent studies suggested that fundamental genetic alterations related to carcinogenesis of each tumor type may be different. In this study, we evaluated the difference of genetic alteration of ACs and SCCs that may be applied for diagnosis of NSCLC. Genomic copy number alterations (CNAS) of 50 primary NSCLC samples (25 ACs and 25 SCCs) as well as paired normal tissue were investigated by using array comparative genomic hybridization (CGH). Common CNAs were evaluated in each subtype and compared each other to establish CNA signature. Total CNAs were more frequently identified in SCCs than ACs. The most common CNAs were gain of 3q in SCCs and 7q in ACs. 44 genes from SCCs and 28 genes from ACs were located in the commonly (> 68%) gained and lost region. The results of gene clustering revealed three clustered groups - Group I: AC, Group II: SCC, and Group III: Genetically distinct another group consisting AC and SCC. The present study characterized genetic differences of the subtype of NSCLC including AC and SCC, which grouped genetically unique and distinct three groups by gene clustering including group III, which has different genetic signature from AC and SCC, but similar histopathology with AC or SCC. The further study of significance of this finding and the possibility of diagnostic application of this genetic marker is necessary.

3331T

The link between the losses of TP53 and ETV6 and del(5q) and/or -7/del(7q) in the progression of myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). *J. Lee[1], R. Zhang[2], Y. Kim[3], X. Wang[3], Y. Li[2], S. Li[3].* 1) Pathology, Korea University, Seoul, South Korea; 2) Department of Hematology, China Medical School, Sheyang, Liaoning, P.R. China; 3) Department of Pediatrics, The University of Oklahoma health Sceinces Center, OK, USA.

-5/del(5q) and -7/del(7q) are the most common chromosomal abnormalities in myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML) and are often accompanied each other with poor prognosis. To evaluate relationship between -5/del(5q) and -7/del(7q) in the different background of acquired genomic alteration, integrated analyses of 26 cases with MDS/AML carrying del(5) and/or -7/del(7) were performed by using karyotype, FISH and array CGH and characterized by grouping; Group I: cases only with del(5q) (6 cases), group II: cases only with -7/del(7q) (11 cases) and group III: cases with concurrent del(5q) and del(7q) (9 cases). The overlapped common deleted region (CDR) of chromosome 5 from group I and III was 5q31.1-33.1 (130,562,020-150,625,216 bp: hg18) with ~29 Mb in size and chromosome 7 from group II and III was 7q31.31-q36.1 (119,547,309-149,033,790 bp: hg 18) with ~29 Mb in size. Total 249 other copy number alterations (CNAs) from the genome except chromosomes 5 and 7, which were ~ 78.3 % of total CNAs (318), were observed. The group III [concurrent del(5q) and -7/del(7q)] is a distinctive entity carrying the most numerous other CNAs, recurrent other CNAs, cryptic CNAs (<5Mb) and complex CNAs. Gains of PDGFD, MLL, ETS1 and ADAMTS8 and/or losses of MANF, TP53 and WRAP53 were highly associated with del(5q) since they are shared in both groups I and III. Whereas loss of ETV6 shown to be specially associated with concurrent del(5q) and -7/del(7q) (group III). Theses CNAs or genes associated with particular group or particular chromosomal abnormality may play secondary role of group specific disease progression and should be further evaluated for their clinical significance and influence on therapeutic approaches in the patient with MDS/AML carrying del(5q) and/or -7/del(7q).

3332F

Targeted genomic DNA and cDNA next generation sequencing identifies a high frequency of kinase gene fusions in Spitz tumors Involving *ROS1*, *ALK*, *RET*, *NTRK1*, and *BRAF*. *K. Wang[1], J. He[1], T. Wiesner[2], G. Otto[1], R. Yelensky[1], MF. Berger[2], R. Esteve-Puig[3], D. Lipson[1], K. Brennan[1], VA. Miller[1], MT. Cronin[1], BC. Bastian[3], PJ. Stephens[1].* 1) Foundation Medicine, Cambridge, MA; 2) Memorial Sloan-Kettering Cancer Center, New York; 3) University of California San Francisco, San Francisco.

Background: Gene fusions that generate chimeric oncoproteins are becoming increasingly important diagnostic markers and drug targets in both hematologic malignancies and solid tumors. However, the development of high throughput methodologies is required to systematically interrogate cancer genomes to characterize gene fusions. We applied targeted genomic DNA and cDNA sequencing to a series of Spitz tumors, a family of melanocytic neoplasms in which biologic behavior which can range from an indolent behavior to widespread metastatic disease, to gain insights into the genetic underpinnings of the poorly understood disease. **Methods:** Genomic DNA and total RNA was isolated from formalin fixed paraffin embedded (FFPE) tissue samples from 20 benign Spitz nevi and 8 atypical Spitz tumors (with morphological features inconsistent with *HRAS* or *BRAF/BAP1* mutation). DNA sequencing was performed for 3,230 exons of 182 cancer-related genes plus 37 introns of 14 genes commonly fused on indexed hybridization-captured libraries to an average unique coverage of 997x, with 99.96% of exons being sequenced at ≥100x coverage. RNA sequencing was performed on indexed libraries captured using the cDNA Kinome hybridization kit (Agilent) generating >50,000,000 unique pairs per specimen. **Results:** Genomic rearrangements were observed in 19/28 (68%) Spitz tumors with only a single known somatic point mutation in *HRAS* detected. The rearrangements fused the intact tyrosine kinase domains of *ROS1*(36%), *ALK*(14%), *RET*(7%), *NTRK1*(7%), and *BRAF*(4%) to a wide range of predominantly novel 5'partners including *PWWP2A, PPFIBP1, ERC1, MYO5A, CLIP1, HLA-A, ZCCHC8, DCNT1, LMNA* and *CEP89*. These gene rearrangements formed constitutively activated chimeric oncogenes that activated oncogenic signaling pathways. All fusions occurred in a mutually exclusive pattern and were more common in younger patients compared to patients whose tumors did not harbor fusions (median age 14 versus 24 years, p=0.02). **Conclusions:** Targeted genomic DNA and cDNA sequencing can be applied to cancer genomes to identify both known and novel gene fusions which may be useful as diagnostic markers and therapeutic targets but thorough analytic validation to determine accuracy is required prior to routine use in the clinic.

3333W

A rare case of de novo AML with basophilic differentiation and abnormal cytogenetics with tetraploidy and structural abnormalities in a 50-year-old male. *A. Yenamandra[1], F.C. Wheeler[1], D. Zalepa[1], A. Gardner[1], M. Guanchez-Lopez[1], M.A. Thompson[1], J. Douds[1], S. Mohan[2], A. Shaver[1].* 1) Dept. of Pathology, Immunology and Microbiology, Vanderbilt University Medical Center, Nashville, TN 37203; 2) Div. of Hematology and Oncology, Dept. of Medicine, Vanderbilt University Medical Center, Nashville, TN 37203.

Massive hyperdiploid and tetraploid karyotype with structural abnormalities has been reported to be rare in de novo AML and MDS especially in male patients. These patients have been reported to have a low remission rate and short survival and define a prognostically unfavorable cytogenetic group in de novo AML (Iyer, RV et al., Cancer Genet and Cytogenet. 1; 148(1):29-34, 2004 and Bene, MC et al., Leukemia 20-725, 2006). We report a 50-year-old male with a history of diabetes who presented with pancytopenia, neutropenia, and worsening hypoxemia, ultimately requiring intubation and transfer to the MICU in March 2013. He was diagnosed with AML on the basis of increased blasts in his peripheral blood smear (sample collected 03/09/13). His bone marrow biopsy (sample collected 03/11/13) was markedly hypercellular with 80-90% cellularity and was involved by AML by morphology (48.5% blasts) and immunophenotype. The blasts were remarkable for large, basophilic granules, and a range of immature basophils were seen in the background. Blasts had an immunophenotype suggestive of basophilic differentiation (CD13+, CD33 moderate, CD34+, CD117-, CD123+). Molecular genetic studies were negative for KIT Asp816Val mutation, FLT3 ITD, or mutations in CEBPA or NPM1. Both peripheral blood and bone marrow samples revealed an abnormal karyotype with tetraploid chromosomal complement and structural anomalies of chromosome 1 and 12. His karyotype was 92,XXYY,dup(1)(q21q32)x2,del(12)(q24.1)[10]/46,XY[10]. Fluorescence in situ hybridization (FISH) for AML and MDS (5,7,8,20,t(8;21), t(15;17), inv(16) and MLL) probes on the bone marrow sample (03/11/13) revealed 4 copies for all the target regions tested. His bone marrow on 03/27/13 on day 14 of induction with HiDAC and etoposide revealed residual acute myeloid leukemia, with persistent blasts that demonstrated more prominent basophilic differentiation and increased background basophilia, as well as persistence of the abnormal tetraploid clone. There was a decrease in the percentage of cells with the abnormal karyotype, as well as a decreased percentage of blasts, compared to the previous bone marrow biopsy. Reinduction chemotherapy was administered and most recent follow up bone marrows were negative for leukemia by morphology and cytogenetics. Acute basophilic leukemia is an extremely rare subset of AML, and tetraploid karyotype is a rare cytogenetic finding; the combination of these two findings is unique in the literature.

3334T

Complex karyotype in a patient with AML-M1. *L. Bobadilla-Morales[1,2], C. Ortega-de la Torre[1,2], HJ. Pimentel-Gutiérrez[1], C. Barba-Barba[2], M.C. Almodóvar-Cuevas[2], G. Serafín-Saucedo[2], G. Macías-Salcedo[2], M.E. Velázquez-RiverA[2], A. Márquez-Mora[2], S. Gallegos-Castorena[3], F. Sánchez-Zubieta[3], A. Corona-Rivera[1,2].* 1) Laboratorio de Citogenética Genotoxicidad y Biomonitoreo, Instituto de Genética Humana 'Dr. Enrique Corona Rivera' Biol Molecular Genomica, Univ Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) Unidad de Citogenética, Servicio de Hematología Oncología Pediátrica, División de Pediatría, Nuevo Hospital Civil "Dr. Juan I. Menchaca', Guadalajara, Jalisco, México; 3) Servicio de Hematología Oncología Pediátrica, División de Pediatría, Nuevo Hospital Civil "Dr. Juan I. Menchaca', Guadalajara, Jalisco, México.

Purpose: We present the cytogenetic findings in a patient with acute myeloblastic leukemia-M1 (AML-M1) at diagnosis. Clinic Presentation: We present a case of a 1 year old male, who presented a tumor in the right side of the neck of approximately 8cm by 10cm size; it was multilobed, without pain and no erythema or heat. In the left side he had nodes smaller than 1 cm size. In inguinal area there was multiple nodal growth of 1 to 3cm diameter. TAC study reported neck solid lesion on the right side. Bone marrow had decreased cellularity, no megakaryocytes, 92% blasts, which were large with abundant chromatin, visible nucleoli and cytoplasm with abundant inclusions. The diagnostic was AML-M1. Method: In cytogenetic studies were performed cultures with RPMI1640 and additives, and marrow max culture media. Conventional cytogenetic study in bone marrow showed a trisomy 8, a rearrangement involving chromosomes 10 and 12, and a marker chromosome that seemed that had chromosome 11 material. For that reason Fluorescent in situ hybridization (FISH) was performed for MLL (Vysis LSI MLL Dual Color, Break Apart Rearrangement Probe), AML1/ETO (Vysis RUNX1/RUNX1T1 DF FISH Probe Kit), ETV6/RUNX1T1 (Vysis LSI ETV6(-TEL)/RUNX1(AML1) ES Dual Color Translocation Probe Set), and finally performed whole chromosome painting (WCP) of 11 and 12 chromosomes (Kreatech). Results: The preliminary karyotype result was: 47,XY, +8,t(10;12)(p11.2;21),-11,+mar. The FISH results were disruption of MLL gene (nuc ish(MLLx2)(5'MLL sep 3'MLLx1)[207/300]) and an extra signal of ETO gene (nuc ish(ETOx3,AML1x2)[59/200]). And Finally the WCP results were: ish t(10;12)(p11.2;q21)(wcp12+),inv(11)(pter->p11.2::q23->p11.2::qter)[cp30]. Conclusions: With all previous data we concluded that there was a trisomy 8, a pericentric inversion of chromosome 11 involving MLL gene and a translocation between chromosomes 10 and 12. All this showed the final result as 47,XY,+8,t(10;12)(p11.2;21), inv(11)(pter->p11.2::q23->p11.2::qter).ish t(10;12)(p11.2;q21)(wcp12+),;),inv(11)(pter->p11.2::q23->p11.2::qter)(wcp 11+)[cp30]. This results stress the importance of an integrated analysis between different methods especially in complex karyotypes. Unfortunately the patient died after influenza disease, and it was impossible to make an association between prognosis and karyotype.

3335F

Single chromosome contribution to karyotypic evolution in tumor formation and metastases. *J. Brown[1,2], B. Flynn[1], C. Obergfell[1], M. Longo[1], M. O'Neill[1], R. O'Neill[1], Peromyscus Genetic Stock Center.* 1) Molecular and Cell Biology, University of CT, Storrs, CT; 2) Allied Health Sciences, University of CT, Storrs, CT.

Genetic lesions that contribute to the progression of cancer from a primary tumor to metastases often involve a complex process of chromosome evolution, either progressive or catastrophic; however, the primary factor(s) that precede complex rearrangements remain largely unknown. As a model to investigate the mechanisms that drive metastatic potential, an inbred line of *Peromyscus leucopus* was isolated that carries a high frequency of malignant Harderian gland tumor formation, which immediately and predictably metastasizes to the lymphatic system, lungs and liver. Employing fluorescence *in situ* hybridization we have identified a recurrent abnormality, intrachromosomal amplification of Chromosome 5, among three individuals. Deep-sequencing of the microdissected Chromosome 5 has been employed to identify a candidate for the initiation of the primary lesion that contributes to both tumor susceptibility and karyotypic evolution in the metastases. Our *Peromyscus* strain is a highly suitable *a priori* model system in which to further study the mechanistic link between the derivation of distinct chromosomal aberrations in a primary tumor and those in secondary metastases.

3336W

The Impact of Microarray in Diagnosing Pediatric Acute Lymphocytic Leukemia. *C.M. Higgins, D.L. Pickering, M.L. Wiggins, W.G. Sanger, B.J. Dave.* Human Genetics Laboratory, Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE.

Acute lymphocytic leukemia (ALL) is the most common form of childhood cancer representing 23% of cancer diagnoses in children. With current therapeutic regimens, long-term survival can be expected in approximately 80% of pediatric ALL cases; however, up to 20% will remain treatment refractory. Cytogenetics and FISH have been the gold standard for defining genetic abnormalities and facilitating therapeutic stratification of pediatric ALL cases. More recently, microarray studies, which provide higher resolution and genome wide analyses, have identified novel abnormalities that are significant and recurrent with prognostic value; however, the test is yet to be included in the routine clinical diagnostic armamentarium. To better refine the diagnosis and improve prognosis/risk stratification we included microarray in our pilot studies utilizing all three techniques in six newly diagnosed pediatric B-ALL cases. We found abnormalities in all six cases with all three methodologies: cytogenetics, FISH and microarray. Ploidy changes were noted by all three techniques; known ALL-associated and prognostically significant translocations were observed by cytogenetics and FISH; the subtle translocation involving *TEL/AML* (*ETV6/RUNX1*) was detected only by FISH (2 cases); and microarray identified multiple genomic alterations that were either too subtle to be determined by cytogenetics and/or were not included in the standard ALL-FISH panel. Abnormalities determined by microarray alone included *IGH* deletions in 66% (4 cases), *IKZF1* deletions in 50% (3 cases), deletions in *EVI1* in 33% (2 cases), and a deletion of *TP53* in one case. There were overlaps in detection of abnormalities between FISH, cytogenetics and microarray studies. A translocation involving the *EVI1* gene region was determined by cytogenetics but could not be confirmed by FISH. Only microarray detected the microdeletion within the *EVI1* region. One hyperdiploid case exhibited a deletion of *TP53* which was deciphered by microarray and confirmed by FISH. These abnormalities that are known to confer poor prognosis, including the *IKZF1* deletions, would not have been apparent without using a combination of all three techniques. Our studies suggest that consistent use of combined testing may play a critical role in the state of the art diagnosis, and subsequently assist in therapeutic stratification to determine treatment regimens that are most appropriate for the disease state of these young patients.

3337T

Molecular characterization of der(1)t(1;19) in a patient with myelodysplastic syndrome. *J. Kim[1], J. Choi[2], J. Choi[3], Y. Kim[3], K. Lee[3,4].* 1) Lab Med, Yonsei University Wonju College of Medicine, Wonju, South Korea; 2) Pathology, Yonsei University Wonju College of Medicine, Wonju, South Korea; 3) Lab Med, Yonsei University College of Medicine, Seoul, South Korea; 4) Corresponding.

Translocation (1;19)(q23;p13), creating a fusion between *E2A* and *PBX1* genes, is a chromosomal rearrangement associated with childhood pre-B cell acute lymphoblastic leukemia (ALL), which is detected in about 5% of pediatric patients diagnosed with ALL. In contrast, rare case of der(1)t(1;19)(p13;p13.1) has been reported in mostly myeloid neoplasia or myelodysplastic syndrome (MDS). Only about 9 cases of such translocation have been reported in the literature and the specific break point has not been studied. Here, we report a case of t(1;19)(p13;p13.1) in a MDS patient and the characterization of the breakpoint by using conventional karyotyping, multicolor FISH and SNP array. The karyotyping reavealed 47,XX, +der(1)t(1;19)(p13;p13.1) in 20 metaphase cells, and involvement of chromosome 1 and 19 and the breakpoint was confirmed by multicolor FISH. In order to refine the breakpoint region, Affymetrix Cytoscan 750K array was carried out, and gain in the region of 1q21.2q44 (143,932,349-248,660,805) and 19p12p13.3 (260,911-24,177,726) was found, indicating a whole arm translocation. Because it is a rare chromosomal rearrangement but found recurrently in a subset of myeloid neoplasms, the possible role of such unbalanced whole arm translocation in the leukemogenesis and the possibility of gene involved in such chromosomal rearrangement need to be determined.

3338F
Characterization of Uterine Leiomyomas by Whole-genome Sequencing. *M. Mehine[1], E. Kaasinen[1], N. Mäkinen[1], R. Katainen[1], K. Kämpjärvi[1], E. Pitkänen[1], H. Heinonen[1], R. Bützow[2], O. Kilpivaara[1], A. Kousmanen[1], H. Ristolainen[1], M. Gentile[4], J. Sjöberg[3], P. Vahteristo[1], L. Aaltonen[1].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Pathology, Haartman Institute, University of Helsinki, Helsinki, Finland; 3) Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland; 4) CSC-IT Center for Science, Espoo, Finland.

Uterine leiomyomas are benign but impact the health of millions of women. We performed whole genome sequencing and expression profiling of 38 leiomyomas and corresponding myometrium from 30 patients. We detected complex chromosomal rearrangements (CCRs) resembling chromothripsis in our leiomyoma samples. CCRs appears to be an unexpectedly frequent phenomenon in myometrium and had occurred in the presence of normal TP53 alleles. These rearrangements are best explained by a single event of multiple chromosomal breaks and random reassembly, and had created tissue-specific driver changes such as rearrangements between HMGA2 and RAD51B loci, aberrations at the COL4A5/COL4A6 locus and interstitial deletions on chromosome 7. In some cases we found that CCRs had occurred more than once in single tumor cell lineages. We also found multiple separate tumor nodules to be clonally related. This could in part explain the common occurrence of synchronous lesions in affected uteri. Further work should examine whether the mechanisms underlying CCRs are identical to those causing chromothripsis.

3339W
Fluorescence in situ hybridization (FISH) on abnormal metaphases helps unmask the location of hidden genes/genomic segments in cases with abnormal karyotypes and abnormal FISH panels. *N. Mitter.* Cytogenetics and FISH Labs, Dianon Pathology (Lab Corp), Shelton, CT.

Some complex rearrangements result in an ‘apparent’ loss of some chromosome segment or a chromosome rearrangement not detectable by classic cytogenetics analysis; but a limited FISH analysis shows the presence of two or more copies of the apparently missing chromosome segment or the splitting of a gene at a breakpoint involved in a ‘masked’ chromosome rearrangement. Microarray analysis can confirm the copy number variations for all genomic regions, but it cannot point the location of these masked/ apparently missing regions. In such cases, a FISH analysis with appropriate probes on the cytogenetically abnormal looking metaphases comes to the rescue. We describe here two such cases, where in each case it was cytogenetically a real puzzle compared to the FISH panel studies, but metaphase FISH analyses solved these puzzles. In the first case, fifteen of the twenty cells examined had only one copy of a normal chromosome 5 but also a copy of chromosome 14 with apparent genetic material from the long arm of chromosome 5 attached to its short arm, and presence of extra genetic material of indeterminate origin on a few other chromosomes. FISH results for MDS panel, however, revealed not only a loss of EGR1 gene, but also two normal signals for genes on 5p (D5S23 and D5S721). The cytogenetic analysis by itself had failed to identify the location of the second 5p. Follow-up FISH analysis on the karyotyped metaphases revealed the presence of chromosome 5 short arm material (band 5p15.2) inserted in the long arm region of chromosome 5 with a deletion of EGR1 gene at band 5q31. This implies a two-break event for chromosome 5 (most likely a pericentric inversion followed by an unbalanced translocation to the short arm of chromosome 14, resulting in presence of two copies of the probed short arm region, as well as del(5q). This analysis, therefore, also helped in understanding the series of events that led to the unique FISH panel results. In second case, there was only one ‘normal’ copy of chromosome 3, along with presence of a long segment of extra genetic material on chromosome 11, besides other abnormalities. Add(11q) material had a complex banding pattern. FISH analysis for BCL6 gene revealed presence of three copies of the gene but the location of two copies was not apparent. Follow-up metaphase FISH analysis revealed presence of two copies of BCL6 gene next to each other on add(11q) material, indicating a duplication of 3q segment.

3340T
SNP Chromosomal Microarray Analysis with DNA extracted from Carnoy's fixed cell pellets of Myelodysplastic Syndrome (MDS)/Acute Myeloid leukemia (AML). *N. Rao, D. Cherukuri, I. Amarillo, F. Quintero-Rivera.* Department of Pathology & Laboratory Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA.

SNP chromosomal microarray analysis (SNP-CMA) is an important tool in detecting copy number changes and loss of heterozygosity (LOH) in patients with inherited genetic disorders and in various cancers. The common protocol for SNP-CMA testing requires DNA extraction from fresh tissue samples. Carnoy’s fixed cell pellets are typically available after routine karyotype and FISH studies for any additional studies. In this pilot study, we wanted to determine the concordant/ discordant results from karyotype/ FISH and with SNP-CMA obtained using the Affymetrix Cytoscan® HD and Agilent CytoGenomics array platforms with DNA extracted from Carnoy’s fixed cells. For this study twelve specimens from patients diagnosed with MDS or secondary AML and with abnormal karyotype and/or FISH results, were selected. Our observations indicate that SNP-CMA is superior to karyotype/FISH in detecting LOH regions. However, routine FISH/karyotype is more sensitive than SNP-CMA for the detection of small clones, such as in cases with 2 abnormal metaphases or with 8% abnormal interphases, both of which are clinically relevant for monitoring of residual/recurrence disease or its progression. Copy number changes were accurately detected with either of the array platforms when the chromosomal abnormalities are present in 30% of the cells analyzed. SNP-CMA analysis detected additional chromosomal aberrations in 4 of the 12 cases. However, these aberrations did not change the cytogenetics prognostic score. In the second part of our study, we performed SNP-CMA in 8 MDS cases (< 19% blast) but with normal karyotype/ FISH results. There were no cases with copy-neutral loss of heterozygosity (CN-LOH) of >5 Mb, but one showed a pathogenic deletion. Our data suggest that DNA extracted from Carnoy’s fixed pellets is a reliable source for identification of CNVs and CN-LOH by SNP-CMA. The diagnostic yield in MDS patients with normal karyotype/FISH is increased by 12.5% with SNP-CMA testing. In conclusion, our study shows the utility of SNP-CMA with DNA extracted from Carnoy’s fixed pellets as a reflex test in patients diagnosed with MDS with a normal karyotype/FISH. This is especially useful in a clinical setting where it can prevent the need for a repeat or fresh bone marrow biopsy and the patient’s re-evaluation. Such studies will also aid in the identification of additional genomic aberrations that can have an impact on the molecular sub-classification, treatment or prognosis.

3341F
Genomic aberrations in myeloid sarcoma (MS): characterization of formalin-fixed paraffin-embedded (FFPE) samples by whole-genome SNP arrays and next-generation sequencing. *M. Sukhanova[1], K.M. Mirza[2], Z. Li[1], F. Stolzel[4], K. Onel[3], M.M. Sasaki[3], P. Reddy[2], L. Joseph[2], G. Raca[1].* 1) Department of Medicine, The University of Chicago Medical Center, Chicago, IL; 2) Department of Pathology, The University of Chicago Medical Center, Chicago, IL; 3) Department of Pediatrics, The University of Chicago Medical Center, Chicago, IL; 4) Medizinische Klinik und Poliklinik I, Universitatsklinikum Carl Gustav Carus, Dresden, Germany.

Genetic abnormalities in tumor cells are the strongest prognostic indicator for response to therapy and survival in patients with acute myeloid leukemia (AML). However, when AML presents as a tumor of malignant granulocytic precursor cells localized outside of the bone marrow (so-called myeloid sarcoma), it initially does not get recognized as a hematologic malignancy, and fresh tumor samples do not get obtained for cytogenetic and molecular testing. FFPE tissue is often the only available specimen type for analysis of MS. The purpose of this study was to determine whether the analysis of FFPE samples using whole-genome SNP arrays and next-generation sequencing (NGS) allows detection of genetic abnormalities of prognostic significance in MS. We analyzed five cases of MS without BM involvement, where cytogenetic and molecular studies were either not available, or did not identify prognostically significant genetic abnormalities. Array testing was performed using CytoScan HD array (Affymetrix Inc., Santa Clara, CA). Targeted resequencing of AML associated genes was performed on the Personal Genome Machine (PGM) from Ion Torrent (Life Technologies, Carlsbad, CA), with two custom primer sets (AML and MDS panel) designed to amplify coding regions of 19 genes associated with myeloid malignancies. Somatic, disease-associated genetic abnormalities were identified in all tested samples. Additionally, aberrations of clear prognostic significance were observed in four out of five cases. In two cases array analysis detected multiple unrelated copy number abnormalities and LOH events; the presence of numerous aberrations is analogous to a complex karyotype, which is associated with a very poor prognosis in AML. Additional two cases showed an NPM1 mutation without a concomitant FLT3-ITD, a combination associated with a favorable prognosis. In conclusion, array analysis and NGS using FFPE samples revealed previously unidentified disease-associated genetic abnormalities in all five samples of MS, and in four cases provided information that would have been of major prognostic importance if available at the time of diagnosis. Whole-genome arrays and NGS are becoming increasingly available in the clinical setting, and should be used for detection of prognostic genomic aberrations in MS in the absence of fresh material for cytogenetic studies.

3342W

A case of pediatric acute lymphoblastic leukemia presenting with a (9;12) translocation involving *JAK2* and rearrangement of *MLL* at 11q23 with an apparent insertion at 6q27. *C. Tirado, M. DeNicola, D. Rao, P. Delgado, A. Jarrin, L. Yang, N. Rao.* Pathology & laboratory Medicine, UCLA, Los Angeles, CA.

Acute lymphoblastic leukemia (B-ALL) is the most common malignancy in pediatric patients and the leading cause of cancer-related death in children and young adults. Herein we present a 13-year-old boy who presented with abdominal pain for three months and transient fevers over the last three weeks. On presentation, he was found to have leukocytosis (WBC 76.5 × 10^3/uL), anemia (hemoglobin 5.3 g/dL), and thrombocytopenia (platelet count 15.3 × 103/uL). A differential count showed 94% blasts which expressed CD34, bright CD10, CD19, partial CD20, partial CD38, partial TdT, CD79a, and HLA-DR by flow cytometry. A bone marrow biopsy was performed, and showed a hypercellular marrow extensively involved (~95%) by sheets of lymphoblasts with irregularly shaped nuclei, immature chromatin, and occasional cells with vacuolated cytoplasm. The immunophenotype of the blasts was the same as that found in the peripheral blood. A diagnosis of B-lymphoblastic leukemia was rendered. Chromosome analysis of the bone marrow showed 5/20 cells examined with an MLL insertion on 6q27 and a balanced translocation between 9p24 and 12p11.2. This findings were confirmed by metaphase FISH. The karyotype was described as : 46,XY,ins(6;11)(q27;q23q23),t(9;12)(p24;p11.2)[5]/46,XY[15]. FISH analysis using interphase nuclei also showed MLL rearrangement: *MLL* (11q23) split signals in 23.6% (71/300) of the nuclei examined, suggestive of an *MLL* (11q23) gene rearrangement . Additionally, deletion of the 5' *IGH@* region, corresponding to the variable segment in 88.3% (265/300) of the nuclei analyzed, was observed, suggestive of a deletion or an unbalanced rearrangement involving chromosome 14q32. These findings were described as: nuc ish(MLLx2)(5'MLL sep 3'MLLx1)[71/300] nuc ish(3'IGH@x2,5'IGHx1)(3'IGH@ con 5'IGH@x1)[265/300] . Rearrangements of 9p24 usually involving *JAK2* (confirmed by FISH) induce dimerization or oligomerization of *JAK2* without ligand binding, resulting in constitutive activation of *JAK2*, and are seen in B- Acute lymphoblastic leukemia (B-ALL) [1]. Rearrangements of the short arm of chromosome 12 are also seen in B-ALL. Correlation with other clinical and hematological data is required in cases such as this.

3343T

Utility of CD-138 negative fraction for chromosome analysis in Plasma cell dyscrasias (PCD): A novel approach. *G. Velagaleti, G. Mohamed, W. Ehman Jr., C. Mendiola, V. Noronha, V. Ortega.* Dept Pathology, Univ Texas Hlth Sci Ctr, San Antonio, TX.

FISH analysis is superior to chromosome analysis in detecting important prognostic genetic abnormalities in PCD. However, its sensitivity is hampered due to paucity of plasma cells in whole bone marrow and often shows false-negative results when frequency of abnormal cells is below the laboratory's cut-off values. Studies have shown that the abnormality detection rate in enriched plasma cells is greater than unselected plasma cells, but purification techniques are limiting to only FISH when bone marrow volumes are inadequate. The inability to perform chromosome analysis may compromise patient care since chromosome analysis is equally important for detecting non-plasma cell related abnormalities, such as secondary myelodysplastic syndrome or when diagnosis is undefined. To resolve this critical issue and optimize limited quantity received, we designed a study where an immnuno-magnetic CD138 enriched positive selection was used for FISH while the negative fraction was used to retrieve the remaining cellular components (RCC) for chromosome analysis. After validating this approach in a pilot study, we implemented this strategy in 2012 for routine clinical diagnosis in patients with PCD. When there was adequate sample volume available, both whole bone marrow and RCC were used for chromosome analysis. Results showed 100% (96/96) success rate for chromosome analysis using RCC. PCD related genetic abnormalities had concordant results on both FISH from isolated plasma cells and chromosome analysis in 8.3% (8/96) of cases while 4.2% (4/96) of cases showed discordant results. Population variants such as loss of Y chromosome were observed in 6.3% (6/96) of cases. Abnormal karyotypes of myeloid origin or population variants were found both in whole bone marrow and RCC cultures. Karyotypes with PCD related aberrations were seen only in whole bone marrow cultures in 37.5% of the cases (3/8) while the remaining 62.5% (5/8) of cases showed them in both whole bone marrow and RCC cultures. Further analysis of the discordant cases revealed non-myeloma related abnormalities by CA [+8, del(5q), der(9) and del(13q)] while FISH showed either normal or myeloma related abnormalities. Our results confirm the feasibility of retrieving the RCC from the CD138 negative fraction for chromosome analysis and prove to be an innovative strategy for karyotyping in PCD patients with insufficient sample volumes.

3344F

A Unique Rearrangement of PDGFRA and ETV6 in a Three-way Translocation t(4;12;6) in a Patient with Acute Myeloid Leukemia Progressed from Chronic Myelomonocytic Leukemia. *N.M. Guruju, R. García, K. Wison, S. Monaghan, P. Koduru.* Det of Pathology, UT Southwestern medical center, Dallas, TX., USA.

Cryptic deletion at 4q12 leading to fusion between FIP1L1 and PDGFRA is a genetic lesion underlying myeloid neoplasms associated with hypereosinophilia. Reciprocal translocation(s) involving 4q12 leading to fusion of PDGFRA with other partners have also been infrequently reported. Here we report a unique rearrangement of PDGFRA with ETV6 due to a three-way translocation t(4;12;6) in a 70-year-old man. The patient had an 8-month history of chronic myelomonocytic leukemia that was treated with high dose hydroxyurea and azacitidine. He then presented with abdominal swelling and pain and was found to have WBC of 119×109L. Imaging revealed splenomegaly and widespread lymphadenopahty. A needle core biopsy of an abdominal mass revealed a low-grade follicular lymphoma. A bone marrow evaluation revealed acute myeloid leukemia with monocytoic differentiation and low-level involvement by follicular lymphoma. The myeloid blasts expressed CD13, CD33, CD34, CD36, CD45, CD64, CD71, CD117 and HLA-DR. Cytogenetic analysis of bone marrow cells by G-banding demonstrated a 46,XY,t(4;12;6)(q12;p13;q21) karyotype in eighteen of the 20 analyzed cells. By FISH, there was evidence of FIP1LI/PDGFRA (4q12) gene rearrangement by both interphase and metaphase analysis which showed the PDGFRA portion of the probe translocated to 12p13. Further FISH evaluation with the ETV6 break-apart probe revealed the translocation of the 5'-end of the ETV6 gene at 12p13 to chromosome band 6p21. Thus, results from both cytogenetics and FISH studies were consistent with the presence of a PDGFRA and ETV6 rearrangement. Additional studies are necessary to identify the partner at 6p21 that may have fused with ETV6. The PDGFRA/ETV6 fusion has previously been reported in one patient with chronic eosinophilic leukemia, who was responsive to imatinib. In AML, t(4;12)(q12;p13) is a rare recurrent abnormality with CHIC2/ETV6 fusion. One prior reported case of AML with t(4;12) refractory to chemotherapy was unresponsive to imatinib. Similarly, our patient did not respond to imatinib. He also failed subsequently induction chemotherapy with idarubicin and cytarabine. To the best of our knowledge, this is the first reported case showing a three-way translocation involving PDGFRA and ETV6 genes that developed into an acute myeloid leukemia without eosinophilia.

3345W

Detection of the EML4-ALK fusion gene in non-small cell lung cancer (NSCLC): our FISH service to date. *C. Durajczyk[1], D. Massie[1], K. Kerr[2], D. Stevenson[1].* 1) Cytogenetics Department, Aberdeen Royal Infirmary, National Health Service, Aberdeen, Scotland, United Kingdom; 2) Pathology Department, Aberdeen Royal Infirmary, National Health Service, Aberdeen, Scotland, United Kingdom.

The anaplastic lymphoma kinase (ALK) gene, located on 2p23, encodes a receptor tyrosine kinase involved in regulating cell proliferation and survival. Chromosomal rearrangements of the 2p23 locus can result in the production of an ALK fusion gene. One example of this is the EML4-ALK fusion gene, which is thought to be found in 3-5% of non-small cell lung cancers (NSCLC). Tyrosine kinase inhibitors (TKIs) such as Crizotinib (Xalkori, Pfizer) have been identified as potential therapies for EML4-ALK positive NSCLCs. This fusion oncogene therefore represents a significant target for novel treatments, necessitating a robust diagnostic test for evaluation of the ALK gene status in this subset of lung cancer patients. The gold standard method for identification of the EML4-ALK fusion gene is fluorescent in situ hybridisation (FISH) on formalin fixed paraffin embedded (FFPE) tissue sections. The North East of Scotland Cytogenetics laboratory has offered an ALK FISH service since March 2011, using the Vysis LSI ALK Break Apart probe. We have employed a three-tiered testing strategy in conjunction with our Pathology department, which has resulted in a selected cohort of patients tested (36 diagnostic cases) with a high abnormality rate observed (76%). In addition we have also participated in the European Thoracic Oncology Platform (ETOP) Lungscape study which has involved analysing over 40 cases so far. We present details outlining our experience of the service to date, including our technical and analytical experience, as well as examples of different abnormal cases.

Identification of novel Fusion transcripts in ALL patients. *M. Walter[1], C. Schroeder[1], C. Kyzirakos[2], P. Lang[2], M. Sturm[1], P. Bauer[1], O. Riess[1], M. Bonin[1].* 1) Dept Medical Genetics, Inst Human Genetics, Tuebingen, Germany; 2) Pediatric Hematology and Stem Cell Transplantation, Childrens Hospital, Tuebingen.

We describe a general workflow for the identification of tumor specific genetic variants as potential personalized therapeutic targets for the treatment of terminally ill ALL patients. Exom and transcriptome sequencing was performed to identify genetic differences between Tumor and normal tissue. One hallmark of cancer is genetic instability leading to large deletions, duplications or rearrangements, thereby generating novel fusion transcripts. these fusions very often are responsible for disease outbreak or progression. however, besides their important role in tumor biology, these fusions are found exclusively in the tumor and thus represent potential targets for treatment. In our cohort of 10 ALL patients we could identify and validate 5 gene fusion events in 4 samples. All gene fusions were copy number neutral an most likely result from balanced translokations. Three gene fusions were well-known, previously described fusion events in ALL patients. However, even in this very small cohort of 10 samples, we could identify two novel yet undiscribed gene fusions, which have a high probability of being responsible for tumorigenesis underlining the importance of individual tumor characterization.

3347F

Whole Genome Sequencing of Li-Fraumeni Families Reveals Heterogeneous Mutational Signatures. *K. Bhutani[1,4], D. Quarless[2,4], Q. Peng[4], K. Standish[2,4], E. Scott[4,5], S. Head[6], S. Williams[9], T. Kunicki[9], P.B. Hedlund[8], D. Nugent[9], N.J. Schork[3,4,7].* 1) Bioinformatics Graduate Program, University of California San Diego, La Jolla, CA; 2) Biomedical Sciences Graduate Program, University of California San Diego, La Jolla, CA; 3) Department of Psychiatry, University of California San Diego, La Jolla, CA; 4) The Scripps Translational Science Institute, The Scripps Research Institute, La Jolla, CA; 5) Department of Biology, The Scripps Research Institute, La Jolla, CA; 6) Next Generation Sequencing Laboratory, The Scripps Research Institute, La Jolla, CA; 7) Department of Molecular and Experimental Medicines, The Scripps Research Institute, La Jolla, CA; 8) Department of Molecular and Cellular Neuroscience, The Scripps Research Institute, La Jolla, CA; 9) Center for Inherited Blood Disorders, Children's Hospital of Orange County, Orange, CA.

Li-Fraumeni syndrome is a rare, autosomal dominant disease caused by a germline p53 mutation. We report the first human genome-wide investigation of somatic mutations arising in individual carriers of Li-Fraumeni-associated p53 mutations in two unrelated nuclear families. We sequenced eight whole genomes (two children and both parents in each family) using Complete Genomics, Inc technology, and conducted gene expression profiling to characterize the molecular profiles of the family members. The sequence data demonstrate a dramatic increase in somatic mutation rates among carriers of p53 mutations, with Non-negative Matrix Factorization analysis revealing differing mutational signatures between carriers of zinc-finger stabilization and DNA-binding mutations. Additionally, we explored the potential of genomic analyses to influence targeted therapies for individuals using germline sequence, somatic variants, tumor sequence variants, and tumor and blood gene expression profiles.

3348W

A role for telomere length in the genetic etiology of hematological malignancies. *N.B. Blackburn[1], J.C. Charlesworth[1,2], J.R. Marthick[1], T.D. Dyer[2], T.A. Thornton[3], R.J. Thomson[1], E.M. Tegg[4,5], K.A. Marsden[1,4], V. Srikanth[6], J. Blangero[2], R.M. Lowenthal[1,4], S.J. Foote[7], J.L. Dickinson[1].* 1) Menzies Research Institute Tasmania, University of Tasmania, Hobart, Tasmania, Australia; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, Texas; 3) Department of Biostatistics, University of Washington, Seattle, WA; 4) Royal Hobart Hospital, Hobart, Tasmania, Australia; 5) School of Medicine, University of Tasmania, Hobart, Tasmania, Australia; 6) Department of Medicine, Monash University, Melbourne, Victoria, Australia; 7) Australian School of Advanced Medicine, Macquarie University, New South Wales, Australia.

Haematological malignancies (HMs) are blood cancers including leukemia, lymphoma and myeloma. One of the striking features of HMs is their propensity to cluster within families indicating that genetic variation is an important risk factor for disease. Given that telomere length has been shown to be heritable in families and genetic variants are known to influence telomere length it is hypothesised that telomere length contributes, at least in part, to the familial risk of HMs. Telomere length is a known risk factor for a range of cancers with excessive telomere shortening leading to genetic instability and resulting in the malignant transformation of cells. Increasingly telomere biology is being shown to be important in the development of HMs.

Using our Tasmanian familial HMs resource, a collection of large families with multiple cases of HMs, we measured telomere length using the monochrome multiplex quantitative PCR method in 49 familial HM cases, 169 unaffected relatives of familial HM cases, 66 non-familial HM cases and 669 population controls. Variance components modeling of telomere length in SOLAR, taking into account familial relationships, was used to determine factors that contribute to variation in telomere length in the study samples.

Through SOLAR, the heritability of telomere length was calculated to be 64.9% ($P=3.2\times10^{-4}$, SE=0.15) indicating that around 2/3 of the variation in telomere length in these families is influenced by genetics. Adjusting for age and sex we found that overall HM cases had shorter telomeres ($P=7.3\times10^{-6}$) than unaffected relatives and population controls and in contrast to our hypothesis this was observed across both familial (P=0.001) and non-familial HM cases ($P=6.9\times10^{-6}$). This finding supports the involvement of telomere length in the genetic etiology of both familial and non-familial HMs. Most recently we have used SNP data from Illumina 610 Quad arrays from the HM families and a genome wide quantitative trait association analysis using both the QM-QXM method and SOLAR to explore whether genetic variation associated with telomere length in these families is linked to disease. Our work provides further evidence for the role of telomere length in the genetic etiology of HMs.

3349T

Identification of novel mechanisms of drug resistance in BRCA1-deficient cancer cells by exome and RNA sequencing. *K.K. Dhillon[1], T. Walsh[2], S. Gulsuner[2], T. Taniguchi[1,3].* 1) Divisions of Human Biology and Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA; 3) Howard Hughes Medical Institute.

Acquired resistance to platinum-based therapy is an obstacle for effective treatment of ovarian and breast cancers. BRCA1 or BRCA2 loss is commonly observed in these cancers and platinum compounds, such as cisplatin and carboplatin, are initially effective for the treatment of BRCA-deficient cancers. We have shown that re-expression of BRCA1/2 due to secondary BRCA1/2 mutations in recurrent ovarian cancers is associated with platinum resistance. However, restoration of BRCA1/2 does not account for all occurrences of platinum resistance. Therefore, we hypothesize that restoration of DNA repair even in the absence of functional BRCA1/2 may lead to platinum resistance in cancer cells. To test this hypothesis, we developed an in vitro model of cisplatin resistance using the BRCA1-mutated breast cancer cell line, HCC1937. We generated cisplatin-resistant clones by culturing cells in cisplatin. Surprisingly, none of the resistant clones showed BRCA1 re-expression or secondary BRCA1 mutations. However, consistent with our hypothesis, a subset of clones restored DNA damage-induced foci formation of CtIP, RAD51 and FANCD2, which are required for DNA repair and normally require functional BRCA1. To identify mechanisms of cisplatin resistance, we performed exome and RNA-sequencing of parental HCC1937 cells and four cisplatin-resistant clones. Data from cisplatin-sensitive HCC1937 parental cells were used as a baseline to identify genetic and expression variations unique to cisplatin-resistant clones. We found that a subset of DNA repair genes is differentially expressed in cisplatin-resistant clones that have restored DNA repair foci. In the non-DNA-repair-foci-restored clone, we identified missense mutations in RAD18 and XPC, genes involved in translesion synthesis and nucleotide excision repair, which are critical for cellular resistance to cisplatin. Additionally, we observed global up-regulation of a vast majority of histone genes across all cisplatin-resistant clones, suggesting that changes in DNA packaging may contribute to cisplatin-resistance. Currently, we are conducting functional studies to assess the role and mechanism of these observed changes in cisplatin resistance. In summary, our studies showed that altered expression of DNA repair genes and histones may lead to restoration of DNA repair and cisplatin resistance in BRCA1-deficient cancer cells.

3350F

Rhabdoid tumour in a 13 year old with Ring 22: A special case of the two-hit hypothesis. *H. Druker[1, 2, 4], L. Zahavich[1], D. Malkin[1, 3, 4, 5], S. Meyn[1, 2, 3, 5, 6].* 1) Cancer Genetics Program, Hospital Sick Children, Toronto, ON, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Department of Paediatrics, University of Toronto, Toronto, ON, Canada; 4) Division of Oncology, Hospital for Sick Children, Toronto, ON, Canada; 5) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 6) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada.

We present a case of a severely developmentally delayed, hypotonic child with dysmorphic features and a de novo ring chromosome abnormality, 46,XX,r(22)(p11.1q13.2), who developed an abdominal rhabdoid tumour at 13 years of age. We propose a genetic mechanism and surveillance considerations for individuals with ring chromosome 22. Rhabdoid tumour syndrome is caused by germline mutations in SMARCB1, a tumour suppressor gene located at 22q11.2. Classically, young children with a germline SMARCB1 mutation have a high risk for developing atypical teratoid rhabdoid tumours of the central nervous system as well as renal and extra-renal rhabdoid tumours. Imaging is suggested for SMARCB1 mutation carriers from birth until four to six years of age for early detection and improved prognosis. Ring chromosome 22 is a rare human constitutional cytogenetic abnormality. Karyotype and FISH analyses of the patient's blood revealed an imbalance consistent with monosomy for chromosome region 22q13.2 to 22qter but retention of the SMARCB1 gene (22q11.2) within the ring. FISH and microarray analyses of tumour tissue revealed a total loss of SMARCB1 and flanking genes in the first allele and a partial deletion of SMARCB1 in the second allele (exons 6-9). Our findings are consistent with a specific modification of the classic two hit model of tumourogenesis in which the first hit is somatic loss of the unstable ring chromosome during mitosis. In those somatic cells that have lost the ring chromosome 22, a mutation in the SMARCB1 gene on the remaining chromosome 22 (the second hit) can result in tumour development. This mechanism has been previously proposed in relation to patients with ring chromosome 22 who developed NF2 associated tumours. Increased tumour risks have also been observed in carriers of other constitutional ring chromosomes, such as r(11) and Wilms' tumour (WT1) and r(13) and retinoblastoma (RB1). We conclude that tumours can arise by biallelic loss of a tumour suppressor gene through the combination of loss of a ring chromosome carrying the gene and a pathogenic second mutation. Our findings suggest that patients with a ring chromosome 22 should be monitored for SMARCB1 and NF2- related tumours, and possibly CHEK2-related tumours. As the timing of the loss of the ring may be unpredictable, surveillance should be considered in these individuals beyond what is normally considered as an appropriate age cut-off.

3351W

ATM and MDC1 independently modulate resection of DNA Double-Strand Breaks for Homologous Recombination Repair in Human Cells.
P.S Bradshaw[1,2], M. Komosa[1], M.S Meyn[1,2]. 1) Dept Gen & Genomic Biol 15-601F, Sick Kids Res Inst, Toronto, ON, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Canada.

Ataxia-Telangiectasia (A-T) is a human multisystem genetic disorder caused by mutation in the ATM gene and characterized by progressive ataxia, immunological defects, radiation sensitivity, cancer predisposition and genomic instability. Current models suggest that the ATM protein plays a major role in the activation of the cellular DNA Damage Response (DDR) following detection of DNA Double Strand Breaks (DSBs). Establishment of a protein platform encompassing megabase regions of modified chromatin distal to the DSB thought to facilitate the ATM-mediated DDR. We find that the ATM protein is not a member of the megabase protein platform. ATM belongs to a novel class of DDR proteins whose spatial-temporal behavior following DSB induction differs from members of the megabase protein platform and from proteins directly involved HRR. Following DNA damage induction ATM rapidly, but transiently, localizes to sites of DSBs and forms small discrete foci at damage sites that, unlike foci of γH2AX and Mre11, do not diffuse across megabase chromatic regions. While MRN is required for ATM foci formation, ATM and MDC-1 independent MRN foci do not co-localize 1 hour post-irradiation, suggesting that MRN is not required for the retention of ATM at sites of DSBs. DNA damage-induced ATM foci do not co-localize with foci of the HRR-associated proteins RPA and Rad51, suggesting that ATM is associated with unresected DSBs and may not play a direct role in HRR after DSB resection has begun. RPA Ionizing Radiation Induced Foci (IRIF) in ATM- cells are of normal intensity but fewer in number. This effect is dependent on CtIP, a protein implicated in DNA resection and a target for ATM phosphorylation. In addition, depletion of CtIP in ATM+ cells results in a decrease in the number of both RPA and Rad51 IRIF and an increase in ATM IRIF. Taken together, these data support a model where ATM-mediated activation of CtIP initiates resection followed by generation of RPA-coated single-stranded DNA and the concomitant displacement of ATM from DSB sites. While loss of ATM appears to affect the proportion of DSBs that undergo resection but not the extent of resection, depletion of MDC1 increases the intensity of RPA IRIFs without affecting their number. This result suggests that ATM and MDC1 independently modulate HRR through control of DSB resection: ATM facilitating the CtIP-dependent decision to undergo resection and MDC1 limiting the extent of resection.

3352T

Identification of an extragenic mutation of *BUB1B* gene for PCS (MVA) syndrome and functional analysis using TAL effector nucleases.
T. Miyamoto[1], H. Ochiai[1,2], A. Kanai[3], K. Hosoba[1], S. Kume[1], T. Sakuma[2], T. Kajii[4], T. Yamamoto[2], S. Matsuura[1]. 1) Genetics & Cell Biol, RIRBM, Hiroshima University, Hiroshima, Japan; 2) Math & Life Sci., Grad. Sch. Sci., Hiroshima University, Higashi-Hiroshima, Japan; 3) Mol.Oncol., RIRBM, Hiroshima University, Hiroshima, Japan; 4) Hachioji, Tokyo 192-0023, Japan.

Cancer-prone syndrome of premature chromatid separation with mosaic variegated aneuploidy (PCS (MVA) syndrome) is a rare autosomal recessive disorder, characterized by growth retardation, microcephaly, and childhood cancer. Monoallelic mutations in *BUB1B* encoding BUBR1, a mitotic spindle assembly checkpoint regulator, has been found in individuals with the syndrome, but no second mutation was found in the second allele although a decrease of their transcript was identified. To uncover the molecular basis of the second allele, we searched for mutation in a 200-kb genomic region using a next generation sequencer.

A novel single nucleotide substitution was identified in an extragenic region of *BUB1B* in the second allele. We then introduced it into human cultured cell lines by genome-editing technique using TAL effector nucleases (TALENs). The cell clones obtained all showed reduced *BUB1B* transcripts, suggesting that the nucleotide substitution is the causal mutation for the disease. Combination of next-generation sequencing and TALEN-mediated genome editing is a very powerful approach to study the molecular pathology of the disease with hitherto undetectable mutations.

Immunohistochemical Expression of Afadin-6 (AF-6) in Sporadic Neurofibromas.
M. Sulaiman[1], A. Dodson[2], T. Helliwell[2], C. Kudi[1], I. Hussaini[1], S. Ojo[1], J. Hambolu[1]. 1) Vet Anatomy, Ahmadu Bello University, Zaria, Nigeria; 2) Institute of Translational Medicine, University of Liverpool, UK.

Background Neurofibromatosis type 1 (NF1) - is a neurocutaneous single-gene (neurofibromin) disorder which is mapped on the long arm of chromosome 17(17q12).NF1 is inherited in an autosomal dominant manner with an incidence of about 1 in 3000. Tight junctions are specialized cell-cell point of adhesion that contributes to the regulation of differentiation and proliferation. The loss of epithelial differentiation in tumours often correlates with mutations in small GTPase Ras. The AF-6 protein is a protein that contains two potential Ras binding domains. The AF-6 functionally links the cytoskeleton through the intercellular junctions. This study was carried out to demonstrate the immunolocalization and cellular expression of AF-6 in sporadic neurofibroma by immunohistochemistry. Methods Informed patient consent was obtained before surgery and the study has an ethical approval (06/1505/137) of Liverpool Research Ethics Committee. Standard Operating Procedure of the Institute of Translational Medicine, University of Liverpool was used in the immunohistochemistry technique. Both the test and control tissues were immunostained with Rabbit Anti-AF-6 polyclonal antibody diluted at 1:100-1:200 at (pH 7.0) (Cat # 433280, Invitrogen). Slides were visualised under light microscopy. Results The AF-6 moderately localizes to the membrane of endothelial cells and at perineurial fibroblast cell-cell junction. Additionally, the expression of AF-6 in Schwann cells of all the Sporadic NF1 was nuclei in localization. Conclusion The study suggests that AF-6 may be involved in cell proliferation in neurofibroma cells and therefore becomes a target protein in the management of neurofibromatosis type 1.

Fragile site FS2 instability stimulates mitotic recombination in the yeast *Saccharomyces cerevisiae*.
K. Kapellas, S. Miller, D. Rosen, E. Younkin, A. Casper. Department of Biology, Eastern Michigan University, Ypsilanti, MI.

Common fragile sites (CFS) are regions of chromosomes in mammalian cells that are prone to DNA breaks under replication stress. CFS are prevalent throughout the human genome and some lie near or within tumor suppressor genes or oncogenes. Breaks at CFS can lead to gene deletions and amplifications that can result in the genesis of cancer cells. We hypothesize that fragile site breaks also contribute to tumorogenesis by stimulating mitotic recombination events, including reciprocal crossovers (RCOs) and break-induced replication (BIR), leading to loss of heterozygosity at tumor suppressor genes. We have examined the role of fragile site instability on the stimulation of mitotic recombination using a yeast model system. The yeast *Saccharomyces cerevisiae* possesses the native fragile site FS2 on chromosome III. Yeast fragile site FS2 exhibits double strand DNA breaks in response to DNA replication stress, but differs in structure to mammalian CFS, being composed of simple inverted repeats. We used a galactose-inducible promoter to regulate expression of the *POL1* gene of S. cerevisiae to control replication stress by galactose concentration in the medium. Three diploid yeast strains were used: an experimental strain with the native FS2 structure (AMC310), one control strain (Y382) with the FS2 region interrupted and inactivated by the insertion of a drug resistance gene, and a second control strain with the native *POL1* promoter and native FS2 (AMC324). Under low-galactose conditions that cause replication stress in this strain, experimental diploid AMC310 had a RCO frequency of $15.6*10^{-4}$, a BIR frequency of $23.8*10^{-4}$, and a chromosome loss frequency of $5.7*10^{-4}$. Under no-galactose conditions, the control strain with stabilized FS2 region, Y382, exhibited a RCO rate 5-fold lower than that of AMC310, a BIR rate 12.5-fold lower than that of AMC 310, and no chromosome loss was observed. Similar results were obtained from control strain AMC324. The results indicate that FS2 is a hotspot for mitotic recombination events that lead to LOH. Future research will determine whether human CFS instability contributes to an increase in mitotic recombination and LOH in tumors.

SirT7 promotes genomic stability and adequate DNA damage response. *B. Vazquez[1], J. Thackray[1], S. Bunting[2], J.A. Tischfield[1], L. Serrano[1].* 1) Human Genetics Institute of New Jersey Rutgers University, Piscataway, NJ; 2) Dept. of Molecular Biology and Biochemistry, Rutgers University Piscataway, NJ.

The Sir2 family of proteins, or Sirtuins, is a major player in sensing and coordinating cellular stress response by modulating chromatin structure, cell cycle progression and mitochondrial function. Mammals have seven Sirtuins, denoted SirT1-7. They exhibit different enzymatic activities such as deacetylation, have a myriad of substrates (histone and non-histone proteins) and present a diverse pattern of cellular localization. Sirtuin deficiency in mice has also been associated with increased mutagenesis, defective DNA repair pathways, tumorgenesis and accelerated aging. SirT7 is the least studied mammalian Sirtuin. Opposing roles have been attributed to SirT7 in cancer development. Up-regulation of SirT7 expression has been observed in breast and thyroid cancer and human hepatocellular carcinomas, indicating it may be involved in the promotion and/or maintenance of oncogenic features. However, down regulation of SirT7 expression is also observed upon human and mouse cell transformation suggesting that it may have a role in cancer prevention. We investigate the role of SirT7 in the maintenance of genome integrity by characterizing SirT7 knockout mice. Our results show that SirT7-/- pups are born at sub-mendelian ratio and a high proportion died within the first month of age. In vivo mutagenesis analysis show increased mutant frequency and polyploidy in SirT7 deficient cells. Moreover, SirT7-/- fibroblasts showed increased levels of DNA double strand breaks measured by immune detection of γ-H2AX foci and comet assays. Furthermore, SirT7-/- thymocytes present reduced survival upon X-ray irradiation, and mature B cells are reduced in number and present impaired immunoglobulin class switching. Overall, the loss of SirT7 is associated with embryonic lethality, increased levels of spontaneous DNA damage and an impaired DNA damage response supporting the importance of SirT7 in the maintenance of genome integrity. Acknowledgments: The authors are supported by a grant from the Human Genetics Institute of New Jersey. BN Vazquez is supported by post-doctoral fellowship EX-2010-278 from the Spanish Ministry of Education, Culture, and Sports.

The Fanconi anemia pathway regulates ALT telomere maintenance in human cells. *H. Root[1], M. Komosa[1], A. Larsen[1,2], D.P. Bazett-Jones[1,2], M.S. Meyn[1,3].* 1) Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Biochemistry, University of Toronto, Toronto, ON, Canada; 3) Molecular Genetics, University of Toronto, Toronto, ON, Canada.

Mutations in 15 different genes give rise to Fanconi anemia (FA), a genome instability syndrome characterized by bone marrow failure, malformations and cancer. FA proteins play roles in DNA repair, replication, meiotic recombination and telomere maintenance. The alternative lengthening of telomeres (ALT) pathway is a telomerase-independent recombination based mechanism active in cancer and immortalized human cells. We find that siRNA knockdown of FANCD2, FANCA, FAN1 or FANCP all cause rapid and dramatic increases in ALT telomeric DNA, demonstrating a central role for the FA pathway in the regulation of ALT.

Depletion of FANCD2 in ALT cells leads to increases in telomere length and extrachromosomal telomeric repeat (ECTR) DNA content. ECTR DNA molecules were analyzed using our novel halo-FISH technique, wherein cells are deproteinated and treated with NaOH prior to Q-FISH analysis. NaOH disrupts plectonemic interactions between ECTR DNA molecules, which normally tether ECTR DNAs together within ALT-associated PML bodies (APBs). APBs are putative sites of telomeric recombination, as well as ECTR DNA generation and storage. Electron spectroscopic imaging of APBs primarily reveals non-nucleosomal DNA, likely extrachromosomal in nature. FANCD2-depletion leads to APBs that also contain chromatin intrusions, potentially representing telomeres themselves, within APBs. FISH analysis shows that in FANCD2-depleted cells the frequency and stability of interactions between telomeres and ECTR DNAs is increased, suggesting that FANCD2 normally suppresses interactions between ALT telomeric DNAs.

FANCD2 regulates a mechanism of telomeric recombination that is independent of RAD51, but requires BLM and FANCJ expression. Knockdown or inhibition of DNA-PKcs, or KU80 does not limit telomeric DNA amplification in FANCD2-depleted ALT cells, suggesting that the critical role of FANCD2 in ALT is not to limit aberrant end-joining reactions. Interestingly, we also find that depletion of ATR does not result in increased telomeric DNA synthesis in ALT cells, but rather ATR expression is required to mediate the FAND2-depletion phenotype. This suggests that the role of FANCD2 in ALT is not tied to the response to stalled/collapsed replication forks. Together, our results indicate a direct role for FANCD2 and other members of the FA pathway in the regulation of recombination in the ALT pathway.

Anaplastic rhabdomyosarcoma in TP53 germline mutation carriers. *S. Hettmer[1], N. Archer[1], G. Somers[2], A. Novokmet[3], A. Wagers[4], L. Diller[1], C. Rodriguez-Galindo[1], L. Teot[5], D. Malkin[3].* 1) Department of Pediatric Oncology, Dana-Farber Cancer Institute and Division of Pediatric Hematology/ Oncology, Boston Children's Hospital, Boston, MA 02115, USA; 2) Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada M5G 1X8; 3) Division of Oncology, Department of Pediatrics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada M5G IX8; 4) Howard Hughes Medical Institute, Department of Stem Cell and Regenerative Biology, Harvard University, Harvard Stem Cell Institute, Cambridge, MA, and Joslin Diabetes Center, Boston, MA 02115, USA; 5) Department of Pathology, Boston Children's Hospital, Boston, MA 02115, USA.

Rhabdomyosarcoma (RMS) represents a diverse category of myogenic malignancies with marked differences in molecular alterations and histology. To determine if RMS predisposition due to germline TP53 mutations correlates with certain RMS histologies, we performed a retrospective review of RMS diagnosed in 8 consecutive children with TP53 germline mutations at Boston Children's Hospital and the Hospital for Sick Children, Toronto. All 8 tumors exhibited non-alveolar, anaplastic histology as evidenced by the presence of enlarged hyperchromatic nuclei with or without atypical mitotic figures. Additionally, TP53 germline mutations were found in 3 out of 7 consecutive children with anaplastic RMS (anRMS) and previously unknown TP53 status. Thus, the frequency of TP53 germline mutations was 73% (11 out of 15 children) in pediatric anRMS patients. AnRMS was the first malignant diagnosis for all 11 TP53 germline mutation carriers in this cohort, and median age at diagnosis was 40 months (mean 40±15 months, range 19-67 months). The frequency of germline TP53 mutations in children with anRMS was 100% (5 out of 5 children) for those with a family cancer history consistent with Li-Fraumeni syndrome (LFS), and 80% (4 out of 5 children) for those without an LFS cancer phenotype. Our data suggest that individuals who harbor germline TP53 mutations are predisposed to develop anRMS at a young age; we propose extending the Chompret criteria for LFS to include children with anRMS irrespective of family history.

3358T

Polymorphisms of MTHFR, prothrombin and factor V (Leiden) genes in children with acute lymphoblastic leukemia. *E. Maly[1], O. Zajac-Spychala[2], J. Kedzierska[2], J. Nowak[3], D. Januszkiewicz-Lewandowska[1,2,3].* 1) Department of Medical Diagnostics, Poznan, Poland; 2) Department of Pediatric Oncology, Hematology and Transplantation, University of Medical Sciences, Poznan, Poland; 3) Institute of Human Genetics Polish Academy of Sciences, Poznan, Poland.

The onset of thrombosis in children with acute lymphoblastic leukemia (ALL) in the course of treatment varies according to different authors, from 2.5% to 11.6% of the patients. In addition to factors related to the underlying disease and its treatment (steroids, L-ASPA, MTX, central catheter implantation), it is not without significance the presence of genetic predisposition leading to the development of thrombosis. The most common cause of congenital thrombophilia outside deficiency of protein S, C, and antithrombin, are the gene mutations of factor V Leiden, prothrombin, and MTHFR. The aim of this study was to evaluate the prevalence of polymorphisms C677T and A1289C of MTHFR, as well as prothrombin gene mutation G20210A and factor V G1691A mutation. The study was performed in 29 children (19 boys, 10 girls) treated for ALL in the Department of Pediatri Oncology, Hematology and Transplantation, University of Medical Sciences Poznan. Homozygous C677T polymorphism of MTHFR gene was found in five (17.9%) and heterozygous in 11 patients (39.2%), whereas homozygous A1289C polymorphism of MTHFR gene was observed in 4 (14.3%) and heterozygous in 11 patients (39 , 3%). Heterozygous mutation G1691A of factor V was found in 5 (17.2%) children. No G20210A prothrombin gene mutation was observed in the study group. The simultaneous presence of two or more polymorphisms of studied genes were found in 11 (38%) children. 3 (27%) of these patients had symptomatic thrombosis requiring treatment with unfractionated heparin. In conclusion the frequency of homo-and heterozygous gene polymorphisms in children with ALL was similar to the data for Caucasians. Only the simultaneous presence of two or more polymorphisms of studied genes seems to be a predisposing factor for symptomatic thrombosis in the course of treatment of children with ALL.

3359F

Offspring of Couples Who Both Survived Cancer. *J.J. Mulvihill[1], J.F. Winther[2], L. Madanat-Harjuoja[3,4], P.M. Lähteenmäki[3,4], J.D. Boice Jr.[5,6].* 1) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA; 2) Danish Cancer Society Research Center, Copenhagen, Denmark; 3) Finnish Cancer Registry, Helsinki, Finland; 4) Turku University Hospital, Turku, Finland; 5) National Council on Radiation Protection and Measurements, Bethesda, MA, USA; 6) Vanderbilt University, Nashville, TN, USA.

To date and contrary to intuition and mouse studies, no environmental exposure has been proven to cause new heritable disease in human beings, not among children born to survivors of the American atomic bombs in Japan nor to survivors of cancer in childhood, adolescence, or young adulthood who received chemotherapy, radiotherapy or both. In our population-based studies of reproduction by cancer survivors in Denmark and Finland, we had the opportunity to study the birth defects, cancer, and possibly genetic disorders in offspring of that rare event when BOTH parents were cancer survivors. We identified all cases of connubial cancer in two population-based cancer survivor cohorts comprising 54,349 cancer survivors in the Danish or Finnish cancer registries with cancer under age 35 years between the start of the respective registries (1943 in Denmark and 1953 in Finland) through 2004, who survived to reproductive age. Offspring were linked to health registries to identify malformations, cancer, deaths (including stillbirths), selected single gene disorders and chromosomal abnormalities. A total of 58 connubial cancer families with a total of 110 offspring have been identified. Only 14 children were born (in 4 families) after the cancer diagnoses of BOTH parents: In 3 families each offspring had an adverse outcome (pyloric stenois, cleft lip and palate, and brain ependymoma, the last in a Li-Fraumeni syndrome family); in the fourth family, 2 of 11 offspring had an abnormality (branchiogenic cyst, terminal phalangeal aplasia of toes 1-3). In the 9 other affected offspring (born after just one parent had cancer), the father was the cancer survivor in 8 cases. No offspring has a *de novo* mendelian trait. Although numbers are small, they are reassuring that therapy that is reputed to be highly mutagenic in somatic cells (seen as second cancers and chromosomal breakage in the survivors) is not causing an excess of germ cell mutations.

3360W

Pleuropulmonary blastoma (PPB) type and distant metastases are significantly associated with disease-free survival: a report from the International PPB Registry. *D.R. Stewart[1], P.S. Rosenberg[2], G.M. Williams[3], J.R. Priest[3], KA.P. Schultz[3], A. Harris[3], L. Doros[4], D.A. Hill[4], L.P. Dehner[5], Y.H. Messinger[3].* 1) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 2) Biostatistics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 3) International PPB Registry and Children's Hospitals and Clinics of Minnesota, Minneapolis, MN; 4) Department of Pathology, Children's National Medical Center, Washington, DC; 5) Department of Pathology and Immunology, Washington University in St. Louis School of Medicine, St. Louis, MO.

BACKGROUND. Pleuropulmonary blastoma (PPB) is the most common primary malignancy of the pulmonary parenchyma in childhood. Three types of PPB have been recognized: type I (purely cystic), type II (cystic and solid) and type III (purely solid). Type I PPB may also regress (or not progress), resulting in a cyst with the architecture of type I PPB but without the primitive cells (type Ir). Familial PPB is an autosomal dominant, pleiotropic, tumor-predisposition disorder with incomplete penetrance that arises secondary to mutations in *DICER1*, a gene critical in microRNA biogenesis; mutations in *DICER1* are also observed in sporadic PPB. Since 1987 the International PPB Registry (IPPBR) has collected clinical and follow-up data on centrally-reviewed pathology from PPB cases collected world-wide. The last IPPBR report (1997) on the natural history, treatment and survival experience of PPB was based on 50 cases. We now report analysis of disease-free survival, prognostic factors and overall survival from 350 cases. METHODS/ RESULTS. IPPBR pathologists (LPD, DAH) performed central review of all cases; PPB was excluded in 20%. Of the 350 confirmed cases, there were 88 type I, 26 type Ir, 124 type II, 21 type II/III and 91 type III PPBs from 187 males and 162 females (1 unknown gender). In 97 PPB patients tested, 64 (66%) had germline *DICER1* loss-of-function mutations. Disease-free survival 3 years post PPB-diagnosis was significantly different by PPB type (P-value = 1.6×10^{-10}): 86% for type I, 93% for type Ir, ~64% for type II and II/III and 36% for type III. Type III had a 2.3-fold worse disease-free survival when compared to type II (relative hazard, 95% CI: 1.5-3.5; P-value = 5.0×10^{-5}). Within PPB types II, II/III and III, presence of distant metastases was significantly associated with poorer overall (P-value < 0.002) and disease-free survival (P-value < 0.01). Preliminarily, *DICER1*-mutation status did not influence survival in the limited number of patients tested to date. CONCLUSIONS. We have demonstrated, for the first time, significantly worse disease-free survival in type III vs type II PPB. In the largest cohort to date, we observed that PPB clinical subtype confers significant differences in disease-free and overall survival, suggesting biologic differences between the cystic types I and Ir and within the solid types II, II/III and III.

3361T

Improved detection of FLCN mutations in patients with Birt-Hogg-Dubé Syndrome. *J.R. Toro[1, 2], B. Friedman[3], S. Bale[3].* 1) National Cancer Institute, Bethesda, MD; 2) Dermatology Department, Veterans Affairs Medical Center, Washington, DC, USA; 3) GeneDx, BioReference Laboratories, Inc., Gaithersburg, MD Maryland, USA.

Background: Birt-Hogg-Dubé syndrome (BHDS) (MIM 135150) is an autosomal dominant predisposition to the development of follicular hamartomas (fibrofolliculomas), lung cysts, spontaneous pneumothorax, and kidney neoplasms. Germline mutations in FLCN are associated with the susceptibility for BHDS. To date 153 FLCN germline mutations have been reported in the online Folliculin sequence variation database. Objective: To characterize methods for improved FLCN mutation detection and novel mutations. Methods: Initial screening was conducted with direct bidirectional DNA sequencing of the coding regions and splice sites of exons 4-14 of FLCN. If no mutation was identified by sequencing analysis, large intragenic insertion and deletion mutations were screened by RQ-PCR and targeted arrays comparative genomic hybridization with exon-level resolution. Results: The FLCN mutation detection rate by direct sequencing was 89 percent. We detected 56 unique novel FLCN germline mutations: 22 deletions, 11 insertions, 13 missense,7 nonsense, 2 splice site and 1 deletion/insertion. To date only eight large unique intragenic mutations have been reported. We identified one whole gene FLCN deletion and eleven unique large FLCN intragenic deletions: four involving exon 1, one in exon 6 and six encompassing: exons 1-6, exons 2-5, exons 2-13, exons 6-14, exons 7-8 and exons 10-14. Including this report, to date there are 214 unique FLCN mutations identified: 76 deletions, 32 insertions, 99 substitutions and 7 deletion/insertion. A comprehensive worldwide review of published FLCN mutations and current ongoing efforts to detect novel BHDS causing mutations will be discussed. Conclusion: A systematic approach combining accurate and sensitive methods to detect FLCN mutations provides evidence that most patients with BHDS have mutations in FLCN.

3362F

Gene Expression in P53 and Bcl-2 in Biopsy Samples of Ulcerative Colitis and Colon Cancer in Iraqi Patients. *Z. Jaafar.* Biotechnology Center, Ministry of Science and Technology - Iraq, Baghdad, Baghdad, Iraq.

The investigation done on the biopsy samples from patients suffered from ulcerative colitis (UC)and colon cancer. The aim of the study is to detect the genetic alteration for P53 and Bcl-2 which consider prognostic factor for chronic ulcerative colitis that show a relation between chronic ulcerative colitis and increased risk with colon cancer by using in situ hybridization technique . The results showed an increase in genetic expression for p53 and Bcl-2 in chronic UC patients as a result of accumulative mutation in P53 gene and Bcl-2 when compared with colon cancer and it can be considered as a biomarker to detect the increase sensitivity to carcinogenesis . The extent of gene Bcl-2 in UC was 8.4% and 25% and 66.6%in low ,moderate, high grade respectively while in colon cancer gave 25% in moderate grade and 75 % in high grade . The extent in P53 in UC was 8.3 and 27.7 and 64 % in low , moderate , high grade respectively . The intensity of Bcl-2 in UC was 21.3 % in low grade and 50.8% in moderate grade and 17.8 % in high grade , while the intensity in colon cancer was 3% in low grade and 56% in moderate grade and 42% in high grade . The intensity of P53 in UC was 33.3% and 47.2% and 18.47 % in low, moderate ,high grade respectively while the intensity in P53 in colon cancer gave 8.3% and 36.1% and 55.6% and in low, moderate ,high grade respectively .

The conclusion study indicate there were an increase in gene expression in P53 and Bcl-2 genes which can be used as prognostic factor to follow the chronic stage of UC and detect the UC -associated neoplasm lesion in the early stage and therefore decrease the risk of developing to colon cancer .

3363W

Integrative analysis of acute myeloid leukemia with genetic, epigenetic, and transcriptional data. *S. Li[1], F. Garrett-Bakelman[1], J. Patel[2], T. Hricik[2], M. Guzman[1], M. Carroll[3], A. Brown[4], R. D'Andrea[4], R. Levine[2], A. Melnick[1], C. Mason[1].* 1) Weill Cornell Medical College, New York, NY; 2) Memorial Sloan-Kettering Cancer Center, New York, NY; 3) University of Pennsylvania, Philadelphia, PA, USA; 4) The Queen Elizabeth Hospital, Woodville, South Australia.

Understanding the molecular mechanisms that lead to a patient's recurrence of cancer is one of the most important aspects of cancer research. Leukemia often presents as an abrupt cancer at diagnosis, and even after treatment, many patients experience relapse. The relapse of leukemia is hypothesized to occur when sub-clones of leukemia cells resist the chemotherapy during the treatments and then emerge to re-populate the cancerous cells in the patient. This relapse of the leukemia represents one of the greatest challenges towards improving the clinical outcome for patients. The current study has identified the evolution of molecular changes in tumors at diagnosis and relapse stages in acute myeloid leukemia (AML) patients. We observe thousands of diagnosis-specific and relapse-specific changes at the genetic, epigenetic and transcriptome level. We have detected both known and novel somatic variants from Exome-seq data and validated them using Enhanced Reduced representation bisulfite sequencing (ERRBS) and RNA-seq with a high validation rate (96-99%). We also found known/novel fusions and differentially expressed genes from RNA-seq data. Also, we detected differentially methylated CpGs and regions from ERRBS data. Furthermore, we found distinct DNA methylation patterns associate with gene expression from CG poor to CG rich promoters. These molecular changes are potential candidates of prognostic factors and targets for relapse treatment and provide a wealth of new information about the evolution of cancer, which will be useful for AML as well as other tumors.

3364T

Tissue-of-origin chromatin organization shapes the mutational landscape of cancer. *P. Polak[1,2], R. Karlic[3], A. Koren[4,2], B. Thurman[5], R. Sandstrom[5], A. Reynolds[5], E. Rynes[5], J. Stamatoyannopoulos[5], S. Sunyaev[1,2].* 1) Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Broad Institute, Boston, MA; 3) University of Zagreb, Zagreb, Croatia; 4) Harvard Medical School, Boston, MA; 5) University of Washington, Seattle, WA.

Density of somatic mutations in cancers varies greatly along the genome, and chromatin organization has been implicated as a major determinant of the mutational landscape in cancer. However, both the regional variation of somatic mutations and chromatin organization are highly cell type specific properties. We analyzed genomes of five major types of cancer representing a range of tissues of origin and mutational mechanisms and signatures. We compared the genomic distribution of cancer mutations to a large set of epigenetic properties that included chromatin accessibility as measured by DNaseI hypersensitivity, histone modifications and DNA replication timing from multiple cell types. In order to evaluate the contribution of different epigenetic properties to the local variation in mutation density, we used a machine learning tool called Random Forest regression. Random Forest provides a framework to rank individual predictors and to identify the set of strongest predictors of local mutation density, and also numerically scores the contribution of each individual predictor. For each cancer type, we focused on the predominant mutation type and initially combined all mutations from the different genomes of that same cancer type. We analyzed mutation density variation at 1Mb scales. Remarkably, epigenetic marks explain a large fraction of variance in mutation density for all cancer types. Variance explained ranges from 65% to 88%. This is substantially higher than in earlier studies, and indicates that, at least for several cancer types, we have identified a set of epigenetic variables that almost fully predict the mutation variability along the genome. Furthermore, chromatin marks from the matched tissue of the cell-of-origin of a cancer, e.g. melanocytes and melanoma, explain a much larger proportion of the variance than the chromatin marks from non-matched tissues.

Association of eNOS 4 a/b polymorphism in Mexican patients with Breast Cancer. *R. Ramírez[1,2], MP. Gallegos[1], A. Ramos[1,3], L. Gómez'Flores[1,2], D. Carrillo[1,2], O. Soto[1,3], I. Gutíerrez[1,2], I. Delgado[5], AM. Puebla[5], LE. Figuera[4], RP. Mariaud[6], GM. Zúñiga[7].* 1) Laboratorio de Genética Molecula , Division de Médicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) Doctorado en Genética HUmana, CUCS, Universidad de Guadalajara; 3) Doctorado en Farmacología, CUCS, Universidad de Guadalajara; 4) División de Genética, CIBO, IMSS; 5) Laboratorio de Inmunofarmacologia, CUCEI, Universidad de Guadalajara; 6) Departamento de Clínicas Odontológicas Integrales, Centro Universitario de Ciencias de la Salud, Universidad Guadalajara; 7) Laboratorio de mutagénesis, CIBO, IMSS.

Breast cancer (BC) is one of the most common diseases in developing countries in the world. It is estimated that there are millions of symptomatic women affected by BC and millions more currently asymptomatic that will develop cancer. Several polymorphisms in the gene for endothelial nitric oxide synthase (eNOS) have been associated with the different diseases including cancer, one of the most studied has been the 4a/b, and however the results have been contradiction in different parts of the world. The aim of this study was to determine the association of eNOS 4a/b polymorphism in BC patients. Were included samples from 429 BC patients and 281 controls from the general population, and were genotipified to eNOS 4 a/b polymorphism in the intron 4 of gene. The allele identification was performance by polyacrylamide gel electrophoresis after staining with silver nitrate. The observed genotype frequencies for controls and BC were 0.6% and 0.7% for a/a, 12% and 22% for a/b, 0.6% for allele b/c only control group and 87% and 77% for b/b, respectively. The frequencies of the genotype aa-ab of eNOS 4 a/b polymorphism showed significant differences ($p < .05$) when comparing the study groups. We conclude that the genotypes a/a-a/b of the eNOS 4 a/b polymorphism contribute significantly to breast cancer susceptibility in the analyzed sample from the Mexican population.

3366W

Analysis of methylation pattern of candidates genes regulated by TDG in patients with germline mutations in TP53 gene. *F. Fortes[1], H. Kuasne[2], F. Marchi[2,4], S. Rogatto[2,3], M. Achatz[1].* 1) A.C. Camargo Cancer Center. Department of Oncogenetics. São Paulo/SP- Brazil Sao Paulo, Brazil; 2) CIPE - NeoGene Laboratory, AC Camargo Cancer Center, Fundação Antonio Prudente, São Paulo, São Paulo, Brazil; 3) Department of Urology, School of Medicine, UNESP - São Paulo State University, Botucatu, São Paulo, Brazil; 4) Inter-institutional Grad Program on Bioinformatics, Institute of Mathematics and Statistics, USP - São Paulo University, São Paulo, São Paulo, Brazil.

Li Fraumeni syndrome (LFS) is a rare autosomal dominant syndrome caused by germline mutations in the tumor suppressor gene *TP53* that predispose to hereditary cancer. In Brazil, a LFS variant form is often due to the occurrence of a founder effect, characterized as a mutation which corresponds to the exchange of an arginine by a histidine at codon 337 (p.R337H mutation). It is known that p53 regulates several cellular pathways important to cell cycle regulation, including Thymine DNA glycosylase (TDG), a specialized glycosylase that protects the hypermethylation of CpG islands and activates demethylation of promoters and tissue-specific enhancers. TDG is transcriptionally regulated by p53 and is responsible for epigenetic regulation of several "sentinel" genes. DNA methylation is one of epigenetic alterations common in human cancer. The aim of this study was to evaluate the methylation pattern of "sentinel" genes regulated by TDG: JUN, OCT4, SOX2, HOXD8, SOX17, FOXA1, NKX2.2 and repetitive regions ALUyB8 of LFS patients with and without TP53 mutations. Using quantitative bisulfite pyrosequencing the pattern of gene methylation was evaluated from DNA extracted of peripheral blood (five groups with 10 patients) and DNA extracted of tumor tissue (one group with 7 LFS patients). The 5 groups were composed by patients with (1) cancer and p.R337H mutation, (2) without cancer and p.R337H, (3) cancer and other mutation in TP53, (4) relatives without cancer and without mutation in TP53, (5) controls without cancer history and (6) 7 tumors of patients with LFS. It was not found any statistical difference between the peripheral blood group, but the genes SOX17 and HOXD8 showed altered methylation levels in the tumor group compared to peripheral blood groups. The methylation patterns had not changed when the tissue analyzed was blood and possibly these genes are epigenetically regulated by other factors than TDG. Regarding to the tumor tissue, the role of TDG in regulating HOXD8 and SOX17 methylation cannot be assumed and it will be better assessed in other groups with and without TP53 mutation. These results reinforce the importance of other mechanisms which may be related to carcinogenesis in LFS.

Functional characterization of mutations in the spliceosomal component SF3B1 in uveal melanoma. *A. Bowcock[1, 2], M. Sentmanat[1], H.N. Anbunathan[2], E.D.O. Roberson[3], J.W. Harbour[4].* 1) Department of Genetics, Washington University, St. Louis, MO; 2) National Heart & Lung Institute, Imperial College London, London, UK; 3) Division of Rheumatology, Washington University School of Medicine, St. Louis, MO; 4) Bascom Palmer Eye Institute, University of Miami, Miami, FL.

Spliceosome components have recently been implicated as oncogenic drivers of tumor progression for a variety of human cancers. We recently reported recurrent mutations at amino acid 625 of splicing factor 3b subunit 1 (*SF3B1*) in ~20% of uveal melanomas. SF3B1 is a component of the U2 small nuclear ribonucleoprotein complex and the minor U12-type spliceosome. The presence of an *SF3B1* mutation is a key genetic indicator of prognostic outcome in uveal melanoma. *SF3B1* mutations are rarely seen in tumors that metastasized and their presence is inversely correlated with the presence of deleterious mutations in BRCA1 associated protein 1 (*BAP1*) that are associated with strong likelihood of metastasis. Mutations in *SF3B1* have also been reported for chronic lymphoid leukemia, myeloid dysplastic syndromes, breast cancer, and other solid tumors - emphasizing the need to functionally characterize the effects of these *SF3B1* mutations. To achieve this we have performed knockdown and overexpression studies of *SF3B1* in cell culture followed by expression analysis with array-based approaches and RNA-Seq. Knockdown of *SF3B1* in uveal melanoma cell lines from primary tumors results in the differential regulation of several oncogenes with roles in cell proliferation, angiogenesis and apoptosis. Transient overexpression of mutant forms of SF3B1 (p.R625C, p.R625H, p.R625L, and p.R625G) found in primary uveal melanomas leads to the upregulation of tumor promoting transcripts such as *E2F3*. No overlap of differentially regulated transcripts was observed between knockdown and *SF3B1* mutant-expressing lines consistent with SF3B1 mutations being gain-of-function alterations. *CLK4,* which regulates effectors involved in splice-site recognition was among the upregulated transcripts identified in SF3B1-mutant expressing lines. Data on these cell lines are being compared with RNA-Seq data from *SF3B1* mutant and wildtype uveal melanoma tumors to identify critical changes mediated by these mutations that are involved in tumorigenesis.

3368F

Role of rs9620497 with CRYBB2 expression levels in African American women with invasive breast cancer. *S.M. Brown[1], C.D. Shriver[2], R.E. Ellsworth[3].* 1) Windber Research Institute, Windber, PA; 2) Walter Reed National Military Medical Center, Bethesda, MD; 3) Henry M Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD.

Expression levels of crystallin, beta-B2 (CRYBB2) has been found to be significantly higher in sex-derived tumors such as prostate and breast from African American compared to Caucasian individuals. Because African Americans have less favorable outcomes compared to Caucasians, overexpression of CRYBB2 may contribute to these outcome disparities. SNP rs9620497 has previously been associated with increased risk of prostate cancer in African American men, thus, we evaluated the association between rs9620497 and breast cancer risk in African American women (AAW). Genomic DNA from AAW with invasive breast cancer (n=200), AAW controls (n=244) and Caucasian women with invasive breast cancer (n=243) was genotyped using a TaqMan SNP assay. Gene expression levels were evaluated by qRT-PCR using RNA isolated from breast tumors from 41 CW and39 AAW. Genotype frequencies were analyzed using chi-square analysis and gene expression levels by a Mann-Whitney U-test; P<0.05 was used to define significance. Genotype frequencies did not differ significantly between any of the groups with GT/TT genotypes found in 19% of AAW cases, 14% of AAW controls and 21% of CW cases. Gene expression levels did not differ significantly (P=0.70) between patients with GG and GT/TT genotypes. Thus, these data do not support findings presented at an earlier ASHG meeting that rs9620497 is associated with cancer risk in African Americans. In addition, this SNP is not correlated with expression levels of CRYBB2 and whether higher levels of CRYBB2 in tumor from AAW is associated with differences in tumor etiology and outcome disparities or whether this is the result of population stratification must be determined.

Functional characterization of melanoma-associated common variants in *PARP1*. *J. Choi[1], M.M. Makowski[1], W.J. Kim[1], T. Zhang[1], M.H. Law[2], M. Xu[1], M. Kovacs[1], H. Parikh[1], L.G. Aoude[2], M. Gartside[2], H.H. Yin[3], J.M. Trent[3], S. Macgregor[2], N.K. Hayward[2], K.M. Brown[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Queensland Institute of Medical Research, Brisbane, QLD, Australia; 3) Translational Genomics Research Institute, Phoenix, AZ.

Recent genome wide association studies (GWAS) identified several new loci for melanoma susceptibility. While these results highlight potential pathways predisposing to melanoma, functional risk variants in these regions, as well as mechanism by which they influence risk, have yet to be elucidated. To nominate potential functional variants we assessed whether SNPs in melanoma loci affect flanking gene levels by expression quantitative trait loci (eQTL) analysis. Transcript levels were measured in 62 melanoma cell lines using Affymetrix U133Plus2 expression microarray. SNPs were then typed on Illumina OmniExpress arrays and further imputed to 1000 genomes (v3) using IMPUTE2. Regional copy number variations were also estimated and adjusted in the analysis using mach2qtl. Among 16 loci two chromosome 1 loci exhibited significant cis-eQTL. Subsequent validation using Taqman quantitative PCR (qPCR) demonstrated that Poly [ADP-ribose] polymerase 1 (*PARP1*) expression is significantly associated with the GWAS lead SNP (p=0.03). Namely, the risk allele is correlated with an increased *PARP1* transcript levels. We then further interrogated the genotype-expression correlation by Taqman allele discrimination qPCR in 21 melanoma cell lines heterozygous for the lead SNP. The results demonstrated significantly higher proportion for the risk allele in *PARP1* transcripts (p=0.0001). These findings were also cross-validated using RNA sequencing on a subset of the heterozygous cell lines. To identify functional risk variants mediating these effects we annotated *PARP1* locus using ENCODE database. Among 43 SNPs of strong linkage disequilibrium with the GWAS lead SNP (r2>0.8), three exhibited strong evidence as potential transcriptional enhancers in melanoma relevant cell types. Luciferase assays on these candidate SNPs demonstrated that the protective allele of rs1417765 displayed four-fold higher reporter gene expression (p=0.001). Consistent with these results, Electro Mobility Shift Assays indicated stronger nuclear protein binding for the same allele. Protein identification using antibody super-shift and mass-spectrometry will provide further explanation for the correlation of this SNP with *PARP1* expression. Our data suggest that increased *PARP1* levels are correlated with melanoma risk. Further analyses will better elucidate *PARP1* function in melanoma susceptibility.

Genetic polymorphisms in DNA base excision repair gene XRCC1 and the risk of Head and Neck Cancer. *K. Chukka[1], Z. Vishnuvardhan[2], U. Radhakrishna[3].* 1) Department of Biotechnology, Acharya Nagarjuna University, Guntur, India; 2) Department of Botany & Microbiology, Acharya Nagarjuna University, Guntur, India; 3) Green cross Pathology and Molecular Biology laboratory, Paldi, Ahmedabad.

Introduction: Head and neck cancers (HNC) are among the most common types of cancer and represent a major health problem; there are approximately 540,000 new cases and 271,000 deaths annually worldwide for a mortality of approximately 50%. Single-nucleotide polymorphisms (SNPs) are the most common form of genetic variations found in the human population. The aim of this study was to evaluate the association between polymorphism XRCC1 gene and patients with head and neck cancer. Materials and Methods: 30 head and neck cancer patients selected from the local government general hospital. An age- and sex-matched cancer-free control group (n-30) was used to compare the frequency of polymorph variants. DNA was extracted from peripheral blood. SNP were genotyped by direct sequencing. Results: Data showed no significant allelic associations for XRCC1 347bp/445bp. 80% (n-24) of the head and neck cancer cases were Heterozygous only 20% (n-6) of the cases were Homozygous. All the controls were Heterozygous. Conclusion: XRCC1 SNPs 347bp/445bp may not be biomarker for head and neck cancer. The complex analysis of these factors may provide the basis for personal risk assesement and an opportunity for individualised therapy.

3371F

Characterization of immunogenetics variants of the *CCR2*, *CCR5*, and *HLA-G* genes as potential targets for diagnosis, prognosis and treatment in women with sporadic and familial breast cancer. *C. de Oliveira Giongo[1], A.P. Carneiro Brandalize[2], P. Ashton Prolla[1,2], J.A. Bogo Chies[1].* 1) Universidade Federal do Rio Grande do Sul, Porto Alegre, Rio Grande do Sul, Brazil; 2) Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil.

Breast cancer is the most common cancer among women. It is estimated that 5 to 10% of the breast cancers are represented by familial breast cancers and 90 to 95% are represented by sporadic breast cancers. Mutations can lead to a change or loss of expression a different genes and this allows the appearance of genetic and phenotypic features which contribute to tumor progression. Among these features is the ability of tumor cells to evade from the immune cells or even use immune cells in the promotion of a inflammatory microenvironment promotion which may help angiogenesis and, later, metastasis. The aim of our study was to evaluate four polymorphic variants of genes which encode important immune system molecules, two related genes encoding chemokine receptors, *CCR2* (rs1799864) and *CCR5* (rs333), and two related to *HLA-G* gene (rs1704 and rs1063320) in 105 women with familial breast cancer, 83 with sporadic breast cancer and 151 without cancer and family history of cancer (control group), such as potential markers for diagnosis and prognosis of breast cancer. Rs1799864 and rs1063320 polymorphisms were genotyped by PCR-RFLP. Rs333 and rs1704 polymorphism were genotyped by PCR. Allelic, genotypic and haplotypic frequencies were estimated and compared using the Chi-square test or Fisher's exact test and subsequently were associated to diagnostic and prognostic factors. We observed a higher allelic frequency of the *CCR2* wild type allele, *Val* (p=0.040, OR 0.61, CI 95%=0.38-0.98) e *CCR5* wild type allele, *Wt* (p=0.032, OR 0.46, CI 95%=0.23-0.94) and higher haplotype frequency of the double wild type variants (*Wt/Val*) of these same genes in women on the control group (p=0.030) compared to women with familial breast cancer. All polymorphisms were evaluated together with the clinical parameters and it was observed that women with breast cancer showed sporadic cancer latter (57.29±8.457 years and 44.23±12.092 years for women with sporadic and familial breast cancer respectively, p<0.001) and more invasiveness (p=0.001) as compared to women with familial breast cancer. Moreover, the rs1704 and rs1799864 polymorphism showed a positive association with tumor aggressiveness in women with sporadic breast cancer (p=0.039 and p=0.005, respectively). Our data suggest that invasive cancers may be associated with increased immune cells infiltration and inflammation in the tumor microenvironment mediated by both CCR2 receptor and HLA-G molecule. Financial support: CNPq and FIPE.

A common germline deletion of APOBEC3B alters the somatic mutation profile in breast cancer. *R.J. Delahanty[1], Y. Zhang[1], Y. Guo[2,4], Y. Shyr[3,4], W. Zheng[1], J. Long[1].* 1) Vanderbilt Epidemiology Center, Vanderbilt University, Nashville, TN; 2) Department of Cancer Biology, Vanderbilt University Medical Center, Nashville, Tennessee; 3) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, Tennessee; 4) Center for Quantitative Sciences, Vanderbilt University Medical Center, Nashville, Tennessee.

Breast cancer is the most commonly diagnosed cancer and the leading cause of cancer deaths in women worldwide. Members of the APOBEC3 cytosine deaminase family (A3s) have been identified as the mutational source in breast cancer and likely other cancers. We recently found a strong association between a common deletion in the *APOBEC3B* gene with increased breast cancer risk. However, the biological mechanism underlying this association is unknown. In this study, we hypothesized that the deletion may alter the balance of gene expression levels of the APOBEC3 family members and the mutation spectrum of breast cancer. Using data from TCGA, the *APOBEC3B* deletion was called based on the Affymetrix SNP 6.0 data in blood and tumor samples of 842 breast cancer patients. Among them, 170 women were heterozygous and 30 were homozygous for the deletion in tumor. RPKM (gene expression in reads per exon kilobase per million mapped sequence reads) values were used to represent the expression level based on RNA-seq (level 1) data from 788 tumor and 108 matched normal samples. Among those tumor samples with RNA-Seq data, somatic mutation profile (level 2) was available for 762 samples. As expected, the *APOBEC3B* deletion was associated with decreased expression of the *APOBEC3B* gene. After adjustment for the *APOBEC3B* expression level, tumors with homozygous deletion of the *APOBEC3B* gene had higher level of somatic mutations, including overall mutation load, C-to-T mutation, and the mutations located in known breast cancer genes. We did not see any difference regarding the mutation load between the heterozygous deletion and those without deletion, suggesting that breast cancer risk and somatic mutations in women carrying homozygous deletion may occur by mechanisms other than APOBEC3B. This study identifies possible mechanisms for the association between the *APOBEC3B* gene deletion and breast cancer risk.

3373T

Functional Variants at the 5q11 Breast Cancer Risk Locus Regulate MAP3K1 Expression through Long-Range Regulatory Elements. *S.L. Edwards[1,5], D.M. Glubb[1], M.J. Maranian[2], K.B. Meyer[3], K.A. Pooley[4], K. Michailidou[2], K.M. Hillman[1], S. Kaufmann[1], G. Chenevix-Trench[1], D.F. Easton[2,4], J.D. French[1,5], A.M. Dunning[4], Breast Cancer Association Consortium.* 1) Functional Cancer Genomics, Queensland Institute of Medical Research (QIMR), Brisbane, Australia; 2) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK; 3) Cancer Research UK, Cambridge Research Institute, Li Ka Shing Centre, Cambridge, UK; 4) Centre for Cancer Genetic Epidemiology, Department of Oncology, University of Cambridge, Cambridge, UK; 5) School of Chemistry and Molecular Biosciences, University of Queensland, Brisbane, Australia.

Despite the success of genome-wide association studies (GWAS) in identifying common genetic variants associated with complex diseases, it has been difficult to demonstrate which variants are causal and how they contribute to disease risk. GWAS have previously identified a variant on 5q11.2 near MAP3K1, which is associated with breast cancer risk (rs889312; OR = 1.13; 95% CI 1.10-1.16; p=7×10-20). MAP3K1 is a key component of the mitogen-activated protein kinase (MAPK) signal transduction pathway and is responsible for regulating important cancer genes such as c-Myc, c-Jun and c-Fos. In an attempt to determine the causal variant(s) underlying this association, we analysed 300 genotyped and 609 imputed variants within the 305kb surrounding rs889312 in 89,050 Europeans in 41 case-control studies within the Breast Cancer Association Consortium (BCAC). We identified three independent association signals for estrogen receptor (ER)-positive but not ER-negative breast cancer. Using ENCODE and other published ChIPseq data, we have identified three putative regulatory elements (PREs) corresponding to the three association signals and each containing several candidate causal variants. Chromatin conformation studies showed long-range physical interactions between the PREs and MAP3K1, their likely target gene. The strongest signal mapped to a transcriptional silencer element in which the risk alleles of candidate causal variants increased MAP3K1 promoter activity in luciferase reporter assays. Electrophoretic mobility shift assays (EMSAs) have detected allele-specific protein-DNA interactions for several candidate causal variants. In conclusion, we have identified candidate variants at 5q11 that are likely to be causally related to breast cancer risk and act by controlling MAP3K1 expression.

3374F

Transcriptional regulation and prostate cancer risk loci. *R.J. Klein[1], J. Hayes[1], X. Xu[1], J. Farber[1], R.-M. Väänänen[2], P. Taimen[3], J. Vijai[1], H. Lilja[4,5], K. Pettersson[2], K. Offit[1].* 1) Clinical Genetics Service, Department of Medicine, and Cancer Biology and Genetics Program, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Division of Biotechnology, University of Turku, Turku, Finland; 3) Department of Pathology, University of Turku and Turku University Hospital, Turku, Finland; 4) 5.Department of Laboratory Medicine, Surgery, and Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA; 5) Nuffield Department of Surgical Sciences, University of Oxford, Oxford, UK.

While genome-wide association studies (GWAS) have identified numerous loci at which common single nucleotide polymorphisms (SNPs) are clearly associated with the risk of developing prostate cancer, the mechanism by which these variants influence disease is not clear. Based on the observation that regions of the genome with marks of transcriptional regulatory elements harbor SNPs that are more likely to be under negative selective pressure, we hypothesized that many prostate cancer associated SNPs, or their correlated proxies in linkage disequilibrium, function by altering regulation of nearby genes through alteration of transcription factor binding sites. As a first test of this hypothesis, we previously identified several cis-acting expression quantitative trait loci (eQTLs) in which prostate cancer risk SNPs correlate with expression of nearby genes in prostate tumors. Here, we further test this hypothesis by 1) asking to what extent prostate cancer risk SNPs can be explained by variants that alter transcriptional regulatory elements and 2) asking to what extent prostate cancer risk SNPs are correlated with nearby gene expression in normal tissue. Using data from the ENCODE Project, we find that prostate cancer risk SNPs overlap DNase hypersensitive sites more often than expected by chance in prostate-derived cell lines and several other tissue types. Many of these sites are predicted to alter binding of specific transcription factors. We further find that while many prostate cancer risk SNPs are associated with expression of nearby genes in tumor tissue, fewer such associations are observed in benign tissue. No significant association with distal genes (trans eQTLs) were found. Overall, these data support the hypothesis that many GWAS-identified risk SNPs alter transcriptional regulation of nearby genes though further studies are needed to demonstrate gene functionality and causality of prostate cancer.

3375W

Drug-sensitivity assay for sequence variants verification. *K. Tao, S. Tavtigian.* Huntsman Cancer Institue, Salt Lake City, UT.

[Background] Individual sequence variant may confer different level of drug sensitivity and affect the outcome of treatment. Emerging poly (ADP-ribose) polymerase (PARP) inhibitor-based synthetic lethal approach is beneficial for the patients with defective function in homologous recombination repair system. High-throughput sequencing technologies provide us numerous sequence variants and majority of them are missense substitutions that are difficult to interpret. However, the assay to determine which sequence variant create clinical significance or increase drug sensitivity has not been well established. Here, we developed a drug-sensitivity assay system to verify sequence variants of genes involved in HR pathway. [Method] Total twelve sequence variants were analyzed in this method. Stable cell lines that have either a wild-type or mutant construct were generated using PiggyBac (PB) transposase (PB 5' terminal repeat_EF1alpha promoter_CDS_IRES_RFP_PB 3'terminal repeat). For accurate and high-throughput screening, the cells expressing the same level of fluorescence intensity were sorted and plated in 96 well plates using FACSAria cell sorter. Cross-linking agent (Mitomycin, Cisplatin), poly ADP-ribose polymerase (PRRP) inhibitor (AZD-2281, MK4827), and Topoisomerase I (Camptothecin) were used individually or as combination. Following the drug exposure for 5-7 days, cell viability was assessed based on the amount of ATP. The ATP-generated luminescent signal of each well was measured in EnVison 2104 plate reader. [Result] Three sequence variants (5'UTR variant, missense substitution, and frameshift deletion) showed an increase sensitivity to the drugs compared to wild-type, These three mutants were sensitive to both cross-linking agent and PARP inhibitor and the combination of these two agents augumented drug effect. . [Conclusion] It is critical to select appropriate treatment for individual cancer patient and for that, the development of system for accurate measurement of drug sensitivity in each sequence variant is urgent. Our strategy allows to see the effect of one-week treatment, which is necessary to determine the effect of PARP inhibitor and three mutants were confirmed as pathogenic variants. However, pathogenicity of the remaining mutants are not yet clear. Further improvement of sequence verification system is necessary to detect smaller functional difference and it is ideal to conduct the assay using isogenic human mutant cells.

3376T

SNP Variation in MicroRNAs Targeting the Tumor Suppressor Gene *PTEN*. *V.A. Ware, A. Jones, C. LaViolette, C. Corcoran, A. Maletz, J.A. Wilder.* Northern Arizona University, Flagstaff, AZ.

MicroRNAs play important roles in a broad range of biological processes and previous studies have demonstrated that SNP variation in microRNA sequences can affect pathways associated with cancer progression through diverse mechanisms. Here we describe sequence variation in microRNAs that target *PTEN* (Phosphatase and Tensin Homolog), an important tumor suppressor gene in a number of cancers including prostate, breast and lung cancer. We screened 41 Native American samples to find SNPs in microRNA encoding genes unique to Native American populations. A SNP (rs13136737) was found in the pri-miRNA of mir302D and mir367, which we are evaluating via quantitative PCR for potential allele-specific patterns of expression. Further evaluation of microRNA-encoding genes may uncover variation affecting cancer progression.

3377F

Missense Mutation of the Last Nucleotide of Exon 1, CDH1 c.48 G>C (Q16H), Contributes to Cancer Predisposition through Disruption of Normal Splicing and Generation of Missense Mutation. *L. Zhang[1], A. Xiao[2], J. Ruggeri[1], R. Bacares[1], S. Melo[3], J. Figueiredo[3], J. Simões-Correia[3], R. Seruca[3], M. Shah[4].* 1) Department of Pathology, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Northwestern University, Evanston, IL; 3) IPATIMUP - Institute of Molecular Pathology and Immunology of the University of Porto, 4200-465 Porto, Portugal; 4) Department of Medicine, Weill Cornell Medical College, New York, NY.

Purpose: The objective of this analysis was to assess the molecular mechanisms through which the CDH1 c.48 G>C (Q16H) missense mutation contributes to cancer predisposition. Mutation screening of CDH1 that contributes to the Hereditary Diffuse Gastric Cancer (HDGC) is important for patients with early-onset gastric cancer and/or with strong family history. Classification of variants in CDH1 is critical for cancer patient management. A particular challenge is the classification of rare non-truncating CDH1 sequence variants because it is not known whether these subtle changes can affect E-cadherin protein function sufficiently to predispose cells to cancer development. Patients and Methods: Our case is a 22 year old woman who was diagnosed with gastric cancer at the age of 18. Her grandmother, one great aunt and one great uncle were diagnosed with gastric cancer in their 30s and died of this disease in their 30s or 40s. The other great aunt was diagnosed with abdominal cancer at 16 and died subsequently. The CDH1 c.48G >C variant was identified in the patient and her living great uncle. RT-PCR products from the patient and her great uncle were cloned into the TOPO vector and subsequent sequencing was performed on individual clones from these two patients. In vitro functional studies were performed by transient transfection of CHO cells with the vectors encoding the WT and the mutant protein, as well as the empty vector (Mock), as a control. Upon transfection, cells were analysed for E-cadherin expression and localization and more importantly, for the two main functions of E-cadherin: cell-cell adhesion and invasion suppression. Results: Using RT-PCR and subsequent cloning strategy, we were able to detect a low level of mutant transcripts (5/27 clones had the 'C' allele, Q16H) in our patient. However, we were unable to detect any mutant transcripts in her great uncle (0/17 clone had the 'C' allele). In vitro functional studies of the Q16H missense mutation demonstrated it did not affect the expression, localization and cell-cell adhesion function of the E-cadherin. Instead, we observed loss of anti-invasion function in the E-cadherin protein with this substitution. Conclusion: These results support the conclusion that CDH1 c.48 G>C (Q16H) variant is a deleterious mutation and contributes to HDGC through disruption of normal splicing and inducing increased cell invasion.

3378W

The K-Type Human Endogenous Retroviral Element Encodes Fusogenic Activity in Melanoma Cells. *J. Dong[1], G. Huang[1], Z. Li[2], X. Wan[3], Y. Wang[4].* 1) Department of Pathology, University of Texas Medical Branch, 301 University Boulevard, Galveston, TX, USA; 2) Key Laboratory of Carcinogenesis and Translational Research (Ministry of Education), Department of Pathology, Peking University School of Oncology, Beijing Cancer Hospital & Institute, Beijing, China; 3) Department of Laboratory Medicine, Beijing Tongren Hospital, Capital Medical University, Beijing, China; 4) The Center for Medical Genetics, 7400 Fannin St, Suite #700, Houston, TX, USA.

Nuclear atypia with features of multinuclei have been detected in human melanoma specimens. We found that the K-type human endogenous retroviral element (HERV-K) is expressed in such cells. Since cellular syncytia can form when cells are infected with retroviruses, we hypothesized that HERV-K, which is expressed in melanoma cells and may play a role in melanomagenesis, contributes to the formation of multinuclear cells in melanoma. We specifically inhibited HERV-K using RNAi and monoclonal antibodies and observed dramatic reduction of intercellular fusion of cultured melanoma cells. Importantly, we identified loss of heterozygosity (LOH) of D19S433 in a cell clone that survived and proliferated after cell fusion. Our results support the notion that proteins encoded by HERV-K can mediate intercellular fusion of melanoma cells, which may generate multinuclear cells and drive the evolution of genetic changes that provide growth and survival advantages.

3379T

Detection of P16, Cyclin D1 and Bcl-2 Expression in Pancreatic Neoplasms. *S. Lai[1,2], X. Zhou[3].* 1) Pathology, Michael E. DeBakey VA Medical Center, Houston, TX; 2) Baylor College of Medicine, Houston, TX; 3) Internal Medicine, University of Texas Medical School at Houston, Houston, TX.

P16 and cyclin D1 genes play a critical role in the regulation of the G1-S transition of the cell cycle, and their expression are frequently altered in several neoplastic entities. Bcl-2 gene in apoptosis pathway has important function in tumorigenesis of cancers. Analysis of the protein products of these genes by immunohistochemical methods provides information on their functional status and allows for their phenotypic evaluation of tumor cells. Studies of the correlation between these gene expression levels and clinicopathologic characteristics of pancreatic neoplasms are not ample. We constructed a tissue microarray block from 24 pancreatic neoplasms including 17 adenocarcinoma, 6 neuroendocrine neoplasm and 1 intraductal papillary mucinous neoplasm, and stained for P16, cyclin D1 and Bcl-2 by immunohistochemistry. Protein expressions were correlated with tumor histologic type, grade, perineural invasion, lymphovascular invasion and lymph node status. Loss of P16 expression was correlated with malignancy ($p<0.001$), and lymphovascular invasion ($p=0.032$). Cyclin D1 overexpression was also associated with malignancy ($p=0.035$). Our study indicates the absence of p16 in most of the malignant neoplasms are associated with an early tumorigenic event. High P16 expression level in pancreatic tumors predicts a better prognosis. P16 and cyclin D1 immunoreactivity may be used as a prognostic marker for pancreatic neoplasms.

3380F

Exome-based method to determine cancer tissue of origin. *K. Robasky[1], E. Aronesty[1,2], W.D. Jones[1,3].* 1) Expression Analysis a Quintiles Company, Durham, NC; 2) Bioinformatics Program, Johns Hopkins University, Washington D.C; 3) Department of Pathology and Laboratory Medicine, University of North Carolina School of Medicine, Chapel Hill, NC.

Identifying the source of newly presenting tumor fails to yield definitive results in a significant number of cases, with cancer of unknown primary organ (CUP) accounting for 3-5% of all cancer diagnoses. Tumors are commonly classified via visual inspection alongside of immunohistochemistry and expression profiling, neither of which can consistently identify a molecular signature by which to guide treatment. Misclassifying a cancer's primary site can have wide-ranging effects, including: 1) masking the true primary cancer, 2) misinforming the patient treatment plan 3) obfuscating clinical trial results by enrolling misclassified subjects. Here we present a method for using cost-effective, high-throughput sequencing exome data to find the molecular signatures of various tissue-specific cancers. We do so by first scoring the genes from individual exomes based upon the level of mutational burden. We then perform an unsupervised analysis to reduce the dimensionality of the scored genes. Using exomes from The Cancer Genome Atlas, we apply this method to classify cancers into tissue-specific clusters. This model can thus be used with new tumor exomes to aid in identifying the tissue-of-origin of the primary cancer.

A novel statistic method for drug response prediction with big RNA-seq data. *M. Xiong[1], L. Ma[1], M. Chen[1], S. Guo[2,1].* 1) Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX; 2) Fudan University, Shanghai, China.

Digital transcriptome analysis by next-generation sequencing discovers substantial mRNA variants. Variation in gene expression underlies many biological processes and holds a key to unraveling mechanism of common diseases and drug response. However, the current methods for drug response prediction using overall gene-expression are originally designed for microarray expression data and overlook a large number of variations in gene expressions. The challenge for application of gene expression to pharmacogenomics is how to accurately measure variation in gene expression and how to develop statistical methods to fully explore information on expression variation for predicting response of a patient to a particular treatment regimen with extremely big RNA-seq data. To fully utilize expression information at genomic positional level we use sufficient dimension reduction (SDR) techniques which project the original high dimensional data to very low dimensional space while preserving all information on response phenotypes, functional principal component analysis which further reduce the dimension of the big RNA-seq data, and penalization methods for optimal feature selection as a powerful tool to develop novel statistical methods for classifying drug response of patients with RNA-seq data. The proposed methods are applied to ovarian cancer drug response RNA-seq and microarray expression data from TCGA database where expressions of 163 sensitive and 70 resistant to drug ovarian cancer samples were measured by RNA-seq and microarray. Tenfold cross validation was used to evaluate the performance of classifier. We can reach almost 100%, 100% and 100% average classification accuracy, sensitivity and specificity, respectively, in the test datasets with RNA-seq data, and 63.54%, 88.85% and 10.43% average classification accuracy, sensitivity and specificity, respectively, in the test datasets with microarray-measured expression dataset. Our results strongly demonstrate that the prediction based on RNA-seq substantially outperforms the prediction based on the microarray expressions and open a new avenue for cancer pharmacogenomics studies.

Leukemia relapse in donor cells ten years after allogeneic hematopoietic stem cell transplantation for acute myeloid leukemia. *G. Calabrese[1,2], L. Militti[1], R. DiGianfilippo[2], M. Alfonsi[1], P. Guanciali-Franchi[1], D. Fantasia[1], P. Bavaro[3], P. DiBartolomeo[3], G. Palka[1,2].* 1) Dept S Med, Oral & Biotec, Univ Chieti, Chieti Scalo, Italy; 2) Medical Genetics Dept, Pescara Hospital, Pescara, Italy; 3) Bone Marrow Transplantation Center, Pescara Hospital, Pescara.

Leukemic relapses after allogeneic hematopoietic stem cell transplantation (HSCT) in most instances arise from the original recipient leukemia clone. Exceptionally, leukemic relapse can originate from the donor hematopoietic cells. A recent review listed 65 cases of donor cell leukemia, with an estimated risk to be about 12 per 10,000 HSCT. Exposure to radiant therapy and to chemotherapy are regarded as involved in donor cell leukemogenesis, though causes are still unclear. In 2000, a female patient, 42-yrs-old, was diagnosed with acute myeloid leukemia (AML) M2 subtype having a diploid karyotype. After achieving remission by induction chemotherapy and total body radiotherapy the patient underwent a HSCT with cells from her brother. Six months later the patient showed a complete chimerism with a normal male karyotype which persisted for nine years. In 2010 the patient was treated with metabolic radiotherapy for a thyroid carcinoma. Six months later showed pancytopenia and FISH analysis with X/Y chromosome probes revealed a partial chimerism (0.08% recipient cells). Six months after loss of complete chimerism the patient showed clinical-hematologic features of leukemic relapse. Cytogenetic analysis performed on bone marrow aspirate revealed an abnormal male karyotype with chromosomes 8, and 13 clonal anomalies, and including a marker chromosome in all cells analyzed. This result was confirmed by FISH. The patient deceased two weeks later. In the present case AML occurred in donor cells ten years after HSCT with a phenotype overlapping patient original disease. Although rarely reported, the chromosomal anomalies in donor cells were specific of therapy-related AML. Radiotherapy for thyroid carcinoma and possible immune system disturbance might be associated with leukemogenesis. Chimerism study with the finding of clonal chromosomal anomalies confirm cytogenetic analysis role as of relevance for both HSCT follow up surveillance and investigation of biological mechanism of leukemogenesis.

3383F

Photodynamic therapy effect in EGF pathway gene expression in glioblastoma as a biological model. *L.B. de Paula[1,2], F.L. Primo[1,3], N.T.A. Peres[2,4], N.M. Martinez-Rossi[2,4], A. Rossi[2,4], A.C. Tedesco[1,3], Supported by CNPQ, FAPESP, FAEPA.* 1) Center of Nanotechnology and Tissue Engineers - Photobiology and Photomedicine research Group, School of Philosophy, Sciences and Letters of Ribeirao Preto, University of Sao Paulo, Sao Paulo, Ribeirao Preto, Brazil; 2) Department of Genetics, Medical School of Ribeirao Preto, University of Sao Paulo, Ribeirao Preto, Sao Paulo, Ribeirao Preto, Brazil; 3) Department of Chemistry, School of Philosophy, Sciences and Letters of Ribeirao Preto, University of Sao Paulo, Sao Paulo, Ribeirao Preto, Brazil; 4) Laboratory of Laboratory of Genetics and Molecular Biology of Fungi, Medical School of Ribeirao Preto and University of Sao Paulo, Sao Paulo, Ribeirao Preto, Brazil.

Glioblastoma multiforme (GBM), the most malignant human brain tumor, may develop de novo or through progression from low-grade or anaplastic astrocytoma. The deadly nature of GBM originates from explosive growth and invasive behavior, which are fueled by dysregulation of multiple signaling pathways. Dysregulated epidermal growth factor receptor (EGFR) pathway is frequently in high-grade gliomas via gene amplification or dominant-active mutation, is a leading cause of gliomagenesis. New methods to achieve widespread distribution of therapeutic agents have shown a significant improvement in brain tumor therapy. Photodynamic therapy (PDT) has been used mainly as an anticancer therapy, which relies on the absorption and retention of a photosensitizer molecule in the tumor cells associated with further irradiation with an appropriate visible light. We investigated whether similar changes in gene expression EGF pathway in GBM cell lines pre and post treatment with PDT could be detected and correlating the incorporation of this nanotechnology as an alternative treatment for drug-resistant tumors.Gene expression EGF pathway resulted in hipoexpression EGFR, SOS1, SOS2, STAT1, PIK3R1, PIK3C2A, PIK3CA, PIK3CB, MAP2K4, MAP3K1, MAPK1, MAPK10, and MAPK8 MAPK9 in the post-PDT. The complex EGFR-TK (tyrosine kinase) has key role in many processes that affect tumor growth and progression, including proliferation, dedifferentiation, apoptosis inhibition, invasiveness and loss of dependence on adhesion. Phosphorylation of tyrosine kinase residues in EGFR functions as binding domain Grb2/Sos complex, which activates the signaling cascade Ras/Raf/ MAPK pathway, which influences the proliferation, migration and differentiation. Members of the MAPK pathway have been associated with various functions within the process of tumorigenesis, since this pathway is responsible for the regulation of proliferation, differentiation, survival, angiogenesis and metastasis in many tumor types. These findings confirmed that the engineering of nanocarriers associated with PDT procedures led to hipoexpression of the genes that are directly involved in the tumor process the EGF pathway in vitro by advanced protocols that can be useful for future in vivo trials available to clinical oncology. With the development of protocols associating photodynamic therapy and cancer, we aim to develop advanced treatments with nanotechnological tools for highly resistant diseases such as human gliomas.

3384W

Elevated expression of maspin mRNA as a predictor of survival for stage II Gallbladder Cancer. *K. Baghel[1,2], HR. Kazmi[1], S. Raj[1], A. Chandra[1], RN. Srivastava[2].* 1) Department of Surgical Gastroenterology, King George's Medical University, Lucknow, Uttar Pradesh, India; 2) Department of Orthopaedic Surgery, King George's Medical University, Lucknow, Uttar Pradesh, India.

Introduction: Prognostic significance of Maspin gene has reported in various cancers but has not been evaluated for Gallbladder Cancer (GBC). In present study, we investigated maspin mRNA expression in normal, cholelithiasis and GBC patients along with its prognostic importance in cancer patients. Methodology: Gallbladder tissue from normal (n=25), cholelithiasis (n=25) and cancer patients (n=31) were analysed for maspin mRNA expression by semi-quantitative reverse transcriptase PCR and quantitative real time PCR. Statistical analysis was carried out using student t test and ANOVA. Kaplan-Meier method was used for survival analysis and the difference between survival curves was analyzed by log-rank test. Results: Significant increased(P<0.0001) expression of maspin mRNA was observed in GBC as compared to cholelithiasis, whereas no expression was found in normal tissues. Significant correlation (Pearson's coefficient(r)=-0.829;P<0.0001) was observed between relative quantification of maspin mRNA and survival of cancer patients after surgery. The Kaplan-Meier survival curves demonstrated that overall survival was significantly shorter(P=0.0002) in GBC patients with RQ >1.5 as compared to patients with RQ≤1.5. Patients with RQ >1.5 had a hazard ratio [HR] of 5.527 for death as compared to patients with RQ≤1.5 (95% Confidence interval [CI]=2.223-13.75). Statistically significant difference(P=0.0371) in overall survival was observed for stage II patients with RQ >1.5 in comparison to patients with RQ≤1.5. For stage III, there was no significant difference(P=0.126) in overall survival between patients with R.Q.>1.5 and R.Q.≤1.5. The HR for stage II and III disease was 5.236(95% CI =1.104-24.83) and 4.608(95% CI = 0.6507 - 32.63) respectively. Conclusion: Higher expression of maspin mRNA in gallbladder cancer has prognostic significance, especially for resected stage II cancer, which needs to be investigated further.

3385T

Prognostic signature in papillary thyroid carcinoma patients that undergone total thyroid ablation. *M.C. Barros Filho[1], F.A. Marchi[2], C.A. Pinto[1], S.R. Rogatto[1,3], L.P. Kowalski[1].* 1) AC Camargo Cancer Center, Sao Paulo, Brazil; 2) Sao Paulo University, Sao Paulo, Brazil; 3) Faculty of Medicine/UNESP, Botucatu, SP, Brazil.

Purpose. Papillary thyroid carcinoma (PTC) is the most common endocrine malignancy. Despite of the low mortality rate, recurrence is frequent and associated with patient morbidity. Currently, clinical and pathological procedures are insufficient to determine the risk of relapse. Although *BRAF* mutation is often associated with tumor aggressiveness, no molecular marker is used in clinical routine. The aim of this study is to identify molecular markers able to predict recurrence in PTC patients. **Patients and Methods.** Eighty-three patients submitted to total thyroid ablation were retrospectively enrolled. Primary fresh-frozen tumors (RNA integrity score> 7) from 58 cases were evaluated by expression oligoarray using Sure Print G3 8x60K slides (Agilent Technologies). Cases without suspicion of active disease (normal imaging screening and serum Tg) with at least five years of follow up (group 1= 46) were statistically compared with cases with confirmed recurrent disease (group 2= 12) by SAM (FDR< 20%) and t test (P< 0.005). Six transcripts were selected for further RT-qPCR confirmation in a technical validation group (samples previously evaluated by microarray) and in an independent validation group (group 1= 15 and group 2= 10) **Results.** By expression oligoarray, two genes were underexpressed (*FBXL5* and *F2RL2*) and 13 overexpressed (*FOXP2, SLC2A4, GADD45B, C6ORF223, LYSMD3, UTP23, C10ORF79, NCRNA00203, FLJ45950, S1PR1, DNTT, MBD2* and *PROM2*) in the recurrence group. Four out of six transcripts evaluated by RT-qPCR were highly correlated with microarray data (Pearson correlation test, r> 0.75 and P< 0.001). *GADD45B* remained associated with recurrence in the validation test (log rank, P< 0.004). A multivariable analysis identified *GADD45B* as an independent marker of disease free survival (Cox regression, P= 0.015). Compared to well-established clinical parameters, as lymph node involvement and extrathyroidal extension, *GADD45B* presented superior value in predicting recurrence (AUC= 0.741; CI 95%= 0.615-0.868). **Conclusion.** *GADD45B* was identified as an independent marker of poor outcome and can be useful to better stratify PTC patients according to the risk of recurrence.

3386F

LOX-1, A Novel Metabolic Target in Human Breast and Colon Cancer. *M. Biancolella, M.J. Zonetti, T. Fisco, P. Mazzarelli, F. Sangiuolo, L. Saieva, M. Murdocca, G. Novelli, S. Pucci.* Dept Biomedicine and Prevention, Univ Rome Tor Vergata, Rome, Italy.

Targeting the metabolic pathways of cancer is a hot topic for drug discovery. An emerging theme in cancer biology is that a number of lipid metabolic genes, consistently over-expressed in human cancers, are critical to cellular transformation and in maintaining the transformed state. OLR1 gene, encoding the cell membrane receptor LOX-1 (lectin-like oxidized low density lipoprotein receptor), emerged as one of the most important for maintaining the malignant state. LOX-1 may have at least two independent pro-oncogenic mechanisms of action, one based on activation of NF-kB signaling pathway and the other as regulator of lipogenesis.. We observed that LOX-1 is overexpressed in human breast and colorectal carcinomas, at different stages of disease, as compared to normal tissues. Moreover, we demonstrated that the metabolic oncogene FASN (fatty acid synthase), is overexpressed in the breast and colon neoplastic cells. Silencing ORL1 gene in a colon cancer cell line (DLD1), we observed a strong down regulation of FASN and an evident inhibition of the secreted isoform of Clusterin (sCLU) a cytoprotective protein, involved in tumor progression. Conversely, a strong up regulation of the nuclear clusterin isoform (nCLU), was observed. These data suggest a role of LOX-1 in the cancer insurgence and progression. Therefore, this protein could be considered a novel target for cancer therapy.

Increased frequencies of GSTM1 and GSTT1 null genotypes in Indian patients with Leukemia.
S. Caplash[1], S. Kaur[1], R. Arora[2]. 1) Human Genetics, Punjabi University, Patiala, Punjab, India; 2) Oswal Cancer Hospital, Ludhiana.

Glutathione S-transferases (GST) isoenzymes play a significant role in phase II biotransformation and detoxification of many xenobiotics including environmental carcinogens, pollutants and drugs. Both the genetic polymorphisms and expression pattern of GST genes may have a major impact on cancer susceptibility, inter-individual variability in the prognosis, drug effects and toxicity. Of these, GSTT1 and GSTM1 isoenzymes are highly polymorphic with homozygous deletion of either or both genes resulting in absence of enzyme activity. We carried out a trial case-control study involving 142 Leukemia patients and 60 normal healthy controls from Punjab (North India). Multiplex PCR was carried out to determine GSTM1 and GSTT1 polymorphism. The frequency of individuals carrying GSTM1 and GSTT1 null genotypes was higher among Leukemia patients (42 % and 23 %) as compared to the control group (38 % and 17 %), but the difference found was not statistically significant (p>0.05). Follow up of patients is in process to analyze the association of GST genotypes with differential chemotherapy drug response.

Two different *BRCA2* mutations found in a multigenerational family with a history of breast, prostate, and lung cancers.
D. Caporale, E. Swenson. Biology, University of Wisconsin-Stevens Point, Stevens Point, WI.

Breast and lung cancer are two of the most common malignancies in the United States, causing approximately 40,000 and 160,000 deaths each year, respectively. Approximately 5 to 10 percent of breast cancer cases are hereditary, with about 84 percent of those cases due to mutations in two large breast cancer predisposition genes, *BRCA1* and *BRCA2*. These are normally tumor-suppressor genes associated with DNA repair. Since the discovery of these two genes in 1994 and 1995, respectively, several other breast cancer predisposition genes have been identified, including the *CHEK2* gene, which is another tumor-suppressor gene. Recently, studies have begun investigating the roles of *BRCA1* and *BRCA2* in lung cancer. We conducted two case studies, one on an extended family of Italian heritage with several cases of breast cancer and associated cancers through multiple generations, and another on a non-blood relative of Scottish/Irish descent who was consecutively diagnosed with breast and lung cancer. Cancer history and environmental risk factors were recorded for each family member. To investigate possible genetic risks, we screened for mutations in specific hypervariable regions of the *BRCA1*, *BRCA2*, and *CHEK2* genes. DNA was extracted and isolated from the individuals' hair follicles. PCR, allele-specific PCR (AS-PCR) and DNA sequencing were performed to identify and verify the presence or absence of mutations in these regions. Genotypes of each family member were determined and carriers of mutations were identified. Specifically, three Italian family members were found carriers of the *BRCA2-3036del4* mutation, a 4-nucleotide deletion in an exon, which is a nonsense mutation that causes a frameshift in the genetic code, rendering the BRCA2 product nonfunctional. The individual with breast and lung cancer was not a carrier of this mutation, but rather a carrier of the *BRCA2-6503delTT*, which is also a nonsense mutation but more common in the Irish heritage.

Negotiating a Minefield: Which Variants to Return in a Large Prospective Whole Exome Sequencing Project?
A. Church[1,2], E. Van Allen[3,4,6], E. Hiller[3], I. Rainville[3], H. Rana[3,4], D. Treacy[3], K. Karalis[2,5], F. Huang[3,4,6], M. Giannakis[3,4,6], F. Wilson[3,4,6], E. Stover[3,4,6], J. Bohkari[1], L. Sholl[1], N. Lindeman[1], J. Garber[3,4], N. Wagle[3,4,6], L. Garraway[3,4,6]. 1) Pathology, Brigham and Women's Hospital, Boston, MA; 2) Pathology, Boston Children's Hospital, Boston, MA; 3) Medical Oncology, Dana Farber Cancer Institute, Boston, MA; 4) Medicine, Dana Farber Cancer Institute, Boston MA; 5) Wyss Institute, Boston, MA; 6) Broad Institute, Boston, MA.

The CanSeq study is a prospective whole exome sequencing project currently enrolling patients at the Dana Farber Cancer Institute and Brigham and Women's Hospital. Whole exome sequencing is performed at the Broad Institute on both somatic cancer tissue as well as germline DNA derived from blood. As a large collaborative effort, the aims of the project include identification of somatic and germline alterations, the identification of potentially actionable and consequential variants, and to prioritize events for treatment. Enrolled patients, who have undertaken informed consent, receive curated results of both somatic and germline sequencing.

Herein we describe the process we have undertaken to identify genes and variants of clinical significance to return to patients and their treating physicians. Lists of genes include somatic (122 genes), germline risk and carrier (149 cancer and 35 non-cancer genes), pharmacogenomics (70 cancer and 18 non-cancer genes). Our process has evolved over years and incorporates available literature, committee guidelines including the recent ACMG recommendations, ethical considerations such as beneficence, non-maleficence and justice, and the consensus of our expert collaborators.

3390W

Analysis of *BRAF* mutations (*BRAF* ^{V600E}) in gliomas.
L. DA SILVA[1], P. VIDIGAL[2], N. BINDA[1], P. COUTO[1], L. BASTOS-RODRIGUES[1], L. DE MARCO[1]. 1) INCT of Molecular Medicine (INCT-MM), Faculty of Medicine, Universidade Federal de Minas Gerais (UFMG) - Belo Horizonte, MG, Brazil; 2) Faculty of Medicine, Universidade Federal de Minas Gerais (UFMG) - Belo Horizonte, MG, Brazil.

Background: Gliomas are the most common tumors of the Central Nervous System and are classified to grades I-IV according to the WHO. Despite remarkable progress in characterizing the molecular pathogenesis of gliomas, these tumors remain incurable and, in most cases, refractory to treatment, due to its molecular heterogeneity. To improve the survival rate of gliomas patients, a better understanding of tumor biology is required as well as the subsequent development of new therapeutic strategies. *BRAF* represents one of the most frequently mutated protein kinase genes in human tumors. *BRAF* is a key mediator of the RAS-RAF-MAP kinase signaling pathway and is involved in a wide variety of cellular functions, including cell proliferation, cell cycle arrest, terminal differentiation and apoptosis. Ninety percent of the reported mutations of *BRAF* are the somatic missense mutation V600E. *BRAF*^{V600E} are present in roughly 25% of low grade gliomas but the overall impact of these mutations on clinical outcome in gliomas remains unclear. Methods: In this study, we investigated the prevalence and histopathological grade of brain tumors and correlated with the incidence of mutations in *BRAF*. The target regions of exon 15 of the *BRAF* gene were amplified using specific primers, purified and sequenced in 30 fresh tumor samples. Using immunohistochemistry, we analyzed 38 FFPE brain tumors, including 14 gliomas (grade I), 11 (grade II), 3 (grade III) and 11 glioblastomas (grade IV). Statistical analyses were made by Student's t test. Results and conclusions: In our sample, no *BRAF*^{V600E} mutations were found. The cytoplasmic *BRAF* expression was higher in neoplastic cells compared to benign cells, suggesting that the higher the grade, the greater is the immunoreactivity of *BRAF*. Several studies have shown genetic alterations in *BRAF*, mainly *BRAF*^{V600E}, in low but not in high-grade brain tumors. We found an increased expression of *BRAF* in high-grade gliomas compared to low-grade. Although we unexpectedly did not find *BRAF* mutations in any of the fresh tissue we analyzed, the increased expression suggests that other proteins and/or transcription factors-related pathways may be altered.

3391T

MtDNA copy number alteration and association with clinicopathological features in Breast Cancer patient. *M. Ghaffarpour, M. Houshmand.* Medical Genetics, National Institute of Genetic Engineering and Biotechnology, Tehran, Tehran, Iran.

Large-scale depletion in mitochondrial DNA (mtDNA) has been extensively detected in various human cancers. However, it still remains unclear whether the alterations in mtDNA content are related to the clinicopathological parameters and patient with breast cancer. To explore the role of mtDNA copy number in breast cancer etiology and association between clinicopathological features, in the present study, we performed the copy number of mtDNA in 59 cases of breast tumors and paired non-tumor tissues using quantitative real-time PCR. Our data showed that the level of mtDNA was significantly increased in tumor tissues in compared to the adjacent non-tumor counterparts (P<0.05). The increased copy number in mtDNA was not significant association with clinicopathological features such as age ,grade,stage, lymph node involvement, ER, PR and Her-2/neu expression.However, there was a significant association between decreased overall Survival (5yr %)and increased copy number in mtDNA(p=0.049). Together, our results suggested that high copy number of mtDNA may be involved in breast neoplastic transformation and mtDNA content might be potentially used as a tool to prognosis factor with the other risk factors.

3392F

TNFA-308 G>A is associated with HER-2/neu expression in women with breast cancer. *L. Gomez-Flores-Ramos[1,2], A. Escoto-De Dios[1], A. Ramos-Silva[1,3], R. Ramirez-Patiño[1,2], I. Gutierrez-Hurtado[1,2], MP. Gallegos-Arreola[1].* 1) Laborotorio de Genetica Molecular, CIBO, IMSS, Guadalajara, Mexico; 2) Doctorado en Genetica Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara; 3) Doctorado en Farmacologia, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara.

Introduction. The tumor necrosis factor-alpha gene (*TNFA*) plays an important role in cell proliferation, differentiation, apoptosis, lipid metabolism, coagulation, insulin resistance, and endothelial function. *In vitro* and *in vivo* experiments have shown the tumorigenic effects of TNF, and elevated plasma levels of TNF have been associated with a poor prognosis in Breast Cancer (BC). The TNFA-308G>A (rs1800629) polymorphism has an effect on the gene expression, increasing the production of TNF protein. The aim. To determine the association between the TNFA-308G>A in Mexican women with BC with Her-2/neu expression. **Methods.** Blood samples were collected after a written informed consent approved by the ethical committee from 371 controls and 465 patients with clinical and histological confirmation of BC living in Guadalajara, Mexico. Genotyping was performed by RFLPs. The genotype frequencies at the control group were in Hardy-Weinberg equilibrium. Statistical analyses were performed using PASW Statistic Base 18 software, 2009 (Chicago, IL). **Results and discussion.** Our results show an association between the genotypes GA-AA and the expression of Her-2/neu in BC cells (OR 1.6, 95% CI 1.06-2.4, p=0.025). The patients with the genotypes GA-AA at tumor stages I-II were also associated with Her-2/neu positivity (OR 2.5, 95% CI 1.31-4.8, p=0.004) as well as patients with BMI >30>40 and Her-2/neu (OR 2.8, 95% CI 1.2-6.6, p = 0.016). In BC patients the presence of HER-2/neu has been correlated with metastases, insulin resistance and overexpression of fatty acid synthase, and its expression is regulated by metformin in *in vitro* models. HER-2/neu serum concentrations in patients with diabetes type 2 were associated with serum TNF receptor 1, thus TNF might be behind concomitant insulin resistance and EGF resistance, leading to increased circulating HER-2/neu levels. Although the mechanisms of how the overexpression of HER-2/neu oncogene induces resistance to TNF is unknown; different studies have been observed their overexpression is associated with poor prognosis in BC, because it induces metastatic potential and resistance in cancer cells. Another mechanisms proposed is that the overexpression of Her-2/neu is mediated by signaling pathways and cytotoxicity, suggesting that the overexpression of TNF receptor-1 is important in TNF sensitivity in HER-2/neu-overexpressing cancer cells.

3393W

The anti-cancer activity of propolis in colorectal cancer. *M. Gunduz[1,2], G. Nas[1], M. Acar[1], O.F. Hatipoglu[1], B. Yilmaz[1], G. Kaya[1], E. Gunduz[1].* 1) Medical Genetics, Turgut Ozal University Medical Faculty, Ankara, Turkey; 2) Department of Otolaryngology Head and Neck Surgery, Ankara, Turkey.

Colorectal cancer is the third most commonly diagnosed cancer in the world. It originates from the epithelial cells lining the colon or rectum. Colorectal cancer is commonly observed in developed countries and is the second deadliest type of cancer. . Colorectal tumorigenesis proceeds through an accumulation of specific molecular alterations and one of the most important of these mechanisms is inhibition of apoptosis. The Inhibitors of Apoptosis (IAP) are a family of functionally and structurally related proteins, which serve as endogenous inhibitors of programmed cell death (apoptosis). Survivin is a member of the IAP family and functions as an inhibitor of caspase activation, thereby leading to negative regulation of apoptosis. This has been shown by disruption of Survivin induction pathways leading to increase in apoptosis and decrease in tumor growth. Propolis is a resinous mixture that honey bees collect from tree buds, sap flows, or other botanical sources. It is used as a sealant for unwanted open spaces in the hive and possesses anti-microbial, anti-oxidative, anti-ulcer and anti-tumor activities. The survivin protein is expressed highly in most human tumors but is completely absent in terminally differentiated cells. Our study investigated the effect of propolis onHT29 colorectal cancer cells. Propolis exhibits anticancer activity in a dose dependent manner by inhibition of survivin gene expression. Decreased Survivin expression results in a decrease in tumor growth and prevents carcinogenesis by inducing programmed cell death. Consequently, Propolis may become a strong candidate molecular agent for cancer therapy.

Identification of Complete Hydatidiform Mole Pregnancy-associated MicroRNAs in Plasma. *Y. Hasegawa[1], K. Miura[1], A. Higashijima[1], S. Miura[1], J. Tsukamoto[1], S. Abe[1], A. Kinoshita[2], H. Mishima[2], K. Yoshiura[2], H. Masuzaki[1].* 1) Obstetrics and Gynecology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 2) Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, , Nagasaki, Japan.

Objective: The aim of this study was to identify the complete hydatidiform mole (CHM) pregnancy-associated microRNAs in plasma. Methods: First, by comparative analysis of next generation sequencing-generated microRNAs expression profiles, we selected the candidate CHM pregnancy-associated microRNAs in plasma, which showed a higher expression in CHM tissues than in normal villous tissues, but no expression in blood cells. Then, expression levels of these microRNAs in CHM tissues (n:14) and normal villous tissues (n:20) were investigated to identify CHM-associated microRNAs with increased expressions in CHM tissues than in normal villous tissues. Subsequently, when the plasma concentrations of cell-free CHM-associated microRNAs were significantly higher in CHM pregnant women (n:14) than in uncomplicated pregnant women (n:20), these microRNAs were identified as CHM-associated microRNAs in plasma. Finally, to identify CHM pregnancy-associated microRNAs in plasma, circulating levels of CHM-associated microRNAs in plasma samples from CHM pregnant women (n:14) were measured before and after evacuation. Results: First, hsa-miR-520b, hsa-miR-520f and hsa-miR-520c-3p were selected as candidate CHM pregnancy-associated microRNAs in plasma, and then all of them were confirmed as CHM-associated microRNAs in tissue samples. Subsequently, all CHM-associated microRNAs were identified as CHM-associated microRNAs in plasma. Finally, the circulating levels of all CHM-associated microRNAs in plasma were decreased significantly after evacuation (Wilcoxon signed rank test, p=0.001), suggesting that all of these microRNAs were pregnancy-associated molecules. Conclusions: As CHM pregnancy-associated microRNAs in plasma, hsa-miR-520b, hsa-miR-52Of and hsa-miR-520c-3p were identified. Circulating levels of three CHM pregnancy-associated microRNAs in plasma can be potential molecular marker for CHM pregnancy.

3395F

Eukaryotic translation initiation factor 4E (eIF4E) expression is associated with breast cancer tumor phenotype and predicts survival after anthracycline chemotherapy treatment. *T. Heikkinen[1], T. Korpela[2], R. Fagerholm[1], S. Khan[1], K. Aittomäki[3], P. Heikkilä[4], C. Blomqvist[5], O. Carpén[2, 6], H. Nevanlinna[1].* 1) Department of obstetrics and gynecology, Helsinki university central hospital, Helsinki, Finland; 2) Department of pathology and Medicity laboratory, University of Turku, Turku Finland; 3) Department of medical genetics, Helsinki university central hospital, Helsinki, Finland; 4) Department of pathology, Helsinki university central hospital, Helsinki, Finland; 5) Department of oncology, Helsinki university central hospital, Helsinki, Finland; 6) Turku university hospital, Turku Finland.

Abnormal translation of mRNAs, which frequently occurs during carcinogenesis, is among the mechanisms that affect the expression of proteins involved in tumor development and progression. Eukaryotic initiation factor eIF4E is a key regulator of translation of many cancer-related transcripts, including VEGF, Cyclin D1, and MMP-9. It is over-expressed in many cancers and has been associated with worse survival of cancer patients. The protein levels of eIF4E were determined with immunohistochemistry (IHC) in 1,233 paraffin-embedded breast tumors on tissue microarrays. The effects of the IHC expression level were analyzed on tumor characteristics and patient survival. The survival analyses were also stratified by tumor properties and adjuvant chemotherapy treatment. A number of 1,085 tumors were successfully stained. A high level of eIF4E protein expression was associated with several characteristics of aggressive breast cancer, namely grade, estrogen and progesterone receptor negativity, HER2 receptor positivity and high expression of p53 and Ki67 (p<0.001). High eIF4E expression was also associated with worse breast cancer-specific survival with a hazard ratio (HR) of 1.99 (95% CI:1.32-3.00, p=0.0008). In multivariate analysis high expression of eIF4E was found to be an independent prognostic factor. High eIF4E expression was also associated with worse survival after detection of distant metastasis (HR=1.88, 95% CI:1.20-2.94, p=0.0060). In the stratified survival analyses the survival effect was strongest among patients treated with anthracycline chemotherapy (HR=3.34, 95% CI:1.72-6.48, p= 0.0002), whereas no effect was seen among patients who had not received anthracycline with significant difference in heterogeneity between the two groups (p=0.0358). Our results confirm that high expression of eIF4E is associated with adverse tumor characteristics and with poor prognosis of breast cancer patients. The strongest survival effect was seen in patients treated with anthracycline-based chemotherapy, suggesting eIF4E to have predictive value as a biomarker. These results highlight the importance of the regulation of mRNA translation in the biology of breast cancer and emphasize the potential of eIF4E as a therapeutic target. Further studies are required to validate eIF4Eas a treatment predictive factor in breast cancer.

Personalized Genomics of Metformin Therapy for Improved Cancer Survival. *C.C. Iverson[1,2], H. Xu[3], Q. Chen[4,5], A. Shah[5], Q. Dai[6], J. Warner[5,7], N.B. Peterson[7], L. Olson[1], D.C. Crawford[1], D.M. Roden[7,8], J.C. Denny[5,7], M.C. Aldrich[1,2,6].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Thoracic Surgery, Vanderbilt University, Nashville, TN; 3) The University of Texas School of Biomedical Informatics at Houston, Houston, TX; 4) Department of Biostatistics, Vanderbilt University, Nashville, TN; 5) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 6) Division of Epidemiology, Vanderbilt University, Nashville, TN; 7) Department of Medicine, Vanderbilt University, Nashville, TN; 8) Department of Pharmacology, Vanderbilt University, Nashville, TN.

Increasing evidence supports a role for metformin as a therapeutic for improved cancer survival. To determine the potential use of metformin in a personalized genomic medicine approach for the treatment of cancer, we performed a genome-wide association study of overall survival in cancer patients. Using the Vanderbilt University large-scale biorepository linked to electronic medical records, we identified 1,106 individuals (674 with type 2 diabetes (T2D), 432 non-diabetics) of European ancestry diagnosed with cancer between 1995 and 2010. Among cancer patients with T2D, 461 individuals were on metformin therapy and 213 were treated with other T2D medications. Patients were followed a median of 2.3 years (IQR: 1.3-3.8) for overall mortality or loss to follow-up. Participants were genotyped using either the HumanOmni5-Quad or Illumina OMNI-Quad genotyping platforms. We estimated hazard ratios (HRs) and accompanying 95% confidence intervals (CI) for overall mortality using Cox proportional hazard models, adjusted for age and sex, to evaluate associations between genetic variants and mortality, using an additive model. Genomic control was applied to correct for potential population stratification occurring in the study. Among cancer patients who were metformin users, we identified one marker, rs153047, near genome-wide significant and associated with a two-fold higher mortality (HR=2.22, 95% CI: 1.91-2.54, $p=5.6 \times 10^{-7}$). This SNP was not associated with mortality in T2D cancer patients on other drugs or non-diabetic cancer patients (p>0.20 for all groups). Assessment of gene-environment interactions demonstrated that the association with rs153047 may vary by metformin use (p=0.15). Among individuals homozygous for the reference allele, metformin use was associated with a significantly reduced mortality compared to non-metformin use (HR=0.58, 95% CI: 0.25-0.92, p=0.0023). Metformin use was not significantly associated with improved survival for individuals with the variant allele (HR=0.98, 95% CI: 0.47-1.49, p=0.95). This marker is located within *SNTB2* on chromosome 16q22.1, which has been previously shown to be associated with invasive breast cancer. Additional SNPs on chromosomes 3, 10, 12 13, and 16 had $p<10^{-6}$ and deserve further investigation. Our findings suggest the survival benefit of metformin therapy may be modulated by specific genomic loci. If replicated, this finding may be useful to target metformin therapy in cancer patients.

3397T

Comparison of mRNA expression profiles in familial and sporadic breast cancers in Finnish population. *S. Khan[1], P. Heikkilä[2], K. Aittomäki[3], C. Blomqvist[4], H. Nevanlinna[1].* 1) Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 2) Department of Pathology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Clinical Genetics, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland; 4) Department of Oncology, University of Helsinki and Helsinki University Central Hospital, Helsinki, Finland.

Although majority of breast cancers initiate from somatic alterations, familial aggregation and twin studies have suggested that hereditary predisposing factors are involved in up to one third of all breast cancers. The underlying inherited mutations in breast cancer families may also affect the progression and mRNA expression profiles of the tumors. In order to investigate the differences in mRNA expression profiles of familial and sporadic tumors, we performed a comparative study of mRNA levels in 211 familial and sporadic tumors from Southern Finland. Altogether we had mRNA expression data (Illumina HumanHT-12 platform) from 139 sporadic and 72 familial samples. The expression data was quantile normalized and the comparison in mRNA expression levels between familial and sporadic samples were performed by empirical Bayes t-test. By comparing the gene expression in familial vs. sporadic breast tumors overall we did not find any genes with expression greater than 1.2-fold above or below expression threshold. Since the estrogen receptor (ER) status has been shown to affect gene expression profiles in breast cancer, we further analysed the tumor samples according to the ER status. In the ER positive subgroup, we found 3 genes upregulated and 2 genes downregulated above and below 1.2-fold expression threshold in the familial vs. sporadic subgroups. The largest differences between the familial and sporadic subgroup were obtained in ER negative subgroup where we identified 25 up- and 25 downregulated genes (9 up- and 6 downregulated genes with greater than 2-fold expression threshold). The results help pinpointing genes with aberrant expression in putative germline mutation carriers compared to sporadic cases, especially in the ER defined subgroups and thus might indicate novel susceptibility genes.

3398F

Discovering latent cancer characteristics predictive of drug sensitivity.
D.A. Knowles, A. Battle, D. Koller. Stanford University, Stanford, CA.

Several recent studies have involved assaying the sensitivity of a library of cancer cell lines to an array of anti-cancer compounds, in particular the Cancer Cell Line Encyclopedia (CCLE), Genomics of Drug Sensitivity in Cancer (GDSC) and the Heiser dataset on which the DREAM challenge was based. Along with growth curve measurements, molecular characteristics of the cell lines are assayed: CCLE for example includes gene expression microarrays (GE), copy number variation (CNV), and oncogene mutation status assays. We extend previous per drug regression analysis using biologically informed dimensionality reduction and performing joint analysis across drugs in order to improve statistical power. We perform two stages of dimensionality reduction on the cell line characteristics, both using biological knowledge. In the first stage, we use a one dimensional factor analysis model for each gene, so that each data modality is considered an observed variable, explained by the latent factor which we envisage as the activation level of this gene. This is distinct from simply averaging across the different modalities: for example, methylation might be negatively correlated with gene expression, which we can account for. In the second stage, we use a hand curated collection of 1987 known pathways, collected from resources including GO, KEGG, and published GWAS hits, to construct a per pathway activation level, again using a one dimensional factor analysis. This approach gives easily interpretable results since the predictive pathways are associated with particular functions. While cancer is an incredibly heterogeneous disease there are characteristics shared across many cancers: disruption of apoptosis, cell cycle regulation, or DNA repair mechanisms, or addiction to specific oncogene pathways. We develop a model that hypothesizes a finite set of such unobserved, latent characteristics, which explain the observed drug sensitivity patterns and which are encouraged to be related to the pathway activation levels found by the dimensionality reduction procedure. The presence or absence of these characteristics confers sensitivity or resistance to specific therapeutic compounds. Our initial results on the CCLE dataset suggest five such latent characteristics are key predictors of drug sensitivity across cell lines and drugs. The top two most frequently used pathways involve vasculature development and TGF-beta signalling.

Prognostic significance of syndecan-1 expression in colorectal carcinoma.
S.H Lee[1], E.J Choi[2], J.A Yoon[2], E.S Jung[1], S.Y Kim[2]. 1) Department of Hospital Pathology, College of Medicine, Seoul St. Mary's Hospital, The Catholic University of Korea, Seoul, South Korea; 2) Department of Pathology, College of Medicine, The Catholic University of Korea, Seoul, South Korea.

Background: Syndecan-1 (SDC1) is reported to modulate several key processes of tumorigenesis and have variable expression in many cancers. The cause provoking altered expression is not known to date. In this study, we compared SDC1 status with various clinicopathologic parameters and molecular markers to evaluate clinical implications in colorectal carcinoma. Methods: With 219 surgical specimens of primary colorectal carcinoma, treated between 2008 and 2010 at the Seoul St. Mary's hospital, the catholic university of Korea. The study group consisted of 136 men and 83 women. The mean age was 62.3 years (range 32-93 years). We screened SDC1 expression using immunohistochemistry and analyzed the relationship between SDC1 expression and various clinicopathological parameters and molecular markers. Results: The tumors were located mainly in the left colon (68.5%) and especially in the rectum (37.9%). There were 206 (94.1%) adenocarcinomas, 10 (4.6%) mucinous adenocarcinomas and 3 other tumors. Most of the carcinomas were pT3 and pT4 (n=150 and 49, respectively). Regional lymph nodes contained metastases in 138 patients. SDC1 expression was found in cancer cells in 212 cases (96.8%) of colon cancer. Of the SDC1 expression cases, 131 cases dominantly showed membranous immunopositivity, 81 cases showing cytoplasmic pattern. 154 cases showed mixed membranous and cytoplasmic pattern. In 93 cases, stromal SDC1 reactivity was noted. It was significantly associated with primary tumor (T) (p=0.000) and perineural invasion (p=0.043). In addition, it was correlated with EGFR immunohistochemical reactivity (p=0.004). On the contrary, it was not significantly correlated with lymph node metastasis (N), distance metastasis (M), lymphatic and vascular invasion, and K-ras mutation states Conclusions: We showed that SDC1 expression is associated with T stage, status of perineural invasion and EGFR immunoreactivity in colorectal carcinoma. The expression profiles of SDC1 may be of prognostic value in colorectal cancer and may help in identifying aggressive forms of colorectal carcinoma. Further studies are necessary to better understand the role of SDC1 in the progression and invasiveness of colorectal carcinoma.

3400T

Mutations and copy number changes identified in primary brain tumors using complementary analyses and formalin-fixed, paraffin-embedded (FFPE) tissues.
A. Ligon[1,2,3], B. Alexander[2,3], S. Ramkissoon[1,2,3], P. Wen[2,3], D. Reardon[2,3], E. Lee[2,3], M. Rinne[2,3], A. Norden[2,3], L. Nayak[2,3], S. Nuland[2], L. Doherty[2], D. Lafrankie[2], L. Brown[2], N. Arvold[2], S. Santagata[1,2,3], I. Dunn[2,3], N. Lindeman[1,3], L. MacConaill[1,2], B. Rollins[2,3], R. Beroukhim[2,3,4], K. Ligon[1,2,3]. 1) Department of Pathology, Brigham & Women's Hospital, Boston, MA; 2) Department of Medical Oncology, Dana Farber Cancer Institute, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Broad Institute, Cambridge, MA.

Routine and integrated genomic approaches for genotyping clinical oncologic specimens have not yet been well-established. Whole genome testing in of oncologic specimens can inform diagnosis, prognosis and genotypic stratification with respect to clinical trials. However, the accessibility of such data is constrained by the frequent need to rely on routine formalin-fixed, paraffin-embedded (FFPE) samples as starting material. In this study, whole genome copy number analysis was performed as a routine clinical test for 400 primary adult and pediatric FFPE brain tumors. The tumors, which included meningiomas and gliomas, were analyzed by array-based comparative genomic hybridization (aCGH) using stock 1x1M Agilent SurePrint G3 arrays. Twenty-three copy number aberrations relevant to diagnosis, prognosis or clinical management were scored for each tumor. In addition, as part of a clinical trials research program, we profiled somatic mutations using the Oncomap v4.4 platform (Sequenom), which queried 471 known cancer-related mutations in 41 genes. We identified *PIK3CA* mutations in grade I meningothelial subtype tumors and found that sequence mutations, including *IDH1* and *IDH2* mutations, were present in ~30% of gliomas, mostly in tumors of WHO grade II or III. Both mutation and copy number data were obtained for a subset of the gliomas, 68% of which were classified as glioblastoma (GBM). Copy number changes identified in GBM varied with the patient age and *IDH1* mutation status, and included polysomy 7, *EGFR* amplification, identification of the EGFRvIII structural variant, as well as losses of *CDKN2A*, *PTEN*, *RB1* and *TP53*. Copy number profiles for *IDH1*(p.R132H) mutant tumors generally showed less complexity than that of tumors with wild-type *IDH1*. 1p/19q co-deletions were readily identified in oligodendroglial tumors, as were single copy gains involving *BRAF* that are consistent with the *BRAF* duplication event observed in pilocytic astrocytomas and related tumors. In summary, we developed complementary assays for detecting common cancer-specific mutations and genome wide copy number changes from FFPE tissues. Together, these assays have been integrated to generate data that are diagnostic (e.g., 1p/19q co-deletion), prognostic (e.g., *IDH1* and *IDH2* mutation status), or that illuminate genomic aberrations (e.g., identification of EGFRvIII variant) for use in advancing clinical trial enrollment and therapeutic management.

A leukemic stem cell score associated with patient prognosis and tumor histopathology in ovarian cancer.
B.A. Logsdon[1], S.L. Battle[1], M.H. Rendi[2], R.D. Hawkins[1], S-I. Lee[1,3]. 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Anatomic Pathology, University of Washington Medical Center, Seattle, WA; 3) Department of Computer Science and Engineering, University of Washington, Seattle, WA.

We derive a novel leukemic stem cell (LSC) score based on the gene expression levels of ten genes associated with both patient prognosis and leukemic stem cells in acute myelogenous leukemia (AML). Using gene weights estimated from AML patients across multiple studies, we generate the LSC score in three independent gene expression data-sets for patients with ovarian cancer. The LSC score is significantly associated with poor patient prognosis in ovarian cancer (Cox proportional hazard inverse normal meta-analysis p-value: 8.55×10^{-7}). The LSC score is also significantly associated with the optimal debulking status of tumors (Fisher meta-analysis p-value: 4.93×10^{-4}). In data available from The Cancer Genome Atlas on patients with ovarian serous carcinoma we show that the LSC score is associated with abnormal tumor stroma, increased desmoplastic response, and increased tumor invasiveness. Additionally, there is evidence of increased abnormal angiogenesis in patients with high LSC scores, suggesting an opportunity for targeted interventions with anti-vascular endothelial growth factor therapies. This strategy is further motivated by recent efforts to target tumor vascularization with anti-angiogenic therapies in AML. Our results suggest the LSC score is a novel biomarker that is informative for cancer stem cell populations, abnormal tumor histopathology, and patient prognosis in ovarian cancer.

Coupled Use of Family-based Exome Sequencing and TCGA Germline Data Analysis to Identify Novel Breast and Ovarian Cancer Susceptibility Genes. *J.A. Martignetti[1], P. Dottino[1], M. Babcock[1], L. Jara[3], K. Moysich[2], L. Sucheston[2], S. Lele[2], K. Odunsi[2], S. Sanga[4].* 1) Genetics & Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 2) School of Medicine and Biomedical Sciences State University of New York at Buffalo, Buffalo, NY, USA; 3) Human Genetics Program, University of Chile School of Medicine, Santiago, Chile; 4) Station X, Inc., San Francisco, CA, USA.

Family history is the strongest single predictor of a woman's risk for developing breast and/or ovarian cancers. Genetic studies seeking to identify breast and ovarian cancer susceptibility genes have therefore focused on those families with a high incidence of cancer across multiple generations. While they represent the strongest known genetic predictors, BRCA1/2 mutations account for less than half of all families containing two or more cases in first-degree relatives and explain less than half of the excess familial cancer risk. Our hypothesis is that the residual risk of familial breast and ovarian cancers is attributable to mutations and/or genetic variants in genes other than BRCA1/2. To identify novel susceptibility genes, we exome sequenced the germlines of a discovery cohort of selected families with hereditary breast and ovarian cancer but who lacked deleterious BRCA mutations. The discovery cohort was sequenced using Illumina technology at the Icahn School of Medicine at Mount Sinai and Beijing Genomics Institute. Permutations of BWA sequence alignment, GATK re-calibration/re-alignment, SRMA re-alignment, GATK variant calling, and VarScan2 variant calling were used to identify small genomic variations (SNVs, small INDELs). These variants were annotated, visualized, analyzed, and evaluated within GenePool™ (Station X, Inc., San Francisco, CA) for rare variants consistent with an autosomal dominant model of inheritance. All exome-defined candidate mutations were then triaged by leveraging biological annotations, filtering capabilities, and cross-referencing the interactive genome browser within GenePool™. Once this highest tier of candidates was established, they were then compared within and between families, and candidate genes mutated in multiple families were identified. To further refine this list and begin to gain an understanding of the extent of their mutation in a larger cohort, we compared our findings to germline and somatic variant allele frequencies derived from the most up-to-date TCGA breast and ovarian cancer genome data. The somatic and germline variants in the TCGA cohorts were called using bioinformatics pipelines consistent with those used for the discovery cohort, and made accessible through GenePool™ at varying granularities along with the relevant clinical metadata per sample. The final variant list of novel breast and ovarian susceptibility genes, and functional validation studies will be discussed.

3403T

KiSS1 suppressor metastasis gene rs12998 and rs5780218 polymorphisms in Mexican patients with breast cancer. *M.C. Moran Moguel[1], S.E. Flores Martínez[1], L.A. Juarez Aguilar[2], J. Sanchez Corona[1], I.P. Davalos Rodriguez[1], R.C. Rosales Gomez[1], S.A. Gutierrez Rubio[1], M.I. Torres Moran[3], E.G. Cruz Quevedo[1].* 1) Centro de Investigación Biomedica de Occidente, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, Mexico; 2) Doctorado en Genética Humana. CUCS. Universidad de Guadalajara. Guadalajara, Jalisco. Mexico; 3) IMAREFI. CUCBA. Universidad de Guadalajara. Guadalajara, Jalisco. Mexico.

Aims. KiSS1 is a metastasis suppressor gene that has been associated with inhibition of cellular chemotaxis and invasion attenuating the metastasis in melanoma and breast cancer cell lines. Along the KiSS-1 gene have been described at least 130 SNPs however the association of these polymorphisms as genetic markers for metastasis in breast cancer studies has not been investigated. Here we describe two simple PCR-RFLPs protocols to identify the 9DelT (rs5780218) and E20K (rs12998) KiSS1 polymorphisms and the allelic, genotypic and haplotype frequencies in Mexican general population (GP) and patients with benign breast disease (BBD) or breast cancer (BC) in any histological stage. Results. Individually, none of the polymorphisms were associated with breast cancer, since when comparing alleles and genotypes between the BC group vs BBD and GP groups, no differences were finded ($p > 0.05$); however, for polymorphism rs 12998 comparing GP vs case (BC and BBD) groups, statistically significant differences were found. The haplotype consisting of the wild-type allele of rs12998 and variant allele of rs5780218 polymorphisms (G/del) occurred more frequently in the BC group (0.4256) whereas haplotype G/T (both wild type alleles) was the most prevalent in BBD group (0.4674). Conclusions. Our data indicated that these polymorphisms individually do not confer susceptibility for development of breast cancer or metastasis in Mexican population, however, a possible role as genetic marker in breast cancer metastasis for H1 haplotype (Wt/Variant) in KiSS1 gene, must be analyzed in other populations.

3404F

Initial viral load in cases of single human papillomavirus 16 or 52 persistent infection is associated with progression of later cytopathological findings in the uterine cervix. *K. Ohashi[1], K. Miura[1], S. Abe[1], A. Kinoshita[2], S. Miura[1], D. Hamaguchi[1], KI. Yoshiura[2], H. Masuzaki[1].* 1) Obstetrics and Gynecology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Nagasaki, Japan; 2) Human Genetics, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Nagasaki, Japan.

Objectives: The aim of this study was to investigate the relationship between viral load in single human papillomavirus (HPV) 16 or 52 persistent infection and the progression of later cytopathological findings in the uterine cervix. **Methods:** Cervical cytological tests and HPV genotyping tests were repeated within 3-6 months in 305 women with oncogenic HPV. Then, 24 cases of a single HPV52 persistent infection and 24 cases of a single HPV16 persistent infection were identified. Cases of later cytological findings showing progression were defined as 'progression' group, while cases of no-change or regression were as 'non-progression' group. Relative HPV DNA loads were determined by quantitative real-time polymerase chain reaction and expressed relative to human albumin (ALB) DNA. Differences between the two groups were evaluated. **Results:** The median relative HPV 52 DNA load was 2.211 in the progression group and 0.022 in the non-progression group (Mann-Whitney U test, $P=0.003$). The median relative HPV 16 DNA load was 4.206 in the progression group and 0.103 in the non-progression group ($P=0.001$). **Conclusions:** HPV 52 or 16 DNA load, which is measured by quantitative real-time methods, may be useful as a short-term marker to identify women at high risk for progression of cervical cytological findings.

Conventional and Molecular Cytogenetic Techniques in Comparison with mRNA and DNA Based Quantitative Real-Time PCR to Monitor Minimal Residual Disease in Chronic Myeloid Leukemia. *I.S. Pagani[1,4], C. Pirrone[1], D. Pigni[1], O. Spinelli[2], C. Boroni[2], T. Intermesoli[2], U. Giussani[2], F. Pasquali[1], F. Lo Curto[1], A. Lanfranchi[3], F. Porta[3], A. Rambaldi[2], G. Porta[1].* 1) Department of Clinical and Experimental Medicine, Insubria University, Varese, Italy; 2) Paolo Belli Haematology Division, Papa Giovanni XVIII Hospital, Bergamo, Italy; 3) Hematology and BMT Unit Children's Hospital Spedali Civili Brescia, Italy; 4) Dept. of Experimental Medicine and Surgery, University of Rome Tor Vergata, Italy.

The Imatinib mesylate (IM) is the first line therapy against Chronic Myeloid Leukemia (CML), through the inhibition of the BCR-ABL1 proliferation pathway. Despite its efficacy in prolonging overall survival, discontinuation of treatment is associated with molecular relapse. So, to maintain an operational cure IM is required indefinitely, despite financial cost to the community and side effects. To evaluate the degree of response to therapy and to highlight the persistence of the disease after treatment, patient should be monitored routinely. The gold standard for diagnosing CML is the cytogenetic analysis, a direct not-sensitive method to detect Ph-positive cells. Quantitative real-time RT-PCR (qRT-PCR) based on mRNA is the most sensitive technique available for the detection of BCR-ABL1 transcripts and it is used to follow the progression of CML after initial diagnosis and treatment. However mRNA levels are not directly related to number of leukemic cells and negative results are difficult to interpret, because undetectable levels of chimeric transcript can reflect either an effective elimination of leukemic cells, or the presence of a leukemic cell transcriptionally silent. Here we will propose a new sensitive approach to directly detect the number of leukemic cells using a DNA-based biomarker specific for each patient. For the first time we developed a DNA Q-PCR assay based on the genomic breakpoint found with Next-generation sequencing and a formula to calculate the number of Ph+ cells. We monitored eight CML patients in their early chronic phase and in follow-ups up to 8 years under Imatinib treatment. We carried out patient specific Q-PCR assays to monitor minimal residual disease, testing the same samples in parallel by cytogenetic analysis and by standard qRT-PCR. In all positive samples for chimeric transcript we measured positive levels of corresponding genomic DNA, confirming the sensitivity of the method. Furthermore, we showed the persistence of leukemic cells transcriptionally-silent by Q-PCR in 33% of samples with undetectable levels of mRNA. Finally, we applied our technique in the evaluation of BCR-ABL1 presence in CD34+ sorted cells in order to enrich the cancer stem cells. In conclusion the DNA Q-PCR is a sensitive and direct technique to identify leukemic cells and patients that could be candidate to stop the therapy. Thanks to AIRC, AIL.

3406T

ALK gene copy number gain in a series of 350 NSCLC: a single institution experience. *L. Pecciarini[1], A. Talarico[1], G. Grassini[1], E. Dal Cin[1], S. Foti[2], C. Lazzari[2], V. Gregorc[2], M.G. Cangi[1], C. Doglioni[1].* 1) Pathology Unit, San Raffaele Scientific Institute, Milan, Italy; 2) Oncology Department, San Raffaele Scientific Institute, Milan, Italy.

Anaplastic lymphoma kinase (ALK) gene translocations are involved in the tumorigenesis of a small group of non-small cell lung carcinomas (NSCLCs) and identify patients sensitive to ALK inhibitors. Therefore fluorescence in situ hybridization (FISH) analysis for ALK rearrangements is routinely performed in NSCLC patients for correct therapy selection. ALK gene copy number (GCN) gains are known to play an oncogenic role in tumors such as neuroblastoma, but they are poorly characterized in NSCLC. Indeed in our experience ALK GCN changes represent common incidental findings of the ALK FISH test in NSCLCs. In this study we report the prevalence of ALK GCN gain and its correlation to ALK protein expression, epidermal growth factor receptor (EGFR) gene and v-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS) gene mutational status, and clinicopathological data in a series of 350 NSCLC patients treated at our Institution. ALK translocations and gene status was evaluated by fluorescence in situ hybridization (FISH), using a commercial split-apart ALK (2p23) probe. Specimens positive for a ALK split signal were studied for echinoderm microtubule-associated protein-like 4 (EML4, 2p11) gene involvement using a three color FISH probe. Gain of ALK GCN was defined in 2 categories: low gain = 4<ALK<12 copies in ≥40% of tumor cells and high gain = ALK ≥12 copies in ≥5% of tumor cells. ALK expression was assessed by immunohistochemistry. EGFR and KRAS mutational status were also assessed by both direct sequencing and pyrosequencing. ALK translocations were identified in 10% of the analyzed cases and none of them were either EGFR or KRAS mutated. Interestingly ALK GCN gains were observed in 15% of the ALK translocation negative cases: 10% with low gain and 5% with high gain. EGFR gene and KRAS gene were mutated in respectively 20% and 8% of the samples with ALK GCN gains. ALK translocations, but not ALK GCN gains were associated with ALK protein overexpression. In order to better characterize ALK GCN gains in NSCLCs, correlation with clinico-pathological data and both EGFR gene and KRAS gene mutations are under evaluation and results will be presented.

3407F

Shortened telomere length and survival in bladder cancer patients. *A. Russo[1,2], F. Modica[1], S. Guarrera[1], G. Fiorito[1,2], A. Allione[1], B. Pardini[1], R. Critelli[1,2], F. Ricceri[1], A. Bosio[3], G. Casetta[4], G. Cucchiarale[5], P. Destefanis[3], P. Gontero[4], L. Rolle[3], A. Zitella[4], D. Fontana[6], P. Vineis[1,7], C. Sacerdote[8], G. Matullo[1,2].* 1) Human Genetics Foundation, Turin, Turin, Italy; 2) Department of Medical Sciences, University of Turin, Turin, Italy; 3) Department of Urology 2, San Giovanni Battista Hospital and University of Turin, Turin, Italy; 4) Department of Urology 1, San Giovanni Battista Hospital and University of Turin, Turin, Italy; 5) Department of Urology, Clinica Cellini, Turin, Italy; 6) Department of Epidemiology, Biostatistics & HTA, Radboud University Medical Centre, NL-6500 HB, Nijmegen, The Netherlands; 7) Imperial College London, UK; 8) CPO Piemonte, Turin, Italy.

Telomeres are the specialized DNA-protein structures composed of a variable number of simple repetitive nucleotide repeats (TTAGGG) that cap the ends of linear eukaryotic chromosomes. They are responsible for the protection of the chromosome ends from nucleolytic degradation, end-to-end fusion, irregular recombination, and other lethal events to a cell. Replicating somatic cells in vivo lose ~50-105 bp per year, because of DNA polymerase's inefficient replication of linear DNA ends. Excessive or accelerated telomere shortening results in critically short telomeres, inducing cellular senescence and apoptosis. If protective mechanisms, such as the TP53 tumor-suppressor gene, are inactive, thus allowing continued proliferation, telomeres become extremely short and dysfunctional; end-to-end fusions ultimately cause chromosomal instability that may contribute to the development of several types of cancer. Moreover, as a marker of cumulative cellular aging, short telomere length may also be associated with increased risk of early death in elder individuals. In the present study, we analyzed blood telomere length (TL) in 463 bladder cancer patients followed for up to 18 years using quantitative PCR to evaluate its association with risk of death. Patients with non-invasive tumor had significantly longer telomeres than patients with invasive tumor (RQ=0.78 vs. 0.71, p=0.03). Decreasing quartiles of TL were associated with decreasing survival after cancer (log-rank test, p=3.9×10-4). Finally, Cox model adjusted by age, cancer extension, radical cystectomy, radiotherapy and chemotherapy, showed an independent effect of TL on bladder cancer survival (HR=2.03 95% CI, 1.27-3.23, p=0.003). In conclusion, our results suggest that TL inversely correlates with tumor extension and that shortened telomeres act as an independent prognostic predictor for survival of bladder cancer patients.

Generating Hypotheses for Targeted Therapies with Cancer In silico Drug Discovery Tools. *F.A. San Lucas[1,2], J. Fowler[2], S. Kopetz[1,4], E. Vilar[1,3,4], P. Scheet[1,2].* 1) The Graduate School of Biomedical Sciences, The University of Texas Health Science Center at Houston, Houston, TX; 2) Epidemiology, The University of Texas M.D. Anderson Cancer Center, Houston, TX; 3) Clinical Cancer Prevention, The University of Texas M.D. Anderson Cancer Center, Houston, TX; 4) GI Medical Oncology, The University of Texas M.D. Anderson Cancer Center, Houston, TX.

We have developed *Cancer In silico Drug Discovery (CIDD) Tools* to empower clinical researchers to perform preliminary analyses for drug discovery projects by facilitating the setup, execution and evaluation of *in silico* cancer drug experiments. CIDD is a toolset that integrates genomic mutation data, tumor gene expression profiles and drug-induced gene expression profiles from public data sets to help researchers generate hypotheses for three general problems: (1) to determine if a particular somatic mutation or a set of mutations in a cancer is functional, producing unique gene expression signatures, (2) to find candidate drugs to treat, or repress, these alterations in gene expression, and (3) to identify cell-lines for subsequent lab experimentation that most closely represent the cancer being studied. CIDD integrates publicly available experimental data and annotation databases, such as data from *The Cancer Genome Atlas (TCGA)*, the *Connectivity Map (CMap)* and the *Cancer Cell-line Encyclopedia (CCLE)* to perform the in silico experiments. CIDD characterizes generated tumor expression signatures using *MSigDB* and describes candidate drugs by integrating data from annotation databases such as *DrugBank* and *SuperDrug*. An end result of a CIDD execution is a statistically derived, biologically interpretable candidate drug list. This empowers clinical researchers to make biologically informed decisions on candidate drugs. To illustrate its use, we applied CIDD to the study of BRAF-mutant colorectal cancers. CIDD identified BRAF-mutant (V600E) samples from the TCGA colorectal cancer (CRC) project, extracted RNA-seq and microarray gene expression data for BRAF-mutant and BRAF-wildtype samples, verified a BRAF-mutant gene expression signature that was previously proposed by Popovici et al (2012, Journal of Clinical Oncology, 30:1288-1295), and then identified and characterized a list of candidate drugs to target BRAF-mutant CRCs. Through CIDD, we identified EGFR and proteasome inhibitors to target BRAF-mutant CRCs, and CIDD proposed 7 possible cell-lines from the CCLE as the best candidates on which to test the drugs. CIDD is written in Python and requires R. CIDD will be available at http://scheet.org/software.

Decreased gene expression and localization of alkaline phosphatase (L/B/K) to the microvillus membrane of renal cells in renal cell carcinoma. *U. Sharma[1], D. Pal[1], S.K. Singh[2], N. Kakkar[3], A.K. Mandal[2], R. Prasad[1].* 1) Biochemistry, PGIMER, Chandigarh, Chandigarh, India; 2) Urology, PGIMER, Chandigarh, chandigarh, India; 3) Histopathology, PGIMER, Chandigarh, chandigarh, India.

The present study was conducted to explore the expression and localization of Liver/Bone/kidney alkaline phosphatase (L/B/K ALP) on renal tubular cells in clear cell renal cell carcinoma (RCC). A total of 50 patients of histopathologically confirmed cases of RCC were included in this study. The L/B/K ALP protein level was determined by immunohistochemistry, immunofluorescence and flow cytometry in renal cell carcinoma and adjacent normal renal parenchyma tissue. The mRNA expression of L/B/K ALP was detected using real time PCR. All the parameters were statistically analyzed. Immunohistochemistry showed mean immunoreactivity in all normal renal sections (n = 50) was 2.9. Whereas, mean L/B/K ALP immunoreactivity in all tumor samples (n = 50) was 0.7. Similarly, immunofluorescence showed mean L/B/K ALP immunoreactivity in all normal renal sections (n = 50) was 3.2. Whereas, it was 0.5 in tumor (n=50).The flow cytometric studies documented a significant reduction in the ALP presentation on microvillus membrane of RCC (291.9±16.8 vs 191±15.9; P<0.05). Further, Real time PCR analysis revealed a significant depreciation in the ALP mRNA transcript in the RCC tissue (0.65±0.09 vs 1.0±0.18; P<0.01). These findings conclude that reduced activity of ALP in BBM could be associated with reduced ALP gene expression and as well as decreased localization to microvillus membrane of RCC cells.

Hif1a and PHD gene expression levels in CML patients. *A. TOYLU[1], O. Altiok Clark[1], O. Salim[2], A. Timuragaoglu[2], M. Okur[3], OK. Yucel[2], M. Ulubahsi[3], K. Eker Guler[3], N. Sayin Ekinci[3], I. Karadogan[2], L. Undar[2].* 1) Department of Medical Genetics, Akdeniz University Medical Faculty, ANTALYA, Turkey; 2) Department of Hematology, Akdeniz University Medical Faculty, ANTALYA, Turkey; 3) Laboratory of Hematology, Akdeniz University Hospital, ANTALYA, Turkey.

Hif1a is a transcription factor regulating the expression of multiple genes responsible for the cancer development and metastasis. The expression of Hif1a gene is regulated by transcriptional and post-transcriptional mechanism which is related with the proteosomal degradation of Hif1a protein by PHD family proteins. It has been reported that Hif1a protein itself also regulates the expression of PHD family genes by a feedback mechanism. The high level of Hif1a expression was found in various types of cancer but the expression levels of PHD family genes were remain unclear. Recent studies on hematologic malignancies indicated the differential expression of Hif1a gene in leukemia cells. In particular, chronic myeloid leukemia (CML) stem cells express Hif1a gene accompanied by increased survival capacity. But still there is no data about the expression level of the PHD genes in leukemia cells. Our study was performed to investigate the expression of Hif1a and PHD genes in CML cells. The expression levels of Hif1a and PHD genes compared among each other and the relationship between the BCR-ABL which is the marker gene of CML, and Hif1a expression analyzed. Peripheral blood and bone marrow samples of 29 CML patients, who have been receiving imatinib therapy, were obtained to investigate mRNA expression of Hif1a, PHD1 and PHD2 genes. RPL13A gene was used as a reference gene. Real time quantitative PCR and REST analysis were performed to measure expression levels. Hif1a and PHD2 gene expressions were higher in BCR-ABL negative CML patients compared to BCR-ABL positive patients. There was no difference in the expression of PHD1 gene among these two groups. The patients who have a high level of Hif1a expression also showed high level of PHD2 expression but PHD1 expression levels were unchanged. These results indicate that Hif1a and PHD2 genes have a similar expression pattern among CML patients. According to our data, the expression of PHD1 and PHD2 genes is most likely regulated by Hif1a. But there might be another mechanism that is independent from Hif1a for the regulation of both PHD1 and PHD2 genes. The relationship between Hif1a and PHD family genes needs to be further analyzed in CML.

3411W

Applicability of high-resolution multicapillary electrophoresis for molecular characterization of immune gene rearrangement profiles in acute lymphoblastic leukemia (ALL). *H. Trautmann[1], M. Kozulic[2], A.-W. Kruse[1], M. Kneba[1], M. Brüggemann[1].* 1) Second Medical Department, University Hospital Schleswig-Holstein, Kiel, Germany; 2) QIAGEN Instruments AG, Hombrechtikon, Switzerland.

Analysis of clonally rearranged immunoglobulin (IG)- and T-cell receptor (TCR) genes is used to identify markers for minimal residual disease (MRD) diagnostics in ALL. Therefore, products of standardized IG/TCR PCR assays are applied to GeneScan, dHPLC and/or heteroduplex analysis to distinguish polyclonal from clonal rearrangements. In this setting, we tested the applicability of an automated high-resolution capillary electrophoresis, the QIAxcel Advanced system (QIAGEN), as alternative option for fragment analysis. The performance of QIAxcel for analysis of IG/TCR PCR products was compared to GeneScan and dHPLC. A panel of 15 multiplex PCRs (BIOMED2), targeting different immune gene rearrangements (6 IGH, -L, -K and 9 TCRB, -G, -D PCRs) was applied to 10 B-lineage-ALL samples resulting in a total of 150 PCR products that were analyzed by QIAxcel, GeneScan and dHPLC. IG/TCR profiles were validated by sequence analysis. Additional sensitivity testing was performed via dilution experiments with patient samples in polyclonal DNA. Just as dHPLC and GeneScan, QIAxcel accurately detected all amplifiable clonal IG- and TCR-rearrangements (61/150) as well as all polyclonal signals (89/150). In addition, depending on the individual PCR target, the detection limit was 10-5% of clonal cells in a polyclonal background. The applicability of QIAxcel to identify IG/TCR markers in ALL is on a par with dHPLC and GeneScan. In addition, it reduces manual handling errors, eliminates the need for gel preparation and ensures electronic documentation of data. Our results indicate that it is a reliable, cost-effective and accurate high-throughput tool for IG/TCR marker characterization in ALL.

3412T

Investigation of Resveratrol/AT-101`s Molecular Targets of Apoptotic Effect to the Hormon Sensitive and Hormon Nonsensitive Prostate Cancer Cell Lines. *Y. YUKSELTEN[1], N. AKTEPE[2], A. KISIM[3], H. ATMACA[3], B. KARACA[4].* 1) Department of Medical Biology, Medicine Faculty of Ankara University, Ankara, Turkey; 2) Department of Nursing, Health High School of Artuklu University, Mardin, Turkey; 3) Department of Molecular Biology and Genetics, Faculty of Arts and Sciences- Celal Bayar University, Manisa, Turkey; 4) Department of Oncology, Medicine Faculty of Ege University, Izmir, Turkey.

Objective: Resveratrol, which is used in the cancer treatment, shown to have occurred DNA damage repair features and inhibits cancer cell proliferation by including anticancer activity, is a phytoalexin derived from the skin of grapes. AT-101, an (-)- enantiomer of gossypol, is a potent anticancer agent that it was reported to be an inhibitor of Bcl-2/Bcl-XL. In this study, the possible synergistic cytotoxic and apoptotic effects of Resveratrol in combination with AT-101 were investigated in human hormone refractory prostate cancer cell lines, PC-3 , DU- 145 and LNCaP in a time- and dose-dependent manner.

Material and Methods: Cytotoxicity was determined by XTT Cell Proliferation Kit (Roche). Drug synergy was assessed by using CalculSyn 2.1 software (Biosoft). Apoptosis was detected by Cell Death Detection Elisa Plus Kit (Roche) and confirmed by Caspase-Glo 3/7 Assay. The expression levels of apoptotic proteins were assessed by human apoptosis antibody array. Expression levels of proteins associated with apoptosis were investigated by Human Apoptosis Array Kit (R&D Systems, UK).

Results: The IC50 values of AT- 101 and Resveratrol were found 5.51 µM, 10 µM, 7.5 µM and 114 µM, 166 µM, 150.5 µM in human prostate cancer cell lines DU-145, PC3 and LNCaP, respectively. Combined treatment (100 µM + 5 µM AT-101) was shown to have strong synergistic cytotoxic and apoptotic effects in DU-145 cell line, at 72 hours. The combined use of AT-101 and Resveratrol resulted in an increase at Bax, Fas/TNFSF6, Pro-Caspase-3, Cleaved-Caspase-3, FADD, Phospho p53 (S46), p21/CIP1/CDNK1A, Cytochrome c, Smac/DIABLO and a decrease in Bcl-2, Bcl-x, XIAP, p27/Kip1, cIAP-1 proteins in DU-145 prostate cancer cells.

Conclusion: Our data revealed that the combination of AT-101 with Resveratrol may hold great promise for development as a novel chemotherapeutic approach to human prostate cancer. In determined synergism combination rates, it needs confirmation of promising cytotoxic and apoptotic effects in other prostate cancer cell lines; and also clarification of impact mechanism and confirmation of these data in animal experiments.

3413F

Cytogenetic and FISH monitoring of t(16;21)(p11.2;q22) FUS-ERG fusion gene in an AML NOS patient. *L. Militti[1,2,3], D. Fantasia[1], A. DiTecco[3], D. Onofrillo[4], A. Spadano[4], G. Calabrese[1,3], G. Palka[1,3].* 1) Dip. S. Mediche, Orali & Biotec, University of Chieti, Chieti, Italy; 2) AIL Associazione Italiana contro le Leucemie - Linfomi e Mieloma, Pescara Section, Pescara, Italy; 3) Medical Genetics, Pescara Hospital, Pescara, Italy; 4) Hematology Dept., Pescara Hospital, Pescara, Italy.

Reciprocal t(16;21)(p11.2;q22) is a rare chromosomal abnormality in acute myeloid leukemia (AML), being about 60 cases described to date, associated with dismal prognosis. In this rearrangement the ERG gene on chromosome 21 and the TLS/FUS gene on chromosome 16 result in a TLS/FUS-ERG fusion gene which is thought to be responsible for leukemogenesis. We report on a AML NOS new case (WHO 2008) with t(16;21)(p11.2;q22) investigated with different approaches. At diagnosis the karyotype of the 16 year-old male patient, as from conventional cytogenetic, SKY-FISH and MCB, was: 46,XY,t(16;21)(p11.2;q22)[12]/46,XY,inv(11)(p14q22),t(16;21)(p11.2;q22)[5]/46,XY,t(11;15)(p15;q13),t(16;21)(p11.2;q22)[3]/46,XY[1]. FISH analysis with a novel FUS (16p11) break-apart probe (Kreatech, NL) revealed 77% of cells with split signals. The patient received induction chemotherapy according to AIEOP protocol, resulting in normalization of karyotype and reduction of leukemic cells by FISH up to 1.35%. Five months from diagnosis he underwent sex-matched allogeneic bone marrow transplantation (BMT). At this time he had normal karyotype, while FISH revealed 0.4% of split signal cells. Five months later he relapsed with a new abnormal clone: 46,XY,der(10)add(10)(p15)dup(10)(q23q26),t(16;21)(p11.2;q22)[17]/46,XY[7]. FISH showed 20% of cells bearing FUS split signal, confirmed by quantitative RT-PCR and STR polymorphisms analysis. The patient had chemotherapy using FLAN protocol and achieved complete hematological and cytogenetic remission. FISH monitoring displayed progressive reduction of FUS splitted cells being 0.47% of cell population at time of 2nd BMT, 4 months from relapse. Six-month 2nd BMT follow up using FISH showed lowering of leukemic clone up to complete molecular remission. Present report shows MRD monitoring feasibility using FISH analysis for this rare translocation, and demonstrates genetic instability of FUS-ERG rearrangement cells as evidenced by sequential occurrence of three different leukemic clones during disease course.

Intrafocal Heterogeneity of Gene Rearrangements in Prostate Cancer: Implications to Genomic Targeting Therapeutics. *I. Tereshchenko[1,2], H. Zhong[1], U. Santanam[1], W. Petrosky[1], N. Kane-Goldsmith[2], J.A. Tischfield[2], R.S. DiPaola[1].* 1) The Cancer Institute of New Jersey, Rutgers University, New Brunswick, NJ; 2) Department of Genetics, Rutgers University, Piscataway, NJ.

Efforts to develop targeted therapy based on genomic findings are complicated by the polygenic nature of drug resistance and genetic heterogeneity between separate biopsy cores. These findings have led to the conclusion that analysis of multiple biopsy cores and consideration of multiple targeted agents will be important. Because of our concern that these assessments may be missing an additional layer of heterogeneity within even a single biopsy core, which sequencing alone may not identify, we studied the genetic heterogeneity of cells in focal areas within single biopsy cores. Using the TMA slides and confocal microscopy, we analyzed the most common and prostate cancer specific gene rearrangement (TMPRSS2-ERG fusion) in neighboring single cells in a tumor focus without changing the stromal micro-environment. We evaluated 55 patients that underwent radical prostatectomy at CINJ with pathological assessment, grading, and ERG rearrangement status. A minimum of 50 cells in each TMA core was scored using the ERG break-apart FISH assay. Overall, ERG rearrangements occurred in 24/55 (44%;) patients. The most frequent mechanism of rearrangements was deletion (58%), while a split event was confirmed in 25% of the ERG-rearranged cases. In 88% of cases the ERG rearrangement was associated with TMPRSS2-ERG gene fusion. A copy number gain of the non-rearranged ERG gene occurred in 10/55 (18%) cases. A heterogeneous mix of ERG deletions, translocations, and copy number changes occurred in 8/24 (33%) patients, with a combination of deletions and translocations alone occurring in 4/24 (17%) cases. These results support the notion that TMPRSS2-ERG gene fusions may arise independently within the same tumor focus and that additional heterogeneity may be present even in a focus of a single biopsy core. These data are extremely important and urgently require further study to understand heterogeneity of genetic changes, because clinical studies have already been launched using genetic changes such as TMPRSS2-ERG fusions found in a single core biopsy to direct a specific therapy.

3415T

Trisomy of chromosome 8 in children with haematological malignancies. *D. Januszkiewicz-Lewandowska[1,2,3], O. Zajac-Spychala[2], E. Maly[3], J. Nowak[1].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 2) Department of Pediatric Oncology, Hematology and Transplantation, University of Medical Sciences, Poznan, Poland; 3) Department of Medical Diagnostic, Poznan, Poland.

Trisomy of chromosome 8 is one of the most common numerical aberrations in adults with AML and MDS, which is present in 5-20% of the cases. Much less frequently is observed in ALL and CML (up to 5% of patients). According to the IPSS cytogenetic classification of MDS trisomy of chromosome 8 is an indirect risk marker. There is no clear data on the prevalence and role of trisomy 8 in pediatric haematological malignancies. In 2009-2012 trisomy of chromosome 8 was found in 5 (4.4%) patients out of 113 children (82 ALL, 26 AML and 5 MDS) treated at the Department of Pediatric Oncology, Hematology and Transplantation in Poznan. In two of them were diagnosed ALL (2/82 - 2.4%), in one AML-M4/M5 (1/26 - 3.8%) and in other to MDS (2/5 - 40%). In three children, trisomy 8 was isolated aberration, in the remaining two, accompanied by monosomy of chromosome 7 (children with MDS) or t(9;22), transcript p210/230 BCR/ABL (child with ALL). In 4 patients (one child with ALL was treated only by ALL IC BFM 2002), out of chemotherapy, treatment included HSCT. Only one boy with relapsed leukemia with transformation of primary pre T-ALL to AML-M0 failed treatment. In general observed frequency of trisomy of chromosome 8 in haematological malignancies in children (4.4%) appears to be lower as compared to adults. The decision about the early use of HSCT in the treatment of studied children could be the cause of received good treatment results.

3416F

Joint effect of multiple common SNPs predicts melanoma susceptibility in place of or beyond traditional risk factors. *S. Fang[1], J. Han[2], M. Zhang[2], L. Wang[1], Q. Wei[1], C. Amos[3], J. Lee[1].* 1) University of Texas MD Anderson Cancer Center,Houston, TX; 2) Harvard Medical School, Boston, MA; 3) Dartmouth College, Lebanon, NH.

Genome-wide association studies have identified several genes that are associated with melanoma risk. However, most common genetic variants identified by those studies have only weak effects on melanoma risk, as well as on pigmentation or nevi. We hypothesized that the joint analysis of multiple single-nucleotide polymorphisms (SNPs) may detect a larger effect and improve the predictive value of models using standard phenotypic risk factors. In this study, we analyzed 11 SNPs that were associated with melanoma risk in previous studies and were also genotyped in The University of Texas MD Anderson Cancer Center melanoma case-control study and the Harvard Medical School Nurse Health and Health Professionals Follow-Up studies. All 11 SNPs were replicated in the MD Anderson study, but only 5 in the Nurse Health study and 2 in the Health Professionals Follow-Up study were confirmed. Participants who carried 15 or more risk alleles were more than five times as likely to have melanoma as compared to those carrying ≤6 risk alleles in the MD Anderson study. A weighted polygenic risk score (PRS) was constructed using the 11 SNPs to evaluate their joint effect on melanoma risk. In a data set pooled from all 3 studies, per unit increase of PRS led to 1.12 times more likely to have melanoma disease with adjustment for age, sex and pigmentation(95%; CI, 1.06-1.18, P= 4.63×10-5); Individuals in the highest PRS tertile were 1.69 times more likely to have melanoma than were those in the lowest PRS tertile (95%; CI, 1.28-2.25; P = 2.24 × 10-4), after adjustment for age, sex, and pigmentation, in the pooled dataset. Furthermore, PRS significantly improved the predictive value and discriminability of a conventional phenotypic melanoma risk model, and PRS alone had almost the same predictive value as the conventional model in the MD Anderson study. These results indicate that PRS may be used to replace standard phenotypic variables for melanoma risk assessment; Inclusion of PRS contributes to a small increase of risk predictive value of standard phenotypic model.

3417W

Radiogenomics: Using Genetics to Identify Cancer Patients at Risk for Development of Adverse Effects Following Radiotherapy. *S.L. Kerns[1,2], H. Ostrer[2,3], B.S. Rosenstein[1,4,5], Radiogenomics Consortium.* 1) Department of Radiation Oncology, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Pathology, Albert Einstein College of Medicine, Bronx, NY; 3) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY; 4) Department of Radiation Oncology, New York University School of Medicine, New York, NY; 5) Departments of Dermatology and Preventive Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

Radiogenomics (RGx) research aims to identify genetic predictors of response to cancer radiotherapy. RGx focuses on common clinical endpoints, such as fibrosis in irradiated breast tissue, pneumonitis in irradiated lung tissue, and urinary and bowel symptoms following radiotherapy of pelvic cancers. It parallels pharmacogenomics with respect to clinical aims and research methods. RGx is a relatively young discipline with many opportunities for discovery and clinical impact, but to date, the majority of RGx papers have been published in the radiation oncology literature. This abstract aims to increase understanding of RGx among human geneticists and genetic epidemiologists by addressing 4 major points. 1) What is the evidence of a genetic basis for RGx phenotypes? The strongest evidence that common genetic variation underlies such phenotypes comes from a study in breast cancer patients comparing intra- with inter-patient variation in skin toxicity, which attributed 80-90% of the variability to genetics. 2) What have RGx studies shown to date and where is the field going? Early RGx studies focused on SNPs in DNA repair, inflammation and radiation response pathways. This approach yielded conflicting results, and the field has recently shifted to a genome-wide approach with an effort to build large cohorts. To date, two published GWAS have identified SNP associations with adverse effects from radiotherapy for prostate cancer, including rs7120482 and rs2268363 that reached genome-wide significance for association with rectal bleeding and erectile dysfunction (ED) respectively, and rs17779457 that approached genome-wide significance for association with urinary morbidity. 51 additional loci have been replicated in multiple validation cohorts at levels nearing genome-wide significance. 3) What types of models have been built? Robust multi-SNP models have been developed using re-sampling or external validation, and show stronger association signals compared to single-SNP models. Addition of SNPs improves models based on clinical predictors. 4) What are the plans for building big GWAS in RGx? Future directions focus on large, well-powered GWAS, meta-analysis, fine-mapping and polygenic models incorporating gene-environment interaction. This has been enabled by formation of the NCI-supported Radiogenomics Consortium (http://epi.grants.cancer.gov/Consortia/single/rgc.html), which aims to foster collaboration and encourage translation to clinical practice.

3418T

RLIP76 expression levels in CML patients. *O. Altiok Clark[1], A. Toylu[1], O. Salim[2], A. Timuragaoglu[2], M. Okur[3], OK. Yucel[2], N. Sayin Ekinci[3], M. Ulubahsi[3], K. Eker Guler[3], I. Karadogan[2], L. Undar[2].* 1) Department of Medical Genetics, Akdeniz University Medical Faculty, Antalya, Turkey; 2) Department of Hematology, Akdeniz University Medical Faculty, Antalya, Turkey; 3) Laboratory of Hematology, Akdeniz University Hospital, Antalya, Turkey.

The Ral-interacting protein (RLIP76) is a member of the non-ABC transporter group of multiple drug-resistance proteins, involved in the export of intracellular drugs, GSH conjugates, and lipid peroxication end products out of the cell. While it is believed that this protein might be responsible for the drug resistance observed in various types of cancers, the expression of RLIP76 has yet to be studied in hematologic malignancies. Furthermore, while it is known that the RLIP76 gene is expressed in the HL60 and K562 leukemia cell lines, the role of the RLIP76 protein in both the pathology of leukemia and chemotherapeutic resistance remains largely unknown. As the prevalence of the drug resistance phenotype, and the resultant grim prognoses, both increases among leukemia patients, the need to better understand the role of the RLIP76 protein is imperative. It was thought that the expression levels of RLIP76 might be important for giving accurate prognoses for CML cases that can't otherwise be explained by any of the other known drug-resistance genes. Therefore, based on the potential at RLIP76 to be a new and useful prognostic marker for investigating drug-resistance in CML, the expression levels of the RLIP76 gene were measured in CML patients that were receiving imatinib, in this study. Analysis of RLIP76 mRNA showed that BCR-ABL positive patients had a lower level of RLIP76 than did BCR-ABL negative patients and this could be due to the effects of patient age, duration of treatment, and BCR-ABL expression levels.

3419F

Circulating microRNAs in acute lymphoblastic leukemia during chemotherapy treatment. *T.M. Marques[1], L.H. Sakamoto[2], C.P.C. Gomes[1], G.P. Oliveira Jr[2], G.R. Fernandes[1], R.W. Pereira[2].* 1) University of Brasilia, Brasilia, Distrito Federal, Brazil; 2) Catholic University of Brasilia, Distrito Federal, Brazil.

Circulating microRNAs have been found in all body fluids and could be associated with modulation of tumor microenvironment and progression of diseases. In the presence of cancer cells, active components present in normal microenvironment, become deregulated, promoting cell survival, disease progression and drug resistance. Several microRNAs act as participants in the process of development of leukemia either increasing or decreasing the expression levels. Here, we show data where circulating microRNAs were found in bone marrow serum from acute lymphoblastic leukemia (ALL) patients. We investigated, by smallRNAseq, the presence of microRNAs in tumor microenvironment from four patients, collected at diagnosis (phase one), during chemotherapy treatment (phase two and three). After statistical analysis, only microRNAs with expression difference between treatment phases with a p value under 0.05 ($p \leq 0.05$) were considered. In totally, 946 known microRNAs were identified, 83 presented significant difference expression between phase one and two, 57 between phase one and three and 56 comparing phase two to three. miR-146a, identified in disease progression, with expression inversely proportional to patient survival, appeared with reads count decaying through chemotherapy phases, suggesting a reduction in the expression within cells and subsequent reduction in the microenvironment. miR-181, described in studies as participating in leukemia development also presented significativity alteration during chemotherapy treatment. The presence of circulating microRNAs in bone marrow of ALL patients shows their potential as tumor microenvironment regulators and biomarkers.

3420W

microRNA expression profiling in metastatic cutaneous squamous cell carcinoma. *A.E. Toland[1,2,3], L.E. Skeeles[2], S.B. Peters[3], T. Teknos[3], T. Olencki[3], D.C. Allain[1,3].* 1) Human Cancer Genetics and Comprehensive Cancer Center, Ohio State University, Columbus, OH; 2) MVIMG, Ohio State University, Columbus, OH; 3) OSU Wexner Medical Center, Columbus, OH.

Cutaneous squamous cell carcinoma (cSCC) is the second most common form of cancer with approximately 700,000 cSCCs diagnosed in the United States each year. The majority of cSCCs are readily treated surgically; however, 2-6% of all cSCCs metastasize leading to approximately 2500 deaths annually. Metastatic cSCC is associated with a survival rate of 56% with distant metastases and a worse outcome in recurrent cSCCs and immunocompromised individuals. No published studies have been performed to date to assess microRNA (miRNA) profiles of metastatic cSCC samples. In order to develop specifically targeted therapies for metastatic cSCC and to determine which factors are predictive of metastatic cSCC from early stage lesions, it is crucial to understand the molecular events which lead to metastasis of cSCC. We hypothesized that aberrant expression of miRNAs enhances the metastatic potential of cSCCs. To test this hypothesis, we performed miRNA expression analysis using the nCounter miRNA panel of approximately 800 miRNAs in 48 samples including 10 trios of normal, primary tumor and metastatic samples and 9 paired normal/non-metastatic primary cSCCs. We identified ~225 miRNAs expressed in the skin and performed analysis on the top 100 expressed miRNAs. Multiple miRNAs showed significant differences between primary cSCCs that did not metastasize compared to metastatic cSCCs or their corresponding primary tumor. These include *miR-let-7f*, *miR-4286*, *miR-15*, *miR-16*, *miR-29a* and *miR-29b*; all of which have been previously associated with metastatic cancers, suggesting the validity of these results. Interestingly, *miR-4286* is up-regulated in metastatic melanoma and shows a 6 to7-fold up-regulation in our metastatic cSCC samples. *miR-21* has been shown to be associated with metastasis in multiple tumors including esophageal SCC. Differentially expressed miRNAs are currently being evaluated in a second cohort of cSCCs and metastatic samples. In summary, several miRNAs show differential expression between non-metastatic and metastatic cSCCs; these may be useful as biomarkers for cSCC metastasis or as targets for therapy.

3421T

Prognostic significance of K-ras codon 12 mutation with resected Gall Bladder Cancer. *H.R. Kazmi[1], A. Chandra[1], D. Parmar[2], N. M[1].* 1) Surgical Gastroenterology, King George's Medical University, Lucknow, Uttar Pradesh, India; 2) Developmental Toxicology Division, Indian Institute of Toxicology Research, Lucknow, Uttar Pradesh, India.

Introduction: Prognosis of Gall bladder cancer (GBC) is dismal due to aggressive behavior and lack of effective treatment. High incidence and mortality rates have been observed in Northern India. In present study, we had analyzed K-ras mutation in normal (undiseased) and GBC tissue samples and investigated its prognostic significance. Materials and Methods: Histopathologically proven GBC (n=39, stage II: n=22 and stage III: n=17) and normal gall bladder (n=24) tissue samples were studied. DNA was isolated and mutation was detected by Restriction Fragment Length Polymorphism analysis. Statistical analysis was carried out using chi-square test with Yates correction and Fisher exact test. The effect of K-ras mutation on patient survival was estimated using the Kaplan-Meier method and the difference between curves was analyzed by log-rank test. Results: The mean age (years + S.D.) of normal and GBC patients were 41.41+13.42 (range 19-65) and 43.87+12.39 (range 22-67) respectively. K-ras codon 12 mutation was observed in 1/24 (4.17%) and 16/39 (41.03%) of normal and GBC tissue samples respectively with statistically significant difference (p= 0.001).The overall survival time was significantly shorter (p=0.003) in patients having K-ras mutation. The median survival for GBC patients was shorter with K-ras mutation as compared to patients without K-ras mutation (12.5 vs. 17 months). Statistically significant difference in overall survival was also observed for stage II (p=0.012, median survival -15 months) and Stage III (p=0.009, median survival -8 months) GBC patients with K- ras mutation. Overall K-ras mutation significantly affects prognosis for GBC (Hazard ratio [HR] = 3.54; 95% Confidence interval [CI] = 1.54-8.14). For stage II GBC, K-ras positive patients carry 4.31 times higher risk of failure as compared to K-ras negative cases (95% CI = 1.37-13.55). Similarly, the HR for stage III disease was 7.42 (95% CI = 1.66-33.11). Conclusion: High frequency of K-ras codon 12 mutation in GBC is present in Northern Indian population. Its presence indicates poorer outcomes in patients undergoing surgery for this disease.

3422F

"Genetic polymorphisms in the apoptotic-associated genes Fas (-670 ag) and Fas L (-844 tc) & acute myeloid leukemia risk". *Vuree. Sugunakar[1], C. Anuradha[1], Dunna. Nageswara rao[4], G. Manjula[1], EM. Prajitha[1], D. Raghnadharao[3], Sinha. Sudha[2], Atili. Venkat Satya Suresh[2], Satti. Vishnupriya[1].* 1) Genetics and Biotechnology, Osmania University, Hyderabad, Andhra Pradesh, India; 2) MNJ Institute of Oncology, Red Hills, Hyderabad; 3) NIMS, Panjagutta, Hyderabad; 4) Sastra University, Thanjavur, Tamilnadu.

Acute Myeloid Leukemia (AML) is a cancer of myeloid lineage of blood cells, characterized by the rapid growth of abnormal white blood cells that accumulate in the bone marrow and interfere with the production of normal blood cells. FAS (TNFSf6/CD95/APO-1) belongs to the family of tumor necrosis factor receptors, and binding to the receptor by the FAS ligand (CD95L) triggers receptor trimerization and subsequent assembly of the death-inducing signaling complex. This gene is silenced in many tumor types, resulting in an inability to respond to proapoptotic signals. The FAS promoter is polymorphic, including an A to G substitution at -670bp, and T to C substitution at -844bp, which occur within SP1 and signal transducers and activators of transcription 1 transcription factor binding sites, respectively. The present study on the association of Fas Receptor (Fas R) and Fas Ligand (Fas L) promoter polymorphisms with AML were analyzed by PCR-RFLP method. GG genotype of Fas -670 AG showed a significant association with respect to the AML as well as with epidemiological variables like Sex of the proband, Area of living (Urban), WBC (30,000), no significant trend was observed with platelet count and Complete Remission. Whereas in FasL-844TC, C allele of FasL-844 was elevated in cases when compared with controls. Further, MDR analysis was performed between the two promoter SNPs which showed a significant trend.

3423W

TRAPing Telomerase Activity Using Droplet Digital PCR (ddPCR). *D.N. Shelton[1], J. Lin[2], J.F. Regan[1], G. Karlin-Neumann[1], E.H. Blackburn[2].* 1) Bio-Rad Laboratories, Digital Biology Center, Pleasanton, CA; 2) UCSF School of Medicine, Dept. of Biochemistry and BioPhysics, San Francisco, CA.

The aim of this work was to develop a more sensitive and high throughput assay for measuring telomerase activity. Telomeres are the protective structures at the ends of chromosomes consisting of 6 bp repeat sequences. In young cells, these regions can be as long as 15kb and act as caps which protect the DNA ends. These ends naturally degrade with each passing cell division, usually losing 25-200 base pairs per division. Once they are shortened below a critical length (estimated to be 200-300 bp) the cells arrest and become senescent, or 'old'. Telomeres can be thought of as a cellular or mitotic clock. Once the clock has wound down, the cells either die or pass through crisis and become immortal. One of the mechanisms of immortality is the activation of the enzyme, telomerase. Telomerase is the endogenous reverse transcriptase responsible for adding repeats to telomeres, rewinding the clock and enabling a cell to continuously divide. Abundant telomerase activity is found in the majority of cancers, fetal and adult stem cells, and germ cells. It is also present at much lower levels in non-pluripotent cells, such as immune cells, but these levels are currently difficult to measure. The telomerase repeat amplification protocol (TRAP) measures the presence of active telomerase by measuring the activity of the enzyme on a starting template, which is then amplified by PCR. For samples with abundant telomerase activity, SYBRGreen® qPCR assays provide high throughput. However, the current most sensitive method of detection still uses radioactivity and laborious PAGE sequencing gels followed by densitometry to quantify telomerase. In this study, the PAGE detection method is replaced by single molecule counting of telomerase-extended templates using droplet digital PCR technology.

3424T

Splicing of HRAS exon 2 is vulnerable - The splicing efficiency of activating mutations in codons 12 and 13 determines Costello syndrome phenotype. *B.S. Andresen[1], A.M. Hartung[1], J. Swensen[2], I.E. Uriz[1], M. Lapin[1], J.C. Carey[3], A. Calhoun[4], P. Yu[2], C.P. Vaughn[2], S.F. Dobrowolski[5], M.R. Larsen[1], H. Hanson[3], D.A. Stevenson[3].* 1) Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark; 2) University of Utah School of Medicine, ARUP Laboratories, Salt Lake City, Utah; 3) Division of Medical Genetics, University of Utah School of Medicine, Salt Lake City, Utah; 4) Division of Pediatric Genetics and Metabolism, University of Minnesota, Minneapolis, Minnesota; 5) Department of Pathology, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania.

Costello syndrome (CS) is most frequently caused by a c.34G>A (p.G12S) activating mutation in HRAS with modest transforming activity. G12V mutations have the highest transforming activity, the greatest frequency in cancers, but are very rare in CS. So far, all CS patients with p.G12V mutations (c.35G>T; c.35_36delinsTT; c.35_36delinsTA), have had a severe, early lethal, phenotype. Sequence analysis of a 12-year-old boy with an attenuated CS phenotype revealed, to our surprise, a new germline p.G12V mutation, c.35_36delinsTG, without evidence of mosaicism. In silico analysis shows that exon 2 has a weak 3' splice site and that c.35_36delinsTG simultaneously abolishes exonic splicing enhancer (ESE) motifs and creates exonic splicing silencer (ESS) motifs indicating that it may disrupt splicing. Analysis of patient HRAS cDNA showed that c.35_36delinsTG results in exon 2 skipping and consequently little mutant protein, explaining the attenuated phenotype. Transfection of several different cell lines with HRAS mini genes with the four known p.G12V mutations and the common c.34G>A mutation showed that only c.35_36delinsTG results in exon 2 skipping. Deletions of nucleotides c.32-37 cause exon 2 skipping, indicating presence of an ESE in this region. Optimization of the weak 3' splice site corrected splicing from the mutants confirming vulnerability of exon 2. Testing of wild type and several mutant HRAS exon 2 sequences in different splicing reporter minigenes showed that ESE strength is increased by the other p.G12V mutations and by other mutations with strong transforming potential, whereas c.35_36delinsTG inactivated splicing. RNA affinity purification, ITRAQ labeling followed by MS/MS, showed that c.35_36delinsTG increases binding of hnRNPF/H splicing inhibitory proteins, whereas c.35G>T increased binding of several splicing stimulatory SR proteins consistent with the observed effect on splicing. Replacement in the HRAS minigene of the wild type sequence with hnRNPF/H binding ESS motifs confirmed that binding of hnRNPF/H results in exon 2 skipping. Our study illustrates that phenotype of Costello syndrome and likely somatic cancers are not only determined by the transforming potential of the mutant HRAS protein, but is also determined by the efficiency of exon 2 inclusion. This has important implications for our understanding of the correlation between genotype and phenotype in diseases caused by HRAS mutations and for development of new therapies.

3425F

Familial intracranial meningioma without *NF2* and *SUFU* mutations: searching for additional predisposing genes.
M. Aavikko[1], H. Ristolainen[1], E. Kaasinen[1], P.A. Koivisto[2], M. Pöyhönen[3], K. Claes[4], T. Van Maerken[4], M. Artama[5], E. Pukkala[5], L.A. Aaltonen[1], P. Vahteristo[1]. 1) Department of Medical Genetics, Genome-Scale Biology Research Program, University of Helsinki, Helsinki, Finland; 2) Seinäjoki Central Hospital, Department of Neurology, Seinäjoki, Finland; 3) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 4) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 5) The Finnish Cancer Registry, Helsinki, Finland.

Meningiomas are the most common tumors of the central nervous system (CNS) accounting for one third of all primary CNS tumors in adults. Majority of meningiomas are slowly growing benign tumors arising from the leptomeninges covering CNS. Most commonly they occur sporadically, but they are also commonly seen in individuals with Neurofibromatosis type 2 tumor suppressor syndrome.

We recently reported a candidate predisposing gene defect in the *Suppressor of Fused homolog* (*SUFU*) in a family of five siblings with intracranial meningiomas, four of whom had multiple lesions. All seven studied meningiomas from the family displayed loss of the wild type allele following the two-hit model for tumor suppressor genes. In addition, we showed that the mutant SUFU had lost its ability to bind GLI1 transcription factor causing dysregulated Hedgehog signaling. Mutations in *SUFU* have previously been identified in familial and sporadic medulloblastomas. Our results suggested that in addition to medulloblastomas *SUFU* defects may also predispose to a subset of meningiomas.

Here we describe a Finnish *NF2* and *SUFU* mutation negative family of five affected individuals with intracranial meningiomas. The family display autosomal dominant inheritance pattern with affected individuals in three generations. We have performed genome-wide SNP genotyping and linkage analysis in combination with exome and genome sequencing. We have identified candidate chromosomal regions and gene variants in this family and we are studying the pathogenicity of these variants in the meningioma tumors from the family and in additional familial and sporadic intracranial meningioma cases, these include a Belgian family with four affected individuals in four generations and Finnish familial and sporadic meningioma patients identified through Finnish Cancer Registry. Increased understanding of meningioma predisposition is of great clinical importance in providing tools for better diagnosis and management of the patients.

BACKGROUND: DICER1, a non-coding small RNA processing enzyme, cleaves micro RNA (miRNA) precursors into mature miRNAs, which are known to regulate mRNA expression. Germ-line mutations in *DICER1* have recently been found to predispose to a rare cancer syndrome consisting of primarily childhood tumours. The main manifestations of the syndrome include pleuropulmonary blastoma (PPB), cystic nephroma (CN), Sertoli-Leydig cell tumours (SLCT), multinodular goiter and other rare childhood sarcomas and dysplasias. We and others have shown that germ-line *DICER1* mutations are often accompanied by specific somatic mutations in the *DICER1* RNase III catalytic domain in several tumour types, and we hypothesized that both germ-line and somatic mutations might also occur in children with pituitary blastoma (PitB). PitB, identified as a distinct entity in 2008, is a very rare, potentially lethal childhood brain tumour. Since the discovery by our team of an inherited mutation in *DICER1* in a child with PitB in 2011, we have identified a further 12 pathologically-confirmed PitB cases. Histological studies suggested perturbation of pituitary stem cells could underlie the pathogenesis of PitBs. OBJECTIVES: We aim to determine the contribution of germ-line and somatic *DICER1* mutations to PitB and to analyse the effect of the mutations on the mi/mRNA landscape. We hypothesize that targets involved in the regulation of pituitary stem cells will be dysregulated in these tumours. RESULTS: To date, 6 of 6 PitB cases analysed genomically harbour a germ-line *DICER1* mutation, suggesting that mutation of DICER1 is a key predisposing genetic event. Furthermore, we identified likely contributory "second hits" in *DICER1* in 6 of the 7 PitBs tested thus far for somatic mutations. Five of these 6 mutations occur within the RNase IIIb catalytic domain, a domain essential to the generation of miRNAs from the 5' arm (5p) of precursor miRNAs. Work is underway to complete the analysis of the remaining samples and to determine the effect of these *DICER1* mutations on the generation of miRNAs. CONCLUSION: Germ-line *DICER1* mutations are a major contributor to PitB. Second somatic 'hits' in *DICER1*, within the RNase IIIb domain, also appear to be critical steps in their pathogenesis. Further studies will focus on mRNA, miRNA and gDNA profiling of these rare tumours.

3427T

Targeted sequencing of *MLH1*, *MLH2*, and *MSH6* in defective mismatch repair colorectal cancer cases with no identified mutation. *M. DeRycke[1], S. Gunawardena[2], S. McDonnell[1], S. Middha[1], S. Riska[1], Z. Fogarty[1], B. Eckloff[3], D. Schaid[1], E. Goode[1], N. Lindor[4], S. Thibodeau[1], Colon Cancer Family Registry.* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Advanced Genomics Technology Center, Mayo Clinic, Rochester, MN; 4) Health Sciences Research, Mayo Clinic, Scottsdale, AZ.

Approximately 25% of colorectal cancers (CRC) are clustered in families expected to harbor predisposing genetic mutations. Of all CRC cases, ~3-5% are caused by Lynch Syndrome (LS), an autosomal dominant condition resulting from mutations in the mismatch repair (MMR) genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Currently, when LS is suspected, germline testing of the proband can be done to determine the underlying mutation and facilitate testing relatives who may be at increased risk. Typically, the entire coding region and exon/intron boundaries of the gene are targeted for sequencing, and identified variants found are classified as deleterious, variants of uncertain significance (VUS), or common polymorphisms. A significant fraction of cases show loss of protein expression by immunohistochemistry but no detected variant or deletion in the affected gene, presenting a problem for families with suspected LS: no mechanisms exist to determine which family members share the variant and are at increased risk for developing CRC. In this study, we completed targeted sequencing of *MLH1*, *MLH2*, and *MSH6* in 130 individuals with defective MMR CRC in which previous sequencing studies failed to detect any disruptive germline MMR variants. We targeted exonic, intronic, and nearby intergenic regions of *MLH1*, *MSH2*, *MSH6*, as well as the 3' end of *EPCAM*. Agilent's SureSelect Custom Capture system was used to target the genes and samples were indexed then pooled for sequencing on a HiSeq 2000. Samples underwent extensive quality control, which resulted in the exclusion of 10 samples due to low coverage (n=7) or high read duplication (n=3). Mean coverage for the remaining 120 samples was 633x (range 164 - 3,114x; median 367x). Transition-Transversion ratios for known and novel SNPs were 2.34 and 2.29, respectively. Samples had an average of 3,124 SNPs (range 2,639 - 4,168) and 386 (range 249 - 464) INDELs in the capture region. Previously completed genotyping results were compared with sequencing results for 118 samples, resulting in 99.6% concordance. Preliminary analysis of the 85 cases with loss of MLH1 protein expression identified the -93G>A transition in 45 cases, with six individuals being homozygous recessive. This variant has been reported to reduce expression of MLH1 and has been considered a low penetrance mutation contributing to CRC development. Further results from the analysis will be presented.

3428F

Annotation of Rare Variants from Exome Sequencing in Families with Lymphoid Malignancies. *L.R. Goldin[1], M.L. McMaster[1], M. Rotunno[1], J. He[2], L. Burdette[2], A. Hutchinson[2], J. Boland[2], M. Yeager[2], M.A. Tucker[3], S.J. Chanock[2], N.E. Caporaso[1].* 1) Genetic Epidemiology Branch, DCEG/NCI, Bethesda, MD; 2) Cancer Genomics Research Laboratory, DCEG/NCI, Bethesda, MD; 3) Human Genetics Program, DCEG/NCI, Bethesda, MD.

Several variants with relatively small effects have been identified from GWAS of lymphoid malignancies but single high penetrance genes have not been identified. We have conducted exome sequencing in 178 individuals from 49 families at high risk for lymphoid malignancies including chronic lymphocytic leukemia, Hodgkin lymphoma, and non-Hodgkin lymphomas. We used Nimblegen v2.0 and v3.0 for exome capture followed by sequencing on the Illumina HiSeq2000. We required that 80% of coding sequences had at least 15x coverage. Novoalign v.2.07.14 was used for alignment and GATK was used for local re-alignment and variant calling. We sequenced 3 or more patients or obligate carriers from the families. A large number (~1000) of rare (<1% frequency in European populations) non-synonymous variants were shared among patients/carriers in each family. In order to eliminate other possible sequencing artifacts, variants found in more than 1% of samples sequenced in our laboratory from other studies were excluded, leaving ~20-100 variants per family. We prioritized variants for further validation and follow-up by looking for genes with the same shared variant in more than one family that were predicted to be damaging by at least one program (or were in a regulatory region), were highly conserved, and had a literature link to cancer or a cancer-related pathway. The program, Ingenuity Variant Analysis, was used to facilitate filtering and annotation. Variants in 7 genes (*BORA, FAF1, ITGB2, PRDM2, TXNDC17, ZNF189, and ELMO3*) met these conditions. We will conduct targeted sequencing of these genes in 366 patients from an additional 170 multiplex families. There were an additional 40 genes where different variants from the same gene were found in more than 1 family and selected genes from this group will also be sequenced in the new sample. Results of our validation/follow-up studies will be presented.

3429W

Constitutional mismatch repair deficiency syndrome caused my MMR gene founder mutations with a high prevalence in Israel. *I. Kedar-Barnes[1], Z. Levi[2], H. Toledano[3], M. Halpern[4], I. Lerer[5], T. Peretz[6], R. Kariv[7], E. Half[8], N. Magal[1], K. Wimmer[9], Y. Goldberg[6], D. Berkovich[10], H.N. Baris[1].* 1) The Raphael Recanati Genetics Inst, Rabin Med Ctr, Petah Tikva, Israel; 2) Gastroenterology Division, Rabin Medical Center, Beilinson Hospital , Petach Tikva, Israel; 3) Pediatric Oncology, Schneider Children's Medical Center, Petach Tikva, Israel; 4) Department of Pathology, Rabin Medical Center, HaSharon Hospital, Petach Tikva, Israel; 5) Deprtment of Human Genetics, Hadassa-Hebrew University Medical Center, Jerusalem, Israel; 6) Sharett Institute of Oncology, Hadassa-Hebrew University Medical Center, Jerusalem, Israel; 7) Deaprtment of Gastroenterology& Liver Disease, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel; 8) Gastroenterology Department, Rambam Health Care Campus, Haifa, Israel; 9) Division of Human Genetics, Medical University Innsbruck, Austria; 10) GGA-Galil Genetic Analysis, Kazerin, Israel.

Heterozygous germline mutations in one of the 4 mismatch repair (MMR) genes, *MLH1, MSH2, MSH6* and *PMS2* cause Lynch syndrome (LS), an autosomal dominant cancer predisposition syndrome conferring a high risk of colorectal, endometrial and other cancers in adulthood. Offsprings of couples, both having LS, have a high risk to inherit biallelic MMR gene mutations. The cause constitutional MMR deficiency (CMMRD), a severe recessively inhereted childhood cancer syndrome with a very broad tumor spectrum including mostly hematological malignancies, brain tumors and childhood colon cancer. Most of CMMRD children also present with café au lait spots and axillary freckling mimicking Neurofibromatosis type I. We describe our experience in Israel with 5 CMMRD families. The clinical presentation included: brain tumors at age 2-19 years, colon cancer at ages 9-20 years, and one patient with lymphoma at age 12. In two non-consangineous Ashkenazi families, the common founder Ashkenazi mutation were detected: one family was homozygous for c.1906G>C in *MSH2* and the 2nd family heterozygous for c.3984_3987dupGTCA and c.3959_3962delCAAG in *MSH6*. In the 3 other consanguineous families, different homozygous mutations were identified: c.2192T>G (p.L731X) in *PMS2*, a recurrent mutation among Iranian Jews, *PMS2* c.686_687delCT and *MSH6* 3603_3606delAGTG were found in large pedigrees of Bedouin and Arab ancestries, respetively. Given the prevalence of these mutations among Israeli population, we want to raise the awareness of CMMRD syndrome and open a discussion regarding screening for MMR founder mutations among spouses of LS patients for the purpose of prenatal diagnosis.

3430T

Magnetic Resonance Imaging screening In Li Fraumeni Syndrome: An exploratory whole body MRI study (the SIGNIFY study). *E. Killick[1, 2], E. Bancroft[3], N. Taylor[3], DG. Evans[4], M. Leach[1, 3], R. Eeles[1, 3], The SIGNIFY collaborators and steering committee.* 1) Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, United Kingdom; 2) Cancer Care, University Hospital Southampton NHS Foundation Trust, Southampton, Hampshire, United Kingdom; 3) Royal Marsden NHS Foundation Trust, Chelsea, London, United Kingdom; 4) Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdon.

Background Li Fraumeni Syndrome predisposes individuals to a range of different malignancies with a lifetime cancer risk of up to 90% in women and 70% in men. Current national screening recommendations are for dual modality breast screening with mammography and MRI in women. Some centres employ family specific screening tailored to malignancies found at increased frequency within certain families with most centres having an 'open-door' policy. Recent evidence suggests there may be a survival benefit for more intensive screening, including whole body MRI; there are no published data on the psychological impact of such screening programmes. Aims The primary end-point is to assess the incidence of malignancies diagnosed in asymptomatic TP53 mutation carriers using whole body MRI, against general population controls. The secondary end-points are to assess the incidence of non-malignant relevant disease, to assess the incidence of irrelevant findings and the investigations required to determine relevance of MRI findings and finally to assess the psychological impact of whole body MRI screening in TP53 mutation carriers. Methodology We will recruit 44 TP53 mutation carriers and 44 population controls aged 18 - 60 years, who will undergo conventional and diffusion weighted whole body MRI. The MRI will be reported independently by two radiologists blinded to the mutation status of the individual, with a consensus read with a third radiologist in cases of discordance. The results will be relayed to the individual and any necessary further investigations arranged. An intersite virtual MDT will be held at regular intervals to discuss the diagnosis and management of incidental findings. A series of questionnaires will be used from time of recruitment up to a year after the MRI scan to assess the psychological impact of screening. Results The study recently opened to recruitment; thus far 4 individuals have been enrolled. Results from these and further recruits will be shown.

3431F

Characterization of RB1 mutations and incidence of undetected defects in retinoblastoma. *P.S. Lai[1], A.P. Alcasabas[1], G. Sundar[2], B.L. Quah[3].* 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) Dept Ophthalmology, National University Hospital, Singapore; 3) Singapore National Eye Centre, Singapore.

Retinoblastoma (RB) is a retinal tumor associated with biallelic loss of RB1 gene. Most cases are diagnosed by five years of age and occur in both hereditary and sporadic forms. Bilateral RB cases are usually associated with constitutional or germline mutations while approximately 15% of sporadic unilateral cases may carry heritable constitutional mutations. Recently, there has been speculation that some rare RB tumors may arise by mechanisms other than RB1 mutations. In this study, we characterized RB1 mutations in 40 retinoblastoma cases in order to determine the incidence of non-detectable RB1 mutations. To detect large deletions, segregation analysis using polymorphism makers, quantitative multiplex PCR or MLPA assays were carried out while small point mutations were detected by sequencing analysis. RB1 promoter methylation was analysed by methylation-specific PCR. RESULTS: Large deletions were present in 27 out of 40 (67.5%) tumors. Germline mutations were detected in 11 out of 13 bilateral cases (84.6%). Among the 27 unilateral RB cases, germline mutations were detected in 4 cases (14.8%). The mutation spectrum shows RB1 mutations (7 nonsense and 2 frameshift mutations) in 16 cases as distributed among exons 12-22 which codes for the RB protein pocket domain known to be critical for transcriptional repression. The most frequent mutations were nonsense (24/35; 68.6%) followed by frameshifts (7/35; 20%) with splice site and missense mutations contributing towards the remaining genetic defects. Most of the mutations identified in this study correspond to C to T transitions in 7 CGA-arginine codons in exons 8, 10, 11, 14, 15, 17 and 23 of the RB1 gene. No mutations were found in four other CGA codons located in exons 1, 18 and 27. These findings correspond with previously published data analysed by meta-analysis. RB1 promoter hypermethylation was rare and observed only in 1 tumor. CONCLUSIONS: Mutation in only one RB1 allele was detected in 5 cases while no RB1 mutations on both alleles were found in 2 unilateral cases. This could be due to (1) undetected translocations, deep intronic mutations, or alterations in unknown RB1 regulatory regions, (2) presence of low level RB1 mosaic mutations not detectable by Sanger sequencing, or (3) involvement of other genetic mechanisms or genes. Further investigations are warranted in these 5 cases.

3432W

Exome Sequencing of Family with Carcinoid Cancers. *D.W. Neklason[1, 2, 3], G.W. Gilcrease[1,2], N.R. Sargent[1], A. Snow[1], C. Teerlink[2,3], M. Bailey[3], R.W. Burt[1,2].* 1) Huntsman Cancer Inst, Univ Utah, Salt Lake City, UT, 84112; 2) Department of Medicine, University of Utah, Salt Lake City, UT 84112; 3) Division of Genetic Epidemiology, University of Utah, Salt lake City, UT 84112.

We describe here genetic study of a family with carcinoid tumors of the gastrointestinal tract. Two siblings and a first cousin were diagnosed with carcinoid tumors at ages 41, 63, and 59. Carcinoids are rare neuroendocrine tumors and most neuroendocrine tumors are not familial. Incidence of neuroendocrine tumors is 2.47 per 100,000 with the rate steadily increasing over the past 20 years. The majority of neuroendocrine tumors occur in the GI tract (67%), primarily in the small intestine as represented in this family. Carcinoid tumors derive from enterochromaffin cells of the neuroendocrine system in the gut. These cells contain a large amount of the body's store of serotonin and in response to stimuli in the lumen (chemical, mechanical, pathological), the serotonin release signals nausea to the brain. The two more advanced cases in the family were associated with carcinoid syndrome, which includes flushing, nausea and diarrhea from secretion of serotonin from the tumor. We performed whole exome sequencing using Agilent SureSelect capture on all three individuals with mean coverage of >60X on Illumina HiSeq. Genomes were aligned and variants called using standard best practices. Variants were filtered and prioritized using the VAAST (the Variant Annotation, Analysis & Search Tool) algorithm (Yandell et al, 2011) within the Omicia Opal 1.7.0 tool. Each individual had ~18,500 exonic mutations with a protein impact. No deleterious variants were identified in genes known to cause familial neuroendocrine cancers (MEN1, MEN2, VHL, NF1, TSC1, TSC2, and PPKAR1A). When scored as deleterious by a metaclassifier (Omicia Score >0.5), filtered for frequency <5% in the population, shared by all 3 family members, and not shared by a control family sequenced at the same time, 38 variants were identified. Three variants reside in large regions of shared genomic segments identified through SNP genotyping. Interesting genes include ones associated with metastasis (LRRC59), telomerase (TEP1), cell cycle (WDR35), and a neurotensin receptor (NTSR1). The identified variants will be verified by Sanger sequencing and examined in an unaffected sibling. Likely candidate genes will be discussed.

3433T

Frequencies of *BRCA1*, *BRCA2*, *PALB2*, and *CDKN2A* germline mutations in familial pancreatic cancer (FPC): A PACGENE study. *D.B. Zhen[1], K.G. Rabe[1], S. Gallinger[2], S. Syngal[3], A.G. Schwartz[4], M.G. Goggins[5], R.H. Hruban[5], M.L. Cote[4], K. Moyes[6], R.J. Wenstrup[6], A.R. Hartman[6], D. Seminara[7], A.P. Klein[5], G.M. Petersen[1].* 1) Mayo Clinic, Rochester, MN; 2) Toronto General Hospital, Toronto, Ontario, Canada; 3) Dana-Farber Cancer Institute, Boston, MA; 4) Karmanos Cancer Institute, Detroit, MI; 5) Johns Hopkins University, Baltimore, MD; 6) Myriad Genetic Laboratories, Inc, Salt Lake City, UT; 7) National Cancer Institute, Bethesda, MD.

Background: FPC (defined as at least two affected first degree relatives (FDR) in a kindred) accounts for 5-10% of pancreatic adenocarcinoma and is thought to be genetically heterogeneous. Genetic testing is available for germline mutations in several genes known to predispose to FPC. However, our knowledge is limited because published studies to date have been small and have been non-systematic.

Methods: The Pancreatic Cancer Genetic Epidemiology Consortium (PACGENE) has assembled a registry of 1747 kindreds containing two or more relatives affected with pancreatic cancer. Five PACGENE sites tested germline DNA samples from 234 unrelated cases affected with pancreatic adenocarcinoma (80 met criteria for FPC) for four genes: *BRCA1* and *BRCA2* (including analysis of deletions and rearrangements), *PALB2*, and *CDKN2A*. The cases who were tested were not previously known to carry germline mutations in these genes. We also studied mutation frequencies between FPC versus familial non-FPC cases (at least two affected blood relatives, but not FDR).

Results: Frequencies for deleterious/suspected deleterious (D/S) mutations and variants of uncertain significance (VUS) among **FPC cases** were: *BRCA1* 2/68 (2.9%), no VUS; *BRCA2* 3/68 (4.4%), no VUS; *PALB2* 1/77 (1.3%), no VUS; *CDKN2A* 4/80 (5.2%), 3 VUS. Among **Familial non-FPC** cases, frequencies were: *BRCA1* 0/123, no VUS; *BRCA2* 1/123 (0.8%), 1 VUS; *PALB2* 1/147 (0.7%), 4 VUS; *CDKN2A* 0/153, 3 VUS. FPC cases carry more mutations than familial non-FPC cases. Because we had excluded known mutations in our registry from this study, these frequencies may be a lower estimate. No case carried more than one mutation.

Conclusions: This is the first comparative study of four susceptibility genes in a large sample of FPC cases. The data support genetic heterogeneity of FPC. Genetic testing for cases meeting FPC criteria may be warranted, but multiple genes must be evaluated. The genetic basis for the majority of FPC remains to be determined.

3434F

Common Somatic Variations Identified in Maffucci Syndrome. *M. Amyere[1], V. Wouters[1], A. Dompmartin[2], O. Enjolras[3], I. Kaitila[4], P.L. Docquier[5], J.B Mulliken[6], L.M Boon[1,7], V. Vikkula[1,8].* 1) Human Molecular Genetics, de Duve Institute, Brussels, Belgium; 2) Université de Caen Basse Normandie, CHU Caen, Department of Dermatology; 3) Consultation des Angiomes, Hôpital Lariboisière, Paris, France; 4) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 5) Division of Orthopedic Surgery, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 6) Department of Plastic Surgery, Children's Hospital and Harvard Medical School, Boston, MA, USA; 7) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 8) Walloon Excellence in Lifesciences and Biotechnology (WELBIO), Université catholique de Louvain, Brussels, B-1200, Belgium.

Maffucci syndrome (MS) is a rare congenital disorder characterized by multiple central cartilaginous tumors (enchondromas) that are accompanied by cutaneous spindle-cell hemangiomas. These patients have a high incidence of malignant transformation. No familial case is known and the etiopathogenic cause remains unknown. In enchondromatosis (Ollier's disease, OD), which is comprised of enchondromas only, four mutations in the PTHR1 gene have been identified in four patients; three were somatic and one was germline. No PTHR1 mutation has been detected in MS. On the other hand, in 77% of patients with MS and 81% of patients with OD, somatic IDH1 and more rarely IDH2 mutations have been observed. These changes are shared with other tumors, including glioblastomas, leukemias and thyroid cancers, and seem to be markers of cellular transformation. To search for underlying somatic genomic causes, we screened MS tissues using Affymetrix SNP-chips. We looked for copy number variations (CNV), loss of heterozygosity (LOH) and uniparental (iso)disomy (UPD) by performing pairwise analyses between allele intensities in tumoral DNA versus the corresponding blood-extracted DNA. While common chromosomal anomalies were absent in constitutional DNA, several shared CNVs were identified in tumors. The most frequently observed somatic alterations are localized in 2p22.3, 2q24.3 and 14q11.2. In the single chondrosarcoma studied, large chromosomal amplifications and/or deletions were observed in chromosomes 3, 6, 9, 10, 12, 13 and 19. Some of these have been reported in other chondrosarcomas underscoring their etiopathogenic role. No LOH/UPD was observed in any Maffucci tissue. Our findings identify frequent somatic chromosomal rearrangements, implicating 2p22.3, 2q24.3 and 14q11.2 in the formation of enchondromas and spindle cell hemangiomas in Maffucci syndrome. WES are performed on MS tissues and blood paired and variations are in validation process to identify Maffucci causative mutations.

3435W

A survey of *HRAS* mutations in a large cohort of patients with Costello Syndrome reveals a predisposition for embryonal rhabdomyosarcoma with paternal uniparental disomy. *K.M. Robbins[1,3], D.L. Stabley[1], A. Sadreameli[1], J. Holbrook[1], S. McCahan[1], R. Sahraoui[1,4], K.W. Gripp[2], K. Sol-Church[1].* 1) Center for Pediatric Research, AI duPont Hospital for Children Wilmington , DE; 2) Medical Genetics, AI duPont Hospital for Children, Wilmington, DE; 3) University of Delaware Biological Sciences, Newark, DE; 4) Delaware State University Biological Sciences, Dover, DE.

Costello Syndrome (CS) is a rare condition resulting in failure to thrive, intellectual disabilities, short stature, coarse facial features, skeletal abnormalities, and congenital heart disease. CS is a rasopathy, caused by heterozygous mutation in the *HRAS* oncogene. Though most mutations are *de novo*, originating in the paternal germline, we identified a few cases of somatic mosaicism. CS patients have an increased risk for malignancies, specifically embryonal rhabdomyosarcoma (ERMS). In the general population, non-syndromic (NS) ERMS, is a relatively common pediatric cancer. It is rarely associated with *HRAS* mutations, but is characterized at the molecular level by loss of heterozygosity (LOH) at 11p15.5. The goal of this study was to molecularly evaluate our cohort, identify dysregulated pathways in CS skin fibroblasts and identify genetic alterations associated with ERMS in CS patients and in NS ERMS. Parental origin of *HRAS* germline mutations was established using either restriction enzyme digestion or allele specific PCR amplification and sequencing. Differential gene expression analysis was performed with Affymetrix Human Gene 1.0 ST arrays, 6 CS patient derived fibroblast lines and 6 control fibroblast lines. Characterization of the genetic lesions in ERMS was performed using chromosome 11 STR markers, fluorescence *in situ* hybridization using centromere 11 probe, as well as Affymetrix CytoScan arrays on CS and NS ERMS tumors and cell lines. We molecularly identified *HRAS* mutations in 104 CS patients. There were 63 cases of paternally derived mutations, 3 maternally derived and the remainder was non-informative. Eleven unrelated patients developed ERMS, and a few relapsed due to residual disease or *de novo* tumor formation. Nine ERMS tumors from 6 unrelated CS patients were available for molecular evaluation. All patients carried germline paternally derived p.G12S (4) or p.G12A (2) mutations in HRAS. We established a pure ERMS primary cell line using a fresh tumor sample from a patient with a p.G12A germline mutation. Loss of imprinting of *H19* and **CDKN1C** at 11p15.5 was identified, and additional functional analysis and drug screens are currently ongoing. Using CS and NS ERMS tumors, complete LOH was observed along chromosome 11. In CS samples, paternal uniparental disomy is observed in all but one recurrent primary tumor. This molecular characterization will aid in developing new treatments for ERMS.

3436T

Clinical characteristics and genotype-phenotype correlations in a large cohort of Brazilian Li-Fraumeni syndrome patients. *M. Achatz[1, 2], C. Sagne[3], P. Ashton-Prolla[4, 5], V. Marcel[3, 6], A. Nobrega[1], J. Hall[3, 6], P. Hainaut[7].* 1) Oncogenetics, A.C. Camargo Cancer Center, Sao Paulo, Sao Paulo, Brazil; 2) National Institute of Science and Technology in Oncogeneomics (INCITO), São Paulo, Brazil; 3) INSERM U612, Centre Universitaire, Orsay, France; 4) Department of Genetics and Molecular Biology, Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, Brazil; 5) National Institute of Science and Technology in in Populational Medical Genetics (INAGEMP), Porto Alegre, Brazil; 6) Institut Curie, Centre de Recherche, Centre Universitaire, Orsay, France; 7) International Prevention Research Institute, Ecully, France.

Li-Fraumeni syndrome (LFS), an inherited cancer predisposition syndrome, is associated with germ line mutations in TP53. It is characterized by high risk of multiple, early cancers in children and young adults. Carriers of a mutation in DNA-binding domain have a lifetime risk of 90% to develop a cancer. In Brazil, a variant form of LFS is exceedingly frequent due to a widespread founder TP53 mutation, p.R337H, detected in 0.3% of the general population in South and Southeastern Brazil. This mutation occurs in p53 oligomerization domain and its effect is supposed to be dependent upon pH conditions. Individuals with the TP53 p.R337H mutation have lower cumulative lifetime cancer risk (50-65%), with a number of mutation carriers being cancer-free. To identify genetic modifiers of penetrance in TP53 mutation carriers, we have analyzed a panel of 87 single-nucleotide-polymorphisms in the TP53 locus in 402 members of Brazilian families with LF traits, with or without TP53 mutations. We have identified two insertion variants associated with a 12-18 years delay in age at first cancer diagnosis, PIN3 (16bp duplication in intron 3; rs17878362 p=0.082) and DUP3'UTR (6bp duplication in 3'UTR; rs17880560, p =0.067). These SNP are known to regulate p53 pre-mRNA, suggesting that variations in pre-mRNA dynamics may accelerate cancer onset in TP53 mutation carriers. Genotyping these SNP may help in defining personalized follow-up strategies in Brazilian carriers of p.R337H, who have more heterogeneous phenotypes than carriers of 'classic' TP53 mutations.

3437F

Identification of *BRCA1* and *BRCA2* mutations in mexican patients with inherited breast and ovarian cancer by full-exon pyrosequencing. *R.M. Alvarez[1], F. Vaca[2], V. Fragoso[2], S. Vidal[3], L.A. Herrera[4,5], D. Cantu[6], J.E. Bargallo[7], A. Mohar[8], C.G. Perez[1,2].* 1) Unidad de Genómica y Secuenciación Masiva, Instituto Nacional de Cancerología, Mexico , Distrito Federal, Mexico; 2) Laboratorio Oncogenómica, Instituto Nacional de Cancerología, Mexico; 3) Laboratorio de Diagnóstico molecular, Instituto Nacional de Cancerología, Mexico; 4) Unidad de Investigación Biomédica en Cáncer, Instituto Nacional de Cancerología; 5) Instituto de Investigaciones Biomédicas, Universidad Nacional Autónoma de México (UNAM), México; 6) Subdirección de Investigación Clínica, Instituto Nacional de Cancerología, México; 7) Departamento de Tumores Mamarios, Instituto Nacional de Cancerología, México; 8) Dirección General, Instituto Nacional de Cancerología, México.

It has been estimated that 10% of women diagnosed with breast cancer have a hereditary form of the disease, primarily caused by mutations in *BRCA1* or *BRCA2*, the most prevalent and high susceptibility genes for hereditary breast and ovarian cancer. Worldwide, it is common practice to offer high-risk patients genetic counseling and DNA testing. Even though, molecular approach of these genes is not a common practice in Latin American public institutions because the cost and time consuming of the methods used. We proposed the implementation of massive pyrosequencing for screening of BRCA mutations in patients with suspected hereditary breast/ovarian cancer. Therefore, we used this technology for evaluation of germline mutations in the entire exonic and splice site regions of *BRCA1* and *BRCA2* in 163 patients with breast and ovary cancer and with familial history of breast cancer or with clinical features suggestive for BRCA mutations. In a first step, the method was evaluated with positive and negative controls for BRCA1 and BRCA2 germline mutations. We found 30-550 reads per sequence and identified all the BRCA pathogenic mutations; the negative controls did not showed deleterious variants, confirming the suitability of their use. Then, we used in the 163 patients previously described. We found twenty-eight deleterious mutations (eighteen in BRCA1; ten in BRCA2), six of them, had not been reported previously. All the mutations identified were verified by Sanger sequencing. The frequency of BRCA mutations in these patients was 17%. Direct molecular study (PCR and Sanger sequencing) was extended to 55 relatives of index cases, where pathogenic mutations were found. Twenty percent of them were carriers of the familial mutation studied. Patients and their families were enrolled in a clinical follow-up with regular screening and the recommended risk reduction measures. Moreover, we discovered a 40% of missense variants; most of them had been reported as variants of unknown clinical significance (VUS). We analyzed VUS according to a multifactorial model. Our results support the suitability of the use of this method in other public institutions, in order to achieve a personalized medicine.

3438W

Exome sequencing identifies potential new candidate genes for unexplained colorectal adenomatous polyposis. *S. Aretz[1], D. Drichel[2], M. Kerick[3], J. Altmueller[4], A. Laner[5,6], S. Horpaopan[1], S. Vogt[7], T. Becker[2,8], P. Nuernberg[4], S. Perner[9], E. Holinski-Feder[5,6], M.M. Noethen[1,10], P. Hofmann[1,10,11], B. Timmermann[12], M. Schweiger[3], I. Spier[1].* 1) Institute of Human Genetics, University Hospital Bonn, Bonn, Germany; 2) German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany; 3) Department of Vertebrate Genomics, Max Planck Institute for Molecular Genetics, Berlin, Germany; 4) Cologne Center for Genomics (CCG), University of Cologne, Germany; 5) Medizinische Klinik und Poliklinik IV, Campus Innenstadt, Klinikum der Universität München, Germany; 6) Medizinisch Genetisches Zentrum, München, Germany; 7) MVZ Dr. Eberhard & Partner, Dortmund, Germany; 8) Institute of Medical Biometry, Informatics, and Epidemiology, University of Bonn, Germany; 9) Department of Prostate Cancer Research, Institute of Pathology, University Hospital Bonn, Germany; 10) Department of Genomics, Life & Brain Center, University of Bonn, Germany; 11) Division of Medical Genetics, University Hospital Basel, Department of Biomedicine, University of Basel, Switzerland; 12) Next Generation Sequencing Group, Max Planck Institute for Molecular Genetics, Berlin, Germany.

Background: In up to 50 % of families with colorectal adenomatous polyposis no germline mutation in the currently known genes APC causing familial adenomatous polyposis (FAP) or MUTYH causing MUTYH-associated polyposis (MAP) can be identified. Methods: To uncover new causative genes, the exomes of eleven unrelated APC and MUTYH mutation negative polyposis patients were sequenced (Illumina HiSeq platform). For data analysis and variant filtering the GATK software 2.1-8, ANNOVAR, and in-house tools were applied. The variants were filtered for truncating variants and frequent alterations were excluded. Results: In one patient, an APC nonsense mutation in mosaic state (10% of reads, coverage 249) was recognized, which could be confirmed by target sequencing with high coverage (read depths >1000). By Sanger sequencing only a very discreet peak was detectable. In the remaining 10 cases, 66 genes were affected by biallelic truncating variants (recessive model) in at least one patient and 63 genes were affected by truncating heterozygous variants (dominant model) in at least two patients. After detailed visual inspection of the variants in a read browser (Integrative Genomics Viewer) to exclude obvious sequencing artifacts, and data mining according to functions and pathways, six genes of high interest remained (two for the recessive, four for the dominant approach), some of which are involved in cell adhesion, proliferation, or recombination repair. By Sanger sequencing one of the recessive genes (ZSWIM7) and three of the dominant genes could be confirmed (DSC2, HEATR5A and PDE4DIP). Two mutations were artifacts which could not be validated (heterozygous intronic mutation, dominant model) or presented in heterozygous rather than homozygous state (recessive model; the coverage was only 7). Subsequently, one of the two different HEATR5A mutations was also identified in the unaffected mother (no symptoms at 79 years of age, but no colonoscopy). From the other patients no parental blood samples were available. Conclusions: Using exome sequencing we identified new potentially causative genes for adenomatous polyposis. The clinical relevance of the genes is presently clarified in a validation sample of 200 polyposis patients. The study was supported by the German Cancer Aid and BONFOR programme of the University of Bonn.

3439T

Prevalence of BRCA1 mutations in hereditary breast/ovarian cancer families and sporadic triple negative breast cancer patients from Algeria. *F. Cherbal[1], R. Bakour[1], W. Abdou[1], C. Mehemmai[1], K. Gassi[1], H. Gaceb[1], K. Boualga[2], N. Kanoun-Zitouni[3], W. Benbrahim[4].* 1) Unit of Genetics, LBCM, Faculty of Biological Sciences, USTHB, Algiers, Algeria; 2) Anti Cancer Center, Blida, Algeria; 3) Central Hospital of Algiers, Algiers, Algeria; 4) Medical Oncology Service, Anti Cancer Center, Batna, Algeria.

Bakground: Breast cancer is the leading cause of cancer death in Algerian women. The present work aimed to establish the frequency of the three most common *BRCA1* mutations in Algerian cohort of 96 hereditary breast/ovarian cancer families and sporadic TNBC patients. The identification of common mutations in *BRCA* genes may facilitate genetic testing and counseling. The three *BRCA1* mutations screened have previously been reported in hereditary breast/ovarian cancer families and sporadic breast cancer patients from Algeria. Methods: 66 hereditary breast/ovarian cancer families and 30 sporadic breast cancer patients (most of them had triple negative status) were screened for the recurrent *BRCA1* mutations c.181T>G and c.798_799delTT. The *BRCA1* mutation c.83_84delTG has been screened in 51 hereditary breast/ovarian cancer families. The approach used is based in PCR-direct sequencing. Results: The *BRCA1* mutation c.83_84delTG detected previously in two unrelated Algerian breast cancer patients has been identified here in a young breast cancer patient with a strong hereditary breast/ovarian cancer history with the frequency of 1.9% (1/51). Interestingly, the *BRCA1* mutation c.83_84delTG has been reported one time in BIC database in Caucasian family, could be specific of Algerian population. The c.181T>G/p.Cys61Gly mutation, has been detected here in a young bilateral breast cancer patient with a strong breast cancer family history with the frequency of 1.5% (1/66). To date, the Cys61Gly pathogenic variant is one of the most frequent founder mutation identified in Central European populations, has been previously reported for the first time in Maghrebian population in two Algerian and Moroccan families.In addition, haplotype analysis of Maghrebian and central European carriers of the *BRCA1* mutation c.181T>G will establish if the origin of this mutation in Maghrebian populations is linked to the Vandals, an East Germanic tribe, who invaded and established a kingdom in North Africa during the antiquity.The *BRCA1* mutation c.798_799delTT detected previously with a frequency of 4.93% in 4 families from Algeria,has not been detected in the present study.The sporadic TNBC patients were negative for the three *BRCA1* mutations. Conclusions: the screening for *BRCA1* and *BRCA2* germline mutations in large series of Algerian breast/ovarian cancer patients/families will allow to know about the frequency, the spectrum and the contribution of the prevalence of *BRCA* genes mutations.

3440F

Combination of founder mutation screening and genomic capture using BROCA yield high rate of loss of function mutations in early onset and familial breast and ovarian cancer in Greece. *F. Fostira[1], T. Walsh[2], S. Casadei[2], M.K. Lee[2], A. Vratimos[1], G. Fountzilas[3], I. Konstantopoulou[1], M.-C. King[2], D. Yannoukakos[1].* 1) NSCR Demokritos, Athens, Greece; 2) Dept of Medicine (Medical Genetics), University of Washington, Seattle, WA, USA; 3) Aristotle University of Thessaloniki, Thessaloniki, Greece.

The antiquity of the Greeks as a population defined by language and culture, and the complexity of Greek historical demography, present challenges to genetic testing, including genetic testing for predisposition to cancer. On the one hand, the Greek population harbors ancient founder mutations in many genes, including five damaging alleles of BRCA1, of which three are multiple kb genomic deletions. We screened for these founder alleles in patients with breast and ovarian cancer at a young age (<35 years) or with severe family history of breast, ovarian, and/or pancreatic cancer and discovered that 15% (109/754) carry one of the five mutations. On the other hand, many of the patients who were wildtype at these sites have equally young and familial disease. In order to determine the frequency and range of mutations beyond the Greek BRCA1 founder alleles, we carried out additional Sanger sequencing of BRCA1 and BRCA2 and undertook multiplex massively parallel sequencing using BROCA, which captures the entire loci of 30 breast and ovarian cancer genes, detecting all classes of mutations in each gene. Point mutations were validated by diagnostic PCR and Sanger sequencing. Genomic deletions were validated by MLPA. Of 376 patients with breast or ovarian cancer evaluated thus far, 51 patients (14%) carry loss-of-function mutations, other than the BRCA1 founder mutations, in one of the known breast and ovarian cancer genes. Frequencies are: 25 in BRCA1, 10 in BRCA2, 9 in CHEK2, 2 in PALB2, 2 in ATM, 2 in MSH2 (both patients had endometrioid ovarian cancer), and 1 in MLH1 (in a patient with both colon cancer and early onset bilateral breast cancer). Two missense mutations, CHEK2 p.I160M and CHEK2 p.G167R, which are known to abrogate DNA repair activity, and one genomic deletion, MSH2 del exons 1-7, have been observed in multiple Greek families and appear to be founder alleles. We conclude that among Greek patients with familial and early onset breast cancer, where the mutation rate in founder alleles is rather high, the mutational spectrum is nonetheless highly heterogeneous with respect to both loci and alleles. Half of mutation carriers are missed by screening only for founder alleles. A population that has a significant number of founder mutations in breast cancer susceptibility genes can still benefit by an approach that detects all classes of mutations in all known breast cancer genes.

3441W

A constitutional translocation disrupting NUP98 associated with bilateral renal angiomyolipomas. *A. Lehman, M. Steinraths, Z. Zong, L. Brown, K. Mungall, K.M. Nip, I. Birol.* University of British Columbia, Vancouver, Canada.

A 41 year old woman was incidentally found from amniocentesis to have a balanced reciprocal translocation: 46,XX,t(11;12)(p15.3;q14.2). This woman has significant bilateral renal angiomyolipomas, and no other features to suggest a diagnosis of tuberous sclerosis on extensive investigation. The woman's 2-year-old daughter is a carrier of the same translocation. Her parents are not available for investigation. Whole genome sequencing was performed on genomic DNA isolated from blood using the Illumina Hi-Seq 2000. Three lanes of data were generated and a de novo assembly was conducted with ABySS for chromosomes 11 and 12. The breakpoint was identified in 2 reads and 5 reads from each translocated chromosome. It disrupted NUP98, located at 11p15.4, in intron 1, prior to the translation start site in exon 2. The breakpoint on chromosome 12 was located a gene desert. Nuclear pore complex protein Nup98-Nup96 is encoded by NUP98, a gene recurrently involved in translocations, being fused to an activating partner, associated with blood cancer. Somatic loss of function mutations appear in NUP98 in a variety of cancers. Mice haplo-insufficient for NUP98 have decreased nuclear pore density. This is the first report of a germline translocation involving NUP98 to our knowledge.

3442T

An unusual case of Lynch syndrome - should chromosome analysis be offered routinely in the investigation of this condition? *A. Murray, E. Kirk, M. Prothero, D. Barrell, S. Rolleston, S. Palmer-Smith, P. Thompson.* All Wales Medical Genetics Service, Institute of Medical Genetics, University Hospital of Wales, Cardiff, United Kingdom.

Lynch syndrome is an inherited cancer predisposition syndrome, usually caused by germline mutations in a component of the DNA mismatch repair (MMR) system. We present an interesting Lynch syndrome family with an unusual mechanism of loss of MMR function. Our consultand, an asymptomatic, 47-year-old woman, was referred with a family history of colorectal, small bowel, and stomach cancer. We initiated tumour testing on an affected relative, whilst referring our consultand for regular colorectal screening. On her first colonoscopy, an adenocarcinoma was found in the tranverse colon. Local hospital immunohistochemical testing of this tumour, for MLH1 and MSH2 only, showed loss of MSH2 expression; molecular genetic testing in our laboratory showed microsatellite instability (MSI), with absence of the BRAF V600E mutation. More comprehensive immunohistochemical testing showed loss of expression of both MSH2 and MSH6, but sequence and dosage analysis of the MSH2 and MSH6 genes did not reveal any mutations. Karyotyping showed the presence of a small paracentric inversion of the short arm of chromosome 2, with breakpoints at p21.1 and p22.2. There is one report in the literature of a similar inversion in a patient with Lynch syndrome although breakpoints were not assigned. This result appears to confirm the clinical diagnosis of Lynch syndrome in our family. We are currently undertaking karyotyping of other affected family members, with a view to offering predictive testing to unaffected relatives, to clarify their risks and screening needs.

3443F

Germline *BAP1* mutations in uveal melanoma patients with a personal and/or family history of renal cell carcinoma. *R. Pilarski[1], C.M. Cebulla[2], O. Saqr[2], K. Rai[1], J.B. Massengill[2], F.H. Davidorf[2], M.H. Abdel-Rahman[2].* 1) Dept. of Internal Medicine and James Cancer Hospital,; 2) Dept. of Ophthalmology, Ohio State Univ, Columbus, OH.

Background: Germline mutations in the BAP1 gene have recently been shown by us and others to cause uveal melanoma (UM), mesothelioma, cutaneous melanoma, and possibly other cancers. Noting the occurrence of renal cell carcinoma (RCC) in several families, we investigated the frequency of germline mutations in BAP1 in patients with a personal history of UM and also a personal and/or family history of RCC. **Methodology:** Six patients were included in the study, including five females and one male. Average age was 52.6 years (range 41 to 72 years). Germline mutations in BAP1 and VHL were assessed in peripheral blood DNA by direct sequencing. In one patient with both UM and RCC somatic mutation in VHL was assessed in both the ocular and renal tumors. **Results:** We identified germline pathogenic mutations in BAP1 in 2/6 patients. Family histories of mesothelioma and other cancers including lung, colon, breast and pancreatic carcinomas were reported in these two families. No germline VHL mutation was identified; however, a somatic mutation in VHL was detected in the RCC tumor tissue but not in the UM tumor tissue from a patient with both primary tumors. **Conclusion:** BAP1 is a candidate gene in patients with a personal history of UM and a personal or family history of renal cell carcinoma.

3444W

Combined effect of germline mutations in *MUTYH* and DNA mismatch repair genes on risk of colorectal cancer. *A.K. Win[1], J.P. Young[2], D.D. Buchanan[2], S.P. Cleary[3,4], H. Kim[3,4], J.G. Dowty[1], R.J. MacInnis[1,5], T. Burnett[6], L. Le Marchand[6], P.A. Newcomb[7], R.W. Haile[8], N.M. Lindor[9], J.L. Hopper[1], S. Gallinger[3,4], M.A. Jenkins[1].* 1) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The Univ Melbourne, Carlton, VIC, Australia; 2) Cancer and Population Studies Group, Queensland Institute of Medical Research, Clive Berghofer Cancer Research Centre, Herston, Queensland, Australia; 3) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Cancer Care Ontario, Toronto, Ontario, Canada; 5) Cancer Epidemiology Centre, Cancer Council Victoria, Carlton, Victoria, Australia; 6) University of Hawaii Cancer Center, Honolulu, Hawaii, USA; 7) Cancer Prevention Program, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA; 8) Department of Medicine, Division of Oncology, Stanford University, California, USA; 9) Department of Health Science Research, Mayo Clinic Arizona, Scottsdale, Arizona, USA.

Background Identifying modifiers of cancer risks is important for understanding carcinogenesis in carriers of *MUTYH* mutations and for genetic counselling, screening and risk-reduction strategies. As the MUTYH protein interacts with the DNA mismatch repair (MMR) system, we hypothesized that the combination of a monoallelic *MUTYH* mutation with an MMR gene mutation increases colorectal cancer (CRC) risk. It has been controversial that MMR gene mutations, especially *MSH6*, are more frequent in CRC-affected carriers of monoallelic *MUTYH* mutation than CRC-unaffected carriers of monoallelic *MUTYH* mutation. **Methods** Using the data from the Colon Cancer Family Registry Cohort and Cox proportional hazards regression weighted to correct for the method of ascertainment, we investigated (i) effect of MMR gene mutations on CRC risk for monoallelic *MUTYH* mutation carriers, and (ii) effect of monoallelic *MUTYH* mutations on CRC risk for MMR gene mutation carriers. **Results** In a cohort of monoallelic *MUTYH* mutation carriers, we observed that frequency of MMR gene mutations was higher in CRC-affected carriers (8/158, 5.1%) compared with CRC-unaffected carriers (2/225, 0.9%) (p=0.02). CRC risk for monoallelic *MUTYH* mutation carriers with an MMR gene mutation was higher than those without an MMR gene mutation (hazard ratio [HR] 13.2, 95% confidence interval [CI] 5.42-32.11, p<0.001). In a cohort of MMR gene mutation carriers, we observed that frequency of monoallelic *MUTYH* mutation was not different between CRC-affected (8/411, 2.0%) and unaffected carriers (2/68, 2.9%) (p=0.64). There was no evidence of difference in CRC risk for MMR mutation carriers with or without a monoallelic *MUTYH* mutation (HR 0.65, 95% CI 0.24-1.76, p=0.40). **Conclusion** In this study, there was no evidence of modifying effect by monoallelic *MUTYH* mutation on CRC risk for MMR gene mutation carriers whereas MMR gene mutation increased risk of CRC for monoallelic *MUTYH* mutation carriers.

3445T

Towards scoring all 35,397 possible missense variants of BRCA1 for activity. *L.M. Starita[1], J.O. Kitzman[1], J.G. Gullingsrud[1], J.D. Parvin[2], J. Shendure[1], S. Fields[1,3].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Department of Biomedical Informatics, The Ohio State University Comprehensive Cancer, Columbus, OH; 3) Howard Hughes Medical Institute.

BRCA1 is a breast and ovarian cancer-specific tumor suppressor gene that has been subject to much diagnostic sequencing. Multiple cancer-predisposing mutations have been identified along with >500 missense variants classified as Variants of Uncertain Significance or VUS. The BRCA1 protein consists of 1863 amino acids. The N-terminus contains a RING domain that is part of an active ubiquitin ligase, and the C-terminus contains tandem BRCT (BRCA1 C-Terminus) repeats that bind to phosphorylated peptides and activate transcription. BRCA1 is required for double-strand DNA break repair via homologous recombination; mutations found throughout the protein have deleterious effects on this function. We are devising assays to score all 35,397 possible missense mutations of BRCA1 for their effects on the protein's biochemical and cellular functions.

Our approach is to employ deep mutational scanning, a method that uses high throughput DNA sequencing to analyze protein variants that are expressed in a coupled genotype-phenotype system. To assess the effect of mutations on the function of the RING domain, we displayed residues 2-304 of BRCA1 in a phage-based assay that allows us to select variants active for *in vitro* auto-ubiquitination. This assay allowed us to score 2,413 (40%) of the possible 5,757 missense variants of this region of BRCA1. Among the variants scored, 57 have been identified in patients as VUS. In our assay, these variants ranged in ubiquitin ligase activity from totally inactive to fully functional, suggesting that some of the variants of BRCA1 that are classified as VUS are nonfunctional ubiquitin ligases.

We are currently developing three additional assays to score the effects of mutations in BRCA1. First, we are developing a phage display assay to select for BRCT variants that are able to bind to phosphorylated peptides. Second, we are using a yeast one-hybrid assay to analyze transcriptional activation mediated by the BRCT domain. Finally, we are working on a cell-based assay to score the effect of mutations in full-length BRCA1 on the cell's ability to carry out DNA repair via homologous recombination.

3446F

Clinical presentation of patients with mutations in the *APC* regions associated with AFAP. *P. Kaushik, K. Moyes, C. Arnell, M. Landon, R. Wenstrup.* Medical Services, Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

Familial Adenomatous Polyposis (FAP) has been characterized by the development of 100s to 1000s of colorectal adenomas, while Attenuated Familial Adenomatous Polyposis (AFAP) has been characterized by the development of less than a 100 colorectal adenomas. Both FAP and AFAP are associated with mutations in *APC*. Studies looking into the phenotype/genotype correlation associated with the *APC* gene have highlighted specific areas in which mutations are more likely to lead to AFAP. Three significant areas are the 3' end, 5' end, and exon 9. This study aims to describe the polyp history of patients with mutations in these specific areas compared to mutations in the remainder of the *APC* gene. A retrospective analysis was performed on patients who underwent full *APC* gene analysis or targeted *APC* mutation analysis between January 1st 2006 and May 22nd 2013. Demographics and clinical characteristics were reviewed based on data reported on test request forms submitted to a commercial testing laboratory. Mutational testing results were also reviewed. The regions of the *APC* gene considered to be associated with AFAP were codons 1-157 (5' end), 312-438 (exon 9), and 1595-2855 (3' end). A total of 1534 individuals with mutations in the *APC* genes were included in this study. *APC* mutations in the three gene regions associated with AFAP were identified in 461 of 1534 patients (30.1%). Of these, 303 (65.7%) were reported to have developed less than 100 colorectal adenomas. A total of 1073 patients (69.9%) were found to carry an *APC* mutation in the remainder of the gene not associated with AFAP. Of these, 268 (25%) were reported to have developed less than 100 polyps. The majority of patients with an *APC* mutation in the three regions associated with AFAP were over the age of 40 at the time of testing (72.7%), while the majority of patients with mutations in the remainder of the *APC* gene were aged 20-40 at the time of testing (57.1%). This data shows that there appears to be a trend of less severe polyposis and later age of testing among patients with a mutation in the three main regions of *APC* associated with AFAP. However, a substantial number of patients were found to have over 100 colorectal adenomas regardless of the region the mutation was found in, suggesting that there is no definitive genotype/phenotype correlation between *APC* mutations and FAP/AFAP.

3447W

High sensitive detection of colorectal cancer mutations using third generation sequencing. *G. Russo[1], A. Patrignani[1], L. Poveda[1], F. Hoehn[2], R. Schlapbach[1], A. Garvin[2].* 1) Functional Genomics Center Zurich - ETH/UZH, Zurich, Switzerland; 2) Droplet Diagnostic SAS, France.

Colorectal cancer (CRC) is a major cause of cancer mortality. Unlike methylation, which occurs to some extent in normal tissue, mutations in the oncogenes and tumor suppressor genes that drive CRC are highly specific for tumor tissue. Mutations in patient samples can be found at many locations in these genes, therefore a scanning method for mutation detection is needed for high sensitivity. **Objectives:** To determine the sensitivity and specificity of single molecule, third generation sequencing for an assay that detects rare mutations in the genes that drive CRC. **Methods:** We performed three experiments in which mutant DNA from CRC derived cell lines and mixtures of mutant and wildtype DNA were PCR amplified and sequenced on the PacBio RS. High accuracy reads on short amplified fragments were obtained using circular consensus sequencing (CCS) to correct random errors. The assay consists of 15 amplicons covering regions of five genes mutated in CRC: KRAS, CTNNB1, BRAF, APC and P53. The amplicons were optimized at the same size to ensure uniform coverage and therefore uniform power of detecting mutations. The length of the total test sequence is about 5,000 bp. The results from the PacBio RS instrument were directly compared with Illumina MiSeq on a sample of amplified DNA containing three mutations (two substitutions and one, one base, deletion) present at the 1.5% level. **Results:** The quality of the CCS-called bases is orders of magnitudes higher than those of the Illumina sequences. Using DNA with mutations present at 1.5%, PacBio RS shows 100 % sensitivity and specificity while Illumina MiSeq, due to its systematic bias and higher background noise, missed one of the two substitutions and reported 10 false positives. **Conclusions:** We performed third generation, single molecule sequencing to detect low frequency CRC mutations in 15 short amplicons. A variety of sane and mutated cell lines and their mixtures at different concentrations was employed to simulate the real case of stool DNA. With no systematic bias and a much higher CCS base-calling quality, PacBio RS is superior than Illumina MiSeq. **Future work:** We generated mixtures with lower levels of mutant DNA (1 and 0.5 %) so to investigate the lowest possible frequency at which the detections occur; we have also sequenced two real samples, obtained from excised polyps, so to have our first test on a real tissue where the exact mutations are not known a priori. The data are currently being analysed.

SNV calls using RNA-Seq complements Exome-Seq variant calling in tumor cell lines. *S. Wong, P. Ebert, S. Bray, J. Calley, T. Barber.* Tailored Therapeutics, Eli Lilly and Company, Indianapolis, IN.

Whole-exome sequencing (exome-seq) and RNA sequencing (RNA-seq) have been widely utilized to uncover critical mutations and expression changes that drive tumorigenesis, drug resistance, or tumor evolution in cancer. Typical genomic approaches have relied on exome-seq to call single nucleotide variants (SNVs), while RNA-seq is primarily used for differential gene expression analysis or identifying tumor-specific translocation events. Though not routinely done, calling SNVs with RNA-seq data could provide additional benefit, including confirmation of exonic variants, however, RNA-seq variants are limited exclusively to expressed genes, which could also affect the detection of variants that result in reduced expression, such as some tumor suppressor mutations. To explore the concordance between exome-seq variants and RNA-seq called variants, we performed whole-exome sequencing and RNA sequencing from cancer cell lines and assessed the variant calls in genes expressed at differing levels. To address whether deleterious variants in tumor suppressor genes could be identified in RNA-seq data, we analyzed all nonsense and frame-shift mutations identified in exome sequencing for their presence in RNA-seq variant calls. In conclusion, RNA-seq variant calling can complement the variant calling from exome sequencing and can be a valued tool for calling somatic variants in expressed tumor genes.

Novel genetic and epigenetic alterations in the von Hippel-Lindau gene in a cohort of sporadic renal cell carcinoma patients from Pakistan. *A. Abid[1], S. Ajaz[1], S. Firasat[1], S. Shahid[1], A. Shehzad[2], G. Sultan[2], R. Mohsin[2], A. Hashmi[2], M. Mubarak[3], S.A.A. Naqvi[4], S.A.H. Rizvi[4], S.Q. Mehdi[1], S. Khaliq[1,5].* 1) Centre for Human Genetics, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; 2) Department of Oncology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; 3) Department of Histopathology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; 4) Department of Urology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; 5) Department of Human Genetics, University of Health Sciences (UHS), Lahore, Pakistan.

Abstract: Background: Renal cell carcinoma (RCC) is the most frequent form of kidney cancer in adults and somatic mutations that inactivate the von Hippel-Lindau (VHL) gene are the most common cause of RCC. VHL gene alterations have been associated with clear cell subtype of RCC (ccRCCs), though there have also been reports on other types of RCCs, albeit at lower frequencies. Huge variations have been reported in the frequencies of mutations in the VHL gene in sporadic RCCs from different parts of the world ranging from 45% to 71%. However, there is still no data available on the involvement of the VHL locus in RCC cases from South Asian region. This report presents, for the first time, the genetic and epigenetic changes in a cohort of 300 renal cell carcinoma patients from Pakistan. Methods: To identify mutations in the VHL gene, direct DNA sequencing was carried out and epigenetic silencing was investigated by using methylation-specific polymerase chain reaction. Results: Our data showed molecular alterations in the VHL gene in 144 (48%) renal cell carcinoma patients. Somatic mutations were found in 87 (29%) patients and 35 novel mutations were identified. VHL promoter hyper-methylation analysis showed epigenetic changes in 83 (39.7%) out of 209 patients. A total of 105 ccRCC patients (52%) and 22 papillary RCC patients (41%) had a molecular abnormality in the VHL gene. A total of 26 RCC cases (12%) carried both types of molecular alterations i.e. somatic mutations as well as the VHL promoter hypermethylation. Patients who had no evidence of molecular alterations in the VHL gene were significantly younger than patients who carried some molecular change. However, there was no significant correlation of a genetic and/or epigenetic change in the VHL gene with other prognostic markers of renal cell carcinomas including tumour grade, size and stage. Molecular alterations in the VHL gene were not restricted to clear-cell renal cell carcinomas (ccRCC). Conclusions: The comparatively lower frequency of somatic mutations and higher frequency of epigenetic changes in the Pakistani cohort should be considered for developing specifically tailored preventive and therapeutic regimens against non-familial renal cell carcinomas.

Exome sequencing of cancer cell lines uncovers mutations not reported in commonly used COSMIC and CCLE databases. *S. Bray, K. Yu, Y. Webster, S. Wong, Y. Yue, I. Wulur, T. Barber.* Tailored Therapeutics - Genetics, Eli Lilly and Company, Indianapolis, IN.

Genomic characterization of cancer cell lines has become a critical tool for preclinical modeling of cancer. This is especially true for the interpretation of drug response data of targeted therapies, which relies on the accurate annotation of putative somatic mutations in the screened cell lines. Publicly available databases of likely somatic variants, such as the COSMIC Cell Line Project and the Cancer Cell Line Encyclopedia (CCLE), are valuable resources for annotating genetic variants in commonly utilized cell lines. These public databases, however, only provide sequence data for a relatively small panel of candidate cancer genes and the availability and affordability of next-generation sequencing have now made it more feasible to sequence the whole genomes or exomes of cell lines for additional genetic coverage. We used whole-exome sequencing to characterize the likely somatic variants across cancer cell lines and compared our variant calls to the public data for the mutually covered genes. We found very good sensitivity of our exome data to detect variants reported in COSMIC and CCLE. We also identified 'novel' mutations in candidate cancer genes that were not identified in either COSMIC or CCLE. We chose a subset of these novel variants to validate by Sanger sequencing and all were confirmed to be true variants. While we cannot exclude the role of cell-line divergence, our data suggest there may be many false negatives in the frequently used public databases that could ultimately impact interpretation of cell line behavior in functional studies.

3451T

Hierarchical models of mutational recurrence and allelic burden in prostate cancer. *R. Cowper[1,2], N. Sinnott-Armstrong[1,2], M. Lupien[3,4,5], M. Kellis[1,2].* 1) MIT Computer Science and Artificial Intelligence Laboratory, Cambridge MA USA; 2) The Broad Institute of MIT and Harvard, Cambridge MA USA; 3) Ontario Cancer Institute, Princess Margaret Cancer Centre-University Health Network, Toronto ON Canada; 4) Ontario Institute for Cancer Research, Toronto ON Canada; 5) Department of Medical Biophysics, University of Toronto, Toronto ON Canada.

Genome wide association studies (GWAS) have identified hundreds of prostate cancer risk-associated alleles. Similarly, whole genome sequencing (WGS) projects have identified thousands of mutations found in prostate tumors. Although the fields of post-GWAS and post-WGS aim to characterize the variants found thus far, many remain to be discovered. Indeed, all of these variants are still only able to account for a fraction of the heritability and a portion of tumor mechanisms. The main confounder in variant discovery is heterogeneity at the level of the population and of tumors. This heterogeneity precludes discovery through epistasis, whereby sets of variants manifest phenotypically as the same trait. Because the majority of GWAS and WGS studies have focused on individual alleles or mutations, heterogenous sets of causal variants have remained hidden. The notions of burden and recurrence have emerged as mechanisms for the integration of alleles and mutations in GWAS and WGS data respectively. However, both of these approaches are still founded on a model where contiguous genomic elements constitute the units being tested. But the set of genomic elements that can affect a gene is large and scattered across the entire genome. In order to overcome this limitation, we have studied non-contiguous sets of interacting variants that impinge on the same gene. We therefore use chromatin conformation and open chromatin data to identify the sets of elements that affect each active gene in prostate tissue. Through this process we build a hierarchical structure where smaller genomic elements are nested in larger functional aggregates. We then traverse this hierarchical structure looking for nodes that are recurrently mutated in tumors or that carry a high allelic burden in patients. We use WGS data from ten prostate adenocarcinomas and the entire set of prostate cancer risk-associated variants identified through GWAS. Furthermore, we characterize the mechanisms through which these variants disrupt gene expression through the analysis of affinity modulation and chromatin states.

Genomic Characterization 0f Invasive Cervical Cancer in Guatemala and Venezuela: Common Activation of the PIK3CA Pathway. *M. Dean[1], E. Gharzouzi[2], E. Alvirez-Freites[3], G. Villagran[2], G. Calabrese[3], J. Sawitzke[4], H. Lou[4], J. Boland[5], S. Chanock[5], M. Yeager[5].* 1) Lab Experimental Immunology, NCI-FCRDC, Frederick, MD; 2) Instituto Cancerologia, Guatemala City, Guatemala; 3) Hospital Central Universitario 'Dr. Antonio M Pineda', Barquisimeto, Lara State. Venezuela; 4) SAIC-Frederick; 5) DCEG, NCI, NIH.

Cervical cancer represents the most dramatic cancer health disparity of women in the world, with over 270,000 deaths annually, concentrated in poor, rural, and indigenous populations. Guatemala and Venezuela are illustrative of this disparity as cervical cancer is the predominant cause of cancer cases and deaths in women. The average age of the subjects is 50, and smoking and oral contraceptive use is low. The affected women have an average of 6 children and adeno- or adenosquamous pathologies represent 25% of the tumors. To determine the genomic changes in invasive tumors, we initiated a prospective collection of invasive cervical cancer tissue. To determine the most frequently mutated genes we sequenced the exomes of 23 tumors in the Ion Torrent Proton and followed up with targeted sequencing of genes by Ampliseq in an additional 80 tumors. The exome sequence revealed potential driver mutations in several known cancer genes such as PTEN, PIK3CA, TSC1, SETD2, HRAS, PTCH, ARID1A, ARID4A and RB1. Targeted resequencing in a larger set of tumors of commonly mutated genes in the COSMIC database (PIK3CA, TP53, STK11, PTEN, KRAS, HRAS, and CDKN2A) revealed 40% mutation in PIK3CA and 11% in PTEN (a negative regulator of the PI kinase pathway). TP53 and STK11 were significantly mutated (10 and 8% of tumors, respectively) but HRAS, KRAS and CDKN2A at a very low level (0-2%). The PIK3CA mutations were concentrated in the known activating sites in the helical domain (E542K and E545K). To determine HPV stain types we amplified the HPV L1 gene found detectable in HPV in 96% of samples with HPV16 in 53%, HPV18 in 12%, HPV45 in 10% and HPV 26, 31, 33, 35, 39, 52, 56, 58, 67, 68, 69, and 73 in 0.8-4.9% of samples. In conclusion, invasive cervical cancers display frequent mutation of the helical domain of PIK3CA and activation of the PI kinase pathway, suggesting that targeted inhibition of this pathway may provide an avenue for therapy in this largely untreatable, common cancer.

3453W

Whole Genome Sequencing of High-Grade Treatment-Naïve Prostate Tumors. *B.J. Decker[1,2], D.M. Karyadi[1], E. Karlins[1], L.S. Tillmans[3], S.N. Thibodeau[3], E.A. Ostrander[1].* 1) Cancer Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, United States; 2) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, Cambridge, United Kingdom; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN, United States.

Prostate cancer (PCa) will impact one in six American men and many low-risk men endure therapy, while other men die of PCa. Optimal treatment selection depends on distinguishing indolent tumors from those that will cause prostate cancer specific mortality (PCSM). To date, sequencing of prostate tumor DNA has highlighted the fact that prostate tumors develop differently than other cancers. Instead of recurrent protein-altering mutations, many prostate tumors harbor 'closed chain' structural rearrangements that may mediate tumor evolution. However, we do not yet understand which somatic mutations are involved in aggressive disease and PCSM. To address this crucial question, we are using whole genome sequencing to pinpoint somatic genetic features in tumor/normal paired samples from four PCSM and six non-PCSM patients with treatment-naïve, Gleason 8+; tumors. Tumor and normal DNA were sequenced to a mean coverage of 95.3X and 48.3X, respectively. Tumor DNA purity ranged from 49%-79%; and tumor ploidy ranged from 1.96 to 2.22. To define the genomic landscape of aggressive PCa, we will compare our findings with published studies and genotype high-priority candidates in at least 50 additional low- and high-grade tumors. We will also compare somatic mutations in PCSM versus non-PCSM cases and use network analysis to identify pathways that may be involved in progression and metastasis. Finally, we will characterize the clonal evolution of PCa tumors using deep digital sequencing to distinguish mutations that were present in the original tumor clone from subclonal mutations that arose after oncogenesis. In this way, we aim to identify potential oncogenic drivers and candidate mediators of progression and metastasis. Ultimately, we aim to 1) Uncover somatic mutations that are specific to aggressive tumors 2) Determine whether PCSM tumors have unique genetic features, and 3) Understand the role of clonal evolution in oncogenesis and progression. As more tumors are sequenced, this approach may yield valuable markers for diagnosis, prognosis and treatment selection.

3454T

Genomic landscape of 2 gastric cancer cases. *D. Esser[1], N. Holze[2], J. Haag[2], S. Krüger[2], V. Warneke[2], S. Schreiber[1,3], C. Röcken[2], P. Rosenstiel[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 2) Institute of Pathology, Christian-Albrechts-University, Kiel Germany; 3) Department of General Internal Medicine, University Hospital Schleswig-Holstein.

Gastric cancer is the fourth most common cancer type. With a 5-year survival rate of 26% gastric cancer causes 10% of all cancer deaths worldwide. In order to understand the genetic background we sequenced the whole exome and the whole genome of one microsatellite stable as well as one microsatellite unstable tumor and the matched healthy tissue on two different next generation sequencing (NGS) platforms (Illumina HiSeq and Solid 4). The samples were from two female patients at the same age with gastric cancer of the same tumor stage without histological evidence of EBV-infection. The average coverage in the whole exome sequencing was between 41- and 66-fold and in the whole genome sequencing between 14- and 78-fold. The study combines the analysis of single nucleotide variations (SNV) as well as structural variants like small and large insertions/deletions, translocations, inversions and tandem duplications and can be used as a blueprint for further gastric cancer genome analysis. Relevant mutations, pathways (KEGG) and functional terms (GO) were filtered out using population-based whole genome resources. The databases OMIM, HGMD and GWAS were accessed to detect known cancer associated variations. We further analyzed the mutation pattern and could show differences in the relative contributions of each of the six base substitution classes between tumor and healthy control samples. Additionally, we investigated the sequence context of each SNV by considering the bases immediately 5' and 3' to each base substitution and observed a tumor specific signature. Rainfall-plots were applied to identify chromosomal regions of high SNV density, however, in the preliminary results no obvious intragenic SNV clusters were detected. The results highlight a strategy of an exemplary tumor genome analysis that combines both exome and whole genome sequence information with two different NGS platforms and is one of the first gastric cancer whole genome studies. Using that comprehensive strategy we were able to identify a multitude of novel potentially damaging mutations, which were partially validated in an independent gastric cancer sample cohort of 452 independent samples.

3455F

The Application of Next Generation Sequencing (NGS) for Mutation Analysis of MyeloProliferative Neoplasms (MPNs) Patients in the State of Qatar. *Q. Fernandes[2], N. Al-Dewik[1,2], YK. Naidu[2], B. Cassinat[3], JJ. Kiladjian[4], H. El Ayoubi[2], N. Hammadi[2], G. Perkins[2], M. Yassin[2].* 1) Qatar Medical Genetics Center, Hamad Medical Corporation, Doha, Qatar; 2) Molecular Genetics of Cancer - Research Lab, NCCCR-HMC, Doha, Qatar; 3) Unité de Biologie Cellulaire, France; 4) Centre d'Investigations Cliniques, Hôpital Saint-Louis, Paris, France.

Since the last two decades, there has been major advances in studying the genetic basis of MPNs. Research in cancer genetics has enabled the identification of several genes in MPNs. However, there is still a significant number of MPN cases that are negative to most common genetic anomalies and many mutations are still unknown. Advanced genomic technologies like NGS play an important role in identifying and elucidating genetic defects causing polygenic disorders such as MPNs. 7 MPN patients and 7 healthy individuals from 3 consanguineous families were recruited into the study. DNA was extracted and sequenced using Ion Torrent PGM with 318 Chip. The hg19 human genome was used as the reference sequence. 190 amplicons targeting 739 cancer associated mutations in 604 loci from 46 key cancer genes were amplified. The NGS data analysis was done using Ion Reporter, Ingenuity Variant Analysis and Catalog Of Somatic Mutations in Cancer (COSMIC) Out of four PV patients, three were positive for the JAK2 V617F mutation. One patient had mutations in PDGFRA 838-840delGLA, APC Q1285fs, NPM1 Splice Site Loss and PTEN S10N. The second patient had mutations in KIT M541L, KDR Q472H, TP53 P72R and the third patient had PI3KCA I391M, KIT M541L, KDR Q472H, P53 P72R mutations. The fourth patient negative to the JAK2 V617F mutation had PDGFR A838-840delGLA and SMARCB1 T72K mutations. Out of three ET patients, one patient was positive for JAK2 V617F, SMARCB1 T72K, IDH1 K115Q and PDGFRA 838-840delGLA. two patients were negative for the JAK2 V617F and MPL mutations, out of which one patient had mutations in PDGFRA 838-840delGLA, APC Q1285fs and SMAD4 198-200delPAL. The other patient had mutations in CDKN2A S73R, APC Q1285fs and PDGFRA 838-840delGLA. It was identified that PDGFRA 838-840delGLA and APC Q1285fs mutations were also found in healthy individuals. This study was able to identify a list of deleterious somatic mutations such as missense mutations, frame shift mutations, in-frame deletions, splice loss sites and Single Nucleotide Variation (SNV) in MPNs patients and healthy individuals. Our preliminary results suggest that the MPNs patients in Qatar have complex mutations. Evidences show that there exists a possibility of the disease arising out of the accumulation of genetic alteration and not as the consequence of a single genetic event. This could possibly be due to high rate of consanguineous marriages in Qatar ie. the 'Founder Effect'.

3456W

Massive parallel sequencing of BRCA1 and BRCA2: detection of deleterious mutations and variant of unknown significance in breast cancer patients from Colombia - South America. *L. Galeano Petro[1,2], G. Guevara Pardo[1], H. Groot De Restrepo[2], D. Restrepo Montoya[1].* 1) Instituto Colombiano de Genética y Oncología Molecular, Bogotá - Colombia; 2) Universidad de los Andes, Bogotá - Colombia.

Introduction: This study describes how the high -throughput or massive parallel sequencing technology can be implemented in a diagnostic setting for the breast cancer susceptibility genes, BRCA1 and BRCA2. At the present, genetic testing is offered in many centers in North America, Europe, Australia and Israel, but is not generally available in developing countries as Colombia-South America. Genetic testing is gaining acceptance worldwide because of the increasing numbers of preventive options available to women with a mutation, and because of the development of novel, individualized, cancer therapies. Purpose: We performed deleterious mutations and variant of unknown significance analysis of BRCA1 and BRCA2 on patients with breast cancer from Colombia using massively parallel sequencing. Methods: Of 120 patients, initially sequenced by the method of Sanger, were subselected 12 patients for the massive parallel sequencing of BRCA1 and BRCA2. The throughput was maximized by increasing uniformity in coverage, obtained by target enrichment of BRCA1 and BRCA2 in 21 amplicons ranging from 1.2-5.9kb and 6 reactions by long PCR multiplex approach. The preparation and sequence of fragment library was performed using NanoDrop quantification of PCR products, shearing of PCR products using the Covaris S220 System and verification using the Agilent Bioanalyzer, end-polish and size-select the DNA by Agencourt AMPure XP reagent, verification on the Agilent Bioanalyzer, add a dA-tail to the size-selected DNA, ligation of adaptors to the DNA, quantification the ligated DNA, check the size distribution of the library, pool equal molar barcoded libraries and quantitate the library, emulsify and amplify the beads, enrich the template beads, modify the 3' ends of the DNA, deposit the beads and sequence the library in 5500xl SOLiD Sequencer, post-run data export and analysis by LifeScope 2.5.1 Software and finally, confirmation of all sequence variants by Sanger sequencing. Results: deleterious mutations and variants of unknown significance were identified and confirmed by Sanger sequencing with 100% concordance. Conclusion: Our workflow illustrates the potential of massive parallel sequencing of large genes in a diagnostic setting which is of great importance to meet the increasing expectations of genetic testing. A wider spectrum of at risk women in Colombia will be able to benefit from therapeutic and prophylactic interventions.

Understanding the Significance of Individual Tumor Genetic Heterogeneity by Developing Next Generation Genetic Databases as Advanced Analysis Tools. *B. Gottlieb[1, 2, 3], L.K. Beitel[1, 2, 3, 4], M. Trifiro[1, 2, 3. 4].* 1) Dept Cell Gen, Lady Davis Inst Med Res, Montreal, QC, Canada; 2) Segal Cancer Centre, Jewish General Hospital, Montreal, QC, Canada; 3) Dept Human Genetics, McGill University, Montreal, QC, Canada; 4) Dept Medicine, McGill University, Montreal, QC, Canada.

The discovery of intra-tumor genetic heterogeneity in cancer tissues has had a significant effect on cancer ontogeny by making it even more difficult to assess which gene alterations are drivers and which are passengers within individual cancer patients. To resolve this issue, we have developed a new approach to sequencing that has allowed us to create a distribution profile of mutant variants within tumors. This has allowed us to measure the frequency of distribution of an androgen receptor (AR) repeat length variant associated with breast cancer. Initial data indicate that the relationship of AR mutations and breast cancer is complex and cannot be explained solely by the presence of specific mutations within breast cancer tissues. Understanding intra-tumor genetic heterogeneity and its possible relationship to cancer ontogeny, is further complicated by the presence of genetic heterogeneity in normal breast tissues as well. Thus, it is becoming clear that most individual cancers will have their own unique genetic profiles. In addition to intra-tissue genetic heterogeneity, the discovery that post-genomic events such as epigenetics can play an important role in determining cancer phenotype, have combined to challenge a number of classic genetic paradigms with regards to the genotype to phenotype relationship. It is the exact nature of this relationship that will need to be resolved to eventually understand carcinogenesis, and we are proposing the creation of next generation genetic databases (NGDBs) as a solution. These NGDBs will incorporate the new genotype to phenotype paradigms, as well as include powerful systems biology analysis tools to actively process and evaluate the vast amounts of both genomic and post-genomic information that will undoubtedly be revealed. The Human Variome Project (HVP) will be an essential element to ensure the effectiveness of NGDBs with its goals of setting up a worldwide network of nation-based genome collection nodes and creating standards for next generation sequencing. Thus, NGDBs, and the HVP can become the instruments for achieving real breakthroughs in understanding the genetic basis of individual cancers as well as their prevention and treatment.

Utilizing Publically Available NGS Tumor Data to Identify Novel Oncology Targeted Therapies. *D. Greenawalt[1], J. Bradford[2], M. Wappett[2], A. Dulak[1], K. Vasudevan[3], K. Jacques[3], S. Guichard[3], J. Dry[1].* 1) Oncology Bioinformatics, AstraZeneca, Waltham, MA; 2) Oncology Bioinformatics, AstraZeneca, Alderley Park, UK; 3) Cancer Biosciences, AstraZeneca, Waltham MA.

Public tumor consortiums, including the The Cancer Genome Atlas (TCGA1) and International Cancer Genome Consortium (ICGC2) are generating and making publically available a large amount of molecular data on a diverse set of tumor types. Through tumor type specific publications the TCGA is releasing intensive, integrative analysis of specific tumor types and many groups are clamoring to extract novel findings from the data through deep mining and novel integrative analysis. These analyses will lead to an abundance of novel targeted oncology therapies emerging over the next few years. We will present our integrative analysis methods for identifying novel genetic targets from publically available molecular datasets, integrating mutations, gene expression, copy number and fusions from the TCGA data; how these targets are filtered and screened to identify novel drug targets with the highest probability of success, and the pitfalls identified mining primary, treatment naïve datasets. These methods can then be translated to data released from the ICGC and additional datasets to learn how the disease segmentation for targets identified translate across tumors from diverse populations. 1.http://cancergenome.nih.gov/ 2.http://icgc.org/.

Mutation Status of P53 in Head and Neck Squamous Cell Carcinoma. *E. GUNDUZ[1], G. NAS[1], M. ACAR[1], S. DEDE[1], K. ERDOAN[1], C. MOROSKI ERKUL[1], M. GUNDUZ[1,2].* 1) MEDICAL GENETICS, TURGUT OZAL UNIVERSITY MEDICAL FACULTY, ANKARA, Turkey; 2) DEPARTMENT OF OTOLARYNGOLOGY, HEAD AND NECK SURGERY, TURGUT OZAL UNIVERSITY MEDICAL FACULTY, ANKARA, Turkey.

Head and Neck Squamous Cell Carcinoma (HNSCC) occurs in the Oral Cavity, oropharynx, larynx or hypopharynx and is the sixth most frequent cancer worldwide. Although molecular mechanisms of HNSCC have not yet been revealed completely, p53 alterations are the most frequent event that occurs during carcinogenesis. TP53 is a tumor suppressor protein encoded by the TP53 gene in human and responds to diverse cellular stresses to regulate expression of target genes, thereby inducing cell cycle arrest, apoptosis, senescence or DNA repair. Mutations in the p53 gene result in loss of function or decreased levels of gene expression and is associated with a variety of human cancers. Also, p53 inactivation is clinically important because of a strong correlation to an acquired or innate resistance to chemotherapy. Hence, p53 mutation status is one of the most important biomarkers for carcinogenesis and therapy. Our laboratory aimed to identify the mutation status of p53 in HNSCC by full exon sequencing from exon 4 to exon 9 where the most mutations of p53 are located. P53 mutation status was investigated in 31 Head and Neck Squamous cell carcinoma patients and 12 different HNSCC cell lines and these mutations were compared with those in the literature. Our results not only verified previously identified mutations, but also uncovered new mutations that may have functional and clinical importance. Consequently, newly discovered p53 mutations in HNSCC suggest new targets may be important in carcinogenesis, drug resistance and gene therapy.

3460T

Next-generation sequencing of paired drug-sensitive and resistant cell lines identifies spectrum of DNA changes associated with drug resistance. *P. Jia[1], H. Jin[2], C.B. Meador[2], J. Xia[1], K. Ohashi[2], L. Liu[3,4], V. Pirazzoli[5,6], K.B. Dahlman[7], K. Politi[5,6,8], F. Michor[3,4], Z. Zhao[1,7], W. Pao[2,7].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Departments of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Biostatistics and Computational Biology, Dana-Farber Cancer Institute, Boston, MA; 4) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 5) Department of Pathology, Yale University School of Medicine, New Haven, CT; 6) Yale Cancer Center, Yale University School of Medicine, New Haven, CT; 7) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN; 8) Department of Medicine, Yale University School of Medicine, New Haven, CT.

Somatic mutations in genes encoding kinases are associated with increased sensitivity of some solid tumors to kinase inhibitors, but patients with metastatic cancer eventually develop disease progression. So far, known resistance mechanisms have been identified such as the second-site mutation, *EGFR* T790M, amplification of the gene encoding an alternative kinase, *MET*, and epithelial-mesenchymal transition (EMT). However, the full spectrum of DNA changes associated with EGFR TKI acquired resistance remains unknown. Here, we used next-generation sequencing and bioinformatics analysis to characterize mutational profiles associated with 4 populations of *EGFR* mutant drug-sensitive cell lines and 5 matched drug-resistant cell lines. We developed a data analysis pipeline to detect SNVs, small insertions and deletions (indels), and CNV changes. By comparing resistant cells with their parental counterparts, we identified 16-89 coding SNVs/indels that were acquired and 1-27 that were lost; few SNVs/indels were shared across resistant lines. Comparison of two related parental lines revealed no unique coding SNVs/indels, suggesting that the changes in the resistant lines were due to drug selection. We further analyzed the genomic features of the SNVs identified through whole genome sequencing, and found that SNVs tend to occur more frequently in 'constant late' replication timing zones as compared to 'constant early' replication timing zones (chi-squared p-value $< 10^{-5}$). An enrichment of SNV frequencies was observed in genomic regions harboring lamina-associated domains compared to the remainder of the nucleus (chi-squared p-value $< 10^{-5}$). Surprisingly, we observed a higher burden of CNV changes across all resistant lines, and the one line that had an EMT phenotype displayed significantly higher levels of CNV changes than the other lines with acquired resistance. These results demonstrate a framework for studying the evolution of drug-related genetic variants over time and provide the first genome-wide spectrum of mutations associated with the development of cellular drug resistance in an oncogene-addicted cancer. Collectively, the data suggest that CNV changes may play a larger role than previously appreciated in the acquisition of drug resistance and highlight that resistance may be heterogeneous in the context of different tumor cell backgrounds.

Somatic Mutation Profiles of Non-Syndromic Early-Onset Colorectal Cancer. *N. Jinawath[1], T. Pongrujikorn[1], S. Ngernna[2], C. Songpattanasilp[1], J-S. Su[3], A. Jinawath[4], A. Tunteeratam[5], B. Suktitipat[6].* 1) Research Center, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 2) Department of Biology, Faculty of Science, Mahidol University, Bangkok, Thailand; 3) Illumina, Taiwan; 4) Department of Pathology, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 5) Department of Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 6) Department of Biochemistry, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Colorectal cancer (CRC) is the third most common cancer in the world and the fourth most common cause of cancer death worldwide. As a result of dietary westernization, the incidence rates of CRC in Asian countries such as Thailand, where rates were previously low, are rising. Less than 10% of CRC are diagnosed in patients younger than 50 years old. Among these, most cases have no known family history of cancer or genetic predisposition, and are considered to be sporadic despite the fact that high genetic burden is likely involved. Although the sequential genetic alterations underlying CRC have been extensively studied, the somatic changes of non-syndromic early-onset CRC have been largely unexplored. Using a set of Formalin-Fixed-Paraffin-Embedded (FFPE) samples from 119 Thai CRC patients, we have analyzed the differential somatic mutation profiles between the 63 early-onset non-syndromic CRCs (< 50 years) and 56 average-age-of-onset sporadic CRCs (> 50 years). Illumina's TruSeq Amplicon Cancer Panel which comprises of 212 amplicons containing somatic mutation hotspots from 48 known cancer-related genes were utilized in our study, and pooled amplicon sequencing was carried out on a MiSeq platform. Variants were called by Somatic Variant Caller, and filtered according to default settings with sequence coverage of at least 100X. Furthermore, immunohistochemical analyses of MLH1, MSH2, MSH6, and PMS2 expression to rule out Hereditary Nonpolyposis Colorectal Cancer (HNPCC), the most common inherited CRC syndrome, and to indirectly assess microsatellite instability (MSI) status were performed. Among the 119 CRCs, the commonly mutated genes *KRAS*, *BRAF*, and *TP53* were mutated in 44%, 40%, and 76%, respectively. Their mutation frequencies in Thai CRCs were in line with those previously reported. Single variant analyses did not identify any variant associated with early-onset CRC. However, using gene-based burden test for rare variants (MAF < 0.02), we identified 10 genes associated with early-onset CRC, namely *BRAF*, *PDGFRA*, *ATM*, *ABL1*, *EGFR*, *RB1*, *APC*, *KDR*, *GNAQ*, and *IDH1* ($p < 0.0002$ after Bonferroni correction). Our results indicate that the development of CRC in non-syndromic early-onset patients may have different underlying genetic alterations than those of average-age-of-onset patients.

Goetz[6,7]. 1) Department of Health Science Research, Mayo Clinic, Rochester, MN,55905 USA; 2) Cancer Research, Mayo Clinic, Florida 32224 USA; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester,MN 55905 USA; 4) Department of Radiology, Mayo Clinic, Rochester, MN 55905 USA; 5) 5Department of Surgery, Mayo Clinic, Rochester, MN 55905 USA; 6) Medical Oncology, Mayo Clinic, Rochester, MN 55905 USA; 7) Division of Clinical Pharmacology, Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN 55905 USA; 8) Center for Individualized Medicine, Mayo Clinic, Rochester, MN 55905 USA; 9) Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN 55905 USA.

Basal breast cancers (BBC) are typically negative for ER, PR and HER2. It is known that the underlying genomic alterations and drug response phenotypes in BBC are different compared to other breast cancer subtypes. There are no validated markers associated with paclitaxel response. We performed next generation sequencing to investigate biomarkers of paclitaxel drug response in women who enrolled in the prospective Breast Cancer Genome Guided Therapy (BEAUTY) neo-adjuvant clinical study. In this study, women undergo tumor biopsies for NGS at baseline, after 12 weeks of paclitaxel and following anthracyline-based chemotherapy. Subsets of women with BBC in which both sequencing data along with paclitaxel drug response as measured by MRI were considered in this study. From a cohort of 54 patients, we identified the extremes of phenotype response to paclitaxel in 12 patients with BBC, 5 with evidence for a complete response by MRI and 7 with stable disease (no tumor shrinkage). As expected, BBC showed a high frequency of somatic mutations. 11/12 patients have at least one or more somatic mutations in TP53, PTEN, RB1 and PIK3CA. Several TP53, BRCA1 and MYO3A germline mutations were also identified. In addition, we identified tumor amplification of MYC, PIK3CA, and MYO3A in 7/12 samples. We obtained basal gene expression data for these 12 patients and performed differential gene expression (DGE) analysis based upon these MRI response phenotypes. We identified 805 genes differentially expressed between two groups with a p-value < 0.05. Our analyses of 4 different pathway tools (cytoscape, IPA, SPIA, metacore) demonstrated that tight junction, Jak-STAT, ErbB, and Wnt signaling pathways are activated and maturity onset diabetes pathway is inhibited in stable group compared to the complete response patients. Significant pathways obtained from DGE analysis were integrated to build a basal transcriptomic landscape (T1) for paclitaxel response. Key nodes in T1 will be further investigated with a variety of genomic features such as splicing, expressed single nucleotide variants, fusion transcripts, and copy number alterations. For this same cohort of BBC, we have also obtained RNA-Seq data after paclitaxel treatment. Hence, we plan to compare and contrast the transcriptomic landscape (T1) with the genomic features obtained from second time point. Integration of such comprehensive OMICS data will help us identify novel molecular targets for BBC treatment.

3463T

Next Generation sequencing of osteosarcoma identifies the PI3K/mTOR pathway as a unifying vulnerability to be exploited for targeted therapy.
A. Kiezun[1], K. Janeway[2], P. Tonzi[2], J. Mora[3], S. Aguiar[5], G. Mercado[4], J. Melendez[4], L. Garraway[2], C. Rodriguez-Galindo[2], S. Orkin[2], T. Golub[1], G. Getz[1], JA. Yunes[5]. 1) Cancer Program, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 2) Dana Farber Cancer Institute, Boston, MA, USA; 3) Sant Joan de Déu Hospital, Barcelona, Spain; 4) Instituto Nacional de Medicina Genómica, Mexico City, Mexico; 5) Centro Infantil Boldrini, Sao Paulo, Brazil.

Background: Osteosarcoma is an aggressive bone cancer often presenting in childhood or adolescence. Due to the complexity of the osteosarcoma genome, identification of tractable therapeutic targets has been challenging and there have been no substantial therapeutic advances in osteosarcoma in over 2 decades. Methods: We examined 59 matched tumor/normal sample pairs from osteosarcoma patients by whole-genome sequencing (WGS; 12 cases), whole-exome sequencing (WES; 59 cases), and RNA-Sequencing (RNASeq; 35 cases). Statistical approaches were used to identify genes and pathways likely to be involved in oncogenesis. We applied a heuristic algorithm (PHIAL) to identify the spectrum of clinically actionable alterations in osteosarcoma. In addition, comparative oncology was employed by whole exome sequencing of 9 TN pairs from a murine model of osteosarcoma. Results: The average non-silent somatic nucleotide variant frequency was to 1/Mb. The MutSigCV algorithm, identified two genes mutated at significant frequency across the 59 samples (at q-value threshold of 0.1): *TP53* and *PRB2*. Additionally, *PTEN* had qvalue of 0.13. Analysis performed using the MutSig2.0 algorithm identified 37 pathways as being significantly ($q<0.1$) affected by mutations across the 59 samples. The 26 most significant pathways contained *TP53*. Of the remaining 11 significant pathways, 5 implicate the PI3K/AKT/mTOR signaling pathway. *PTEN* and *PIK3R1* were affected by somatic mutations in both mouse and human tumors, including a nonsense mutation in Pten in one mouse. Osteosarcoma cell lines treated with PI3K/mTOR inhibitors BEZ235 and PIK75 had decreased pAKT and pS6. IC50s of these inhibitors in osteosarcoma cell lines were 8 to 82nM. *TP53* germline mutations were present in 7 (12%) patients. Somatic rearrangements were extremely common with an average rate of 10/Mb and there was chromoplexy in 11/12 cases with WGS data. **Conclusions:** This study identifies the PI3K/mTOR pathway as a unifying vulnerability to be exploited for targeted therapy in osteosarcoma with supporting evidence from patient-derived samples and comparative oncology, genomic and functional approaches. These results support further study of dual PI3K/mTOR inhibition in osteosarcoma.

3464F

RNA-seq revealed alternative splicing and fusion transcripts in non-small cell lung cancer.
W. Kim, S. Park, M. Cheon. Kangwon National University, Chuncheon, South Korea.

Lung cancer is the most common cause of cancer related death. Alterations of sequence or structure of genes and their expression have important role in the pathogenesis of lung cancer. Fusion genes and alternative splicing of cancer-related genes can have the potential oncogenic activity. In the current study, we performed RNA-seq to investigate potential fusion genes and alternative splicing in non-small cell lung cancer. RNA was isolated from lung tissues obtained from 86 subjects with lung cancer. The RNA samples from lung cancer and normal tissues were processed with RNA-seq using the HiSeq 2000 system. Fusion genes were evaluated using deFuse and Chimerascan. Candidate fusion transcripts were validated by Sanger sequencing. Alternative splicing was analyzed using multivariate analysis of transcript sequencing (MATS) and validated using RT-PCR. From RNA-seq data of 86 paired samples, 3 known fusion genes were identified. Nine cnadidate fusion transcripts were selected using DeFuse or Chimerascan. Among them, 5 fusion genes including *HNRNPA2B1-SKAP2* were validated by Sanger sequencing. MATS revealed twenty-nine tumor specific skipped exon events and six mutually exclusive exon events. Among skipped exon variants, 8 were known splice variants and 21 were novel variants. *ITGB4* and *PYCR1* were top genes that showed significant tumor specific splice variant. In conclusion, novel potential fusion transcripts and splice variants were identified. Their functional significance in pathogenesis of lung cancer should be evaluated.

3465W

Exome sequencing of mammospheres and primary tumors indicates dynamic transitions between stem-like and differentiated states in breast cancer. *D. Klevebring[1,2], G. Rosin[3,4], R. Ma[4], J. Lindberg[1,2], K. Czene[1], J. Kere[2,3,5], I. Fredriksson[6,7], J. Bergh[4,8], J. Hartman[4,9].* 1) Department of Medical Epidemiology & Biostatistics, Karolinska Institutet, Stockholm, Stockholm, Sweden; 2) Science For Life Laboratory, Stockholm, Sweden; 3) Department of Biosciences and Nutrition, Center for Biotechnology, Karolinska Institutet, Stockholm, Sweden; 4) Department of Oncology-Pathology, Karolinska Institutet, Stockholm, Sweden; 5) Research Programs Unit, University of Helsinki, and Folkhälsan Institutet of Genetics, Helsinki, Finland; 6) Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 7) Department of Breast and Endocrine Surgery, Karolinska University Hospital, Stockholm, Sweden; 8) Radiumhemmet - Karolinska Oncology, Karolinska University Hospital, Stockholm Sweden; 9) Department of Clinical Pathology, Karolinska University Hospital, Stockholm, Sweden.

Breast cancer stem-like cells (CSCs) are a slow-proliferating although highly tumorigenic subpopulation of cells defined by expression of embryonic stem cell markers and tumor- initiating capacity. Although a minority in tumors, CSCs have been shown to resist chemotherapy, and are consequently considered as a cause of therapy resistance and late tumor relapse. In order to understand the origin of CSCs, we performed exome sequencing of CSCs from ten breast cancer patients, along with paired primary tumor samples. Our analysis revealed that the majority of somatic mutations are shared between CSCs and bulk primary tumor. Furthermore, we show that the allele frequencies of these shared mutations do not differ significantly between the two components. The results indicate that CSCs are a population of cells that can dynamically switch from differentiated tumor cells, and vice versa. This finding increases our understanding of the central role of CSCs in tumor heterogeneity and the importance to identify drugs to counter dedifferentiation rather than targeting CSCs.

3466T

Genomic alterations during disease evolution in CML patients displaying an isochromosome 17q. *N. Larsson[1], H. Liljebjorn[1], M. Rissler[1], C. Högberg[1], J. Richter[2], t. Fioretos[1].* 1) Clinical Genetics, Lund University, Lund, Sweden; 2) Department of Hematology, Lund University Hospital, Lund, Sweden.

Chronic myeloid leukemia (CML) is a clonal disease of hematopoietic stem cell that is characterized by a t(9;22) (q34;q11), also known as the Philadelphia chromosome. The translocation gives rise to the BCR/ABL1 fusion gene that encodes a constitutionally active tyrosine kinase. However, further genetic changes are needed for CML to progress from chronic phase to the more advanced disease stages; accelerated phase and/or blast crises. Isochromosome for the long arm of chromosome 17, i(17q), is one of the most common cytogenetic abnormalities detected at the disease progression of CML, but the changes at the molecular level still remain elusive. We have analyzed the clinical features and mutation patterns in three CML patients that acquired an i(17)(q10) during disease progression. Samples representing different stages of CML were subjected to SNP-array analysis and exome sequencing. Mutations in genes involved in DNA repair, cell cycle control and epigenetic modification such as *TP53, ASXL1* and *EZH2* were detected, but no recurrent mutations were identified. In one case, a *TP53* mutation was detected before the occurrence of i(17q), suggesting that the loss of 17p-material partly served to unmask the effect of the *TP53* mutation. However, no *TP53* or other mutations on chromosome 17 were detected in the other two patients, suggesting that i(17q)-formation leads to disease progression by causing dosage imbalances of several genes encoded by chromosome 17 rather than via specific gene mutations.

3467F

Whole exome sequencing identifies different sets of gene mutations in various subtypes of early-onset breast cancers. *C.Y. Lee[1], W.H. Kuo[2], C.H. Lin[3], Y.S. Lu[3], H.I. Yang[1,4], K.Y. Lo[1], C.K. Liu[5], C.H. Chang[6], C.N. Hsiung[5], N. Leng[7], K. Nobuta[7], C.D. Haudenschild[7], C.H. Chen[5], J.Y. Wu[5], K.P. Chiu[1], A.L. Cheng[3], K.J. Chang[2,8], C.Y. Shen[5,9], C.J. Chen[1].* 1) Genomics Research Center, Academia Sinica, Taipei, Taiwan; 2) Department of Surgery, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Oncology, National Taiwan University Hospital, Taipei, Taiwan; 4) Molecular and Genomic Epidemiology Research Center, China Medical University Hospital, Taichung, Taiwan; 5) Institute of BioMedical Sciences, Academia Sinica, Taipei, Taiwan; 6) Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan; 7) Illumina Inc., Hayward, CA, USA; 8) Department of Surgery, Cheng Ching General Hospital, Taichung, Taiwan; 9) School of Public Health, China Medical University Hospital, Taichung, Taiwan.

Breast cancers in young women manifest differently from those diagnosed at later ages. They are typically aggressive and most patients are candidates for adjuvant therapy. Knowledge of genomic changes is therefore valuable for optimizing treatment strategy. This study identified single nucleotide variations (SNVs) using whole-exome sequencing to provide a comprehensive view of genetic alterations in these patients. Somatic and germline SNVs were investigated in 81 patients diagnosed at 40-years-old or younger. Based on the expression of estrogen receptor (ER), progesterone receptor (PR), human epidermal growth factor receptor 2 (HER2), and Ki67, tumors were classified into five subtypes: luminal A (ER- and/or PR-positive, HER2-negative, Ki67 <14%, 34 cases), luminal B-HER2-negative (ER- and/or PR-positive, HER2-negative, Ki67 >=14%, 13 cases), luminal B-HER2-positive (ER- and/or PR-positive, HER2-positive, any Ki67, 14 cases), HER2-positive-non-luminal (ER- and PR-negative, HER2-positive, 9 cases), and triple-negative (ER- and PR-negative, HER2-negative, 11 cases). To define which SNVs were functional or related to functional changes, we only included non-synonymous/synonymous changes in regions evolutionally conserved across 44 species. To focus on mutation and not polymorphism, any genetic changes reported in the 1000 Genomes Project and dbSNP were excluded. Nine hundred and thirty-six (877 somatic and 59 germline) SNVs were detected. In the highest-mutation-frequency genes, only PIK3CA and TP53 have been previously reported. All triple-negative and five non-triple-negative patients had a high-mutation-frequency phenotype involving mutations in genes maintaining genomic stability. In the remaining non-triple-negative patients, 32.4% harbored mutation in the PI3K pathway-related genes, but almost all of these (tyrosine kinase receptor genes, G protein-coupled receptor genes and PIK3CA) play an upstream role in the pathway. Mutated genes involved in diverse and unrelated tumorigenic mechanisms were identified in cancers of the same subtype, and tumors of different subtypes were found to harbor genes in the same functional pathways. These findings not only reveal the complexity of the etiology, but also provide valuable clues for developing therapeutic targets and predictive biomarker for early-onset breast cancer.

3468W

Exome sequencing of cell-free plasma DNA in prostate cancer patients. *J. Lindberg[1], M. Neiman[1], D. Klevebring[1], P. Wiklund[2], L. Egevad[3], H. Grönberg[1].* 1) MEB, Karolinska Institutet, Stockholm, Sweden; 2) Department of Urology, Karolinska Hospital, Stockholm, Sweden; 3) Department of Pathology and Cytology, Karolinska Hospital, Stockholm, Sweden.

Circulating nucleic acids have previously been detected in serum and plasma of both healthy and diseased individuals. In cancer patients, somatic events, such as translocations and point mutations can be identified in the circulation. The main bulk of circulating tumor DNA (ctDNA) are short (<300 bp) and have been proposed to be of apoptotic origin. Various methods have been used to track ctDNA. The detection of structural rearrangements is highly specific, which allows for the detection of single copy cancer genomes in milliliters of plasma. Sequencing, based on amplification, of a selected set of point mutations has demonstrated robust detection of ctDNA down to 0.02%. Therefore, whole-genome sequencing and exome sequencing, by using all point mutations in a tumor collectively to increase signal, has the potential to allow for effective monitoring of systemic tumor load. Since whole-genome sequencing remains ten times as expensive relative whole-exome sequencing, it is still not applicable in large patient cohorts where serial plasma samples are available over time. Here we report on a careful technical evaluation of various approaches to perform whole-exome sequencing performed directly on cell-free DNA. Also, the chosen methodology was applied on paired primary tumor material and plasma from ten prostate cancer patients to estimate the proportion of ctDNA.

3469T

Mutational enrichment of cancer-related gene sets in 11 aggressive prostate cancers. *K.J. Lindquist[1], R. Kazma[1], TJ. Hoffmann[1], BA. Rybicki[2], A. Levin[2], PL. Paris[1], JS. Witte[1].* 1) UCSF, San Francisco, CA; 2) Henry Ford Health System, Detroit, MI.

Prostate cancer is a leading cause of cancer mortality. Many prostate tumors are benign, but some are aggressive and lethal. The mutation profile of aggressive prostate tumors may differ from that of other tumors. To investigate whether somatic mutations in aggressive prostate tumors are more frequent in gene sets previously identified as functionally involved in benign prostate and other cancers, we sequenced the tumor and matched normal tissues of 11 aggressive prostate cancer patients using Complete Genomics' platform. After removing low-confidence calls, we selected mutations within any gene or gene regulatory region (using data from the Encyclopedia of DNA Elements) in the human genome. Then, we determined if 22 gene sets were associated with mutation rates using a mixed-effects Poisson regression model. The gene sets included 18 cancer-related pathways from the Kyoto Encyclopedia of Genes and Genomes (KEGG), 2 differential expression indicators from the Prostate Expression Database, and 2 indicators of cancer drug sensitivity or resistance from the Genomics of Drug Sensitivity in Cancer database. Membership in the KEGG prostate cancer pathway was independently associated with higher mutation rates in our samples ($p=0.024$), but stronger predictors of high mutation rates were the KEGG transcriptional misregulation pathway ($p<0.001$), differential expression in response to androgen ($p=0.001$), and two other KEGG cancer pathways (non-small cell lung and endometrial cancers, $p=0.001$ for both). Our work paves the way for future studies to link the mutational enrichment of cancer-related gene sets with the aggressiveness of prostate cancers.

3470F

Retrospective analysis of genomic and transcriptional changes in a case of Ewing's sarcoma tumor progression determined by whole transcriptome and exome semiconductor-based sequencing. *G. Reynolds[6], T. Triche[7].* 1) Life Technologies, South San Francisco, CA; 2) Life Technologies, Austin, TX; 3) Life Technologies, Carlsbad, CA; 4) St. Laurent Institute, Providence, RI; 5) Keck School of Medicine of USC, Los Angeles, CA; 6) Texas Tech University Health Sciences Center, Lubbock, TX; 7) The Saban Research Institute Childrens Hospital Los Angeles, Los Angeles, CA.

Ewing's sarcoma is a pediatric cancer that often presents in the second decade of life and is usually associated with a chromosomal translocation t(11;22)(q24;q12) that results in a EWS/FLI1 gene fusion. Long term survival rates for patients with metastases can be less than 10%. Four independent cell-lines have been established from a patient who succumbed to metastatic disease following relapse after myeloablative chemotherapy. Whole-transcriptome and exome sequencing of normal primary bone marrow-derived stromal fibroblasts (cell-line COG-FB-425), Epstein-Barr Virus (EBV) transformed normal lymphoblasts (cell-line COG-V-455), a pre-therapy primary tumor-derived cell-line (CHLA-9), and a post-chemotherapy metastatic tumor-derived cell-line (CHLA-10), was conducted on an Ion Torrent Proton™ system to profile the differences in gene expression and differences in exonic DNA sequence to characterize the molecular changes associated with primary tumorigenesis and disease persistence after treatment. All cell lines matched by short-tandem repeat analysis. The presence of the EWS/FLI1 fusion gene in the tumor cells was confirmed and the breakpoint determined from both observation of chimeric reads in the RNA-seq data and exome sequence analysis. Exome datasets, collected to >140X average depth of coverage, indicate apparent loss of heterozygosity genome-wide in CHLA10 consistent with cytogenetic analysis that shows tetraploidy in this cell-line. Results from RNA-seq also indicate numerous instances, genome-wide, of differing transcript isoform expression and exon usage between normal, primary tumor, and metastatic tumor cells suggesting an increasing genomic mutational burden in the evolution of the disease, and pointing in particular toward aberrant regulation of RNA-splicing components. One co-expressed, first exon-sharing pair of sense/antisense transcripts corresponding to the gene FEZF1 and transcript FEZF1-AS1 that is unique to the tumor lineage is the subject of further investigation. Taken together, the combination of RNA-seq and exome-sequencing on normal cells and primary vs. post-chemotherapy tumor is providing a broad and deep view of molecular signatures in tumor progression and indicating that a significant role is played by changes in non-coding RNA expression.

Immunohistochemical analysis of uterine leiomyomas, histopathological uterine leiomyoma subtypes, and uterine leiomyosarcomas. *N. Mäkinen[1], K. Kämpjärvi[1], R. Bützow[2], P. Vahteristo[1].* 1) Department of Medical Genetics, Genome-Scale Biology Research Program, University of Helsinki, Helsinki, Finland; 2) Department of Pathology, The Laboratory of Helsinki University Central Hospital (HUSLAB), Helsinki University Central Hospital and Haartman Institute, University of Helsinki, Helsinki, Finland.

Uterine leiomyomas (ULMs) are benign tumors that arise from smooth muscle cells of the myometrium. Regardless of their benign nature, leiomyomas can cause difficult symptoms, such as excessive bleeding, abdominal pain and discomfort, pregnancy complications, and infertility. Based on histopathology, ULMs can be divided, in addition to common leiomyomas, into various relatively rare subtypes that mimic malignancy in one or more aspects. Cellular, atypical, and mitotically active leiomyomas are examples of these subtypes. Rarely, ULMs may undergo malignant transformation and develop into a leiomyosarcoma. We have previously shown by exome sequencing that MED12 exon 2 is mutated in approximately 70% of ULMs. All the mutations affect an evolutionary conserved region of the MED12 protein. Our subsequent studies have revealed that mitotically active leiomyomas display a MED12 mutation frequency that is not statistically different from common leiomyomas, whereas the rest of the histopathological ULM variants and uterine leiomyosarcomas harbor significantly less MED12 exon 2 mutations than common leiomyomas. The aim of this study is firstly to examine the frequency and respective proportions of known mutations of ULMs, such as mutations in FH and HMGA2, and secondly to scrutinize the possibility that one of the histopathological ULM subtypes would undergo malignant transformation and develop into a leiomyosarcoma by immunohistochemistry. The study material consists of 199 formalin-fixed paraffin-embedded samples including 66 common leiomyomas, 103 histopathological ULM variants (cellular, atypical, and mitotically active leiomyomas), and 30 uterine leiomyosarcomas. We are constructing tissue microarrays of these different sample groups for immunohistochemical stainings. Antibodies for proteins, such as Ki67 and HIF1α, are utilized to analyze the similarities and differences between the histopathological variants and uterine leiomyosarcomas. It is clinically relevant to recognize possible tumor subtypes with different molecular genetic background to provide better tools for more accurate diagnosis and drug development. It is also important to understand the mechanisms behind the progression to malignancy, because uterine leiomyosarcomas are usually diagnosed as late as in the surgery.

3472T

LOH Analysis of the ING 3 and 5 genes in Breast Cancer. *G. NAS[1], E. GUNDUZ[1], M. ACAR[1], E. UCTEPE[1], M. BOZER[3], C. DENER[3], S. YENIDUNYA[4], M. GUNDUZ[1,2].* 1) TURGUT OZAL UNIVERSITY MEDICAL FACULTY, ANKARA, Turkey; 2) DEPARTMENT OF OTOLARYNGOLOGY HEAD AND NECK SURGERY, TURGUT OZAL UNIVERSTY MEDICAL FACULTY, ANKARA, Turkey; 3) DEPARTMENT OF GENERAL SURGERY, TURGUT OZAL UNIVERSTY MEDICAL FACULTY, ANKARA, Turkey; 4) DEPARTMENT OF PATHOLOGY, TURGUT OZAL UNIVERSTY MEDICAL FACULTY, ANKARA, Turkey.

The tumor suppressor genes (TSG) ING3 and ING5, the members of inhibitor of growth gene family, are effective in inhibition of cell growth and induction of apoptosis to eliminate cancerous cells. However, in many cancer types, one of the alleles of a TSG is lost through carcinogenesis, while the rest allele is usually inactivated through a process called as loss of heterozygosity (LOH). Previous studies in head and neck cancer revealed that allelic loss and reduced expression is a common pattern of ING gene family members but our study showed that despite the high proportion of LOH in HNSCC, allelic loss of ING3 and ING5 does not commonly occur in breast cancer. 50 paraffin embedded breast cancer tissues were analyzed and the allelic deletion frequency of ING3 and ING5 gene were detected as 12% and 16% respectively. We used to Kaplan-Meier survival analysis to evaluate overall(OA) and disease-free survivals (DFS) in the groups of breast cancer patients with LOH negative and LOH positive ING genes. Both ING 3 and ING 5 LOH status have no significantly difference in OA and DFS of breast cancer patients. These results provide a rational explanation and relative contribution for complexity of tumor formation that allelic loss of ING3 and ING5 gene are not major factors for breast cancer but a part of big complex mechanism.

3473F

Characterization of molecular alterations in urologic cancers. *M.L. Nickerson[1], K.M. Im[1], S. Turan[1], T. Andresson[2], L.E. Moore[3], M. Dean[1].* 1) Cancer & Inflammation Program, National Cancer Institute, Frederick, MD; 2) Laboratory of Proteomics and Analytical Technologies, Advanced Technology Program, SAIC-Frederick, National Cancer Institute, National Institutes of Health, Frederick, MD; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD.

Metastatic cancer is the primary cause of death among patients with urologic and other cancers. Metastatic prostate cancer (mPC) alone is responsible for over 258,000 deaths worldwide each year and is poorly controlled using existing therapies. The molecular chronology from primary to metastatic disease is not known in sufficient detail and detailed molecular markers that differentiate indolent from aggressive subtypes of cancer are needed. We employed exome and targeted sequencing strategies to examine mutated genes in prostate, bladder, and kidney cancers. We present detailed analysis of an index patient with metastatic, castration-resistant prostate cancer where we sequenced the exomes of five metastatic tumors and non-cancer kidney tissue. We observed sequential acquisition of somatic alterations in the primary tumor, including a deletion associated with formation of a TMPRSS2-ERG fusion transcript and a missense alteration in the acetylated lysine binding pocket of a bromodomain in polybromo 1. The majority of somatic alterations, including an alteration of the CpG demethylase, TET2, were not observed in the primary tumor but were observed in all metastatic tumors, indicating mutations likely contributing to metastatic disease may not be detected by analysis of primary tumor tissue. Alterations observed in individual metastatic tumors allowed us to anatomically map the spread of disease. We show TET2 is altered in additional mPC tumors and identify signaling pathways likely affected by TET2 loss. This data is used to discuss observations in urologic cancers that indicate common features of these cancers. We show combinations of rare germline and somatic alterations, and combinations of sequence alterations and loss of heterozygosity differentially target individual cancer genes. Sequential accrual of somatic alterations during disease progression represents a challenge to identify therapies targeting individual cancer genes.

Exome sequencing identifies putative drivers of progression of transient myeloproliferative disorder to AMKL in infants with Down Syndrome. *S.I. Nikolaev[1], F. Santoni[1], A. Vannier[1], E. Falconnet[1], E. Giarin[2], G. Basso[2], A. Hoischen[3], J.A. Veltman[3], J. Groet[4], D. Nizetic[4], S.E. Antonarakis[1].* 1) GeDev, University of geneva, geneva, geneva, Switzerland; 2) Department of Pediatrics, University of Padua, Padua, Italy; 3) Department of Human Genetics, Nijmegen Center for Molecular Life Sciences, Institute for Genetic and Metabolic Disease, Radboud University Medical Center, Nijmegen, Netherlands; 4) Queen Mary University of London, Blizard Institute of Cell and Molecular Science, Barts and The London School of Medicine, London, United Kingdom.

Some neonates with Down Syndrome are diagnosed with self-regressing TMD and 20-30% of those progress to AMKL. To elucidate the molecular mechanisms of these neoplasias we have performed exome sequencing in 7 cases and copy number analysis in these and 10 additional cases. All TMD/AMKL samples contained GATA1 mutations. None of 7 exome-sequenced TMD/AMKL samples had any other recurrently mutated genes. However 2 of 5 TMD cases, and all sequenced AMKL cases, showed mutations/deletions other than GATA1, in genes proven as transformation-drivers in non-DS leukaemia (EZH2, APC, FLT3, JAK1, PARK2-PACRG, EXT1, DLEC1 and SMC3). One patient at the TMD stage revealed two clonal expansions with different GATA1 mutations, of which one clone had an additional driver-mutation. Interestingly, it was the other clone (with just a GATA1-mutation) that gave rise to AMKL after accumulating mutations in 7 other genes. Our data suggest that GATA1-mutations alone are sufficient for clonal expansions, and additional driver mutations at the neonatal TMD stage do not necessarily predict AMKL progression. Later in infancy, leukaemic progression requires 'third-hit-driver' mutations/SCNAs found in non-DS leukaemias. Putative driver-mutations affecting WNT, JAK-STAT or MAPK/PI3K pathways were found in all cases, aberrant activation of which converges on overexpression of MYC. Thus the study of DS-AMKL established the 'three-hit' hypothesis for this neoplasia: trisomy 21, GATA1 and variable third driver on the MYC pathway.

3475T

Characterization of somatic alterations in the novel tumor suppressor DEAR1 using ultra-deep targeted next generation sequencing. *J. Reuther[1,2], N. Chen[2], A. Sahin[3], S. Lott[4], A. Killary[1,2].* 1) Human and Molecular Genetics Program, University of Texas Graduate School for Biomedical Science, Houston, TX; 2) Genetics, MD Anderson Cancer Center, Houston, TX; 3) Pathology, MD Anderson Cancer Center, Houston, TX; 4) Clinical Implementation, Life Technologies, Carlsbad, CA.

Ductal Carcinoma In Situ (DCIS) accounts for 12-24% of all diagnosed breast cancers and is one of the earliest pre-invasive forms of breast cancer. Without treatment, DCIS can progress to invasive disease with recorded frequencies from 14-60%. There is an urgent need to identify prognostic markers for women with a heightened risk of progression from DCIS to invasive breast cancer (IBC) for which more aggressive surveillance and treatment might be warranted, as well as individuals with favorable prognosis, who might be spared rigorous therapeutic regimens and for whom breast conservation therapy might be the preferred surgical option. We previously identified the novel tumor suppressor Ductal Epithelium Associated Ring Chromosome 1 (DEAR1) as a gene, located at 1p35.1, the expression of which is downregulated or lost at the DCIS stage. Our previous work has also shown that loss of expression of DEAR1 by immunohistochemistry significantly predicted local recurrence in early onset breast cancer. Our sequencing efforts, in addition to analyses of the TCGA cohorts, have identified over 30 non-synonomous mutations in DEAR1 in a variety of epithelial cancers including breast, pancreatic and colon cancer, many of which undergo copy number losses within chromosome 1p35. In order to better understand DEAR1's role in cancer and specifically, its potential role in the progression of DCIS lesions to IBC, our lab is currently undergoing efforts to determine if DEAR1 undergoes mutation in DCIS utilizing the Ion Torrent PGM platform. We are performing targeted ultra-deep sequencing of a 52kb locus containing DEAR1 in both pure DCIS samples and DCIS with associated invasive components, as well as IBC lesions in order to determine the earliest stage in breast cancer in which mutations in DEAR1 can be observed and whether mutations correlate with DCIS that progress to IBC. Targeted deep sequencing has yielded a mean depth of coverage of 9,000x, allowing us to identify both common as well as rare variants. Preliminary results indicate that DEAR1 is mutated at the earliest stage of breast cancer and include the identification of novel variants in DCIS as well as missense mutations that have been found previously in IBC. To our knowledge, only few other genes are known to be mutated in DCIS, which suggests the importance of the characterization of this novel tumor suppressor and the determination of its role as a tumor suppressor in breast cancer.

3476F

Individualized analysis of somatic mutations and CNV from exomes obtained from breast cancer core needle biopsies in women with newly diagnosed locally advanced breast cancer. *H. Sicotte[1], S. Hart[1], J.P. Sinwell[1], S. Baheti[1], P.T. Vedell[1], K.R. Kalari[1], X. Tang[1], K.J. Thompson[1], D.W. Mahoney[1], P. Barman[1], J.M. Evans[1], C. Wang[1], Y.W. Asmann[2], J.P.A. Kocher[1], T.J. Dockter[1], K.N. Jones[3], A.L. Conners[3], A.M. Moyer[3], D.W. Visscher[3], V.J. Suman[1], J. Eckel Passow[1], R. Weinshilboum[1], L. Wang[1], J.C. Boughey[4], M.P. Goetz[5].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Health Sciences Research, Mayo Clinic, Jacksonville, FL; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 4) Department of Surgery, Mayo Clinic, Rochester, MN; 5) Department of Oncology, Mayo Clinic, Rochester, MN.

Introduction: Individualization of cancer therapies based on tumor sequence data is increasing and guidance is needed on what platforms should be used to detect actionable genomic variations or alterations. In the Breast Cancer Genome Guided Therapy Study (BEAUTY), women with locally advanced breast cancer undergo core needle breast tumor biopsies to study genome variations prior to initiating neoadjuvant chemotherapy. Those biopsies are profiled using exome sequencing (tumor and germline) and RNASeq.We will present our methods of analyzing the exome for mutations and somatic copy number variations as well as some cross-platform comparisons. Exome sequencing is rapidly becoming the platform of choice for tumor sequencing because it affords much higher coverage of actionable variants (in coding region and around splice sites of genes) and is cheaper than whole genome sequencing, but it suffers from the lack of accurate tools for calling somatic CNV.

Results: We have developed a somatic CNV calling tool based on the pattern CNV method (submitted), which uses reference samples to learn the pattern and variance of the exome sequencing coverage to better enable somatic CNV calling. This tool is able to detect with high sensitivity EGFR amplifications (FISH validated) in low clonality tumors from core needle biopsies. We will also present the comparison of the efficiency of CNV detection with changes detected using RNASeq. Somatic variant calling in exomes, and in particular low tumor purity samples, is a challenging problem. We are calling somatic variants using multiple somatic calling tools:, Joint SNVMix2, SomaticSnipper, Mutect, and GATK Somatic indel detector. These tools call sets of variants with very little overlap. We will present our protocol for integrating multiple callers as well as for our tiering system for judging the technical validity, functional significance, and clinical significance of variants.

3477W

Subclonal evolution and genomic drivers of relapse in childhood acute lymphoblastic leukemia. *JF. Spinella[1], R. Vidal[1], J. Healy[1], V. Saillour[1], C. Richer[1], P. Cassart[1], M. Ouimet[1], S. Busche[2], B. Ge[3], T. Pastinen[2,3], D. Sinnett[1,4].* 1) Sainte-Justine UHC Research Center, University of Montreal, Montreal, Qc, Canada; 2) Department of Human Genetics, McGill University, Montreal, QC, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 4) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Qc, Canada.

Precursor B-cell acute lymphoblastic leukemia (pre-B ALL) is the most frequent pediatric cancer. Increased understanding of the pathobiology of this disease has led to risk-targeted treatment regimens and increased survival rates. However, close to 20% of patients still do not respond to current treatment protocols. Refractory ALL is the leading cause of death by disease among children. Genetic intratumoral heterogeneity is one of the major mechanisms leading to treatment resistance; whereby clonal evolution and interclonal competition give rise to the accumulation and maintenance of subclonal mutations with a relapse driving potential. However, the clinical significance of these relapse driver mutations and their underlying impact on childhood ALL outcome remain elusive. We are using high throughput sequencing technology to better understand the genomic landscape of primary and relapsed childhood ALL. Using a unique experimental design that consists of ten matched tumor (at diagnosis), normal (remission) and relapse samples, we performed whole exome and whole genome sequencing, as well as genome-wide genotyping, to identify copy number aberrations (CNAs) and somatic single nucleotide variants (SNVs) potentially driving primary leukemic transformation and relapse. We found gain of function mutations in the RAS-MAPK signaling pathway, as well as SNVs in the HAT domain of CREBBP that were associated with both ALL onset and relapse. SNV clustering analysis will allow us to describe clonal evolution and analyze the dynamics of interclonal competition within individual ALL tumors. Ultimately, this work will provide invaluable insight of the genetic mechanisms underlying pediatric ALL which could lead to the development of powerful clinical tools to improve detection, diagnosis and treatment of this childhood cancer.

3478T

Ultra-high quality sequencing assay for comprehensive genetic panel analysis of rare tumor-derived circulating cell-free DNA. *A. Talasaz, D. Sebisanovic, G. Mei, L. Siew, H. Eltoukhy.* Guardant Health, 2686 Middlefield Rd, Suite D, Redwood city, CA.

Background: Current approaches based on invasive biopsy genetic analysis can fail to capture an accurate picture of the real-time tumor genetic profile due to high tumor heterogeneity and cannot be in practice for serial monitoring of disease progression or acquired resistance. Analysis of circulating tumor nucleic acids (ctDNA), on the other hand, presents a new tool for the monitoring and treatment of cancer. However, due to high-quality false positives in current NGS assays, the majority of studies on ctDNA have been limited to hotspot analyses, amplicon sequencing approaches and typically only involve patients where ctDNA fractions are high (>1-5%). **Methods:** We have developed a differentiated sequencing assay, Digital Sequencing Technology (DST) that enables ultra-sensitive and ultra-specific detection of rare genomic abnormalities. Standard NGS workflows are plagued by extremely high noise and distortion in sample-prep and sequencing. DST is able to eliminate the error and distortion created by these processes and produce near-perfect representations of all rare variants. Moreover, our DST workflow enables the vast majority of DNA molecules (even in <10ng input samples) to be converted to sequencing libraries, enabling ultra-sensitive detection. **Results:** We first compared the sensitivity and specificity of conventional Illumina SBS sequencing versus DST. We have shown that in sequencing a comprehensive cancer panel of 70kbp in 0.1% cancer cell line titration samples, standard Illumina SBS generates many high-quality false positive variant calls in the range of 0.05-5% (even with a rigorous methodology of overlapped paired-end read bases with Qscore>30 filtering) while DST resulted in highly sensitive and completely error-free variant calls across the entire panel. We then applied DST to rare tumor-derived cell-free DNA on more than 25 cancer patient plasma samples across different cancer types. We investigated the concordance of tumor mutation profiles derived from ctDNA with those derived from matched tumor biopsies. We found higher than 90% concordance between tumor and ctDNA somatic mutation profiles in colorectal, breast, esophagus and melanoma cancers across all patients studied and multiple stages (II-IV). **Conclusion:** This work indicates the potential of using DST in deep analysis of ctDNA, thereby allowing researchers and clinicians to comprehensively and non-invasively monitor the genetic dimension of cancer throughout the body.

3479F

Next-generation sequencing of BRCA1 and BRCA2 in Bulgarian breast cancer patients and controls. *D.I. Toncheva[1,3], L. Balabanski[1], G. Antov[2], I. Dimova[3], S. Ivanov[1], M. Nacheva[4], I. Gavrilov[4], D. Nesheva[3], B. Rukova[3], S. Hadzhidekova[3], M. Malinov[1].* 1) Medical Genetics, Medical University-Sofia, Sofia, Sofia, Bulgaria; 2) nstitute of Genetics, Bulgarian Academy of Sciences, "Acad. Doncho Kostov". Sofia-1113; 3) Department of Medical Genetics, Medical University of Sofia, Zdrave str. 2, 1431 Sofia, Bulgaria; 4) Specialized Hospital for Active Treatment in Oncology, Sofia, "Plovdivsko Pole" str. 6, Bulgaria.

Breast cancer is the most common type of cancer in women. Most of its hereditary forms are caused by mutations in the BRCA1 and BRCA2 genes whose main function is DNA repair of the double-stranded ruptures. Genetic testing of women with family history is therefore recommended to determine whether they have hereditary predisposition for this type of cancer. The variants with no clear clinical significance are problematic to make a diagnosis when performing target re-sequencing. After taking the informed consent, DNA samples from 24 patients (average age of 35 ±10) diagnosed with breast cancer and having family history and 71 age matched not affected women were collected. Sequence-targeted BRCA1 and BRCA2 libraries were then prepared using the TruSeq Custom Amplicon method, and these were then sequenced on Illumina MiSeq system. A wide range of variants was found in BRCA1 and BRCA2 genes. In patients' group were found two pathological/presumably pathological variants: mutation in BRCA2 at position chr13:32890665 that affect the first position of the 5' splice region following exon 2 and mutation in BRCA1 at position chr17:41219635 - in-frame triple nucleotide deletion of Valine 1688 (8,3%). In the both groups (patients/control) we have detected 7 likely polymorphic variants and 13 common variants in BRCA1 and BRCA2 genes. For the first time 3 common polymorphisms in BRCA2, characteristic only for Bulgarian population, were detected: chr13:32973737, T/-, SNP within 3'-UTR of exon 27; chr13:32973280, A/-, mononucleotide deletion within 5'-UTR of exon 27; and chr13:32973924, T/-, mononucleotide deletion, downstream of gene sequence. This is the first next generation targeted sequencing of BRCA1 and BRCA2 genes in Bulgarian population, and it paves the way for finding local founder mutations as well as variants typical for this region.

3480W

Recurrent Somatic Mutations in Loss of Heterozygosity Regions of Hepatocellular Carcinoma. *S. Tsai, Y. Lin.* Molecular and Genomic Medicine, Nat. Health Research Institutes, Zhunan, Miaoli, Taiwan.

BACKGROUND Hepatocellular carcinoma (HCC), the most common liver malignancy, is characterized by frequent loss of heterozygosity (LOH) at multiple chromosomal locations. Genetic alterations in these LOH regions have not been systematically examined. METHODS We investigated 58 target genes in the LOH regions by using Agilent SureSelect enrichment technology in 12 HCC paired samples. Eight candidate genes identified by capture sequencing were further examined by TruSeq custom amplicon sequencing technology to uncover mutation hotspots in 95 HCC tumors. DNA mass spectrometry was used to validate the findings in independent cohorts. RESULTS Initially we discovered 15 nonsynonymous mutations in 7 genes (CSMD1, DOCK5, KCNH1, HHAT, PCCA, RYR2 and ZNF423) by capture sequencing. Then 113 variants were identified by amplicon sequencing, including 5 nonsense mutations. Among them, only 11 were reported in the dbSNP137. Eight missense mutations in 4 genes (CSMD1, DOCK5, PCCA, and PCDH7) and one nonsense mutation in RYR2 gene occurred in at least two patients. CSMD1 is a known tumor suppressor gene and 9/95 HCCs contained a CSMD1 mutation at sites that are critical for protein-protein interactions. Furthermore, a single mutation in PCCA gene encoding propionyl CoA carboxylase occurred in 8/95 HCCs. CONCLUSIONS Focused investigation of selected genes in the LOH regions revealed frequent and recurrent somatic mutations. Genetic alterations discovered by this approach can be used to identify distinct HCC subtypes for developing patient-specific management.

Importance of genetic analysis in the prediction of retinoblastoma in South Indian patients. *A. Vanniarajan[1], G. Namrata[2], K. Usha[2], RS. Akram[1], K. Thirumalairaj[1], I. Jeyaram[3], R. Santhi[4], R. Kim[5], VR. Muthukkaruppan[6].* 1) Department of Molecular Genetics, Aravind Medical Research Foundation, Madurai, Tamil Nadu, India; 2) Department of Orbit, Oculoplasty and Oncology, Aravind Eye Hospital, Madurai, Tamil Nadu, India; 3) Statistics Division, Lions Aravind Institute of Community Ophthalmology, Madurai, Tamil Nadu, India; 4) Department of Pathology, Aravind Eye Hospital, Madurai, Tamil Nadu, India; 5) Retina Clinic, Aravind Eye Hospital, Madurai, Tamil Nadu, India; 6) Department of Immunology and Stem Cells Biology, Aravind Medical research Foundation, Madurai, Tamil Nadu, India.

Purpose: India has the highest incidence of retinoblastoma (RB) among the developing countries. Genetic analysis was performed in south Indian RB patients to understand the mutation pattern of RB1 gene in order to predict the risk of RB in siblings and offspring. Methods: The study population included 73 patients of RB who attended Orbit, Oculoplasty and Oncology Department of Aravind Eye Hospital during January to October 2012. A semi log plot was derived to understand the significance of age at diagnosis of RB. Quantitative Multiplex PCR and Exonic sequencing were carried out in tumor samples, wherever available and blood samples of patients and their families. Results: Out of 73 patients, 31 had bilateral and 42 had unilateral RB. Pedigree showed positive family history in 14 patients (19%) that include 12 bilateral and 2 unilateral RB. Bilateral RB occurred much earlier (9.82 ±11.52 months) than unilateral RB (24.02± 15.11 months), in accordance with Knudson's hypothesis. Further genetic analysis of tumor samples of 2 unilateral cases showed somatic, nonsense mutations that were present only in tumor but not in blood samples of probands and parents and hence the risk of RB was predicted to be less than 1% in siblings. Among 3 bilateral cases without family history, two patients had deletions of RB1 and one patient had a nonsense mutation in blood, which is more likely to be inherited to next generation, although parents did not have those mutations. Out of 2 cases with family history the deletions of exons affecting the Pocket domain was observed in both the proband and father. In another family, proband and mother were having a splice site mutation and hence predicted the next sibling had 50% risk of getting RB. When the child was born, clinical examination and genetic testing confirmed RB with same mutation as that of proband. Because of early detection, the child was treated successfully and vision was preserved. Conclusion: Genetic analysis confirmed the Knudson's two-hit hypothesis in Indian population for the first time. Detection of somatic mutations in sporadic unilateral cases predicted a lesser chance of RB in future generation. The identification of heritable mutation in bilateral cases predicted an increased risk of RB in siblings and next generation, thereby providing early diagnosis and treatment.

3482F

Exome sequencing identifies recurrent somatic mutations in EIF1AX and SF3B1 in uveal melanoma with disomy 3. *M. Zeschnigk[1], M. Martin[2], L. Maβhöfer[1], P. Temming[3], S. Rahmann[2], C. Metz[4], N. Bornfeld[4], J. van de Nes[5], L. Klein-Hitpass[6], A.G. Hinnebusch[7], B. Horsthemke[1], D.R. Lohmann[1].* 1) Institute of Human Genetics, Faculty of Medicine, University of Duisburg-Essen, Essen, Germany; 2) Genome Informatics, Faculty of Medicine, Institute of Human Genetics, University of Duisburg-Essen, Hufelandstrasse 55, 45122 Essen, Germany; 3) Department of Paediatric Haematology and Oncology, University Hospital Essen, Hufelandstrasse 55, 45122 Essen, Germany; 4) Department of Ophthalmology, Faculty of Medicine, University Duisburg-Essen, Hufelandstrasse 55, 45122 Essen, Germany; 5) Institute of Pathology and Neuropathology, Faculty of Medicine, University Duisburg-Essen, Hufelandstrasse 55, 45122 Essen, Germany; 6) Biochip Laboratory, Institute for Cell Biology, Faculty of Medicine, University Duisburg-Essen, Hufelandstrasse 55, 45122 Essen, Germany; 7) Laboratory of Gene Regulation and Development, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Building 6, Room 230, Bethesda, MD 20892, USA.

Uveal melanoma (UM), a rare eye cancer, can be divided into two major classes based on molecular features. Tumors of either class are distinct by metastatic potential and patients' prognosis. Specifically, tumors with monosomy 3 (UM-M3), present in about half of patients, lead to metastases and poor survival. Tumors with disomy 3 (UM-D3) rarely metastasize. To capture the mutational differences underlying the diverse classes of UM we performed exome sequencing on 10 UM-D3 and 12 UM-M3. We identified six genes -GNAQ, GNA11, BAP1, SF3B1, EPB41L3,and EIF1AX- as targets of recurrent somatic protein-altering mutations. GNAQ and GNA11 are known to be mutated in both UM classes. Mutations in BAP1 and SF3B1 were reported in some UM-M3 and UM-D3 tumors, respectively. We sequenced EPB41L3 in 89 UM and found an overall low mutational frequency at this locus (<2%) thus suggesting a minor role of this gene in UM biology. Mutations in EIF1AX, an X-chromosomal gene which codes for a translation initiation factor, have not been reported in cancer so far. We performed re-sequencing of EIF1AX and SF3B1 in 31 UM-D3 and found somatic missense and in-frame mutations at a frequency of 48% (15) and 29% (9), respectively. Of note, in UM-D3 mutations of SF3B1, which encodes a subunit of the U2 snRNP splice complex, mostly affected codon 625. This mutational pattern is distinct from that in other tumors, specifically CLL and MDS, which show more diverse patterns of SF3B1 mutations. In 35 UM-M3 re-sequencing revealed that mutations of EIF1AX and SF3B1 are infrequent (2 tumors, 5.7%). Notably, EIF1AX and SF3B1 mutations are mutually exclusive in UM suggesting a complementary role of both genes in UM tumorigenesis. Re-sequencing of 13 UM with loss of parts of chromosome 3 (partM3), which are rare, showed SF3B1 mutations in 7 (53%) and an EIF1AX mutation in one other (8%) sample. The presence and type of EIF1AX and SF3B1 mutations in UM-partM3 hints at a common tumor biology of at least the mutant UM-partM3 and UM-D3. We also sequenced SF3B1 and EIF1AX in 10 rare UM-D3 tumors that developed metastases (UM-D3met) and found SF3B1 mutations in 3 samples. However, all 3 mutations were outside of codon 625 thus suggesting that the rare cases of UM-D3met are molecularly distinct. Interestingly, SF3B1 and EIF1AX mutations were biased towards UM from male patients. This lead us to hypothesize that a Y linked gene(s) is part of the pathway targeted by altered EIF1AX and SF3B1 function.

Exome sequencing characterize the somatic mutation spectrum of early serrated lesions in a patient with *BRAF* negative hyperplastic polyposis syndrome. *P. Hoffmann[1,2,3], S. Horpaopan[1], J. Altmueller[4], R. Hueneburg[5], P. Kahl[6], D. Drichel[7], H. Thiele[4], I. Spier[1], M. Odenthal[6], M.M. Noethen[1,2], C. Strassburg[5], H. Froehlich[8], P. Nuernberg[4], R. Buettner[6], S. Aretz[1].* 1) Institute of Human Genetics, University of Bonn, Germany; 2) Department of Genomics, Life & Brain Center, University of Bonn, Germany; 3) Division of Medical Genetics, University Hospital and Department of Biomedicine, University of Basel, Switzerland; 4) Cologne Center for Genomics (CCG), University of Cologne, Germany; 5) Department of Internal Medicine I, University of Bonn, Germany; 6) Institute of Pathology, University of Cologne, Germany; 7) German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany; 8) Department of Bonn-Aachen International Center for IT (B-IT), Algorithmic Bioinformatics, University of Bonn, Germany.

Background. Hyperplastic polyposis syndrome (HPS) is a yet poorly defined colorectal cancer (CRC) predisposition characterized by the occurrence of multiple and/or large serrated lesions throughout the colon. A serrated polyp-CRC sequence (serrated pathway) of CRC formation has been postulated, however, to date only few molecular signatures of serrated neoplasia (*BRAF*, *KRAS* mutations, CpG Island Methylation, microsatellite instability) were described in a subset of HPS patients and neither the etiology of the syndrome nor the distinct genetic alterations during tumorigenesis have been identified.

Methods. To describe the mutational landscape of serrated polyps and the involved pathways we sequenced the exomes (Illumina HiSeq platform) of 11 early hyperplastic polyps without the *BRAF* V600E mutation obtained from a 41 year-old female patient with clinically confirmed HPS. For data analysis the VARBANK pipeline of the Cologne Center for Genomics was used. Somatic mutations were identified by comparison with leukocyte DNA and validated by Sanger sequencing.

Results. By analyzing the exome data we initially identified 25 unique somatic alterations in 8/11 serrated tumors. All variants are single basepair substitutions. The predominant mutation type seemed to be missense mutations caused by G>T transversions. However, all but one of the G>T transversions could not be validated by Sanger sequencing, pointing to technical artifacts. The remaining validated seven somatic mutations in seven genes (*ABI3BP, CATSPERB, CCBP2, COL8A1, VGLL2, CALD1, DNAI1*) are each present in one polyp only. Four mutations occurred in the same single polyp, the other three were identified each in another polyp. No known cancer genes are among the seven candidates, however, some of them are described to be involved in cell adhesion, proliferation, or cell invasion.

Conclusions. Somatic mutations seem to be rare events in early hyperplastic lesions of HPS patients without a *BRAF* mutation. No frequently affected genes and no enrichment of specific pathways have been observed. Thus, other alterations such as epigenetic changes or variants in regulatory regions might be the major driving force of tumor progression.

The study was supported by the German Cancer Aid (project no. 108421).

3484T

First identification of frequent somatic *VHL* gene alterations in head and neck paragangliomas. *A. Merlo, S. Bernaldo de Quirós, I. Saenz de Santamaría, C. Suarez, M.D. Chiara.* Hospital Central Asturias, Oviedo, Spain.

Head and neck paragangliomas (HNPGLs) are rare tumors arising from parasympathetic paraganglia. 30-45% of HNPGLs are hereditary caused by germline mutations in succinate dehydrogenase genes (*SDHs*). The molecular connection between SDH dysfunction and tumor development is still unclear. The most accepted hypothesis proposes a central role for the pseudohypoxic pathway activated by the hypoxia inducible factor (HIF). Paradoxically, we recently showed that activation of HIF in HNPGLs is restricted to a subset of non-*SDHx*-mutant-HNPGLs. This consisted in accumulation of HIF-1α protein, and over-expression of both, HIF target genes and the HIF-inducible microRNA, miR-210. The present study aimed at unraveling the *SDH*-independent mechanisms involved in the activation of HIF in HNPGLs. To this end, we analyzed *VHL* gene in 53 tumors from patients with HNPGLs by direct gene sequencing, Multiplex-Ligation-dependent Probe amplification, qPCR and array CGH. *VHL* mRNA and protein levels were analyzed by RT-qPCR and immunohistochemistry, respectively. Meta-analysis of the gene expression signature of pseudohypoxic-HNPGLs was performed using Oncomine platform. Meta-analysis of the gene expression signature of pseudohypoxic-HNPGLs revealed that these tumors are highly related to clear cell carcinomas suggesting that HIF/miR-210 pathway is activated via pVHL deregulation in HNPGLs. Accordingly, we identified, for the first time, somatic *VHL* inactivating mutations (c.482G>A and c.227_229delTCT) in two of four pseudohypoxic-HNPGLs with concomitant LOH in one of them. *VHL* gene mutations were not found in HNPLGs that lack activation of HIF. However, partial or complete deletion of *VHL* was found in 32% of non-pseudohypoxic-HNPGLs regardless of the presence or absence of germline *SDHx* mutations. In addition, low VHL protein levels were detected in 64% tumors in association with decreased *VHL* mRNA levels. Taken together, our results suggest that the *VHL* gene is the most frequent target of somatic gene alterations in HNPGLs; and may be an important player in the development of a subset of sporadic HNPGLs via activation of HIF-1α-dependent pathways. Moreover, *VHL* may also have a previously unrecognized role in the pathogenesis of the vast majority of hereditary and sporadic HNPGLs by activating HIF-independent pathways yet to be identified. This provides the foundation for the development and use of therapeutic approaches that target the pVHL and/or HIF pathway in HNPGLs.

Sensitive, highly multiplexed somatic mutation analysis of FFPE tissues by deep amplicon sequencing on MiSeq®. *C. Lin, K. Chang, E. Upsall, I. Lewis, A. Tian, A. Iyer, G. Costa, R. Shen.* Illumina, Inc, San Diego, CA.

DNA extraction from formalin-fixed, paraffin-embedded (FFPE) tumor tissues typically results in low quantities of poor-quality, damaged DNA, which presents challenges for sequencing. Here we provide a fast, streamlined FFPE sample-to-answer workflow using probe design software and sample preparation methods optimized to overcome these challenges. DesignStudio® allows for the targeting of up to 1,536 user-defined genomic regions and supports amplicon sizes ideal for characterizing genomic hotspot regions or sequencing of whole exons with FFPE DNA (amplicons down to 125-bp, with tiling optimums at 175-bp median or higher). The TruSeq® Custom Amplicon (TSCA) workflow delivers high target enrichment specificity (>80% of reads on target), robust target multiplexing (up to 1,536 amplicons per reaction), and scalable sample indexing (up to 96 libraries). The improved protocol allows lower DNA input (≥100 ng) as compared to previous methods, and supports reduced error rates by means of optimized reagent formulations. Importantly, target representation demonstrates 3x - 47x more read depth in some regions with 80-90% GC. The TSCA assay is highly sensitive, detecting variants down to 2.5% allele frequency using FFPE reference samples verified with digital PCR. As a result of increased MiSeq output, 96 FFPE DNA samples can be targeted with the TruSeq Amplicon Cancer Panel and sequenced at 1,000x mean read depth in a single MiSeq run. For germline variant detection, 80 high-quality DNA samples can be targeted with a 1,536-amplicon custom panel and sequenced in a single MiSeq run. In support of a sample-to-answer workflow, the TSCA software analysis tools significantly reduce false-positive variant calls, and enable annotation and filtering of variants. In conclusion, we have developed an integrated FFPE DNA sequencing solution for highly accurate and reproducible detection of somatic variants implicated in cancer biology.

3486W

Alternatively spliced *DICER1* transcripts arising from genomic point mutations. *M. Wu, L. de Kock, L. Witkowski, M.R. Fabian, W.D. Foulkes.* Medical Genetics, Lady Davis Institute, McGill University, Montreal, Quebec, Canada.

DICER1 is a key endoribonuclease involved in generating small non-coding RNAs, including microRNAs (miRNAs) and short interfering RNAs (siRNAs). Several germ-line *DICER1* mutations have been identified and are associated with a pleiotropic tumour predisposition syndrome. The RNase IIIb domain of DICER1 is responsible for generating 5p miRNAs and is encoded largely by exon 25. We recently identified two tumour-specific somatic single base substitutions (c.5429A>G and c.5438A>G) that result in exon 25 skipping from the *DICER1* transcript. We postulate that these point mutations create novel exonic splicing silencer motifs that lead to exon 25 exclusion. After surveying the literature and documenting novel exon 25 mutations from our own studies, we examined whether another 8 other point mutations in exon 25 could also result in its skipping. In total, we found that 4/10 of the exon 25 mutations resulted in either exon skipping or alternative splicing. Here we demonstrate *in vitro* that the mutation c.5429A>T results in an exon 25 exclusion event while the mutation c.5428G>T creates a cryptic splice site. Importantly, we show that *DICER1* transcripts lacking exon 25 or bearing part of exon 25 can be translated. Since exon 25 encodes much of the DICER1 RNase IIIb domain, we plan to determine the impact of these DICER1 mutants on miRNA generation and to compare the functional significance of different mutations in RNase IIIb. This study highlights the importance of examining the effects of genomic mutations at the level of transcript maturation.

A personalized mutation network approach to detect putative cancer driver genes from next generation sequencing data. *Z. Zhao[1,2,3,4], P. Jia[1].* 1) Department of Biomedical Informatics, Vanderbilt Univ, Nashville, TN; 2) Department of Psychiatry, Vanderbilt Univ, Nashville, TN; 3) Department of Cancer Biology, Vanderbilt Univ, Nashville, TN; 4) Center for Quantitative Sciences, Vanderbilt Univ, Nashville, TN.

Next generation sequencing (NGS) of an individual genome typically reveals a large volume of point mutations. A major challenge in interpreting such mutation data is to distinguish clinically relevant or driver mutations from neutral passenger mutations, thus, facilitating the identification of actionable mutations and drug's target genes. Current approaches are primarily frequency-based to identify highly recurrent genes in sequenced samples; these approaches lack the power to detect moderately or rarely mutated driver genes and ignore functional interconnection and regulation among cancer genes. To tackle these issues, we proposed a novel, personalized mutation network method, VarWalker. VarWalker first estimates the probability of a gene to be mutated in each sample as a function of its cDNA length through a resampling-based test. It then applies the Random Walk with Restart algorithm for each individual sample to search for neighborhood interactors of the mutation genes in the reference network, which can be defined by the user. Finally, it builds a consensus mutation network based on the recurrent significant interactions at the cohort level. We demonstrated our approach in two NGS datasets: a lung adenocarcinoma (LUAD) sample cohort including 183 matched tumor/normal patients and a melanoma patient cohort including 121 matched pairs. For both datasets, the resultant mutation networks were significantly enriched with known cancer genes from Cancer Gene Census (CGC): the LUAD network recruited 70 CGC genes (p-value $< 2.2\times10^{-16}$, Fisher's Exact Test) and the melanoma network recruited 65 CGC genes (p-value $< 2.2\times10^{-16}$). Specifically for the LUAD network, for which we extracted a total of 57 known LUAD genes from previous studies, the mutation network recruited 31 of them (p-value $< 2.2\times10^{-16}$, Fisher's Exact Test). Importantly, within the major functionally connected, cancer-gene driven subnetworks that VarWalker identified, we detected moderate- and low-frequency cancer genes, demonstrating VarWalker's effectiveness on detecting these categories of driver genes, which are ignored by current frequency-based approaches. We expect VarWalker can be applied broadly to NGS-based disease studies for identification of disease candidate genes and their functional interactions.

DNA copy number variation and expression of miRNA150 suggestive as prognostic factor for Colorectal cancer. *R.V. Andrade[1], N. Gasparini[1], L. Sakamoto[3], G. Pereira[2], T. Lins[3].* 1) Universidade Católica de Brasília, Brasília, Brazil; 2) Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, RS, Brazil; 3) Universidade de Brasília, Brasília, DF, Brazil.

Colorectal cancer (CRC) is the third most common cancer worldwide. It is caused by adenocarcinomas that arise from polyps. The survival rate for CRC is lower as the disease progresses, influencing the prognosis of the patients. Several molecular mechanisms were already described, such as copy number variation (CNV) and miRNA differential expression. MiRNAs can regulate the gene expression by the inhibition of translation or cleaving target mRNAs, and CNVs could regulate gene expression by deletion, translocation, duplication and insertion of these regions. MicroRNA genes embedded in copy number variation can have the expression affected by gene dosage effect. Both molecular mechanisms can be part of cell maintenance, and also modulate the prognosis of cancer. This work aimed to correlate the copy number variation of microRNA genes with clinical features of patients with CRC. Copy number variation and microRNA were evaluated by qPCR using TaqMan assays in normal, tumor and lymph node tissues. The Mantel-Cox test along with the Kaplan-Meier test was used to determine the survival time between the group of diploid (2 copies of microRNA genes) and non-diploid carriers. The expression of miR150 was statistically different between normal and tumoral (p=0.001); and between normal and lymph node tissues (p=0.001) showing that the expression of tumor is downregulated in relation to normal tissue, and the expression of lymph node is upregulated in relation to normal tissue. However, there was no significance between survival rates and up or downregulation (p>0.05). For the CNV, the Wilcoxon test did not indicate statistical difference in the gain of CNV between normal and tumor, and with lymph node tissues (p>0.748). However, when groups were defined by diploid and non-diploid individuals it indicated that the CNV-miR150 diploid genotype is associated with lower survival rates (p=0.022). Data showed that the diploid copy of CNV-miR150 is associated with lower survival rates. This indicates that CNVs containing genes of variable nature may behave differently to the gene dosage altering the functional expression in a tumor sample. For future experiments it is suggested to evaluate whether other genes are inserted within the CNVs in addition to miRNAs and quantify their expression in relation to normal tissue.

MicroRNA-192 regulates cellular proliferation in medulloblastoma seeding by targeting of dihydrofolate reductase. *S.A. Choi[1,2], S.Y. Yang[3], H.A. Kim[1,2], K.C. Wang[1,2], J.H. Phi[1,2], J.Y. Lee[1,2], J.H. Choi[1,2], D.Y. Um[1,2], Y.J. Moon[1,2], P.A. Kwak[1,2], E.J. Kwon[1,2], S.K. Kim[1,2].* 1) Division of Pediatric Neurosurgery, Pediatric Clinical Neuroscience Center, Seoul National University children's Hospital; 2) Adolescent Cancer Center, Seoul National University Cancer Hospital; 3) Division of Neurosurgery, Dongguk University Hospital.

Medulloblastoma (MB), a most common malignant brain cancer in children, frequently disseminates throughout the cerebrospinal fluid. The treatment of leptomeningeal dissemination (seeding) of the MB is challenging and the prognosis is extremely poor. In this study, we profiled miRNA expression and investigated the effect of miR-192 regulated DHFR (Dihydrofolate reductase) expression to get a better understanding of biology in MB seeding. miRNA profiling was carried out using agilent human miRNA microarray kit and qRT-PCR and western blot were performed using tissues and MB cell lines. For the further studies, MB cell lines were transfected miRNAs and investigated the luciferase activity, viability, proliferation assay and cell cycle analysis. The expression level of miR-192 is down-regulated in seeding group and three different MB cell lines compared to non-seeding MB and/or normal cerebellum. MiR-192 directly binds to the 3'-untranslated region (3'UTR) of DHFR mRNA, resulting in over 50% decrease in DHFR protein level in MB cell lines. The overexpressed miR-192 reduced the cell proliferation and induced cell cycle arrest by controlling DHFR target protein. The miR-192 overexpression considerably inhibited vimentin protein level suggesting that it might control the anchorage-dependent cell growth not migration. Our results demonstrate that DHFR is a direct target of miR-192 regulation and overexpression of miR-192 reduced tumor cell proliferation by inhibiting the expression level of the DHFR. Our findings describe a new mechanism for the regulation of DHFR/miR-192 and vimentin link providing a better understanding of signal pathway of MB seeding.

Genome Wide miRNA Expression Profile in Oral Cancer: An Exploratory Study. *N. De Sarkar, B. Roy.* Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India.

MicroRNAs (miRNAs) are a family of small non-coding RNA molecules of about 20-23 nucleotides in length, which is known to regulate expression of protein-coding genes at post-transcriptional level. Aberrant miRNA expression contributes to tumorigenesis and cancer progression and new member/s of miRNAs aberrantly expressed in various cancer types is also being reported frequently. Using TLDA array (a real-time-TaqMan Assay, Life technologies) we have checked expression of 762 human miRNAs in 18 pairs of Gingivo-Buccal cancer-adjacent control tissues and identified 7 miRNAs whose expression levels were significantly altered. Known oncogenic miRNAs, e.g. hsa-miR-31and hsa-miR-7, are among the miRNAs whose expression is up-regulated in this study. Besides these, we have also noticed significant up regulation of expression of hsa-miR-31*, which also act as Onco-miR via RHOA mediated pathway. Tumor suppressive miRNAs, such as hsa-miR-206, hsa-miR-204 and hsa-miR-133a, are also significantly down-regulated in this study. For the first time, we are reporting that expression of hsa-miR-204 is being down regulated in oral cancer. Besides we have also noticed significant up-regulation of expression of hsa-miR-1293, for the first time, in 9 of the 18 cancer samples. To explore the possible roles of these miRNAs in the disease process of Gingivo-Buccal carcinoma, we looked into the expression data with the help of different web databases and bioinformatics tools. Several biological pathways that are well characterized in cancer are significantly targeted by these seven miRNAs and they include MAPK and PI3-AKT pathways. These results indicate that these aberrantly expressed miRNAs may regulate, coordinately, several oncogenic pathways in Oral Cancer.

Malignant mesothelioma (MM) is the only tumor due to exposure to a single carcinogen, asbestos. Only 10-17% of subjects exposed to high levels of asbestos develop MM, suggesting the role of individual genetic susceptibility. In two GWA studies we have reported several SNPs that cause a 2-3 fold increase in MM risk, but a much higher risk is due to asbestos exposure (Matullo et al 2013, Cadby et al 2013). Predisposition to MM may also occur with an autosomal dominant fashion. Germline loss-of-function (LOF) mutations in the BAP1 oncosuppressor gene are responsible for an inherited syndrome with predisposition to MM, uveal and keratinocytic melanoma, renal carcinomas and other malignancies (Testa et al 2011, Popova et al 2013). So far germline mutations in BAP1 were identified in 28 families, 9/28 showed multiple cases of MM and 3/28 showed a single case of MM. Germline mutations have been identified also in sporadic MM cases (2/26, Testa et al 2011). In this study, we report the analysis of BAP1 in four multiplex families and in 103 sporadic MM cases with the two aims of further investigating BAP1 related cancer syndrome and of estimating the role of germline BAP1 mutations in sporadic MM. One family carried a new LOF germline mutation (c.46_47insA). By using immunohistochemistry we show that BAP1 is not expressed in tumor tissue, according with Knudson's two hits hypothesis. Interestingly, whereas the three patients (mutation carriers) that were possibly exposed to asbestos developed MM, a further individual (mutation carrier) who was not exposed developed a different tumor type, i.e.mucoepidermoid carcinoma. This suggests that carcinogen type exposure may be important for the cancer type that is developed by mutation carriers. The other families did not show mutations in BAP1. None of the 103 sporadic patients showed mutations in BAP1, with an estimated confidence interval computed using Poisson distribution from 0 to 3.58% . Our data show that germline BAP1 mutations have a very limited role in sporadic MM. On the other hand, our study focused on familial aggregation of MM identifies a new BAP1 mutation, extends the cancer types associated with these mutations and suggests the existence of other yet unknown genes in the pathogenesis of familial MM.

3492W

The role of genetic ancestry in DNA repair capacity among Puerto Rican women with breast cancer. *H.J. Diaz-Zabala[1], L. Morales[2], J. Matta[2], J. Dutil[1].* 1) Department of Biochemistry, Ponce School of Medicine, Ponce, PR; 2) Department of Pharmacology, Ponce School of Medicine, Ponce, PR.

Introduction: Breast cancer incidence and tumor characteristics have been shown to vary among different ethnic populations. Previous studies in Puerto Rico have shown that breast cancer patients have a reduced DNA repair capacity (DRC) when compared to non-cancerous controls. In the Hispanic population of Puerto Rico, the contribution of genetic ancestry to breast cancer and associated risk factors is currently unknown. Objective: This study aims to determine the role of genetic ancestry in DNA repair in a group of breast cancer cases and controls. Methods: The study population consisted of 317 breast cancer patients and 364 non-cancerous controls that were recruited from private oncology practices in Puerto Rico. A panel of 106 ancestry-informative markers was genotyped using iPLEX sequencing technology. Individual genetic ancestry was estimated using a maximum likelihood approach. DRC levels were measured using a modified host-cell reactivation assay. An epidemiological questionnaire with clinical information from each patient was assessed for statistical associations with genetic ancestry. Results: The distribution of genetic ancestry among the 681 individuals varied from 0 to 100% African, 0 to 100% European, and 0 to 39% Native American. There was no significant difference in the average European (p= 0.163), African (p=0.382) and Native American (p=0.243) ancestry proportions between breast cancer cases and controls. We observed that low DRC levels were significantly associated (p=0.047) with higher proportions of Native American ancestry in non-cancerous controls. In cases, low DRC levels were significantly associated with higher proportions of European ancestry (p=0.011) and lower proportions of African ancestry (p=0.027). Conclusion: Our data indicate that global genetic ancestry is not associated with breast cancer risk in Puerto Rican women. However, we provide evidence that African, European and Native American ancestries are associated with changes in DRC.

3493T

A Non-Smad TGF-β Signaling Pathway Govern Adult Stem Cell State and Breast Cancer Metastasis with the Cooperation of SLUG and SOX9. *H. Fazilaty[1], B. Behnam[2].* 1) Medical Genetics, Tehran University of Medical Sciences, Tehran, Iran; 2) Medical Genetics and Molecular Biology, Iran University of Medical Sciences, Tehran, Iran.

Transforming growth factor (TGF)-β superfamily has shown to be crucial in development, homeostasis and malignancies. TGF-β promotes metastasis by the induction of epithelial to mesenchymal transition (EMT), a process involved in gastrulation, wound healing and induction of cancer stem cells. Interestingly, EMT has been connected to stem cell traits of epithelial tissues by the induction of stemness. Although master regulatory networks are expected in adult stem cells, our knowledge of such network is still poor. Cancer stem cells are the only capable population of tumor cells to progress to overt metastasis, and are known share adult stem-like cells features. On the other hand, occurrence of appropriate microenvironmental conditions would be critical for stem/cancer stem cells. Master regulators not only determine stem/cancer stem cell state, but also may have regulatory roles in niche elements. Meanwhile, both stem/cancer stem cell and niche factors may function like two sides of the same coin. TGF-β superfamily, also, may play crucial roles in regulation of niche elements as well. In this regard, we hypothesize presence of a possible emerging molecular pathway in the biological process of breast stem/cancer stem cells induction and maintenance. In this process, non-Smad TGF-β induced signaling connects stem/cancer stem cell and niche elements by the mediation SLUG and SOX9 master transcription factors, and TNC and POSTN ECM components.

3494F

Copy number variation and the expression of miRNAs in colorectal cancer. *N. Gasparini[1], T. Lins[2], S. Andreoli[1], L. Lemos[1], J. Lima[1], G. Pereira[3], L. Sakamoto[2], R. Pereira[1,2], R. Pogue[1], R. Andrade[1].* 1) Ciências Genômicas e Biotecnologia, Universidade Católica de Brasília, Brasília, DF, Brazil; 2) Universidade de Brasília, Brasília, DF, Brazil; 3) Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, RS, Brazil.

Colorectal cancer (CRC) is a pathology that affects the colon and rectum. It arises from polyps that become adenocarcinomas, and these polyps may occur sporadically or be inherited. It is the third most common cancer worldwide, and accounts for 8% of cancers in Brazil. Several molecular mechanisms such as mutation, copy number variation (CNV) and miRNA expression have been evaluated in CRC. MiRNAs (non-coding RNAs that regulate gene expression by inhibiting translation or cleaving target mRNAs) and CNV (DNA sequences susceptible to deletion, duplication, translocation, inversion and insertion) are of great importance in the regulation of cell growth, differentiation, proliferation and apoptosis. MiRNAs and CNVs are associated with various types of cancer, and show differential expression in tumor tissues, and miRNA sequences frequently occur in CNV regions; thus it is reasonable to speculate that their differential expression in cancer may be due presence of differing numbers of copies of the miRNA genes. In this context, this work aimed to investigate the association between copy number variation of miRNA genes and the respective differential expression of miRNAs in normal, tumor and lymph node tissues of patients diagnosed with CRC. We selected 10 miRNAs that are known to be differentially expressed in CRC, and located within CNV regions. miRNA expression and copy number variation in 30 patients were analyzed by qPCR, using TaqMan assays. Relative quantitation of miRNAs was examined by ddCq, and quantification of copy number was performed using the CopyCaller software, normalized to RNAseP endogenous reference gene. The t-test significance for tumor and lymph node showed that miR570, miR338, let7g, miR1, miR150, miR183, miR650 and miR31 were differently expressed. The Wilcoxon signed-rank test showed that CNV-miR570 and CNV-miR650 had different copy number when comparing normal and cancerous sample tissues. Finally, a non-parametric correlation assessed the existence of a link between variation in copy number and expression levels of miRNAs. In only one CNV-miRNA (CNV-miR16 in tumor samples), was the correlation was significant, which indicates that in general, CNV probably does not influence gene dosage of miRNAs related to CRC. This study was essential to contribute for the understanding of the molecular mechanisms that which elucidates better diagnosis and prognosis of CRC.

3495W

Expression profiling of cofilin-1 in breast cancer cell lines and biopsies. *A. Hadjisavvas[1], C. Sutton[2], S. Shaheed[2], P. Loadman[2], V. Speirs[3], A. Hanby[3], K. Kyriacou[1].* 1) The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) Institute of Cancer Therapeutics University of Bradford, Bradford, UK; 3) Leeds Institute of Molecular Medicine, Leeds, UK.

Breast cancer is a significant cause of death since many tumors do not respond to treatment or acquire resistance. Hence there remains the need to identify novel targets for therapy and biomarkers for prediction of response to treatment. A quantitative proteomics study of matched normal and tumor biopsies identified 63 proteins to be significantly increased or decreased in stage-specific tumors. Some have previously been associated with breast cancer, while others such as cofilin-1 represent new targets for investigation. Cofilin-1 was subject to a range of analyses to determine its association with breast cancer. Western blotting (WB) was performed on protein extracts from breast cancer cell lines and matched normal and tumor biopsies from Cypriot patients with different stages of the disease. Immunohistochemistry (IHC) was carried out on core biopsies. Multiple reaction monitoring (MRM) mass spectrometry was performed on trypsin-digested protein extracts from biopsies.WB indicated that cofilin-1 was ubiquitously expressed in tumor cell lines, representative of Luminal A and B, basal-like, claudin-low and HER2 phenotypes, at higher levels than normal breast cell lines. WB also indicated increased expression of cofilin-1 in invasive carcinoma tissues, compared to matched normal. Patients with ductal carcinoma in situ or fibroadenoma exhibited less clear results, either increasing slightly or remaining unchanged. MRM analysis of three cofilin-1 peptides in tissue extracts of invasive carcinoma patients indicated expression only in tumor. IHC of core biopsies exhibited strong staining for cofilin-1 in ductal invasive carcinoma tissues with no staining in normal breast cells. Genomics and proteomics databases indicate that cofilin-1 is expressed in a diverse range of normal tissues. However, mRNA and protein levels are observed to be increased in skin,liver, pancreatic and breast tumors. The original quantitative proteomics data indicated only relatively small changes in expression (<2-fold) due to dynamic range limitations of the technique. Additional analytical approaches substantiated that cofilin-1 is significantly up-regulated in advanced breast cancer patients. Further patient sets are required to confirm the importance of cofilin-1 levels in early stages of breast cancer compared to benign tissues. Bioinformatics provided further confidence in our findings, highlighting the value of utilising databases for evidence of disease-specific proteins.

Angiogenesis in Chronic Hepatic Patients. *I.A. Helwa[1], H.A. El Dakhakhny[1], N.M. Kholoussi[1], R.F. Mahmoud[1], A. Hamada[2].* 1) Immunogenetics Department, National Research Centre, Cairo, Egypt; 2) Ain Shams University Hospitals, Cairo, Egypt.

Introduction: Hepatocellular carcinoma (HCC) is one of the most aggressive cancers worldwide. In Egypt, the disease is usually detected in an advanced stage at which no treatment may be effective including surgery. Early detection of the disease is thus an important goal allowing the patient to be treated before the enlargement of the tumor or its metastasis to distant organs. Objectives: To determine the role of Vascular Endothelial Growth Factor (VEGF) and Angiopoitin-2 (Ang-2) levels in prognosis of Hepatocellular Cancer (HCC) and Cirrhosis. Subjects and Methods: Eighty subjects were recruited in this study from Ain Shams University Hospitals; 29 patients suffering from liver cirrhosis, 36 HCC patients in addition to 15 apparently healthy control subjects. Serum levels of VEGF were assayed using a standard sandwich enzyme linked immunosorbent assay (ELISA) (RayBio Human VEGF ELISA Kit) with a minimum detectable dose less than 10 pg/ml. Moreover, serum Angiopoitin-2 (Ang-2) levels using ELISA technique (Invitrogen) with a minimum detectable dose <6 pg/mL. Results obtained were analyzed using Statistical Package for the Social Sciences (SPSS). Results: The serum VEGF levels in the HCC patients were significantly elevated as compared to the liver cirrhosis group and the apparently healthy control group. Nevertheless, serum Ang-2 levels in HCC patients were significantly elevated as compared to the liver cirrhosis group and the apparently healthy control group. Conclusions: Angiogenesis plays a crucial role in carcinogenesis, growth and progression of HCC, which is one of the most vascularized human cancers. Serum VEGF and Ang-2 levels appear to be critical angiogenic factors regulating angiogenesis in HCC and hepatic cirrhosis. Nevertheless, further directions aim at linking the 61*G allele polymorphism to EGF expression to assess as well the association between the EGF polymorphism and HCC risk.

Cancer Phenotypes of Germline Monoallelic *ATM* Mutation Carriers and Their Families. *H. LaDuca, A. Stuenkel, S. Keiles, T. Pesaran, S. Tandy, E. Chen, V. Speare, C. Radford, C. Gau.* Ambry Genetics, Aliso Viejo, CA.

Monoallelic *ATM* mutations have been associated with an increased risk of both breast and pancreatic cancers. *ATM* sequence and gross deletion/duplication analyses are included in three hereditary cancer panels offered by our laboratory, and to date, 26 *ATM* pathogenic mutation carriers have been identified. The purpose of this study is to describe the clinical characteristics of these *ATM* mutation carriers and their families. Retrospective test requisition form review was used to obtain clinician-reported clinical history information, including patient clinical history, testing history, and family history, for all pathogenic *ATM* mutation carriers. Follow-up contact with referring providers yielded additional clinical data for select patients. Chi-square analysis was used for statistical comparison of the observed mutation frequency in our Caucasian patients with that expected in the European American general population. All 26 *ATM* mutation carriers had a reported personal history of cancer, with 9 (34.6%) having a personal history of more than one primary cancer diagnosis. All but one patient (n=25) also had a family history of cancer. The spectrum of primary cancers observed in our *ATM* probands included breast, pancreatic, colorectal, ovarian, fallopian tube, leukemia, lymphoma, lung, basal cell carcinoma, cervical, and squamous cell carcinoma of the perineum. Twenty (76.9%) *ATM* carriers had a personal history of breast cancer, with an average age of 43 at first breast cancer diagnosis (range 31-69 years). Four (20.0%) of these breast cancer patients had a history of more than one primary breast cancer. Seven (26.9%) carriers had personal and/or family history of pancreatic cancer. *BRCA1/2* testing information was reported for 18 (69.2%) mutation carriers, and all reported results were negative. The observed frequency (1.8%) of pathogenic *ATM* mutations in our Caucasian patients was significantly elevated compared to the frequency in the European American general population (0.4%) (OR= 4.84, $p=1.3\times10^{-7}$, 95% CI= 2.54-9.25). Despite the selection bias of our testing population and the limitations of clinician-reported clinical history details, our data contributes to the growing body of literature on cancer risks in monoallelic *ATM* mutation carriers. Efforts are being made to determine co-segregation of mutations with disease in these families and will increase our knowledge of the penetrance of mutations in families and any additional cancer associations.

3498W

Contralateral Mastectomy and Survival after Breast Cancer in BRCA1 and BRCA2 Mutation Carriers. *K. Metcalfe[1], S. Gershman[1], P. Ghadirian[2], H. Lynch[3], C. Snyder[3], N. Tung[4], C. Kim-Sing[5], A. Eisen[6], W. Foulkes[7], B. Rosen[8], P. Sun[9], S. Narod[9]*. 1) Faculty Nursing, Univ Toronto, Toronto, ON, Canada; 2) Epidemiology Research Unit, Centre Hospitalier de Université de Montreal (CHUM), Montreal, Canada; 3) Department of Preventive Medicine and Public Health, Creighton University School of Medicine, Omaha, NE,; 4) Beth Israel Deaconess Medical Center, Boston, MA; 5) BC Cancer Agency, Vancouver, Canada; 6) Toronto Sunnybrook Regional Cancer Center, Toronto, Canada; 7) Program in Cancer Genetics, McGill University, Montreal, Canada; 8) University Health Network, Toronto, Canada; 9) Women's College Research Institute, Toronto, Canada.

Background: Women who carry a mutation in either the BRCA1 or BRCA2 gene face a lifetime risk of breast cancer and once diagnosed, face a high risk of second primary breast cancer. Contralateral mastectomy is an option to reduce the risk of contralateral breast cancer. However, it is unclear if contralateral mastectomy impacts on survival. The objective of the current longitudinal study was to compare the survival rates of women with BRCA-associated breast cancer who did and who did not undergo a contralateral (bilateral) mastectomy. **Methods:** Patients were 390 women with stage I or II breast cancer and a BRCA1 or BRCA2 mutation who were initially treated with unilateral or bilateral mastectomy. These patients were selected by pedigree review of families who received counselling at one of 12 participating clinical genetics centers. The medical records were reviewed for clinical presentation, medical and surgical treatments and outcome. Patients were followed for up to 20 years from diagnosis. Survival experience was compared for women who did and who did not have a contralateral mastectomy. **Results:** 79 women died of breast cancer in the follow-up period. At twenty years, the survival rate was 88% for women who had a contralateral mastectomy and 66% for women who did not. In a multivariable analysis, controlling for age and year of diagnosis, treatment and other prognostic features, contralateral mastectomy was associated with a 49% reduction in death from breast cancer (HR = 0.51; 95% CI: 0.51 to 0.28; p = 0.03). **Conclusions:** BRCA-positive women who are treated for breast cancer with bilateral mastectomy are less likely to die from breast cancer than women who are treated with unilateral mastectomy.

3499T

Genetic diagnosis of a series of Brazilian patients with pheochromocytomas and paragangliomas. *O. Moraes[1], D. Oliveira[1], B. Araújo[1], C. Meireles[1], L. Vianna[1,2], J. Mazzeu[1], M. Batista[3], A. Lofrano-Porto[1,2]*. 1) Universidade de Brasília, Brasilia, Distrito Federal, Brazil; 2) Hospital Universitário de Brasília, Distrito Federal, Brazil; 3) Hospital Regional de Taguatinga, Brasilia, Brazil.

INTRODUCTION: Pheochromocytomas (PCC) and Paragangliomas (PGL) are neuroendocrine tumors originating from chromafin cells, located in the adrenal medulla and extra-adrenal tissue, respectively. PCC and PGL are usually benign, with morbidity and mortality related to the production of catecholamines. Malignancy is reported in approximately 10% of cases. Recent studies have shown that at least 25% of all PCC/PGL cases may have a genetic basis. METHODS: 15 patients with PCC/PGL were included. Clinical, biochemical and radiological data were obtained from medical records. Histopathological and immunohistochemical studies for neuroendocrine markers were performed. Genomic DNA was extracted and the coding regions of VHL, SDHB and SDHD were amplified and automatically sequenced. Multiplex ligand-probe amplification (MLPA) was used for screening large deletions/insertions. RET gene analysis was also performed in one patient with clinical evidence of multiple endocrine neoplasia type 2A (MEN2A). Genuine consent was obtained from all. RESULTS: Our series consisted of 4 PGLs and 11 PCCs patients; 5 had familial history and 2 were malignant. Immunohistochemistry confirmed the neuroendocrine origin of all tumors. Genetic analysis revealed the (p.Q164R) VHL mutation in a woman with PCC and cerebellar hemangioblastoma and her asymptomatic daughter. A RET mutation was found (p.C618R) in a woman with PCC and thyroid medullary carcinoma (TMCa; MEN2A) and her 2 daughters with TMCa. A large deletion of SDHB exon 1 was found in 3 patients: Two sisters with paraortic PGL, and an apparently sporadic case presenting with relapsing retroperitoneal PGL. DISCUSSION: Molecular diagnosis done by Sanger's sequencing combined with MLPA constitute an adequate strategy to search for both point mutations and large deletions. Genotype-phenotype associations for VHL and RET are well described, but the pathophysiological effects of large deletions on SDHB are still unclear. No phenotype correlations have been characterized for large SDHB deletions due to a highly variable presentation. SDHB may act as a tumor suppressor, and a large deletion may lead to a tumor phenotype. Rational recommendations for genetic studies in PCCs and PGLs are in progress given that mutations may also be found in apparently sporadic cases, and that a positive result might influence clinical monitoring and genetic counseling of patients and their offspring.

3500F

Prevalence of Succinate Dehydrogenase-deficient GIST in adults with GIST. *I.R Rainville[1], E.J. Root[1], A.J. Wagner[2], S. George[2], C.L. Corless[4], J.E. Garber[1], J.A. Hornick[3]*. 1) Center for Cancer Genetics and Prevention, Dana-Farber Cancer Inst, Boston, MA; 2) Center for Sarcoma and Bone Oncology, Dana-Farber Cancer Inst, Boston, MA; 3) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 4) Portland VA Medical Center and Oregon Health and Sciences University Knight Cancer Institute, Portland, OR.

Introduction: GIST is the most common mesenchymal tumor of the GI tract, often associated with somatic gain-of-function mutations in *KIT* or, less commonly, *PDGFRA*. Deficiency of the mitochondrial complex II succinate dehydrogenase distinguishes a class of GISTs wild-type for *KIT/PDGFRA* with distinctive histopathology and clinical behavior. Germline mutations in *SDHX* with somatic loss of heterozygosity in tumors characterize the syndrome of GIST and paraganglioma and a subset of pathologically similar, apparently sporadic GIST, and correlate with loss of expression of SDH subunits by immunohistochemistry (IHC). We are systematically reviewing GIST pathology, family history, and germline status in our multicenter study to estimate the prevalence of SDH-deficiency among adults with GIST. We report the results from our Dana-Farber Cancer Institute (DFCI) cohort thus far. Methods: Individuals ≥ age 18 years with history of confirmed GIST were enrolled through the sarcoma clinic at the DFCI. Gastric GISTs were screened for features of SDH deficiency: epithelioid or mixed morphology, multinodular or plexiform growth pattern, and lymph node metastasis. Somatic *KIT/PDGFRA* genotype was noted when available. Suspected *SDH*-deficiency was confirmed by IHC for SDHA/B. Germline testing, if not done previously, was offered to study participants. Results: From March, 2008 through February, 2010, we enrolled 214 study participants with GIST in the DFCI sarcoma program. To date, IHC has identified 19 SDH-deficient GISTs (8.9%; CI 5.1% to 12.7%). Age of diagnosis ranged from 15 to 55 years (mean 31.9 years). *KIT/PDGFRA* mutation screening was available for 12 tumors, all of which were wild-type. Seven of 17 cases in which the family history was reviewed were apparently sporadic. Three cases had family history of GIST in a first or second-degree relative. Germline *SDHX* analysis of 9 cases performed in our study or elsewhere identified mutations in 7: 5 in *SDHB* and 2 in *SDHA*. Conclusion: SDH-deficient GIST comprises a significant fraction of all GISTs in this cohort. Family history of GIST or paraganglioma, when present, can inform genetic testing. In the absence of family history of other associated tumor, tumor histopathology with SDHA/B IHC are highly sensitive screening tools to identify patients with GIST who are at high risk to carry germline mutations.

3501W

Value of microRNA-based molecular profiling in Cancer of Unknown Primary (CUP) cases for familial cancer risk assessment and genetic counseling. *E.R. Wassman[1], E. Goren[1], J. Hale[2], C. Hogan[1], B. St.Cyr[1], M.O. Sanden[1]*. 1) Rosetta Genomics, Philadelphia, PA; 2) Hunterdon Regional Cancer Center, Flemington, NJ.

Background: Cancer risk assessment and counseling is dependent upon accurate diagnosis of historical malignancies in family members. It is confounded by lack of availability, incompleteness, and inaccuracy due in part to variability in histopathology. Cancer of unknown or uncertain primary (CUP) represents a unique challenge for counseling as they represent failure to reach a diagnosis in late stage cancers. Recently, molecular profiling with microRNAs was shown to effectively identify the underlying tumor type in CUP cases. This series illustrates how this methodology can identify otherwise unrecognized genetic risk. Methods: MicroRNA was isolated from 258 consecutive specimens, analyzed on a custom microarray, and 64 microRNAs interpreted for any of 42 specific tumor types as previously described. We routinely collect follow-up information on correlation of test prediction with other clinical-pathological findings, treatment response, and outcome. Results: 192 cases had sufficient tumor material and were successfully reported. The most common cancers identified were colorectal (12%) and breast (10.4%). Of the breast cancer cases, 5 (3% overall) were in males. Ovarian cancer was found in 6.8% and a total of 32 other tumor types were diagnosed. Referring doctors affirmed confidence and utility in a high percentage of cases. Discussion: MicroRNA resolved diagnoses provide valuable information for family members when no previous specific diagnosis was available. 28.4% of CUP cases analyzed by this method revealed diagnoses (colorectal, breast, ovarian) with particular significance for genetic counseling. The 5 male breast cancer cases described here suggest over a 20-fold enrichment in CUP compared to the observed population rate, where they represent only about 1% of all breast cancers. These are of particular relevance for counseling their sisters and daughters. Depending on the family history, a specific diagnosis of other cancers may also be contributory. MicroRNA has been shown to be particularly stable in FFPE preserved tumor blocks, providing a potential tool for investigation of the etiology of a deceased relative's cancer when CUP or doubtful results confound family history risk assessment. Conclusion: MicroRNA profiling in CUP patients has an additional clinical utility in uncovering important genetic risks associated with specific cancer diagnoses in at least one-third of cases, potentially directing specific genetic testing for relatives.

Identification of tissue-specific long intergenic non-coding RNAs in normal prostate tissue.
Y. Zhang, A.J. French, A.A. Nair, S. McDonnell, S. Middha, S. Riska, Z. Fogarty, D. Schaid, S.N. Thibodeau. Mayo Clinic, Rochester, MN.

Long intergenic non-coding RNAs (lincRNAs) have been found to perform various functions in a series of important biological processes. Because the transcription of lincRNAs is tissue and temporal specific, it is important to examine a variety of tissue types as part of the discovery process. Recently, genome-wide transcriptome deep sequencing technology and computational approaches have provided an unprecedented opportunity to analyze such transcripts. In this pilot study, we performed RNA-seq on 40 normal prostate tissue samples to investigate and characterize the entire transcriptome. Regions of normal prostate tissue were histologically confirmed from specimens obtained during radical prostatectomy for prostate cancer (n=38) or cystoprostatectomy in patients with bladder cancer (n=2). Specifically, we focused on the identification of prostate-specific lincRNAs. In total, we identified 22,176 candidate lincRNA transcripts at 16,145 loci. Candidate lincRNA were defined as having evidence from assembly for at least two samples. Overall, there was significant overlap between the lincRNAs identified in this study with lincRNAs annotated in GENCODE V16 (75% overlap at loci level). Importantly, 5544 novel lincRNAs were not previously reported. The prostate derived lincRNAs were further examined for evidence of transcriptional activity using the H3K4me3-H3K36mer3 domains generated from nine cell lines in the ENCODE project. Overall, 3659 lincRNAs (~35%) have evidence of a signature consistent with an actively transcribed gene across the entire locus (both H3K4me3 across the promoter region andH3K36me3 along the transcribed region). Of the remaining transcripts, 2797 (27%) overlap a H3K4me3 peak alone (promoter region) and 1221 (12%) overlap a H3K36me3 peak alone (transcribed region). Some future directions to characterize these lincRNA transcripts include differential expression analysis of these lincRNAs between different clinical groups, co-expression analysis of lincRNAs and protein-coding RNAs, and analysis of disease-associated SNPs in these lincRNA regions. Additionally, an expression quantitative trait loci analysis will be investigated between prostate cancer risk-SNPs and their neighboring lincRNAs surrounding the risk-SNPs.

The novel founder MSH6 mutation c.10C>T is an important cause of Lynch syndrome in the French Canadian population.
E. Castellsague[1], J. Liu[2], A. Volenik[3], R. Gagne[4], B. Maranda[5], S. Giroux[6], J. Latreille[7], L. Palma[3], L. Kasprzak[3], V. Marcus[8], M. Breguet[9], S. Nolet[10], AM. Mes-Masson[11], D. Provencher[11], G. Chong[2], F. Rousseau[12], W. Foulkes[1,3,13,14,15]. 1) Human Genetics, McGill University, Montreal, Canada; 2) Pathology Department, JGH, Canada; 3) Medical Genetics Department, McGill, Canada; 4) Génétique Médicale Departament, CHUL, Canada; 5) Pédiatrie Département, Université-Sherbrooke, Canada; 6) CHU Quebec, Canada; 7) Hematology and Medical Oncology Division, HCL, Canada; 8) Pathology Department, McGill, Canada; 9) Service de Medecine Genique, CHUM, Canada; 10) Pathologie Departement, CHUM, Canada; 11) Centre de recherche CHUM, Hôpital Notre-Dame, Canada; 12) Biologie moléculaire, biochimie médicale et pathologie Département, Université Laval-CHU Quebec, Canada; 13) Cancer Prevention Centre, JGH, Canada; 14) Cancer Genetics Program, McGill, Canada; 15) Medicine Department, McGill, Canada.

Lynch syndrome (LS) is the most common autosomal dominant condition predisposing to colorectal cancer (CRC). It is characterized by early onset cancers of the colorectum and endometrium (EC) among others. LS is caused by germline mutations in mismatch-repair genes MLH1, MSH2, MSH6 and PMS2. Founder mutations among them are an important cause of LS and facilitate genetic testing in specific ethnic populations. We have recently identified a new truncating mutation in MSH6, c.10C>T (p.Gln4X), in 10 Quebec French Canadian families presenting clinical features consistent with LS. Sixteen carriers of the mutation were also identified among 6,433 newborns screened in Quebec City. These data strongly suggest that MSH6 c.10C>T is one of the most common mutations causing Lynch syndrome discovered until now, and point to a common founder origin. We confirmed that MSH6 c.10C>T occurred as a unique event in a single founder individual by the existence of a shared haplotype in carrier individuals (≈3.3 Mb). To determine the age of the mutation, 150 French Canadian controls are currently under analysis. Regarding the clinical features, the mutation co-segregates with LS-spectrum cancers in 13 of the 19 carriers (average age at diagnosis: 44.8y). The remaining 6 non-affected carriers have a mean age of 34.3y. None of the non-carriers have developed a tumor belonging to LS spectrum (average age 50.8y). In accordance with a previously described increased risk of EC in MSH6-mutated LS families, 8 out of 9 affected women developed EC (in addition to CRC in 4 of them). The implication of MSH6 in the tumorogenesis of affected carriers is being assessed at a tumoral level: twelve tumors from different patients have been tested by MSH6 immunohistochemistry, and except for an inconclusive result, all show loss of MSH6 protein expression; similarly, 8 out of 10 analyzed tumors show microsatellite instability; and finally, until now, no loss of heterozygosity from the mutation has been found at tumoral level. To assess the relative risk that this highly frequent mutation (1/402) is conferring to develop LS-tumors, we will genotype around 200 CRC and 500 EC cases from French Canadian patients. Our results will increase the efficiency of molecular genetic testing for Lynch syndrome in the French Canadian population of Quebec. Also, careful clinical characterization of this founder mutation will lead to mutation-specific counseling and improved clinical care.

3504W

Whole-Exome Sequencing of Familial Aggregations of Radiation-Associated Meningiomas (RAM). *A. Pathak[1], R. Bruchim[2], D.R. Stewart[1], S. Sadetzki[2].* 1) NIH NCI Division of Cancer Epidemiology and Genetics, Rockville, MD; 2) Cancer & Radiation Epidemiology Unit, Gertner Institute, Israel.

Sporadic and radiation-associated meningioma are rare diseases in the general population, and familial meningioma occurs in (5-10%) of all cases. Our group has previously demonstrated that 11% of families with RAM have two to four first degree relatives who develop meningioma after exposure to radiation in childhood. However, the key genetic drivers of this ~25-fold increased cancer susceptibility have yet to be fully elucidated. We subjected 18 individuals from 6 RAM families to whole-exome sequencing. All individuals in the study were irradiated for tinea capitis. Five families had 2 affected individuals and 1 unaffected individual. One family had 1 affected individual and 2 unaffected individuals. The study population was derived from the Israeli Tinea Capitis (TC) cohort which included a group of 10,842 individuals treated during the 1950s with radiation therapy for TC. The sequencing revealed 42,860 non-synonymous variants. In our initial bioinformatics analysis, we implemented a custom PERL script to perform automated PubMed queries for the 706 genes of biological interest and the keyword 'meningioma.' This resulted in the identification of 16 variantsin genes associated with meningioma. Further investigation of this literature revealed that a missense mutation in C1D and a stop codon in UBAP1 (a protein involved in the ubiquitinization pathway) may be associated with RAM. Next, we filtered these variants based on disease status and ESP count (<0.5%). In addition to the stop codon in UBAP1, we also identified a stop codon in PTPN7, a protein tyrosine phosphatase. For missense mutations, we further filtered our variants based on having a polyphen-2 score of possibly damaging or probably damaging. We prioritized these variants based on the literature and based on occurrence in multiple families. We found 5 variants in all that occurred in several families. Specifically, we detected two damaging mutations in the RNA polymerase POL2RF and a single damaging variant in two families in a ubiquitinization gene UBQLN3. Further sequencing of these candidate genes in larger validation groups may elucidate the molecular mechanisms underlying the significant genetic predisposition to RAM. The fact that no single locus was found in these families may indicate that the mode of inheritance of familial RAM is based on the combined inheritance of several low-risk variants rather than a single high-penetrance gene.

3505T

Global differential expressions of isoforms of miRNA in retinoblastoma: correlation with level of expressed 3'-5'-exonucleases. *A. Ganguly[1], J. Leipzig[2], J. Richards-Yutz[1], J. Purrazzella[1].* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Bioinformatics Core Center for Biomedical Informatics The Children's Hospital of Philadelphia.

MiRNAs are short, 21-24nt, oligonucleotides that function as post-transcription regulators of gene expression. Dysregulation of miRNA expression plays an important role in cancer. Retinoblastoma (RB) is the most common intraocular malignancy of childhood. To understand the role of miRNAs in RB, we profiled the miRNA transcriptome of normal neonatal retina, two RB cell lines, WERI and Y79, and three matched retina/RB samples using next-generation sequencing on Illumina platform.

Members of the let-7 family of miRNAs were differentially expressed between normal retina and two RB derived cell lines when sequenced on GAIIx platform. Additionally, pervasive presence of length variations at the 3'-ends of miRNAs, specifically in let-7b, let-7i and miR-181b were observed. The number of reads corresponding to each miRNA was greater than 100 in any one sample. The proportion of canonical to variant miRNAs was significantly different between normal retina and the two RB cell lines. This data was validated by comparison with the sequence data obtained from three sets of matched retina and RB on the Illumina HiSeq platform. The data on let-7i, was compared to published data in 293T cell line and found to be similar.

It has recently been shown that nibbler, a 3'-5'exoribonuclease, mediates 3'-end processing of miRNA that results in miRNA diversity and stability in Drosophila. We searched for the expression of human homologs of 3'-5'exonucleases in the retina and retinoblastoma. The expression of EXD2, a 3'-5'exonuclease was statistically different between normal retina, retinoblastoma and two cell lines - WERI and Y-79. The differential expression of EXD2 correlated with the relative abundance of the canonical/variant miRNA and with the degree of differentiation/aggressive behavior of the retinoblastoma tumors.

3506F

MALAT1 is deregulated and co-expressed with CREBBP in the long non-coding transcriptome of childhood Acute Lymphoblastics Leukemia. *R. Vidal[1], C. Richer[1], JF. Spinella[1], V. Saillour[1], M. Ouimet[1], S. Langlois[1], P. Cassart[1], J. Healy[1], E. Bareke[1], A. Droit[3], D. Sinnett[1,2].* 1) Centre de recherche, CHU Sainte-Justine, Montreal, QC, Canada; 2) Département de Pédiatrie, Faculté de Médecine, Université de Montréal, Montreal, QC, Canada; 3) Centre de recherche du CHUQ, Université Laval, Laval, QC, Canada.

Long non-coding RNAs (lncRNAs) are capable of influencing diverse cellular processes through various modes of action including regulation of gene expression. Consequently, lncRNAs are deregulated in a number of human diseases including cancers. Using RNA-seq technology, we describe the long non-coding transcriptome of childhood pre-B acute lymphoblastic leukemia (ALL) and identify, for the first time, lncRNAs that regulate downstream gene expression and that could be involved in driving leukemic transformation. We sequenced total RNA from 56 patients from the Quebec childhood ALL cohort and found a set of 352 deregulated lncRNAs significantly co-expressed with 1713 coding genes involved in key signaling pathways, including Wnt, PPAR and NF-kappa B, as well as genes involved in p53-regulated cell cycle control. Moreover, childhood ALL-specific lncRNAs also appear to play an important role in RNA processing mainly through the spliceosome and RNA degradation. Among the lncRNA identified in childhood ALL, MALAT1, known to control cell proliferation by regulating expression of a number of oncogenes, was found to be co-expressed (spearman correlation above 0.9) with the transcriptional coactivator and histone acetyltransferase CREB-binding protein (CREBBP), a gene known to be associated with bad prognosis in ALL. Our data suggest that transcriptional regulation by lncRNAs could be an important mechanism in promoting and/or maintaining leukemia development and in the future may assist in biomarker development and even be used in RNA-based therapies to ultimately improve diagnosis and prognosis of ALL in children.

3507W

Prediction of GWAS-identified risk loci in breast cancer and correlated SNPs through mapped epigenetic phenomena. *P.S. Rajagopal[1], Q. Li[2], P. Kraft[1], M. Freedman[2].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Medical Oncology, The Center for Functional Cancer Epigenetics, Dana-Farber Cancer Institute, Boston, MA.

INTRODUCTION: The majority of loci identified from GWAS are located outside of known protein-coding regions. Projects such as ENCODE and GENCODE have begun epigenetic and non-coding RNA annotation of these regions. These databases have been used to associate GWAS findings en masse with putative function. However, this has been minimally explored for individual diseases, individual SNPs or predictive ability. Using breast cancer as an example, we correlated GWAS-identified risk loci with functional information from these databases to create a model that predicts a SNP's likely association with disease. **METHODS**: 76 index SNPs and 946 proxy SNPs (r^2=0.9) were selected based on the COGS breast cancer GWAS ($p \leq 10^{-7}$). These were matched to randomly selected non-GWAS SNPs by chromosome, minor allele frequency (MAF), r^2 and number of proxy SNPs. Information was collected on GRCh37.p12 position, MAF and presence(1)/absence(0) of a set of features: DNase I hypersensitivity, H3K4me3 histone modification and CTCF binding in MCF-7 breast cancer cells and human mammary epithelial cells (HMEC); RNA polymerase II binding in MCF-7; RegulomeDB score$\leq$4; interactions with promoters, enhancers and motifs from HaploReg; and presence in a transcript's coding region. We evaluated these elements for enrichment among GWAS-associated SNPs compared to the randomly selected SNPs. For each index SNP, binary counts were summed across all proxies such that values per SNP ranged between 0 and the total number of proxies for that SNP (sum). Variables were also created for any proxy having a trait (binary) and average across all proxies (average). A conditional logistic regression model was developed using forward selection ($p \leq 0.05$). **RESULTS**: Our final model included: RegulomeDB score $\leq$4 (binary) (OR=4.79, 95% CI:1.52-15.17), enhancers (sum) (OR=1.13, 95% CI:0.99-1.29), MCF-7 RNA polymerase II interaction (binary) (OR=9.02, 0.97-84.04) and SNP presence in transcripts (average) (OR=2.51, 95% CI=0.95-6.68). HMEC DNase I hypersensitivity (average) correlated closely with RegulomeDB score. We lacked enough information to evaluate individual RNA types, H3K4me3 or CTCF. **CONCLUSIONS**: We have demonstrated the feasibility of deriving a SNP-based predictor of association with disease based on genomic and epigenetic features enriched in known risk loci vs. random loci. This method synthesizes readily accessible information to bring GWAS findings to the post-GWAS era.
