Reduction limb defects have an estimated incidence of 1 in 1692 live births, with terminal transverse limb defects (TTLD) being the most common. Diagnosis to consider in patients with TTLD include: amniotic bands, teratogenic exposures, Adams Oliver Syndrome (AOS), Poland Anomaly, Moebious and Oromandibular-limb hypogenesis syndromes. Vascular disruption has been thought to play a major role in all of these disorders. We present an 11 year old boy of Italian descent with TTLD, hypotrichosis patchy alopecia suggestive of cutis aplasia, intellectual disability and brain malformations. We performed Proton AmpliSeq whole-exome sequencing with a trio design and prioritized variants in genes known to be associated with AOS (*ARHGAP31*, *RBPJ*, *DOCK6* and *EGOT*). No pathogenic variants were identified in these genes. Further analysis of the sequence data revealed a *de-novo* variant in the *ACVR1* gene (c.983G>A; p.G328E) that resides in a well-conserved glycine residue in the protein kinase domain of ACVR1. Mutations in *ACVR1* have been previously associated with Fibrodysplasia Ossificans Progressiva (FOP), a syndrome characterized by heterotopic ossification of soft tissues. Most patients with FOP carry the same mutation in the glycine-serine rich domain (c.617G>A; p.R206H), have normal intelligence and great toe malformations. Only 3% of cases of FOP have atypical forms, and only 4 patients have ever been described with the G328E mutation. These patients present with TTLD, absent nails sparse scalp hair and cognitive impairment, supporting the causative role of this mutation. In addition the 5 other patients with atypical FOP and TTLD reported to date share mutations within the protein kinase domain (p.G328W and p.G328D). We analyzed the molecular pathways disrupted in AOS and postulate that the Cdc42/Rac1 regulator (*ARHGAP31* and *DOCK6* genes) and the Notch pathways (*RBPJ*) converge in a common signaling route that is critical for vasculogenesis. Activating mutations in ACVR1 in endothelial cells have been shown to cause endothelial-to-mesenchymal cell fate transition, which could result in abnormal vascular development. Together, this data suggests that the original theory of vascular injury and impaired arterial angiogenesis in AOS and TTLD is still valid. With this report, we expand the diagnostic spectrum of TTLD to include atypical mutations of ACVR1 and suggest a unifying pathophysiologic mechanism linking vascular disruption events to single gene mutations.

2685M

A novel homozygous mutation in FGFR3 causes tall stature, severe lateral tibial deviation, scoliosis, hearing impairment, camptodactyly and arachnodactyly. *S.A. Temtamy[1], P. Makrythanasis[2], M.S. Aglan[1], G.A. Otaify[1], H. Hamamy[2,3], S.E. Antonarakis[2,3].* 1) Clinical Genetics Department, Centre of Excellence for Human Genetics, Human Genetics & Genome Research Division, National Research Centre, Cairo, Egypt; 2) Department of Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 3) Service of Genetic Medicine, University Hospitals of Geneva, Geneva, Switzerland.

Most reported mutations in the FGFR3 gene are dominant activating mutations that cause a variety of short-limbed bone dysplasias including achondroplasia and syndromic craniosynostosis. We report the phenotype and underlying molecular abnormality in two brothers, born to first cousin parents. The clinical picture is characterized by tall stature and severe skeletal abnormalities leading to inability to walk, with camptodactyly, arachnodactyly and scoliosis. Whole exome sequencing revealed a homozygous novel missense mutation in the FGFR3 gene in exon 12. The variant is found in the kinase domain of the protein and is predicted to be pathogenic. It is located near a known hotspot for hypochondroplasia. This is the first report of a homozygous loss-of-function mutation in FGFR3 in human that results in a skeletal overgrowth syndrome.

2686T

Longitudinal observation of clinical and radiological findings in a patient with Spondyloepimetaphyseal dysplasia with joint laxity, leptodactylic type caused by a heterozygous mutation in KIF22. *B. Tuysuz[1], S. Yilmaz[2], T. Erener-Ercan[1], C. Celen[2], K. Bilguvar[2], M. Gunel[2].* 1) Cerrahpasa Medical School, Department of Pediatric Genetics, Istanbul University, Istanbul, Turkey; 2) Department of Neurosurgery, Program on Neurogenetics, Yale School of Medicine, New Haven, Connecticut, USA.

Spondyloepimetaphyseal dysplasia with joint laxity, leptodactylic type (SEMDJL2), is a rare disorder, and characterized by postnatal short stature, midface hypoplasia and generalized ligamentous laxity. Radiological hallmark includes severe involvement of the epiphysis and the slender appearance of the metacarpals and phalanges. Recently, heterozygous missense mutations in KIF22 gene was reported as the underlying cause in SEMDJL2. The aim of the study was to evaluate of radiological and clinical findings of SEMDL2 during follow-up of a female patient. Evolution of the clinical and radiological findings of the patient from the age of 2 years and 9 months to 11 years was recorded. KIF22 gene was analysed by using whole-exome sequencing. We identified a single nucleotide de novo p.Pro148Leu mutation in KIF22 gene. The patient had postnatal short stature, midface hypoplasia, hip dislocation and generalised laxity of the joints. Walking difficulty due to knee subluxation and bilateral severe genu valgum became prominent after 3.5 years of age. Short stature became evident gradually with increasing age and height was at -3.6 SD at 11 years. Small epiphyses with delayed maturation, metaphyseal vertical striations at the distal metaphysis of femur were observed on initial radiographs. The slender metacarpals and proximal phalanges, progressive degeneration of epiphyses and narrowed epiphyseal plates on both wrist and knees became more prominent after 7 years. In conclusion typical radiological findings became apparent after early childhood. SEMDJL2 should be considered in a child who has short stature with joint laxity and midface hypoplasia.

2687S

Novel mutation in CLTC associated with multiple malformations and developmental delay. *J. DeMari[1], R. Miller[1,3], S. Tang[2], J. Nimeh[3], R. Lebel[1,3].* 1) Section of Medical Genetics, SUNY Upstate Medical University, Syracuse, NY; 2) Ambry Genetics, Aliso Viejo, CA; 3) Division of Pediatrics, SUNY Upstate Medical University, Syracuse, NY.

This female was large for gestational age at 35 weeks, delivered to a 27 year old primigravid Caucasian whose pregnancy was complicated by pre-eclampsia. Neonatal period was notable for hypoglycemia, apnea, bradycardia, hyperbilirubinemia, grade I intraventricular hemorrhage, subdural hematoma, laryngomalacia, hypotonia and feeding difficulties. She presented in the emergency department at 5 months of age with lethargy, emesis and MRI revealing progressive ventricular enlargement with cerebral atrophy; VP shunt was placed promptly. Etiology of hydrocephaly was unknown. She has central apnea and hypothyroidism. Vitamin-K dependent clotting factor deficiency (VKCFD1) was diagnosed, and is now under good control with high dose vitamin K supplementation. At 18 months of age, she was diagnosed with a neuroblastoma. She has numerous minor dysmorphic features. At two years of age, the patient has global developmental delays and nystagmus. Karyotype and oligo-microarray were normal. Whole exome genomic analysis was undertaken. Mutations in 9 genes were identified (14 mutations), and these genes underwent medical review at Ambry Genetics. A de novo, frameshift mutation resulting in a truncated protein was identified in the CLTC gene. CLTC encodes clathrin heavy chain 1 (CHC1), one of the components of clathrin, which serves as the vesicle coat protein involved in intracellular trafficking and endocytosis. Mutations in CLTC have not been previously identified in human disease. However, CLTC is expressed at high levels in the brain, and it has been shown that inactivation of CHC1 in rat and fruit fly models prevents the recycling or release of vesicles in the pre-synaptic terminal. Mutations in CLTCL1, the second member of the Clathrin Heavy Chain family, have been associated with neurological disease: seizures, intellectual disability, autism and schizophrenia. Patients with a deletion of 17q23.1, including CLTC, have been reported with microcephaly, developmental delay, and growth retardation. A single patient with non-syndromic hydrocephalus has been reported with a duplication overlapping the CLTC gene. We propose that this mutation in the CLTC gene is the cause of neurological disease in this patient.

2688M

Two cases of lissencephaly with marked hydrocephalus caused by *TUBA1A* mutation. *N. Ishihara[1,2], S. Yokoi[2,3], H. Yamamoto[2], J. Natsume[2], M. Tsutsumi[3], T. Ohye[3], M. Kato[4], S. Saitoh[5], H. Kurahashi[3].* 1) Dept Pediatrics, Fujita Health Univ Sch Med, Toyoake, Japan; 2) Dept Pediatrics, Nagoya Univ Grad Sch Med, Nagoya, Japan; 3) Div Molecular Genetics, ICMS, Fujita Health Univ, Toyoake, Japan; 4) Dept Pediatrics, Yamagata Univ Faculty Med, Yamagata, Japan; 5) Dept Pediatrics and Neonatology, Nagoya City Univ Grad Sch Med Sci, Nagoya, Japan.

Objective: *TUBA1A* encoding α-1a tubulin is one of the genes responsible for lissencephaly (LIS). Despite of wide spectrum of phenotypes associated with *TUBA1A* mutations, pathophysiology underlining the severity is still under discussion. Here we present two cases of LIS with marked hydrocephalus, the most severe phenotype of the spectrum, to clarify the function of mutated protein. Subjects and methods: Case 1 is a 2-year-old boy. Ventricle dilation was pointed out in fetal period. After birth, he was diagnosed as LIS. He had severe developmental delay with quadriplegia, but he had social smile and he could breathe and swallow by himself. At the age of 8 months, he began suffering from West syndrome, and visited our pediatric neurology office. Case 2 is a 3-year-old girl with marked hydrocephalus pointed out in fetal period. After birth, hydrocephalus rapidly progressed to become hydranencephaly, with cerebellar and brainstem hypoplasia. She did not have either spontaneous breathing or swallowing reflex, necessitating mechanical ventilation and gastrostomy for survival. Both patients were subject to exome sequencing for diagnosis. Results: Case 1 had c.74G>T (p.C25F) missense mutation in exon 2 of *TUBA1A*, and case 2 had c.190C>T (p.R64W) in exon 2 of *TUBA1A*. Both mutations were confirmed by Sanger sequencing. Mapping of the mutations on to 3D structure of microtuble complex showed both C 25 and R63 were not located at the contact surface of the tubulin interaction. Discussion: According to the spectrum of phenotypes associated with *TUBA1A* described by Kumar, case 1 is classified in group 4, most severe type of LIS, and case 2 is much more severe than those of group 4. Microtubules are polymers comprising tandem repeats of α/β tubulin heterodimers which assemble to form a sheet of longitudinal protofilaments, and lateral interactions between neighboring protofilaments cause the sheet to close, thereby forming the microtubule body. Lateral interactions allow microtubules to curve and bend without breaking. Microtubules are arranged in neuronal dense network, so lateral interactions may play an important role for maintaining structural integrity of microtubules especially in neurons. C25 and R64 are predicted to be associated with lateral interactions and mutations in the residues caused most severe phenotype, indicating the disruption in lateral interactions of tubulins may cause extremely severe malformation of the brain.

2689T

Comprehensive clinical characterization of VCP associated multisystem proteinopathy. *V.E. Kimonis[1], A. Surampalli[1], M. Khare[1], M. Wencel[1], C. Nguyen[2], S. Wigal[2], S. Graf[3], A. Wang[4], S. Donkervoort[1,6], M. Milad[1], T. Mozaffar[4], V. Caiozzo[5].* 1) Pediatrics, UC Irvine School of Medicine, Irvine, CA; 2) Child Development Center, Pediatrics, University of California, Irvine, CA; 3) Department of Pediatric Exercise Medicine, University of California, Irvine, CA; 4) ALS and Neuromuscular Center, University of California, Irvine, CA; 5) Department of Orthopedics and Physiology & Biophysics, University of California, Irvine, CA; 6) National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD.

VCP disease, also called multisystem proteinopathy is characterized by hereditary inclusion body myopathy with Paget's disease of bone and frontotemporal dementia (FTD) and other less common varied phenotypes including amyotrophic lateral sclerosis, Parkinson's, and cardiomyopathy,. TDP43 and ubiquitin positive inclusions are seen in affected tissues. We studied 41 individuals (24 affected/ 5 presymptomatic carriers/ 12 unaffected; M18/ F23, mean ages 50.8, 44.9, 49.7 y. respectively) in 8 families harboring three missense mutations, R155H, R155C and R155P; 14 with myopathy, 8 with myopathy and Paget's disease and 2 also with FTD. Average age of onset for myopathy and Paget's disease was 42.47 y. and 37.28 y. respectively. Functional capacity was measured using IBM Functional Rating Scale (IBMFRS), Fatigue Severity Scale (FSS), 6 minute walk test (6MWT); motor function by handheld dynamometry and MRC (Medical Research scale) scores. The mean IBMFRS scores for affected, carriers and unaffected relatives was 28.42±10.37, 38.25±2.36 and 39.83±0.40 (P=.01); MRC scores for all muscle groups was 203.47±64.11; 273.5±9.14; 279.50±1.0 respectively (P=.01) and the Fatigue score was 44.26±13.86; 34.50±24.77; 25.71±13.31 (P=.01 respectively). There was significantly reduced muscle strength in flexors of upper limbs (shoulder & elbow) and lower limbs (hip, knee and ankle); and extensors of knee equally on right and left limbs of affected group, however the strength in the carriers was similar to the unaffected relatives. There was a trend for lower average scores for 6MWT was in affected individuals when compared to carriers and unaffecteds. Spirometry revealed mean scores for FEF25-75% were found out to be significantly lower in affected when compared to controls (2.35±1.0; 4.4 ±0.14, 3.36±1.0, P=.03 for affected group) indicating the early involvement of small airways. Our data also showed that IBMFRS, fatigue scale and MRC scores associated with motor function alongwith FEF25-75% showed correlation and could be used to monitor the progression of respiratory and motor involvement in VCP disease. Early recognition of respiratory muscles involvement, using the functional rating scales could allow an early intervention in VCP patients. This study represents the most comprehensive evaluation of individuals with VCP disease to date which will help establish baseline studies for future clinical trials in this underserved population.

Identification of a novel variant in TMEM67 gene responsible for JBTS6 by whole exome sequencing. *A. Najmabadi[1], M. Hosseini[2], Z. Fattahi[2].* 1) University of California, San Diego, San Diego, CA., Select a Country; 2) Genetic Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Joubert syndrome (JBTS) is a clinically and genetically heterogeneous disorder with autosomal recessive pattern of inheritance. The disorder is characterized by cerebellar hypoplasia, intellectual disability (ID), ataxia and oculomotor apraxia. Other clinical features include retinal degeneration, renal anomalies, hepatic fibrosis, and skeletal involvement. The hallmark of JBTS is a radiological pattern in magnetic resonance imaging (MRI), named "molar tooth sign". In 2007 Baala et al. identified a new form of Joubert syndrome designated JBTS6 with a causative mutation in the TMEM67 gene. Until now only 5 mutations in this gene have been identified as responsible for JBTS6. Here, we are reporting an autosomal recessive Iranian family with novel mutations in the TMEM67 gene. This family has two-affected child, one whom has profound ID, seizure, strabismus, and renal failure while the other child only shows signs of ID. Exome sequencing was performed for one of the probands and we were able to identify a number of variants. Following in silico analysis and checking our variant with 300 population specific controls, two candidate pathological changes remained; of which only one of these changes co-segregated in the family. Upon MRI examination of the affected boy, molar tooth sign was observed. We can conclude the missense changes in TMEM67 gene are responsible for Joubert syndrome in our family. Underlying causes of ID remain unknown in many cases because of clinical and genetic heterogeneity; therefor exome sequencing is an effective and helpful technique in detection of de novo mutation in this type of disorders. This approach results in more precise genotype-phenotype correlation and clinical diagnosis.

Truncating mutation of NFIA causes a brain malformation and urinary tract defect. *Y. Negishi[1], A. Hattori[1], K. Mizuno[2], I. Hori[1], N. Ando[1], F. Miya[3], T. Tsunoda[3], N. Okamoto[4], M. Kato[5], M. Yamasaki[6], Y. Kanemura[7,8], K. Kosaki[9], S. Saitoh[1]*. 1) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Science, Nagoya, Japan; 2) Department of Nephro-Urology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 3) Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 4) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 5) Department of Pediatrics, Yamagata University School of Medicine, Yamagata, Japan; 6) Department of Neurosurgery, Takatsuki General Hospital, Osaka, Japan; 7) Division of Regenerative Medicine, Institute for Clinical Research, Osaka National Hospital, National Hospital Organization, Osaka, Japan; 8) Department of Neurosurgery, Osaka National Hospital, National Hospital Organization, Osaka, Japan; 9) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan.

Chromosome 1p32-p31 deletion syndrome (OMIM #613735) involving the NFIA gene is characterized by corpus callosum hypoplasia or defects, hydrocephalus or ventricular enlargement, and urinary tract defects. Here, we report on the first case complicated by brain malformation and urinary tract defects observed with a truncating mutation in the NFIA gene. This male patient was born to healthy Japanese parents. Callosal agenesis had been suspected from the 28th gestational week. The boy was born by caesarean section on the 41st gestational week due to enlargement of the head circumference and post-term pregnancy. His birth weight was 3180g (+0.4SD), with a head circumference of 38.2cm (+3.3SD). Head MRI on the 3rd day of life revealed multilocular glioependymal cysts, ventricular enlargement, and callosal agenesis. Regarding his developmental milestones, he started walking without support at 1 year and 3 months. He was observed speaking meaningful words at 2 years, with a slight delay in language. Although sharp waves in the frontal head area were detected in EEG at 11 months, epileptic seizures have not been observed to date. Voiding cysturethrogram performed at 5 years of age showed bilateral grade IV vesicoureteral reflux. We performed whole exome sequencing on the proband and his parents, and identified a frameshift mutation (c.1093delC; p.P365fs) in the NFIA gene, which is absent in his parents, indicating that the mutation occurred de novo. Lu et al. reported 5 patients with balanced translocations or interstitial deletions of chromosome 1q31-q32 involving the NFIA gene. Recently, Rao et al. reported a case exhibiting a similar phenotype with an intragenic deletion of the NFIA gene confirmed by CGH microarray. This is the first report, to our knowledge, of a single nucleotide deletion (frameshift mutation) in the NFIA gene associated with brain malformation and urinary tract defects, confirming that the NFIA gene plays a fundamental role in development of brain as well as in urinary tract.

2692T

***De novo* 109 kb microdeletion of *MED13L*: report of a new patient with developmental delay, facial abnormalities and hypotonia.** *E.A. Repnikova[1,3,4], C.E. Lawson[2,4], S.D. Fiedler[1], J.M. Joyce[1], P.V. Thakor[1], L.D. Cooley[1,3,4], H.H. Ardinger[2,4]*. 1) Pathology Dept, Children's Mercy Hospital, Kansas City, MO; 2) Pediatrics Dept, Children's Mercy Hospital, Kansas City, MO; 3) Pathology Dept, University of Missouri-Kansas City Medical School, Kansas City, MO; 4) Pediatrics Dept, University of Missouri-Kansas City Medical School, Kansas City, MO.

The MED13L gene is one of the subunits of the large mediator complex that functions as a transcriptional coactivator for most RNA polymerase II transcribed genes and encodes a primary transcript of ~319 kb in size. MED13L is highly expressed in the brain, heart, skeletal muscle, kidney, placenta, and peripheral blood leukocytes. Missense mutations in *MED13L* have been linked to transposition of the great arteries and non-syndromic intellectual disability. Deletions in *MED13L* have been recently proposed to result in a distinct syndromic phenotype consisting of motor and speech delay, moderate intellectual disability, hypotonic open-mouth appearance and facial dysmorphism. Only three cases with various size deletions (17 kb (exon 2), 41 kb (exons 6-20) and 115 kb (exons 3 and 4) in *MED13L* have been recently reported. In this study, we performed molecular and clinical characterization of a patient with an approximate 109 kb *de novo* deletion of exons 5 through 31 of *MED13L* detected by oligonucleotide array comparative genomic hybridization. The patient is the third child of healthy non-consanguineous parents born at 39 weeks gestation after a pregnancy complicated by polyhydramnios. At the age of 2 years, she had mild hypotonia, wide-based gait, drooling, motor and speech delay, and dysmorphic features that included triangular face with tall forehead, sparse scalp hair (especially on the sides), extra subcutaneous tissue over glabella, sparse lateral brows, columella extending below alae nasi, prominent chin, and mildly uplifted ear lobes. Brain MRI showed nonspecific gliosis. At ages 4 and 6 years, she continued to have delays and poor balance. She had an excessive appetite with height and weight in the 90th percentile. Physical exam did not identify cardiac concerns. Similar to the previously reported cases, our patient has moderate intellectual disability, distinctive facial dysmorphism and hypotonia. However, she lacks cardiac anomaly, a phenotypic feature reported in cases with *MED13L* missense mutations and two cases with deletions of exon 2, 3 and 4. This observation supports the hypothesis recently proposed by van Haelst et al. that the cardiac phenotype may have reduced penetrance. The expression of cardiac phenotype may also be dependent on the type of mutation and its location within the *MED13L* gene. Our study thus adds to the increasing body of cases describing the existence of the novel *MED13L* haploinsufficiency syndrome.

2693S

Novel gene mutation in Schimmelpenning syndrome (nevus sebaceous syndrome). *Y. Kuroda[1, 2, 5], I. Ohashi[1], T. Naruto[1], Y. Enomoto[1], N. Okamoto[3], T. Niihori[4], Y. Aoki[4], K. Kurosawa[1]*. 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 2) Department of Pediatrics, University of Tokyo, Tokyo, Japan; 3) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Japan; 4) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 5) Department of Epigenetics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan.

We have identified a novel causative gene for Schimmelpenning syndrome. Schimmelpenning syndrome is a rare neurocutaneous disorder characterized by craniofacial nevus sebaceous with central nerve system, ocular, or skeletal abnormalities. Nevus sebaceous represents yellowish, waxy skin lesion and can undergo neoplastic degeneration in 24% in cases. Somatic mutations of HRAS and KRAS have been reported in patients of nevus sebaceous and Schimmelpenning syndrome. The proposita had nevus sebaceous at right frontal and vertex robe, angioma of the right postauricular skin, and bilateral preauricular tags. Ocular examination revealed retinal coloboma and macular hypoplasia of right eye. Head MRI revealed polymicrogyria and hemimegarencephaly of the right robe and bilateral cerebellopontine lipoma. She had also developmental delay and seizure. No mutation was detected by direct sequencing of exon 1 of HRAS in the nevus. Patient's sample from nevus was sequenced by MiSeq (Illumina Inc., San Diego, CA) by 121 bp pair-end reads, after the enrichment with TruSight Tumor. TruSight Tumor (Illumina Inc., San Diego, CA) was designed for targeted next-generation sequencing for 26 oncogenes and tumor suppressor genes, covering all coding regions, in total, 21 kb. Deep panel sequencing (average coverage of 15896) detected novel mutation of RAS-MAPK pathway gene with the nevus, but not with the lymphocyte, indicating postzygotic mutation. The mutation has been reported as the recurrent mutation in other neurocutaneous disorder. RAS promotes cell growth through activation of the mitogen-activated protein kinase (MAPK) signal transduction pathway. Activating mutations in the RAS-MAPK signaling pathway play a pivotal role in cancer-predisposition shown in epidermal nevus syndrome.

2694M

Neurofibromatosis type 1 and Optic Gliomas. *E. Parkhurst, S. Abboy.* Dept Genetics, Kaiser West Los Angeles, Los Angeles, CA.

Introduction: Neurofibromatosis type 1 (NF1) is a common autosomal dominant disorder that affects approximately 1 in 3,500 people. One of the most common tumors in children with NF1 is optic glioma with reported incidences ranging from 5-30%. Controversy surrounds the recommended frequency of eye exams and neuroimaging in asymptomatic individuals with NF1.

Methods: We queried the Southern California Kaiser Permanente electronic medical record database (Clarity) to find patients diagnosed with NF1 and seen in Opthalmology to determine the incidence of optic glioma. Medical records showing a diagnosis of optic glioma were reviewed.

Results: 708 patients under 21 years-old have a diagnosis of NF1 in the Southern California Kaiser system. 347 of these patients were seen in the opthalmology department and included in the study. Of the 347 with an opthalmology exam, 30 (8.6%) had a diagnosis of optic glioma. Average age of diagnosis was 5 yrs; the youngest was diagnosed at age 18 months and the oldest was diagnosed at 12 yrs. 30% (9/30) of patients with optic glioma required treatment other than corrective lenses; two patients had surgery alone and seven had chemotherapy. Treated patients had an age of diagnosis ranging from 19 months to 10 yrs. The youngest treated patient was asymptomatic and had 10 weeks of chemotherapy before 2 yrs. 60% (18/30) of patients found to have an optic glioma on MRI presented with symptoms (vision loss, proptosis, precocious puberty, etc.) and 40% (12/30) were asymptomatic. 63% (19/30) of the gliomas were bilateral; 23% (7/30) right sided and 13% (4/30) left sided. 53% (16/30) of the gliomas involved the optic chiasm. The four patients diagnosed with precious puberty all had chiasmal gliomas and were treated with chemotherapy.

Discussion: Current standards of care for children with NF1 include annual ophthalmologic examination, especially for children <6 years of age. Baseline MRI to detect asymptomatic optic glioma is not warranted. Our findings show that most optic gliomas are asymptomatic and never require treatment. Children with vision changes or precious puberty are most likely to require treatment such as surgery or chemotherapy, although very young asymptomatic children may have actionable gliomas as well.

2695T

Genetic heterogeneity in Van der Woude syndrome. *P. Kumari[1], A. Ali[2], SK. Singh[3], R. Raman[1].* 1) Cytogenetics Laboratory, Department. of Zoology, Banaras Hindu University; 2) Centre for Genetic Disorders, Banaras Hindu University, Varanasi; 3) G. S. Memorial Plastic Surgery Hospital and Trauma Center, Varanasi, India.

Van der Woude syndrome (VWS; OMIM 119300), an autosomal dominant disorder, is one of the most common syndromic forms of cleft lip and palate with lower lip pits as additional phenotype. *IRF6* (OMIM 607199) is the foremost candidate gene in several populations. *WDR65* (OMIM 614259), *GRHL3* (OMIM 608317) and 17p11.2-11.1 have also been identified to be in linkage with VWS, showing locus heterogeneity. In earlier studies from India on several cases *IRF6* is not found to be associated with VWS. Here we present results from genomic studies in two VWS families having 8 and 11 affected individuals, respectively. Initial analysis of *IRF6* did not reveal any mutation in the total coding region, and no association with the polymorphism, rs642961, in the enhancer region. Genome-wide linkage study (GWLS) using Affymetrix 10K SNP microarray in one of the families resulted in 3 linked loci (chromosome #1: q31.3-q42.2, #16: q23.1-q24.4 and #18: q11.2-q21.2) which had a LOD score of 2.4. Since microsatellite marker-based linkage analysis from the 3 high LOD score regions did not narrow down the mapped region, NGS was performed for whole genome with paired-end read which obtained a novel mutation in *NOL4* (OMIM 603577) that could affect its function by creating target site for a micro RNA. In the second VWS family, a haplotype involving an intron and two regulatory regions of *IRF6* co-segregated with the affected family members. *IRF6* haploinsufficiency being the major cause of VWS, its expression level was checked in blood of the affected and unaffected members of the family. Compared with the normal haplotype, *IRF6* expression was 2.27 fold lower in the risk haplotype. In silico analysis discovered a putative repressive transcription factor that would bind to one of the variants in the risk haplotype. Thus we not only identify a novel candidate gene (*NOL4*) but find a novel haplotype in *IRF6* as causal factor for VWS.

2696S

EXOMIC SEQUENCING AND MOLECULAR ANALYSIS OF IRF6 GENE IN PATIENTS WITH VAN DER WOUDE SYNDROME OR FAMILIAR HISTORY OF CLEFTING IN PATIENTS FROM SMILE BOGOTA COLOMBIA. *L. Patino[1], I. Briceno[2,3], j. martinez[2], D. mosquera[3].* 1) Bogota, Colombia; 2) Universidad de La Sabana; 3) Unmiversidad Javeriana.

The advent of technologies for massively parallel sequencing has resulted in thousands of sequenced genomes. The Van der Woude syndrome (VWS [MIM 119300]).is a skull - facial malformation characterized by the association of dimples or pits of the lower lip with cleft lip and / or palate. It represents the most common form of cleft lip and palate syndrome associated with two percent of the cases. With a prevalence in the general population of about 1 in 35,000 to 1 in 100,000. 3.4 The diagnosis can be confirmed by sequencing the IRF6 gene in 72% of cases. 5 However other mutations in different regions have been associated with the same clinical features. Among these mutations some have been described in the MSX1 gene, TP63 and FGFR120 -6. Moreover, recent studies have correlated clinical findings in patients with mutations in the gene GRHL3. 7.8 The description of the mutations of the Colombian population are of high importance since the Van der Woude syndrome is an entity that must be checked to give appropriate genetic counseling to the patient and family, as a vague genetic counseling will give them less than 50 % risk. Which is the proper genetic counseling due to its autosomal dominant inheritance. 2.3 In our study population coming from a reference center of cleft lip and palate treatment, we will be able to transfer our research to the Colombian population. In this population is where these mutations were sought by exomic sequencing. In patients with clinical suspicion of Van der Woude syndrome. We will transfer this data to a simpler and cheaper method of sequencing selected exons in which we have found a higher number of pathogenic mutations in our community. In individuals with a family history of cleft palate up to the second degree of consanguinity (this broader group represents another clinical spectrum of patients that do not fulfill the diagnostic criteria of Van der Woude syndrome). Performing the IRF6 gene sequencing sample of patients would get only 72 percent of the causal mutations of disease 5. But by exomic sequencing we should get better results to detect new mutations in different genes, which can be compared with the effectiveness of the technique IRF6 gene sequencing. So we can give a sufficient external validity to the results. Depending on the outcome, they will narrow or expand the range of mutations to be considered for the diagnosis of Van der Woude syndrome in our population.

WNT signalling and eye development disease genes. *I. Prokudin[1], V. Kumar[3], S. Davila[3], R. Jamieson[1,2].* 1) Eye Genetics Research Group, Children's Medical Research Institute; The Children's Hospital at Westmead; Save Sight Institute, Sydney, Australia; 2) Sydney Medical School, University of Sydney, Australia; 3) Genome Institute of Singapore, Singapore.

Microphthalmia and coloboma are rare genetic disorders often associated with other ocular abnormalities including anophthalmia, anterior segment dysgenesis and cataracts. A number of causative variants have been identified in genes including SOX2, OTX2, CH×10, BMP4 and RAX. However, for the majority of patients the disease genes are still not known. Low penetrance and variable expressivity are among the factors contributing to the low detection rate in microphthalmia and coloboma patients. In this study we performed whole exome sequencing on 4 affected individuals from two generations in an Australian family with autosomal dominant microphthalmia and coloboma. Heterozygous variants shared by all four affected family members were selected for the analysis. The variants were filtered based on their population frequency, pathogenicity prediction and conservation scores. Subsequently we prioritised variants in previously investigated animal disease genes and pathways known to be involved in eye disease. The top candidate variant, a frameshift deletion, was in a gene in the WNT signalling pathway. The variant was confirmed by Sanger sequencing and further processed for in vitro analysis using a WNT reporter assay in HEK293 cells. Our results indicate a role for the WNT signalling pathway in the microphthalmia and coloboma phenotype in humans.

A novel mutation in two patients with Fabry disease. *L. Wong-Ley, J. Medrano Valenzuela, A. Zambrano Parra.* Dept Gen, SSN-UAN, Tepic, Tepic, Nayarit, Mexico.

Fabry disease--a genetic disorder characterized by the accumulation of globotriaosylceramide in cell lysosomes resulting from an X-linked deficiency of α-galactosidase A activity--presents with multiorgan manifestations. We report, mother and daughter with Fabry disease, the mother of 36-year-old is asymptomatic and daughter 1 year old with neurological, renal, cardiac and ophthalmological disorders. At 4 months of age begins with proteinuria and recurrent infection of urinary tract, such as kidney problems. Later are noted cardiac (left ventricular enlargement and leaky heart valves), gastrointestinal (abdominal cramps, frequent bowel movements shortly after eating and diarrhea) and neurological (transient ischemic attacks) disturbances. Was performed gene sequencing (GLA HPLC/Tandem MS lyso-Gb3). The GLA gene was analysed by PCR and sequencing of the entire coding region and the highly conserved exon- intron splice junctions. Deep intronic mutations are not tested. The reference sequence of the GLA gene is: NM_000169.2. The biomarker lyso-Gb3 was measured by HPLC and tandem mass spectrometry. Was detected a previously unreported heterozygous variant in exon 6 of the GLA gene (c.968C>G p.P323R). It is located in a moderately conserved nucleotide and highly conserved amino acid position, with moderate physiochemical differences between the amino acids proline and arginine. Software analyses show inconsistent predictions: Mutation taster indicates this variant is probably damaging, whereas PolyPhen, SIFT and Align- GVGD predict toleration. The concentration of the biomarker lyso-Gb3 was normal. Our findings therefore suggest that the defective gene in the heterozygote has resulted from a new mutation. Genetic counselling is recommended for our patient and other relevant family members, also the detection of other possible asymptomatic carriers of the mutation.

2699S

Rasopathies and RAS/MAPK pathway disorders: Genetic screening of a cohort of 37 Tunisian children. *N. Abdelmoula[1], R. Louati[1], I. Trabelsi[2], S. Kammoun[2], M. Zenker[3], T. Rebai[1].* 1) Lab Histology, Univ Medicine, Sfax, Tunisia; 2) Dep Cardiology , Hedi Chaker Hospital, Sfax, Tunisia; 3) Institute of Human Genetics, University Hospital Magdeburg, Magdeburg, Germany.

Introduction: Recent studies have shown that a group of genetic disorders baptized RASopathies results from genes mutations of the Ras/MAPK pathway. These disorders include Noonan syndrome caused by mutations in PTPN11, SOS1, RAF1, KRAS, BRAF, NRAS and RIT1; Costello syndrome caused by activating mutations in HRAS; CFC syndrome caused by mutations in BRAF, MAP2K1/2 and KRAS; LEOPARD syndrome caused by mutations in PTPN11 and RAF1; Noonan-like syndrome caused by mutations in SHOC2 or CBL; Neurofibromatosis type I caused by haploinsufficiency of neurofibromin; NF-1 like syndrome caused by haploinsufficiency of SPREDI; Hereditary gingival fibromatosis caused by a mutation in SOS1; Capillary malformation-arteriovenous malformation caused by haploinsufficiency of RASA1 (p120 GAP). Because the underlying molecular mechanism for these syndromes is dysregulation of the Ras/MAPK pathway, the RASopathies exhibit numerous overlapping phenotypic features, including reduced growth, characteristic facial features, cardiac defects, cutaneous abnormalities, neurocognitive delay, and a predisposition to neoplasia, both benign and malignant. Materiel and Methods: Using HRM screening and bidirectional sequencing (of the whole gene or hot spot gene mutations) in all genes involved in Rasopathies (PTPN11, SOS1, RAF1, KRAS, BRAF, NRAS, RIT1, HRAS, BRAF, MAP2K1/2, KRAS, RAF1, SHOC2 or CBL), we have investigated a cohort of 37 Tunisian children. Results: A total of 12 mutations have been retrieved: 8 mutations of PTPN11, 2 mutations of SOS1, 2 mutations of Braf. No mutation of the new described gene; RIT1 was detected for negative Noonan patients. Neurobehavioral and dysmorphic features in patients with confirmed RASopathies developmental disorders have been compared to negative patients. Conclusion: Our findings indicate that mutations promoting dysregulation of the RAS-MAPK cascade mark an increased psychopathological risk and highlight that probably other new genes may be involved in Tunisian patients with mild, non-specific or atypical features. Using whole exome sequencing for molecular investigation of our negative patients will be a very powerful tool to infirm of confirm our hypothesis.

Prenatal and natal findings in a patient with Timothy syndrome type 1. *J.R. Corona-Rivera[1,2], R. Bloise[3], S. Priori[3], C. Napolitano[3], R. Nieto-García[2], E. Barrios-Prieto[4], L. Bobadilla-Morales[1,2], A. Corona-Rivera[1,2], E. Zapata-Aldana[2], C. Peña-Padilla[2], E. Chavana-Naranjo[2].* 1) Instituto de Genetica Humana "Dr. Enrique Corona-Rivera", Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Centro de Registro e Investigación sobre Anomalías Congénitas (CRIAC), Servicio de Genética y Unidad de Citogenética, División de Pediatría, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Hospital-Escuela, Guadalajara, Jalisco, México; 3) Molecular Cardiology Laboratories, IRCCS Fondazione Maugeri, Pavia, Italy; 4) Unidad de Medicina Materno-Fetal, División de Ginecología y Obstetricia, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Hospital-Escuela, Guadalajara, Jalisco, México.

Introduction. Timothy syndrome (TS) or long QT (LQT) syndrome 8 (LQTS 8) (MIM #601005), is a rare multisystemic disorder characterized by cardiac defects (corrected QT (QTc) intervals of 480-700 ms, atrioventricular (AV) block, and congenital heart defects), hand and/or foot syndactyly, facial dysmorphism, and neurodevelopmental abnormalities, with almost 25 cases molecularly confirmed of *CACNA1C* gene mutations. Here, we report a propositus with TS type 1 who prenatally showed fetal hydrops due to congenital AV block, as a previously unreported fetal presentation. **Clinical report.** He was the first child of a 23-year-old mother. During the first 4 months of pregnancy the mother was treated with amitriptyline. The ultrasound at 34 weeks of pregnancy found complete AV block, and fetal hydrops (hydrothorax, ascites, and hydrocele). Delivery was carried out via cesarean in the 36th week of gestation. Apgar scores were 2, 7, and 7 at 1, 5, and 10 minutes, respectively. Birth weight was 3,400 g (>90th centile), length was 48 cm (75th centile), and occipitofrontal circumference was 36 cm (>90th centile). Physical examination showed macrocephaly, telecanthus, frontal hemangioma, abdominal distention and bilateral hydrocele. He showed a "mitten" hand with cutaneous syndactyly of the second to fifth fingers, and synonychia; cutaneous syndactyly of toes, and talipes equinovarus of right feet. A chest radiograph in the first day confirmed a bilateral hydrothorax, mild ascites, and 11 pairs of ribs. Echocardiogram showed a PDA and a PFO. The ECG confirms 2:1 AV block, and LQTS with prolongation of the QTc interval of 570 ms. The ECG and echocardiography were normal in both parents. . The parents were negative for targeted mutation analysis on *CACNA1C*. At the age of 3 months developed multiple episodes of ventricular tachycardia and fibrillation related to a gastrointestinal infection, and unfortunately died. **Conclusions**. The fetal hydrops can be attributed to the rythmogenic abnormality inherent to its TS type 1 and probably, they were exacerbated by maternal exposure to amitriptyline, a tricyclic antidepressant that can cause prolongation of QT interval. Despite the fatal outcome for our patient, prenatal diagnosis of TS may help to prevent life-threatening events or early death in future patients, especially in developing countries where availability of therapies such as cardioverter defibrillator is very limited, or required time for its sponsorship.

2701T

Antithrombin deficiency in a founder population: different genetic architectures for types 1 & 2. *P. Salo[1,2,3], M. Puurunen[4], J. Corral[5], S. .Engelbarth[4], K. Javela[4], M. Perola[1,2,6].* 1) Public Health Genomics, Natl Inst Health & Welfare, Helsinki, Finland; 2) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 3) Hospital District of Helsinki and Uusimaa, Finland; 4) Hemostasis Laboratory, Finnish Red Cross Blood Service, Helsinki, Finland; 5) Centro Regional de Hemodonación, Servicio de Hematología y Oncología Médica, University of Murcia, Spain; 6) Estonian Genome Center, University of Tartu, Estonia.

Hereditary thrombophilia due to antithrombin deficiency (ATD) is a rare autosomal dominant disorder. It is caused by mutations in *SERPINC1* coding for antithrombin, a central anticoagulant molecule in the blood. The affected individuals have an approximately 30-fold increase in risk for thrombotic complications such as deep vein thrombosis and pulmonary embolism. ATD is designated as type 1 when both antithrombin levels and its activity are reduced. In type 2 deficiency the level of antithrombin is normal but its activity is diminished. We characterized the genetic background of ATD in a sample containing the majority of patients (N=221) diagnosed with ATD in Finland using capillary sequencing, Sequenom genotyping, and multiplex ligation-dependent probe assays. The two ATD types have remarkably different genetic architectures in the Finnish population. Type 1 is dominated by allelic heterogeneity with 28 distinct mutations explaining the disease in the 36 families with type 1 ATD. Following from the requirement of decreased antithrombin levels for diagnosis with type 1 deficiency, these patients carried either frameshift-causing or exon-spanning indels, or point mutations affecting splice-sites or introducing premature stop codons. In stark contrast, only 5 distinct mutations were found in the 48 families with type 2 deficiency. A single mutation (p.Pro73Leu) explained almost 90% of the type 2 deficiency cases. The genetic structure of the Finnish population is a result of the small number of founding individuals, relative isolation, and slow population growth until a rapid expansion to the current size of 5.4 million inhabitants. This has reduced the allelic heterogeneity of most Mendelian diseases in Finland, where one or a few major disease-causing mutations typically explain most of the cases for a given disease. These major mutations were present in the population at the onset of the population growth and increased in number together with the expanding population. In the case of ATD, this phenomenon is strikingly limited to only type 2 deficiency, possibly indicating historically stronger negative selection against alleles causing type 1 ATD. Given that both types are malignant and their phenotypic differences are not large, this may have interesting implications for association studies of disease traits, including the search for low-frequency variants associated with complex diseases.

2702S

Novel mutation in SCN3A associated with multiple anomalies and encephalopathy. *S. Jhaveri[1], R. Miller[2,4], A. Braxton[3], F. Xia[3], J. Zhang[3], P. Ward[3], R. Dracker[4], R. Lebel[2,4].* 1) William Carey College of Osteopathic Medicine, Massena, NY; 2) SUNY Upstate Medical University, Section of Medical Genetics, Syracuse, NY; 3) Baylor College of Medicine, Houston, TX; 4) SUNY Upstate Medical University, Division of Pediatrics, Syracuse, NY.

Our patient was born at term to an 18-year-old primigravid Caucasian woman after an uncomplicated pregnancy with no suspected teratogen exposures; the union is not known to be consanguineous. Pierre Robin anomaly was apparent at delivery. Respiratory compromise required intubation at 14 days, and she underwent mandibular distraction and tracheostomy. Her course was complicated by cryptogenic pediatric partial seizures and apneic episodes. At age 24 months, she is notable for microcephaly, poor ponderal and longitudinal growth, intellectual disability, optic atrophy and hypotonia. Brain MRI has shown pachygyria, hydrocephalus, and hypoplasia of the corpus callosum. She has had multiple admissions, including for recurrent skin infections and autonomic storming. Nutrition is provided through a G-J tube. Family history is significant for cleft palate in the mother. Oligo-microarray revealed no anomalies. Whole exome analysis was undertaken at Baylor College of Medicine. A heterozygous novel, de novo, missense, likely pathogenic variant was discovered in the SCN3A gene. SIFT and Polyphen 2 predict the variant to be damaging. This gene encodes a voltage-gated sodium channel. There is only one previous report of a patient with cryptogenic pediatric partial epilepsy with a heterozygous missense variant in SCN3A. However, mutations in the voltage gated sodium channels (SCN1A, SCN1B, SCN2A, SCN9A) have a well known role in epileptic encephalopathy. We propose that this novel de novo variant could be the cause of encephalopathy in this patient. Functional studies would help further evaluate this likely pathogenic variant.

2703M

Evidence of germline mosaicism in Fibrodysplasia Ossificans Progressiva post discovery of the ACVR1 gene. *M.B. Alcausin[1,2], F.S. Kaplan[3,4,5], E.M. Shore[3,4,6], M.P. Baluyot[1,2].* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines-Manila, Manila, Philippines; 2) Department of Pediatrics, Philippine General Hospital, Manila, Philippines; 3) Department of Orthopaedic Surgery, Perelman School of Medicine, The University of Pennsylvania, Philadelphia, Pennsylvania, USA; 4) Center for Research in FOP and Related Disorders, Perelman School of Medicine, The University of Pennsylvania, Philadelphia, Pennsylvania, USA; 5) Department of Medicine, Perelman School of Medicine, The University of Pennsylvania, Philadelphia, Pennsylvania, USA; 6) Department of Genetics, Perelman School of Medicine, The University of Pennsylvania, Philadelphia, Pennsylvania, USA.

Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant disorder of connective tissue characterized by malformed great toes and by progressive heterotopic endochondral ossification in characteristic anatomic patterns. The transformation of soft tissue into bone causes disfiguration and inhibition of normal motor functions, which in most cases, can be severely debilitating. Most affected individuals have FOP as a result of a spontaneous new mutation but the occurrence of germline mosaicism has previously been suggested in a report of a family with two affected siblings born to unaffected parents. We report the occurrence of FOP in a Filipino family with two affected brothers who have the classic FOP mutation ACVR1/ALK2 c.617G>A; R206H. Their parents are phenotypically and genotypically unaffected. This provides further evidence of the occurrence of germline mosaicism in this condition which impacts on recurrence risk assessment. In other autosomal dominant genetic disorders for which germline mosaicism has been established, recurrence risk for future pregnancies has been estimated at 5-6%. This is the first reported family with this genetic test result after the discovery of the causative gene, ACVR1.

2704T

Multi-systemic Involvement in NGLY1-related disorder Caused by Two Novel Mutations. *J. Heeley, M. Shinawi.* Department of Pediatrics, Division of Genetics and Genomic Medicine, Washington University in St. Louis School of Medicine, St. Louis, MO.

Background: NGLY1-related disorder is a newly described autosomal recessive condition characterized by neurological (global developmental delay, severe hypotonia, movement disorder, seizures or EEG, acquired microcephaly, diminished reflexes and nerve conduction abnormalities), hepatic (neonatal jaundice, elevated liver enzymes, fibrosis, intrahepatic cytoplasmic inclusions), ophthalmological (alacrima/hypolacrima, strabismus, chalazion, apraxia) findings and associated with dysmorphic features, constipation and scoliosis. The gene encodes an enzyme, N-glycanase 1 [MIM 615273], involved in deglycosylation of glycoproteins, an essential step in endoplasmic reticulum-associated degradation pathway. It was hypothesized that loss of function of NGLY1 causes accumulation of misfolded glycoproteins in the cytoplasm. The condition has been described so far in 8 patients. Methods: Clinical and molecular characterization of a proband with novel mutations in the NGLY1 gene detected via whole exome sequencing. The findings in the proband are compared with previously reported cases. Results: The proband is a 13-year-old boy with profound hypotonia and elevated transaminases diagnosed in infancy. Liver biopsy at age 1 year showed lipid accumulation with dilated endoplasmic reticulum. The patient exhibits severe global developmental delay and is nonverbal and non-ambulatory. He has severe scoliosis and osteopenia. He has acquired microcephaly after 10 months, involuntary movements, poor weight gain, muscle atrophy, absent reflexes, and seizures. He has had multiple procedures for lacrimal duct stenosis and strabismus and has intractable blephiritis. We also noted persistent hypocholesterolemia, which was not previously reported. Whole exome sequencing revealed two novel variants in the NGLY1 gene: a maternally inherited truncating mutation, c.347C>G (p.S116X), and paternally inherited splicing mutation, c.881+5G (p.IVS5+5G>T), predicted to abolish the splice donor site of exon 5. Neither change was previously reported in NHLBI. Conclusion: Mutations in the NGLY1 gene cause a severe, multisystemic but recognizable phenotype. This study along with previously reported cases suggests that targeted sequencing of the NGLY1 gene should be considered in patients with the typical combination of neurological, hepatic, and ophthalmologic findings. Our data reveal that osteopenia and hypocholesterolemia can be part of the phenotypic spectrum of NGLY1-related disorder.

2705S

Is SMN2 related to severity in Spinal Muscular Atrophy? : a case report. *PM. Hurtado, AI. Sanchez.* Ciencias Básicas de la Salud, Pontificia Univ Javeriana, Cali, Colombia.

Introduction: Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disease characterized by progressive degeneration and loss of the anterior horn cells in the spinal cord leading to progressive muscle weakness and atrophy. Incidence is 1 in 6,000 and carrier frequency is 1 in 35. It is caused in 96% of patients by homozygous absence of the survival motor neuron gene (SMN1). Copy number of SMN2 has been proposed to determine severity of the disease. SMA is classified by age of onset and severity of the disease. Case Presentation: This is a 15 years-old (y/o) male patient who was born at first gestation from non-consanguineous parents. Mother was 18 y/o. Patient started to have frequent falls and trouble walking up and down stairs at 4 years. Progressive muscular weakness was evident first in legs and then in arms. After that, he started to have difficulty to solid swallowing. At 6 y/o, patient was not capable of deambulate anymore. He has had presented respiratory failure in several opportunities, requiring hospitalization. He has a 13 y/o brother with similar phenotype but with symptoms starting after 4 y/o. Physical examination revealed generalized muscular hypotrophy, tongue twitching and knee retractions. Muscular biopsy showed muscular dystrophy. Spinal cord MRI evidenced left lumbar scoliosis and paravertebral muscle atrophy. MRI of the brain was normal as well as EKG. CPwK levels were mildly elevated. Polysomnography evidenced obstructive sleep apnea. Leg electromyography showed demyelinating axonal neuropathy. Quantitative PCR evidenced no copies of the SMN1 gene, but ≥ 3 copies of SMN2. Discussion: This individual is affected with SMA type III because onset was after age ten months and no copies of SMN1 were seen at molecular testing. It is known that SMN2 genes are capable to produce a protein identical to that of the SMN1 gene but at reduced capacity (10-20%). As a result, more than 3 copies of SMN2 are related to milder severity of the illness. Despite the anterior fact, muscular weakness in this patient was rapidly progressive and severity was significant. This case is also noteworthy because patient's brother quantitative PCR showed SMN1 exon 7 and 8 homozygous deletion. This SMN1 homozygous deletion is typically detected by demonstrating the absence of exon 7 (≈96% of SMA patients). Conclusions: Further studies are necessary to elucidate mechanisms of severity of the disorder and to promote development of new treatments.

2706M

Stargardt Disease (Juvenile Macular Degeneration), Clinical Analysis in Patients of the Colombian Population. *L.Ma. MORA[1,2], F.J RODRIGUEZ[2], M. VALENCIA[2], M.L TAMAYO[1,2].* 1) CLINICAL GENETICS, PONTIFICIA UNIVERSIDAD JAVERIANA, INSTITUTO DE GENÉTICA HUMANA, BOGOTA, COLOMBIA; 2) CLINICAL GENETICS, FUNDACION OFTALMOLOGICA NACIONAL (FUNDONAL), BOGOTÁ, COLOMBIA. M.D.

INTRODUCTION. Stargardt disease or Juvenile Macular Degeneration, initially described in 1909 by Karl Stargardt, is known as a nosological entity of autosomal recessive inheritance. It is the most frequent cause of macular degeneration in childhood, due to the accumulation of lipofuscin in the endothelium of retinal pigmentation and the limited energy exchange in the photoreceptors; clinically manifested as a progressive deterioration of visual acuity (VA), preserving the peripheral vision. It has been reported a global incidence of 1 per 10.000; however not local epidemiology is available in Colombia. RESULTS. 1. Ten patients had best corrected (VA) major 20/100. 2. 8 of the evaluated are in stage I/II. 3. Inverse correlation was found between foveal thickness and VA (Fig.3). 4. The symptoms start in the first two decades of life for 9 of the evaluated. 5. As the worldwide information, autosomal recessive mechanism of inheritance is the most frequent in the Colombians. 6. Night-blindness and reduced vision are the most common initial symptoms. DISCUSSION. Stargardt disease is a progressive disease, which affects individuals in the first decade of life. The clinical and paraclinical characteristics are unknown in Colombian population. We made a description of ten individuals in collaboration with the Instituto de Genética Humana at the Pontificia Universidad Javeriana and the Fundación Oftalmologica Nacional, it allowed us to establish for our population the most frequent symptoms, night-blindness and low vision with a slow progression. The majority of the patients are in stages I and II, this being compatible with a VA of major 20/100; with an average time of evolution of 20 years. The findings on the Optical coherence tomography (OCT) show reduced thickness and loss of photoreceptors in the macular area, which may be useful in the diagnosis of Stargardt disease, because strong correlation was found between the foveal thickness and visual function in patients in the sample.

2707T

Atrophic skin patches with abnormal elastic fibers, as a presenting sign of MASS phenotype associated with mutation in the Fibrillin-1 gene. *E. Reinstein[1], R. Bergman[2], J. Nevet[2], H. Shosany[2].* 1) Medical Genetics Inst, Beilinson Medical Center, Petach-Tikva, Israel; 2) Dermatology dept, Rambam Medical Center, Haifa, Israel.

Marfan syndrome (MFS) is a dominantly inherited disorder of connective tissue caused by mutations in the Fibrillin-1 (FBN1) gene. The most common skin finding in MFS is striae distensae. Particular individuals referred for suspicion of MFS whom do not completely fulfill the MFS diagnostic criteria are classified as having a MASS phenotype. The acronym represents the phenotype's apparent manifestations: a prolapsed Mitral valve, Myopia, Aortic root enlargement, Skeletal and Skin manifestations. Mutations in FBN1 have been shown to be associated in a few cases with MASS phenotype. Skin manifestations may be an important clue to the diagnosis of these disorders. We studied a case referred for unusual atrophic skin patches on the buttocks. Histopathology and electron microscopy demonstrated markedly abnormal elastic fibers. Consequent medical genetics evaluation led ultimately to the diagnosis of MASS phenotype, and to the discovery of an underlying FBN1 mutation. Though the clinical suspicion and diagnosis of MFS and related disorders are usually established by its main associated clinical features including the eye, skeletal and vascular involvement, clinicians should be aware of the associated skin manifestations, including unusual atrophic patches with abnormal elastic fibers that can sometimes be the first noted sign of the genetic disorder.

2708S

Congenital ophthalmoplegia: Dysinnervation, myasthenia or myopathy? Can genetics have an answer? *S. Shaaban[1,2,4,5,7,8], W. Chan[1,4,5,6,8], C. Andrews[1,4,5, 6,8], E. Engle[1,3,4,5,6,7,8].* 1) Department of Neurology, Boston Children's Hospital; 2) Department of Ophthalmology, Mansoura University, Egypt; 3) Department of Ophthalmology,Boston Children's Hospital; 4) F. B. Kirby Neurobiology Center, Boston Children's Hospital; 5) Program in Genomics, Boston Children's Hospital; 6) Howard Hughes Medical Institute, Chevy Chase, Maryland; 7) Dubai Harvard Foundation for Medical Research; 8) Manton Center for Orphan Disease Research, Boston Children's Hospital.

Congenital cranial dysinnervation disorders (CCDDs) are congenital, non-progressive, sporadic or familial disorders that result from developmental abnormalities of one or more cranial nerves/nuclei and are often characterized by abnormal eye, eyelid, and/or facial movements. Previous work in our lab has identified gene mutations that underlined a set of these CCDDs. In a subset of the patients we studied; the congenital fibrosis of extraocular muscle (CFEOM) was associated with a constellation of findings in other systems (e.g E410K TUBB3 syndrome in which patients in addition to CFEOM and facial palsy had developmental delay, vocal cord paralysis, stridor, tracheomalacia and abnormal EMG/NCS). Interestingly in a subset of syndromic patients presenting to us with CFEOM, facial palsy, gross motor delay, hypotonia, bulbar dysfunction, feeding problems and episodic apnea that were mutation-negative when tested for known CCDDs genes; recent work in our lab using next-generation sequencing (NGS) identified disease-causing mutations in four pedigree. We identified mutations in three genes known to cause congenital myasthenia (*CHRND, CHRNE* and *SCN4A*) in three pedigrees and mutations in *NEB* which causes Nemaline myopathy in the fourth pedigree. The mutations were two novel compound heterozygous missense mutations (c.308T>C; p.L103P and c.991C>T; p.L331F) in *CHRND* (cholinergic receptor, nicotinic, delta), a recurrent frameshift mutation (c.130dupG; p.P45Afs*2) in *CHRN*E (cholinergic receptor, nicotinic, epsilon), a novel missense mutation (c.2890C>T; p.V964I) in *SCN4A* (sodium channel, voltage-gated, type IV, alpha subunit) and two compound heterozygous missense mutations (c.18164T>C; p.M6055T and c.7441A>G; p.R2481G) in *NEB* (Nebulin). The overlap of phenotypes resulting from mutations in some of the CCDDs genes or those causing congenital myasthenia or congenital myopathies makes it challenging to differentiate between them at the clinical level. These results delineate a spectrum of genetic disorders that overlap phenotypically, yet can result from mutations in different genes disrupting any point from the nervous system, to the neuromuscular junctions to muscles' structure and/or function. NGS proves to be a powerful tool that could help physicians and geneticists reach a definite diagnosis when clinical findings are not as conclusive.

2709M

Chromosome deletion 11q13.1 involving deletion of the CLCF1 gene in a female with features of Cold-Induced Sweating Syndrome. *J.D. Weisfeld-Adams, K.E. Brown.* Department of Pediatrics, University of Colorado, Denver, CO.

The CLCF1 gene (cardiotrophin-like cytokine factor 1) is known to be implicated in some cases of autosomal recessive Cold-Induced Sweating Syndrome (CISS). CISS, a designation used synonymously with "Crisponi syndrome", is characterized by paradoxical sweating response, high-arched palate, scoliosis, facial weakness, prominent ears, feeding difficulties in infancy, hyperthermia, and velopharyngeal insufficiency or hypernasal speech. CLCF1 is a member of the glycoprotein 130 cytokine family and encodes cardiotrophin-like cytokine factor 1 (CLCF1). CLCF1 partners with cytokine receptor-like factor 1 (CRLF1) to form the CRLF1/CLCF1 protein complex, with CLCF1 mutations accounting for significantly fewer historical CISS cases than CRLF1mutations. The complex binds to ciliary neurotrophic factor receptor (CNTFR) and activates the Jak-STAT signaling cascade. CLCF1 is a potent neurotrophic factor, B-cell stimulatory agent and neuroendocrine modulator of pituitary corticotrophic function. Mutations in the CLCF1 gene may disrupt CNTFR signaling leading to disruption of sympathetic nervous system development, and resultant dysregulation of temperature homeostasis, manifesting as hyperthermia and pathologic sweating response. The CNTFR pathway is also implicated in motor neuron and skeletal development which may explain facial dysmorphology, facial weakness and skeletal abnormalities observed in some affected individuals. Here we report a 10 year old female with a history of frequent, unexplained fevers, lack of sweating with activity, feeding difficulties, short stature, scoliosis, subtle facial dysmorphism, and hypernasal speech. Chromosomal microarray analysis revealed a heterozygous de novo deletion at 11q13.3, of approximately 0.153 Mb in size and incorporating CLCF1. We believe this patient likely has a point mutation on the non-deleted CLCF1 allele. Research testing with sequencing of CLCF1 is currently underway. To our knowledge, this is the first CISS patient reported with a genomic rearrangement incorporating CLCF1.

2710T

Functional studies of *EZH2* histone methyltransferase activity in Weaver syndrome. *A.S.A. Cohen[1,2], D. B. Yap[3,4], J. Denny[5], S. M.E. Lewis[1,2,6], C. Chijiwa[1,6], M.A. Ramos-Arroyo[7], N. Gibson[1,2].* 1) Dept of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Child and Family Research Institute, Vancouver, BC, Canada; 3) Dept of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; 4) Dept of Molecular Oncology, British Columbia Cancer Research Centre, Vancouver, BC, Canada; 5) Centre for Molecular Medicine and Therapeutics, Vancouver, BC, Canada; 6) British Columbia Children's and Women's Health Center, Vancouver, BC, Canada; 7) Dept of Medical Genetics, Complejo Hospitalario de Navarra, Pamplona, Spain; 8) Medical Genetics Unit, Centro de Genética Médica Dr Jacinto Magalhães, Oporto Hospital Center, Porto, Portugal; 9) Instituto di Genetica Medica, Università Cattolica del Sacro Cuore, Policlinico Universitario Agostino Gemelli, Roma, Italy; 10) PH Génétique Clinique, Hôpital SUD, Rennes, France; 11) Center for Integrative Brain Research, Seattle Children's Hospital, Seattle, WA, USA; 12) Dept of Pediatrics, University of Washington, Seattle WA, USA; 13) Dept of Neurology, University of Washington, Seattle WA, USA; 14) Dept of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA.

In late 2011, we and others found that constitutional mutations in the epigenetic regulator *EZH2* (enhancer of zeste homolog 2) cause Weaver Syndrome (WS). WS is a rare congenital disorder characterized by generalized overgrowth, advanced bone age, intellectual disability, neuronal migration defects and susceptibility to various cancers. We are now investigating the link between *EZH2* mutations and the clinical features of WS. Normally, EZH2 acts as a histone methyltransferase in the polycomb-repressive complex 2 (PRC2), and silences transcription through methylation of histone H3 lysine 27 (H3K27). Somatic mutations of *EZH2* found in various cancers lead to enhanced trimethylation activity; thus, functional investigations can provide insights into the pathogenesis of WS.

Last year at ASHG (63rd annual meeting, 2013), I provided an update on our cohort, where 9 out of 35 individuals with Weaver-like phenotypes were found to have mutations in *EZH2*. Since then, we have identified a mutation in *EZH2* in one more patient in our cohort (currently 45 patients), as well as 2 mutations in *NSD1*, the Sotos syndrome gene.

At the time of my presentation, I also showed results of an *in vitro* functional assay which supported the hypothesis that WS is caused by loss-of-function mutations in *EZH2*. These findings suggested that EZH2 inhibitors being developed for cancer treatment may not be as effective in rare cancers associated with WS. As such, a more detailed investigation of our WS mutants was required. Our most recent results suggest that WS mutants may be classified into different groups based on variable degrees of loss-of-function, which could explain some of the variability in the observed phenotype and also suggests a need for different therapeutic approaches based on the mutation identified.

2711S

Cantu syndrome: Delineation of cardiovascular abnormalities in six affected individuals evaluated at a research clinic. *D. Grange[1], B. Kozel[1], G. Singh[1], M. Levin[1], P. Stein[2], C. Nichols[3].* 1) Dept Pediatrics, Washington University; 2) Dept Internal Medicine, Washington University; 3) Dept Cell Biology and Physiology, Center for the Investigation of Membrane Excitability Diseases, Washington University, St Louis, MO.

Cantu syndrome (CS) is associated with hypertrichosis, neonatal macrosomia, macrocephaly, craniofacial dysmorphic features, osteochondrodysplasia, edema and cardiovascular abnormalities including PDA, cardiomegaly, pericardial effusion and abnormal cerebral vasculature. CS is caused by heterozygous activating mutations in either ABCC9 or KCNJ8 which encode the regulatory SUR2 and Kir6.1 subunits, respectively, of the ATP-sensitive potassium channels (KATP). KATP channels formed from SUR2 and Kir6.1 subunits are prominent in cardiovascular tissues, and KATP activation in vascular smooth muscle results in decreased vascular contractility. Six individuals with CS were evaluated in the first Cantu Syndrome Research Clinic, included 4 females and 2 males ranging in age from 12-46 years of age. All patients had heterozygous mutations in ABCC9. Participants had cardiovascular testing including ECG, echocardiograms, 24 hour Holter monitoring with heart rate variability (HRV) assessment and pulse wave velocity testing via SphygmoCor. Blood pressures were below the 50th percentile for age for all participants, although none had orthostatic changes with positional change. They had full pulses with normal peripheral perfusion. Echocardiograms revealed cardiomegaly with enlarged ventricles. Left ventricular diastolic volumes were +3 SD from the mean. Cardiac mass was +2.5 SD from the expected values for age, gender and body surface area. Left ventricular systolic strain, a measure of cardiac contractility, was increased compared to age and sex matched normative values. Echocardiogram-derived cardiac output showed increased output when compared to controls. Pulse wave velocity was slow in the younger individuals, but average in the adults, suggesting a trend toward lax vasculature in childhood that becomes stiffer with age. Most participants showed peripheral edema. Although there was no clinical heart failure, overall, the findings were suggestive of a high output, hypercontractile state with low peripheral vascular resistance in the absence of hypertrohic cardiomyopathy. 12-lead ECGs showed a repolarization abnormality with inverted T-wave and flat ST segment in inferior leads in 4/6 patients. The Holter analysis revealed autonomic dysregulation manifested by increased sympathetic activity and decreased vagally modulated HRV in all participants. The oldest participant had extremely depressed HRV values. Cardiac function may deteriorate with age in patients with CS.

2712M

Exome sequencing reveals compound heterozygous mutations in *ATP8B1* in a *JAG1/NOTCH2* mutation-negative patient with clinically diagnosed Alagille syndrome. *C.M. Grochowski[1], R. Rajagopalan[1], A.M. Falsey[1], K.M. Loomes[1], I.D Krantz[1,2], M. Devoto[2,3], N.B. Spinner[1,2].* 1) The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) University La Sapienza, Rome, Italy.

Exome sequencing is helping to revolutionize genetic screening, as it permits unbiased testing, demonstrating erroneous clinical diagnoses. Alagille syndrome (ALGS) is an autosomal dominant disorder characterized by bile duct paucity and the presence of distinct facial features, cardiac findings, musculoskeletal malformations, and ocular abnormalities. Prior to genetic testing, ALGS was diagnosed clinically in individuals with bile duct paucity plus 3 of 4 secondary findings. Currently, 94% of ALGS patients with a clinically confirmed diagnosis have mutations detected in *JAGGED1 (JAG1)* and an additional 2% of patients have mutations in *NOTCH2*. We report a patient who presented with 4/5 features of ALGS including bile duct paucity, a cardiac murmur, posterior embryotoxon and facial features (high broad forehead, triangular face), leading to a clinical diagnosis of the disorder. Genetic testing revealed no mutations in *JAG1* or *NOTCH2*, warranting an expanded search for causal genes. Exome sequencing uncovered compound heterozygous mutations in the gene *ATP8B1*, previously reported to cause Progressive Familial Intrahepatic Cholestasis Type 1 (PFIC1), which has very limited overlapping clinical findings with ALGS. A splice-site mutation (c.3400+2;T>C) inherited maternally and a frameshift mutation (c.1889_1890insGTAAC p.His630fs) inherited paternally were detected and validated through Sanger sequencing. A similar splice site mutation has been previously reported in a patient with a clinical presentation similar to our patient, and a diagnosis of atypical PFIC1. We are investigating further clinical features within this patient to determine the consistency of a PFIC diagnosis versus an ALGS diagnosis. This work helps to delineate the phenotypic spectrum of Alagille syndrome and more precisely characterize clinical diagnostic criteria and avoid confounding diagnoses.

2713T

New dominant mutations in SF3B4 encoding an mRNA spliceosomal protein important in embryonic limb patterning underlie Rodriguez acrofacial dysostosis. *M.D. Irving[1,2], B. Dimitrov[2], D. Chitayat[3], J.I. Rodriguez[4], M.W. Wessels[5], M.A. Simpson[2].* 1) Department of Clinical Genetics, Guy's and St Thomas' NHS Foundation Trust, London, London, United Kingdom; 2) Division of Medical and Molecular Genetics, King's College, London, United Kingdom; 3) The Hospital for Sick Children, Toronto, Canada; 4) Department of Pathology, Hospital Universitario La Paz, Madrid, Spain; 5) Department of Clinical Genetics, Erasmus Medical Centre, Rotterdam, The Netherlands.

Acrofacial dysostosis syndrome of Rodriguez (RADS) (OMIM 201170) is a lethal condition comprising multiple congenital abnormalities. It is characterised by severe mandibular hypoplasia, upper limb phocomelia with oligodactyly, absent fibulae, cleft palate and microtia. Abnormal lung lobulation results in pulmonary hypoplasia and early neonatal demise. It was first reported by Rodriguez et al. who described three siblings with multiple congenital anomalies affecting the limbs, cardiovascular and neurological systems, and severe mandibular hypoplasia, resulting in lethal respiratory insufficiency. Thereafter five additional cases have been described in the literature expanding the clinical phenotype to include abnormal lung lobulation, absent fibulae, cleft palate and arhinencephaly. Given the occurrence in three siblings, RADS has been considered to be an autosomal recessive genetic condition. There are obvious similarities with RADS and other syndromes associated with severe mandibular hypoplasia, such as Nager syndrome (NS)(OMIM 154400) and Miller syndrome (OMIM 263750). Whilst there are clinical features to distinguish these conditions from RADS, such as eyelid colobomata and accessory nipples, there is clear phenotypic overlap, raising the possibility that RADS and NS are indeed allelic. Heterozygous loss-of-function mutations in SF3B4, encoding the mRNA spliceosomal protein Splicing factor 3B, subunit 4 that has a role in bone morphogenetic protein signalling in early embryogenetic limb patterning, have been shown to underlie NS. Recently a de novo mutation in SF3B4 exon 4 that is predicted to disrupt splicing was demonstrated in a patient with RAD. In this study, we obtained DNA samples for whole exome sequencing from four fetuses with RADS, including one originally described by Rodriguez et al., to investigate the underlying molecular basis and to explore the concept that there is both phenotypic and molecular overlap between this and other acrofacial dysostosis conditions. Results demonstrated two heterozygous frameshift mutations of SF3B4 in three of the four cases. In addition, inheritance studies failed to identify mutations in unaffected parents of one fetus, supporting new dominant inheritance and not recessive transmission, which will significantly influence genetic counseling. The clinical and molecular data will be presented, as well as a discussion of the role of SF3B4 mutations in causing this distinctive phenotype.

2714S

New case of a small AFF2 (FMR2) intragenic deletion associated to development delay causing a Fragile X E phenotype. *E. Pipiras[1], Ch. Beldjord[2], L. El Khattabi[3], B. Héron-Longe[4], B. Benzacken[1], A. Delahaye[1].* 1) AP-HP, Hopital Jean Verdier, Laboratoire d'Histologie-Embryologie-Cytogénétique, Hopital Jean Verdier, Bondy, France; 2) AP-HP, Hopital Cochin, Laboratoire de Biochimie et Génétique Moléculaire, Paris, France; 3) AP-HP, Hopital Cochin, Laboratoire de Cytogénétique, Paris, France; 4) AP-HP, Hopital Jean Verdier, Service de Pédiatrie, Bondy, France.

Fragile X E (FRAXE) disorder is an X-linked form of intellectual disability characterized by mild to moderate mental retardation associated with learning difficulties, speech delay, communication deficits, attention problems, hyperactivity and autistic behavior. The typical FRAXE phenotype is due to (CCG)n repeats expansions in the AFF2 gene which leads to silencing of the AFF2 gene. We describe clinical features and molecular characterization of an intragenic deletion of AFF2 gene in a 15 year-old boy born to non consanguineous parents. The patient was referred to genetics department for mild mental retardation, learning difficulties, speech delay and developmental delay. Usual analysis of (CCG)n repeat expansions in the AFF2 gene was normal. Chromosomal microarray analysis using whole genome HumanCyto-12 SNP (Illumina) array revealed a 60.3 kb intragenic deletion within AFF2 on Xq28 band. PCRq analysis confirmed this rearrangement and showed its maternal inheritance (arr[hg19] Xq28(148,004,585-148,064,903)x0 mat). The mother is apparently normal. X-inactivation study is ongoing. We are reporting a new case of small AFF2 (FMR2) intragenic deletion. We studied genotype-phenotype correlations for this patient and the previously reported patients with CCG expansion or intragenic deletion of AFF2.

2715M

Disruption of *HDAC8* gene due to partial duplication in a female with Cornelia de Lange syndrome diagnosed by SNP microarray. *S. Ramanathan, R.D. Clark.* Pediatric Genetics, Loma Linda University, San Bernardino, CA.

The clinical diagnosis of Cornelia de Lange syndrome (CdLS [MIM 122470]), a cohesinopathy, is evolving as its genetic heterogeneity is better understood. To date, mutations in 5 genes, 3 core cohesion subunits (*SMC1A* [MIM 300040], *SMC3* [MIM 606062], *RAD21* [MIM 606462]) and 2 cohesin-regulatory proteins (*NIPBL* [MIM 608667], *HDAC8* [MIM 300269]) have been identified in CdLS. The distinctive features in classic CdLS include synophrys, arched eyebrows, long prominent philtrum, small, upturned nose and upper limb reduction defects. Significant growth and cognitive impairment are typical. Milder, subtle phenotypes have also been reported, with the variability likely due to inter- and intragenic mutation spectrum (Mannini L et al., 2013).

We report a 4-month old female with CdLS due to a partial duplication of the *HDAC8* gene, who presented as a newborn with IUGR, tetralogy of Fallot, bifid uvula and asymmetric crying face due to right facial palsy. Her dysmorphic features did not raise suspicion for CdLS until SNP microarray analysis detected a *de novo* 201 kb duplication on chromosome X at Xq13.1 that disrupted the *HDAC8* gene. An X-inactivation ratio of 100:0 in peripheral blood was highly skewed. At 2 months, she had a wide open anterior fontanel, depressed supraorbital ridges with hooded appearance of the eyes, mild synophrys and long, prominent philtrum with thin upper lip. The 5th fingers were short with a single crease and clinodactyly. She had failure to thrive, dysphagia and G-tube dependency. She did not have hirsutism or arched eyebrows.

Mutations in *HDAC8*, most of which are missense, have been recently identified in CdLS. The facial features can be atypical, with some overlap with that of classic CdLS. Distinguishing features are delayed anterior fontanelle closure, hooding of the eyelids and a broader nose with no gross limb abnormalities (Deardorff MA et al., 2012, Kaiser FJ et al., 2014). Most patients are heterozygous females with marked X-inactivation skewing in peripheral blood, favoring the normal allele. To our knowledge, this is the first patient with CdLS caused by a partial duplication of the *HDAC8* gene. The atypical phenotype associated with *HDAC8*, which was not recognized on clinical evaluation, illustrates the emerging phenotypic variability in CdLS.

2716T

Exome sequencing of individuals with non-deletion Smith-Magenis syndrome reveals potentially causative genic variants. *J.J. White[1], C.R. Beck[1], T. Gambin[1], T. Harel[1], J.R. Lupski[1,2,3].* 1) Molecular & Human Genetics, Baylor College of Medicine, houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 3) Texas Children's Hospital, Houston, TX, USA.

Smith-Magenis syndrome (SMS; MIM #182290) is a developmental disability/multiple congenital anomaly disorder often resulting from haploinsufficiency of RAI1 and manifesting with a wide range of phenotypes. The clinical manifestations of SMS varies widely with roughly 90% of cases manifesting intellectual disability, speech delay and hypotonia, and 70% developing hearing loss, sleep disturbances and stereotypic behaviors including self-hugging and self-injurious behaviors. We investigated a cohort of 154 patients with SMS and subjected DNA samples to a targeted, high-density array comparative genomic hybridization (aCGH) specific for chromosome 17p. Samples lacking a copy number variant (CNV) in the SMS critical region were then sequenced for point mutations in RAI1, of which seven (5%) contained a mutation within the RAI1 coding sequence. On the remaining 16 individuals without a molecular diagnosis, whole exome sequencing (WES) was implemented using extensive filtering of variants common in the Atherosclerosis Risk in Communities (ARIC), Exome Sequencing Project (ESP), and our in-house Exome sequencing databases. We found predicted damaging variants and putative de novo variants in other genes known to cause developmental delay and/or intellectual disability in six patients. Additionally, subsequent genome-wide high exon-targeted aCGH identified a potentially causative 15q11.2 deletion in a singleton case. The initial clinical diagnosis of SMS with each of these patients underscores the challenge of clinical diagnosis for complex disorders with variable phenotypes, and highlights the benefit of WES in patients with normal CMA. Moreover, it suggests that the genes underlying phenotype mimics of SMS may share common networks with RAI1, and presents this as a further venue of research.

2717S

Cervical myelopathy in a patient with metatropic dysplasia caused by a TRPV4 mutation. *E. Zapata-Aldana[1], L. Arnaud-López[1], E.L. Mellín-Sánchez[1], C. Peña-Padilla[1], J. Rivera-Vargas[1], F.J. Martínez-Macías[1], L. Bobadilla-Morales[1,3], A. Corona-Rivera[1,3], A. Superti-Furga[2], J.R. Corona-Rivera[1,3].* 1) Servicio de Genética, División de Pediatría, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 2) University of Lausanne, Centre Hospitalier Universitare Vaudois, Lausanne, Switzerland; 3) Instituto de Genética Humana "Dr. Enrique Corona Rivera", CUCS, Universidad de Guadalajara, Jalisco, México.

Introduction. The name of metatropic dysplasia (MD[MIM #156530]) is derived from the Greek "metatropos," (changing patterns), because initially exhibit a long thorax with short limbs and later a short-trunked dwarfism. MD is an autosomal dominant disorder caused by mutations in the *TRPV4* gene (MIM #156530), which encodes for a calcium channel that participates in the ossification of the chondrocytes, however, *TRPV4* produces also other skeletal dysplasias and neurodegenerative disorders. Here, we present the clinical, radiological and molecular findings in a female patient with a classic form of MD, complicated by a cervical myelopathy. **Clinical report.** The *proposita* was born from healthy, and remotely consanguineous parents. She was born after an uncomplicated term pregnancy and a normal vaginal delivery. At birth, she weighed 3.5 Kg (50th percentile). Physical examination at 2.5 years of age showed a weight of 11 Kg (-2.9 SD), height of 81 cm (-3.4 SD), span of 87 cm. She had short trunk, severe kyphoscoliosis, hypermobile fingers, enlarged joints at knees and elbows, and hallux valgus. Radiographies demonstrated thoracolumbar scoliosis, platispondyly, wide intervertebral space, lumbar hyperlordosis, halberd-shaped pelvis, dumbbell-shaped metaphyses in femurs, and wide-irregular metaphyses in fingers and toes. The spine MRI showed C1-C2 subluxation, cervical instability, and spinal cord compression. At the age of 5 years the *proposita* undergo thru a surgical procedure with cervical arthrodesis, unfortunately, she progressed to quadriparesis six months after the surgery. The molecular study of the TRPV4 confirmed the mutation P799L at the heterozygous state. **Conclusions.** The clinical and radiographic features, in addition to the molecular study in our patient confirmed the diagnosis of MD. All of the cases with a P799L heterozygous mutation in the *TRPV4* gene have been reported as MD, in ours with a suitable genotype-phenotype correlation, even considering the cervical myelopathy. Early detection with a careful neurological assessment, spine MR imaging, and appropriate surgical treatment should be carried out in all patients in whom MD is suspected, to prevent the observed neurological sequelae and improve its life quality.

2718M

CNS Involvement in OFD1 syndrome: a Clinical, Molecular, and Neuroimaging study. *B. Franco[1,2], M. Macca[1], F. Imperati[2], A. D'Amico[3], P. Parent[4], L. Pasquier[5], V. Layet[6], S. Lyonnet[7], V. Stamboul-Darmency[8], C. Thauvin Robinet[9,10], E. del Giudice[1], Oral-Facial-Digital Type I (OFD1) Collaborative Group.* 1) TIGEM, Fondazione Telethon, Naples, Italy; 2) Department of Translational medical Sciences, Federico II University of Naples, Italy; 3) Department of Radiological Sciences, Neuroradiology Unit, Federico II University of Naples, Naples, Italy; 4) Service de Pédiatrie et de Génétique, CHU Brest, France; 5) Service de Génétique Médicale - Centre de Référence Maladies rares Labélisé « Anomalies de Développement et Syndromes Malformatifs » de l'Ouest, CHU Rennes, France; 6) Consultation de Génétique, Groupe Hospitalier du Havre, CH Le Havre, France; 7) Département de Génétique, Hôpital Necker-Enfants Malades, APHP, Paris, France; 8) Service de Pédiatrie 1, Hôpital d'Enfants, CHU Dijon, France; 9) Centre de Génétique et Centre de Référence Maladies rares Labélisé « Anomalies de Développement et Syndromes Malformatifs » de l'Est, Hôpital d'Enfants, CHU Dijon, France; 10) EA 4271 GAD « Génétique des Anomalies du développement », IFR 100 - Santé STIC, Université de Bourgogne, Dijon, France.

Background: Oral-facial-digital type 1 syndrome (OFD1; OMIM 311200) belongs to the expanding group of disorders ascribed to ciliary dysfunction. With the aim of contributing to the understanding of the role of primary cilia in the central nervous system (CNS), we performed a thorough characterization of CNS involvement observed in this disorder. Methods: A cohort of 117 molecularly diagnosed OFD type I patients was screened for the presence of neurological symptoms and/or cognitive/behavioral abnormalities on the basis of the available information supplied by the collaborating clinicians. Seventy-one cases showing CNS involvement were further investigated through neuroimaging studies and neuropsychological testing. Results: Seventeen patients were molecularly diagnosed in the course of this study and five of these represent new mutations never reported before. Among patients displaying neurological symptoms and/or cognitive/behavioral abnormalities, we identified brain structural anomalies in 88.7%, cognitive impairment in 68%, and associated neurological disorders and signs in 53% of cases. The most frequently observed brain structural anomalies included agenesis of the corpus callosum and neuronal migration/organisation disorders as well as intracerebral cysts, porencephaly and cerebellar malformations. Conclusions: Our results support recent published findings indicating that CNS involvement in this condition is found in more than 60% of cases. Our findings correlate well with the kind of brain developmental anomalies described in other ciliopathies. Interestingly, we also described specific neuropsychological aspects such as reduced ability in processing verbal information, slow thought process, difficulties in attention and concentration, and notably, long-term memory deficits which may indicate a specific role of OFD1 and/or primary cilia in higher brain functions.

2719T

Neurofibromatosis type 1: Familial case and retroperitoneal neurofibroma. *M.A. Aceves-Aceves[1], I.M. Salazar-Dávalos[1], S.A. Alonso-Barragán[2], R.E. Jiménez-Arredondo[2], D. García-Cruz[1], N.O. Dávalos[1], A.G. Puebla-Mora[3], M. Salazar-Páramo[4], I.P. Dávalos[1,2].* 1) Instituto de Genética, DGH, Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) Doctorado Genética Humana, CUCS, Universidad de Guadalajara, CIBO-IMSS, Guadalajara, México; 3) Servicio de Anatomía Patológica, UMAE, HP, CMNO, IMSS, Guadalajara, México; 4) Depto. Fisiología, CUCS, Universidad de Guadalajara, Div. Investigación, UMAE, HE, CMNO, IMSS, Guadalajara, México.

INTRODUCTION: Neurofibromatosis type I (NF1), OMIM #162200, is an autosomal dominant disorder characterized by café-au-lait spots, Lisch nodules (iris hamartoma), fibromatous tumors of the skin and development of benign and malignant tumors. It is caused by mutation in the neurofibromin gene on chromosome 17q11.2. The incidence of NF1 is 1 in 3000 individuals. OBJECTIVE: To present a familial case with NF1 and retroperitoneal neurofibroma in the propositus. CASE REPORT: Family data: Patient 1 (propositus): 9 year-old, product of the 4th pregnancy, obtained by vaginal delivery; from non-consanguineous parents, mother (40 years), father (50 years, patient 3), sister (14 years, patient 2) and a healthy sister (13 years). Physical examination: weight 22kg (pc10), height 127cm (pc25), head circumference 53cm (pc90), café-au-lait spots in thorax (>30), axillary freckles, post extirpation scar of plexiform neurofibroma on right costal region, congenital pseudoarthrosis of the left tibia, treated with intramedullary nail placement. Abdominal ultrasonography studies reported retroperitoneal mass, confirmed by CT as a solid lobulated mass, from the upper border of the pancreas extending to retroperitoneum, embracing aorta and left renal vessels, displacing the left kidney, lymph nodes in large vessels; the histopathological study reported intraneural neurofibroma. Patient 2: (sister) 14 year-old female, product of 2nd pregnancy, obtained at 40 weeks. Physical examination: weight 51 Kg (pc25), height 152cm (pc10), head circumference 59cm (pc>97), café-au-lait spots in thorax and abdomen, axillary freckles, surgically removed subcutaneous nodule in left arm, histopathological study reported plexiform neurofibroma. Pelvic ultrasonography revealed right polycystic ovary. Patient 3: (father) 50 year-old male with a history of surgical resection of nodule on right arm 20 years ago. Physical examination: weight 65kg, height 162 cm, café-au-lait spots in thorax and abdomen and axillary freckles. CONCLUSIONS: According to the NIH Consensus Development Conference established criteria we present a NF1 family case. The propositus presented a retroperitoneal tumor and the histopathological analysis demonstrated an intraneural neurofibroma, an uncommon finding in NF1. Early diagnosis of NF1, close clinical evaluations, periodical imaging studies and a multidisciplinary approach allows an opportune detection and treatment of complications improving patient's prognosis.

2720S

Clinical-pathological features in a female infant with Pfeiffer syndrome type 3 negative for FGFR2 mutation. *AK. SANDOVAL TALAMANTES[1], C. PEÑA-PADILLA[1], E.L. MELLIN-SANCHEZ[1], J. RIVERA-VARGAS[1], E. ZAPATA-ALDANA[1], L. VIRAMONTES-AGUILAR[1], J. TAVARES-MACIAS[1], L. BOBADILLA-MORALES[1], M. CUNNINGHAM[2], S. PARK[2], J.R. CORONA-RIVERA[1].* 1) Centro de Registro e Investigación sobre Anomalías Congénitas (CRIAC), Servicio de Genética y Unidad de Citogenética, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca·, Guadalajara, Jalisco, Mexico; 2) Craniofacial Center, Seattle Children's Hospital, Washington, USA.

Introduction. Pfeiffer syndrome (PS) is a genetic disorder characterized by craniosynostosis, broad thumbs and big toes, and variable syndactyly (OMIM # 101600). Cohen classified three types of PS: Type 1, have a better prognosis, usually familiar and could have normal intelligence. Type 2, is lethal with cloverleaf skull, severe ocular proptosis, elbow ankylosis and visceral anomalies. Type 3, share the same features that type 2, without cloverleaf skull, and can have abdominal wall defects. All of the cases with PS types 2 and 3 are caused by different mutations in *FGFR2* gene, 80% of them in exons 8 and 10. Here, we describe the clinical-pathological features found in a female infant with PS type 3. **Clinical report.** The proposita was the product of the first pregnancy of a healthy 21-year-old mother and a 25-year-old father, who were non consanguineous. Prenatal ultrasonography reported omphalocele and craniosynostosis. The mother has positive serology for parvovirus B19. Vaginal delivery was at the 40th week of gestation. Apgar scores were 5, 3, and 1 at 1, 5 and 10 min, respectively. Birth weight was 3200 g, length 50 cm, and occipitofrontal circumference 31.3 cm (<3rd percentile). Physical examination showed turribrachycephaly, ocular proptosis, midfacial hypoplasia, down-slanting palpebral fissures, low-set ears, hemangioma on dorsum of the nose, prominent abdomen with prune-belly appearance, supraumbilical midline omphalocele; limitation of elbow extension, and square shaped first toes. He died at 30 min after birth. Autopsy was performed adding: brain microgyria, laryngotracheal stenosis, patent ductus arteriosus, omphalocele, hepatomegaly, partial intestinal malrotation with a subhepatic cecal appendix. Karyotype with G-bands was normal 46,XY, at a 550 band-level resolution. Sequencing of the exons 3, 7, 8, 10, 11, 14, 16, 17 of the *FGFR2* gene, was negative for mutation. **Conclusions**. Turribrachycephaly, broad and square shaped big toes, limitation of elbow extension, abdominal wall defects, visceral anomalies, and early death supports the clinical diagnosis of PS type 3. Four previous patients with PS and prune belly have been reported -two with cloverleaf skull, however, molecular study was not performed in none of them. The negative result obtained for the search of common mutations in *FGFR2* gene, probably implies a new or atypical mutation for the severe PS phenotype in our patient and consequently, further investigations are necessary.

2721M

Identification of structural alterations in the *CX50* gene in patients with congenital cataracts. *A.L. Araujo[1], E.S. Figueiredo[2], P.R.S. Cruz[1], B.B. Souza[1], C.E.L. Arieta[2], M.B. Melo[1].* 1) Center of Molecular Biology and Genetic Engineering (CBMEG), University of Campinas, Campinas, São Paulo, Brazil; 2) Department of Ophthalmology, Faculty of Medical Sciences (FCM), University of Campinas, Campinas, São Paulo, Brazil.

Congenital cataract is the leading cause of reversible blindness in childhood, with a prevalence of one to five cases per 10,000 live births. The hereditary form represents about 50% of these cases. The most common mode of inheritance is autosomal dominant with high penetrance, although autosomal recessive and X-linked inheritance are also observed. Genetic alterations responsible for non-syndromic congenital cataracts lead to changes in lens proteins, such as crystallins, membrane transport proteins (connexins, aquaporin) and cytoskeletal proteins (BFSP2). Connexins are structural proteins that compose an extensive network of intercellular channels of low resistance (gap junctions) present between the lens fibers. These proteins allow ions, metabolites and second messengers flow between cells, maintaining the balance of intercellular communication and ensuring the transparency of the lens. Connexins are encoded by *CX46* and *CX50* genes (among others), both previously linked to congenital cataract. In order to better understand the molecular basis of the disease, structural alterations in the *CX50* gene were evaluated in patients with nuclear and lamellar bilateral congenital cataract with hereditary etiology by means of PCR and direct sequencing. Patients' recruitment and blood collection were approved by the Ethics Committee of FCM-UNICAMP (Campinas-SP, Brazil). Twenty seven patients from ten families were analyzed to date, sixteen affected and eleven unaffected. We observed eight point mutations, among which two were not yet described. There were alterations common to both affected and unaffected individuals (two), unique for affected individuals (five, including the novel ones) and unique for unaffected individuals (one) as well. Five alterations are located in the coding region, being three missense variations, including both novel ones, and two synonymous. All three missense variations were predicted to be probably damaging by SIFT, PolyPhen-2 and MutPred softwares. Noteworthy, the missense variation already described was observed exclusively in both affected members of a family of three individuals, being absent in the unaffected member. This might suggest a possible segregation with the disease, although the family size restricts the analysis power. The remaining members of the families are being analyzed to allow further conclusions about the alterations. Financial Support: Capes and FAPESP.

Female with a Complex Phenotype Associated with Variants in Two Neurodegenative Genes Detected by Whole Exome Sequencing: Diagnostic and Counseling dilemma. *M. Khalifa[1], L. Naffaa[2].* 1) Medical Genetics and Genomics, Akron Childrn Hospital, Akron, Ohio., USA; 2) Lena Naffaa. Department Radiology, Akron Children's Hospital, Akron, Ohio, USA.

We report on a female child with severe intellectual disability, aphasia, short stature, ataxia, and structural brain abnormalities. A brain MRI obtained in infancy showed hypomyelination involving the central periventricular white matter and thinning of the corpus callosum. Initial reporting of Whole Exome Sequencing (WES) identified three POLR3A 3 missense heterozygous variants: two, a maternal variant (c.1724A>T) and a paternal variant (1745G>A) on exon13, and a novel maternally inherited variant (c.346A>G) on exon 4. These variants are likely damaging. The patient's clinical features, early MRI findings, and WES results supported the diagnosis of hypomyelinating leukodystrophy type 7, and the family was counseled accordingly. An updated WES report revealed a novel WDR45 deleterious frameshift mutation in Exon 9 (c.587-588del). This, with later brain MRIs that showed progressive iron accumulation in the globus pallidus and substania nigra, raised the possibility of Neurodegeneration with Brain Iron Accumulation (NBIA). Both WDR45 and POLR3A are newly recognized genes; each is associated with a distinct neurodegenerative disease. WDR45 is an X-linked gene associated with a dominant form of NBIA, manifested by progressive neuropsychiatric abnormalities, dystonia, cognitive decline, spastic paraplegia, and iron deposition in the basal ganglia. POLR3A, on the other hand, is an autosomal gene causing a recessive form of a hypomyelination with leukodystrophy disease, also known as 4H syndrome. This syndrome is characterized by variable manifestations including congenital Hypomyelination with thinning of the corpus callosum, Hypodontia and Hypogonadotropic Hypogonadism. This patient's complex clinical presentation and mixed brain neuroimaging findings might be attributed to the confounding effects of the expression of these two genes. Alternative, they may represent an expansion of the phenotype of either condition. In any event, these made the diagnosis and genetic counseling of the family challenging.

2723S

Whole exome sequencing allows the identification of a novel large deletion in *PRPF31* in a family with autosomal dominant retinitis pigmentosa. *B. Almoguera[1], P. Fernandez-San Jose[2,3], Y. Liu[1], J. Liang[4], R. Golhar[1], M. March[1], R. Pellegrino[1], M. Corton[2,3], F. Blanco-Kelly[2,3], MI. Lopez-Molina[3,5], B. Garcia-Sandoval[3,5], Y. Guo[1], L. Tian[1], X. Liu[4], L. Guan[4], B. Keating[1], X. Xu[4], C. Ayuso[2,3], H. Hakonarson[1].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Genetics and Genomics, IIS-Fundacion Jimenez Diaz, 28040, Madrid, Spain; 3) Center for Biomedical Network Research on Rare Diseases (CIBERER), ISCIII, Spain; 4) BGI-Shenzhen, Shenzhen 518083, China; 5) Department of Ophthalmology, Fundacion Jimenez Diaz, 28040, Madrid, Spain.

With all types of Mendelian inheritance patterns described and an extreme phenotypic, clinical, genetic and allelic heterogeneity, diagnosis of patients with retinitis pigmentosa (RP) is a complex task. Next generation sequencing (NGS) is increasingly being applied to the diagnosis of highly heterogeneous monogenic diseases, such as RP, as a rapid and affordable alternative to the former methods. However, one of the main limitations of NGS is the detection of copy number variants (CNV), which can account for a significant number of RP cases. In this study, we identified a large deletion in *PRPF31* using whole exome sequencing (WES) data in a family with autosomal dominant RP. Eight members of the family were enrolled in the study and two affected and two unaffected members were subjected to WES using Illumina Hiseq 2000 instruments. The Burrows-Wheeler alignment tool, Genome Analysis Tool Kit and ANNOVAR were used for mapping, genomic variant detection and variant functional annotation, respectively. Single nucleotide variant (SNV) analysis was performed searching among all potentially functional variants and for CNV analysis the standard Exome Hidden Markov Model (XHMM) was used. CNV validation was performed using TaqMan predesigned probes (Life Technologies) and the Universal Probe Library (Roche). SNV analysis did not yield any candidate variant. A heterozygous deletion in the genomic region chr19: 54600186-54628017, spanning the entire *PRPF31* gene, was identified by XHMM in the two affected members of the family. Both CNV assays used confirmed that the entire coding sequence of *PRPF31* was hemizygously deleted in the two affecteds and not in the unaffecteds. With this study we demonstrate the feasibility of detecting CNVs in RP genes using WES, thus expanding the potential of this tool in the diagnosis of this disease.

2724M

Whole gene duplication and partial duplication and triplication of *OPHN1*. *J.G. Pappas[1], E. Ward[1], P.R. Papenhausen[2].* 1) Dept Pediatrics, Clin Genetic Scvs, New York Univ, Sch Med, New York, NY; 2) Cytogenetics, Laboratory Corporation of America, Research Triangle Park, NC.

Inactivating mutations and intagenic deletions in *OPHN1* cause X-linked mental retardation with cerebellar hypoplasia, ataxia, seizures and distinctive facial appearance (Al-Owain M et al 2011). Duplication X(q12q13.3) containing *OPHN1* along with other OMIM annotated genes has been associated with developmental delay, microcephaly, short stature and autism in males (Bedeschi, MF et al 2008, Kaya N et al 2012, Prontera P et al 2012). We present a 14 year old boy (case 1) with dup(X)(q12q13) that includes *OPHN1* and *AR* and a 3 year old boy (case 2) with duplication and triplication in Xq12q13.1 involving *OPHN1* only. Our cases are unrelated and presented with mild to moderate mental retardation. Case 1 was born full term male, small for gestational age with microcephaly. He continued to grow below the 3rd percentile. Routine karyotype was normal. His cognitive development was delayed throughout childhood. Our evaluation at age 14 revealed mild to moderate mental retardation, short stature, microcephaly, elongated face, hypotelorism, narrow palpebral fissures and long nose with bulbous tip. Case 2 was born full-term without complications and normal anthropometrics. His growth followed the 50th centile for height, 95th for weight and 25th for head circumference. Developmental delays and strabismus were noted in infancy. He started walking at 17 months. At 28 months, he was speaking a few words; his face was triangular and elongated with prominent forehead, hypotelorism and bulbous tip of the nose. Blood from case 1 was analyzed by SNP microarray (Affymetrix 6.0) which showed a 983 KB interstitial duplication of X(q12q13): arrXq12q13.1(66,720,159-67,702,721)x2. This de novo copy number change was confirmed by the RP11-963N10 region specific BAC. Case 2 was tested with a higher resolution microarray (Affymetrix Cytoscan) which revealed a maternally inherited duplication Xq12(67,295,132-67,404,398) and triplication Xq12q13.1(67,501,664-67,908,008). The mother was phenotypically normal. The duplication in case 1 shares only *OPHN1* with the previously reported duplications and it contributes to the association of the phenotype to *OPHN1* only. Case 2 is unique because it lacks ataxia and seizures which are common in cases with disruption of *OPHN1*. Our cases have common facial features with cases reported with duplications, intragenic deletions and inactivating mutations in *OPHN1* and this observation may help elucidating the role of this gene during development.

2725T

A Unique Family with Progressive Pseudorheumatoid Arthropathy of Childhood. *A. Neogi[1], V. Kimonis[1], J. Soni[2], E. Chao[1].* 1) Division of Genetics and Genomic Medicine, Department of Pediatrics, University of California, Irvine, CA; 2) Gandhi Lincoln Hospital, Deesa, Banas Kanta, Gujarat, India.

We report a family in India with five affected female siblings with an unusual manifestation of *progressive pseudorheumatoid arthropathy of childhood.* Progressive pseudorheumatoid arthropathy of childhood is an autosomal recessive condition that affects the bones and cartilage of joints with a childhood onset. Major symptoms include stiffness of joints, bony swellings of toes and fingers, weakened muscles, fatigue and bowed legs. The disorder is progressive and occurs due to mutations in the WISP3 gene encoding for a signaling protein that is essential for normal postnatal skeletal growth and cartilage homeostasis. In the affected girls, symptoms typically started around 3-5 years of age and lead to crouching followed by a squatting gait. They developed severe joint contractures of the elbows, knees, ankles and hips, with motor weakness and difficulty sitting and walking. The girls developed joint swellings. They do not have pain but have severe restriction of their mobility, which has been documented in a video clip. Skeletal X-Rays revealed enlargement and cystic malformations of the epiphyses and metaphyses and joint erosions. We performed **exome sequencing** through Ambry Genetics for the affected individuals. Two novel mutations in the WISP3 gene were reported after assessment. These c.172A>T, p.K58X and c737_738del, p. L246LfxX32 mutations are considered most likely contributory to the progressive arthropathy. The girls have an unaffected brother and two unaffected sisters and consanguinity was denied in the family. **Confirmatory testing** is in progress in the parents in order to confirm phase (cis/trans) of the variants and provide further support for the molecular etiology of the disorder in this family. Future research of this pathway could lead to promising therapies to modify this progressive disease.

2726S

Mutation in the EZH2 gene in a Brazilian family - Complex clinical findings. *D.L. Polla[1], N.M. Kokitsu-Nakata[2], M.C.B. Silva[1], I.C.C. Cardoso[1], A. Richieri-Costa[2], R. Pogue[1].* 1) Catholic University of Brasilia, Brasilia, Distrito Federal, Brazil; 2) Hospital for Rehabilitation of Craniofacial Anomalies - University of Sao Paulo, Bauru, Sao Paulo, Brazil.

Weaver syndrome (WS) is a multi-systemic pre- and post- natal overgrowth syndrome associated with variable intellectual disability. Most of the reported cases have been described as sporadic, however in a few instances vertical transmission has been documented indicating autosomal dominant inheritance. Here we describe a family with 3 affected patients (mother, son and daughter), and an unusual clinical presentation within the family. There was a wide variation in clinical manifestations ranging from severe vestibule-cochlear anomalies in the proposita to behavioral disturbance, delayed language acquisition and learning difficulties in her brother. The original diagnostic hypothesis was Sotos syndrome. However, sequencing was carried out using an NGS (Illumina) skeletal dysplasia-specific panel which included the Sotos syndrome genes (NDS1 and NFIX) and the WS gene, EZH2. The affected individuals shared a c.149A>G; p.50L>S variant in EZH2, confirming a diagnosis of WS. Panel sequencing was therefore useful and important in determining the definitive diagnosis. Unknown modifier loci may be responsible for the clinical heterogeneity within the family.

A Novel Mutation, p. (Lys1474*), in a Female adds Seizures and Ptosis to Clinical Findings in MED13L Haploinsufficiency Syndrome. *M.M. Ali[1], N. Smaoui[2], A.M. Slavotinek[1].* 1) Genetics, UCSF, San Francisco, CA; 2) GeneDx, Gaithersburg, Maryland, USA.

We describe a 12 year old female with a history of seizures and epileptiform activity on EEG, choreiform movements, moderate developmental delays, macrocephaly (OFC >97th centile), central obesity and dysmorphic findings, including a prominent and square forehead, left ptosis, epicanthic folds, a right ear pit, prominent lower jaw with underbite, thin and tapered fingers, cubitus valgus and an increased lumbar lordosis. An MRI showed T2 hyperintense foci in the periventricular and subcortical white matter with low white matter volume and a dysmorphic craniocervical junction. Whole exome sequencing demonstrated heterozygosity for a de novo, nonsense mutation in the Mediator Complex Subunit 13-like (MED13L) gene, p.(Lys1474*), that has not been reported previously and is predicted to cause loss of normal protein function. The MED13L protein is a subunit of the Mediator complex, a large complex of proteins that functions as a transcriptional coactivator for most of the RNA polymerase II-transcribed genes. MED13L is highly expressed in early development of the heart and brain. Heterozygous, missense mutations in MED13L were first described in patients with transposition of the great arteries, dextro-looped (dTGA) and one patient with a translocation disrupting MED13L between exons 1 and 2 had intellectual disability (ID) and dTGA. Subsequent reports have described mutations and translocations hypothesized to disrupt MED13L expression in patient with phenotypes including non-syndromic ID, hypotonia, conotruncal and septal heart defects, facial anomalies and a 'Noonan-like' phenotype with hypotonia and facial anomalies. MED13L dosage is important and mutations have been non-penetrant, heterozygous or homozygous; a de novo triplication of chromosome 12q24.2 including MED13L and MAP1LC3B2 has also been reported to result in a milder phenotype. Our case is a further example of MED13L haploinsufficiency syndrome and adds seizures, choreiform movements and ptosis as possible clinical findings in this condition.

2728T

Case report: Acromesomelic dysplasia with primary congenital glaucoma, and a distinct pattern of brachydactyly in a Brazilian patient. *W.A.R. Baratela[1], G.L. Yamamoto[1,2], C.A. Kim[1], D.R. Bertola[1,2].* 1) Unidade de Genética, Instituto da Criança - Hospital das Clínicas - Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Centro de Estudos do Genoma Humano - Departamento de Genética e Biologia Evolutiva - Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil.

The (acro)mesomelic skeletal dysplasias, classified as n # 16 and 17 under the current skeletal dysplasias nosology, comprise a heterogeneous group of disorders, ranging from mildly affected Leri-Weill, Robinow dominant, Maroteaux type to more severe phenotypes such as Langer, Kantaputra, Nievergelt, and Savarirayan types. We report on a 14 year-old girl with disproportionate acromesomelic short stature and bilateral congenital glaucoma. Product of an uneventful pregnancy, she was born by cesarian section at term, small for gestational age, BW: 2320g, BL: 38,5cm (below 5th%ile), OFC: 34,5cm, Apgar score 4/9. Parents are nonconsanguineous, with a negative family history. Primary congenital glaucoma surgery was performed at 1mo. She evolved with normal developmental milestones and cognitive function. Echocardiogram, abdominal US, brain CT scan, and chromosome analysis were all normal. At 12 y 3mo she presented with H: 98.5cm (below 5th%ile), and normal OFC. Mesomelic shortening of the upper and, especially, lower limbs, brachydactyly with hypoplastic nails and an increased distance between the 1st and the 2nd toes were observed. Radiological findings included a mild deformity of the forearm, hypoplastic middle and distal phalanx and carpal bone fusions, and a more prominent deformity of the lower limbs, with short and broad tibiae-fibulae, brachymetatarsalia with fusion of the 2nd metatarsal and the intermediate cuneiform bone. Small iliac wings with coxa vara were also found. The skeletal findings presented by our patient seem distinct from the previous described acromesomelic disorders, although the mesomelic involvement resembles the one described in Savarirayan type. Besides, the eye abnormality is rarely reported in skeletal dysplasias. The etiological genetic background for some of the acromesomelic dysplasias is still unknown. NGS of the exome for the case here described is underway, with preliminary results. This could soon unmask the causative gene, and whether this is a unique entity or part of the spectrum of a known genetic defect.

2729S

An autosomal recessive microcephaly syndrome with primordial growth failure and pigmentation changes is caused by mutations in the gene *ANKLE2*. *R. Clark[1], C. Curry[2], W. Dobyns[3], J. Lupski[4], H. Bellen[4], M. Wangler[4].* 1) Division of Medical Genetics/Peds, Loma Linda University Medical Center, Loma Linda, CA; 2) UCSF/Genetic Medicine Central California, Fresno, CA; 3) Center for Integrative Brain Research, University of Washington, Seattle, WA; 4) Dept. of Human and Molecular Genetics, Baylor College of Medicine, Houston, TX.

We report a non-consanguineous Hispanic family with two children affected with severe congenital microcephaly, primordial growth failure, pigmentation changes and novel mutations in *ANKLE2* identified through whole exome sequencing (WES). The proband, now aged 8, presented with a history of mildly low birth weight (2.67 kg) and severe microcephaly. His growth parameters have been severely reduced with weight at -4 SD, height at -6 SD and OFC at -9 SD. His development is at the <6 mos level. He has had unexplained anemia, glaucoma, seizures and feeding issues requiring a G tube. His examination is notable for hyperpigmented and hypopigmented macules over his entire body, a sloping forehead, ptosis, micropenis and generalized spasticity. Brain MRI revealed a simplified gyral pattern, absence of the corpus callosum, thick cortex and small frontal horns of the lateral ventricles with mildly enlarged posterior horns. Normal evaluations included chromosomes in blood and skin, a microarray, and studies for the Njimegen breakage syndrome and Fanconi Anemia. His affected sister had a similar phenotype and died within hours of birth of progressive cardiac failure without a pathological etiology. Her OFC at 37 wks GA was 26.5 cm and she had diffuse hyperpigmented and hypopigmented skin macules. A severe autosomal recessive microcephaly was suspected in this family and given the skin findings and severity of the brain abnormality, this appeared to be a unique phenotype.

DNA from both siblings and parents was sent for WES, and no mutations were found in previously published microcephaly loci. Among the candidates that met Mendelian expectation in this family, four genes were conserved and expressed in the CNS. One of these genes had been flagged as a potential novel Mendelian disease gene from a forward mutagenesis screen of the Drosophila X-chromosome which identified 165 fly genes. A subsequent study of variants in the human homologs from 1,929 exomes performed at Baylor led to prioritization of *ANKLE2*. See abstracts by Wangler et al. and Charng et al. Compound heterozygous variants in *ANKLE2* are the best candidate for disease-causing mutations in this family because of the unique combination of the human genetic evidence and the consistent neurologic phenotype in mutant flies with small brain size, and loss of neurons and support cells of the fly sensory organs.

2730M

A new craniofacial syndrome caused by localized mutations in *TWIST1*. *A.L. Fenwick[1], H. Cox[2], E. Sweeney[3], T. Lester[4], H. Lord[4], A.O.M. Wilkie[1].* 1) WIMM, University of Oxford, John Radcliffe Hospital, Oxford, United Kingdom; 2) Birmingham Women's NHS Foundation Trust, Mindelsohn Way, Edgbaston, Birmingham, UK; 3) Royal Liverpool Children's Hospital, Alder Hey, Liverpool, UK; 4) Genetics Laboratories, Oxford University Hospitals NHS Trust, Churchill Hospital, Oxford, UK.

Background: The association of *TWIST1* haploinsufficiency with Saethre-Chotzen syndrome (SCS [MIM 101400]; coronal synostosis with ptosis, small ears, and minor limb anomalies) is well known. Here we present evidence that mutations at a specific residue of *TWIST1* lead to a radically different craniofacial phenotype, possibly through a dominant-negative mechanism. **Patients and Results:** The proband was a 3-year old male with hypertelorism, a wide anterior fontanelle, upper eyelid colobomas, deficient bony orbits with pseudoproptosis, small low-set dysplastic cupped ears, syndactyly of fingers, bilateral talipes, bilateral undescended testes, imperforate anus and hypertrichosis. Parent/child trio-based exome sequencing revealed a *de novo* c.350A>T (p.Glu117Val) substitution in *TWIST1*. As the patient did not resemble typical SCS, the remaining exome was analysed but no other convincing pathogenic changes were identified. Presentation of the findings at the UK Dysmorphology group prompted *TWIST1* sequencing of a female subject with similar, but more severe features including bilateral eyelid colobomas, hypertelorism, choanal atresia, camptodactyly and abnormal hair distribution. This revealed a different heterozygous mutation at the identical nucleotide (c.350A>G; p.Glu117Gly). Of note, mutations at TWIST1-Glu117 have never been reported in association with SCS. This residue lies in the DNA binding domain, is highly conserved and makes specific contacts with bases involved in DNA binding sequence specificity. A heterozygous mutation at the equivalent residue (p.Glu29Lys) in the *C.elegans* homolog *hlh-8* shows dominant inheritance whereas null alleles are recessive (Corsi *et al*, *Development* **129**:2761;2002). We are currently investigating the transactivating activity of the above mutations, as well as previously reported SCS mutations, on E-box-luciferase reporter constructs. **Discussion:** On the basis of the similarity of the patients' clinical features, and their dissimilarity to SCS, we propose that heterozygous substitutions at Glu117 of TWIST1 are associated with a unique, severe phenotype. Whereas in SCS, haploinsufficency of *TWIST1* causes a change in homo/heterodimer balance in the coronal suture leading to craniosynostosis, in the cases presented here, a dominant-negative mechanism may act at an earlier stage of development to disrupt facial tissues derived from the cranial neural crest.

2731T

Autosomal Dominant Opitz GBBB Syndrome. *PS. Kruszka[1], BD. Solomon[2], RK. Iyer[2], M. Ahmad[2], DC. Thach[2], D. Bodian[2], WS. Wong[2], RA. Hart[1], AF. Martinez[1], NH. Robin[3], JM. Opitz[4], JG. Vockley[2], J. Niederhuber[2], M. Muenke[1].* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Inova Translational Medicine Institute (ITIMI), Falls Church, VA; 3) Department of Genetics, University of Alabama Birmingham, AL; 4) Department of Pediatrics, University of Utah, Salt Lake City, UT.

Background: Opitz GBBB syndrome is a well-described genetic syndrome characterized by hypertelorism, hypospadias, dysphagia, and congenital heart disease. Opitz GBBB syndrome has been linked to Xp22 (XLOS) and 22q11 (ADOS) previously by our group. The gene XLOS has been identified, *MID1*; however, the gene for ADOS has not been identified. A number of case reports have found 22q11.2 deletions in patients described as having Opitz GBBB syndrome. Phenotypic differences have been described between XLOS and ADOS by our group in the past; however, with newer genetic information available, further discernible genotype-phenotype relationships can be made. We present 24 families with ADOS for phenotyping and genotyping. **Methods:** 24 families with Opitz GBBB syndrome were identified and family history and linkage analysis were completed as previously described using highly polymorphic microsatellite markers. All families were tested for the *MID1* mutation. Probands negative for *MID1* mutations underwent chromosomal microarray analysis, and are currently undergoing whole exome sequencing for chromosome 22. **Results:** 24 families were found to be autosomal dominant based on linkage to 22q11, male-to-male transmission in their pedigrees, and/or negative for mutations in *MID1*. The 19 probands that underwent chromosomal microarray analysis tested negative for copy number variations in the 22q11 deletion syndrome critical region. **Conclusion:** We have shown that ADOS is a clinical entity distinct from XLOS and from 22q11.2 deletion syndrome. Whole exome sequencing of chromosome 22 will likely identify the causative gene for this syndrome, and gene discovery for ADOS will have a significant impact on counseling affected families about transmission risks and in their decision for reproductive options. Additionally, finding the responsible gene including functional studies will add scientific insight into molecular pathways involved in normal and abnormal midline craniofacial, cardiac and urogenital development.

2732S

Clinical and pathological features of an infant with concurrence of C syndrome and renal-hepatic-pancreatic dysplasia. *C. Peña-Padilla[1], G. Razo-Jiménez[2], G. Tavares-Macías[2], L. Arnaud-López[1], L. Bobadilla-Morales[1,3], E. Zapata-Aldana[1], E.L. Mellín-Sánchez[1], J.R. Corona-Rivera[1,3].* 1) Centro de Registro e Investigación sobre Anomalías Congénitas (CRIAC), Servicio de Genética y Unidad de Citogenética, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 2) Anatomía Patológica, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jalisco, Mexico; 3) Instituto de Genética Humana "Dr. Enrique Corona Rivera", CUCS, Universidad de Guadalajara, Jalisco, México.

Introduction. C syndrome [(CS) MIM 211750] is an autosomal recessive (AR) entity manifested by trigonocephaly, mental retardation, congenital cardiac defects, facial dysmorphism, postaxial polydactyly, CNS and renal malformations. CS is caused by mutation in CD96, mapped on 3q13. Otherwise, renal-hepatic-pancreatic dysplasia [(RHPD) MIM 208540] is a rare AR ciliophatie characterized by renal cystic dysplasia (RCD), hepatic fibrosis (HF), hepatic cyst (HC), and pancreatic cyst (PC) or dysplasia, due to mutations in NPHP3, whose locus was at 3q22.1. The concurrence of these two entities in a same patient has not been reported previously. Here we present a male infant with clinical pathological findings of CS and RHPD, supporting a common pathogenesis as both entities have the same mode of inheritance and chromosome localization. **Clinical report.** The *propositus* was the product of the third pregnancy of nonconsanguineous, young, and healthy parents. He was born after uncomplicated pregnancy and normal vaginal delivery at 38 weeks of gestation. Birth weight was 2340 g (below 10th centile); length was 48 cm (25th centile), and occipitofrontal circumference (OFC) was 34 cm (below 10th centile). Physical examination showed trigonocephaly, metopic ridge, upward slant palpebral fissures, *oral frenula*; postaxial polydactyly, and brachydactyly of both hands, and syndactyly of 2-3 toes. The CT brain scan showed corpus callosum hypoplasia and colpocephaly. 3D CT skull reconstructions confirm craniosynostosis of the metopic suture. He showed a 46,XY karyotype at the 550-band level. The patient died of renal failure and sepsis at 1 month of age. Autopsy results found congenital HF, bilateral RCD and multiple PC, and additionally a right double ureter. using the AmpFLSTR Identifiler PCR Amplification kit we found homozygosity for allele 15 in *locus* D3S1358. **Conclusions.** Clinical and pathologic findings confirm the diagnoses of CS and RHPD in our patient. Although RCD has been occasionally reported in CS, other obligate features of RHPD such as PC or HF, are not parts of the CS. This is the first time that the combination of CS and RHPD is reported. Since uniparental isodisomy poses a theoretical risk for AR disorders, as in the case of the CS and the RHPD, both located in 3q, a complete or partial chromosome 3 isodisomy is proposed to explain this unusual concurrence.

2733M

Molecular genetic study of 75 patients with X-linked alpha-thalassemia and mental retardation (ATR-X) syndrome in Japan. *H. Shimbo[1], K. Kurosawa[1], N. Okamoto[2], S. Ninomiya[3], T. Wada[4].* 1) Kanagawa Children's Medical Center, Yokohama, Kanagawa, Japan; 2) Osaka Medical Center and Research Institute for Maternal and Child Health; 3) Department of Clinical Genetics, Kurashiki Central Hospital, Kurashiki, Japan; 4) Department of Medical Ethics and Medical Genetics, Kyoto University Graduate School of Medicine, Kyoto, Japan.

[Introduction] ATR-X syndrome (MIM#603040) is an X-linked intellectual disability syndrome caused by mutations in the ATRX gene. The syndrome is characterized by severe intellectual disability, dysmorphic facies, hypotonia, genital and skeletal abnormalities, and the presence of α-thalassemia. More than 200 patients have been diagnosed worldwide; more than 80 reside in Japan. We have been studying ATR-X syndrome for more than a decade and have diagnosed almost all of the Japanese patients molecular genetically. In order to delineate molecular and clinical characteristics, we reviewed identified mutations in the *ATRX* gene of 75 patients from 62 families in Japan. [Methods] We analyzed genomic DNA and/or cDNA synthesized from RNA extracted from the leucocytes of patients. PCR was performed using 40 and 12 pairs of primers for genomic DNA and cDNA, respectively, followed by sequencing by Sanger method. [Results] Most of the mutations are clustered in two functionally important regions: 35 out of 75 mutations (47%) reside in ADD (ATRX-DNMT3-DNMT3L) domain, 27 (36%) in helicase domain, and the other 13 (17%) are outside of these domains. The types of mutations are as follows: 55 missense mutations, 2 nonsense mutations, 5 small deletions, 5 frame shifts, 3 intragenic deletions, 2 nucleotide exchanges in introns, 1 large insertion in an intron, 2 nucleotide exchanges in 5'- and 3'-UTR, and 1 large deletion. [Discussion] We did not find a clear correlation between genotype and phenotype. However, patients with typically severe clinical features tended to have mutations in ADD domain. We identified several cases with atypical clinical features. (1) A case with intractable seizures with an intragenic deletion of exon 1 of the 35 exons in the *ATRX* and exons 2-10 in the neighboring gene MAGT1, which would result in a premature translation stop codon. (2) Two siblings presented with clinically quite different severity with the intragenic deletion involving exons 2-5 in the *ATRX,* resulting in a prematurely truncated protein, [p.Ser7-Argfs*13]. A null mutation of *ATRX* is lethal because the *Atrx* knockout mouse cannot be viable. Proteins of ATR-X patients should have some residual functions. However, the proteins of these patients are considered to have no functions, because their stop codons reside near the 5' end. This may suggest the existence of a mechanism of re-initiation at the downstream ATG codon, or the possibility of other mechanisms.

Impact of Plexiform Neurofibromas on Adult Patients with Neurofibromatosis type 1. *S. Stueber, R.J. Hopkin, E. Schorry, L. Martin, K. Wusik.* Cincinnati Children's Hospital, 3333 Burnett Ave, Cincinnati, OH.

Neurofibromatosis type 1 (NF1) is one of the most common autosomal dominant genetic conditions diagnosed today. Up to 50% of patients with NF1 will develop a specific type of neurofibroma tumor called plexiform neurofibromas (PNFs), which develop along the nerve endings or along multiple nerve systems. Though typically benign, these tumors can cause significant complications. Some of the more common morbidities reported to be associated with PNFs are pain, loss of function, disfigurement, risk of malignancy development, mortality, and risk of bleeding complications. We performed a retrospective chart review of 69 adult patients that investigated rates of surgery and development of malignancy in patients with NF1 and PNFs. Results demonstrated that 50.7% of patients required surgery, and patients with greater numbers of PNFs were more likely to have surgery ($p = 0.02$). PNFs located in the head/neck and paraspinal region had a higher frequency of surgeries compared to those located in the pelvis or extremities ($p = 0.026$). In our patient population malignancies arising from PNFs were significantly more likely to occur in a core location as opposed to in the extremities or head/neck ($P<0.05$). While pain was not consistently documented in patient charts, in the 35 patients where pain could be reported, 60% had chronic pain. Taken together these results suggest that the adult population has significant tumor morbidity associated with PNFs in relation to surgery rates and malignancies. Currently, there is not a lot of information about how adult patients are experiencing PNFs, or how to manage this population. This study highlights the need of adult NF1 patients with PNF to have ongoing monitoring of their tumors due to significant morbidities. Future studies will be needed to determine modality and intervals of screening for best outcomes.

Early Onset Epileptic Encephalopathy Caused by *de novo SCN8A* Mutations. *H. Saitsu[1], C. Ohaba[1,2], M. Kato[3], S. Takahashi[4], T. Lerman-Sagie[5], D. Lev[6], H. Terashima[7], M. Kubota[7], H. Kawawaki[8], M. Matsufuji[9], Y. Kojima[10], A. Tateno[10], H. Goldberg-Stern[11], R. Straussberg[11], D. Marom[11], E. Leshinsky-Silver[12], M. Nakashima[1], K. Nishiyama[1], Y. Tsurusaki[1], N. Miyake[1], F. Tanaka[1], N. Matsumoto[1].* 1) Dept Human Gen, Grad Sch Med, Yokohama City Univ, Yokohama, Japan; 2) Dept Clin Neurol & Stroke Med, Yokohama City Univ, Yokohama, Japan; 3) Dept Pediatrics, Yamagata Univ Sch Med, Yamagata, Japan; 4) Dept Pediatrics, Asahikawa Med Univ, Asahikawa, Japan; 5) Ped Neurol Unit, Wolfson Medical Center, Holon, Israel; 6) Metabolic Neurogenetic Clinic, Holon, Wolfson Medical Center, Holon, Israel; 7) Div of Neurol, Nat Center for Child Health and Dev, Tokyo, Japan; 8) Dept of Pediatric Neurol, Osaka City General Hosp, Osaka, Japan; 9) Dept Pediatrics, Japan Community Health Care Org Kyusyu Hosp, Kitakyushu, Japan; 10) Dept Pediatrics, Toho Univ Sakura Med Center, Chiba, Japan; 11) Dept of Neurogenetics, Schneider's Children Med Center, Petah Tiqwa, Israel; 12) Institute of Med Genetics, Wolfson Medical Center, Holon, Israel.

Purpose: *De novo SCN8A* mutations have been reported in patients with epileptic encephalopathy. Here we report 7 patients with *de novo* heterozygous *SCN8A* mutations, which were found in our comprehensive genetic analysis (target capture or whole exome sequencing) for early-onset epileptic encephalopathies (EOEEs).

Methods: A total of 163 patients with EOEEs without mutations in known genes, including 6 with malignant migrating partial seizures in infancy (MMPSI), and 60 with unclassified EOEEs, were analyzed by target capture (28 samples) or whole exome sequencing (135 samples).

Results: We identified *de novo SCN8A* mutations in 7 patients: 6 of 60 unclassified EOEEs (10.0%), and 1 of 6 MMPSI cases (16.6%). The mutations were scattered through the entire gene: 4 mutations were located in linker regions, 2 in the fourth transmembrane segments, and 1 in the C-terminal domain. The type of the initial seizures was variable including generalized tonic-clonic, atypical absence, partial, apneic attack, febrile convulsion, and loss of tone and consciousness. Onset of seizures was during the neonatal period in 2 patients, and between 3 and 7 months of age in 5 patients. Brain MRI showed cerebellar and cerebral atrophy in 1 and 6 patients, respectively. All patients with *SCN8A* missense mutations showed initially uncontrollable seizures by any drugs, but eventually one was seizure-free and 3 were controlled at the last examination. All patients showed developmental delay or regression in infancy, resulting in severe intellectual disability. Our data reveals that *SCN8A* mutations can cause variable phenotypes, most of which can be diagnosed as unclassified EOEEs, and rarely as MMPSI. Together with previous reports, our study further indicates that genetic testing of *SCN8A* should be considered in children with unclassified severe epilepsy.

2736M

Recessive *TBC1D24* mutations cause early-onset epileptic encephalopathy and sensorineural hearing loss. *K. Writzl[1], D. Neubauer[2], D. Paro Panjan[3], B. Gnidovec Stražišar[2].* 1) Institute of Medical Genetics, University Medical Centre, Ljubljana, Slovenia; 2) Department of Child, Adolescent & Developmental Neurology, University Children's Hospital, Ljubljana, Slovenia; 3) Department of Neonatology, University Children's Hospital, Ljubljana, Slovenia.

Recent studies have shown that recessive mutations in the *TBC1D24* gene cause a variety of epilepsy syndromes (familial infantile myoclonic epilepsy, early infantile epileptic encephalopathy 16), nonsyndromic deafness and DOORS syndrome (Deafness, Onychodystrophy, Osteodystrophy, Mental retardation and Seizures). We report on two siblings with early-onset epileptic encephalopathy and deafness. The patients presented with clonic and myoclonic jerks within one hour after birth. The seizures were resistant to treatment. They had severe neurological impartments with axial hypotonia, upper limb dystonia, dyskinetic limb movements and poor eye contact. The older sibling died at the age of two years due to respiratory failure following severe respiratory infection. Audiologic examination showed bilateral sensorineural hearing loss in both siblings. The clinical and radiological investigations didn't show any fingers or toes abnormalities. Genetic analysis using next-generation sequencing panel for epileptic encephalopathy revealed compound heterozygous mutations in the *TBC1D24* gene: a novel missense mutation c.32A>G (p.Asp11Gly) in exon 2 and a frameshift mutation c.1008delT (p.His336Glnfs*12) in exon 4. Interestingly, the frameshift mutation was previously reported as unique to DOORS syndrome, yet our siblings did not meet the DOORS syndrome criteria. This report supports previous observations that mutations in *TBC1D24* cause diverse phenotypes. We recommend testing all infants with early onset epileptic encephalopathy and sensorineural hearing loss for *TBC1D24* mutations.

2737T

Kindler Syndrome: Novel and Recurrent *FERMT1* Mutations in Iranian Families. *L. Youssefian[1,2], H. Vahidnezhad[1,2,3], M. Barzegar[4], Q. Li[2], S. Sotoudeh[1], A. Yazdanfar[5], AH. Ehsani[1], AM. Kajbafzadeh[1], F. Agha-hosseini[1], S. Zeinali[3], M. Tabrizi[1], J. Uitto[2].* 1) Tehran University of Medical Sciences, Tehran, Iran; 2) Thomas Jefferson University, Philadelphia, PA., USA; 3) Pasteur Institute of Iran, Tehran, Iran; 4) Shahid Beheshti University of Medical Sciences, Tehran, Iran; 5) Hamedan University of Medical Sciences, Hamedan, Iran.

The Kindler syndrome (KS) is a rare autosomal recessive genodermatosis characterized by diffuse poikiloderma, cutaneous atrophy, acrokeratosis, trauma-induced blisters and photosensitivity. Mutations have been previously disclosed in the *FERMT1* gene which encodes kindlin-1, a component of keratinocyte focal adhesions. The incidence of KS is expected to be high in Iran due to high rate of consanguineous marriages. We identified a total of 13 Iranian families with KS, including ~40 affected individuals. Pedigree analysis of these families suggested high degree of consanguinity. The patients demonstrated characteristic clinical features, and the diagnosis was confirmed by skin biopsy in one of the cases while the parents, obligate heterozygote carriers, were clinically unaffected. Mutation analysis of *FERMT1* by amplification of all 15 exons and flanking intronic sequences, followed by bidirectional sequencing, revealed homozygous nonsense mutations in 7 Iranian families, both recurrent and novel, including c.1176T>G, c.1383C>A, c.550_551insA, c994_995delCA, and c.910G>T. In other 2 families three novel mutations including one missense and two splice site mutations [c.889 A>G, c.1139+2 T>C], c.957+1G>A were detected. There was no mutation in *FERMT1* gene in the other remaining families; promoter analysis and further studies are ongoing. These families, some with atypical clinical features, may present new entities with clinical overlapping features with the Kindler syndrome. These previously unpublished mutations in the *FERMT1* gene expand the spectrum of the mutations underlying KS. The identified mutation database forms the basis to confirm the clinical diagnosis by genetic testing and to identify heterozygous carriers, coupled with genetic counseling to reduce the burden of KS in Iran.

2738S

A Case report of disorders of sex development: Female patient whit novel mutation in AR gene and 45,X[5]/46,XY[95] karyotype. *J. Prieto, G. Giraldo, LP. Barragan-Osorio.* Inst de Gen Humana, Univ Javeriana, Bogota Cundinama, Colombia.

Introduction: Disorders of sex development (DSD) are a group of rare conditions usually presented in early infancy with external and/or internal reproductive organs abnormalities usually caused by gonadal disorders, adrenal or hormonal function impairment. DSD overall birth prevalence is estimated to be higher than 1 in 300. Androgen insensitivity syndrome (AIS) is typically characterized by evidence of feminization (i.e., undermasculinization) of the external genitalia at birth, abnormal secondary sexual development in puberty and infertility in individuals with a 46,XY karyotype. Here we report a novel mutation in AR in a female patient with 45,X[5]/46,XY[95] karyotype. Case Report: 26-year-old female patient who consulted by primary amenorrhea. At physical exam she presented a female phenotype with breast and pubic hair tanner of I-II/V. She had not body or axillary hair. Also she presented an adhered mass to the deep planes in the right inguinal region. The pelvic ultrasound did not show uterus neither ovarian follicles. We ordered an MRI which displayed an appropriate differentiation of the urethra, a short vagina that ends in blind pouch, defect in the formation of Muller and Wolf duct derivatives, a gonadal tissue in right inguinal region and a lower left cavity with solid appearance without cysts. The breast ultrasound evidenced heterogeneous breast tissue without masses. Her karyotype was 45,X[5]/46,XY[95]. With all of these findings we decided to order AR gene sequencing which reported a deleterious mutation c.202C>T (p.Q68X). Discussion: Here we presented a clinical chart consistent in AIS, female phenotype and 45,X[5]/46,XY[95] karyotype. The sequence analysis identified a c.202C>T change in the AR gene, which predicts an amino acid substitution of Glutamine to a premature termination codon at residue 68(p.Q68X). This mutation has not been previously reported but is interpreted as disease-causing in databases.

Complex Genomic Presentation in the NICU. *A. Khromykh[1], B.D. Solomon[1,3], D.L. Bodian[1], R.K. Iyer[1], R. Baveja[2], S.W. Wong[1], K.C. Huddleston[1], E.Z. Klein[1], D. Ascher[3], J.G. Vockley[1], J. Niederhuber[1].* 1) Inova Translational Medicine Institute, Falls Church, VA; 2) Fairfax Neonatal Associates, Falls Church, VA; 3) Inova Children's Hospital, Falls Church, VA.

Congenital anomalies are a leading cause of infant morbidity and mortality. The goal of our IRB-approved 'Impact of Genetic Disorders' study is to use trio-based whole genome sequencing (WGS) to elucidate the genetic and genomic factors that contribute to the etiologies of congenital anomalies, as well as assess these methods in real-time clinical practice, evaluating feasibility and cost-benefit ratio vs. conventionally available clinical genetic tests. Analysis was done through our ongoing trio-based (mother, father, proband) study (n=80+) that focuses on the subset of the NICU patient population suspected of having an underlying etiological genetic component and who underwent a comprehensive but unrevealing clinical/genetic workup. Our research utilizes trio-based WGS, RNA expression, methylation, and miRNA characterization. Clinical data are obtained from the electronic health records as well as parental input on nutrition, stress, behavior and environmental exposure via study-specific surveys. A variety of principal component, familial-based, pathway and genomic network analyses are utilized to identify the underlying genomic explanation of the observed clinical pesentation. Our analyses are bolstered by our database of >5,000 WGS (along with other biological data and clinical information) derived from multiple ongoing trio-based genomic studies. Data generated from an initial subset of 30 probands reveals that not only were we able to bioinformatically identify the causative genetic/genomic mutations in multiple probands in our cohort utilizing WGS including molecular evidence for novel findings as well as known conditions such as IMAGE syndrome, DiGeorge syndrome, Rubinstein-Taybi II, D-bifunctional protein deficiency, CHARGE syndrome, GATA4, none of which were diagnosed through standard means, but that the current cost of clinical genetic/etiological testing was ~$3,500 per patient, roughly double the cost of single proband WGS in our research institute (and approximately 2/3 the cost of trio-based WGS). Our study demonstrates the potential of WGS analysis to identify molecular etiologies for previously undiagnosed patients in an efficient and increasingly cost-effective way. The establishment of our analysis pipeline can allow effective, timely analysis of hundreds of cases per year. Our genomic counseling infrastructure provides physicians and patients with a wide range of services, making WGS a usable diagnostic tool.

2740T

Deep sequencing detects very low-grade somatic mosaicism in the unaffected mother of siblings with nemaline myopathy. *E. Koshimizu[1], S. Miyatake[1], Y.K. Hayashi[2,5], K. Miya[3], M. Shiina[4], M. Nakashima[1], Y. Tsurusaki[1], N. Miyake[1], H. Saitsu[1], K. Ogata[4], I. Nishino[5], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Department of Neurophysiology, Tokyo Medical University, Tokyo, Japan; 3) Department of Pediatrics, Faculty of Medicine, University of Toyama, Toyama, Japan; 4) Department of Biochemistry, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 5) Department of Neuromuscular Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan.

When an expected mutation in a particular disease-causing gene is not identified in a suspected carrier, it is usually assumed to be due to germline mosaicism. We report here very-lowgrade somatic mosaicism in ACTA1 in an unaffected mother of two siblings affected with a neonatal form of nemaline myopathy. The mosaicism was detected by deep resequencing using a next-generation sequencer. We identified a novel heterozygous mutation in ACTA1, c.448A>G (p.Thr150Ala), in the affected siblings. To explore the effect of this mutation, we mapped the mutation onto reported crystal structures. Thr150 is located near the polymerization/interaction interfaces between actin monomers and between actin and its interacting proteins. Thus, p.Thr150Ala may affect polymerization and/or the interactions of actin with other proteins. In this family, we expected autosomal dominant inheritance with either parent demonstrating germline or somatic mosaicism. Sanger sequencing identified no mutation. However, further deep resequencing of this mutation on a next-generation sequencer identified very-low-grade somatic mosaicism. The total read depth at c.448A in ACTA1 was 131495× to 425933×. Very-low-grade somatic mosaicism was confirmed in the mother: 0.4%, 1.1%, and 8.3% in the saliva, blood leukocytes, and nails, respectively. We used allele-specific PCR to confirm the presence of the mutation in the mother. Both the wild-type and mutant alleles were amplified in the proband and the affected sister at a similar level. Both alleles could also be amplified in the mother, but the wild-type allele was amplified at a much greater level than the mutant allele. The wild-type allele only was amplified in the father. We performed High Resolution Melting (HRM) analysis using DNAs from normal controls, the affected siblings, the father (all DNA derived from blood), and the mother (DNA derived from the nails, which showed the highest rate of mosaicism (8.3%)). The melting curves of both affected siblings were aberrant and were called mutant, but those of the father and mother were called normal. Our study demonstrates the possibility of very-low-grade somatic mosaicism in suspected carriers, rather than germline mosaicism.

2741S

Identification of *RIT1* mutations in patients with RASopathies by clinical whole exome sequencing. *P. Liu[1], F. Xia[1], W. He[1], L. Potocki[1], F. Scaglia[1], P. Magoulas[1], D.M. Muzny[2], A.L. Beaudet[1], R.A. Gibbs[1,2], C.M. Eng[1], Y. Yang[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

RASopathies including Noonan syndrome (NS) are a group of autosomal dominant developmental syndromes characterized by short stature, distinctive facial features, and congenital heart defects. These disorders are caused by germline mutations that alter the activity of the RAS/MAPK signaling pathway and the number of causal genes has increased to 14 over the years. Recently, potential gain-of-function mutations in *RIT1*, which encodes a small GTPase that belongs to the Ras superfamily of low molecular weight GTP-binding proteins, were reported in nine unrelated Japanese patients with NS, indicating *RIT1* as a new RASopathy gene (Aoki *et al., AJHG* 2013 *93*:173). Seventy percent of the reported patients with *RIT1* mutations presented with hypertrophic cardiomyopathy. Here, we report additional patients with potentially gain-of-function mutations in *RIT1* identified by clinical whole exome sequencing (WES). Patient 1 is a 2-year-3-month old Latin American female with developmental delay, dysmorphic features including low set ears, broad and flat face, malar hypoplasia, downturned corners of the mouth, crowded dentition, widened neck posteriorly, congenital cardiovascular disease with pulmonary valve stenosis, infundibular stenosis, and pulmonary regurgitation, history of cystic hygroma *in utero*, history of bronchopulmonary dysplasia, prematurity, history of bilateral moderate hearing loss. She was found to have a *de novo* novel heterozygous c.229G>T (p.A77S) mutation in the fourth exon of *RIT1*. Patient 2 is an 8-month-old Latin American male with developmental delay, dysmorphic features including upslanting palpebral fissures and clinodactyly of fifth fingers bilaterally, failure to thrive, aortic stenosis and pulmonic stenosis. He was found to have a *de novo* heterozygous c.104G>C (p.S35T) mutation in the second exon of *RIT1*. The same mutation was also reported previously in two unrelated probands with NS. Both of these two mutations are located within the evolutionarily conserved GTPase domain in *RIT1*. Additionally, we identified the recurrent c.104G>C (p.S35T) mutation in a third patient who has a clinical diagnosis of NS, demonstrating the c.104G position as a mutation hotspot and p.S35T as a common mutation for *RIT1* related RASopathy. Our results expand the molecular and phenotypic spectrums of RASopathy caused by *RIT1* mutations, and demonstrate the advantage of WES in diagnosing newly delineated genetic disorders.

2742M

Splicing mutation in *IQSEC2* gene modulating the phenotype in three siblings with intellectual disability. *I. Madrigal[1,2], J. Rosell[3], L. Rodriguez-Revenga[1,2], MI. Alvarez-Mora[1,2], O. Karlberg[4], D. Elurbe[1,2], A. Bayes[5], S. Sauer[4], AC. Syvänen[6], M. Mila[1,2].* 1) Hospital Clinic Barcelona and IDIBAPS, Barcelona, Spain; 2) Centre for Biomedical Research on Rare Diseases (CIBERER), Spain; 3) Genetics Section, Hospital Universitari Son Espases, Palma de Mallorca, Spain; 4) Department of Medical Sciences, Molecular Medicine and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 5) Molecular Physiology of the Synapse Laboratory IIB, Sant Pau, Barcelona, Spain; 6) Max-Planck Institute for Molecular Genetics Ihnestrasse 63-73 D-14195 Berlin Germany.

The *IQSEC2* (IQ motif and Sec7 domain 2) gene is located on chromosome Xp11.22 and encodes a guanine nucleotide exchange factor for the ADP-ribosylation factor family of small GTPases. This gene is known to play a significant role on cytoskeletal organization, dendritic spine morphology and synaptic organisation. Mutations in *IQSEC2* cause moderate to severe intellectual disability (ID) in all affected males and a variable phenotype in females due to this gene escapes X chromosome inactivation. Here, we report on a novel splicing mutation in *IQSEC2* gene (g.83032_83033delCA) that cosegregates with the disease in a family diagnosed with a nonsyndromic form of X-linked ID. The mutation is a deletion of 2bp (c.3116-2delCA) that activates an intraexonic splice acceptor site resulting in 78 nucleotides deletion in exon 12 (c.3116_3194del). The activation of this acceptor site abolishes 26 amino acids from the highly conserved PH domain of *IQSEC2* and creates a premature stop codon 36 amino acids latter in exon 13. Two separate PCR products were obtained when *IQSEC2* mRNA from exons 9 to 13 was analyzed. Interestingly, the percentage of aberrant splicing in each patient correlates with the severity of their clinical features. As far as we are concerned, we are describing the first splicing mutation affecting *IQSEC2* gene that, moreover, modulates the severity of phenotype in these patients. Acknowledgements: This study was supported as a transnational access project at the European Sequenicng and Genotyping Infrastructure (ESGI) which has received funding from the Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 262055. Exome sequencing was performed by the SNP&SEQ Technology Platform (www.sequencing.se), Department of Medical Sciences, Science for Life Laboratory at Uppsala University, a national infrastructure supported by the Swedish Research Council (VR-RFI) and the Knut and Alice Wallenberg Foundation. We also thank AGAUR from the Autonomous Catalan Government (2009-SGR1337) and Fundación Agrupación Mutua (Premio Discapacidad 2012). The CIBER of Enfermedades Raras is an initiative of the ISCIII.

GAPO syndrome is a rare autosomal recessive disease and is an acronym composed of growth retardation, alopecia, pseudoanodontia, optic atrophy. Only few cases are reported in literature and the clinical spectrum of this rare disease has been expanded . Recently we described on a new patient with GAPO syndrome associated with hypoacusis and bilateral vestibular hypofunction (1) and the details of the progression of the clinical findings of GAPO syndrome in the girl from her birthday to 10 years of life. The genetic cause of GAPO syndrome has now been identified and mutation in ANTXR gene1, which encodes anthrax toxin receptor 1 has been reported by Stránecký et al. (2) in four ethnically unrelated affected individuals. We performed a molecular analysis in our case and homozygous deletion potentially affecting splicing of ANTXR1 (NM_032208.2:c.704-2_720del19) has been identified. Both parents are heterozygous carriers of the mutation. This mutation is not reported in previously described cases. 1 Concolino D et. al, GAPO syndrome associated with vestibular dysfunction and hearing loss. Am J Med Genet A. 2013 Aug;161A(8):2102-4. 2 Stránecký V et al., Mutations in ANTXR1 cause GAPO syndrome, Am J Hum Genet. 2013 May 2;92(5):792-9.

Mutation identification in New Zealand populations: a pilot study in neurodevelopmental disorders. *J. Jacobsen[1], S. Robertson[2], C. Wilson[3], B. Swan[1], E. Glamuzina[3], J. Taylor[4], R. Hill[5], D. Love[6], K. Lehnert[1], R. Snell[1].* 1) Centre for Brain Research and School of Biological Sciences, The University of Auckland, New Zealand; 2) Dunedin School of Medicine, The University of Otago, New Zealand; 3) Adult and Paediatric National Metabolic Service, Auckland City Hospital, New Zealand; 4) Genetic Health Service New Zealand, Auckland City Hospital, New Zealand; 5) Department of Neurology, Auckland City Hospital, New Zealand; 6) Diagnostic Genetics, LabPLUS, Auckland City Hospital, New Zealand.

New Zealand has a unique and diverse population for genetic studies. We are currently investigating the genetic underpinnings of genetically undiagnosed neurodevelopmental disorders in the New Zealand population. In a pilot study, using an exome sequencing approach, we have sequenced two affected individuals from each of four families and have searched for mutations assuming a recessive mode of inheritance. We have found putative mutations in three of the families, two of which are novel and are presented here.

The first family consists of two affected female siblings who presented with gait ataxia at 12 and 18 months of age. MRI revealed vermian hypoplasia and increased spaces between the folia. WES identified compound heterozygous inheritance of two novel mutations (non-synonymous and splice site) in the aarF domain containing kinase 3 (*ADCK3*) gene in both individuals. Interestingly, mutations in this gene result in coenzyme Q_{10} deficiency, with the possibility of treatment with oral Q_{10} supplementation.

The second family consists of two male siblings who presented with profound muscular hypotonia and developmental delay. Investigations revealed mildly low CSF neurotransmitter metabolites (HVA and 5_HIAA). The children were a result of a consanguineous union, and regions of homozygosity were identified by array CGH. Using WES we identified a missense mutation in a conserved transmembrane domain of the monoamine transporter *SLC18A2* gene (solute carrier family 18, member 2; VMAT2), which was present in both boys and located within a region of homozygosity. Successful treatment of a previously reported family with an *SLC18A2* gene mutation and similar clinical presentation has initiated a treatment strategy with the dopamine agonist pramipexole.

The success of this pilot sequencing study is due to the close cooperation between the research team, physicians and a strong genetic hypothesis. As the study expands in scope it has the potential to identify mutations unique to our New Zealand population, and deliver a genetic diagnosis for the participating families.

2745M

Whole exome sequencing identified a novel RAB3GAP1 mutation in Turkish patient with Micro Warburg Syndrome. *B. Yuceturk[1,2], H. Ulucan[1], A. Koparir[1], E. Kirat[1], O.F. Karatas[1,3], E. Fenercioglu[1], M. Seven[1], A. Yuksel[1,4], M. Ozen[1,5].* 1) Istanbul University, Cerrahpasa Medical School, Medical Genetics Department, Istanbul, Turkey; 2) TUBITAK, Kocaeli, Turkey; 3) Erzurum Technical University, Faculty of Science, Molecular Biology and Genetics Department, Erzurum, Turkey; 4) Biruni University, Istanbul, Turkey; 5) Baylor Collage of Medicine, Department of Pathology & Immunology, Houston, TX, USA.

Micro Warburg syndrome (#600118) is a rare autosomal recessive inherited disorder characterized by facial dysmorphism, eye abnormalities including cataract, microphthalmia, microcornea, brain abnormalities and endocrine abnormalities. Three genes, RAB3GAP1, RABGAP2 and RAB18 have been identified to be related with this syndrome. Martsolf syndrome is an allelic and milder form of Micro Warburg syndrome. Here we present a female with Micro Warburg syndrome. She had facial dysmorphism, severe motor-mental retardation, congenital cataract, microcephaly and corpus callosum hypoplasia. Since the associated genes are various and quite long, we utilized whole-exome sequencing (WES) as a diagnostic tool for identifying the molecular basis of Micro Warburg syndrome and all variants were confirmed by Sanger sequencing. WES is an affordable, efficient and powerful method and it is commonly applied as a diagnostic tool for identifying the molecular basis of genetically heterogeneous disorders. As a result a novel homozygous c. 2607-1G>C splice site mutation was detected in exon 23 of RAB3GAP1 and confirmed by Sanger sequencing. Parents also have been demonstrated to be heterozygous for this mutation.

2746T

Molecular Diagnosis of Congenital Limb Defect Syndromes by Next Generation Sequencing. *G. Mendiratta-Vij, J. Zhang, Y. Kasai, T. Brandt, L. Mehta, R. Kornreich, L. Edelmann.* Icahn School of Medicine at Mount Sinai, NYC, NY, USA.

Congenital Limb Defects (CLD) are etiologically and genetically heterogeneous and can occur as an isolated or syndromic defects. Prevalence of CLD is estimated to be at 1 in 1500 - 1 in 3000 live births. Common presentations include polydactyly, syndactyly, limb reduction or long bone deficiencies, and multiple anomalies or generalized skeletal syndromes. Genetic syndromes including CLD may be caused by germline mutations in genes involved in cell fate regulation and patterning during embryogenesis. Between 70% and 100% of syndromic CLD cases with a Mendelian etiology have a known causative mutation. Based on multiple reports, subject matter experts, and detection rates, we considered Townes-Brocks syndrome, Holt-Oram syndrome, Duane-radial ray syndrome, Greig cephalopolysyndactyly syndrome and Pallister-Hall syndrome, Brachydactyly-syndactyly syndrome, Robinow syndrome (RRS), Al-Awadi/Raas-Rothschild/Schinzel phocomelia syndrome (AARRS) and Werner mesomelic syndrome in the development of a next-generation sequencing (NGS) panel. The 7 well-established CLD genes to be interrogated include: SALL4, SALL1, TBX5, GLI3, HOXD13, ROR2, WNT7A, and a cis-regulatory sequence for SHH: ZRS. Agilent custom SureSelect target enrichment combined with the Illumina HiSeq platform was employed to capture coding exons plus 50 bp of upstream and downstream sequence to ensure capture of splicing regions. Analysis of paired-end reads was performed using NextGENe NGS analysis software. Our panel has been fully validated on different specimen types containing a variety of sequence variants including prenatal samples: direct chorionic villi, amniocytes of direct amniotic fluid, cultured villi, and amniocytes. We obtained 100% capture coverage with all bases in the coding and splicing regions enriched and sequenced to sufficient depth (~400X) in all 20 validation samples. The test sensitivity is 99% for detection of substitutions and 95% for detection of small insertions and deletions. The panel was also validated using the Rapid Run mode on the Illumina HiSeq and MiSeq to achieve faster turn-around-times for prenatal testing. Our panel provides a comprehensive, rapid, accurate and cost effective molecular diagnostic test for patients with CLD and prenatal cases with abnormal ultrasound findings and should improve the diagnostic yield in these situations.

2747S

Mutation spectrum and report of 4 novel mutations in *IDS* gene in Indian patients with Hunter syndrome. *G. Verma[1], M. Kabra[1], N. Gupta[1], P. Kaur[2], P. Mishra[1], S. Shastri[1], S. Sapra[1], M. Roychowdhury[1], S. Gulati[3].* 1) Pediatrics (Genetics), All India Institute of Medical Sciences, New Delhi, Delhi, India; 2) Biophysics, All India Institute of Medical Sciences, New Delhi, Delhi, India; 3) Pediatrics (Neurology), All India Institute of Medical Sciences, New Delhi, Delhi, India.

Introduction: Mucopolysaccharidosis type-II (MPS II, Hunter syndrome) is an uncommon X-linked recessive multisystem disorder with significant variability in both age of onset and rate of progression. It is caused by deficiency in the activity of the lysosomal enzyme, iduronate-2-sulfatase, synthesized by the 24 kb long *IDS* gene, located at Xq28. **Objective:** To identify the mutation spectrum of *IDS* gene in Indian patients with MPS-II. **Method:** Twenty two patients were recruited from 19 unrelated families after institutional ethics committee approval and informed consent based on the deficient leucocyte iduronate-2-sulfatase levels. Genomic DNA was amplified by PCR using 9 sets of primers that covered the entire coding region of the *IDS* gene, flanking intronic-splice regions and 5' and 3' UTRs. Bidirectional Sanger-sequencing was performed using ABI 3130 Genetic Analyzer. Sequences were analyzed using NCBI BLAST. **Results and Discussion:** Based upon the phenotypic analysis of 22 patients, 18 patients were classified as severe MPS II. Mutations were identified in 10 families out of 19. Missense (3/19, 16%), nonsense (2/19, 10%), splice-site (2/19, 10%), small insertion, small duplication and indel (1/19, 5%) each were identified. Four mutations c.1248C>T, c.205_206insAAAACTGGCAT, c.1435_1456dupAAGCCGAGTTTAAAAGATATAA and c.1442delGinsTC were novel and predicted to be pathogenic. Nonsense mutations were associated with severe phenotype in two patients. Prenatal diagnosis was done in one family and the fetus was found to be a carrier. Majority of the mutations (4/19, 21%), though nonrecurrent, were in exon 9 and its flanking splice-site region. *IDS/IDS2* recombination has not yet been tested and this could be the main reason for not finding mutations in the remaining 9 families. **Conclusion:** Mutation analysis of IDS gene is helpful in making a specific diagnosis, carrier testing and prenatal diagnosis. No specific genotype phenotype correlation was observed. Exon 9 appears to be the mutational hot spot in our Indian patients.

2748M

The first two AUTS2 mutations on the nucleotide level causing AUTS2 syndrome. *G. Beunders[1], S.A. Munnik de[2], J. Morton[3], P. Vasudevan[4], E. Voorhoeve[1], A.J. Groffen[1], W.M. Nillesen[2], H. Meijers-Heijboer[1], H.G. Yntema[2], E.A. Sistermans[1].* 1) clinical Gen, VU Med Ctr, Amsterdam, Netherlands; 2) Department of Human Genetics, Radboud university medical centre, Nijmegen, The Netherlands; 3) Department of Clinical Genetics, Birmingham Women's Hospital, Edgbaston, Birmingham, UK; 4) Department of Clinical Genetics, University Hospitals of Leicester, Leicester, UK.

Background: We recently described a new ID syndrome, AUTS2 syndrome that is characterised by low birth weight, feeding difficulties, intellectual disability, microcephaly and mild dysmorphic features. All cases thus far were caused by chromosomal rearrangements. Mutations at the base pair level disrupting AUTS2 have not yet been described.

Methods: Here we present the full clinical description of the first two cases with AUTS2 syndrome caused by mutations at the nucleotide level, found by diagnostic exome sequencing.

Results: The phenotypic features of both cases include: intellectual disability, microcephaly, feeding difficulties, dysmorphic features and mild contractures. Both cases have AUTS2 mutations in exon 7 (one nonsense mutation and one two-basepair deletion), both causing a premature stop of the full length transcript and without an predicted effect on the shorter 3' transcript starting in exon 9 that is also expressed in human brain.

Conclusions: The similarities between the phenotypes of these two cases and formerly described patients with AUTS2 syndrome, further confirm that AUTS2 syndrome is a single gene disorder with a recognizable phenotype that can be caused by haploinsufficiency of the full length transcript of AUTS2.

2749T

Novel mutations and clinical outcomes of copper-histidine therapy in Menkes disease patients. *G. Kim[1], J. Kim[2], J. Choi[2], B. Lee[1,2], H. Yoo[1,2].* 1) Medical Genetics Center, Asan Med Ctr, Seoul, South Korea; 2) Dept. Pediatrics, Asan Med Ctr, Seoul, South Korea.

Menkes disease is a very rare X-linked copper metabolism disorder caused by mutations in the ATP7A gene. With the advent of subcutaneous copper-histidine therapy, the early diagnosis of Menkes disease becomes of utmost importance for patients' prognosis. The clinical characteristics of 12 Korean patients with Menkes disease (11 males and 1 female from 11 unrelated families) were studied along with the mutation spectrum. Only 2 males were diagnosed in the neonatal period, and the other male patients were diagnosed at age 4.3 ± 1.9 months. The presenting signs included depigmented kinky hair, neurologic deficits, and hypotonia. Serum copper and ceruloplasmin levels were markedly decreased. Intracranial vessels were dilated with tortuosity and accompanied by regional cerebral infarctions, even at an early age. Notably, a female patient who presented with developmental delay, was diagnosed at age 18 months by characteristic MRA findings, biochemical profiles, and genetic analysis. CAG repeats in the AR gene at Xq12 were investigated to evaluate the X-inactivation pattern, and the patient revealed a 76% inactivated normal X-chromosome. A total of 11 mutations in ATP7A were identified, including five novel mutations: p.L825fs*1, c.121-930_2626+488del (exons 3-12 deletion), c.3744_4123+576del (exons 19-21 deletion), p.N686fs*1, and p.H1086Pfs*3. Most mutations were truncated (except 1 missense mutation), including 3 frameshift, 2 nonsense, 3 large deletion, and 2 splice-site variants. The age at commencement of copper-histidine treatment was 7.3 ± 7.5 (0.5 - 27) months. Despite treatment, seven patients died before age 5 years, and the remaining patients were severely retarded in neurodevelopment. The poor outcomes of our patients might be related to delayed therapy as well as truncated nature of ATP7A mutations.

2750S

Genetic analysis of an atypical case of Branchio-Oto-Renal (BOR) Syndrome. *R. Birkenhager, T. Jakob, E. Prera, S. Arndt, W. Maier, R. Laszig, A. Aschendorff.* Department of Otorhinolaryngology and Head and Neck Surgery, University Medical Center Freiburg, Killianstrasse 5, D-79106 Freiburg, Germany.

Introduction: Branchio-oto-renal (BOR) (MIM 113650) and Branchio-otic (BO) (MIM 602588) syndromes are one of the most common forms of autosomal dominant syndromic hearing loss. BOR/BO syndromes are genetically heterogeneous and caused by mutations in EYA1, SIX1 and SIX5 genes. The phenotypes of BOR syndrome are highly variable, with common clinical features including hearing impairment (HI), malformations of the pinnae, the presence of branchial fistulae, and various renal abnormalities, collecting system duplications; renal hypoplasia, dysplasia, and agenesis, additional features include inner ear anomalies such as dysplasia or hypoplasia of the cochlea, enlarged vestibular aqueduct or Mondini malformation and facial asymmetry. Middle ear defects described in BOR syndrome include hypodysplastic stapes, malleus-incus fusion and closed oval windows. BOR syndrome is clinically heterogeneous and has reduced penetrance. The prevalence of BOR syndrome was reported to be 1:40,000. In contrast Branchio-otic (BO) syndrome, patients suffer from inner ear and bronchial defects without renal abnormalities. In this study, clinical and genetic analyses were performed in a family with BOR syndrome focusing on auditory characterization and rehabilitation. Methods: Hearing testing BERA/Electrocochleography was only done in the Patient other family members were not tested because they have no hearing impairment or clinical abnormalities. Radiological a high-resolution CT scan was made. Genetic analysis was performed for EYA1, SIX1, and SIX5 genes of the affected individual and first degree relatives using direct sequencing of the coding exon and intron transitions of the genes, including deletion analysis. The modality and outcome of auditory rehabilitation were evaluated. The genotype-phenotype correlation was investigated. Results: One novel SIX1 mutation, a small deletion (c.376_378delGAG, p.Glu126del) was identified in the family with BOR syndrome. EYA1 and SIX5 mutations were not detected in the present study. No renal and branchial defects were observed in the patients. Cochlear implantation performed in one patient resulted in significant hearing improvement. Conclusions: Successful outcome can be expected with cochlear implantation in patients with BOR syndrome who cannot benefit from hearing aids. The novel SIX1 mutations may add to the genotypic and phenotypic spectrum of BOR syndrome in the European population.

2751M

Mutations in ERF gene as a new genetic cause of craniosynostosis - enabling parents and clinicians to understand why a child is affected. *A. Chaudhry[1, 2], P. Sabatini[2,3], L. Han[3], P. Ray[2,3], C. Forrest[2,4], S. Bowdin[1,2].* 1) Division of Clinical and Metabolic Genetics. Department of Paediatrics. The Hospital for Sick Children. 525 University Avenue. Toronto. ON. M5G2L3; 2) University of Toronto. Toronto. ON; 3) Molecular Genetics Division, Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto; 4) Division of Plastic & Reconstructive Surgery, Centre for Craniofacial Care & Research, The Hospital for Sick Children.

Craniosynostosis is a genetically heterogeneous condition resulting from the premature fusion of one or more cranial sutures. Several genes have been identified as a cause of craniosynostosis including FGFR1, FGFR2, FGFR3, TWIST, EFNB1, FAM20C and LMX1B. Twigg et al. recently published mutations in the ERF gene as a cause of 'ERF-related craniosynostosis' syndrome in about 6% of population they screened. The main clinical features included multiple-suture synostosis, craniofacial dysmorphism (hypertelorism, shortening and/or vertical displacement of the nose, prominent orbits and forehead), Chiari malformation, language delay and behavioral issues. These patients presented after infancy and did not need repeated cranial surgeries. ERF encodes an inhibitory ETS transcription factor directly bound by ERK/2(refs. 2-7). With the help of mouse models, the authors were able to show that reduced dosage of the ERF gene causes complex craniosynostosis in humans and mice. In our retrospective study, we sequenced the coding regions of the ERF gene in 43 patients who tested negative for mutations in FGFR1, FGFR2, FGFR3 and TWIST as well as by cytogenetics testing. In our cohort of patients with multi-suture or sagittal suture synostosis, we identified heterozygous pathogenic mutations in the ERF gene in five individuals (11.6%). The review of medical records revealed that three of our patients (60%) presented later in infancy. Subject A1 presented at 6 and half years of age with headaches and visual loss secondary to oxycephaly. 2/5 (40%) of our patients had other abnormalities on head imaging including Chiari I malformation. The dysmorphic features in our cohort include hypertelorism, proptosis, depressed nasal bridge and retrognathia in addition to the abnormal head shape as a result of craniosynostosis. These patients did not have developmental delays other than speech delays in one patient. They did not need repeated cranial surgeries in general. In conclusion, ERF-related craniosynostosis should be suspected in patients who present later in infancy with multiple suture or sagittal synostosis and who have other cranial malformations like Chiari I malformation. For the purposes of counseling, it is important to note that most of these individuals do not have developmental delays, but few might have speech delay. In general, they do not need repeated cranial surgeries.

2752T

COlobomatous Microphthalmia, Macrocephaly, Albinism & Deafness (COMMAD syndrome), a new syndrome caused by biallelic mutation of MITF: clinical characterization and molecular analysis. *A. GEORGE[1], M. RIUS[1], R.K.P ALUR[1], D.J. ZAND[3], S. YURI[1], K. BHARTI[2], B.P. BROOKS[1].* 1) Ophthalmic Genetics and Visual Function Branch, National Eye Institute, Bethesda, MD; 2) Section on Epithelial and Retinal Physiology and Disease, National Eye Institute, Bethesda, MD; 3) Dept. of Genetics, Children's National Medical Center, Washington, DC.

The MITF gene encodes for microphthalmia-associated transcription factor, which is a basic helix-loop-helix protein critical for development of neural crest-derived melanocyte, and neuro-ectoderm derived retinal pigmented epithelium. Mutations in MITF are associated with Waardenburg syndrome (WS). In this study, we report a rare family comprised of previously undiagnosed WS parents with disparate clinical manifestations due to heterozygous MITF mutations and a child with compound heterozygous mutations of MITF. This child exhibited extreme colobomatous microphthalmia, a complete lack of melanin pigment in the skin/hair/eyes, profound hearing loss, macrocephaly and low tone. DNA sequencing revealed a paternally inherited c.952_954delAGA MITF allele and a maternally-inherited c.G921C (p.K307N) allele the latter being previously unreported. For analysis of the two mutations at molecular level, GFP and FLAG peptide tagged wild type and mutant MITF-A isoforms were generated by PCR mediated cloning and site directed mutagenesis and were named as MITF-wt, MITF-K307N and MITF-R318del, respectively. Upon transfection of HEK293 cells with MITF expression constructs, MITF-wt was localized primarily in the nucleus. In contrast, MITF-R318del was observed in both nuclear and cytoplasmic compartments. The K307N mutant localization pattern was similar to MITF-wt. The localization pattern was further confirmed by Western blot analysis on isolated nuclear and cytoplasmic fraction of the transfected HEK cells. MITF-wt activated the M-Box, Tyrosinase related protein (TRP) 1, TRP-2, Tyrosinase (TYR) and Best1 promoters by dual luciferase assay. Interestingly MITF-K307N mutant also activated all of the above-mentioned promoters, while MITF-R318del mutant was unable to activate any of the tested promoters. Current studies are focused on how mutant MITF molecules may interact with the wild type protein, with each other, and with proteins important in ocular and other tissues. These results describe a novel syndrome caused by biallelic mutations in MITF (COlobomatous Microphthalmia, Macrocephaly, Albinism and Deafness (COMMAD syndrome) and a novel "activating" mutation in MITF gene.

2753S

A novel missense mutation of ryanodine receptor 1 (*RYR1*) in a Japanese idiopathic hyper CK-emia family. *K. Sano[1,2], S. Miura[1,2], T. Fujiwara[2], R. Fujioka[2], A. Yorita[1], K. Noda[1], H. Kida[1], K. Azuma[1], S. Kaieda[1], K. Yamamoto[3], T. Taniwaki[1], Y. Fukumaki[2], H. Shibata[2].* 1) Department of Respirology, Neurology and Rheumatology, Department of Medicine, Kurume University School of Medicine, Kurume, Fukuoka; 2) Division of Genomics, Medical Institute of Bioregulation, Kyushu University, Fukuoka; 3) Department of Medical Chemistry, Kurume University School of Medicine, Kurume, Fukuoka.

Persistent elevation of serum creatine kinase (CK) in individuals without any symptoms has been called idiopathic hyper CK-emia. We studied a four-generation pedigree of a Japanese family with idiopathic hyper CK-emia to elucidate the genetic basis of this disease. Nine members of the family including 5 affected individuals were enrolled in this study. Four affected members do not have any neurological abnormalities. Two affected members experienced continuous mild hyperthermia. In one affected member, slightly muscular weakness in bilateral iliopsoas, absence of patellar tendon reflexes, and impaired vibration sense in the lower limbs were observed. No significant distinguishing features on muscle biopsy (HE staining). The multipoint linkage analysis using SNP markers showed seven clear peaks of logarithm of odds scores (>1.4). We identified 65,180 patient-specific single nucleotide variants (SNVs) by exome analysis upon one patient and one unaffected relative. By the filtering processes using the information of the public SNP database, the result of our linkage analysis and the 40 candidate genes for disorders with possibly associated with idiopathic hyper CK-emia, we identified only one novel heterozygous non-synonymous SNV, c.7053 G>C, p.S2345T in the *RYR1* gene (MIM 180901). We confirmed cosegregation of the SNV with the phenotype in the family using the Sanger sequencing method. The PolyPhen-2 and PANTHER subPSEC scores of p.S2345T are 0.911 (possibly damaging) and -3.56 (probably damaging), respectively, indicating the SNV might cause the functional alteration. This variation was not detected in 420 control subjects. Immunochemical staining using the RYR1 antibody of the muscle biopsy specimen of one affected member showed weak staining in some muscle fibers. Moreover, western blotting revealed a substantial decrease of the RYR1 protein level. We also found that the mRNA expression of *RYR1* was reduced in the muscle of the affected member. These results suggest that the substitution of Ser with Thr at the position of 2,345 of *RYR1* may have a dominant negative effect. The *RYR1* gene is a causative gene of malignant hyperthermia or central core disease. In our study, the novel missense mutation of *RYR1* might cause idiopathic hyper CK-emia. In conclusion, when clinicians meet patients with idiopathic hyper CK-emia, it is important to consider *RYR1* mutations. This study was approved by the Ethics Committees of Kurume Univ. and Kyushu Univ..

2754M

***De novo* mutation in *SOX18* causes a novel form of Hypotrichosis-Lymphedema-Telangiectasia with severe vascular defects.** *F. Wünnemann[1,2], C. Preuss[1], V. Kokta[3], S. Leclerc[1], M. Thibault[1], J.C. Grenier[1], G. Andelfinger[1].* 1) CHU Sainte Justine Research Center , Montréal, Quebec, Canada; 2) Department of Biology, University of Münster, Germany; 3) Department of Pathology, CHU Sainte Justine, Université de Montréal, Quebec, Canada.

Hypotrichosis-Lymphedema-Telangiectasia (HLTS) is an ultra-rare, congenital condition that is characterized by blood and lymph vessel dysfunction, as well as hair follicle defects (OMIM #607823). Mutations in the transcription factor SRY (sex determining region Y)-box 18 (*SOX18*) have been implicated in HLTS for less than 10 pediatric cases globally. Here, we describe a 13 year old, female patient with anomalies in hair growth, subcutaneous teleangiectasia and dilation of the ascending aorta. First symptoms were noted from the age of six months on, with salient features being absence of eyebrows, hypertension and skin discolorations. Using a whole-exome sequencing approach, we now identified a novel *de novo* mutation in *SOX18* (c.481C>T) that results in a premature STOP codon (p.Q161*). The mutation in the highly conserved site (GERP score > 3) is located directly after the HMG box domain, truncating the protein of its transactivation domain, likely disrupting transactivation activity. We validated the heterozygous mutation by bi-directional Sanger sequencing and performed immunohistochemical staining of skin biopsies to reveal vascular identity of dilated vessels. These studies showed extensive dilation of subcutaneous capillary vessels, without any anomalies of the lymphatic system. Notably, the vascular defects in the presented case resemble the recently described double knockout Sox18/Vegfd mouse model, suggesting a role of vascular endothelial growth factor D (*VEGFD*) in the progression of HLTS. We highlight the use of whole exome sequencing as a valuable tool for the rapid identification of rare alleles involved in cardiovascular defects in a clinical setting. Taken together, our findings indicate a novel form of HLTS with absence of lymphatic malformations.

2755T

A novel case of Epidermolysis Bullosa with Pyloric Atresia due to homozygous mutation of c.600delC in integrin β4 gene: Clinical, Immunohistological and Molecular Diagnosis. *S. Yilmaz[1], I. Mungan Akin[2], C. Chiaverini[4], A. Charlesworth[4], D. Buyukkayhan[3], J.P. Lacour[4], I. Akalin[1].* 1) Medical Genetics, Istanbul Medeniyet University, Department of medical Genetics, Istanbul, Turkey; 2) Neonatology, Istanbul Medeniyet University, Istanbul, Turkey; 3) Neonatology, Goztepe Training and Research Hospital ,Istanbul Medeniyet University, Istanbul, Turkey; 4) Reference Centre for EBH, University Hospital of Nice, France.

Epidermolysis Bullosa (EB) with pyloric atresia (EB-PA) is a hemidesmosomal subtype of EB characterized by blister formation following minor trauma and pyloric atresia with/without renal disorders. The main pathology in EB-PA is basement membrane disruption due to abnormal expression of integrin and/or plectin proteins that are responsible for adherence of epidermis to lower layers in dermoepidermal junction. The genetic etiology of hemidesmosomal EB is homozygous or compound heterozygous mutations of PLEC, ITGA6 or ITGB4 genes. The proband was a male newborn with the findings of bilateral hydronephrosis, pyloric atresia and large aplasia cutis on four extremities. The parents were 2nd degree cousins and they had another newborn baby with the same clinical findings who died at 1st week. The patient was clinically diagnosed as EB-PA. Immunohistology of the biopsy specimen showed ITGB4 deficiency. Molecular analysis revealed a homozygous c.600delC mutation in exon 7 of ITGB4 gene. To our knowledge there is only one previous case of EB-PA with homozygous c.600delC mutation reported in the literature.

2756S

Increased Suseptibility to Attention Deficit Hyperactivity Disorder risk in Marfan Syndrome and Other Connective Tissue Disorders. *A. Hall, M. Tucker, L. Escobar.* Medical Genetics and Neurodevelopmental Center, St. Vincent Hospital, Indianapolis, IN.

Marfan syndrome is an autosomal dominant connective tissue disorder that involves the cardiovascular, ocular and skeletal systems and is caused by mutations in *FBN1*. Based on clinical observations, an increased susceptibility to difficulties with sustained visual attention and visuoconstructive skills may also be present in Marfan syndrome. We report a population of patients clinically diagnosed with a connective tissue disorder, including Marfan syndrome, seen in our medical genetics and neurodevelopment clinic who had a high prevalence of attention deficit hyperactivity disorder (ADHD). Patients were referred to our clinic for genetic evaluation of various connective tissue disorders, including Marfan syndrome, between 2009-2014. Six out of 20 or 30% of patients with a clinical diagnosis of Marfan syndrome had comorbid ADHD with 3 out of 12 or 25% of patients with a molecular confirmation of Marfan syndrome having a clinical diagnosis of ADHD. In addition, 10 out of 32 or 34% of patients with a clinical diagnosis of a connective tissue disorder were also clinically diagnosed with ADHD. Our clinic observations suggest a possible link between connective tissue disorders, including Marfan syndrome, and an increased susceptibility to ADHD as has been previously reported in the literature. This possible link should be further investigated with increased patient populations.

2757M

A novel mutation in *OPN1MW* in a brazilian patient with x-linked retinal cone dystrophy type 5. *A.CV. Castro[1], A.T. Rassi[1], A.AN. Rocha[1], L.FOB. Chaves[1], L.SM. Mendonca[1], T. Oliveira[1], M.P. Avila[1], I.MM. Silva[1], J. Chiang[2], L.AR. Gabriel[1].* 1) Ophthalmic Genetics Department, Federal University of Goias, UFG , Goiania, Goiania, Brazil; 2) Molecular Diagnostic Laboratory, Casey Eye Institute, Portland, Oregon, USA.

Purpose: To report a novel mutation in the OPN1MW gene in a patient with x-linked retinal cone dystrophy type 5 presenting severe photophobia and tritanopia. Methods: Eye examination was performed. Best corrected visual acuity (BCVA) was done (Snellen chart). Color vision was measured with Farnsworth D-15 Dichromatous Color Blindness Test. Retinography, (TRC50DX Topcon) and optical coherence tomography-OCT (Spectralis Heidelberg Engineering Inc.) were done. Full-field electroretinogram (FF-ERG) was performed (Roland Consult RETIport Science 6.12.5). Direct testing for mutations in the GUCA1A gene was performed by PCR amplification and bidirectional DNA sequencing of all coding exons and exon/intron boundaries in a CLIA certified laboratory. Additionally, whole exome sequencing (WES) was performed. The results were analyzed and compared to their NCBI reference sequences. The bioinformatic tool Mutation Taster was used to predict the effect of the mutation on the protein. Protein domains were identified with the bioinformatic tool SMART. Results: Examination revealed a 65-year-old brazilian male with severe photophobia, obligating the patient to use dark lenses sunglasses all the time and pilocarpine eyedrops in order to obtain some relief. BCVA was 20/20 at the right eye (OD) and 20/40 at the left eye (OS). The Farnsworth D15 test showed trinatopia. Retinography revealed moderate arteriolar vasoconstriction, severe venular vasoconstriction, retinal pigment epithelium atrophy, peridiscal atrophy, and retinal temporal atrophy with dark pigment clumping. The macula was relatively spared. The OCT showed a decreased foveal thickness on both eyes: 174μm in OD and 205μm in OS. The FF-ERG showed an important decrease in cones response (30%) and, in contrast, a discreet decrease in rods response (90%) on both eyes. The GUCA1A sequencing didn't reveal any mutations. WES identified the novel missense mutation c.538G>T:p.Ala180Ser on the OPN1MW gene. This novel mutation was predicted as disease causing by Mutation Taster. It affects the 4th transmembrane helix region of the OPN1MW protein according to SMART. Conclusions: Herein we've described a novel mutation in OPN1MW (c.538G>T:p.Ala180Ser) in a patient with severe photophobia and tritanopia.

2758T

Cerebrofaciothoracic dysplasia: a case report with molecular search for *TMCO1* mutation. *J. Rivera[1], P. Campeau[2], E.L. Mellín-Sánchez[1], F.J. Martínez-Macías[1], L. Bobadilla-Morales[1,3], A. Corona-Rivera[1,3], J.R. Corona-Rivera[1,3].* 1) Centro de Registro e Investigación sobre Anomalías Congénitas (CRIAC), Servicio de Genética y Unidad de Citogenética, Hospital Civil de Guadalajara "Dr. Juan I Menchaca", Guadalajara Jalisco, México, Guadalajara Jalisco, México; 2) Sainte-Justine University Hospital Research Center, University of Montreal, Canada; 3) Instituto de Genética Humana "Dr. Enrique Corona Rivera", Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Guadalajara, México.

Introduction. The cerebrofaciothoracic dysplasia (CFTD), also known as Pascual Castroviejo syndrome type 1 (MIM 213980) belongs to the group of bone dysplasias with spondylocostal/thoracic dysostosis. The CFTD is characterized by macrocephaly, hypoplasia of corpus callosum, elongated septum pellucidum, flat facial profile, hypertelorism, cleft lip and palate, low-set ears, costovertebral abnormalities and intellectual disability. The CFTD is caused by a homozygous nonsense mutation in the human transmembrane and coiled-coil domains protein 1 (*TMCO1*), mapped on 1q23.3-q24.1. We report a Mexican infant with CFTD with molecular analysis negative for *TMCO1* mutation and review the literature regarding to the CFTD. **Clinical Report.** The *propositus* was the product of the first uncomplicated pregnancy from non-consanguineous and healthy parents. Family data included two maternal uncles with hydrocephalus, and two cousins with cleft lip -one maternal and one paternal, respectively. Prenatal ultrasounds reported macrocephaly and suspected of skeletal dysplasia. Delivery was carried out via cesarean in the 36th week of gestation. Apgar scores were 7 and 8 at 1 and 5 min, respectively. The birth weight was 2280 g (10th centile), the length was 44 cm (< 3rd centile), and the infant had an occipitofrontal circumference of 38 cm (> 97th centile). Clinical examination showed broad forehead, flat nasal bridge, posteriorly rotated ears, flat facial profile, short nose, synophrys, short neck, single umbilical artery, and bilateral single palmar crease, clinodactyly, and single crease on both fifth fingers. Echocardiogram revealed a patent ductus arteriosus. On radiographs showed platyspondyly, wedged vertebrae, and multiple thoracic hemivertebras. MRI of the brain exhibited cerebellar atrophy, posterior fossa cyst, corpus callosum hypoplasia, and cavum septum vergae. On fluoroscopy examination with liquid barium, a nasopharyngeal reflux was reported. Karyotype with G-bands was normal 46,XY, at a 550 band-level resolution. The molecular analysis was negative for a *TMCO1* mutation. **Conclusions.** Clinical and radiographics features in our patient were in concordance with the main anomalies reported in the 34 previous reported cases with CFTD up to date. Of them, 16/17 molecularly studied have mutations in the gene *TMCO1*. Since mutation was not found in our patient, further strategies are required in the CFTD for its complete molecular elucidation.

2759S

CFTR: p.I1023R is a rare but recurrent disease-causing mutation found in Chinese patients with Cystic Fibrosis. *B.H.Y. Chung[1,2], K.C. Leung[2], C.C.Y. Mak[1], C.S.K. Chow[1], J.D. Ying[1], Y.W.Y. Chu[1], W.L. Yang[1], Y.L. Lau[1], K.Y.K. Chan[2,3], S.L. Lee[1].* 1) Department of Paediatrics and Adolescent Medicine, Queen Mary Hospital, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HKSAR, China; 2) Department of Obstetrics & Gynaecology, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HKSAR, China; 3) Prenatal Diagnostic and Counseling Department, Tsan Yuk Hospital, HKSAR, China.

Cystic fibrosis (CF [MIM 219700]) is a common autosomal recessive disorder in Caucasians, yet less than 20 Chinese patients with molecularly confirmed CF have been reported in both English and Chinese Biomedical journals. Our department is the only center that offers sweat test in Hong Kong, a city of 7.3 million in southern China. We estimate that the incidence of CF is around 1 in 300,000 live births in Chinese population in Hong Kong. Here, we report 6 unrelated Chinese patients with CF with detailed description of their clinical manifestations. With a molecular approach combining NGS, Sanger sequencing and MLPA, we screened the entire protein coding regions of CFTR and selected deep intronic sites for known disease-causing mutations, deletions and duplications. Molecular diagnosis of 4 patients was confirmed, and interestingly 3 patients were found to carry a missense mutation, p.I1023R (CFTR: NM_000492.3: c.T3068G), reported previously in 2 Taiwanese siblings with CF. All 3 patients inherited the mutation from either parent. Bioinformatics tools predict I1023R is possibly damaging to the protein. The clinical manifestations of patients carrying this recurrent mutation are typical CF features including Pseudomonas aeuroginosa pneumonia, bronchiectasis and meconium ileus. From our search in literature and CFTR mutation database, p.I1023R has not been reported in CF patients of other ethnicities. Furthermore, it is not found in our own exome database (~200 exomes), ESP6500 and 1000GP, suggesting a low allele frequency. Linkage analysis is currently underway to study whether I1023R is a founder mutation in Han Chinese. In conclusion, we propose that I1023R is a rare but recurrent disease-causing CFTR mutation important in Chinese CF patients. p.I1023R is not included in the CFTR panel recommended by the ACMG. This finding has implications in the design of mutation panels/ analysis of NGS for molecular diagnosis of CF in Chinese population.

Identification of a novel *ERCC8* mutation in a 10 year old brazilian female with Cockayne Syndrome type 1. *L.FOB. Chaves[1], A.CV. Castro[1], A.AN. Rocha[1], J. Chiang[2], A.T. Rassi[1], T. Oliveira[1], M.P. Avila[1], L.AR. Gabriel[1].* 1) Ophthalmic Genetics Department, Federal University of Goias, UFG, Goiania, Goias, Brazil; 2) Molecular Diagnostic Laboratory, Casey Eye Institute, Portland, Oregon, USA.

Purpose: To present a case report of a female patient with Cockayne Syndrome type I presenting two mutations on the ERCC8 gene, one being an already known mutation and the other one a novel missense mutation. Methods: Clinical examination was performed. Direct testing for mutations in the ERCC6 and ERCC8 gene was performed by PCR amplification and bidirectional DNA sequencing of all coding exons and exon/intron boundaries in a CLIA certified laboratory. The results were analyzed and compared to the NCBI reference sequences NM_000124.3 (ERCC6) and NM_000082.3 (ERCC8). The bioinformatic tools PolyPhen-2 and Mutation Taster were used to predict the effect of the novel mutation on the resulting protein. Protein domain identification was done with the bioinformatic tool SMART. Results: Clinical examination revealed a female patient born with 38 weeks of gestation by elective cesarean delivery without any maternal or obstetric complications. At birth she presented APGAR (1st and 5th minutes) 8 and 9 respectively, weight of 2850g, height of 48cm, head circumference of 33.5 cm and chest girth of 32cm. She was developing properly until 3 months when started failure of growth associated with developmental deterioration, microcephaly with a final head circumference of 45 cm (08 years old), mental retardation, ataxia, tremors, cutaneous photosensitivity, thin and dry hair. The ocular findings were sunken eyeballs, strabismus (exotropia), pigmentary retinopathy and a persistent miosis. The ERCC8 sequencing revealed a reported mutation IVS7-1G>A and a novel mutation c.1055G>A:p.Gly352-Asp. This novel mutation was predicted as probably damaging by PolyPhen-2 and disease causing by Mutation Taster. The novel mutation affected the 7th WD-40 repeat domain of the ERCC8 protein. Conclusions: Herein, we reported a patient with typical Cockayne Syndrome type I presenting a novel mutation on ERCC8 affecting the 7th WD-40 repeat domain of the ERCC8 protein. Additionally this is the first mutation in the 7th WD-40 repeat domain causing Cockayne Syndrome, since the only mutation on this domain was reported in a patient with UV-sensitive syndrome.

2761T

Identification of a novel *RP1L1* mutation in a 38-year-old brazilian female with retinal cone dystrophy. *A.AN. Rocha[1], A.CV. Jordao[1], I.MM. Silva[1], A.CV. Castro[1], L. Lando[1], J. Chiang[2], M.P. Avila[1], L.AR. Gabriel[1].* 1) Opthalmic Genetics Department, Federal University of Goias, UFG, Goiania, Goias, Brazil; 2) Molecular Diagnostic Laboratory, Casey Eye Institute, Portland, Oregon, USA.

Purpose: To present a case report of a female patient with cone dystrophy presenting a novel missense mutation in the RP1L1 gene. Methods: Eye examination was performed. Best-corrected visual acuity (BCVA) was done using the Snellen chart. Color test was done with Farnsworth D-15 dichromatous color blindness test, visual field was tested using Goldmann semiautomatic kinetic perimetry (Octopus 900, Haag-Streit), and retinography and fluorescein retinal angiography was done with TRC50DX Topcon. Whole exome sequencing (WES) was performed. All the genes accountable for retinal cone dystrophies were analysed and compared to their NCBI reference sequences. The bioinformatic tools PolyPhen-2 and SIFT were used to predict the effect of the novel mutations on the resulting proteins. Protein domain identification was done with the bioinformatic tool SMART. Results: Clinical examination revealed a 38-year-old female patient born from non-consaguineous parents, with slowly progressive decline of her BCVA on both eyes iniciated at 12 years old, having a eye fundus with temporal pallor of the optic disc and diffuse and faint yellow dots between the retinal vessels arcades on both eyes. The fluorescein angiography highlighted these eye fundus alterations, with discreet mottling of the posterior pole. Farnsworth D-15 test demonstrated color blindness, specially deuteranomaly. Goldmann semiautomatic kinetic perimetry demonstrated central scotoma with normal peripheral fields. WES revealed the novel heterozygous c.4004G>T:p.Gly1-335Val RP1L1 mutation. This novel mutation was predicted as probably damaging by PolyPhen-2 and damaging by SIFT. It caused a substitution of a glycine to a valine in an unknown region of the protein between a low complexity region and the first coiled coil region of the protein (two amino acids before the beginning of the next coiled coil domain). Conclusions: Herein we describe a novel mutation on RP1L1 along with a novel phenotype, once this gene was up to now exclusively related to either dominant retinitis pigmentosa, or occult macular dystrophy.

CRANIOFACIAL SYNDROMES AND GENETIC VARIABILITY IN A PEDIATRIC HOSPITAL IN MEXICO. *W. San Martin-Brieke[1], J.M. Aparicio-Rodriguez[2, 3], L. Vázquez de Lara[3], A. Peral García[3], S. Chatelain-Mercado[4].* 1) Maxilofacial Surgery; 2) Genetics, Hosp para el Nino Poblano, Puebla; 3) Estomatology, Benemérita Universidad Autónoma de Puebla; 4) Biothecnology, Universidad Metropolitana de México.

It has been observed that a 60 to 70% of congenital malformations, there is not a definite cause. Within the causes that are known to exist: alterations chromosome 3-5%, 20% genetic mutations, environmental agents, radiation 1%, 2-3-% infections, metabolic disorders maternal 1-3%, drugs and agents chemical 2-3% of the remainder the cause is unknown. The understanding of many of the development and growth disorders affecting craniofacial structures Pinto (1979); Alfaro et al. (1994); Gorlin (1985); Witkop (1975); Slavkin (1996) is achieved through knowledge of embryology, genetics and histology of these structures. The true etiologic factors present in several alterations in the development and growth of the oral cavity, maxillary and various soft tissues. Witkop in 1975 and Gorlin in 1983 stressed that in certain craniofacial diseases; genetic and hereditary factors may be decisive or just contribute to the emergence of a specific disease. Most of craniofacial malformations are of unknown etiology, and, as a result, the classification is mainly based on features of form and structure. There are many types of anomalies relating to the shape, number and structure and it has a hereditary origin. The nature of the abnormalities depends mainly by genetic factors. The frequency which these problems may arise depends on the form of inheritance and other laws of probability. Some anomalies may occur as the only apparent hereditary alteration. Others are presented as part of a much more complex genetic problem. Specifically congenital agenesis of tissues that may also be the only problem of hereditary origin. However, Agenesis and malformations can be part of a syndrome and be related to alterations in other ectodermal tissues such as hair, skin and mucus membranes, assessed as syndromes in this study: Moebius, Goldenhar, Cockayne, Opitz G, Cornelia de Lange, Criduchat, Patau, Edwards, Down, Klinefelter and Turner. In Mexico was established in 1978 the "registration and surveillance epidemiological of the malformations congenital external" (RYVEMCE), generating preventive information programmes targeting the population at risk. For their study, malformations were divided as genetic or congenital abnormalities observed in this study into five groups according to the structural defect of the same as well as the genetic, congenital, and multifactorial cause.

Exploring somatic mosaicism in uterovaginal aplasia. *X. Bonilla[1], P. Makrythanasis[1], F.A Santoni[1], A. Pellet[3], K. Rall[4], S. Eisenbeis[4], M. Guipponi[2], C. Gherig[2], C. Rosenberg[5], S. Lyonnet[3], S.E. Antonarakis[1,6].* 1) Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Department of Genetic Medicine and Laboratories, University Hospitals of Geneva, Switzerland; 3) Department of Genetics and Embryology of Congenital Malformations, Hôpital Necker, Paris France; 4) Department of Obstetrics and Gynecology, Tübingen University Hospital, Tübingen, Germany; 5) Department of Genetics and Evolutionary Biology, Human Genome Research Center, Sao Paulo University, Brazil; 6) iGE3, Institute of Genetics and Genomics of Geneva, Switzerland.

The molecular cause of congenital uterovaginal aplasia, or Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome in unknown. The existence of families with more than one affected individual supports the possibility of a genetic cause; however, the majority of cases are sporadic. The lack of success in identifying the genetic origin of MRKH syndrome so far, points to a complex etiology. This could be due to a reduced penetrance or sex-specific expression of germline mutations or to somatic mosaicism. The objective of our study is to identify candidate genes for the MRKH syndrome through the investigation of genetic somatic differences between monozygotic twins discordant for this disease. We performed whole genome high-throughput sequencing of blood DNA of two pairs of monozygotic twins discordant for MRKH syndrome to a coverage of 35x for >90% of the genome. Variants were called with samtools and Pindel. About 4.5 million variants were identified per individual, 95% of them have been previously seen in the human population and are found in dbSNP. The identified variants were queried with Variant Master (Santoni et al., 2014) in order to detect differences among the individuals from both twinships. After variant filtering, the number of private variants per individual ranged between 34 and 162. After Sanger validation, one of the variants was a true difference between the individuals of a twinship. The SNV causes a non-synonymous change, p.P84L, in the first exon of PI15, a protease inhibitor gene from the CAP family. Validation of this candidate gene in a sample set of matching blood and uterine tissue remnants of patients with MRKH is ongoing in order to assess the role of early somatic mosaicism limited to Müllerian structures in the etiology of this disease. Another validation set is a cohort of more than 40 MRKH individuals' blood DNA. Using targeted high-depth high-throughput sequencing (coverage >1,500x) we will search for low levels of mosaicism in blood, down to 1%. SANTONI, F. A., MAKRYTHANASIS, P., NIKOLAEV, S., GUIPPONI, M., ROBYR, D., BOTTANI, A. & ANTONARAKIS, S. E. 2014. Simultaneous identification and prioritization of variants in familial, de novo, and somatic genetic disorders with VariantMaster. Genome Res.

An extended Turkish family with FBN1 mutation and variable clinical phenotype. *S. Temel[1,2], O. Tetik[3], O. Rodoplu[4], M. Melek[5], L. Van Laer[6], B. Loeys[6].* 1) Dept Histol & Embryol, Fac Medicine, Univ Uludag, Bursa, Turkey; 2) Dept Histol & Embryol, Fac Medicine, Near East University, Lefkosia, North Cyprus; 3) Dep Cardiothorasic Surgery, Fac Medicine, Celal Bayar University, Manisa,Turkey; 4) Bursa Yuksek Ihtisas Hospital, Dept Cardiothorasic Surgery, Bursa, Turkey; 5) Bursa Yuksek Ihtisas Hospital, Dept Cardiology Surgery, Bursa, Turkey; 6) Center for Medical Genetics, Antwerp University Hospital and University of Antwerp, Antwerp, Belgium.

Marfan syndrome is a multi-systemic autosomal dominant condition caused by mutations in the fibrillin-1 gene (FBN1). Here we report on an extended family presenting with skeletal, ocular and cardiovascular clinical features. The 37 year old male propositus was referred to our clinic due to chest pain, dyspnea and shortness of breath. The main findings of the propositus included severe myopia and mild marfanoid facial features. Echocardiography and computerized tomography showed chronic type I aortic dissection, ascending aorta aneurysm (90 mm) and severe aortic valve insuffiency. His family history was significant for sudden death of his father and his older sister, and similar phenotypes for three generation in the family. The patient's 41 year old brother's main findings included chest abnormalities (pectus carinatum), myopia-astigmatism, and lens subluxation. Echocardiography and computerized tomography showed also chronic type I aortic dissection, ascending aortic aneurysm (70 mm) and severe aortic valve insuffiency. The two brothers underwent immediate Bentall Procedure. FBN1 sequencing of the proband, brother and available affected family members revealed the presence of a pathogenic variant (c.7828G>C, p.Glu2610Gln). None of the unaffected family members did reveal this variant. Because of its complete segregation and due to the fact that Glu2610 residue is part of the conserved DINE motif found at the beginning of each cbEGF domain of FBN1, it is considered a pathogenic variant. This variant has been reported before in the FBN1-UMD database by personal communication but so far no phenotype has been reported with this variant. The presented family demonstrated variable clinical expression of the Marfan phenotype.

2765S

Combination Biotin Responsive Encephalopathy and Hemiplegic Migraine Disorder presenting as Autism and episodic limb dysfunction/ seizures in a 10 year old girl. *P. Benke.* Genetic Division, Joe Dimaggio Children's Hosp, Hollywood, FL.

A 10 year old girl presented to Genetic Clinic with findings of autism. She had all the features of autism, including developmental delay/late language and a paucity of verbal expression, poor understanding, poor social skills, poor eye contact and oppositional behaviors. Some improvement in her symptoms had been accomplished with a low gluten, dairy free diet, but she was still far behind an age appropriate level. Physical examination did not yield any clues, but when asked whether or not her hair and nails grow, her mother said that they did not. The mother was asked to observe hair and nail growth for 3 weeks; when it was observed that they did not grow, she was instructed to start 10 mg/day biotin, which resulted in good growth of both. In addition, there was immediate improvement in school performance. The child began to talk better and her memory dramatically improved. She was thought to have had partial seizures from age 2-3 yrs, with changes in her EEG. Antiepileptic medicines and the change in diet decreased, but did not completely eliminate the episodes, during which one or another limb would lose function, and she developed a concurrent inability to talk or communicate. She would recover after a few hours time. She improved and was free of the latter symptoms when she vacationed in Colorado, and took Diamox. She was then treated for presumptive hemiplegic migraine with Diamox, and dramatically improved. Her EEG normalized, and she began to demonstrate normal, even advanced artistic skills. Her school work improved further, with normal reading and math skills, and a gain in IQ scores. An Exon genome scan (GeneDx) demonstrated a new mutation (p.T364M, c.1091 C>T) in the ATP1A2 associated Hemiplegic Migraine gene, not found in either parent, but did not show a mutation in a biotin dependent gene process. This study shows that 2 genetically unrelated disorders together can lead to a diagnosis of autism, and symptoms can improve dramatically when specific gene appropriate measures are employed.

2766M

New cases of patients with developmental delay and incidental findings of chromothripsis. *O. Caluseriu[1], J. Chernos[2], N.J. Leonard[1], C.M. Klotz[1], B. Argiropoulos[2].* 1) Dept Med Gen, University Hospital, Edmonton, AB, Canada; 2) Dept Med Gen, Alberta Children's Hospital, Calgary, AB, Canada.

Chromothripsis refers to a phenomenon of a local apparent shattering event of chromosomes and subsequent reassembly, observed in 2-3% of cancers (Stephens et al, 2011). It has also been identified in the germline of a subset of individuals with congenital developmental disorders (Kloosterman et al, 2011). While the understanding of the complex chromosomal rearrangement (CCR) resulting from chromothripsis has started to be unveiled (Kloosterman et al, 2012), the relation to developmental problems and long term consequences for the patient's health are unknown. We are presenting two paediatric patients with incidental findings of chromothripsis, their clinical phenotypes and potential correlations with their genotype known to date. PATIENT 1 was evaluated at 7 years of age for short stature (H -3SD), relative macrocephaly (OFC 75-90%), non-dysmorphic features, mild global developmental delay, hypothyroidism, breath holding spells with normal EEG, and a query paracentric inversion 13q21-q31. A microarray showed a CCR within chromosome 13q involving 7 copy number imbalances. Five duplications (size 216 kb-5.2 Mb) and two deletions (size 496 kb-5.2 Mb) were identified, and may suggest potential predisposition to cancer and neurobehavioral problems. PATIENT 2 presented at 21 months of age for query Neurofibromatosis type 1 (NF1). No other NF1 signs were seen aside from 15 cafe-au-lait macules, but there were subtle dysmorphic features, normal growth parameters, significant global developmental delay, and a diagnosis of autism. A microarray identified a 1.15 Mb interstitial deletion that partially overlapped the critical region for Potocki-Schaffer syndrome, and a full karyotype revealed at least 8 apparently copy-neutral breaks involving chromosomes 9, 10, and 11. Pair-end next generation sequencing (NGS) studies were undertaken and results pending at this time will better characterize the rearrangement and could provide prognostic information. Recent technologies (NGS) contribute to the understanding of the driving role of chromothripsis, and may well provide information for the management and counseling of a subset of patients with developmental delays.

2767T

PEDIATRIC PATIENTS CLINICAL EVOLUTION WITH POSTOPERATIVE NASAL RETAINER FOR BILATERAL LIP AND CLEFT PALATE (BLCP). *J. Marin-Melo[1], J.M. Aparicio-Rodriguez[2,3], S. Ochoa-Caceres[1].* 1) Estomatology; 2) Genetics, Hospital para el Nino Poblano, Puebla, Puebla; 3) estomatology, Benemérita Universidad Autónoma de Puebla, México.

Treatment of patients with lip and cleft palate requires multidisciplinary management, focused on providing optimal structural, functional, and aesthetic conditions so the patient can develop and achieve a better quality of life. The goal of the estomatologic treatment is to repair altered structures to reach a growth potential and suitable development improving results in surgical times, minimizing adverse effects. One of the treatments for nasal deformity in patients with lip and cleft palate is the use of forming, which are attachments that work the nasal deformity using functional orthopedics; these help avoiding to collapse and relapse the nasal ala, have more permeable airways and eliminate surgical adhesions by secretions or contraction of healing. The objective of this study is to present the case of a female patient of 9-year-old with bilateral lip and cleft palate presenting nasal disorders such as; short nasal projection. It indicated the use of the nasal retainer as postsurgical orthopedic device to improve the structural, functional and esthetic soft tissue deficiencies.

2768S

Clinical Aspects associated with Syndromic forms of Orofacial Clefts in Colombia. *I. Briceno[1,3], jc. martinez[1], a. collins[2], I. arias[3].* 1) Bioscience, U Niversidad de La Sabana, Chia, Colombia; 2) University of Southampton. Southampton . UK; 3) universidad Javeriana. Bogota. Colombia.

Abstract Objectives: 1) to present descriptive epidemiology of Orofacial Clefts (OFCs) and;) to determine the association of syndromic forms with antenatal high-risk conditions, preterm birth, and comorbidities, in a group of patients from Operation Smile Colombia. Design: A cross-sectional study was conducted. Frequencies of cleft type, associated congenital anomalies, syndromic, non-syndromic and multiple malformation forms, and distribution of OFCs according to gender and affected-side were determined. Odds ratios were calculated as measures of association between syndromic forms and antenatal high risk conditions, preterm birth and comorbidities. Setting: Operation Smile Colombia. Participants: A total of three hundred and eleven patients with OFCs treated in a 12-13 month period. Results: The most frequent type of OFC was cleft lip and palate (CLP). CLP was more frequent in males, whereas cleft palate (CP) occurred more often in females. The most common cases occurred as non-syndromic forms. Aarskog-Scott syndrome (ASS) showed the highest frequency. Hypertensive disorders in pregnancy, developmental dysplasia of the hip, central nervous diseases and respiratory failure showed significant statistical associations ($p < 0.05$) with syndromic forms. Conclusions: These data provide an epidemiological reference for OFCs in Colombia. Novel associations between syndromic forms and clinical variables are determined. In order investigate causality relationships between these variables further studies must be carried out.

2769M

Distribution of the AKT1 p.Glu17Lys mutation in a patient with Proteus syndrome. *M.j. Lindhurst[1], M. Doucet[2], H.M. Bloomhardt[1], M.R. Yourick[1], K. Moroz[2], L.G. Biesecker[1].* 1) MGMGB, NHGRI/NIH, Bethesda, MD; 2) Department of Pathology and Laboratory Medicine, Tulane University School of Medicine, New Orleans, LA.

Proteus syndrome (PS) is a rare disorder that occurs sporadically and is characterized by progressive, disproportionate, segmental overgrowth that can affect any tissue in the body. It is caused by a post-zygotic activating mutation, c.49G>A, p.Glu17Lys in *AKT1*, resulting in individuals who have both mutation positive and mutation negative cells. Because the mutation occurs in a somatic cell, each individual has a unique constellation of manifestations making this disorder extremely heterogeneous. Recently, we had the opportunity to assess the mutation level in multiple tissues due to the unfortunate death of a 21-year old woman with PS. We sampled 25 tissues that were visibly affected and 13 tissues that were apparently normal. In most cases, the specimens were subdivided and multiple DNA extractions were performed. The *AKT1* p.Glu17Lys mutation was measured using a custom PCR-based RFLP assay and the levels were averaged for each specimen. Of the 13 unaffected samples, six had detectable levels of the PS mutation (2 - 29%) although four of the mutation positive samples had no significant histopathologic abnormalities. Of the seven unaffected samples that had no mutation, only three were histologically normal. The mutation level in the affected samples ranged from 3 to 35% and all but the kidneys with mutation levels of 15 and 19% had abnormal histopathology. Interestingly, the highest mutation level was in a bone sample from the second digit of the right foot while the lowest levels were found in the soft tissue surrounding that bone, as well as in an omental fat nodule. The ovaries, vagina, breast, as well as several bones and pieces of skin were mutation positive, while the spleen, liver and lungs were mutation negative. Samples from a uterine leiomyoma, splenic hemangioma, intracranial osteoma and an intracranial meningioma, were all mutation positive. In addition, a papillary carcinoma was found in the right lobe of the thyroid that was positive for both the *AKT1* PS and *BRAF* p.Val600GLu mutations whereas uninvolved thyroid was mutation negative. This case has given us a rare opportunity to correlate mutation burden with histopathology in many tissues typically unfeasible to sample.

2770T

Utility Of Genetic Testing In Patients With Suspected Fetal Alcohol Spectrum Disorder. *S.S. Jamuar[1,2], J.M. Stoler[2].* 1) Dept of Paediatric Medicine, KK Women's and Children's Hospital, Singapore, Singapore; 2) Division of Genetics, Boston Children's Hospital, Boston, MA.

BACKGROUND: Fetal alcohol spectrum disorder (FASD) is one of the most common developmental disorders with an estimated prevalence of 1 to 2% in the United States. It is a clinical diagnosis and is based on the presence of growth retardation, microcephaly, neurologic dysfunction and distinct craniofacial features. Genetic testing is not routinely offered. However, in a recent study, 9% of individuals referred to the Genetics clinic for evaluation for FASD were given an alternate diagnosis based on examination and testing, including chromosomal microarray analysis (CMA) (Douzgou et al. ADC 2012). We aim to study the utility of genetic evaluation and testing in patients with suspected FASD referred to our Genetics clinic. METHOD: We performed a retrospective chart review of all patients referred for evaluation for suspected FASD to the Genetics clinic at Boston Children's Hospital between the periods January 2006 to January 2013. Records of all patients were reviewed to obtain the following information: demographic data, referral characteristics, birth history, history of prenatal alcohol exposure, family history, medical history, examination findings and investigations, including genetic testing (karyotype, Fragile X and CMA). RESULTS: Thirty-four patients were evaluated for possible FASD during the study period, at a median age of 4 years (range 0 to 17 years). Definite prenatal exposure was documented in 23 (67%) patients. Polysubstance abuse was noted in 16 (47%) patients. Speech delay and behavioral problems were common complaints seen in >50% of the patients. Facial dysmorphism was noted in 18 (53%) patients. Microcephaly was present in 14 (41%) patients. Three patients did not fulfill clinical criteria for FASD. Of the remaining patients, 15, 13 and 21 patients underwent karyotype, Fragile X and CMA, respectively. Karyotype and Fragile X were normal for all individuals tested. On the other hand, CMA detected 16 copy number variants (CNVs) in 12 patients (average of 1.3 CNV per patient). Pathogenic and potentially pathogenic CNVs were detected in 4 (2q37del, 15q26del, 22q11.22dup and 4q31.21del syndromes) and 2 (2p25.3dup and AOH over Xp11.22q21.1) patients, respectively, giving a total diagnostic yield of 28%. CONCLUSION: Genetic testing, especially CMA, should be routinely offered to patients referred for evaluation of FASD as a significant proportion (>25%) have a clinically significant CNV even when they fulfill diagnostic criteria for FASD.

2771S

Is a computer-based Facial Dysmorphology Novel Analysis ready for the clinic? *L. Basel-Vanagaite[1,2,3], L. Wolf[2,3].* 1) Schneider Children's Medical Center of Israel, Rabin Medical Center, and Felsenstein Medical Research Center, Petah Tikva, Israel,; 2) Tel Aviv University, Tel Aviv, Israel; 3) FDNA Ltd., Herzlyia, Israel.

Introduction: Previously, we were able to demonstrate that the facial dysmorphology novel analysis technology was successful in recognizing the dysmorphology associated with selected syndromes by processing 2D facial images. The computer-generated analyses were able to produce results comparable with those of human experts. In this study we investigated the performance of the system by analyzing a random set of images of dysmorphic individuals affected with a random variety of syndromes. Methods: The images were submitted by more than a hundred medical geneticists using the Face2Gene mobile application. For quality assurance, 350 images were chosen randomly to be reviewed (without any personal information included) independently by a single human geneticist experienced in dysmorphology (LBV) and compared to matches found by the facial recognition software. Images of individuals being affected with rare chromosomal imbalances were excluded. A match was considered positive where the syndrome determined by the geneticist was also listed among the ten best matches suggested by software (either by using FDNA's facial gestalt analysis component or FDNA's proprietary textual search engine, based on a list of HPO terms representing facial features automatically detected by the system and additional features added by the users). Results: In 52/350 cases (15%), the human expert was able to clearly recognize the presence of a specific genetic syndrome, based on gestalt only. In 44 of these cases (85%), there was a positive match between the system and the human expert, of which 38 cases were suggested by the gestalt analysis and 13 cases were suggested by the feature-based search engine (7 cases were suggested by both modalities). Only 8/52 (15%) cases were recognized by the human expert, but not by the system. It is unknown in how many cases the system recognized the "true" syndrome when the human expert did not, since the majority of the cases are submitted without molecular data, other than 2 cases in which a molecular confirmation was indicated, and the system was able to suggest the correct syndrome, while the expert could not. Conclusions: We conclude that computer-based facial recognition system can successfully assist medical professionals in the research of genetic syndromes characterized by dysmorphic features. Possible future applications may include usage of facial analysis software to complement molecular studies, such as whole exome sequencing.

2772M

Phenotypic characterization of Microtia in Bogota, Colombia. *LP. Barragan Osorio[1], M. Garcia[1], I. Zarante[1,2], DV. Luquetti[3].* 1) Instituto de Genetica Humana, Pontificia Universidad Javeriana, Bogota, Colombia; 2) Secretaria Distrital de Salud, Bogotá, Colombia; 3) Seattle Children's Craniofacial Center. University of Washington, Seattle, US.

Introduction: Microtia is a congenital anomaly of the shape and size of the ear with a wide range of severity which is often associated with hearing loss in 80-90%; of cases, and can occurs as an isolated condition. The prevalence in South America is considered to be higher, especially in the Andean population ranging from 8 to 18 per 10.000 newborns. The pathogenesis of this congenital malformation is still unclear, strong evidence supports the environmental role as well as genetic causes of microtia. The aim of this study is to characterize the phenotype and risk factors of a population with isolated microtia in Bogota. Methodology: All potential participants with isolated microtia who were registered in the Bogota congenital malformations surveillance program (BCMSP) database, as well as the patients who assisted to otolaryngology visit or were born in any of following up hospitals, were invited to participated in this study. Each patient was cited to a single clinical valuation during which they were asked to undergo a physical examination, photographs taken and provide blood specimen for later DNA extraction. In addition, the medical history, results of hearing tests and ear computed tomography were collected. Participant characteristics were analyzed using descriptive statistics. Results: 27 patients with isolated microtia were recruited during September 2012 to July 2013. Microtia occurs most frequently in male patients (74%), children of multiparous mothers, 74% had unilateral microtia in whom right ear was mostly affected (80%) and 85% of them had atresia of the external auditory canal regardless the microtia grade. Most patients (11/18) presented hearing loss (moderate, severe or profound) that was not correlated with the type of microtia. All individuals had prenatal ultrasounds with a mean of 4 per patient, however no prenatal diagnosis was made. 63% of the mothers had acute infections during pregnancy. Maternal exposure to physical factors (e.g.: insecticides, organophosphates) was presented in 37% mostly during the first trimester. Discussion: A higher percentage of risk factors exposition was observed as: acute illness and physical risk factors expositions. Also the severity grade and middle ear compromise was higher than previously reported in the literature. These findings could suggest a possible environmental factor association in our population, but is necessary to increase our sample to calculate and extrapolate our results.

2773T

Congenital eye malformations and associated clinical aspects in two Colombian cities (Bogotá- Cali) between 2011-2013. *A.M. Garcia[1], A.I. Sanchez[2], P.M. Hurtado[2,3], I. Zarante[1].* 1) Instituto de Genetica Humana, Pontificia Universidad Javeriana Bogota, Bogota, Colombia; 2) Pontificia Universidad Javeriana Cali; 3) Centro Medico Imbanaco.

Introduction: Congenital malformations of the eye and anexa are known to occur in isolation or as a part of systemic malformation syndromes, and lead to severe visual impairment in newborns. Although less frequent than other birth defects, the global prevalence has been estimated in medical literature in 3-6 per 10,000 births. The causes of more than 70% of all congenital malformations are still unknown, however those for congenital eye malformations (CEM) are known to be defects in genes, which regulate normal eye development (monogenic cause or chromosome abnormality). The most common CEM are Anophtalmia/Microphtalmia, congenital cataract and coloboma, affecting annually ≈2 per 10,000 newborns worldwide. Objective: The aim of this study was to determine the prevalence of CEM and to describe some characteristics associated with the occurrence of these defects in a population from Bogotá and Cali, Colombia between 2011-2013. Materials and Methods: Data regarding CEM from the Latin American Collaborative Study of Congenital Malformations (ECLAMC) was obtained in a period between 2011-2013 from Bogotá and Cali and was analyzed to describe frequencies and clinical aspects. Results: There were 231,035 consecutive births in this period. Fifteen newborns had CEM, for a global prevalence of 6,49 per 100,000 births. The most common CEM were anophthalmia/microphtalmia (2,6*100000 births), Dacryostenosis (1,3 *100000 births), congenital cataract and congenital glaucoma (0,87 *100000 births). Other less common CEM included eyelid defects and corneal opacity. Systemic anomalies coexisting with CEM were seen in 8 newborns (53,3% of all cases of CEM). The most common associated systemic anomalies were auricular/facial defects (87,5%) and limb defects (50%). Conclusions: CEM are structural defects that can be recognizable at birth and are an important cause of visual disability worldwide (4%). We found in our study that prevalence of these defects is lower than that reported in medical literature, however this could be explained through the fact that some CEM appear later in life and are not evident during our examination period (first day of life). We observed specific associations of eye malformations with other birth defects, being limb and craniofacial anomalies the most common associations as literature says. Early diagnosis is an important fact in reducing childhood blindness.

2774S

Phenotypic diversity in patients diagnosed with VACTERL association. *M. Husain[1,2], M. Wencel[2], B. Lemieux[1,2], V. Kimonis[2], B. Solomon[3,4].* 1) UC Irvine, School of Medicine, Irvine, CA; 2) Division of Genetics and Genomic Medicine, Department of Pediatrics, UC Irvine Medical Center, Irvine, CA; 3) National Human Genome Research Institute, NIH, Bethesda, MD; 4) Inova Translational Medicine Institute, Inova Health System, Falls Church, VA.

The combination of vertebral, anal, cardiac, tracheo-esophageal, renal and limb anomalies termed VACTERL association is a clinical descriptor and a diagnosis of exclusion for a specific set of phenotypic manifestations observed to co-occur non-randomly and more frequently than expected by chance. Because VACTERL is clinically heterogeneous with an elusive etiology, we investigated the frequency and variety of these anomalies, other co-occurring manifestations and underlying causes of defects in embryogenesis or genetic mutations that elucidate VACTERL's etiology. Unique cases in our cohort include the first Trisomy 18 male with an associated Dandy-Walker syndrome exhibiting the VACTERL phenotype, another with a 498.59 kb microdeletion in the 16p11.2 region, a 215 kb duplication in the 3p25.2 region with no known clinical phenotypes, and a genotypic female with dysmorphic facies and ambiguous genitalia. These are 4 among the 36 patients described in our study. Phenotypically, the most common clinical feature was vertebral anomalies, ranging from vertebral body/sacral malformations to spinal cord/rib anomalies, reported in 30 (83.3%) patients. 29 (80.6%) had cardiac defects ranging from ASD/VSDs to dextrocardia and atrial septum aneurysms. 24 (66.7%) had tracheo-esophageal anomalies ranging from TEF with esophageal atresia to Sandifer syndrome. 23 (62.9%) had renal anomalies ranging from agenesis/duplex kidneys to multicystic dysplastic kidneys. 21 (58.3%) had anal anomalies ranging from imperforate anus/anal atresia to a variety of GI/GU fistulas and atresias. 19 (52.3%) had limb anomalies encompassing both upper and lower extremities. Lastly, 14 (38.9%) also had urogenital anomalies. Indubitably, VACTERL is more complicated than previously thought. Although we found no evidence of teratogenic exposure of the mother during pregnancy or other contributing factors, our findings are promising nonetheless. The 16p11.2 microdeletions notably identified in patients with mental retardation, autism and learning/speech problems, have also been associated with malformations commonly found in VACTERL. Additionally, the 3p25.2 duplication with no previously known clinical phenotypes can now be scrutinized further, along with other emerging microarray abnormalities, to identify candidate genes responsible for VACTERL association. We hope these findings enlarge upon the current understanding of VACTERL and guide research aimed at exploring its etiologies.

Brooke-Spiegler syndrome: A rare association of thichoepithelioma, cylindroma and spiradenoma. Report of a familial mexican case. *N.O. DAVALOS[1,4], M.E. SANCHEZ-CASTELLANOS[2], I.M. SALAZAR-DAVALOS[1], M.A. ACEVES-ACEVES[1], J.O. HIGAREDA-GONZALEZ[4], M. HERNANDEZ-TORRES M[4], S.A. RAMIREZ GARCIA[3], M. VAN-DICK[4], I.P. DAVALOS[1], D. GARCIA-CRUZ[1], C. GARCIA-SILVA[2].* 1) INSTITUTO DE GENETICA, CUCS, BIOL.MOL., UNIVERSIDAD DE GUADALAJARA, GUADALAJARA, GUADALAJARA, Mexico; 2) INSTITUTO DERMATOLOGICO DE JALISCO, SSJ, ZAPOPAN, MEXICO; 3) UNIVERSIDAD DE LA SIERRA SUR, OAXACA MEXICO; 4) HOSPITAL GENERAL DE OCCIDENTE, SECRETARIA DE SALUD JALISCO, GUADALAJARA, MEXICO.

INTRODUCTION Brooke H (1892) and Spiegler E (1899), independiently described an ephithelioma adenoides cysticum and skin endotelioma, as distinct entities. Brooke-Spiegler syndrome (BSS, OMIM # 605041) characterized by benign adnexal neoplasia. The predominating tumor such as trichoepithelioma, cylindroma and spiradenoma appear in late childhood and early adolescence. BSS is an autosomal dominant entity. The tumors located on head and neck, and increase throughout life with overlapping clinical features. Clinically trichoepithelioma showed flesh-colored papules specially on nasolabial folds; cylindromatosis lesions presents with multiple erythematous nodules arise on the scalp and is associated with alopecia; and blue-colored-painful lesions on breast and back suggested spiradenomas. The pathogenesis in BSS considered as a defect in the diferentiation of folliculo-sebaceous-apocrine unit. Mutations have been identified in CYLD tummor suppressor gene, mapped to chormosome 16q12-q13. CASE REPORT: Case I: The proposita 9 years-old female. Normal psychomotor development. Between 5-6 years-old displayed flesh-colored papules on nose. The physical examination showed clinical and hystopathological features indicating trichoepithelioma, with keratinizing cystic spaces. Case 2:42 years-old female showed since childhood, multiple flesh-colored-pink papules on her scalp, face and trunk. The lesions were asymptomatic. Three biopsies for the patients were reviewed, the first one on right preauricular region revealed trichoepithelioma, the second one on scalp conclusive cylindroma, and the third on lumbar región conclusive ecrine spiradenoma. Patients are being given this cryotherapy treatment and cosmetic surgery with good results. DISCUSSION: BSS an autosomal dominant disease. Female are commonly affected, with a female to male ratio of 3:1. BSS include mutiple skin appendage tumors such cylindroma (OMIM# 132700), thichoepithelioma (OMIM# 601606) and spiradenoma, that share a common genetic basis. It may be associated with other skin disorders such, basal cell adenomas, basal cell carcinomas. Histopathology studies are necessary to diagnosis. The treatment included excision, dermabrasion, cardon dioxide laser, cryotherapy and in some cases radiotherapy. We present a Mexican family, the mother and daugther affected, presenting the clasical clinical features of the disease. Molecular studies are needed to understand the genetic bases of the disease.

2776T

Disruption of the osteogenic niche signaling in craniosynostosis: primary cilium and prostanoid pathways crosstalks. *W. Lattanzi[1, 2], M. Barba[1], C. Cicione[1], L. Massimi[3], G. Di Taranto[1], P. Frassanito[3], F. Pignotti[3], M. Baranzini[1], M. Caldarelli[3], F. Michetti[1,2], C. Di Rocco[3], G. Tamburrini[3], C. Bernardini[1].* 1) INSTITUTE OF ANATOMY AND CELL BIOLOGY, Università Cattolica S. Cuore, Rome, Rome, Italy; 2) Latium Musculoskeletal Tissue Bank, Rome, Italy; 3) Pediatric Neurosurgery Unit, Università Cattolica S. Cuore, Rome, Rome, Italy.

Nonsyndromic craniosynostosis (NSC) is a highly prevalent craniofacial malformation, with a strong and heterogeneous genetic background. A possible involvement of genes involved in the primary cilium signaling has been proposed in recent studies, proposing brand new candidate genes, with variable genotype/phenotype correlations. Through microarray genome-wide expression profiling and in silico bioinformatics analysis we have shown an altered expression of cilium-associated genes, and of genes involved in prostaglandin metabolism, in calvarial tissues and cells of NSC patients. We have developed and in vitro model for the functional assays aimed at demonstrating the functional role of the selected molecular pathways in the aberrant osteogenic process occurring at the site of premature suture closure. The expression on cilium-related genes (BBS9, GLI3, SMO) and of osteospecific genes (BMP2, RUNX2, OSX, OC) was significantly upregulated in cells isolated from fused sutures (syn-cells) compared to cells isolated from matched patent sutures (control cells), and increased upon 5 days of osteogenic induction. Confocal microscopy showed that: syn-cells produced less primary cilia compared to control cells; BBS9 expression was spread throughout the cytoplasm in syn-cells, while appeared organized in polarized structures surrounding the cilium basal body in control cells. Upon BBS9 silencing in syn-cells, the expression of osteo-specific transcription factors (RUNX2 and OSX), and of SMO (key molecule of the hedgehog pathway), were significantly down-regulated. The osteogenic potential of BBS9-silenced syn-cells decreased and reverted to the physiological behavior observed in controls. Also, syn-cells displayed reduced HPGD expression, leading to reduced catabolic degradation of the osteoinductive prostaglandin E2. Interestingly, PGE2 administration induced differential effects in cells overexpressing BBS9, suggesting an unpredicted crosstalk between the primary cilium and prostanoid metabolism. Our data may provide an original insight into the events occurring in the calvarial osteogenic niche and leading to premature suture closure, which may be useful to: 1. clarify unclear etiopathogenic processes, 2 assist prioritization of new genomic variants, 3 pave the way to further translational outcomes.

2777S

Genotype-phenotype correlation in 12 patients with Oculoauriculovertebral spectrum. *S. Bragagnolo[1], M.E.S Colovati[1], R.S. Guilherme[1], A.G. Dantas[1], C.A. Kim[2], M.I. Melaragno[1], A.B. Perez[1].* 1) Universidade Federal de São Paulo, SÃO PAULO, Brazil; 2) Genetics Unit, Instituto da Criança, Universidade de São Paulo, Brazil.

Oculoauriculovertebral spectrum (OAVS [MIM 164210]) is a clinically heterogeneous condition among the syndromes of first and second branchial archs related to embryonic craniofacial development. Most cases are sporadic with probably multifactorial inheritance, but rare familial cases and several chromosomal abnormalities have been associated with OAVS. The minimal criteria according to Tasse et al. [2005] are unilateral or bilateral asymmetric ear anomalies and hemifacial microsomia. Ocular defects, conductive and/or sensorineural hearing loss, vertebral malformations, and more rarely, cardiac, renal and cerebral malformations with intellectual impairment may appear. The identification of the OAVS genes/genomic position is important to the better understanding of the molecular pathways involved in craniofacial development and clarify clinic heterogeneity of the syndrome. Considering a sample of 62 patients that met Tasse et al. [2005] OAVS criteria (Eur J Med Genet 48:397:411), we identified 12 potentially pathogenic copy number variations (CNV). Genomic arrays identified: 7 deletions (4p16.3p15.33, 4q13.3q21.1, 8q13.3, 10q26.2q26.3, 16p13.3, 22q11.21, Xp22.33) and 6 duplications (2q32.1, 4p16.1.1, 16p13.11, 17q11.2, Xp22.33). We have identified the genes contained within these regions and performed a genotype phenotype correlation in our patients. Even though some deleted and duplicated regions found in this study were relevant to the phenotype OAVS as *BAPX1* (hemifacial microsomia HM [MIM 164210]); *HMX1* (Oculoauricular syndrome OAS [MIM 612109]). ; *EYA1* (Otofaciocervical syndrome1 OFC1 [MIM 166780]); *YPEL1* (YIPPEE-LIKE 1 YPEL1 [MIM 608082]) and *ERK1* (MITOGEN-ACTIVATED PROTEIN KINASE 1; MAPK1 [MIM 176948]), larger deletions and duplications found in our patients included many genes described in OMIM and genomic regions that could relate to the phenotype. These genes and / or candidate regions were investigated and correlated by reverse dysmorphology. Financial support: FAPESP, Brazil (2013/04623-2).

An autosomal recessive PGAP3 novel mutation was identified in patients with severe intellectual disability, dysmorphism and hyperphosphatasemia from 2 unrelated families using whole-exome sequencing. *V. Adir, A. Shalata, K. Golinker, E. Shahak, M. Mahroum, S. Tzur, Z.U. Borochowitz.* Molecular Genetics, Bnai Zion Medical Ctr, Haifa, Israel.

Whole-exome sequencing (WES) is very efficient method, that can be used as a diagnostic tool for identifying the molecular basis of genetic syndromes that are challenging to diagnose. In this study we report on hereditary intellectual disability and dysmorphism in two large Arab families with consanguineous marriage in northern Israel. WES revealed that the patients from the two unrelated families carry a novel homozygous mutation in the PGAP3 gene ;Chr17 g.37,829,358T>C; c.845 A>G; p.D282G. According to previous studies, the PGAP3 gene encodes a product which is a post-Glycosylphosphatidylinositol (GPI) attachment to protein factor 3, a protein that is involved in GPI-anchored maturation. The aspartic acid in position 282 is highly conserved from worms to humans, it is likely that this change has critical impact on the PGAP3 function, and ability to interact with other proteins and harm the GPI-anchor maturation process. GPI-anchor is a glycolipid structure that is added to the C-terminus of many proteins and is anchor their attachment to the cell membrane. Thus mutation in proteins that are involved in this process can affect signal transduction, neuronal development and can cause many pathologies including a wide spectrum of intellectual disabilities (Chesebro et al). Recently Howard et al described four different mutations in the PGAP3 gene that causes a subtype of hyperphosphatasia with intellectual disabilities. The four patients we analyzed had normal MRI and have characteristic phenotypic features, they suffer from seizures, sever intellectual disabilities, low head circumference and high body weight. They also have coarse face features which includes narrow foreheads, long palpebral fissures, cleft palates, short noses with a wide nasal tip, full cheeks, tent shape wide mouths and large ear lobes. The phenotype of these patients is similar to the one described previously by Howard et al. Since we found the same mutation in four patients, in two unrelated families, we wanted to develop an easy and affordable test that will allow us to screen the relevant population from the same ethnicity. We developed a PCR RFLP test that would enable easy analysis of the c.845 A>G mutation in the PGAP3 gene. The mutation was not found in 40 control chromosomes from the same ethnicity and geographical region. We suspected that there is a blood relation between the this two families and that they are probably connected via a third family from the same area.

2779T

Significant Secondary Findings of Exome Sequencing in Minor Anomalies with Autism Spectrum disorder. *A. Alsadah.* Benioff Children's Hospital, University of California at San Francisco, San Francisco, CA.

Significant Secondary Findings of Exome Sequencing in Minor Anomalies with Autism Spectrum disorder A. Alsadah, J.T.C. Shieh. Division of Medical Genetics, Department of Pediatrics, Institute of Human Genetics, Benioff Children's Hospital, University of California San Francisco, San Francisco, CA The results of exome sequencing in patients with minor anomalies with autism spectrum is unclear. Secondary or incidental findings on exome testing may also yield unexpected results, however findings of clinical consequence may go beyond current ACMG incidental findings recommendations. We present a instructive example of exome sequencing performed as part of developmental delay/autism genetic work up after normal microarray and metabolic testing at the UCSF Genetics Exome Clinic. A dedicated pre-test counseling visit was performed and incidental findings were discussed. The male patient avoided eye contact and had sloped shoulders and vague knee pains. Whole exome sequencing demonstrated compound heterozygosity for p.(P643L) and p.(G741R) variants in the SLC12A3 gene; both of these mutations have been reported in Gitelman syndrome (Cruz et al., 2001, Simon et al., 1996). Gitelman syndrome is an autosomal recessive disorder characterized by hypokalemia, metabolic alkalosis, hypomagnesemia, hypocalciuria, and hyperreninemia and typically presents in adults. As mutations in SLC12A3 affect the thiazide-sensitive Na/Cl cotransporter, we assessed electrolytes and found low potassium and abnormally low urine calcium confirming an early diagnosis of Gitelman syndrome. Our results demonstrate that exome sequencing can detect significant and treatable secondary findings as in this patient. He was started on potassium supplements to correct his electrolytes and prevent possible complications such as cardiac arrhythmias, which could be fatal. Autism is not the expected presentation for this renal disease, however growth retardation and developmental delays have been reported in few patients with Gitelman syndrome (Skalova et al., 2013). We conclude that large-scale clinical sequencing can reveal important treatable conditions, and future studies will reveal potential effects on clinical outcomes. .

2780S

Association of UBE3B and GRIN2B gene variants with autism spectrum disorders and non-syndromic intellectual disability: a case report. *A.I. Sanchez[1], F. Tobar[1], P.M. Hurtado[1,2].* 1) Pontificia Universida Javeriana Cali, Cali, Colombia; 2) Centro Medico Imbanaco.

Introduction: Autism spectrum disorders (ASD) are neurodevelopmental conditions characterized by language abnormalities, impaired social function and repetitive behaviors. Prevalence among 8-year-old (y/o) children is 1% and intellectual disability (ID) occurs in 70% of them. Together affect 3-5% of population. Genetic causes are identified in 10-20% of ASD and 25-50% of ID. Case presentation: This is an 8 y/o male patient who was born by uncomplicated spontaneous vaginal delivery after an uneventful first full term gestation from non-consanguineous parents. Mother was 21 y/o. Birth weight was 3,4 kg. Patient had normal development until 2 y/o when started to have hampered verbal communication. Significant family history was denied. Physical examination revealed a severe language problems but no other abnormal findings. Hearing tests, electroencephalography and MRI of the brain showed no abnormalities. Whole genome sequence analysis on DNA extracted from patient and parents' blood was performed. Heterozygous variants of unknown clinical significance in UBE3B and GRIN2B genes were detected. Discussion: GRIN2B variant was inherited from mother (autosomal dominant). For UBE3B variant (autosomal recessive), a second allele was not detected in parents. Deletions or duplications cannot be ruled out because both genes are located in chromosome 12. UBE3B codifies for an E3 ubiquitin-protein ligase that plays an important role on neurodevelopment. The variant c.421T>G - pD141A was identified in the exon 6, which is known to be a preserved exon. Other UBE3B variants have been associated with blepharophimosis-ptosis-intellectual disability syndrome (BPIDS), but the patient's phenotype is consistent with ASD and non-syndromic ID (NSID). Therefore we propose a new clinical significance for this variant. Additionally, the variant c.3832A>C - pT1278P was identified in the exon 13 of GRIN2B. This gene codifies for glutamic N-methyl-d-aspartate (NMDA) receptor 2B subunit. Other GRIN2B variants have been related to ASD, ID, psychiatric disorders and problems in retina, skin and testis. Both genes are related to glutamic acid signaling pathway which is important in neurodevelopment, therefore we propose an association between these variants and ASD/NSID. Conclusions: Heterozygous variants in GRIN2B and UBE3B were detected in a patient with autism and NSID. Further studies are necessary to uncover the whole phenotypic spectrum of disruption in these genes.

2781M

Congenital Limb Reduction Defects Associated with Maternal Thrombophilia. *L. Ordal[1], J. Keunen[2], N. Martin[3], N. Shehata[4], G.H. Borschel[5,6], H.M. Clarke[5,6], A. Toi[7], C. Shuman[1,8], D. Chitayat[1,2,3,8].* 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Department of Obstetrics and Gynecology, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 3) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Department of Medicine, Division of Hematology, Mount Sinai Hospital, Toronto, Ontario, Canada; 5) Division of Plastic and Reconstructive Surgery, Hospital for Sick Children; 6) Department of Surgery, University of Toronto, Toronto, Ontario, Canada; 7) Department of Medical Imaging, Mount Sinai Hospital, Toronto, Ontario, Canada; 8) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Congenital limb reduction defects (LRDs) comprise an etiologically heterogeneous group of conditions caused by amniotic bands, early chorionic villus sampling, single-gene disorders, chromosome abnormalities, and teratogen exposure. However, a substantial number of cases occur without an obvious cause. Vascular disruption events may be responsible for some of these cases, especially the terminal transverse reduction defects. Some studies have found an association between maternal thrombophilia and congenital LRDs while other studies have not confirmed this association. We further investigated this association through a review of all prenatally identified LRDs at a major tertiary care center in Toronto, Canada over a 12-year period. Research ethics board approval was obtained at all applicable institutions. Using a Chi-square analysis, our results showed a higher prevalence of inherited thrombophilias (specifically, Factor V Leiden, prothrombin G20210A, and heterozygosity for both mutations) among women with pregnancies affected with an LRD when compared to the general population [$\chi^2(3) = 54.63$, $p < .01$]. Our work was strengthened by the inclusion of affected pregnancies regardless of outcome and using strict criteria to try to eliminate including cases of LRDs with an unrelated etiology. The LRDs in our sample were identified at mean age of 19.7 weeks gestation (SD = 2.8). We found an excess of left-sided defects among terminal transverse but not longitudinal reductions; additionally, all cases of thrombophilia occurred in the terminal transverse group. Our results support the hypothesis that maternal thrombophilia is associated with fetal LRDs. This supports the use of appropriate maternal thrombophilia screening (i.e., screening that is not affected by pregnancy, such as molecular genetic testing or antiphospholipid assays) in pregnancies with an identified LRD. Additionally, our findings emphasize the importance of careful examination of the extremities, including digits, during the routine 18-20 week anatomy ultrasound in women with a known thrombophilia or history of thrombosis.

2782T

Whole Exome Sequencing of Moyamoya Disease. *S. Jang[1], S. Lee[1,2], J. Chae[3], B. Lim[3], J. Kim[1,2].* 1) Biomedical Sciences, Seoul National University, Seoul, South Korea; 2) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, South Korea; 3) Department of Pediatrics, Seoul National University College of Medicine, Seoul National University Children's Hospital, Seoul, South Korea.

Moyamoya disease (MMD) is a cerebrovascular condition distinguished by bilateral stenosis and occlusion in the internal carotid arteries, causing development of an abnormal collateral network of vessels for compensatory circulation. Previous studies have reported RNF213 as a major susceptibility gene for MMD. In this study, we suspected there may be another element that could cause or have an effect on MMD since there are patients with MMD who do not carry any variant in RNF213. To discover additional factors that may cause MMD, we performed exome sequencing on 15 individuals (11 MMD patients and 4 of whom are the parents of 2 of these patients). We narrowed down the variants to SNPs in exonic region that were frequent in MMD patients, but not in general population. Our study discovered 6 nonsynonymous variants: EML6, SYNE1, CHRNB3, CDK5RAP2 , ZEB1 and SIPA1L3: all of these variants were shown twice in our patient samples. All 6 genes are candidate genes for causing MMD and may explain why RNF213 negative patients still display MMD symptoms. Further study is needed for verifying the specific pathways these genes are involved in to be assertive of these results.

2783S

Defining a new syndrome of cutis laxa, holoprocencephaly and cerebellar agenesis with overexpression of NRG3. *A. Ramalingam, K. Scott, G. Preston, A. Janssen, T. Kozicz, T.-J. Chen, E. Morava.* Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA 70112.

Neuregulins are signaling proteins that mediate cell-cell interactions. They play a critical role in the normal growth of organ systems and are essential for the embryologic development of the central nervous system. NRG3, encoding neuregulin3, is located at 10q23.1 and is expressed mainly in brain, testis, skin and muscle. Extracellular cleavage product of NRG3 binds to ERBB4 resulting in ligand-mediated tyrosine phosphorylation. A newborn with alobar holoprosencephaly, monoventricles, cerebellar agenesis and severe cutis laxa was diagnosed with a novel developmental syndrome. Skin biopsy of the patient showed normal elastin and collagen staining but an increased thickness of the epidermis with excessive wrinkling, decreased hair growth and decreased pigmentation. Microarray CGH analysis of the patient's DNA revealed a 34.7kb deletion in intron 5 of the NRG3 gene. The deletion was confirmed by qPCR to be present in the proband but not in the apparently normal mother. Transgenic mice that overexpress NRG3 in skin are hairless and have thick, pale and wrinkled skin as seen in cutis laxa. Patient fibroblasts showed increased cell growth and proliferation suggesting overexpression of cell signaling. The deleted region of the intron 5 of NRG3 contains binding site for a strong transcription repressor. We initiated a reporter assay to evaluate the functional consequences of the intronic NRG3 deletion. Similar to the NRG3 transgenic mice, immunohistochemistry in cell culture confirmed accelerated cell proliferation, compared to control cells, without increased apoptosis. We defined a new syndrome of holoprosencephaly, cerebellar anomalies and cutis laxa. Based on the presence of the strong repressor site in the intron 5 of NRG3, the overexpression phenotype in our patient, and the finding of cutis laxa in the overexpression mice model of NRG3 we hypothesize the pathogenic role of NRG3 in this complex developmental skin and brain anomalies.

2784M

A case of 16p11.2 duplication syndrome and review of the literature. *B.J. Ilagan, G. Ghaffari, M. Rodriguez, C. Hung, SA. Hosseini, OA. Bodamer.* Human Genetics, University of Miami, Miami, FL.

The 16p11.2 duplication syndrome is characterized by a spectrum of clinical findings including autistic behavior, developmental delay, intellectual disability, cranio-facial dysmorphism, microcephaly and epilepsy. Severity and expressivity of clinical symptoms can vary based on duplication size and other yet unknown factors with no evidence of gain or loss of specific gene function. The estimated prevalence of the 16p11.2 duplication syndrome is 3:10,000 individuals and as high as 1% in patients with autism spectrum disorder. The syndrome is a result of genomic structural change likely due to the 16p11.2 locus of about 600 kb (minimal critical duplication region) being situated between flanking segmental duplications having >99 percent sequence identity and regions of non-allelic homologous recombination (NAHR) events. Here we report a five year old female patient with a 3.6 Mb duplication including the 16p11.2 locus obtained by using Illumina's Infinium SNP Array platform. Genes in the duplicated region that may contribute to the patient's phenotype include PRRT2, PKC, DYT10, EKD1, BFIS2, BRIC2, ICCA, FUS, TLS, ALS6 and ETM4. The patient presented with developmental delay involving motor, speech and language, learning difficulties and microcephaly (<3rd percentile). There is no definitive history of seizures and/or autistic spectrum disorders. She was born as the first child of healthy, non-consanguineous parents of mixed ancestry. Diagnostic work-up including EEG, brain MRI/MRS and basic metabolic testing were within normal limits. We report this case to serve as awareness of 16p11.2 duplication syndrome and its complexities as indicated in current literature. Variation in and outside the 16p11.2 locus may or may not be considered part of the syndrome.

2785T

Maternal UPD(16) with IUGR, transient neonatal hypoglycemia and cholestasis. *H. Lesmana, R. Hopkin.* Human Genetics, Cincinnati Children's Hosp Med Center, Cincinnati, OH.

Uniparental disomy (UPD) is defined as the presence of homologous chromosomes from one parent. Maternal UPD of chromosome 16 is the most common reported UPD in the literature other than UPD(15) and has previously been reported to cause intrauterine growth retardation (IUGR) and a variety of congenital malformations. However there is no specific pattern of features documented in these cases suggesting for imprinted genes in this chromosome. Most cases are reportedly associated with confined placental mosaicism of trisomy 16 and some degree of placental insufficiency contributing to IUGR. Neonatal cholestasis has not been previously reported in maternal UPD(16). We report a new case of maternal UPD (16) which was initially suspected due to the presence of long contiguous stretch of homozygosity in chromosome 16 by SNP microarray. Maternal UPD(16) was subsequently confirmed through UPD testing using 12 microsatellite markers spanning chromosomes 16 in the proband, the mother and the father. This test revealed both maternal segmental heterodisomy and isodisomy on chromosome 16. Main clinical features include severe IUGR, transient neonatal hypoglycemia and cholestasis. Metabolic and molecular genetics testings for neonatal cholestasis and other inherited liver disorders failed to reveal any pathologic findings. We discuss reported cases of maternal UPD(16) and consider whether our patient's features may be due to disordered imprinting or unmasking of an autosomal recessive condition.

2786S

Falling serum estradiol levels prior to human chorionic gonadotropin on follicle growth and pregnancy outcomes in in vitro fertilization cycles. *X. Bao, JW. Xu, YP. Sun.* the First Affiliated Hospital of Zhengzhou University, ZhengZhou,China, Henan, China.

Background: Whether the falling of oestradiol on the day of HCG administration could influence in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI) pregnancy outcomes remains unknown. The aim of the study was to analyse the relationship between the falling estradiol levels prior to hCG administration and follicle ruptured before the oocyte retrieval procedure and outcomes on IVF /ICSI treatment. Material and Method: A retrospective study of the database in the First Affiliated Hospital of ZhengZhou University (Zhengzhou, China) to identify 813 IVF /ICSI stimulation cycles whose E2 levels fell prior to the day of hCG administration during IVF/ICSI treatment. Patients were assigned to three groups according to serum E2 drops on the day of HCG administration compare to the day before as follows: group 1 with <10% drop in serum E2 concentration; group 2 with 10-20% drop; group 3 with >30% drop; control group with E2 levels continued to rise until the day of hCG. Results: Follicle ruptured rates (6.1%, 9.1%, 13.5% vs 3.3%, P=0.000) prior to the oocyte retrieval procedure was highly significant among the three groups. The cancellation rates (21.3%,24.4%,28.1% and 17.4%,P=0.018) was significantly higher with the increasing serum E2 drops on the day of HCG administration compare to the control group. Implantation rates (33.0%, 30.9%, 34.6% vs 33.4%, P= 0.826) and pregnancy rates (50.0%, 45.6%, 50.4%, 51.0%, P=0.732) were no statistical significant in all study and control groups respectively. Conclusions: The falling estradiol levels prior to hCG administration might have a potential negative effect on folliclar growth and lead to higher cancellation rates, but the pregnancy rates for embryo transfer cycles are not compromised.

The LH gene mutation and controlled ovarian hyperstimulation. *M.R. Ranjouri[1], R. Davar,M.D.[2], M.H. Sheikhha,M.D.,Ph.D.[2].* 1) Department of Genetics and Molecular Medicine, Zanjan university of medical science, Zanjan, Iran; 2) Yazd Research and Clinical Center for Infertility, Shahid Sadughi University of Medical Science,Yazd,Iran.

Background: One of the most difficult problems of in vitro fertilization (IVF) treatment is the variability in the response to controlled ovarian hyperstimulation (COH) which ranging from poor to high, leading to IVF failure or complications related to ovarian hyperstimulation syndrome (OHSS). Objective: To evaluate the correlation between *LH*β G1502A polymorphisms in exon 3 of the LH gene and ovarian response to COH. Materials and methods: A total of 220 women treated with a long protocol for ovarian stimulation were studied. Three genotypes of GG, GA and AA were detected by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis. Results: The most frequent genotype was GA (55.5%) whereas 44.5% of patients showed GG genotype and there was no patient with AA genotype. In total, 34 patients were poor responder, 154 were normal responder and 12 were hyper responder. In total 54.5% of normal responders, 61.8% of poor responders and 50% of hyper responders showed GA genotype. Discussion: Our results did not establish a significant relationship between this polymorphism and the ovarian response. Therefore it is still very difficult to use the genotype of patients for prediction of the ovarian response to stimulation.

Match Study of Sperm Relative Factors on the IVF Outcome. *M. Zhang, J. Xu, Y. Sun.* The first affiliated hospital of Zhengzhou University, Zhengzhou , Henan, China.

Objective: To investigate the effect of sperm relative parameters on the outcome of fertilization, in order to direct the selection of fertilization method. Methods: Collect 2 601 first Controlled ovulation IVF cycles from January 2012 to June 2013, match female factors(age, weight, cause of infertility, base FSH and LH, endometrial thickness on hCG day and the number of acquiring ovum) and get 457 pairs. Analyze the sperm relative factors on different outcomes. Results: Sperm normal morphology rate in pregnant cycles were significantly higher than those of non-pregnancy cycles(P<0.05), but qualified rate were same; sperm density, activity and survival rate were same in different groups(P>0.05). Conclusions: IVF cycles with different outcomes own different sperm normal morphology rate, which has higher reference values then other sperm factors.

Prenatal diagnosis of Apert Syndrome: fetal brain phenotype on imaging. *Z. Stark[1, 2, 3], G. McGillivray[1, 2], A. Sampson[2, 4], R. Palma-Dias[2, 4, 5], A. Edwards[6, 7], J.M. Said[2, 3, 8], G. Whiteley[9], A.M. Fink[2, 10, 11].* 1) Victorian Clinical Genetics Services, Murdoch Children's Research Institute, Melbourne, Australia; 2) Fetal Medicine Unit, Royal Women's Hospital, Melbourne, Australia; 3) Maternal Fetal Medicine, Sunshine Hospital, Western Health, Melbourne, Australia; 4) Pauline Gandell Imaging Centre, Royal Women's Hospital, Melbourne, Australia; 5) Pregnancy Research Center, Department of Obstetrics and Gynaecology, University of Melbourne, Australia; 6) Fetal Diagnostic Unit, Monash Medical Centre, Melbourne, Australia; 7) The Ritchie Center, Monash Institute of Medical Research, Melbourne, Australia; 8) Northwest Academic Centre, University of Melbourne, Australia; 9) Department of Radiology, Monash Medical Center, Melbourne Australia; 10) Department of Radiology, University of Melbourne, Australia; 11) Medical Imaging Department, Royal Children's Hospital, Melbourne, Australia.

Objectives: The diagnosis of Apert syndrome relies on the identification of the classic triad of complex syndactyly of the hands and feet, craniosynostosis and midface hypoplasia. Diagnosis in the prenatal setting can be difficult as the onset of craniosynostosis is highly variable. We describe the brain imaging findings in 6 fetuses affected by Apert syndrome, and highlight the utility of dedicated neuroimaging as an adjunct to diagnosis. Methods: Retrospective review of ultrasound and MRI brain imaging obtained in 6 fetuses with a diagnosis of Apert syndrome. Results: Five fetuses had attenuation of the septal leaflets, and two had corpus callosum dysgenesis. All six had temporal lobe expansion and overconvolution. The temporal lobe abnormalities preceded the development of cranial deformity in two fetuses. Conclusion: Overconvolution of the temporal lobe cerebral mantle can be detected antenatally and is particularly conspicuous in the fetus when the normal brain is still relatively smooth (approximately 24 to 28 weeks of gestation). Detailed fetal brain imaging by neurosonography or MRI is capable of demonstrating this temporal lobe malformation, and can contribute to diagnostic certainty in cases of suspected Apert syndrome.

2790S

Fibrodysplasia ossificans progressiva: bilateral hallux valgus on ultrasound as clue for the first prenatal diagnosis for this condition -case report. *C. Maftei[1], I. Thiffault[1,3], J. Dubé[2], A-M. Laberge[1], E. Lemyre[1].* 1) Genetics, Ste-Justine Hospital, Montreal, Quebec, Canada, 3175 ch de la Côte-Ste-Catherine, Montréal, QC H3T 1C5, tel: (514) 345-4931, fax : (514) 345 4781; 2) Obstetric & Gynecology, Ste-Justine Hospital, Montreal, Quebec, Canada, 3175 ch de la Côte-Ste-Catherine, Montréal, QC H3T 1C5, tel: (514) 345-4931, fax : (514) 345 4781; 3) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO, USA,64108.

Fibrodysplasia ossificans progressiva (FOP (MIM: 135100)) is a very rare autosomal dominant condition with an incidence of 1:2 000 000. The clinical picture is characterized by congenital malformations of the great toes and progressive disabling heterotopic ossification. The genetic explanation is an activating mutation in the ACVR1, a BMP type I receptor, which promotes osteogenic differentiation of connective tissue progenitor cells. We report here how the presence of fetal bilateral hallux valgus, seen on second-trimester ultrasound, prompted clinicians to consider the diagnosis of FOP in the absence of family history. This classical foot malformation is present in almost all FOP patients reported in the literature. A 35-year-old French-Canadian pregnant woman was referred to our center for investigation and genetic counseling after a second trimester ultrasound identified a right ectopic kidney and a mega cisterna magna. A repeat ultrasound at 23 weeks in our center confirmed a right crossed ectopic kidney fused to the inferior pole of the left kidney, with good cortico-medullary differentiation. Bilateral hallux valgus was also observed. The cisterna magna was normal and all the other structures, including bones, were normal. Fetal growth was normal. Fetal echocardiogram was normal. The karyotype was normal (46,XY), as well as array CGH. A tridimensional ultrasound was performed to better characterize the feet and showed a hallux valgus deformation with plantar deviation of the first phalanx, and the absence of the second phalanx. The fetus was found to have the recurrent c.617G>A; p.R206H mutation in ACVR1 gene, confirming our suspicion of FOP. Post-mortem external examination showed normal growth parameters, some minor dysmorphic features but no other malformations. Bilateral hallux valgus was present and the first metatarsophalangeal articulation was rigid. Fetal X-rays showed important bilateral deviation in hallux valgus, first toes with only one phalanx and plantar deviation. This report highlights that malformed great toes on prenatal ultrasound, especially hallux valgus, should raise the suspicion of FOP even when other atypical anomalies are found. Establishing the diagnosis allows for appropriate genetic counseling and informed decision-making for the family.

Campomelic dysplasia: Prenatal Ultrasound and Autopsy Findings in Early Pregnancy. *K. Chong[1], N. Martin[1], A. Toi[2], S. Keating[3].* 1) Dept OB/Gyne, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada; 2) Dept of Medical Imaging, Mount Sinai Hospital, Toronto, ON, Canada; 3) Dept of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada.

Campomelic dysplasia (CD) is a severe skeletal dysplasia characterized by cleft palate, tracheomalacia with respiratory compromise, bowing of the long bones and ambiguous genitalia. CD is an autosomal dominant genetic condition with few published case reports of gonadal mosaicism. Fetal ultrasound findings of CD have mostly commonly been reported in the second trimester with bent femurs, normal upper limbs and hypoplastic/absent scapula, however, some reports of cystic hygroma with lower limb anomalies have on fetal autopsy revealed CD. Translocations, small rearrangements and mutations involving the SOX9 gene on chromosome 17q have been identified as the cause of CD. We report a couple with 2 early pregnancies affected with cystic hygroma +/- other anomalies in the first trimester. The pregnancies were terminated by dilatation and curretage, however, careful pathology examination and X rays combined with molecular testing for SOX9 revealed a diagnosis of CD. Follow-up testing and examination of parents confirmed gonadal mosaicism in a symptomatic parent. This case highlights the importance of fetal pathology, even in early surgical samples, and the importance of clinical examination of parents in rare cases of skeletal dysplasia recurrence.

2792S

Importance of Fetal Fraction Analysis for cfDNA Testing in the General Pregnancy Population. *E. Wang, C. Struble, C. Kingsley, R. Steeke, A. Batey, D. Hollemon, A. Oliphant, T. Musci.* Ariosa Diagnostics, Inc, San Jose, CA.

Introduction: The Harmony™ Prenatal Test uses an assay method, Digital Analysis of Selected Regions (DANSR™), for analysis of chromosomes 13, 18, 21, X and Y as well as other chromosomes to measure fetal fraction. Products from the DANSR assay are then analyzed with the Fetal fraction Optimized Risk of Trisomy Evaluation (FORTE™) algorithm to assess patient-specific risk of trisomy. Alternative tests, such as those using massively parallel shotgun sequencing, use a Z-statistic or Normalized Chromosome Value (NCV) to discriminate between normal and abnormal chromosomal counts without accounting for fetal fraction. **Methods**: A general pregnancy population cohort of 15,841 women between 10.0 to 14.3 weeks gestation were followed to pregnancy outcome. Z-statistics were computed using previously described standard Z-test of proportions and compared to FORTE risk scores generated by the Harmony test. A Z-statistic of ≥ 3 was considered 'Positive' for trisomy and a FORTE risk score of ≥ 1% was 'High Risk' for trisomy. **Results**: The cohort included 38 cases of trisomy 21 (T21) and 10 cases of trisomy 18 (T18). A subset of participants (n = 11,185) had trisomy 13 (T13) analysis.

PPV: Positive Predictive Value

Method	T21	Non-T21	T21 PPV	T18	Non-T18	T18 PPV	T13	Non-T13	T13 PPV
FORTE (%)	38/38 (100)	9 / 15803 (.06)	38/47 (81)	9/10 (90)	1 / 15831 (.01)	9/10 (90)	2/2 (100)	2 / 11183 (.02)	2/4 (50)
Z ≥ 3 (%)	38/38 (100)	34 / 15803 (.22)	38/72 (53)	8/10 (80)	43 / 15831 (.3)	8/51 (16)	2/2 (100)	65 / 11183 (.6)	2/67 (3)

The cumulative test discordant rate for non-trisomies with FORTE was 0.08% compared to 1.07% with the Z-statistic. **Conclusion**: Analysis using FORTE to incorporate fetal fraction in cfDNA testing yields a >10 fold reduction in discordant results compared to the Z-statistic. This will become increasingly relevant as cfDNA testing gets more broadly used in the general pregnancy population.

2793S

Maternal subchromosomal abnormality identified through noninvasive prenatal testing (NIPT). *C. Settler[1], T. Boomer[1], J. Newell[2], P. Santiago-Munoz[2], N. Teed[1], J. Saldivar[1], N. Dharajiya[1].* 1) Sequenom Laboratories, San Diego, CA; 2) Department of Obstetrics and Gynecology, University of Texas Southwestern Medical Center, Dallas, TX.

Introduction: Noninvasive prenatal testing (NIPT) uses circulating cell free DNA (ccfDNA) for the evaluation of fetal chromosomal abnormalities. Studies indicate that about 10-15% of the ccfDNA in maternal plasma is derived from the pregnancy, and thought to be placental in origin. The remaining ccfDNA is contributed by the mother. Thus, evaluation of ccfDNA to identify chromosomal abnormalities has the potential to identify both fetal and maternal anomalies. Here we report a case of a maternal deletion identified through a combination of NIPT and clinical history. Methods: Maternal blood samples submitted to Sequenom Laboratories for MaterniT21™ PLUS testing were subjected to DNA extraction, library preparation, and whole genome massively parallel sequencing as previously described. Sequencing data were analyzed using a novel algorithm to detect trisomies and other subchromosomal events. Results: A 20 year old G3P1010 had NIPT secondary to positive serum screening. NIPT results were negative, but ultrasound identified multiple anomalies. Karyotyping performed on amniocentesis sample subsequently revealed a ring chromosome 18 [46,XY,r(18)(p11.3q23)]. The patient elected pregnancy termination. Maternal karyotype was normal (46,XX). The patient conceived again and NIPT was again negative; no anomalies identified by 20 weeks' gestation. The history of the ring 18 chromosome was provided to the laboratory, and based on this information, detailed bin data was reviewed for chromosome 18, revealing an apparent 0.75 Mb deletion at 18q22.1>q22.1, likely maternal in origin. Maternal microarray analysis confirmed a 773 Kb interstitial deletion with the following result: arr 18q22.1 (63, 884,429-64,657,305)x1. The patient declined invasive testing for the current pregnancy (ongoing). Familial studies are in progress to characterize the segregation of the chromosomal abnormality. Conclusion: Clinicians should be cognizant that maternal subchromosomal abnormalities may be identified by NIPT using massively parallel sequencing. Accurate clinical information provided to the laboratory is critical for interpretation of test results. Additionally, standard karyotyping and in many cases FISH does not have sufficient resolution to confirm subchromosomal events detected by NIPT. In these cases, microarray studies are superior to standard karyotype and FISH testing for confirmation of the suspected abnormality.

2794S

Thrombophilic Mutations for Recurrent Miscarriage in Iranian women with or without Thrombophilia. *H. Mirtavoos-Mahyari[1,3], B. Poopak[2].* 1) National Institute of Tuberculosis and Lung Disease, Tehran, Tehran, Iran National Institute of Tuberculosis and Lung Disease, Tehran, Iran,MD; 2) Department of Hematology and Laboratory Blood Bank, Tehran Medical Branch, Islamic Azad University, Tehran, Iran, PhD; 3) Department of Medical Genetic, Tehran University,Tehran,Iran, PhD Student.

Background: Inherited thrombophilia may increase susceptibility of fetal loss. This study was performed to investigate the frequency of some factor's mutations in ethnic Iranian patients . Methods: This epidemiologic case study performed with 609 patients whom were referred to Payvand Medical and Specialty Laboratory in Tehran, Iran, from 2011 through 2012. Peripheral blood samples of the patients with abnormal thrombosis were analyzed for mutations in Factor V Leiden, FII , MTHFR and PAI-1 . Mutation analysis was accomplished by PCR-reverse dot blot. Results:The mean age of patients was 29.58 years. The results are shown in Table 1. Table1.Distribution of inherited thrombophilia

	Genotype		
	Homozygous	Heterozygous	Wild type
Factor V Leiden(n=176)	0	17	159
MTHFR(n=195)	21	90	84
FII (n=102)	0	6	96
PAI-1(n=136)	23	78	35

Discussion: MTHFR and PAI-1 polymorphisms were identified in more than fifty percent and factor V lieden mutation is higher than some other countries . Therefore, testing and providing genetic consultation may be needed in Iran.

2795S

Validation of a taxonomy of genetic conditions for pre-conception genetic carrier testing. *T.L. Kauffman[1], N. Neil[3], C. McMullen[1], M.C. Leo[1], J. Reiss[1,2], B. Wilfond[4], J. Davis[1], M. Gilmore[2], P. Himes[2], F. Lynch[1], K.A.B. Goddard[1].* 1) Center for Health Research, Kaiser Permanente Northwest, Portland, OR; 2) Kaiser Permanente Northwest, Portland, OR; 3) Decision Research, Eugene, OR; 4) Truman Katz Center for Pediatric Bioethics, Seattle Children's Hospital, Seattle, WA.

Background: We are studying the use of genome sequencing in the context of pre-conception genetic carrier testing for women and their partners. The study team created a taxonomy of four categories of results that participants could choose to receive categorizing the types of genetic conditions found. With patient input, the categories were revised to: shortened lifespan, serious, mild, unpredictable outcomes, and adult onset. We then used risk perception methodology to obtain support for the taxonomy. Methods: We emailed a link to an online survey to fifteen hundred Kaiser Permanente Northwest members who had previously received preconception genetic carrier testing. The survey included descriptions of genetic conditions and their associated attributes (physical impairments, cognitive impairments, effectiveness of treatment, age at onset, and variability of expression). The study team selected 20 genetic conditions to include that varied according to these attributes. We created five versions of the survey, each with four conditions. Respondents rated their reactions to each condition on a seven point Likert scale, including impact of the condition on a child and the family, predictability and controllability of the condition, and how it would change their plans for pregnancy. Enrollment was limited to the first approximately 40 respondents per version of the survey. Results: We assigned the 20 conditions into the taxonomy categories. We then determined if survey participants' (N=204) reactions to the conditions differed depending on category. Based on the results of factor and cluster analyses, the conditions were grouped according to ratings of hopeful feelings, controllability, predictability, visibility, severity, and negative feelings. Overall, survey responses supported our five category taxonomy of genetic conditions. Conditions in the serious and mild categories were the hardest for patients to distinguish. Conclusions: Survey respondents made meaningful distinctions between the genetic conditions presented to them. While the categories were derived from experts and revised with focus group input, the results provide empirical support for the category distinctions. Future research utilizing the same methodology with a wider variety of conditions could be beneficial.

2796S

Tay-Sachs disease enzyme carrier screening does not perform well in a pan-ethnic population when compared to DNA analysis. *V. Greger, C. Perreault-Micale, A. Frieden, A. Kramer, N. Faulkner, D. Neitzel, S. Hallam.* Good Start Genetics, Cambridge, MA.

Carrier screening for Tay-Sachs disease (TSD [MIM 272800]), an autosomal recessive disorder, is recommended in the Ashkenazi Jewish (AJ) population due to its high frequency. DNA analysis of the *HEXA* gene using a limited panel of mutations focused on the AJ population and HexA enzyme analysis are typically used for TSD carrier screening individually, or in combination. The goal of this study was to compare the effectiveness of DNA testing for TSD using an expanded panel of mutations along with enzyme analysis, in a large pan-ethnic population. Both HexA enzymatic activity and *HEXA* DNA analyses were performed in 7148 individuals referred to us by IVF clinics in the United States for TSD carrier screening. HexA enzyme activities were measured by an outside independent laboratory. Next Generation DNA sequencing (NGS) of the coding region and exon-intron borders was used to assess for the presence of more than 70 variants with our extensive *HEXA* test panel. Our results showed that 181 individuals tested positive by enzyme analysis. A pathogenic variant was identified in 55 (30%), and a pseudodeficiency allele was present in 23 (13%). DNA analysis revealed no pathogenic variants in 103 of the 181 (57%). In 6397 enzyme negative patients, 3 had a pathogenic B1 allele, as determined by DNA analysis. Of the 570 (8%) patients within the enzyme inconclusive range, 6 had pathogenic variants. The observed carrier frequency in non-AJ populations is substantially higher with screening by enzyme analysis (corrected for pseudodeficiency alleles) than DNA analysis: 1/45 vs. 1/111 overall for enzyme vs. DNA analysis respectively, 1/9 vs. 1/252 for African Americans and 1/86 vs. 1/196 in Caucasians. Estimates based on disease incidence place the carrier frequency for TSD in the general population in the range of 1/250 - 1/300, much closer to carrier frequencies derived by DNA analysis. We conclude that while HexA enzyme carrier screening seems to reflect TSD status appropriately in most AJ individuals, it is problematic for carrier screening in pan-ethnic populations due to its high rate of false positive and inconclusive results. Our data indicate that ACOG's recommendation for the use of TSD biochemical analysis may need to be revised for non-AJ populations and/or the normal, inconclusive, and carrier ranges for enzyme analysis should be re-assessed for non-AJ individuals.

2797S

Analysis of Y-chromosomal microdeletions in an azoospermic patient candidate for an assisted reproductive technique. *M. Rongioletti, F. Papa, C. Vaccarella, MB. Majolini, A. Luciano, M. Belli, P. Scotaccia, B. D'Andrea, V. Mazzucchi, G. Liumbruno.* Clinical Pathology Department, San Giovanni Calibita Hospital, Rome, Italy.

Introduction Y-chromosomal microdeletions are the second most frequent genetic cause of male infertility. As stated in the guidelines of the European Academy of Andrology (EAA) for molecular diagnosis of Y-chromosomal microdeletions, this kind of analysis should be performed in patients with azoospermia or severe oligospermia with sperm concentrations < 2×106/ml. In these patients is also convenient analyze other clinical parameters such as hormone levels, testicular volume, varicocele, infections etc, although these parameters do not have any predictive value. Here we report a lab case of an azoospermic patient candidate to a testicular sperm extraction (TESE) for performing an assisted reproductive technology. Methods According to EAA guidelines, we first performed the multiplex PCR amplification of genomic DNA with the Ampli-Y Chromosome and Ampli-Y Chromosome Extension kits (Diachem - Italy). As a confirmatory test we also utilized the Devyser AZF kit (Devyser Ab - Sweden). The execution of kariotype was performed in an external laboratory. Conclusions The Y-chromosomal microdeletions analysis performed showed a lack of AZF b and c regions of Y-chromosome, confirmed by both kit utilized for Y microdeletions diagnosis. The patient had also high levels of FSH and LH, low level of inhibin b and normal levels of prolactin and testosterone hormones. Moreover after the execution of kariotype test, the patient was found to be carrier of a severe form of chromosomal mosaicism (45X[99]; 46XY[1]) that confirmed Y microdeletion diagnosis. In the overall these results suggested clinicians to do not perform TESE since, as reported in literature, the chance for testicular sperm retrieval in these cases is virtually zero. Our case confirm the need of a good laboratory practice to support clinical decisions.

2798S

First Experiences with Non invasive Genetic testing in Switzerland. *J. Esslinger[1], S. Hotz[1], L. Risch[2], U. Wiedemann[2].* 1) Institute for family research and counseling, University of Fribourg, Fribourg, Switzerland; 2) Labormedizinisches Zentrum Dr. Risch, Liebefeld BE, Switzerland.

Introduction In July 2012 the NIPD Praena-Test of Lifecodexx, was implemented in Switzerland. NIPD-testing received high media coverage. Initially, a lack of clarity regarding the target patient-community, the length of reporting time and the indication for this test existed. Referral was made via local gynaecologist, hospital centre or private person. We evaluated data to clarify whether a significant "patient pattern" exists for this new test. **Material und methods** A total of N=378 cases were included in this analysis, representing all NIPT-tests requested in the laboratory Dr. Risch, as a typical big private laboratory in Switzerland, from the beginning in August 2012 until the reference date December 31st 2013. **Results** As expected due to location, most patients were Swiss (92,1%), wherefrom 72,1% from the German-speaking part of Switzerland, 27,6% from the French-speaking part, 0,3% from the Italian-speaking part. Most foreign patients were from Liechtenstein, France and Italy or other European countries. Patients were between 18 and 46 years old, with a mean of 36 years (*SD*=4,4), and a most prevailing age of 39 years. The mean pregnancy week (PW) was 14 (*SD*=2,4); with a min. PW of 9 and max. PW of 28. Declared main indications for testing: maternal age >35 years (46%), conspicuous first trimester screening (1TT) (14%), combination 1TT/age (13%) and wish (13%). Further combinations such as age/wish, age/previous trisomy as well as familiar burden have each been indicated in 2% of patients. Other indications were the case in 1% or less of women. Two thirds (67%) of patients were referred from local gynaecologists, 30% from hospital centres, 3% were self-registered patients. We found no significant difference in indication between gynaecologists and hospital centres. The mean reporting time was 16 days (*SD*=4,8), with a min. of 6 and a max. of 53 days (incl. repetition). In 4% of the cases, the first blood sampling did not provide a valid result. One case showed a trisomy 13, one case a trisomy 18 and 4 cases a trisomy 21. The typical NIPT-patient after 18 months of test-availability was Swiss, 39 years old, with a gestational age of 14 weeks and maternal age as indication. After initially long reporting time, a statistically significant decrease in reporting time was achieved throughout the examination period during months 10-18 (*M=15*, *SD*=3,4) vs. months 1-9 (*M=17*, *SD=6,4*; p=0.001). The majority of patients (66%) receive their result with in 15 days.

2799S

Carrier screening for recessive disorders through exome sequencing. *P. Makrythanasis[1], A. Massouras[1], S.E. Antonarakis[1,2,3].* 1) University of Geneva, Geneva, Switzerland; 2) University Hospitals of Geneva, Geneva, Switzerland; 3) iGE3 Institute of Genetics and Genomics of Geneva, Geneva, Switzerland.

Detection of carrier status for certain recessive Mendelian disorders is a well-accepted health-care practice in several countries since the 70s and aims at the prevention of frequent severe monogenic disorders. Exome sequencing in combination with the increasing knowledge of human pathogenic variation provide the possibility to perform a carrier screening for all the known recessive Mendelian disorders. Such a screening would allow for a much more informative genetic counseling and may alter the total prevalence of the known recessive disorders. In order to test this hypothesis we have used exome sequencing data from 104 individuals of European origin and have identified the total number of likely pathogenic variants in the >1600 recessive disorders for which the responsible gene is known. The mean value was 18.2 variants per individual. Consequently we have randomly paired these exomes in order to create 5356 fictive couples. 33.14% of these couples have at least one gene for which both members are heterozygous for a likely pathogenic variant. These preliminary results exhibit an upper estimate of at risk couples but more precise knowledge and definition of the pathogenic potential of each variant will render the carrier detection more accurate and make it a potent test for family planning.

IL-10 Promoter polymorphism (592C/A) in women with recurrent miscarriages in Punjabi population (India). *A. Kaur, N. Sudhir, B. Badaruddoza.* Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Cytokines, expressed by several cell types and tissues, are diverse family of soluble proteins which play a fundamental role in differentiating the nature of immunologic response. Interleukin -10 (IL-10) a type of cytokine has a dual immunological role as it act as either immunostimulatory or immunosuppressive. IL-10 is fundamental in promoting normal pregnancy outcomes as it is involved in placental angiogenesis and inhibits the secretion of inflammatory cytokines. The promoter region polymorphisms in IL-10 gene have reported to interfere in its regulation. IL-10 down regulation may affect the placental angiogenesis affecting fetal growth and might end in miscarriage. In the present study IL-10 592C/A promoter polymorphism was investigated in women with recurrent miscarriages and in women with atleast one live birth and no history of miscarriages. For this, a total of 182 samples (92 cases and 90 controls) were genotyped using PCR-RFLP method. In the present study, 56.5% of women with recurrent miscarriages has homozygous wildtype genotype (CC), while 4.76% and 2.04% of women were having heterozygous and homozygous mutant genotype, respectively. In case of control group 52.2% showed CC gentotype, 40% had CA genotype and homozygous mutant (AA) was found in 7.8% of women. Three genetic models such as dominant, codominant (additive) and recessive were used to analyze the data, none of the models have been found significant except recessive model which showed positive association (OR: 1.45;0.53-3.98,P= 0.373). no significant difference were also observed in either genotype (P= 0.542) or allele (P=0.907). The present case control study did not show any significant association with recurrent miscarriages. Therefore, no overall significant association was found between IL-10 592C/A and recurrent miscarriages in present population.

2801S

Tay-Sachs carrier screening by enzyme and molecular analyses in the New York City Black population. *G.A. Lazarin[1], E. Spiegel[2], K. Berentsen[1], K. Brennan[2], N. Mehta[1], I.S. Haque[1], R. Wapner[2].* 1) Counsyl, South San Francisco, CA; 2) Department of Obstetrics and Gynecology, Columbia University Medical Center, New York, NY.

Introduction: Carrier screening for Tay-Sachs disease (TSD [MIM 272800]) analyzes the *HEXA* gene or HexA enzymatic activity. The former can be more costly or may not detect all carriers. Enzymatic assay approximates phenotype but is subject to misinterpretation (e.g., indeterminate results). Enzymatic assay is often suggested as the optimal detection method in non-Ashkenazi Jewish people. However, this protocol has only recently been considered for routine, pan-ethnic TSD carrier screening with the advent of expanded carrier screening (ECS). Columbia University implemented universal ECS in 2013. Results of DNA and enzymatic analyses for TSD carrier status in the Black population are reported. **Methods:** 123 individuals reporting Black ancestry underwent ECS, including *HEXA* mutation screening (9 mutations) and lymphocyte HexA activity levels (WBC HexA %). Mutation screening was performed at Counsyl (South San Francisco, CA) and most enzyme assays were performed at Mount Sinai Genetic Testing Laboratory (New York, NY); one enzyme assay was performed at Mayo Medical Laboratory (Rochester, MN). Individuals with carrier or indeterminate enzyme levels and negative targeted mutation analysis were subsequently offered next-generation sequencing (NGS) of exons 1-14, also at Counsyl. **Results:** Of 123 individuals screened by enzyme, n=16 (13.0%) were deemed carriers and n=15 (12.2%) had inconclusive results. Mean WBC HexA % were: 58% in all individuals, 45% in positive results, 52% in inconclusive results and 61% in negative results. All of these 31 individuals were negative for a 9-mutation DNA analysis. At time of writing, NGS was completed on 4 individuals with positive results and 4 with inconclusive results. One likely deleterious variant, c.1510C>T, was found in 1 individual. One individual had no variation from the reference sequence. In the remaining 6, 2-5 known benign variants (total of 6 unique variants detected 34 times) were identified. **Conclusions:** Using enzyme analysis in this Black population, we found an unexpectedly high positive or inconclusive rate. Such results necessitate molecular testing, and we have initially found most do not have pathogenic mutations. We continue to collect data characterizing non-negative enzyme results, which may reveal unrealized deleterious variants or pseudodeficiency alleles. The data may suggest recalibration of enzyme reference ranges or an alternative routine screening protocol for certain populations.

2802S

Prospective exome sequencing of consanguineous couples: First steps. *H. Meijers-Heijboer, M. Teeuw, MD, Q. Waisfisz, PhD, P.J.G. Zwijnenburg, MD, PhD, E.A. Sistermans, PhD, J. Weiss, PhD, L. Henneman, PhD, L.P. ten Kate, MD, PhD, M.C. Cornel, MD, PhD.* VU University Medical Center, Amsterdam, Netherlands.

With 10% of people worldwide in a consanguineous relationship or having consanguineous parents, consanguinity is one of the most frequent risk factors for congenital disorders. In theory, prospective exome sequencing of consanguineous couples could identify couples who are carriers for autosomal recessive diseases, and empower such couples to make informed reproductive decisions. The expected yield of this approach can be investigated in silico, leaving the question unanswered whether expectations would be realized in practice. Therefore, we sent blood samples of 4 pairs of parents, having one or more children affected by an autosomal recessive disorder, without revealing any diagnostic information, to our laboratory (which had not been involved in the testing of the children earlier on). The study was restricted to find, in both parents of each couple, identical, previously described, or evidently pathogenic mutations in over 400 genes known to result in severe autosomal recessive disorders. After de-blinding, results were compared to pre-existing information. Out of the 6 autosomal recessive disorders known to the 4 couples studied, two were correctly identified. As expected, given the pipeline used, large deletions were not identified, explaining one unidentified disorder. The same applied to mutations in genes not present in the gene list, mutations outside the exons and consensus splice sites, and mutations that were not evidently pathogenic and not reported before, each explaining an unidentified disorder. In one of the couples carriership of both partners was found for a disorder which was not known to the family yet. As our approach was not able to identify intronic mutations or large deletions, provisions for frequent disorders with these kind of mutations (e.g. thalassemia's and spinal muscular atrophy) should be realized. The restriction to detecting only couples with identical mutations diminishes the risk of finding unsolicited findings and shortens the time needed for analysis, but also results in missing pairs with different mutations in the same gene. On the other hand, for disorders with all mutations identifiable, finding couples with identical mutations (either by descent or state) reduces the risk of the consanguineous couple to a level below the risk for (untested) non-consanguineous couples. Again special provisions might be needed for frequent disorders with one frequent mutation, such as cystic fibrosis.

2803S

A new computational approach for reproductive genetic risk assessment with over 10-fold greater sensitivity than carrier screening. *A. Silver[1], C. Borrot[1], B. Spurrier[1], M. Silver[1], J. Greisman[1,3], N. Delaney[1,2], R. Lim[1], L. Silver[1,3].* 1) GenePeeks, Cambridge, MA; 2) Broad Institute, Cambridge, MA; 3) Princeton University, Princeton, NJ.

Carrier testing (CT) is unique among diagnostic tests in that disease can only be observed in persons other than those being tested. As a result, clinical validation of many rare disease-causing mutations may be difficult if not impossible. Nevertheless, CT can be applied only to validated mutations in the detection of recessive disease risk prior to conception. CT is a particularly poor indicator of reproductive risk for anonymous donors to sperm and egg banks. We have developed a computational system that simulates the creation of haploid gametes from a person's genomic or exomic sequence information. The Monte Carlo-generated "virtual gametes" from two prospective genetic parents are combined to form a pool of diploid "virtual progeny" (VP) genomes. Each VP genome is analyzed individually for the likelihood that it will induce a disease phenotype based on clinical annotations and the combined biochemical properties of the products of the two copies of each gene. Our isolated variant scoring method shows a sensitivity of 95% on defined clinical variants. We applied our analysis to 440 well-characterized recessive disease-associated genes in virtual matings of 2,500 exomes from phase 3 1000 genomes data. The detected risk of recessive disease is over 10-fold greater than predicted by an ideal all-encompassing carrier testing protocol.

Genetic Polymorphism Of Hsp-70 & Tp-53 Gene In Indian Preeclamptic Women With Placental Vasculopathies. *S. KUMAR, A. LOMASH, A. SINGH, S. KHALIL, SK. POLIPALLI, S. GUPTA, S. KAPOOR.* MAULANA AZAD MEDICAL COLLEGE, NEW DELHI, NEW DELHI, India.

Objective: Complications in the later phases of pregnancy are often summaried as placental vasculopathies, which comprises placental infarction, villous infarct, villous fibrosis, fibroid necrosis of decidual vessels, calcification, cytotrophic proliferation, increases the maternal & fetal morbidity and mortality upto 40%. Polymorphic variation in HSP-70 & TP-53 genes results in convergence of multiple etilogical factors, leading to endothelial cell dysfunction with clinical manifestations of placental vasculopathies with preeclampsia. Aim of the study was to detect polymorphic variation within the HSP70 & TP53 genes with respect to placental vasculopathies in preeclamptic women. Methods: Pilot study consisting 30 preeclamptic (proteinuria & hypertensive) women with placental vasculopathies & 30 healthy pregnant controls were recruited post diagnosis. Polymorphic varation in HSP 70gene (H S P A 1 A G 1 9 0 C { H S P 7 3 } , H S P A 1 B A 1 2 6 7 C { H S P 7 2 } , HSPA1LT2437C{HSP70-hom}) & TP53(p53 Codon 72 polymorphism) were ascertained by using PCR-RFLP Method. Results: Control & Patient group's, gestational age 38.5657+/-1.03138 & 36.4743+/-3.206(p=0.003), maternal age 24.64+/-2.447 & 25.04+/-3.259 yrs, Placental weight 415+ 45 gm & 280+86gms(p=0.004).Immunohistopathological features in Controls/Case were Placental Infarct 0.00%/16.66%, Fibroid necrosis of DV's 0.00% / 20%, Cytotrophoblast proriferation 10.0%/53.33%, Villous fibrosis 20.0%/80.0%, Hypovascularity of villi16.66%/86.66%.Genotypic distribution in Control vs Case for HSP70 gene were , HSPA1A190 (GG,GC,CC) 0.00%,100%,0.00% vs 0.00%,90.0,10% ; HSPA1L2437 (TT,TC,CC) 20%,80%,0.0% vs 0.0%,80%,20% ; HSPA1B1267 (AA,AG,GG) 60%,40%,00 vs 0.00,100%,0.00% & for TP53 gene (p53 Codon 72 Proline/Arginine) were Pro/Pro 36.66% / 23.33% & Pro/Arg 63.33%/76.66%. Conclusion: This is a pilot study to identify that HSPA1B (A1267G) {HSP72},polymorphism is a predisposing genetic risk factor (p value= 0.0022) in preeclamptic women with placental vasculopathies. It shows positive association with gestational age, placental weight , Hypovascularity of villi and along with Fibrous villous in patients. However. HSPA1LT2437C, TP53(p53 Codon 72 polymorphism) (HSPA1AG190C{HSP73}, does not show any association independently or in combination with the disease. The application of the above study to the entire population would greatly enhances its importance.

2805S

Exome chip evaluation of genetic variants for association with uterine fibroids. *M.J. Bray[1], T.L. Edwards[1,2,3,4], K.E. Hartmann[2,3,5], D.R. Velez Edwards[1,3,5,6].* 1) Center for Human Genetics Research, Vanderbilt University , Nashville, TN; 2) Department of Medicine, Vanderbilt University, Nashville, TN; 3) Vanderbilt Epidemiology Center, Vanderbilt University, Nashville, TN; 4) Institute for Medicine and Public Health, Vanderbilt University, Nashville TN; 5) Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 6) Division of Epidemiology Department of Medicine, Vanderbilt University, Nashville, TN.

Uterine fibroids (UFs) affect up to 77% of women by menopause, account for $9.4 billion in yearly healthcare costs, and disproportionately impact minorities. Although UFs are heritable, genetic causes are poorly understood. The first genome-wide association study (GWAS) of UFs was performed in 2011 in a Japanese population. However, to date few large-scale genetic studies have been performed in US populations. The objective of this study is to conduct a whole exome association study of UF risk in European Americans (EA) and African Americans (AA). This is a case-control genetic association study of UFs defined using pelvic imaging data obtained from an electronic medical record biorepository (BioVU DNA Repository). Logistic regression adjusted for ancestry and age was used in 728 EA and AA DNA samples (EA: 246 cases, 243 controls; AA: 121 cases, 118 controls) to evaluate SNPs for association, stratified by race. Meta-analyses of results with fixed effect models were performed to obtain combined evidence for associations across racial groups. Our strongest association within EAs was within t-complex 11, testis-specific like 1 (TCP11L1, rs1064005, OR = 1.79, 95% CI = 1.36-2.32, p = 3.94×10-5) and within multiple SNPs within the HLA region (smallest p 9.28×10-5). It is of note that the exome chip has enhanced coverage of the HLA region compared to GWAS arrays. Among AAs strong associations were observed within glipican 4 (GPC4, OR = 0.46, 95% CI = 0.31-0.68, p = 8.73×10-5). Meta-analysis across EA and AA further strengthened the associations observed at TCP11L1 (smallest meta-p = 4.09x-7, with effect sizes consistent across races). Prior gene expression studies of TCP11L have shown increased expression in tumor tissues compared to normal tissues across several different cancers, and variants within HLA genes have been associated with UF risk in prior studies. These pilot data suggest common variants in exonic regions increase risk for UF in both EA and AA populations. However, further validation of our study findings is needed to confirm our results. We are currently genotyping >4,000 samples for GWAS and exome arrays to further evaluate the relationship between gene variants and UF risk.

Familial Infertility with Sex-limited Autosomal Recessive Inheritance. *H. Huang[1,2], H. Deng[1], H. Xiao[2].* 1) Department of Biostatistics and Bioinformatics, Tulane University, NEW ORLEANS, LA; 2) the Institute of Reproduction & Stem Cell Engineering, Central South University , Changsha, P. R. China.

BACKGROUND: In mammals, the zona pellucida is a glycoprotein matrix surrounds oocytes, which is vital to the production of oocytes in early development, fertilization, and protection of the early prior to implantation. Previous studies of zona pellucida defects in humans have not identified mutations the four genes *(ZP1, ZP2, ZP3,* and *ZP4*) encoding the ZP glycoproteins, which are secreted by growing oocytes. **METHODS:** The clinical and genealogical characterization was collected from the patients who failed in IVF (*in vitro* fertilization). Oocytes were removed away from granular cells and were observed with a visible light microscope. We firstly chose four candidate genes (*ZP1-ZP4*) to screen for potential mutations. We analyzed ZP1 and normal ZP3 in oocytes *in vitro*, from the patients and control subjects using immunofluorescently tagged antibodies. We gave one of the patients ART with oocyte donation, and followed all of the patients' birth situation. **RESULT:** Four sisters of the family were diagnosed with primary infertility. The eggs of two of the four sisters had a similar abnormal phenotype were not surrounded by a zona pellucida. We detected a homozygous frameshift mutation in *ZP1* in six members of the reported family, resulting in the truncation of ZP1 (p. I390fs404X). We propose that this prevents the formation of the zona matrix, and thus sterility. The immunofluorescen in oocytes showed no evidence of extracellular ZP1 and ZP3 surrounding the mutated eggs. ZP3 and mutant ZP1 showed diffuse staining in the patient's eggs. Merged images showed co-localization of signals throughout the cytoplasm in eggs from the patient. The treatment was successful and the patients delivered two babies. Her brother who carried a homozygous mutation had male fertile feedback, because his partner was pregnant after cohabitating for three months. **CONCLUSIONS:** We describe a novel form of infertility with a sex-limited autosomal recessive mode of inheritance, characterized by abnormal eggs that lack a zona pellucida. We identified a homozygous frameshift mutation in *ZP1* in six members of the family. Our data suggest that the aberrant ZP1 results in the sequestration of ZP3 in the cytoplasm, thereby preventing the formation of the zona pellucida around the oocyte, leading to infertility. The egg-donated treatment was effective. **KEY WORDS:** Infertility, ZP1, zona pellucida, oocyte, IVF, ART,sex-limited inheritance, egg donor.

Expression of Aurora Kinase C splice variants in human oocytes and cumulus cells. *J.E. Fellmeth[1], K. Schindler[1], N.R. Treff[2].* 1) Department of Genetics, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States of America; 2) Division of Reproductive Endocrinology, Department of Obstetrics, Gynecology and Reproductive Science, Robert Wood Johnson Medical School, Rutgers University, New Brunswick; Reproductive Medicine Associates of New Jersey, Morristown, New Jersey.

Objective: Accurate chromosome segregation during meiosis I (MI) is essential for generating eggs with the proper chromosome complement. This segregation is highly error-prone in humans leading to miscarriage or offspring with developmental disorders. The Aurora family of protein kinases is a well-established regulator of chromosome segregation during mitosis and meiosis. Aurora kinases A and B (AURKA and AURKB) are expressed in nearly every cell type, whereas Aurora kinase C (AURKC) is only highly expressed in gametes. AURKC was identified in sperm and missense mutations in AURKC are linked to formation of polyploid sperm and infertility. Studies in mouse oocytes indicate that AURKC is also required to regulate MI chromosome segregation in females. To begin to determine if AURKC function is conserved between mouse and human, we used quantitative real-time PCR to detect the presence of AURKC message in single human oocytes. Design: Observational Materials and Methods: To determine which variants are present in human oocytes, we designed Taqman probes that are specific for detecting each variant, 1, 2, and 3. To compare the expression levels between meiotic and mitotic cells, we compared the expression of AURKC in oocytes to that of its expression in oocyte-matched cumulus cell samples. Sperm samples known to express all 3 variants were used as positive controls. Results: We found that AURKC expression levels varied from oocyte to oocyte, and that expression levels are greater in the oocyte than sperm, where variants were originally found. Oocytes express all three variants, however, variant 1 is expressed approximately 10 fold greater than variants 2 and 3. Surprisingly, cumulus cells also express AURKC, although this expression was restricted to variant 1. Similar to the single oocytes, AURKC expression levels varied amongst the cumulus cell samples. Conclusion: In sum, like sperm, human oocytes and cumulus cells express AURKC suggesting that missense mutations may also affect female MI and thereby compromise fertility. Future work may involve characterizing whether varying expression levels amongst oocytes correlate with aneuploidy development. Support: ASRM Research Grant.

Understanding the genetics of spermatogenic failure by resequencing the sex chromosomes of infertile men. *R. George[1], J. Hughes[1], L. Brown[1], L. Lin[2], D. Koboldt[2], K. Meltz-Steinberg[2], R. Fulton[2], R. Wilson[2], R. Oates[3], S. Silber[4], S. Repping[5], D. Page[1,6,7].* 1) Whitehead Institute, Cambridge, MA; 2) The Genome Institute at Washington University, St. Louis, MO; 3) Urology Department, Boston University, Boston, MA; 4) Infertility Center of St. Louis, St. Louis, MO; 5) Academic Medical Center, Amsterdam, The Netherlands; 6) Biology Department, MIT, Cambridge, MA; 7) HHMI.

The sex chromosomes harbor a large number of genes involved in spermatogenesis and are hemizygous in males. For these reasons, mutations that cause spermatogenic failure—the production of very few or no sperm—are disproportionately likely to be found on the X and Y chromosomes. While several genetic causes of spermatogenic failure, such as microdeletions of the Y chromosome and large-scale cytogenetic abnormalities (e.g. Klinefelter's syndrome; XXY), have been identified, they only account for 20-30% of cases and the majority of genetic causes remain unknown. To identify new mutations involved in spermatogenic failure, we have captured and sequenced the coding and conserved non-coding regions of the X and Y chromosomes in 300 men with nonobstructive azoospermia and 300 controls. Our targeted regions include 838 and 53 protein coding genes from the X and Y chromosomes respectively, along with 22 Mb of non-coding sequence that contain ncRNAs and putative regulatory regions. We will describe the initial analysis of these sequences, and the identification of putatively causal coding mutations and copy number variants.

2809S

A rare familial non-Robertsonian translocation involving chromosomes 15 and 21 and failure of reproduction: Is there a correlation? *R. Frikha, F. Turki, S. Daoud, O. Kaabi, R. Louati, O. Trabelsi, T. Rebai, N. Bouayed Abdelmoula.* Histology Laboratory, Univ Medicine, Sfax, Tunisia.

Robertsonian translocations are among the most common balanced structural rearrangements in humans involving two (often non homologous and rarely homologous) acrocentric chromosomes (13, 14, 15, 21 and 22). Nevertheless, non-Robertsonian translocation involving these chromosomes is a rare event and only few cases were reported. Here, we report a familial non-Robertsonian translocation involving chromosomes 15 and 21. The index case is a 38-years-old man for whom chromosomal investigation was carried out to explore a male infertility of 3 years related to azoospermic profile at the semen level, a first unsuccessful attempt of sperm retrieval using TESE and a second diagnostic biopsy of testis showing a sertoli cell only syndrome. Cytogenetic analysis carried out using RHG banding, disclose the presence of a balanced translocation between the long arm of chromosome 15 and the long arm of chromosome 21: t(15;21)(q21;q21). At the genetic counseling, familial history showed that the patient had consanguineous parents , an infertile paternal uncle and two hypofertile brothers with only one son for each of them (as well as another brother and 2 sisters who were fertile). One of hypofertile brother's patient had a history of recurrent pregnancy losses (RPL) (n=3) and a teratozoospermia with a normal count of spermatozoa (98×106/ml). His karyotype revealed at the occasion of familial genetic counseling, was abnormal with the same translocation t(15;21)(q21;q21). Non-Robertsonian translocations, involving chromosomes 15 and 21 are uncommon and were described only three times at literature. However, these translocations involved other break-points and were reported for parents of malformed children harboring partial trisomy 15 [t(15;21)(q13;q22.1)mat], partial trisomy 21 [t(15;21)(q26;q22.1)pat], and Prader willi syndrome [t(15;21)(q15;q22.1)pat]. This new translocation is different by its breakpoints and its association with male infertility and RPL. However, its consequences at the semen level were different for at least the two cases in which the karyotype was done. Molecular delineation using comparative genomic hybridization will be important for phenotype-genotype correlation study which should be considered for genetic counselling and ART.

2810S

Screening Uniparental disomy in recurrent miscarriage couples. *YP. Sun, JW. Xu.* Reproductive Medicine Centre, The First Affiliated Hospital of Zhengzhou University, Zhengzhou, China.

Background: Approximately 15-20% of all clinically recognised pregnancies miscarriage, most commonly between 8-12 gestational weeks. The majority genetic factors of early pregnancy losses is attributed to aneuploid abnormalities. However, the aetiology of approximately 40% of early abortions remains unknown. To investigate additional factors causing spontaneous abortions, we screened uniparental disomies (UPD) in cytogenetically normal diploid spontaneous abortion couples. **Materials and methods:**We screened 165 couples who came for assisted reproduction at Reproductive medical center of The First Affiliated Hospital of Zhengzhou University (Henan, China). And all the patients have undergone more than 2 times miscarriage. The karyotype of these couples was 46,XX and 46,XY detected by G-banding technique. Uniparental disomy was detected by illumine HumanCytoSNP-12 DNA Analysis BeadChip and the protocol has been described previously. **Results:**Our results shows that the UPDs mostly occurred on chromosome 6 (7 couples has at least one UPD located chromosome 6)and 11(4 couples has at least one UPD located chromosome 11). The UPDs were between 1M and 15M length, and the most interesting molecular kyrotype was 46,XX,upd(1)(p21.2→p31.1),upd(2)(q33→q34), upd(6)(q11.1→q13),upd(9)(p23→p24.2),upd(9)(q21.13→q21.32), upd(11)(p11.12→q14.1),upd(16)(p12.3→p13.2),upd(19)(q13.2→q13.33), upd(22)(q12.1→q12.3),upd(22)(q13.2), has UPDs locates on chromosome 1, 2,6,9,11,16,19 and 22.We also showed that a patient with about 4M UPD located on chromosome 1 and a 0.01M deletion located on chromosome 8 (46,XY,upd(1)(p32.3→p33)(49215178→53137328)×2,del(8)(q24.12) (121848163→121861465)×1). However, the association between these genes locate in these region and recurrent miscarriage is still unknown. Further studies need to investigate the susceptibility locus and DNA methylation status of these genes. **Conclusion:** Our study suggests that UPD is a potential genetic aetiology of recurrent miscarriage.

2811S

The correlation between Y chromosome partial micro-deletions and recurrent pregnancy loss. *Z. Sarrafi[1], R. Mirfakhraie[1], M. Salimi[1], G. Modabber[2].* 1) Shahid Beheshti University of Medical Sciences, Tehran, Iran; 2) Tadbir Fan Azma Co. , Tehran, Iran.

Introduction: Abortion is defined as preterm labor with no chance of live birth. It is considered as the end of pregnancy before the 20th week of gestation, or a fetus birth weighing less than 500g. Recurrent pregnancy loss, which involves 5% of couples, means 2 or more consecutive pregnancy losses. The studies made so far on the matter have been mainly focused on female causes however, among men, evaluations have only been made on karyotype and chromosomal abnormalities. There are 3 azoo-spermia factor regions on Yq11, called AZFa, AZFb and AZFc, of which AZFc is more than others prone to deletions. In AZFc, there are a few kinds of partial deletions including gr/gr, b1/b3 and b2/b3 of which the most common sub-deletions among infertile persons are gr/gr and b2/b3. It was only in recent years that some studies were conducted to realize the relation between Y chromosome micro-deletions and recurrent pregnancy losses, in which different results were achieved. Among them the relation between partial micro-deletions of the Y chromosome and recurrent pregnancy losses, has been less investigated. Materials and methods: In this study 87 men of couples with idiopathic RPL and 50 healthy fertile men, who had at least one healthy child were examined. After DNA extraction from peripheral blood by salting out and phenol-chloroform methods, multiplex PCR was used to investigate the existence of gr/gr and b2/b3 micro-deletions. Results: No significant difference in the frequency of gr/gr micro-deletions were observed between cases (5 patients, 5/7%) and the controls (1 person, 2%) (p value = 0.282). There was not any significant difference in the frequency of b2/b3 micro-deletions between the cases (2 persons, 2/3%) and the controls too (1 person 2%) (p Value=0/699). Conclusion: gr/gr and b2/b3 deletions have no correlation with recurrent pregnancy losses among Iranian couples. Key words: Recurrent pregnancy loss, Y chromosome, gr/gr deletion, b2/b3 deletion.

Predictive value of sperm count and motility in the assessment of sperm morphology in infertile men. *S. Daoud, A. Sellami, N. Chakroun-Feki, R. Frikha, N. Bouayed-Abdelmoula, L. Ammar-Keskes, T. Rebai.* Histology-Embryology-Biology of Reproduction Laboratory, Sfax Faculty of Medicine, Sfax, Tunisia.

Introduction: Sperm morphology has an important impact on the success of fertilization. However, it is known that morphology assessment is subjective and highly variable between laboratories and technicians. We thus aimed to determine whether the value of sperm count or motility in routine semen analysis would be predictive of normal morphology. **Patients and Methods :** Data from semen analyses performed in 763 patients undergoing routine fertility evaluation in our laboratory were collected. 689 (90,3%) of them had abnormal morphology. Of the 74 specimens having normal morphology, 61 (8%) had normal count and motility. Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were obtained from 2 x 2 contingency tables of sperm count and motility against sperm morphology, and Fisher's exact test was used for the statistic analysis. **Results:** A significantly greater proportion of normal morphology samples exhibited normal count (96% vs 75,6%; p<0,001) and normal motility (86,3% vs 59,3%; p<0,001). A normal count predicted concurrent normal morphology with a NPV of 96% and a sensitivity of 98,2%. Normal motility predicted normal morphology with a NPV of 86,3% and a sensitivity of 96,4%. A significantly greater proportion of normal morphology samples exhibited either normal count or motility (83,6% vs 53%; p<0,001) and both normal count and motility (83,6% vs 53%; p<0,001). The presence of either normal count or normal motility predicted concurrent normal morphology with a NPV of 83,5% and a sensitivity of 96,3%. The presence of both normal count and normal motility predicted concurrent normal morphology with a NPV of 98,6% and a sensitivity of 99%. **Conclusion:** We have found that normal morphology is more likely in the presence of both normal count and motility compared with the presence of normal count, normal motility, or either normal count or motility. This category includes only 8% of specimens in our study population. So, a complete assessment of sperm morphology remains necessary in order to have all the important keys of male infertility diagnosis.

2813S

Nelf affects GnRH migration and secretion in mouse puberty and fertility. *EK. Ko, SD. Quaynor, RC. Cameron, LP. Chorich, LC. Layman.* Institute of Molecular Medicine & Genetics, Georgia Regents University, Augusta, GA.

The hypothalamic-pituitary-gonadal (HPG) axis controlled by gonadotropin releasing hormone (GnRH) plays a crucial role in normal puberty and fertility. Proper specification, migration, and regulation of GnRH neurons are prerequisites for normal GnRH function. When there is impairment of GnRH action, hypogonadotropic hypogonadism results. These patients present with delayed puberty, low sex steroids, and low or inappropriately normal levels of gonadotropins. Sense of smell may be normal, as in normosmic hypogonadotropic hypogonadism (nHH), or impaired as with Kallmann syndrome (KS). Mutations in the NELF gene have been identified in human nHH/KS patients, but the mechanism of how NELF mutations impair puberty is unknown. To address this question, we have generated Nelf knockout (Nelf -/-) mice, and have shown that females manifest delayed puberty, while both males and females have reduced litter sizes. GnRH neurons occupy a smaller region of the brain in adult female Nelf -/- mice compared with Nelf +/+ mice suggesting altered migration. We hypothesized that pubertal aged mice (30 days) will have impaired GnRH neuron migration and manifest hypogonadotropic hypogonadism. Serum follicle stimulating hormone (FSH) and luteinizing hormone (LH) were drawn on all animals as were serum testosterone (males) and estradiol (females). Brains from 6 Nelf -/- and 6 Nelf +/+ mice of each sex (24 total at 30 days of age) were frozen and 10 um-thick coronal sections collected anterior to the optic chiasm through the posterior cerebrum were processed for immunofluorescence microscopy using antibodies directed against GnRH. Immunolabeled sections were examined at 20x using LSC microscopy and GnRH neuron number determined in sections at 40 um intervals by cell counting. Initial serum assays at 30 days demonstrate no differences in testosterone (males) or estradiol (females) between Nelf -/- and Nelf +/+ mice. Our preliminary findings suggest that Nelf -/- mice have normal sex steroid levels at puberty. Examination of pubertal mice for GnRH neuron number and distribution is ongoing, and could indicate changes that may explain the altered patterns of GnRH neurons observed in adults.

2814S

High throughput sequencing of short sequence tags(STS) uncovers novel Y chromosome deletions associated with non-obstructive azoospermia. *X. Liu[1,2], Z. Li[4], Z. Su[1], Y. Gui[3].* 1) BGI, Shenzhen, Guangdong, China; 2) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 3) Peking University Shenzhen Hospital, Shenzhen, Guangdong, China; 4) 2nd people's hospital, Shenzhen, Guangdong, China.

Male infertility, which affects approximately one in ten men among population, is closely associated with Y chromosome deletions, especially in Azoospermia Factor(AZF) region. Traditional PCR based deletion detection method traces a couple of STS markers located in palindromic regions, to check the existence of long range deletions in AZFa, AZFb and AZFc region. This low resolution technique limits our exploration on extensive and novel Y chromosome deletions associated with male infertility. Here we present a novel methodology by sequencing thousands of short sequence tags(STS) distributed across the entire male specific Y chromosome(MSY) in next generation sequencing platform to identify all Y deletions with significantly increased sensitivity and resolution. By exquisite algorithm and validation the accuracy of our method was proved. We applied this approach in 766 Chinese men with non-obstructive azoospermia(NOA) and 683 ethic matched healthy individuals, and identified 481 and 98 STS deleted in NOA and control group respectively, which enormously expanded the previous picture. Overall, we found NOA patient tended to carry significantly more yet rarer deletions. We also discovered a couple of novel deletions in Y chromosome significantly impact functions of spermatogenic genes thus very likely directly resulted in the incidences. Haplogroup O2* seemed to be associated with NOA in Chinese population. In summary, our work reflected a new high-resolution portrait of deletion in Y chromosome, both in NOA patients and normal population.

2815S

Expression of hsa-miR-34b, hsa-miR-181c, hsa-miR-449b, hsa-miR-517c and hsa-miR-605 in FFPE testicular tissues of infertile men with different impairments of spermatogenesis. *D. Plaseska-Karanfilska[1], K. Popovska-Jankovic[1], P. Noveski[1], V. Filipovski[2], K. Kubelka[2].* 1) RCGEB "Georgi D. Efremov", Macedonian Academy of Sciences and Arts, Skopje, Macedonia; 2) Clinical Hospital “Acibadem Sistina”, Skopje, Macedonia.

Using microarray analysis we have previously detected 32 differentially expressed miRNAs in FFPE testicular tissues of infertile men with hypospermatogenesis (Abstract presented at the 5th Florence-Utah Symposium on the Genetics of male infertility, September 2013, Florence, Italy). Among these, hsa-miR-34b, hsa-miR-449b and hsa-miR-517c were one of the most significantly down regulated miRNAs, while hsa-miR-181c and hsa-miR-605 were up-regulated only in the patients with hypospermatogenesis and AZFc deletion. In this study the expression of these five miRNAs was studied using qRT-PCR in a total of 74 infertile men with different impairments of spermatogenesis. Based on the histopathological examination and molecular analysis the studied men were divided in the following groups: normal spermatogenesis (n=18), hypospermatogenesis (n=27), hypospermatogenesis and AZFc deletions (n=3), Sertoli cell only syndrome (SCOS) (n=8), maturation arrest (MA) (n=2), testicular atrophy/ fibrosis/ hyalinisation (n=8) and Klinefelter’s syndrome (n=8). Total RNA was extracted from FFPE testicular tissues using commercial DNA/RNA FFPE tissue kit (Qiagen, Hilden, Germany). RNA quantity and purity were determined using the NanoDrop Spectrophotometer and Agilent Bioanalyzer 2100. MiRNA quantitation was performed by stem-loop RT-PCR followed by Taq-Man PCR analysis using TaqMan MicroRNA Reverse Transcription Kit, TaqMan Universal PCR Master Mix and 7 TaqMan MicroRNA Assays (miR-34b, miR-449b, miR-517c, miR-181c, miR-605, as well as RNU44 and RNU6b as control genes) (Life Technologies, Carlsbad, CA, USA). The expression of each miRNA relative to RNU6b was determined using the $\Delta\Delta$Ct method. Our results showed that hsa-miR-449b and hsa-miR-34b were down-regulated in all studied groups of infertile men; hsa-miR-517c was also down-regulated in all groups, except in the MA group. Hsa-miR-605 and hsa-miR-181c were up-regulated in all, except the hypospermatogenesis group, although the later with a fold change below 2. In conclusion, the qRT-PCR results of the five studied miRNAs in the patients with hypospermatogenesis were consistent with the microarray data. They, furthermore, suggest that the expression pattern of these miRNAs in patients with hypospermatogenesis who also have AZFc deletions is more similar to that of the men with more severe impairments of spermatogenesis, such as SCOS than to the hypospermatogenic patients without AZFc deletion.

2816S

Novel mutations in spermatogenesis genes in azoospermic and severely oligospermic men. *K.A. Fakhro[1], A. Robay[1], J. Rodriguez-Flores[2], A. Al-Shakiki[1], H. Miqdad[3], C. Abi Khalil[1], M. Arafa[3], H. El-Bardisi[3], S. Said[3], J. Mezey[2], R.G. Crystal[1,2].* 1) Genetic Medicine, Weill Cornell Medical College - Qatar, Doha, Qatar; 2) Genetic Medicine, Weill Cornell Medical College - New York, NY; 3) Urology Department, Hamad Medical Corporation, Doha, Qatar.

Primary male infertility - the inability of a healthy male to achieve pregnancy in a fertile female - affects up to 7% of couples worldwide. In some cases, infertility is a result of physical or hormonal causes, often treatable by surgical or pharmacological intervention. However, in cases with no clear environmental cause, a primary genetic defect may be suspected, prompting routine genetic evaluation. In these cases, the infertile men may present with any combination of impaired sperm motility (asthenospermia), abnormal morphology (teratospermia) and/or reduced count (oligospermia), and in the most severe instances, a complete absence of sperm (azoospermia). At the Urology Department at Hamad Medical Corporation in Qatar, over 80% of these patients are classified as having idiopathic infertility, where cytogenetic testing is negative in addition to environmental causes being ruled out. Of these patients, about 10% have a strong family history of infertility (at least one concordant brother), further implicating a genetic basis. We have collected DNA from 18 such families, each comprising a core set of at least two infertile brothers and one fertile brother, plus other available family members. We use exome sequencing to identify rare, severe protein-altering variants segregating with disease in these families and have found novel candidate mutations in all 12 families sequenced to date. In 2 families, we identified novel deleterious mutations in CFTR and DNAI2, genes in which mutations have previously been reported to cause male infertility. In the remaining 10 families, we identified genes not previously implicated in human infertility, including TEX14, TULP3, MED14, SPO11, PDZD7, SPATA21, NOTCH4, ODF3, EEA1 and SYNPO2. All mutations were novel or very rare in all public databases, including >800 ethnically similar controls sequenced on the same platform. Notably, for the 5 latter genes, we observed the same mutations in 14 additional individuals from a cohort of 128 men with sporadic infertility. Preliminary examination of these genes supports involvement in spermatogenesis, with 8 genes found to either have testicular expression in the Human Protein Atlas and/or to cause infertility when knocked out in mouse. Altogether, we present an approach of identifying genes in a severe sporadic disease by focusing on its familial presentation in Qatar, and believe these findings could enhance understanding of pathophysiology and improve treatment options.

HLA-G gene polymorphisms in Mexican women with recurrent abortions. *A. PORRAS[1,2], A. LAZCANO[3], T. DA SILVA[1,2], C. JUAREZ[1,4], J. JUAREZ[1,2], F. PEREA[1,2], J. GARCIA[2].* 1) DIVISION DE GENETICA, UNIVERSIDAD DE GUADALAJARA, GUADALAJARA, JALISCO, Mexico; 2) DIVISION DE GENETICA, CENTRO DE INVESTIGACION BIOMEDICA DE OCCIDENTE, INSTITUTO MEXICANO DEL SEGURO SOCIAL, GUADALAJARA, JALISCO, MEXICO; 3) SERVICIO DE GINECOOBSTETRICIA, HOSPITAL GENERAL 180, INSTITUTO MEXICANO DEL SEGURO SOCIAL, TLAJOMULCO DE ZUÑIGA, JALISCO, MEXICO; 4) DIVISION DE MEDICINA MOLECULAR, CENTRO DE INVESTIGACION BIOMEDICA DE OCCIDENTE, INSTITUTO MEXICANO DEL SEGURO SOCIAL, GUADALAJARA, JALISCO, MEXICO.

The human leukocyte antigen (HLA)-G is an important immunomodulatory molecule for the maintenance of maternal-fetal relationships because it contributes to the acceptance of semi-allogeneic fetuses. Some single nucleotide polymorphisms (SNPs) in the noncoding regions of the HLA-G gene may influence cellular levels of HLA-G, contributing to pregnancy complications such as preeclampsia or recurrent spontaneous abortions (RSA). In this study, we analyzed the -725C>G (rs1233334), -201G>A (rs1233333) and 14-bp deletion/insertion (14-bp del/ins) (rs66554220) polymorphisms in the HLA -G gene by polymerase chain reaction amplification sequence-specific oligonucleotide probing (PCR-SSOP) and polymerase chain reaction amplification (PCR), respectively in 58 RSA women ($\geq$ 2 miscarriages) without identifiable risk factors and 56 unrelated fertile women ($\geq$ 2 live births). The ages of individuals in both groups ranged from 18 to 42 years. We found no significant differences in the genotype distributions that were analyzed between the RSA women and those who were fertile. In addition, the combinations of SNPs were not in linkage disequilibrium (r2<0.1140). Therefore, this study suggests that these polymorphisms in the HLA-G gene are in linkage equilibrium and do not influence the risk of RSA in Mexican women. Key words: Human leukocyte antigen, recurrent spontaneous abortion.

Performance and Limitations of Sequenced-Based Cell-Free DNA Aneuploidy Screening: Experience of a Tertiary Referral Center and Importance of Confirmatory Follow-Up Studies. *Y. Liu, W. Neufeld-Kaiser.* Dept Pathology, Univ Washington, Seattle, WA.

Non-invasive prenatal screening (NIPS) using cell free DNA in maternal serum has had a major influence on diagnosis of fetal aneuploidies in the clinical setting. Much higher sensitivity and specificity than maternal serum screening was reported in recently published validation studies. Follow-up diagnostic cytogenetic testing and/or ultrasound evaluation can provide the positive predictive value (PPV) and negative predictive value (NPV) of NIPS that are the more relevant metrics in the clinical setting. We performed a retrospective chart review for 56 abnormal cfDNA screen results from March 2012 through December 2013 in high risk pregnancies. Of 648 consecutive patients referred for non-invasive prenatal screening and genetic evaluation for chromosomal aneuploidy, 5 patients (0.8%) were referred either because of inconclusive results or repeated test failures. There were 586 true negative NIPS results and one false negative NIPS finding, resulting in 99.8% negative predictive value. The false negative NIPS case was trisomy 22 mosaicism diagnosed by amniocentesis and microarray analysis. For a variety of aneuploidies, there were 45 true positive NIPS results and 12 false positive NIPS results, resulting in 78.6% Positive Predict Value. Therefore, NIPS had a sensitivity of 97.8% and a specificity of 98% in this clinical setting. Among the 12 false positive results by NIPS, there were 3/33 trisomy 21, 4/12 trisomy 18, 1/2 trisomy 13, 2/5 monosomy X, and 2/3 XXX. Although NIPS has been shown to be the best non-invasive prenatal screen test to date, it is not a diagnostic test as shown by the false positive rate of 21.4%, an indicator of its diagnostic performance. A number of case reports have been published showing that discordant results can be due to a vanished twin, confined placental mosaicism, low-level maternal mosaicism, complex fetal chromosomal imbalances, and statistical false abnormal. Selected cases with some of these interesting findings will be discussed. Our experience shows that clinicians must recognize the limitations of cfDNA as a screening test. Diagnostic testing via fetal chromosome analysis should always be offered following abnormal NIPS results. In addition, the correlation between the maternal age and gestational age and NIPS test results will be discussed.

Referral of patients for pre-implantation genetic diagnosis: a survey of clinicians. *K. Barlow-Stewart[1], A. Morrow[1], S. Seeho[2], B. Meiser[3], J. Fleming[1], J. Karatas[4,5].* 1) Northern Clinical School, University of Sydney, Sydney, NSW, Australia; 2) Perinatal Research Group, Kolling Institute of Medical Research, Sydney, NSW Australia; 3) Psychosocial Research Group, Prince of Wales Clinical School, University of New South Wales, Sydney, NSW Australia; 4) Centre for Genetics Education, Royal North Shore Hospital, Sydney, NSW Australia,; 5) IVF Australia, Sydney, NSW, Australia.

BACKGROUND: Pre-implantation genetic diagnosis (PGD) is an assisted reproductive technique, in which embryos are tested for specific genetic abnormalities to enable the selection of those unaffected for implantation and pregnancy. This provides an alternative to prenatal diagnosis and potential pregnancy termination for couples at risk of transmitting a genetic condition to their children. There is recent Australian evidence to suggest that women who are not informed by their obstetricians about the availability of PGD feel disempowered and distressed about not having been provided this option. This study aimed to explore obstetrician knowledge regarding PGD and to identify potential barriers to referral for PGD. METHODS: An online questionnaire was e-mailed to fellows and accredited trainees of the Royal Australian and New Zealand College of Obstetricians and Gynaecologists. The questionnaire assessed respondents' knowledge of PGD and barriers to referral. RESULTS: Of 372 practicing obstetricians who responded, 315 were fellows and 57 trainees. Obstetricians' perceptions of their patients' financial status and ability to access PGD services were identified as the main barriers to referral. There was variability in obstetrician discussion of referral for PGD and/or to genetic services according to the presenting scenario. Variability was also observed regarding perceived appropriateness of PGD for different indications. Obstetricians who had received training or professional development related to PGD were more likely to discuss the option of PGD than those who had not ($\chi 2 = 6.44$; $p < 0.01$). CONCLUSIONS: Results from this study highlight the need for training opportunities, educational resources and recommendations to guide health professionals and ensure that couples eligible for PGD are informed and appropriate referral pathways are in place.

Four years later: the state of PGD in Quebec. Professional perspectives on medical indications and regulations. *F. Duplain-Laferrière[1], R. Drouin[2], C. Bouffard[1].* 1) Division of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Quebec, Canada; 2) CHR du Grand-Portage, Department of Obstetrics-Gynecology, Quebec, Canada.

For four years now, the Quebec healthcare system has covered costs related to preimplantation genetic diagnosis (PGD), for couples at risk of having a child affected by a serious genetic disease. This minimal and unclear regulation, both concerning medical indications and practices, is leading to significant decision-making, organizational and ethical challenges for health professionals. Objectives: To better understand the situation, we have consulted Quebec geneticists, obstetricians-gynecologists and genetic counselors to learn about their perceptions on: 1) the medicals and social reasons that justify PGD and 2) the principal players that should be involved in the regulation of PGD. Methodology: Qualitative Research Design — Online questionnaire containing 34 questions (13 open, 11 semi-open, 10 closed-ended) has been completed by 15/30 obstetricians, 15/30 geneticists and 17/30 genetic counselors engaged in activities related to prenatal diagnosis in the province of Quebec. Data analysis: General inductive and thematic analysis. Results: Overall, the participants agree that the use of PGD for multifactorial illnesses or for social reasons should be prohibited. For them, PGD should be restricted to fatal or incapacitating illnesses. However, professionals lack consensus on certain diseases or syndromes. Regarding regulation, the majority of participants want PGD to be regulated while allowing them the flexibility to adjust their clinical management or medical counselling to particular cases. While they consider that the patients should be involved in the decision-making process, they do not believe that patients should decide everything. Conclusion: This project has made it possible to develop novel knowledge through the comparison of the perceptions of geneticists, obstetricians and genetic counselors in Quebec. In light of these results, it is necessary to find new approaches to understand the concepts of serious genetic diseases and the sharing of responsibility, to build guidelines that are more adapted to social and professional contexts.

4-Hour Concurrent Preimplantation Genetic Diagnosis of 24-Chromosomes Aneuplody, Single Gene Disorders, And Micro-Deletion and Duplications. *C. Jalas[1], X. Tao[2], A. Fedick[2], C. Bohrer[2], S. Kloskowski[1], D. Gabriele[2], B. Levy[3], R.T. Scott[2], N.R. Treff[2].* 1) Foundation for the Assessment and Enhancement of Embryonic Competence , Basking Ridge, NJ; 2) Reproductive Medicine Associates of New Jersey, Basking Ridge, NJ; 3) Columbia University, NY.

Combining accurate preimplantation comprehensive chromosome screening (CCS) with single gene disorder (SGD) or insertion/deletion (indel) diagnosis from the same biopsy has presented many challenges. Current methods can either fail to detect all origins of aneuploidy, require excessive workup times, involve long PGD turn-around times, or are expensive to perform. The present study develops a method which overcomes each of these limitations using quantitative real-time (q)PCR. Workups involved identifying informative SNPs in the parents using SNP arrays and phasing the markers using qPCR on family members. Blastocyst biopsies underwent targeted multiplex PCR of several loci followed by qPCR for SGD, indel, contamination, and CCS analyses. For insertions, a linkage only approach was used. For deletions, multiple informative markers within the deletion were used along with linked markers outside the deletion. SGD results were compared for consistency and reliability to conventional diagnoses which were obtained from a reference lab. Additional linked informative markers were evaluated to resolve discordant cases. The typical workup involved approximately 4 weeks to complete. 17 SGD cases, including autosomal and X-linked, recessive and dominant, and compound heterozygosity disorders, provided 150 embryos for analysis. 150 (100%) gave a 4-hour diagnosis by SNP qPCR, while 139 (92.7%) gave a result by conventional STR analysis. Concordance in diagnosis was 97%, with 4 discrepancies. Subsequent analysis of additional markers confirmed the SNP qPCR diagnosis in all cases. The use of SNPs rather than STRs generally resulted in having markers nearer the mutation, enhancing the ability to avoid recombination-based misinterpretation or a failure to make a diagnosis in many cases. 14 indel cases were processed including a total of 157 embryos, all of which gave an indel and CCS diagnosis. 7 patients have had embryo transfers from which 5 have delivered, 1 has an ongoing pregnancy, and 1 did not become pregnant. In 2 cases, DNA from the newborns was available for analysis and confirmed the PGD and CCS diagnoses. This new approach to combined CCS and SGD or indel PGD involves a short and inexpensive workup and the ability to reliably and rapidly produce accurate PGD results in parallel with CCS from the same biopsy.

2822S

The frequency, type and classification of chromosome errors differs at the pre-implantation stage from that observed during pregnancy. *M. Schweitz, S. McReynolds, W.B. Schoolcraft, M.G. Katz-Jaffe.* FLC, Lone Tree, CO.

Women at 40 years of age have a 50% reduction in fecundity compared to women a decade younger, primarily due to progressive oocyte depletion and an increase in meiotic errors resulting in aneuploidy. It is well documented that oocyte aneuploidy is a major contributor to spontaneous miscarriage. The aim of this study was to evaluate the frequency, type and classification of chromosome errors in human pre-implantation embryos relative to maternal age. Infertility patients consented, under IRB approval, to an in vitro fertilization cycle with comprehensive chromosome screening (CCS). Embryos were cultured to the blastocyst stage for a trophectoderm (TE) biopsy (n=15,750 blastocysts). Biopsied TE cells were examined for chromosome numeration using quantitative PCR (RMA-NJ). Statistical analysis involved Chi square test with significance at $P<0.05$. Blastocyst CCS results revealed all 22 autosomes and both sex chromosomes were involved in chromosome gains and losses. Aneuploidy was identified in 50.2% (7,905) of these human blastocysts, with close to even numbers of trisomies (51.1%) and monosomies (48.9%) that are not typically observed in pregnancy. Predictably, for younger infertility patients (<38 years) a lower incidence of aneuploidy was observed (35.9%), which was significantly less than for woman of advanced maternal age (AMA; ≥38 = 63.1%; $P<0.0001$). Interestingly, specific chromosome errors were associated with AMA, chromosomes 14, 15, 16, 17, 18, 20, 21 & 22 were more likely (average 2.3 fold) to be aneuploid in human blastocysts from AMA infertility patients ($P<0.05$). In addition, the classification of these chromosome errors was significantly different relative to maternal age. Blastocysts from young infertility patients showed a significant increase in errors involving the large metacentric and submetacentric chromosomes (1-5), which are not typically observed in clinical pregnancy losses (<38=16.5% vs. ≥38=13.5%; $P<0.01$). The frequency, type and classification of chromosome errors in pre-implantation human blastocysts were significantly different in relation to maternal age. In addition, the incidence of aneuploidy in pre-implantation human blastocysts has a different profile to aneuploidy observed in first trimester losses or live births. These results provide valuable information for clinical patient management prior to infertility treatment.

2823S

A Simple and Streamlined Next-Generation Sequencing-based approach to Preimplantation Genetic Screening. *M. Umbarger, J. Gole, A. Gore, G. Porreca.* Good Start Genetics, Cambridge, MA.

Preimplantation genetic screening (PGS) is used to assess the chromosome copy number of embryos. Although increasing evidence indicates that euploid embryo transfer increases and decreases implantation and miscarriage rates, respectively, PGS adoption has been limited at least in part due to the high cost associated with traditional PGS approaches. However, increased use of trophectoderm biopsy followed by vitrification and subsequent frozen embryo transfer, coupled with streamlined workflows employing next-generation DNA sequencing (NGS), are poised to enable broader PGS adoption.

We have developed and implemented an automated PCR-based method that amplifies regions from each chromosome and simultaneously attaches the sequencing adapters and sample-specific barcodes necessary for multiplexed NGS. 12 pg DNA purified from cell lines (~2 diploid cells) or lysate derived from 2-cell isolated cultured lymphocytes served as template for the PCR reactions. The products were sequenced to generate count data for each chromosome, and this data was subsequently used to infer chromosome copy number.

A total of 37 true positive aneuploid chromosome calls were made across the DNA from 21 aneuploid cell lines. The method generated 789 correct diploid chromosome calls, 2 incorrect aneuploid (false positive) chromosome calls, and zero incorrect diploid (false negative) chromosome calls. Both incorrect aneuploid calls were in samples containing other aneuploid chromosomes, thus yielding perfect sample-level specificity and perfect chromosome-level sensitivity. Aneuploidies detected included: trisomy 2, 8, 9, 13, 18, 20, 21, 22, 16+21, 2+21, monosomy X, tetrasomy X, XXY, and disomy Y. The technique also detected trisomy 21 and XXY when lymphocytes were used as a template. Collectively, our results indicate that we have developed a simple and accurate NGS-based PGS approach.

2824S

Preimplantation genetic risk reduction (PGR) - a new concept in the era of microarray CGH and exome sequencing. *G. Altarescu[1], R. Beeri[1], T. Eldar-Geva[2], G. Lazer-Derbeko[1], E. Levy Lahad[1], P. Renbaum[1].* 1) Zohar PGD Lab, Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) In vitro Fertilization Unit, Shaare Zedek Medical Center, Jerusalem, Israel.

While the ESHRE guidelines of best practice standardizes the genetic and IVF workup prior to and during the PGD cycle, new technologies such as Chromosomal Microarray (CMA) and exome or genome sequencing reveal variants of unknown significance (VOUS). These variants raise challenges in the decision making process in respect to the indications calling for preimplantation genetic diagnosis. Results: We present two couples that came to our PGD unit at the Shaare Zedek Medical Center requesting preimplantation genetic diagnosis for VOUS. In the first couple, a healthy male, carrier of the variant V51D in the MLH1 gene requested PGD as risk reduction for lynch syndrome. His family history included his father who died of colon cancer (no DNA sample), paternal grandmother died of gastric cancer (no DNA sample), a paternal uncle with colon polyps carries the familial variant and another paternal uncle who also underwent polypectomy, but is not a carrier of this variant. While the MLH1 V51D has not been reported as pathogenic it is predicted by Polyphen to be probably damaging (score 0.96), by SIFT to be damaging (score 0)and by SNPs@Go to be a polymorphism. Despite the uncertainty of the pathogeneity of this variant as the cause of multiple cancers in this family, the couple, who do not require IVF for infertility, requested PGD to possibly reduce the risk of cancer. The second couple came to our PGD unit with one child diagnosed with PDD. Results from CMA revealed a 570,000 bp microduplication on chr:X p.22.3, and a 637,000 bp microdeletion on chr:17q21.31) in the affected child. The X linked microduplication was maternaly inherited and also present in the couple's healthy daughter, while the microdeletion was "de novo". Both microduplications and microdeletions in these regions have been reported to be associated with intellectual disability and congenital malformations. The couple has requested PGD for both findings. Conclusions: Chromosomal microarrays and exome findings of uncertain significance pose dilemmas for both couples and geneticists in regard to counseling and performing PGD. As CMA and exomes are becoming standard tests, couples are requesting PGD for VOUS to reduce their risk of possible genetic disease. These technologies demand urgent discussion and guidelines for preimplantation risk reduction.

2825S

Fetal intracerebral hemorrhage and cataract: think *COL4A1*. *E. COLIN[1], A. DENOMME-PICHON[1], A. GUICHET[1], M. GORCE[1], S. CHEVALIER[2], M. MINE[3], E. TOURNIER-LASSERVE[3], L. SENTILHES[4], D. BONNEAU[1].* 1) Department of Biochemistry and Genetics, CHU Angers, Angers, France; 2) Department of Ophthalmology, CHU Tours, Tours, France; 3) Reference Center for Rare Vascular Diseases of the Eye and the Brain, Lariboisière Hospital, Paris, France; 4) Department of Obstetrics and Gynecology, CHU Angers, Angers, France.

The *COL4A1* gene (MIM 120130) encodes the alpha1 chain of type IV collagen, a crucial component of nearly all basement membranes. Mutations in *COL4A1* were first associated with cerebral microangiopathy and familial porencephaly and have later been implicated in a clinicopathologic broad-spectrum affecting the brain, eyes, kidneys and muscles. Recently, *COL4A1* mutations have also been identified prenatally in fetuses with intracranial hemorrhage (ICH). We report two additional prenatal cases of *COL4A1* mutations in fetuses with ICH and cataract.

Case 1: Fetal ultrasound examination (US) at 23 weeks' gestation (WG) showed left cataract, left ventriculomegaly and hyperechogenic lesion of basal ganglia. Fetal magnetic resonance imaging (MRI) at 32 WG confirmed the subependymal hemorrhage affecting the left hemisphere.

Case 2: Fetal US examination at 31 WG showed hyperechogenic lesion in left hemisphere with thalamic echogenicity and bilateral cataract. Fetal MRI at 32 WG showed a left-sided periventricular parenchymal hemorrhage and mild ventriculomegaly.

In both these cases, the involvement of *COL4A1* was evoked because congenital cataracts had been previously reported in association with ICH in pediatric cases.

The sequencing of *COL4A1*, performed on fetal DNA after termination of pregnancy, evidenced two heterozygous novel missense mutations c.G2317A (p.G773R) and c.G3005A (p.G1002N) in fetuses 1 and 2 respectively.

The two cases reported here show that the *COL4A1* mutation should be envisaged in fetuses with prenatal ICH especially in the presence of lens abnormalities at US examination. Molecular confirmation of a *COL4A1* mutation may have important implications for the outcome of the pregnancy and for genetic counseling.

The Israeli experience of the first 300 Panorama™ tests that use 19,488 single nucleotide polymorphisms (SNPs) followed by high-throughput sequencing for common trisomies risk assessment. *H.N. Baris Feldman[1], Z. Weiner[2], I. Solt[2], M. Shohat[3], D.M. Behar[1].* 1) The Genetics Institute, Rambam Health Care Campus, Haifa, Israel; 2) OBGYN department, Rambam Health Campus, Haifa, Israel; 3) The Recanati Genetic Institute, Rabin Medical Center, Petach Tikva, Israel.

Background Cell free DNA (cfDNA) has emerged over the last year as an alternative for amniocenthesis for diagnosis of the common aneuploidies looking at trisomy 21, 13, 18, sex chromosomes and triploidy. Methods We present our experience of the first 300 Panorama™ tests sent from Israel. This method is based on massively multiplexed PCR amplification of cfDNA isolated from maternal plasma, targeting 19,488 SNPs, followed by high-throughput sequencing. The fetal fraction is determined. The SNP pattern of maternal DNA (from buffy coat) is compared to the SNP pattern of free DNA from maternal plasma, which contains maternal and fetal DNA. Paternal genomic samples, when available, were included in the analysis; in the absence of a paternal sample, the algorithm considers population allele frequencies. Combining the maximum likelihood ratio with a priori risk generates a risk score. Results The results of the first 300 sequential tests performed in Israel were analyzed. Fifteen samples necessitated redraw, two samples failed analysis. Four samples yielded high risk scores: two cases for trisomy 21, one for Kleifelter syndrome (KS) (47,XXY) and one for trisomy 18. Confirmation of both trisomy 21 and one KS were done by CVS or amniocenthesis. The mother of suspected trisomy 18 was not interested in invasive testing in view of normal ultrasound scans and delivered a healthy baby. Karyotype was not done so mosaic state was not excluded. There are no known false negative results. Discussion Panorama™ test is a reliable tool for identification of pregnancies at high risk for fetuses with the common aneuploidies with a high success rate. We recommend confirmation of the diagnosis for high risk scores pregnancies using invasive tests.

2827S

First trimester trisomy 18 screening using fetal epigenetic marker and nuchal translucency. *D.E. Lee[1], S.Y. Kim[1], S.Y. Park[1], J.W. Kim[1], D.J. Kim[1], D.W. Kwak[2], H.M. Ryu[1,2].* 1) Laboratory of Medical Genetics, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Objective: The association between fetal trisomy 18 and increased nuchal translucency (NT) thickness during the first trimester of pregnancy is well-established. Recently, the placental-derived maspin (U-maspin) gene was applied as a fetal-specific epigenetic marker for noninvasive detection of trisomy 18 in maternal plasma. This study assessed the accuracy of prenatal screening for trisomy 18 by a combination of U-maspin concentration and fetal NT thickness in the first trimester of pregnancy. Methods: A nested case-control study was conducted using maternal plasma samples collected from 65 pregnant women carrying 11 trisomy 18 and 54 normal fetuses. Using real-time quantitative methylation-specific PCR, the concentrations of U-maspin were measured in first trimester maternal plasma. Fetal NT measurement was performed in the first trimester of pregnancy. Results: U-maspin concentrations were significantly elevated in women with trisomy 18 fetuses compared with controls (27.2 vs 6.6 copies/mL; P<0.001). Fetal NT thickness were significantly elevated in women with trisomy 18 fetuses compared with controls (5.9 vs 2.0 mm; P<0.001).The sensitivities of U-maspin concentration and NT thickness for prenatal screening of fetal trisomy 18 were 90.9% and 90.9%, respectively, with a specificity of 98.1%. Combined analysis of U-maspin concentration and NT thickness had the sensitivity of 100% for prenatal screeningof fetal trisomy 18, with a specificity of 98.1%. Conclusions: The combination of U-maspin concentration and NT thickness is highly efficient for prenatal screening of fetal trisomy 18 in the first trimester of pregnancy.

Prenatal array CGH and follow up of fetuses with increased nuchal translucency: results from VUmc. *K.E. Stuurman[1,2], S.L. Bhola[1], M.A.J. Engels[1], E.J. Meijers-Heijboer[1].* 1) Clinical Genetics, VU University Medical Center, Amsterdam, Netherlands; 2) Medical Genetics, University of British Columbia, Vancouver BC, Canada, Women's Hospital & Health Centre Site.

Introduction: Increased nuchal translucency (NT) (≥3.5mm) in pregnancy is associated with chromosomal aneuploidy, genetic syndromes and structural defects. Prenatal array CGH for all fetal anomalies increases the percentage of genetic abnormalities with 2-12% compared to standard karyotyping. We assessed the outcome of prenatal array CGH in a consecutive series of fetuses with increased NT only seen in our clinic. We also followed up this cohort postnatally with respect to clinical outcome. Methods and Materials: Included were all women pregnant between January 2011 and August 2013 with a fetus with increased NT, but without additional abnormalities seen on ultrasound. We offered array CGH (Agilent 180k oligoarray) subsequent to QF-PCR and karyotyping when enough fetal material was present. Results: In total 155 fetuses had increased NT only. 124 had invasive prenatal testing (80%), of which 65 had normal QF-PCR results and karyotype (52%). Of these 65 fetuses, 37 received subsequent prenatal array CGH (60%). Two had an abnormal result (11 Mb duplication on chromosome 10q25.1-q26 and 8 Mb duplication on chromosome 2p25)(5%) and these pregnancies were terminated. In total 48 of 65 fetuses, with and without prenatal array CGH, were followed up in further pregnancy and postnatally (75%). Of these 48 fetuses, five had termination of pregnancy (10%); three because of hydrops foetalis (one was diagnosed with RyR1-related congenital myopathy postnatally), two because of low trust in a good outcome. Two resulted in IUFD (4%) and one had postnatal death (2%). Four syndromes and structural defects were diagnosed postnatally (Noonan syndrome, Beckwith Wiedemann syndrome, RyR1-related congenital myopathy and aniridia)(8%), and three had undiagnosed psychomotor retardation (6%). Conclusion: Prenatal array in fetuses with increased NT only increases abnormal findings with 5%. However, more than 25% of the fetuses had an unfavorable outcome. The abnormalities seen postnatally could not have been picked up with array CGH.

Non Invasive Prenatal Testing and Prevention of chromosomal and Genetic Disorders. *A. Al-Aqeel.* Dapartment of Pediatrics, Prince Sultan Military Medical City, Riyadh, Saudi Arabia.

Background: Noninvasive prenatal testing (NIPT) that will allow genetic testing of a fetus within the first trimester of pregnancy by isolating cell-free fetal DNA (cffDNA) in the mother's plasma raises a range of ethical and legal issues. The goal of this study is to provide an Islamic ethical framework for health care providers and government agencies providing NIPT. Methods: We refer to our previous experience in medical genetics, screening tests and ethics in combination with the Islamic "Shariai'ha" (Figh) principles and authoritative "consensus edicts" "fatwas" of Islamic scholars, literature review and our publications. We developed a set of best practices for the provision of NIPT within an Islamic framework. Results: Applying the Islamic "Shariai'ha" principle "The basic concept in useful matters is permissiveness" which indicates that everything is lawful, as long as it is useful to people, our principal recommendations include promotion of NIPT to high risk pregnant women for the prevention of fetal aneuploidy and in certain cases at high risk of single gene disorders, with the amendment of current informed consent procedures to include attention to the noninvasive nature of this new testing and the potential for a broader range of results earlier in the pregnancy. However, the need for confirmatory testing by amniocentesis must be discussed carefully with the pregnant woman, as abortion in Islam should be done before 120 days of gestation in severe malformations or devastating disorders which are incompatible with life. Conclusions: Pregnant women at increased risk of aneuploidy can be offered cffDNA testing. Its performance in low-risk women and women with multiple gestations is unclear. Such test should be regulated by government agencies. Since limited professional guidance is available clinician performing the test should adopt responsible best practices in the provision of the test within an ethical framework that combines appeal to written precedent with sensitivity to the options of individuals and families dealing with choices and necessities within the laws, norms and traditions of their society.

Susceptibility loci for neurodevelopmental disorders -prenatal genetic counseling and psychological impact. *K.E.M. Diderich[1], L.C.P. Govaerts[1], J. Verhagen-Visser[1], S.L. van der Steen[1], M. Joosten[1], M.F.C.M. Knapen[2,3], F.A.T. De Vries[1], D. Van Opstal[1], M.I. Srebniak[1], S.R. Riedijk[1], R.J.H. Galjaard[1].* 1) Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Dept. of Obstetrics and Prenatal Medicine, Erasmus Medical Centre, Rotterdam, the Netherlands; 3) Foundation of Prenatal Screening South-west Netherlands, the Netherlands.

Objectives: Since 2012 genomic SNP array is used as a first-tier prenatal cytogenetic test for all indications in our laboratory. Next to causative and unexpected diagnoses, array may also detect susceptibility loci (SL) for neurodevelopmental disorders, with a yet unquantifiable risk for the fetus. While some may argue that we should not disclose such uncertain results, potentially leading to unnecessary anxiety, the fact that an abnormal phenotype has been described in association with these SL, may be a reason to disclose SL. We classify SL as pathogenic. With this study we evaluated the effect of reporting and counseling SL and explored the psychological impact of hearing about a SL during pregnancy. Methods: To assess the psychological impact of releasing SL 9 couples with a child that was diagnosed with a SL during pregnancy were approached for an interview. From these, 8 women and 4 men were interviewed by phone 3-18 months after the prenatal diagnosis. During their pregnancy, they all received pre-test counseling. The post-test genetic counseling concentrated on the phenotype of the particular SL, its incidence in the normal and affected population and the difference between postnatal and prenatal ascertainment. Targeted parental array testing was offered. Extensive US examination was offered when the SL was associated with physical abnormalities. Results: Hearing about the SL during pregnancy was initially shocking to 8 and concerning for 4 parents. However, at the time of the interview, eleven parents had no worries anymore about the SL while one mother considered it a stigma. All parents considered their child healthy without concern about the SL. They stressed the importance of pre- and posttest counseling and expressed their wish for a choice regarding SL disclosure during pre-test counseling. Eleven parents indicated they wished to learn about a SL again in a next pregnancy. One mother did not know whether she wanted to learn about a SL again. Conclusions: Although our group is small, it provides a preliminary insight into how couples experienced hearing about a SL as the result of prenatal diagnosis. From these preliminary results it seems that couples are able to cope with the uncertainties associated with this type of chromosome aberration. Further studies have to be carried out in order to investigate the clinical significance of SL when found prenatally and the (dis)advantages of their disclosure in a prenatal setting.

Placenta whispers: Discordant noninvasive prenatal testing (NIPT) results and the role that confined placental mosaicism (CPM) plays. *T. Boomer[1], S. Cherny[2], J. Miles[3], C. Pittore[4], J. Wardrop[1], J. Jesiolowski[5], N. Teed[1], C. Settler[1], N. Dharajiya[1], T. Monroe[5], J.-S. Saldivar[1].* 1) Sequenom Laboratories, San Diego, CA; 2) Central Dupage Hospital Maternal Fetal Medicine, Winfield, IL; 3) Medical University of South Carolina, Charleston, SC; 4) Capitol Health Maternal Fetal Medicine, Pennington, NJ; 5) Sequenom Laboratories, Morrisville, NC.

Background: Noninvasive prenatal testing (NIPT) screening for aneuploidy relies on the presence of circulating cell-free DNA believed to be largely placental in origin. The genetic material in fetal and placental tissue matches in most pregnancies. However, discordance between these tissues can occur due to post zygotic non-disjunction or trisomy rescue, causing uneven distribution of cells between fetus and placenta. A comprehensive study of three confirmed cases of confined placental mosaicism (CPM) identified by positive NIPT are highlighted, detailing invasive diagnostic results, postpartum placental studies, and pregnancy management considerations. Case 1: NIPT performed at 14.6 weeks gestation indicated trisomy 13 in a sample sent for advanced maternal age. Amniocentesis and blood studies at birth were normal. The fetus was small for gestational age in late pregnancy. Postdelivery, chromosome 13 FISH testing revealed three out of four placental sections as mosaic for trisomy 13: 81% (162/200), 34% (67/200), and 76% (152/200). Case 2: NIPT performed at 10 weeks gestation indicated trisomy 13 in a sample sent for advanced maternal age. FISH on chorionic villus sampling (CVS) revealed trisomy 13 in 34/200 cells (17%), though cultured CVS results showed a normal karyotype. Amniocentesis results were normal by FISH (45 cells) and karyotype (37 cells). The pregnancy is ongoing with normal fetal growth. Postnatal studies are pending. Case 3: NIPT performed at 18 weeks gestation indicated trisomy 18 in a case referred for positive biochemical screening (1/11 risk for Down syndrome). Amniocentesis and blood studies at birth were normal. Post-delivery FISH testing on cultured placental tissue revealed 3.2% (8/250 cells) mosaicism for trisomy 18. Conclusions: These cases describe three pregnancies with positive NIPT results, negative amniocentesis results, and confirmed CPM. Postpartum analysis of two placentas and CVS analysis of a third demonstrate a wide spectrum of CPM levels. NIPT provides new and unique insight into the placenta as a whole and may reveal evidence of CPM that would otherwise be unseen or minimized by other test methods. CPM may also be associated with placental dysfunction and present clinically as abnormal biochemical screening, fetal growth restriction, or preterm labor. Cases with discordant 'false positive' NIPT results may warrant more conservative pregnancy management.

Transcriptome expression analysis of amniotic fluid cell free fetal RNA according to gestational weeks in Korean women. *Y. Jung, S. Shim, S. Shim, S. Sung, J. Park, D. Cha.* CHA University, Seoul, Rep of Korea, Seoul, South Korea.

Objective: To characterize the transcriptome expression patterns and biological pathways in amniotic fluid cell free fetal RNA according to gestational weeks in Korean women. Method: The discarded amniotic fluids of Korean women in terms of gestational weeks were prospectively collected from euploid fetuses for this study. Total RNA was extracted from cell free amniotic fluid supernatant and hybridized to Affymetrix GeneChip Human Arrays. Differentially expressed transcripts among 16-18 gestational weeks, 25-26 weeks and 37-38 weeks amniotic fluids were obtained by The Welch's t-test. Hierachial clustering analyses were performed to visualize overall expression characteristics of all samples used for the study. The biological functions of selected genes were analyzed using various online Gene Ontology databases. Results: There were 2902, 6035 and 6289 genes significantly expressed in early second, late second and third trimesters, respectively. Hierachial clustering showed differential transcriptome expression pattern according to gestational weeks. Comparing with the early second trimester, fetus related specific genes were more highly enriched in late second and third trimesters (471 vs 913 and 949, respectively). Gene expression analysis showed enrichment of brain transcripts in the late second trimester as compared with early second and third trimesters. Only 33 genes were differentially expressed in the first trimesters and pathway analysis revealed that those are related to cell proliferation and apoptosis pathway. The transcripts that are related to fetal brain were enriched in late second trimester. Conclusion: This study provides information regarding gene expression changes during normal fetal development in Korean women. Brain specific transcripts are enriched in the late second trimester rather than early second trimester. This data suggests that brain development occurs in late second trimester.

Fragile X prenatal studies suggest mothers with >80 repeats transmit the normal allele in 55% of pregnancies. *S.L. Nolin, A. Glicksman, X. Ding, N. Ersalesi, W.T. Brown, C. Dobkin.* New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

We have performed fragile X prenatal studies for 1,871 pregnancies of women with intermediate, premutation or full mutation alleles from 1991-2013. The studies included 1521 chorionic villus and 338 amniotic fluid samples. The expanded allele was transmitted in 955 (51%) pregnancies with expansion to a full mutation in 308 (32%). Unexpectedly, mothers with large premutation (>80 repeats) or full mutation alleles transmitted the normal allele in 55% (368/671) of pregnancies while mothers with smaller alleles (45-79 repeats) transmitted the normal allele in 46% (548/1200) of pregnancies (p=.00014, Chi square 1df). These surprising results suggest the presence of intermediate and small premutation alleles may provide some early developmental advantage. For larger alleles, some full mutation embryos may be non-viable from loss of the X chromosome carrying the full mutation. This has already been observed in an increased risk for mosaic Turner syndrome in females (Dobkin et al., AJMG, 2009). Early loss of an X in males and females may lead to skewed distributions of the normal versus the fragile X chromosome.

2834S

Differences of transcriptional profiling analyses between cell free mRNA and mRNA originated from amniocytes in amniotic fluid using GeneChip® PrimeView™ Human Gene Expression Array. *D.H. Cha[1,2], S.S. SHIM[1], S.H. SHIM[2], Y.W. Jung[1], S.R. Sung[2].* 1) Dept OB/GYN, Kangnam CHA Hosp, CHA University, Seoul, South Korea; 2) Genetic Research Center, Kangnam CHA Hosp, CHA University, Seoul, South Korea.

Amniotic fluid is the only body fluid in direct contact with the the fetal oropharynx, lungs, gastrointestinal tract, skin, and urinary system and amniotic fluid cell-free fetal RNA(AF cffRNA) can provide biological information on developing fetal organ system. The aim of this study is to compare RNA profile between amniocytes and cell free fetal RNA in amniotic fluid supernatant. The total 10 AF samples were collected each supernatants and cell pellets. The cell free fetal RNA was extracted from 5-10ml of amniotic fluid supernatant. All supernatant samples were performed using the QIAamp® Circulating Nucleic Acid (Qiagen, germany) kit with an on-column DNase digestion step to remove genomic DNA according to the manufacturer's instructions. The RNA was purified with the RNeasy® MinElute® Cleanup kit (Qiagen, germany). The collected amniocytes were cultured in BIO-AMP-2 complete medium (Biological Industries Ltd., Haemek, Israel) at 37°C in a 5% CO2 incubator. The cultured amniocytes were extracted using QIAamp RNeasy ® mini kit. The extracted RNA was hybridized to GeneChip® PrimeView™ Human Gene Expression Array. The data were analyzed with Robust Multi-array Analysis using Affymetrix default analysis settings and global scaling as normalization method. The normalized, and log transformed intensity values were then analyzed using GeneSpring 12.5. We were identified 2902 transcripts in amniotic fluid supernatant and 15,418 transcripts in the cultured cell. We found 403 genes that were differentially expressed in amniotic fluid supernatant compared with cultured cell. Among these genes, we were identified 123 genes that have been known to tissue-specific transcripts through a search of pathway analysis software and Medline. Also, the 63 genes in amniotic fluid supernatant were expressed in brain and the 60 genes were confirmed expressed in various tissues, such as heart, liver, kidney, lung, eye, etc. The gene expression studies for the development of the fetus have been limited by practical problems, such as the collection of the sample. Most studies of the fetus have obtained from tissue specimens after spontaneous abortions, terminations of pregnancy. Our results demonstrate that amniotic fluid cffRNA is reflected in real-time to the development of the fetus. This study might contribute to the further studies for the discovery of biomarkers for abnormal fetal growth.

Methods for Isolation and Enrichment of circulating cell-free fetal DNA (ccff DNA) from maternal plasma, for Non-Invasive Prenatal Tests (NIPT), such as the MaterniT21™ PLUS Laboratory Developed Test. *G. DeSantis, L. Chamberlain, A. Kulkarni, D. Wong, N. Agarwal, E. Kaltgrad, P. Whitley, D. van den Boom, M. Ehrich.* R&D, Sequenom, San Diego, CA.

The use of ccf DNA has enabled the introduction of non-invasive prenatal testing (NIPT) methods such as fetal RHD genotyping and fetal aneuploidy detection from maternal plasma. Methods to process and extract ccf DNA from maternal blood that may enrich fetal fraction are desired to facilitate enhanced performance and decreased costs of NIPT. We aimed to identify key physical or biochemical markers that distinguish the nature and packaging of fetal versus maternal DNA in plasma that could be used to enrich fetal fraction. Several collection and processing conditions along with several methods for DNA extraction, including both manual and automated platforms, were evaluated. The fetal DNA, total DNA and fetal fraction for each method as well as purity for downstream assays and applications (including fetal copy and fetal fraction analysis, library preparation, and next generation sequencing) are compared. Methods explored to enhance fetal fraction include: processing changes, centrifugation protocols, digestion with endonucleases, characterization of micro-particle compartments, and bead based strategies. Fetal fraction assessments are made by various approaches including qPCR, methylation sensitive restriction digestion, mass array analysis and sequencing based fetal fraction determinations. The pre-analytical technologies explored affect the size distribution profile of isolated circulating cell free DNA (ccf DNA) and fetal fraction. Distribution of, and enrichment of, various DNA fragment sizes are discussed as well as mechanisms for enrichment. Micro-particle fractions are correlated to fetal and maternal DNA distribution to provide insights to enrichment approaches explored. Fetal mutations and fetal chromosomal abnormalities can be detected by molecular analysis of circulating cell free fetal DNA (ccff DNA) extracted from maternal plasma and classification may be enhanced by fetal fraction enrichment. The collection and processing methods facilitate efficient extraction of circulating cell-free fetal DNA (ccff DNA) from maternal plasma. The enhanced understanding of fetal fraction enrichment approaches and compartmentalization will lead to enhanced performance and decreased costs for NIPT.

2836S

Prenatal diagnosis of mosaic isochromosome 20q detected in amniocentesis. *S. Ito[1], T. Kuchikata[2], H. Yoshihashi[2].* 1) Division of Nursing, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan; 2) Division of Medical Genetics, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

Mosaicism of abnormal karyotypes in amniocentesis are observed approximately 3-8%, which considered to be either true mosaicism or artifact of cultured amniocytes. When chromosome mosaicism was encountered, the definitive prenatal cytogenetic diagnosis depends on the type of fetal chromosome aberration. However, we often left in a conflict situation and precise information should be offered in prenatal genetic counseling. We describe a case of 34-year-old woman, anxious about the abnormal result of maternal serum screening and underwent the amniocentesis in 17 weeks of gestation. The result of chromosomal analysis was 46,XX,i(20)(q10)[4]/46,XX[11](rate of mosaicism:19%), in which derived from three independent cultures. Whether to continue the pregnancy or not, she was referred for genetic counseling in 19 weeks of gestation. She was informed that the most of fetuses prenatally diagnosed mosaic isochromosome 20q represented normal phenotypic features if not apparent abnormal echo findings, but partly show several malformations and development delay after birth in the previous reports. Decision must be made before 22 weeks of gestation in Japan, and it was impossible to perform further subsequent genetic analysis. After the session, she attended the fetal ultrasonographic examination in 20 weeks of gestation and no major malformation was noted, and decided to carry it to term. At 40 weeks of gestation, female infant was delivered with no distinctive abnormalities. Postnatal chromosome analysis of the lymphocytes cell in infancy showed non-mosaic normal karyotype different from the result revealed in amniocentesis. Although concerns about somatic mosaicism still remained, she showed normal growth and development in good health at 8 months. Discussion: These clinical findings contribute to a better understanding of prenatally diagnosed mosaic isochromosome 20q. The long arm of chromosome 20 is known as gene-rich region, therefore we assume that genetic imbalance due to isochromosome 20q are likely to have no small effect on fetal phenotype and survivability. In this case, the results of ultrasonographic examination were effective and essential for prenatal decision-making. Considerable discrepancy between genotype and phenotype may lead to serial dilemmas during the period of pregnancy and even after birth. In addition to medical information, psychological support in genetic counseling is also necessary.

Phocomelia in Thrombocytopenia-absent radius (TAR) Syndrome due to compound heterozygosity for a 1q21.1 microdeletion and a RBM8A hypomorphic allele. Report of two cases. *R. Jobling[1], S. Unger[2], P. Shannon[3], A. Toi[4], S. Keating[3], D. Chitayat[1,5].* 1) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Molecular Pediatrics, Maternité, Clinique Infantile, Lausanne, Switzerland; 3) Mount Sinai Hospital, 3Department of Laboratory Medicine and Pathobiology; 4) Department of Diagnostic Imaging University of Toronto, Toronto, Ontario, Canada; 5) The Prenatal Diagnosis and Medical Genetics Program; University of Toronto, Toronto, Ontario, Canada.

Thrombocytopenia-absent radius (TAR) syndrome is a rare autosomal recessive disorder characterized by megakaryocytic thrombocytopenia and longitudinal limb deficiencies mostly affecting the radial ray. Most patients are compound heterozygotes for a 200 kb interstitial microdeletion in 1q21.1 and a hypomorphic allele in RBM8A, mapping in the deleted segment. We report two cases with TAR syndrome detected prenatally with phocomelia and involvement of the lower limbs. Case 1: The couple had two pregnancies affected with phocomelia and Roberts Syndrome (RS) was first suspected. In their second offspring the fetus had all four limbs affected with upper limb phocomelia, short femurs and contractures with pterygia of the lower limbs' joints. Case 2: During the couple's fourth pregnancy, routine anatomy ultrasound revealed upper limb phocomelia. The couple elected to terminate the pregnancy. Fetal autopsy revealed upper limb phocomelia, single palmer creases, adducted thumbs, bilateral 5th digit clinodactyly and partial syndactyly of finger 2-5 and lower limbs' contractures with pterygia. Both fetuses had a deletion at 1q21.1 encompassing the RBM8A gene inherited from one parent and a point mutation in the RBM8A gene inherited from the other. Fetal ultrasound finding of phocomelia leads to a wide differential diagnosis including maternal thalidomide exposure, RS, Raas-Rothschild Syndrome, Fuhrmann Syndrome among others. , VACTERL association and. An important addition to this differential diagnosis is TAR syndrome.

Unexpected findings using SNP-array for prenatal diagnosis: benefit or burden? *M. Joosten, M.I. Srebniak, K.E.M. Diderich, L.C.P. Govaerts, S.R. Riedijk, F.A.T. De Vries, R.J.H. Galjaard, D. Van Opstal.* Clinical Genetics, Erasmus MC, Rotterdam, Netherlands.

Background: The array technique is able to detect at least 5% more cytogenetic aberrations than conventional karyotyping in cases of fetal ultrasound abnormalities. Its added value for other indications has also been shown. However, with the increase of resolution the number of pathogenic findings not related to the indication will extend as well. The chance of finding these so-called unexpected diagnoses (UD), which potentially may involve late-onset untreatable disorders, is one of the reasons that the use of this technique in prenatal diagnosis is still controversial. **Methods:** Since 2009 we have performed ~ 2500 prenatal SNP-arrays, initially in pregnancies with ultrasound anomalies, and since 2012 as a first-tier test for all prenatal cytogenetic indications. We retrospectively investigated the prevalence, nature, counseling and pregnancy outcome of UD amongst these cases. **Results:** In approximately 1 in every 200 prenatal SNP-arrays a submicroscopic UD was encountered (n=12). This figure does not include susceptibility loci for mainly neurodevelopmental disorders which can be considered to be UD as well, but which we regard as a separate category of pathogenic findings (Srebniak et al., 2013). The risk of a UD is independent of indication. In most cases (9/12) the UD involved an early-onset disease. In the cases of a severe untreatable disorder (e.g. Angelman syndrome) the UD helped the couples in making a decision about the course of their pregnancy. Prenatal awareness of an early-onset treatable disease (e.g. Leri-Weill dyschondrosteosis) may be considered beneficial for the newborn regarding therapy and follow up. The only late-onset untreatable disorder that we found in 3/12 cases in our cohort, was hereditary neuropathy with liability to pressure palsy (HNPP [MIM162500]), which is generally regarded as a milder disease. None of the dreaded CNVs, such as BRCA1-deletions, were found. **Conclusion:** Due to the added value of detecting extra clinically relevant submicroscopic chromosome aberrations without unmasking any severe late-onset untreatable disease in our cohort of ~2500 prenatal cases, we argue that SNP-array should be the first-tier test for prenatal cytogenetic studies in all indications.

2839S

NIPT in a Clinical Setting: Patient Decisions and Pregnancy Outcomes. *C. Kenyon[1], J. Youngblom[1], B. Blumberg[2], E. Obolenksy[2].* 1) California State University, Stanislaus, Turlock, CA; 2) Kaiser Permanente, Oakland Genetics Department, Oakland, CA.

Noninvasive prenatal testing (NIPT) has recently become clinically available for screening of fetal trisomies, creating an alternative to California State Prenatal Screening (CaPNS) as well as diagnostic tests. The study sought to investigate how NIPT functions in a clinical HMO setting by focusing on the population of women who were eligible for NIPT based on a positive CaPNS result in the Kaiser Permanente Northern California system. Study objectives included identifying the detection rate of screened trisomies, looking at the choice of NIPT based on different factors, describing the range genetic abnormalities not identified by NIPT, and evaluating the use of NIPT as a second-tier test. The Integrated Prenatal Screening database as well as Kaiser Permanente electronic medical records for patients and resulting offspring were retrospectively reviewed for 811 pregnancies eligible for NIPT between October 2012 and June 2013. After receiving a positive CaPNS result, 57.3% of patients chose NIPT as a follow-up test. There were no false-positives or false-negatives and a redraw was requested in 3.87% of all NIPT blood draws. Women who received a trisomy 21 positive CaPNS result were significantly more likely to chose NIPT if they received their CaPNS positive in the first trimester as opposed to the second. CaPNS risk score did not play a significant role in choice of NIPT. A trend that women of Hispanic ancestry were slightly less likely to choose NIPT was observed. Pregnancies with at least one ultrasound abnormality were more often associated with diagnostic testing rather than NIPT, while pregnancies with only one or more soft markers were more likely to choose NIPT. Women age 40 and over were more likely to choose NIPT than women less than 40. As expected, there were some genetic conditions detected in this population that NIPT is not able to screen for. Use of NIPT as a second-tier test was associated with a significantly longer test course than going straight from NIPT to diagnostic testing. These results demonstrate that NIPT has become an important part of prenatal screening and is a popular follow-up choice after a positive CaPNS. However, NIPT is not able to screen for the entire range of genetic conditions that can be screened for by CaPNS or tested for by diagnostic methods. This is important because NIPT has the potential to replace analyte-based prenatal screening as the primary population-based prenatal screening test.

Prenatal array comparative genomic hybridization (aCGH) in fetuses with structural cardiac anomalies in a medium-sized Canadian Prenatal Genetics Clinic. *J. Lazier[1], D. Fruitman[2,3], J. Lauzon[1,4], F. Bernier[1,2,4], J. Chernos[1,5], R. Simrose[6], M.A. Thomas[1,2,4].* 1) Department of Medical Genetics, University of Calgary, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Department of Pediatrics, University of Calgary, Alberta Children's Hospital, Calgary, Alberta, Canada; 3) Section of Cardiology, Alberta Children's Hospital, Calgary, Alberta, Canada; 4) Alberta Children's Hospital Research Institute for Child and Maternal Health; 5) Cytogenetic Laboratory, Alberta Children's Hospital, Calgary, Alberta, Canada; 6) Department of Obstetrics and Gynecology, University of Calgary, Calgary, Alberta, Canada.

OBJECTIVES: To determine the yield of aCGH over karyotype in cases of prenatal structural cardiac anomalies in a medium-sized Prenatal Genetics Clinic.

METHODS: 21 cases referred to the Calgary Prenatal Genetics clinic with a structural fetal cardiac anomaly, either isolated or with additional fetal anomalies, were prospectively recruited between December 2011 and March 2013. Cases with a normal karyotype and FISH for deletion 22q11.2 had an array CGH performed at Signature Genomics using the Prenatal Chip OS.

RESULTS: Of the 19 cases who met inclusion criteria, 12 presented with isolated fetal cardiac anomalies and 7 with additional fetal anomalies. The cardiac and extra-cardiac anomalies were varied. Array CGH was successfully completed on 16 cases. One case had a large 8p deletion that was also seen on karyotype and included the GATA4 gene, which has been associated with congenital heart disease. Three cases provided more information than the karyotype, however, were not clearly the etiology for the cardiac anomaly. Two cases had an inherited CNV, including one with a duplication of 16p11.2 and another with a deletion of 15q11.2. One case had the incidental finding of being a carrier of cystinosis, a recessive disease not associated with cardiac anomalies.

CONCLUSIONS: Recent studies into prenatal aCGH have grouped fetal anomalies together but there is a reported need to better define the diagnostic yield of array CGH in individual fetal anomalies, such as cardiac anomalies, with studies that assess the full cohort of cases with that anomaly (deWit, *et al*., 2014). This study prospectively recruited all cases with a fetal cardiac anomaly who had an aCGH performed. We demonstrated a lower than expected diagnostic yield for pathogenic findings, after the exclusion of deletion 22q11.2 deletion. There was a higher than expected detection (12.5%) of variants of unknown significance that could be defined as potentially clinically relevant CNVs. These CNVs are associated with variable penetrance or expressivity for neurocognitive issues and are challenging to counsel in the prenatal genetics clinic.

Non-invasive Prenatal Diagnosis of Duchenne Muscular Dystrophy: Comprehensive Genetic Diagnosis from Patient to Fetus. *B. Lim[1], J. Chae[1], Y. Lee[2], J. Namkung[2], J. Park[2], S. Yoo[3], S. Lee[3], J. Shin[3], J. Kim[3], J. Seo[3].* 1) Department of pediatrics, Seoul Natinoal University Hospital, Seoul, Seoul, South Korea; 2) Bioinformatics Technology Lab, Healthcare Group, Future Technology R&D Division, SK Telecom, Sungnam, Korea; 3) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, Korea.

Background Non-invasive prenatal diagnosis of monogenic disorders using maternal plasma and targeted massively parallel sequencing has been actively investigated. We previously demonstrated comprehensive genetic diagnosis of Duchenne muscular dystrophy patient could be feasible in a single targeted sequencing platform. In the present study, we aimed to demonstrate extended applicability of this approach to carrier detection and non-invasive prenatal diagnosis. Methods Custom solution-based target enrichment was designed to cover whole DMD region. First, targeted massively parallel sequencing was performed using genomic DNAs of four mother and proband pairs to test whether carrier status could be reliably detected. Then, maternal plasma DNAs were collected in two pregnant carrier mothers who also participated in the preceding carrier testing and were sequenced using the same-targeted platform to predict the inheritance of DMD mutation to fetus. Overrepresentation of an inherited allele was determined by comparing average read fraction of two phased haplotypes after examining and correcting recombination event. Results Carrier status of deletion/duplication mutation was reliably detected through coverage plotting and breakpoint analysis. De novo nonsense mutation was also correctly identified in one family. The presence of inherited DMD mutation status was correctly predicted in two families, as early as 6 weeks of gestation. In one of two families, detecting recombination event and reconstructing phased haplotype resulted in correct diagnosis. Conclusions We successfully demonstrated that comprehensive genetic diagnosis of Duchenne muscular dystrophy from patient to fetus would be feasible in a single targeted massively parallel sequencing platform with tiling design. .

Safeguarding non-invasive prenatal testing with spiked sample tracking barcodes. *K. Neveling, D.T. Thung, L. Beulen, W. Buijsman, I. Gomez, S. van den Heuvel, H. Mieloo, E. Kater-Baats, J. Hehir-Kwa, B.H.W. Faas.* Human Genetics, Radboud university medical center, Nijmegen, Gelderland, Netherlands.

Non-invasive prenatal testing (NIPT) using next generation sequencing (NGS) allows to detect fetal chromosomal aberrations in cell-free fetal DNA present in the mothers' blood. NGS however remains a relatively new technique with not all laboratory processes being automated, hence incidental sample swaps cannot be excluded. For other NGS applications such as exome sequencing, tests are developed that compare exome data and independently derived SNP data, thereby identifying potential sample swaps. However such an approach is not feasible for NIPT due to low sequencing depth. Thus, a reliable sample tracking method for NIPT is currently lacking. We have developed a sample tracking method for NIPT that overcomes the low coverage generally used. Based on a manuscript by Quail et al (2014), we generated PCR products of the bacteriophage PhiX174, including unique 11-mer barcodes. These barcoded amplicons were spiked into DNA isolated from human plasma, followed by library preparation and sequencing. As proof of principle, three different spike-in concentrations (0.1%, 0.5%, and 1%) were tested for three different barcodes. Following sequencing, reads that mapped against PhiX174 (BWA 0.5.9, allowing one mismatch per read) were extracted and inspected for the presence of any of 384 described barcodes. The correct spiked barcode could be unambiguously identified in all samples. A concentration of 1% spiked DNA thereby reflected the best signal to noise ratio (124:1). On average, 24×10^3 PhiX174 reads were assigned to the correct barcode and less than 0.2×10^3 PhiX174 reads were misassigned, thereby leaving enough reads for NIPT (mean 22.0 x 10^6 hg19 mappable reads). In a second experiment, PhiX174 amplicons were directly spiked into human plasma. Again all spiked amplicons could be correctly identified within each sample, for all three different concentrations tested, with an even lower mean signal to noise ratio (3612:1) for the 1% concentration. Consequently, barcoded PhiX174 amplicons can be used for sample tracking in NIPT. The PhiX174 sequences do not map to the human genome, do not interfere with the NIPT data and can be spiked directly into human plasma, without being lost during DNA isolation and library preparation. If these barcodes also remain stable when spiked directly into human blood, the addition of a barcode directly to each NIPT blood sample can be introduced into the diagnostic workflow to facilitate sample tracking and detect sample swaps.

Maternal copy number variants contribute to the burden of false positive prenatal aneuploidy test results. *M.W. Snyder[1], L.E. Simmons[1,2], J.O. Kitzman[1], J. Henson[2], R. Daza[1], J. Shendure[1], H. Gammill[2,3].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Obstetrics & Gynecology, University of Washington, Seattle, WA; 3) Division of Clinical Research, Fred Hutchinson Cancer Research Center, Seattle, WA.

Prospective studies of noninvasive prenatal testing (NIPT) for aneuploidy by analysis of circulating cell-free DNA have demonstrated high sensitivity and specificity in both high- and low-risk cohorts. However, the overall low incidence of aneuploidy continues to limit the positive predictive value of these tests for general screening use. To date, the full spectrum of causes of false positive tests is not well understood. From a series of four pregnancies with discordant prenatal tests, we investigated one potential cause: maternal copy number gains. Here, we demonstrate the potential for maternally carried duplications on chromosome 18 to cause false positive results in prenatal testing of cell-free DNA. Using published metrics from one NIPT methodology, we estimated the minimum size of the maternal duplication required to give rise to false positive test results in NIPT frameworks based on counting statistics. The calculated minimum size depends on several factors, including the total number of reads per sample, the coefficient of variation for the chromosome in question, the fetal fraction, and the fetal inheritance of the maternal duplication. Assuming a fetal fraction of 15%; and no inheritance of the maternal CNV, duplications of 1.13 Mb, 452 kb, and 386 kb are sufficient for chromosomes 13, 18, and 21, respectively. We next estimated the probability that a randomly selected woman of European ancestry would carry a non-pathogenic large duplication on chromosomes 13, 18, or 21, and thus be at potentially elevated risk for a false positive result if electing NIPT. We analyzed a set of copy number calls for 19,584 individuals of European descent and selected all CNVs yielding increased copy number in uniquely identifiable genomic regions and of sufficient lengths, as determined by the minimum size analysis described above. Again assuming a 15%; fetal fraction and no fetal inheritance of the duplication, we identified three such events on chromosome 13, 19 on chromosome 18, and 12 on chromosome 21, representing 0.17% of analyzed controls. If published estimates of NIPT false positive rates are representative, our analysis suggests that up to 50% of T18 and 20% of T21 false positive predictions could be due to maternal CNVs.

2844S

Whole-genome prenatal sequencing and integrative genomics: Detection of structural variation from invasive and non-invasive approaches. *M. Talkowski[1,2,5], V. Pillalamarri[1], H. Brand[1], Z. Ordulu[3,4], S. Pereira[3], T. Kammin[3], J. Kitzman[6], J. Shendue[6], J. Gusella[1,2,5], C. Morton[3,4,5].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Departments of Neurology and Genetics, Harvard Medical School, Boston, MA; 3) Departments of Obstetrics, Gynecology, and Reproductive Biology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 4) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 5) Broad Institute of Harvard and MIT, Cambridge, MA; 6) Department of Genome Sciences, University of Washington.

Technical innovation has had a dramatic impact in prenatal genetic diagnostics, particularly for congenital anomalies where de novo structural variations (SV) represent a major source of risk but are not considered by non-invasive cell free fetal DNA (cffDNA) studies that are limited to detection of aneuploidy. We recently performed the first example of prenatal clinical diagnosis from whole-genome sequencing (WGS) using large-insert 'jumping libraries' at a cost and timeline comparable to karyotyping. Here, we present real-time prenatal sequencing and integrative genomic interpretation of fetal DNA from an ongoing collection of cases referred for advanced maternal age and harboring de novo balanced SVs as part of the Developmental Genome Anatomy Project. In two subjects, DGAP247 and DGAP248, protein-coding genes were disrupted (KHDRBS3 and RCF3, respectively). Convergent genomic interpretation from public databases and clinical microarray data from over 34,000 cases suggested each variant was of unknown significance, with no associated syndromic phenotype. The parents of DGAP247 chose to receive these findings and carried DGAP247 to term, resulting in a well newborn examination. The parents of DGAP248 chose not to receive the findings. In DGAP258, we identified a pericentric inversion that rearranged the known copy number morbid 6p25.3 locus, as well as a cryptic inversion; neither disrupted genic sequence and the twins received a well newborn examination at birth. We also evaluated the capability of deep WGS to detect a balanced SV from cffDNA by generating 53X coverage of DNA isolated from maternal plasma of DGAP247 during the third trimester, with a measured fetal DNA composition of ~25% of reads. We used a split read algorithm to detect the inversion from 14% of reads, demonstrating feasibility of SV detection from cffDNA. These data highlight the power of prenatal WGS by jumping libraries to detect pathogenic SVs of all classes, however they are reliant on invasive methods that carry substantial risk to the fetus. They also illustrate for the first time the feasibility of balanced SV detection without concomitant dosage imbalance by non-invasive methods, though costs and analytical effort were exorbitant. Collectively, our studies emphasize the unique challenges facing development of a comprehensive prenatal genetic screening strategy that accesses the entire pathogenic mutational spectrum but minimizes risks to the fetus.

Demonstration of Equivalent Performance for a Noninvasive Prenatal Test (NIPT) using High Output and Rapid Throughput Modes of a Sequencing Instrument. *R.C. Tim, L. Liu, Z. Zhu, P. Liu, B. Sagoe, P. Oeth, M. Ehrich.* Sequenom Laboratories, 3595 John Hopkins Court, San Diego, CA.

The Illumina HiSeq™ 2500 (Illumina®, San Diego, California) is capable of sequencing in two run modes - one for collecting large amounts of data and the other for acquiring data rapidly. This study demonstrates equivalent sequencing performance of a noninvasive prenatal test, the MaterniT21™ PLUS laboratory-developed test, using both the high output and rapid run modes of the instrument. The two run modes of the instrument were compared with the same set of sequencing libraries in a paired fashion. Five library plates, comprised of 385 euploids, 44 trisomy 21 samples, 8 trisomy 18 samples, and 3 trisomy 13 samples, were analyzed on the same HiSeq 2500 using the high output and rapid run modes with 12-plex multiplexing. In a second experiment focusing on the clustering method using rapid run mode, 48 paired libraries were sequenced with on-board cluster generation in 24-plex or following template hybridization on the Illumina cBot in 12-plex. All sequencing libraries were generated from circulating cell-free (ccf) DNA following extraction from 4 mL plasma aliquots. All flow cells were clustered on the Illumina cBot or using on-board cluster generation, and then sequenced on the HiSeq 2500. Sequencing reads were de-multiplexed, aligned to the human genome (hg19) with Bowtie 2, and chromosomal representations were calculated. Although the HiSeq 2500 rapid run mode generates fewer passed filter reads due to a reduced imaging area per flow cell lane, sequencing performance between high output and rapid run mode is remarkably similar. Representations for chromosomes 21, 18, 13, X and Y are highly correlated between the two modes. No statistically significant differences in z-scores were found for the three aneuploidy types and the discriminatory distance between euploids and aneuploids is similar in either run mode. Trisomy 21 sensitivity/specificity was > 99.9% / > 99.9% for the high output mode and > 99.9% / 99.7% for the rapid run mode. The sequencing metrics for onboard cluster generation and for cBot template hybridization using the rapid run mode were also found to be comparable. Therefore, classification performance of the MaterniT21™ PLUS test was shown to be equivalent using both the high output and rapid run modes of the HiSeq 2500. Comparable results were also found in the rapid run mode using either on-board cluster generation or cBot template hybridization.

False negative NIPT results for trisomy 13, 18 and 21: risk figures derived from cytogenetic investigations in chorionic villi. *D. Van Opstal, M. Srebniak, C. van den Berg, J. Polak, F. de Vries, R-J.H. Galjaard.* Clinical Genetics, ErasmusMC, Rotterdam, Netherlands.

Background: Non-invasive prenatal testing (NIPT) for fetal trisomy detection already revealed that there is a small chance of a false positive and false negative result. This is partly due to the fact that the fetal DNA present in the cell free maternal plasma fraction is derived from the cytotrophoblast of chorionic villi (CV), which is not always representative for the fetus. This we already learned in the eighties from cytogenetic investigations in short-term-cultured CV (STC-villi) in which cells derived from the cytotrophoblast are studied. For this reason, accurate cytogenetic studies in CV should be done by using both STC-villi as well as long-term cultured CV (LTC-villi), the latter investigating cells derived from the mesenchymal core of CV which has the same embryonic origin as the fetus itself. We calculated the risk for a false negative trisomy 13, 18 and 21 NIPT result of a biological nature based on our experience with CV. **Methods** : All cases of fetal trisomy 13, 18 and 21 among ~6000 CV samples that were cytogenetically investigated (STC- and LTC-villi) in our centre between January 2000 and December 2011, were retrospectively studied for the presence of a normal karyotype or mosaicism < 50% in STC-villi. The main indications for CV sampling in these trisomic cases were fetal ultrasound abnormalities, increased nuchal translucency, advanced maternal age > 36 years, and/or abnormal first trimester screening (>1:200). **Results**: 404 (6,7%) cases of trisomies 13, 18 and 21 were found amongst ~6000 samples. Of these 404 cases, 15 (3,7%) had a normal (N=9) or <50% mosaic (N=6) karyotype in STC-villi and therefore would potentially be missed if NIPT was performed in these cases. It involved 6 cases of trisomy 21 and 9 cases of trisomy 18. **Conclusion:** Apart from technical reasons (large BMI, low fetal fraction etc) that may explain false negative NIPT results, in 2 á 3/1000 NIPT samples of patients at high risk, a trisomy 18 or 21 will be missed due to the biological phenomenon of absence of the chromosome aberration in the cytotrophoblast. It is important that patients opting for NIPT are informed about these figures so that an informed choice between invasive an non-invasive testing can be made.

Prenatal detection of fetal aneuploidy on the Ion Torrent Proton platform. *T. Zwiefelhofer, P. Whitley, K. Roy, M. Saha, T. Burcham, D. van den Boom, M. Ehrich.* Sequenom Laboratories, San Diego, CA.

Noninvasive prenatal testing (NIPT) for fetal aneuploidy detection via massively parallel sequencing has been successfully implemented in a number of high throughput clinical laboratories. Automation and parallelization of the complex workflow has reduced turnaround time and labor while maintaining high sensitivity and specificity. As these developments have improved workflow issues, the availability of new sequencing platforms on the market has introduced additional flexibility in implementation. Platform flexibility should encourage competitive pricing, foster innovation and ultimately, improve patient satisfaction. Here, we examine the performance of an NIPT fetal aneuploidy test on the Ion Torrent Proton platform. We examined the performance of the MaterniT21™ assay using the Ion Torrent™ Proton Sequencer (Life Technologies™, San Diego California). One hundred and fifty-four patient samples, including sixteen from women carrying a known trisomy 21 fetus, as determined by fetal karyotyping, were analyzed. Libraries were prepared and sequenced according to manufacturer's recommendations. Sequenced reads were aligned, filtered for quality and normalized for GC bias. Robust statistics were then applied to identify positive samples with a z-score greater than 3. All patient samples were correctly identified according to their karyotype results. The total number of aligned reads and uniformity of genome coverage was sufficient to generate the necessary discriminatory power to indicate aneuploidy status. Fetal aneuploidy status was correctly determined for 154/154 pregnant females, including 16 carrying a T21 fetus. Though the current Proton workflow requires more labor than is optimal for a production environment, significant improvements in that respect are anticipated in the launch of the Ion Chef template preparation system. Sequencing time was brief at < 3 hours and data analysis consistent with standard platforms. In summary, the performance of the MaterniT21™ assay on the Ion Torrent Proton platform in this limited study suggests the possibility of its suitability for implementation in a clinical environment.

2848S

Utilization of a SNP array in prenatal diagnosis of Ellis van Creveld syndrome in a consanguineous couple; a case report. *B. Suskin[1,2], K. Erskine[1,2], J. Gebb[1,2], S. Klugman[1,2], P. Dar[1,2].* 1) Obstetrics & Gynecology and Women's Health, Albert Einstein College of Medicine; 2) Montefiore Medical Center, Bronx NY.

Background: Osteochondrodysplasias and dysostoses include more than 350 disorders. As a group, their pattern of inheritance can be dominant, recessive, X-linked, or secondary to imprinting, somatic mosaicism or teratogens. Individually, they are relatively rare leading to challenges in definitive prenatal diagnosis. Case: 25 year old G2P1 who had a 3 week femur length lag on an 18 weeks dating scan presented for detailed anatomical survey at 20 weeks. History was remarkable for gestational diabetes in her prior pregnancy and consanguinity; the patient and her husband are first cousins. The scan revealed rhizo-mesomelia, polydactyly, syndactyly, mildly shortened ribs, hypoplastic left ventricle, aortic coarctation and ventricular septal defect. Chest circumference was above the 10th percentile. After extensive genetic counseling, the couple opted to undergo amniocentesis with microarray analysis with the understanding the test may not have a diagnostic yield. The array revealed multiple regions of loss of heterozygosity which is to be expected when an individual's parents share a common ancestor. A query on these regions was performed to identify possible candidate genes for the phenotype observed and identified EVC and EVC2. Mutations in these genes are associated with Ellis van Creveld (EVC) syndrome, also known as chondroectodermal dysplasia, the most likely condition based on the sonographic features. Following the SNP array results a direct mutation analysis on EVC and EVC2 was sent. Discussion: EVC is a rare disorder with an incidence of 1 in 60,000. Although it has been diagnosed prenatally in cases with a known family history, this case appears to be among the earliest presumed diagnoses in a family without prior history of EVC. The utilization of SNP array as indirect first step assisted in this case to narrow down the differential diagnosis and direct us towards the most adequate mutation analysis test. The large number of skeletal dysplasias and overlapping sonographic features, makes direct mutation analysis in new and rare cases impractical. The utilization of SNP array, especially in cases with consanguinity, can be incredibly helpful first step to guide us in choosing the correct direct mutation analysis studies. This will allow us to provide the patients with accurate diagnosis and improve our counseling on expected outcomes.

Uniparental origin GWAS of human gestational age implicates genes involved in angiogenesis. *J. Bacelis[1], V. Sengpiel[2], R. Myhre[3], G. Zhang[4], L. Muglia[5], S. Nilsson[6], B. Jacobsson[2,3].* 1) Institute of Clinical Sciences, Sahlgrenska Academy, University of Gothenburg, SE-40530, Gothenburg, Sweden; 2) Department of Obstetrics and Gynaecology, Sahlgrenska Academy, Sahlgrenska University Hospital/Östra, SE-41685, Gothenburg, Sweden; 3) Department of Genes and Environment, Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway; 4) Human Genetics Division, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 5) Center for Prevention of Preterm Birth, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, United States of America; 6) Mathematical Sciences, Chalmers University of Technology, SE-41296, Gothenburg, Sweden.

Background: More than 10% of the pregnancies World-wide end up in preterm delivery (PTD) - the major cause of neonatal death and morbidity. More than 30% of the variation in gestational age can be attributed to genetic factors. Our knowledge of such factors is very limited. **Hypothesis**: Genetic polymorphisms (SNPs) affecting gestational age are located in genomic regions that experience a uniparental silencing (imprinting) and thus are more likely to be detected by genome-wide association study (GWAS) in separated haplotypes of the fetal genome. **Methods**: We used data from 991 mother-child pairs from the Norwegian Mother and Child cohort. Genotypes were phased using family structure data and reference haplotypes from 1000 Genomes Project. SNPs at maternally and paternally derived haplotypes were tested for association with gestational age (in days), while adjusting for child's sex, maternal age and parity. **Results**: None of the 525577 tested SNPs showed a genome-wide significance ($p=2\times10\text{-}6$). The top SNPs from paternal-haploid analysis were located in the introns of angiogenesis-related genes *ZBTB16*, *ANG*, *COL6A1.* Angiogenesis is an essential process during placental vascularisation and can influence nutrient supply to the fetus, thus affecting gestational age. *ANG* gene encodes angiogenin which is induced both by hypoxia and inflammation, and has been shown to be a marker for PTD. *ZBTB16* is known to regulate expression of collagen, metalloproteinases, secretion of interleukins and interferon gamma, all of which are known to be involved in PTD. Moreover, *ZBTB16* showed signs of imprinting in other studies. The top SNPs from maternal-haploid analysis were located in the intron of the gene *ABCC8*, which is involved in insulin (also imprinting-related) secretion. **Conclusion**: Our findings are consistent with the intergenomic-conflict hypothesis, which predicts that imprinting is a way for paternal and maternal genomes to negotiate the distribution of resources between the mother and the fetus. The fact that a hypothesis-free parent-of-origin genotype analysis can detect fetal growth-related and imprinting-related genes while investigating a fetal growth-related phenotype - increases a plausibility of functional involvement of reported genes in PTD. Both top genes (*ZBTB16* and *ABCC8*) are located on chromosome 11, the most imprinted human chromosome. **Replication**: Currently we are carrying out the replication analyses in the Finnish and Danish (DNBC) cohorts.

Long non-coding RNAs associated with ubiquitin pathway involved in preterm premature rupture of membrane. *N. Zhong.* Human Genetics, New York State Institute for Basic Research in DD, Staten Island, NY.

Preterm birth (PTB) is the leading cause of neonatal death. Eighty percent of cases of PTB are spontaneous (sPTB). About 33% of sPTBs result from preterm premature rupture of membrane (PPROM). Although genetic predisposition, maternal exposure to physiopathological condition(s), or gene-environmental interaction(s) have been identified as etiological contributor(s) to PPROM, the genetic mechanism underlying PPROM is yet unclear. Our earlier studies determined that transcriptional/posttranscriptional regulator long non-coding RNA (lncRNA) is associated with PPROM. In this study, we identified that lncRNAs associated with the ubiquitin pathway are up- or down-regulated in PPROM. A total of 125 hits with 38 lncRNAs were identified to associate with the ubiquitin pathway from 40 placentas of groups A, sPTB; B, full-term birth (FTB); C, PPROM; and D, premature rupture of membrane (PROM). Five ubiquitin proteins, including USP10 (ubiquitin carboxyl-terminal hydrolase 10), UBE2B (ubiquitin- conjugating enzyme E2B), UBE2H (ubiquitin-conjugating enzyme E2H), UBE2Q1 (ubiquitin-conjugating enzyme E2Q1), and UBXN6 (UBX domain-containing protein 6) were found up-regulated; and UCHL5 (ubiquitin carboxyl-terminal hydrolase isoform L5) was down-regulated when the non-membrane rupture (AB) group was compared to the rupture of membranes (CD) group. Differentially expressed lncRNAs involved in the ubiquitin pathway could be up- (labeled as red or pink) or down- regulated. Our findings suggested that ubiquitin pathway might present a pathogenic mechanism underlying the membrane rupture in the PPROM, which deserves for further intensive investigations.

Association of candidate gene single nucleotide polymorphisms with the clinical subtypes of preterm birth (PTB). *L.G. Gimenez[1,2], A.M. Momany[5], J.A. Gili[1,2], F.A. Poletta[1,2,4], T. Busch[5], B. Comas[1,2], V. Cosentino[2], C. Saleme[3], H. Krupitzki[1], E. Castilla[2,4], E. Gadow[1], J.C. Murray[5], J.S. Lopez Camelo[1,2,4].* 1) Dirección de Investigación, CEMIC (Centro de Educación Médica e Investigaciones Clínicas), Buenos Aires, Argentina; 2) ECLAMC (Estudio Colaborativo Latinoamericano de Malformaciones Congénitas) at CEMIC, Buenos Aires, Argentina; 3) Maternidad Nuestra Señora de la Merced, Tucumán, Argentina; 4) INAGEMP (Instituto Nacional de Genética Médica Populacional) at CEMIC, Buenos Aires, Argentina; 5) Department of Pediatrics, University of Iowa, Iowa City, USA.

Background. Preterm birth (PTB) is the leading cause of perinatal morbidity and mortality worldwide. The etiology of PTB is multi-factorial, heterogeneous, and there is strong evidence of genetic susceptibility. The aim of this work was to investigate the association between 24 single nucleotide polymorphism (SNPs) and the different clinical subtypes of preterm birth: spontaneous (PTB-I), premature rupture of membrane (PTB-PROM) and medically indicated (PTB-M). These SNPs have been previously studied in a heterogeneous group of PTBs. Methods. The sample included 674 triads (proband, mother, father) recruited at the Nuestra Señora de la Merced Maternity Hospital in Tucumán, Argentina. Of these triads, 233 had probands from PTB-I, 241 had probands from PTB-PROM and 200 had probands from PTB-M. We studied 24 SNPs in 18 candidate genes. Genotyping was performed using Applied Biosystems Taqman probes and the Fluidigm genotyping platform. SNPs were chosen based on previous reports of significant association with preterm birth. Data were analyzed using the Transmission Disequilibrium Test (TDT) (Spielman et al. 1993). The p values (<0.05) were uncorrected for multiple comparisons. Preliminary results. We found a significant association (P<0.05) between a SNP in COL4A3 (rs10178458), a SNP in PON1 (rs2272365), and a SNP in CRHR1 (rs4458044) with PTB-I. A SNP in F3 (rs610277) showed significant association (P<0.05) with PTB-PROM and PTB-M. A SNP in KCNN3 (rs883319) showed significant association (P<0.05) with PTB-M. Conclusions. This study suggests different genetic influences between the different clinical subtypes. These findings may have implications in understanding the pathophysiology of clinical subtypes of preterm birth.

TLR1 SNP associated with preterm birth in a Wisconsin birth cohort. *D. Pillers, S. Tokarz, J. Eickhoff, L. Zyduck, W. Luo, B. Pattnaik, M. Baker.* Pediatrics, University of Wisconsin-Madison, Madison, WI.

Introduction: An important medical challenge is to mitigate the public health impact of preterm birth, both in its cost and complications. More than 30% of extremely premature infants are the products of pregnancies that have been complicated by infection. The fetal unit includes the fetus, the fetal membranes (chorion and amnion) and the placenta. Chorioamnionitis, or infection of the fetal membranes, can lead to preterm birth via rupture of the membranes. Although chorioamnionitis is associated with infants of any gestational age, it is predominantly found in the preterm infant, and its incidence increases as the gestational age decreases. The first line of defense against pathogens is the innate immune system, and the portal of entry is the Toll-like receptor (TLR). TLRs are pattern-recognition receptors that recognize pathogen-associated molecular patterns. Activation of TLRs initiates an inflammation cascade involving downstream signaling moieties and cytokines. Genetic variation in these pathways is associated with a variety of disease processes, including chronic and deregulated inflammation. TLRs are initiators of NF-κB and play a role in mediating the inflammatory events associated with labor. Purpose: We tested the hypothesis that genetic alterations of the fetal innate immune response are associated with an increased risk of prematurity. Approach: We evaluated three TLRs, 1, 2 and 4, using single nucleotide polymorphisms (SNPs). We utilized a unique and valuable set of newborn DNA samples derived from residual newborn screening specimens from over 3000 Wisconsin infants who represent the full spectrum of gestational ages (23 - 42 weeks). A univariate analysis was used to determine whether the TLR1 genotype is a predictor for gestational age and/or birth weight. Results: We found no significant correlation between TLR2 or TLR4 SNPs and preterm birth. There was a correlation between the TLR1 SNP rs4986791 (N248S) genotype in both the birth weight and gestational age analyses when compared to full-term populations (37-42 wks gestational age). There was a significant association between TLR1 SNP (N248S) and preterm birth in the non-Hispanic Wisconsin black population (P< 1×10-8). Conclusions: Our data suggest that TLR1 alterations may be associated with an increased risk of preterm birth in black infants in Wisconsin.

2853S

Whole Exome Sequencing of Hispanic Infants Reveal Novel Pathways Implicated In Spontaneous Preterm Birth. *M.K. Veerapen[1,2], E. Rampersaud[3], L. Pelaez[4], J.E. Potter[5], S. Wu[6], M.M. Rodriguez[4], O.A. Bodamer[1,2,3].* 1) Dr John T. Macdonald Department of Human Genetics; 2) Department of Biochemistry and Molecular Biology; 3) John P. Hussman Institute of Human Genomics; 4) Department of Pathology; 5) Department of Obstetrics and Gynecology; 6) Department of Pediatrics, Division of Neonatology, University of Miami, FL.

Approximately 12% of all infants in the United States are born prematurely with considerable variability based on ancestry, social status and access to health-care. Preterm birth (PTB) is multifactorial with an overall heritability of up to 37% and higher variance in spontaneous PTB (SPTB). Despite an increased risk for SPTB in Hispanic women, few studies have identified genetic factors associated with SPTB in this population. Consequently, much of the heritability remains unexplained. Whole exome sequencing (WES) has the potential to close this knowledge gap through the identification of additional genetic factors. The use of WES on archival tissues is novel, facilitating the study of well characterized cohorts from existing biorepositories.We proposed to utilize a cohort of retrospectively collected umbilical cords from SPTB Hispanic infants for the identification of genetic risk factors to SPTB by WES. Twenty-three Hispanic infants following SPTB were retrospectively identified through an umbilical cord collection at the University of Miami/Jackson Memorial Hospital. gDNA was isolated for ACE-capture WES (Personalis Inc., Menlo Park, CA). Individual exomes were filtered for variants with a genotype quality (GQ)>90 and analyzed using the likelihood ratio test(LRT) against the 1000 Genomes Project as background (VAAST v2.0.4). Significant shared genes (FDR<0.05) and VAAST scores were used for pathway analysis with MetaCore (v6.18 Build 65505). Mean gestational age was 34.1±1.72 weeks; birth weight was 2.36±0.46 kg; and APGAR scores at 10min were 8.8±0.59. gDNA (4.66±1.43 μg) were successfully extracted from archival umbilical cords for WES: average read depth was 44x with a mean coverage of 42 Mb. Individuals exomes were GQ filtered and gene-based VAAST analyses identified 217 shared genes (FDR<0.05). The VAAST scores by LRT were used for pathway analysis which revealed a predominance of novel cytoskeletal and immunological pathways (FDR<0.05): highly scored genes (>20) include *TUBA3E, KRT14*, and *HLA-DQA1*. To the best of our knowledge, this is the first retrospective SPTB study on Hispanic infants utilizing WES to identify novel genes and pathways not previously implicated in SPTB. The genes identified in cytoskeletal and inflammatory pathways likely modulate infant response to inflammatory stimuli contributing to the pathophysiology of SPTB. Our analyses will be further improved once integrated with maternal datasets to increase clinical significance.

2854S

Noninvasive detection of a balanced fetal translocation from maternal plasma. *S. Kim, T. Jensen, D. van den Boom, C. Deciu, M. Ehrich.* Bioinformatics, Sequenom, Inc., San Diego, CA.

Noninvasive prenatal testing based on massively parallel sequencing (MPS) of circulating cell free DNA (ccfDNA) from pregnant plasma offers a powerful tool for detecting fetal chromosomal aneuploidies and other copy number variations; however, copy neutral structural rearrangements have proven challenging. We aimed to detect and characterize a balanced fetal specific translocation event by sequencing ccfDNA from maternal plasma. Simulations were used to develop an algorithm which leverages base incremental changes in mapping characteristics of ccfDNA to identify paired end reads potentially harboring structural rearrangements. We then applied this methodology after performing high-coverage, 100bp paired-end sequencing of ccfDNA isolated from the plasma of a 38 year-old pregnant donor carrying a fetus with a balanced translocation. Our algorithm identified the known translocation (p=1.21e-8) and discounted the likelihood of others, enabling the base specific localization of the breakpoints. Furthermore, while no evidence of chromothripsis existed, we identified a 6bp deletion present within der(8) which is absent from the der(11) reciprocal rearrangement after de novo assembly of 76 chimeric reads. Overall, we have demonstrated here the first proof of concept study detecting and characterizing a balanced fetal specific translocation by non-targeted whole genome sequencing of ccfDNA from maternal plasma.

Low folate levels and MTHFR polymorphism C677T in case-mothers of children with neural tube defects and control-mothers of Pakistani origin. A Case- control study. *N. Nauman[3], S. Jalali[1], S. Shami[1], S. Rafiq[3], G. Groβe[2], A. Hilger[2], M. Draaken[2], M. Nöthen[2], M. Ludwig[2], H. Reutter[2].* 1) Pathology, Rawalpindi Medical College, Rawalpindi, Pakistan; 2) Institute of Human Genetics, Bonn, Germany Department of Neonatology, Bonn, Germany; 3) Department of Pathology, Holy Family Hospital, Rawalpindi, Pakistan.

Introduction: Neural tube defects (NTDs) are congenital malformations of central nervous system which result from a failure of the neural tube to close during the fourth week of embryogenesis. Low folate levels are associated with increased risk of neural tube defects. Genetic studies examining the gene coding for the folate metabolizing methylenetetrahydrofolate reductase (MTHFR) enzyme suggest that the functional 677C/T thermolabile polymorphism contributes a genetic risk to NTDs. Previous studies suggest that not only the fetal genotype but also the maternal genotype might have an impact on the fetal development. The deleterious effects of this mutation can be overcome if folate levels are adequate. Here we carried out a case-control study of case-mothers and control-mothers of Pakistani origin. Patients and Methods: We examined 109 case-mothers of children born with NTDs and of100 control-mothers without history of NTDs in their offspring. Case-mothers and control mothers were of Pakistani origin. Red blood cell folate and serum folate were determined. Genotype and folate level comparisons were carried out using chi-square analysis. Results: In the case mothers mean RBC folate and serum folate were highly significantly low as compared to control mothers (p-<0.0001). Genotype analysis of case-mothers and control-mothers revealed 11(10.09%) and 2(2%) respectively to be homozygous for the MTHFR 677T allele. There were 32(29.35%) case-mothers and 26(26%) control-mothers to be heterozygous for this polymorphism. Genotype comparison by chi-square analysis of case-mothers and control-mothers was significant (p=<0.0393). Conclusion: We found the homozygous MTHFR 677TT genotype to be more frequent among case-mothers compared to control-mothers. Mean RBC and serum folate levels were significantly low in case mothers as compared to control mothers. Combined analysis of these results with the information folate supplementation during the periconceptional period of case-mothers and control-mothers is warranted to further elucidate the role of the MTHFR genotype and folate supplementation per se in the risk of NTDs in pregnancies of women of Pakistani origin. Key words: Case- control study, MTHFR polymorphism, folate levels, neural tube defects.

FETAL DEMISE: DIAGNOSIS AND MANAGEMENT. INITIAL EXPERIENCE IN THE STATE OF INDIANA - 129 PATIENTS. *M. Tucker, L. Escobar, A. Hall.* Medical Genetics , St.Vincent, Indianapolis, IN., Select a Country.

Historically up to 60%; of fetal demise situations have no identifiable etiology. Attempting to determine the cause of fetal death remains important because it may influence estimates of recurrence and future preconceptional counseling, pregnancy management, prenatal diagnostic procedures, and neonatal management. We present data on our experience during the last five years of the state wide Perinatal Loss Evaluation Program in our institution. All patients were referred to our center for evaluation of fetal demise with the majority being second or third trimester losses. We either examined patients directly or through photographic material obtained by previously trained staff. We requested cord blood or tissue material for cytogenetic analysis and further history was obtained by our genetic counselor. Cases were evaluated by a pediatric pathologist, a dysmorphologist, and maternal fetal medicine specialist. The etiology of the demise in each case was suggested after reviewing medical records, autopsy, dysmorphologic exam and cytogenetic analysis.

Preliminary results indicated a likely identifiable cause for the demise in 88% of case (N=129). Fetal (33%), multiple risk factors (15%), placental (8%), infectious (8%), cervical (6%), umbilical cord (6%).

We briefly review here the diagnoses seen, particularly those attributed to fetal abnormalities with likely or proven genetic factors. Our data demonstrates the importance of evaluating fetal demise material in order to provide appropriate information to families in terms of cause and recurrence of their loss. We review the value of appropriate management of fetal tissue by pathology and dysmorphology as well as the value of photographic evaluation post mortem when products of conception are not available.

Molecular and histopathological findings in placentas of newborns with Down Syndrome. *R. García-Robles[1], J. Martinez[2], P. Ayala-Ramírez[2], M. Olaya[3], M. Bermúdez[2].* 1) Instituto de Investigación en Nutrición, Genética y Metabolismo. Universidad El Bosque, Bogotá, Colombia; 2) Instituto de Genética Humana. Pontificia Universidad Javeriana, Bogotá, Colombia; 3) Departamento de Patología. Hospital Universitario San Ignacio - Pontificia Universidad Javeriana, Bogotá, Colombia.

Down Syndrome is the most frequent chromosomopathy with a worldwide incidence of 1/600-700 newborns. Down Syndrome is the main cause of mental retardation and is caused by a trisomy of chromosome 21 involving a specific region named “Down Syndrome critical region”. The locus of the CBS gene is on this region and this gene codes for the enzyme Cystathionine β Synthase that participates in homocysteine metabolism. It has been reported overexpression of this gene in some cells and tissues of individuals with Down Syndrome and it is possible that this abnormal expression could be involved in some phenotypical findings of the disease. However, it has not been described this finding in placentas of affected individuals. The aim of this study was to assess the expression levels of mRNA an protein of Cystathionine β Synthase and histopathological changes in placentas of individuals affected with Down Syndrome and a control group of healthy and normal newborns. Thereby, we studied six placentas of newborns with Down Syndrome and 16 placentas of control group. We evaluated mRNA by real time PCR and protein by immunohistochemistry. An expert pathologist was blinded to diagnosis and evaluated the placentas. We found increased expression of Cystathionine β Synthase mRNA levels (p=0.0465) and protein levels (p=0.0090) in placentas of case group compared to control group. The histopathological changes showed statistically significant differences between groups in the following findings: irregular villous outlines (p=0.0007) and trophoblastic inclusions (p=0.0037). These results suggest overexpression of Cystathionine β Synthase in placentas of individuals with Down Syndrome, possibly causing alteration in homocysteine metabolism locally. Besides, histopathological findings in placenta were associated with trisomy 21. Finally, these molecular and pathological findings could help to identify individuals with Down Syndrome when the placenta is available to be assessed.

Rising Whole Body Counts of ^{137}Cs (WBC) in Pregnant Women and Persistent Elevated Rates of Neural Tube Defects (NTD) and Microcephaly/Microphthalmia (M/M) in a Chornobyl Impacted Region of Rivne (R) Province in Ukraine. *W. Wertelecki[1], L. Yevtushok[2], N. Zymak-Zakutnia[3], Z. Sosyniuk[2], S. Lapchenko[4], I. Kuznietsov[5], A. Korblein[6].* 1) OMNI-Net USA; 2) Rivne Diagnostic Center, Rivne, Ukraine; 3) Medical Genetics Center, Khmelnytsky, Ukraine; 4) OMNI-Net Ukraine; 5) Eastern European University, Lutsk, Ukraine; 6) OMNI-Net Germany.

Purpose: A population-based surveillance of congenital anomalies in R demonstrated elevated rates of NTD and M/M. Two prevalent teratogenic risks in R are alcohol and ^{137}Cs. Analyses indicated that alcohol is an unlikely primary cause. This study concerns WBC of ambulatory patients and pregnant women. **Methods:** Study of 44,438 WBC patterns recorded from adult ambulatory patients (2001-2013) inclusive of 6,425 pregnant women of known gestational age and body weight (2011-2013). Population-based 2000-2012 rates of NTD and M/M were concurrently computed. **Results:** WBC were statistically significantly higher among patients and pregnant women residing in Chornobyl contaminated regions of R. The average WBC of women rose significantly since 2001. Among pregnant women from the contaminated regions of R, the average WBC of ^{137}Cs were 40.7 and 39.7 Bq/kg among those under the age of 20 or older than 29 years respectively. The corresponding values among women from non-contaminated regions of R were 11.2 and 10.8 respectively. The population-based rates of NTD and M/M in polluted regions of R are persistently elevated and do not differ significantly from those reported earlier. Among the highest NTD-M/M rates are those in two counties in proximity to nuclear power plants. One of these counties is considered to be not contaminated by Chornobyl. **Interpretation:** The patterns of NTD and M/M rates in R may reflect impacts of alcohol and ^{137}Cs although the former is an unlikely primary cause. The impacts of two nuclear power plants on NTD-M/M rates in R should be considered by prospective cause-effect investigations.

Assessing the causal relationship between maternal height and birth outcomes: A Mendelian randomization analysis. *G. Zhang[1], J. Bacelis[2], C. Lengyel[3], B. Jacobsson[4,5], L. Muglia[3].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Institute of Clinical Sciences, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; 3) Center for Prevention of Preterm Birth, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Department of Obstetrics and Gynaecology, Sahlgrenska Academy, Sahlgrenska University Hospital/Ostra, Gothenburg, Sweden; 5) Department of Genes and Environment, Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway.

Background: Epidemiologic studies have shown that maternal height is significantly associated with gestational age and various birth outcomes, such as birth length and birth weight. However, it is unclear whether these associations truly reflect causal effects of maternal height. Alternatively, as an indicator of maternal nutrition status, maternal height could be indirectly associated with those birth outcomes. In this study we investigated the causal influence of maternal height on birth outcomes by Mendelian randomization using height genetic score as instrumental variable.

Methods: We used data of 3,486 mother/infant pairs from three birth cohorts collected from three northern European countries (Finland, Denmark and Norway). Genome-wide SNP genotype data were generated by SNP arrays and imputation. We constructed height genetic score using 171 SNPs to estimate the causal effects of maternal height on birth outcomes.

Results: In observational analysis, maternal height was significantly associated with gestational age ($p=1.4\times10^{-6}$), birth length ($p=3.26\times10^{-13}$) and birth weight ($p<2\times10^{-16}$). The constructed height genetic score in mothers was significantly associated with maternal height ($p<2\times10^{-16}$) and could explain more than 8% of the observed variance in maternal height. In Mendelian randomization analysis, height genetic score in mothers was significantly associated with infant's birth length (p=0.0015) and birth weight ($p=1.49\times10^{-5}$) and the estimated causal effects were directionally concordant with the observed associations (i.e. higher maternal height was associated with longer birth length and higher birth weight). The association between maternal height genetic score and gestational age was not significant (p=0.71).

Conclusion: Our results highly suggest that maternal height, as an important component of prenatal environment, causally affects both birth length and birth weight; however, whether maternal height causally impacts gestational age, or reflects nutritional or other influences on overall maternal health, requires further evidence.

2860S

Maternal and placental genome-wide and candidate gene association studies of placental abruption. *M. Denis[1], D.A. Enquohabrie[2,3], M.G. Tadesse[4], B. Gelaye[1], S.E. Sanchez[5,6], M. Salazar[7], C.V. Ananth[8,9], M.A. Williams[1].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Center for Perinatal Studies, Swedish Medical Center, Seattle, WA; 3) Department of Epidemiology, University of Washington School of Public Health, Seattle, WA; 4) Department of Mathematics and Statistics, Georgetown University, Washington, DC; 5) Sección de Post Grado, Facultad de Medicina Humana, Universidad San Martín de Porres, Lima, Peru; 6) A.C. PROESA, Lima, Peru; 7) Department of Obstetrics and Gynecology, San Marcos University, Lima, Peru; 8) Department of Obstetrics and Gynecology, College of Physicians and Surgeons, Columbia University Medical Center, New York, NY; 9) Department of Epidemiology, Joseph L. Mailman School of Public Health, Columbia University, New York, NY.

Introduction: Available evidence supports the role of genetics in the pathogenesis of placental abruption (PA), the premature separation of the placenta from the uterus, an important cause of perinatal mortality. Associations of maternal genetic variants with risk of PA have been demonstrated. However, PA-related variations in the placental genome and interactions between maternal and placental genomes on PA risk have not been investigated. **Methods**: Maternal blood and placental samples collected from participants of the Peruvian Abruptio Placentae Epidemiology study were genotyped using the Illumina Cardio-Metabochip platform. A total of 118,782 genome-wide SNPs and 333 SNPs in 32 candidate genes from mitochondrial biogenesis and oxidative phosphorylation pathways were examined in placental DNA from 280 PA cases and 244 controls. For interaction analyses in maternal and placental genomes, 325 SNPs from 32 candidate genes were assessed among 222 PA cases and 198 controls. Univariate and penalized logistic regression models were fit to estimate odds ratios. We also examined associations of combinations of SNPs with PA risk using weighted genetic risk scores (WGRS) and haplotype-based analyses. A multinomial model was used to investigate maternal and placental genome interactions. Functions of genes represented by significant SNPs were further examined using pathway analyses. **Results**: Overall, in placental genome-wide and candidate gene analyses, no SNP was significant after false discovery rate correction. The top GWAS hits were *rs544201*, *rs1484464* (*CTNNA2*), *rs4149570* (*TNFRSF1A*) and *rs13055470* (*ZNRF3*) (nominal p-values: 1.11e-05 to 5.00e-05). Genes participating in cell cycle, growth and proliferation were overrepresented by the top 200 SNPs of the GWAS. Subjects in the highest quartiles for WGRS (9 SNPs selected by lasso regression) had a 5.5-fold higher risk (95%CI 3.2-9.7) of PA compared with those in the lowest quartile. A haplotype block in *PPARG* was associated with a 50% (95% CI: 0.29-0.88) lower risk of PA compared to the referent haplotype. We found a strong interaction between maternal and placental genomes on PA risk for two SNPs in *PPARG* (*chr3:12313450* and *chr3:12412978* with p-values 8.62E-08 and 7.89E-10). **Discussion**: Variations in the placental genome and interactions between maternal-placental genetic variations can contribute to PA risk. Larger studies in this area can help advance our understanding of PA pathogenesis.

Comprehensive genotype phenotype correlations reveal NLRP7 role in regulating the balance between embryonic tissue differentiation and trophoblastic proliferation. *NMP. Nguyen[1], L. Zhang[1], P. Sauthier[2], C. Dery[1], K. Rahimi[3], R. Reddy[1], J. Arseneau[1], A. Cheung[4], U. Surti[5], L. Hoffner[5], M. Seoud[6], G. Zaatar[6], R. Bagga[7], R. Srinivasan[7], M. Brequet[2], W. Buckett[1], P. Coullin[8], A. Ap[1], R. Slim[1].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Service de Gynécologie Oncologique, Montréal, Québec, Canada; 3) Department of Pathology, Hôpital Notre-Dame, Montréal, Québec, Canada; 4) Department of Pathology, University of Hong Kong, Queen Mary Hospital, Hong Kong, China; 5) University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 6) American University of Beirut, Beirut, Lebanon; 7) Post Graduate Institute of Medical Education and Research, PGIMER, Chandigarh, India; 8) Endocrinologie et Génétique de la Reproduction et du Développement, Clamart, France.

Hydatidiform mole is a human pregnancy with excessive trophoblastic proliferation and abnormal embryonic development. NLRP7, a nucleotide oligomerization receptor, pyrin containing 7, is a major gene responsible for recurrent hydatidiform moles. Recurrent HMs are caused by recessive mutations, mostly in NLRP7, and have diploid biparental genomes To better understand the effect of NLRP7 on the mechanism leading to hydatidiform moles, we used a combination of five different approaches, flow cytometry, fluorescent in situ hybridization, microsatellite DNA genotyping, and p57KIP2 and Ki-67 immunohistochemistry to comprehensively characterize 103 hydatidiform moles from patients with or without NLRP7 mutations and variants. We confirm that most molar tissues from patients with two NLRP7 defective alleles are diploid biparental with a single cellular population. importantly, our data demonstrate significant genotype-phenotype correlation between the nature of the mutations and the histopathological features of thehydatidiform moles. Protein-truncating mutations were associated with more severe molar phenotype such as excessive trophoblastic proliferation and absence of embryonic tissues while missense mutations were associated with milder phenotype and were more permissive for embryonic tissue development. Our data suggest that NLRP7, depending on the severity of its mutations, regulates the time at which embryonic development arrests.

Kidney disease genes linked to Hyperemesis Gravidarum. *M. Schoenberg-Fejzo[1], K. MacGibbon[2], J. Sinsheimer[3], P.L. Reddy[4], P. Pajukanta[4], K. Tabsh[1].* 1) Department of Obstetrics and Gynecology, David Geffen School of Medicine, University of California, Los Angeles, CA; 2) Hyperemesis Education and Research Foundation, Leesburg, Virginia; 3) Departments of Biostatistics, Biomathematics, & Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA; 4) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA.

Hyperemesis Gravidarum (HG), severe nausea and vomiting of pregnancy, often results in dehydration and undernutrition and is the 2nd leading cause of hospitalization in pregnancy after preterm birth. Current treatments are largely ineffective and the cause is unknown. Evidence for a genetic component comes primarily from a classic twin study and reports of familial aggregation. This study was undertaken to elucidate the etiology of HG by identifying predisposing genes. HG reduces reproductive fitness, which makes whole exome sequencing to find rare variants a reasonable approach. We performed exome sequencing of 18 individuals from 5 families with HG. Using a series of filtering steps, we identified rare, damaging, biologically relevant variants exhibiting co-segregation with affection. Potentially causative variants were screened in available family members, additional families, and a replicate group of over 570 cases with HG and over 425 unaffected controls using Sanger Sequencing, Fluidigm, and Taqman. Three of five families carry biologically related rare damaging variants in genes involved in kidney function: *PKHD1*, *PKD1*, and *LAMA5*. None of over 425 controls carried these variants. Thus, a common pathway may be responsible for the majority of cases of familial HG. This novel discovery of rare variants relating to HG susceptibility is the first step in understanding the biology of HG; may be relevant to understanding genetic susceptibility to nausea and vomiting in general; and provides a new path for development of more effective therapies.

2863S

Interbirth interval varies according to HLA inheritance of first and second born siblings. *C.A. GENTIL[1], H.S. GAMMILL[1,3], S.B. KANAAN[1], C.T. LUU[1], T.M. AYDELOTTE[1], J.L. NELSON[1,2].* 1) Clinical Research Division, Fred Hutchinson Cancer Research Center, SEATTLE, WA; 2) Division of Rheumatology, University of Washington, SEATTLE, WA; 3) Department of Obstetrics and Gynecology, University of Washington, SEATTLE, WA.

Background: Interbirth interval (IBI), the time between births of siblings, may reflect disparate evolutionary pressures from mother and each child. Fetal-maternal exchange during pregnancy results in long-term persistence of low levels of exchanged cells in respective individuals, referred to as microchimerism (Mc). Haig recently proposed that maternal acquisition of fetal Mc from an earlier birth could affect the length of time before a subsequent birth (IBI), for example by interfering with implantation of subsequent embryos, thereby maximizing maternal resources for him/herself.[1,2] We hypothesized that for a 2nd child the maternal environment would be most hospitable if the child was HLA-identical with his/her older sibling (shorter IBI) and least hospitable if fully HLA-mismatched (longer IBI), with HLA haploidentical siblings of intermediate IBI. **Methods:** We HLA-genotyped 242 children of 121 healthy mothers, and 96 children of 48 women with systemic sclerosis (SSc). All children were 1st born (C1) or 2nd born (C2). Haplotypes were assigned after determining HLA-DRB1, DQA1 and DQB1 alleles by PCR and probe-specific hybridization, with additional HLA class I typing when needed to assign haplotypes. C2 was classified as HLA-identical (ID), haploidentical (Hap) or fully mismatched (MM) with C1. IBI was calculated for each family. Kruskal Wallis and Mann Whitney were used to compare IBI according to sibling HLA relationships. **Results:** All 169 families were combined for analysis as IBI did not differ between healthy and SSc families. Median IBI (in days) was shortest in the ID group (796 [interquartile interval 626-1086]) and longest in MM (1068 [747-1323]), with Hap intermediate (961 [701-1482]), P=0.03. Pairwise comparisons showed significant differences between ID vs MM (P=0.03) and ID vs Hap (P=0.02) but not between Hap vs MM (P=0.76). Within the Hap group, IBI did not significantly differ considering whether the shared haplotype was maternally or paternally inherited (P=0.67). **Conclusions:** IBI differed significantly according to whether C2 was HLA-identical, mismatched or haploidentical with C1 in normal and SSc families. The finding of shorter IBI between HLA-identical and longest between mismatched siblings supports the hypotheses proposed by Haig. To our knowledge this is the first HLA haplotype analysis of the concept of sibling rivalry (or cooperation). [1]Haig D, Evol Med Public Health 2014, 12-17. [2]Haig D, Chimerism 2014, 1-3.

The genetic basis of preeclampsia in a high altitude indigenous Andean population. *C.R. Gignoux[1], K. Sandoval Mendoza[1], G.L. Wojcik[1], A. Moreno Estrada[1], P. Ortiz-Tello[1], A.F. Adams[1], C. Eng[2], S. Huntsman[2], V. Villanueva Dávalos[3], J. Manzaneda[4], F. Manzaneda[4], M. Hurtado[5], V. Villegas[5], E. González Burchard[2], C. Gallo[5], L. Enrique Lencinas[3], J.C. Baker[1], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 3) Dept of Obstetrics and Gynecology, Hospital Regional "Manuel Núñez Butrón", Puno, Peru; 4) Universidad Nacional del Altiplano, Puno, Peru; 5) Laboratorios de Investigación y Desarrollo, Facultad de Ciencias y Filosofía, Universidad Peruana Cayetano Heredia.

Preeclampsia is the largest killer of pregnant women worldwide. It is a disorder characterized by the sudden onset of maternal hypertension, edema, and proteinuria, with a global prevalence of 3-8% of all pregnancies. The condition in particular has elevated rates in Hispanic/Latino women. Preeclampsia also poses a risk to newborns, particularly in areas of the world where resources are limited. The heterogeneity of the disorder has posed a challenge in our understanding the molecular basis of the preeclampsia. However, the trait is known to be exacerbated in high altitude regions such as the Andes. In order to investigate the genetic basis of preeclampsia and its relationship to altitude we have begun a collaboration with researchers and clinicians in Puno, Peru, a city nearly 4,000 meters above sea level. The local population is primarily of Quechuan and Aymaran descent. Based on population genetic analysis then we expect these groups to have inherited a unique pattern of genetic risk factors from other populations previously studied. We have collected data on almost 500 individuals in affected trios (including maternal, paternal, and cord blood) and population controls, with sections of placenta alongside pertinent medical records. The trio design allows for measuring the contributions of maternal, paternal and proband effect on the expectant mother. We have generated genome-wide data at over 800,000 sites across the genome with the Affymetrix Axiom LAT array on all samples to date. Most individuals have very high levels of Native American ancestry (median value >98% as measured by ADMIXTURE). Using trio-aware genome-wide association analyses we identify several top candidates, including a group of SNPs in LD over a cluster of blood clotting factor genes on 13q34 (*PROZ*, *F7*, *F10*), with a relatively high odds ratio for preeclampsia (OR 3.4, 95% CI 2.0-5.7,$p<4\times10^{-6}$). Although this region has not been previously identified in genome-wide studies, preeclampsia is known to cause changes in clotting levels and blood thinners can be used as preventative treatment. PROZ in particular has been extensively studied as a biomarker in multiple pregnancy disorders. This finding of a novel association in a relevant biological pathway and other genetic discoveries in this study demonstrates the increased power of relevant study design and underscores the importance of more genetic analysis in diverse, understudied populations worldwide.

2865S

Molecular and pathological abnormalities in placentas of pregnancies complicated by preeclampsia. *P.A. Ayala-Ramírez[1], R. García-Robles[2], M. Olaya[3], J.L Rodriguez[3], T. Buitrago[2].* 1) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá, Bogotá D.C., Colombia; 2) Instituto de Investigación en Nutrición, Genética y Metabolismo, Universidad El Bosque, Bogotá D.C., Colombia; 3) Departamento de Patología, Pontificia Universidad Javeriana-Hospital Universitario San Ignacio, Bogotá D.C., Colombia.

Preeclampsia (PE) is a hypertensive disorder of pregnancy of unknown etiology with impact in maternal and fetal health. Its clinical manifestations occur in the second half of pregnancy with a world frequency of 2- 8% and in developing countries occurs in 10%. In Colombia, PE causes 42% of maternal mortality. It is proposed that an alteration in placental homeostasis may be involved in the pathophysiology of this disease. The aim of this study was to compare levels of mRNA and protein of Tissue Factor (F3) and Thrombomodulin (THBD) as well as histopathological findings in placentas with PE. We studied 18 term placentas of patients with diagnosis of PE and 18 term placentas from pregnancies without any complication and healthy newborn. It conducted an evaluation by an expert blinded pathologist of the presence of thrombosis, fibrin deposits, decidual arteriopathy, necrotic villi, leukocyte stasis, hyperplasia of syncitiotrophoblast and edema. The assessment of mRNA and protein levels of F3 and THBD was performed by Real time PCR and ELISA, respectively. The results showed statistically significant differences between cases and controls for these variables: decidual arteriopathy (p=0.027), necrotic villi (p=0.001) and hyperplasia of syncitiotrophoblast (p=0.0017). In addition, it found statistically significant differences in levels of F3 mRNA (p=0.011) and protein (p=0.0001) as well as in mRNA THBD (p=0.0001) and protein (p=0.0001) levels, with an increase in case group. We found an abnormal expression of F3 and THBD with increased levels of protein and mRNA in placenta of pregnancies complicated by PE, suggesting a possible role of these molecules in the pathophysiology of this disease. Also, these results agree with the existence of alterations in hemostatic mechanisms and hystopathological changes in placenta of pregnancies affected by PE.

2866S

A 'conditional-ON' mouse model of Fibrosyplasia Ossificans Progressiva (FOP). *A.N. Economides[1,2], L. Huang[2], L. Xie[2], K. Nannuru[2], K. Feeley[2], T. Persaud[2], P. Yang[2], V. Idone[2], A. Lee[3], P. Yu[4], C. Schoenherr[2], S.J. Hatsell[2], A.J. Murphy[2].* 1) Regeneron Genetics Center, Regeneron Pharmaceuticals, Tarrytown, NY; 2) Regeneron Pharmaceuticals., Tarrytown, NY; 3) National Center for Advancing Translational Sciences, NIH, Rockville, MD; 4) Brigham and Women's Hospital, Boston, MA.

FOP (MIM 135100) is an autosomal dominant disorder characterized by early onset, episodic and progressive ossification of skeletal muscle and associated connective tissue (Pignolo et al., 2011). FOP is driven by mutations in the intracellular domain of ACVR1 (also known as ALK2), with the great majority altering Arginine 206 to Histidine (R206H). In order to enable the development of therapeutic approaches for FOP, as well as mechanistic studies of the disease process, we have engineered a Cre-regulated 'conditional-ON' allele of ACVR1[R206H] in the mouse - *Acvr1*$^{[R206H]COIN}$ - using a FlEx- (Schnutgen et al., 2003) or COIN-like design (Economides et al., 2013). A conditional approach was necessitated because an unregulated *Acvr1[R206H]* knock-in allele cannot be transmitted through the germline in mice (Chakkalakal et al., 2012). *Acvr1*$^{[R206H]COIN}$ was generated by introducing the R206H mutation in exon 5 of *mmuAcvr1*, placing the mutated exon and flanking intronic sequence in the antisense strand. The corresponding region from human ACVR1 was inserted into in the sense strand of *mmuAcvr1* upstream of the inverted exon. To enable Cre-dependent replacement of the wild type exon 5 with its R206H version, the introduced human sequence was flanked by a 'FlEx' array of *lox*2372 and *lox*P sites in parallel orientation, whereas the mutant exon is followed by *lox*2372-*lox*P placed in antiparallel orientation with the *lox*2372 and *lox*P sites flanking human exon 5. This arrangement allows Cre-mediated inversion of the mutant exon into the sense strand and simultaneous deletion of the wild type human exon 5. Body-wide activation of the FOP allele in *Acvr1*$^{[R206H]COIN/+}$; *Gt(ROSA26)Sor*$^{CreERt2/+}$ adult mice resulted in progressive ossification resembling FOP. Heterotopic ossification was evident by μCT on the axial skeleton, as well as long bones, as early as 2 weeks after dosing with tamoxifen, whereas untreated mice were normal, displaying no abnormal bone formation. Heterotopic ossification was spontaneous, and did not require experimentally induced inflammation. The FOP phenotype was obtained in adult mice, enabling the uncoupling of the process observed in these mice from development. Heterotopic ossification was prevented by treatment with the ACVR1 inhibitor LDN-212854 (Mohedas et al., 2013), demonstrating that this physiologic mouse model of FOP can be used for testing candidate therapeutic regimens. This and other novel therapeutic regimens will be presented in detail.

Knock-in human FGFR3 achondroplasia mutation as a mouse model for human skeletal dysplasia and potential therapy evaluation. *Y. Lee[1], S. Chen[2], Y. Chen[2, 3].* 1) Institue of Cellular and Organismic Biology, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Department of Pediatrics, Duke University Medical Center, Durham, NC.

Activating mutations of fibroblast growth factor 3 (FGFR3) lead to several autosomal dominant human skeletal dysplasias with varying degrees of skeletal deformities. Achondroplasia, the most common genetic dwarfism in human, results from a point mutation, G380R, in FGFR3. To facilitate the study of skeletal dysplasias and to assess the potential therapeutic approaches designed to targeting the activating human FGFR3, we have generated a mouse model of which the endogenous mouse FGFR3 gene has been replaced with human FGFR3 G380R cDNA (Fgfr3hG308R). Mice carry the heterozygotes (Fgfr3$^{-/hACH}$) and homozygotes (Fgfr3$^{hACH/hACH}$) for the human FGFR3 G380R mutation have varying degrees of disproportionate, proximal shortening of the limbs, mid-face hypoplasia and relative macrocephaly due to a failure in endochondral proliferation and differentiation. This mouse model offers a generally applicable approach for the assessment of the potential therapeutic approaches designed to the specific protein targets for human diseases.

Retinal vascular lesions associated with mutations in *Col4a1*. *M. Alavi, D. Gould.* Department of Ophthalmology, University of California, San Francisco, School of Medicine, San Francisco, CA.

Type IV collagen alpha 1 (COL4A1) is a major component of almost all basement membranes and mutations in *COL4A1* cause multisystem disorders in humans and mice. Notably, patients and mice harboring mutations in *COL4A1* exhibit ocular defects including anterior segment dysgenesis, optic nerve hyperplasia and retinal vascular tortuosity. Here we present our findings studying the retinal phenotype of mice carrying a dominant-negative *Col4a1* mutation (*Col4a1*$^{\Delta ex41}$).

We examined retinas of *Col4a1*$^{+/\Delta ex41}$ C57BL/6J.129S1/SvImJ mice and *Col4a1*$^{+/+}$ littermate controls at different ages from postnatal day (P) 21 to P720 *in vivo* using fluorescein angiography (FA), fundoscopy and optical coherence tomography. Histology, immunohistochemistry and quantitative PCR analyses complemented our analyses.

FA showed fully penetrant retinal vascular tortuosity and abnormal ramification. Retinal examinations revealed serous chorioretinopathy, retinal hemorrhages, fibrosis or signs of pathogenic angiogenesis with anastomosis of the choroid and the retinal vasculature in approximately 80% of all *Col4a1*$^{+/\Delta ex41}$ eyes at various ages. Retinal hemorrhages and anastomosis were observed as early as P21. We assessed expression levels of candidate genes involved in angiogenesis and found increased vascular endothelial growth factor (VEGF) expression in *Col4a1*$^{+/\Delta ex41}$ retinas compared to *Col4a1*$^{+/+}$ retinas.

Our findings suggest that patients carrying mutations in *COL4A1* may be at risk for sudden vision loss resulting from retinal vascular insults. What is more, retinal exams may help to identify individuals that are at greatly increased risk of suffering from intracerebral hemorrhages. Elevated VEGF expression may be a primary cause or consequence of vascular lesions that then leads to further retinal damage. Currently VEGF is a major target for preservation of vision in patients with age-related macular degeneration. This suggests that anti VEGF therapy may also be an effective strategy to prevent pathogenic vascular defects that result from *COL4A1* mutations.

Inflammatory demyelination in a duplication mouse model of Pelizaeus-Merzbacher Disease. *G.M. Hobson[1,2], L. Sakowski[1,2], K. Clark[1,2], K. Sperle[1].* 1) Nemours Biomedical Res, A I duPont Hosp Children, Wilmington, DE; 2) Dept Biological Sciences, University of Delaware, Newark, DE.

Pelizaeus-Merzbacher disease (PMD [MIM 312080]) is an X-linked leukodystrophy affecting the myelin sheath in the central nervous system (CNS). It is caused by alterations in the proteolipid protein 1 gene (*PLP1* [MIM 300401]) that encodes the most abundant protein in CNS myelin. Our lab has developed the *Plp1*dup mouse model that is a genetically faithful model of the most common cause of PMD, a genomic duplication. Previous characterization on 129/Bl6 mixed background mice has shown disorganized myelin in white matter tracts, abnormal mRNA levels, and impaired gait. Further characterization on an inbred C57Bl/6 strain using the Noldus CatWalk has shown that two major phases of the gait cycle, stand and swing, are affected. *Plp1*dup mice also demonstrated a decreased latency to fall in accelerating trials on the Stoelting Rotarod, indicating a progressive effect on motor coordination and balance. Light microscopy on brain sections of *Plp1*dup mice showed degenerating nerve fibers and abnormal myelin organization with evidence of gliosis and activated microglia, suggesting an inflammatory response. Analysis of markers of gliosis and inflammation in brain mRNA showed upregulation of several key inflammatory markers, including TNF-α, and GFAP. Global transcriptome profiling revealed significant upregulation of 45 genes, many of which are involved in an inflammatory response. Further characterization of the *Plp1*dup mouse model will allow us to better understand the underlying mechanisms for PMD and develop rational treatments for a currently untreatable disease.

***Poc1a*, a component of the centriole and cilia, causes skeletal dysplasia and male infertility: a mouse model.** *K.A. Geister[1], M.L. Brinkmeier[2], D.L. Burgess[3], J. Cavalcoli[4], L.Y. Cheung[2], J.M. Oatley[5], M. Oatley[5], J. Wendt[3], S.A. Camper[1, 2].* 1) Graduate Program in Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Roche-Nimblegen, Inc., Madison, WI; 4) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 5) School of Molecular Biosciences, College of Veterinary Medicine, Washington State University, Pullman, WA.

We report the identification of the lesion responsible for skeletal dysplasia and male infertility in the spontaneous, recessive mouse mutant *chagun* (1). We carried out regional sequence capture and determined that *Poc1a* (protein of the centriole 1a) is disrupted by the insertion of a processed cDNA into exon 8, with a target site duplication suggestive of LINE-1 mediated insertion. This disruption causes exon skipping, but the reading frame is maintained, and the mutant protein is detected in tibial extracts, suggesting that this is a partial loss of function allele. A BAC transgene containing *Poc1a* is sufficient to correct the growth and testis defects. Embryonic fibroblasts from mutant embryos have impaired cilia formation and multipolar spindles. The defects in cell division and cilia likely account for the disorganized proliferative zone of the epiphyseal growth plate because chondrocytes are not polarized properly and undergo increased apoptosis. This explains the mechanism underlying primordial dwarfism in humans with two different mutations of *POC1A* (2, 3). Male infertility is caused by arrested spermatogenesis at the pachytene stage and progressive germ cell loss. Spermatogonial stem cell transplantation studies reveal that *Poc1a* is essential for normal function of both Sertoli cells and germ cells. We hypothesize that partial POC1A function is necessary for viability in mammals. Mutations in a number of genes associated with centrosome function are now known to cause skeletal dysplasias and primordial dwarfisms. This mouse model will provide information about the global functions of POC1A, clarify how centrosome dysfunction leads to defects in skeletal growth and development, and serve as a means to uncover potential therapies. 1. Using electroporation as a model of degeneration/regeneration to investigate the regenerative potential in neuromuscular disorders (NMD). *M. Vainzof, C.F. Almeida, R. Ishiba, A. Martins-Bach, A.L.F. Santos, L. Nogueira.* Human Genome Research Center, University of Sao Paulo, São paulo, Sao Paulo, Brazil.

After injury, the healthy muscle is able to repair and grow new fibers. However, in neuromuscular diseases, the process of regeneration is not completely efficient and its constant activation leads to exhaustion of this ability. Understand all the steps involved in muscle degeneration and regeneration is of major importance for a better comprehension of the genetic muscle diseases. Mouse models for NMD are good molecular models, but not always they reproduce the histopathological and phenotypic characteristics associated to the mechanisms of the respective disease. Protocols for in vivo gene therapies have used electrotransfer to optimize transfection efficiency. However, most of them have reported histological evidence of muscle degeneration and complete regeneration within 15 days. Therefore, we are proposing the use of this model of very fast muscle degeneration and regeneration processes to characterize different patterns of muscle regeneration in NMD. We are studying electroporated lower limb of normal mice and dysferlin deficient SJL mouse model for Limb Girdle Muscular Dystrophy type 2B, with the main objective to study the pattern of alterations along time, both through histological analysis and quantitative mRNA expression of genes involved in the degeneration/regeneration pathways. The animals were anesthetized and received 8 pulses of 100 V, duration of 20 milliseconds and interval of 0.5 second at the calf. Each group of animals was analyzed after 3, 5, 10, 15, 21 and 30 days. In control animals, histological analysis showed small areas with foci of degeneration starting at d3 and d5, and signals of regeneration starting at d5. After d10, large areas of centrally nucleated fibers were observed, continuing in d21 and d30. In SJL model, the degeneration was more intense in d3 and d5, and was also observed in d10. In d21 and d30, large areas of centronucleated fibers were observed. Quantitative mRNA expression of the gene Myod, Myf5 and Myog, showed the activation of the regeneration genes in SJL mice, since d3 up to d10. This new system of acutely induced degeneration and regeneration in mouse models is useful to study and quantify alterations in satellite cells and regeneration impairment in some mildly affected myopathic model, in which the histopathological pattern of the muscle is not comparable to the pattern observed in human diseases. FAPESP-CEPID,CNPq-INCT, CAPES-COFECUB, FINEP.

Definitive Implication of Innate Immunity in the Pathogenesis of Scleroderma. *E. Gerber[1], J. Beckett[1], D. Huso[2], H. Dietz[1,3].* 1) Institute for Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Comparative Medicine, Johns Hopkins University, Baltimore, MD; 3) Howard Hughes Medical Institute, Chevy Chase, MD.

The most common and severe form of scleroderma (systemic sclerosis; SSc) shows sporadic adult onset of skin and visceral fibrosis in association with autoantibody production and other markers of autoinflammation. In contrast, stiff skin syndrome (SSS) shows congenital dermal fibrosis caused by heterozygous mutations in the domain of fibrillin-1 that mediates cell-matrix attachment via integrin binding. Both SSS and SSc show excessive deposition of fibrillin-1 that serves to concentrate the profibrotic cytokine TGFβ. We previously showed that knock-in mouse models of SSS recapitulate dense dermal fibrosis and show all of the autoinflammatory manifestations of SSc including antinuclear and anti-topoisomerase-1 antibodies, Th2 and Th17 skewing and B cell activation in the skin in association with recruitment and activation of plasmacytoid dendritic cells (pDCs), a cell type that performs a surveillance function for pathogens and responds via IL6 and IFNα production upon presentation of RNA or DNA to TLR7/9 receptors, respectively. All therapeutic interventions that prevent fibrosis in SSS mice, including agents that downregulate integrin expression on pDCs and TGFβ and ERK inhibitors, associate with prevention of pDC recruitment and activation. This prompted the question regarding the relative contribution of innate vs. adaptive immunity in disease pathogenesis, an unaddressed question in SSc as well, and the mechanism of cross-talk between the matrix and pDCs. Using a transgenic allele that expresses diphtheria toxin receptor specifically on pDCs, we now show that postnatal pDC depletion is sufficient to prevent fibrosis in SSS mice, while introduction of the null state for Rag2 (no T or B cells or antibodies) had no effect on disease expression. These data unequivocally point to a predominant, if not exclusive, contribution of innate immunity. In other autoimmune diseases such as lupus and psoriasis, abnormal protein aggregates present nucleic acids to TLRs, with the naturally occurring antimicrobial peptide LL37 serving as a critical intermediate. We wondered whether the macroaggregates of fibrillin-1 might be initiating similar events in SSS (and perhaps SSc). In keeping with this hypothesis, introduction of haploinsufficiency for Ll37 or treatment with a synthetic TLR7/9 blocking peptide abrogated fibrosis in SSS mice. These data offer many novel therapeutic strategies in scleroderma and perhaps other more common presentations of fibrosis.

Human-Mouse:Disease Connection, new pathway to discovery. *J.T. Eppig, C.L. Smith, P. Frost, K. Stone, L.E. Corbani, J. Campbell, K.L. Forthofer, J.E. Richardson, S.M. Bello.* Jackson Laboratory, Bar Harbor, ME.

The Human-Mouse:Disease Connection (www.diseasemodel.org) is a translational tool affording simultaneous access to human-mouse genomic, phenotypic, and genetic disease information. Researchers can explore phenotypes and disease relationships, identify candidate genes, and evaluate mouse mutants displaying a spectrum of indicative phenotypes. Within the web display, links are provided to supporting mouse model publications and to repositories supplying mouse resources. Three primary approaches give users flexibility to search from a human or mouse perspective, using (1) genes or gene IDs for either species, (2) genome location(s) from either species, and (3) mouse phenotype or human disease terms. Data also can be uploaded from VCF files. Thus, exploration can begin with a single gene or set of genes, a region for QTL, multiple deletion regions, or using phenotype/disease searches, such as “Crouzon Syndrome”, “neurofibromatosis”, or “cardiomyopathy”. All search methods initially return an interactive grid that presents a visual overview of results facilitating comparison of phenotypes and diseases across multiple genes, phenotypes, and diseases. The grid features color cues reflecting depth of annotated human and mouse data, and grid cells are active links leading to more detailed information, including availability of mouse models from repositories worldwide. Alternate web page displays with gene and disease-focused information are one click away. Integration of mouse and human data related to gene homologs, genomic locations, mutations, phenotypes, and diseases is ongoing in the Mouse Genome Informatics resource (MGI, www.informatics.jax.org), the primary data source for the Human-Mouse:Disease Connection portal. These data include over 1300 OMIM-defined human genetic diseases with at least one experimentally defined mouse model and mouse phenotypes for more than 51,600 unique genotypes. Data (to be released in June 2014) from the systematic screens of knockout mutations analyzed in the International Mouse Phenotype Consortium (IMPC) project will further augment phenotype-genotype associations for mouse mutations. We will discuss the challenges of human and mouse data integration and new developing capabilities of the Human-Mouse:Disease Connection portal to ease translation between human and mouse data and to promote best matching of human disease and mouse model resource data. Supported by NIH grant HG000330.

Social and maternal behaviours are affected by a mutation in *Gtf2ird2* in Williams-Beuren Syndrome mouse model system. *N. SHARMIN[1,2], M. Tassabehji[2], R. Hager[1].* 1) Faculty of Life Sciences, University of Manchester, Manchester, Lancashire, United Kingdom; 2) 1.Genetic Medicine, Faculty of Medical and Human Studies, St Mary's Hospital, University of Manchester, Lancashire, United Kingdom.

Human social behaviour is affected by both environmental and genetic factors. The human genetic disorder Williams-Beuren Syndrome (WBS) is characterised by neurological deficits that impact social and cognitive behaviour. Our hypothesis is that deletion of the *Gtf2ird2* gene, from the Gtf2i-family of transcription factors, affects social and neuropsychological development and consequently affects maternal behaviour during early development. By phenotyping maternal behaviour in a single-gene knockout mouse model of WBS, we show, for the first time, that deletion of *Gtf2ird2* influences key maternal and social behaviours in homozygous and heterozygous animals, affecting offspring development. In addition, *Gtf2ird2* heterozygous mothers exhibit high rates of filial cannibalism compared to either knockout or wild type mothers. These results show that this single gene mutation has an important role in the hyper-social behavioural symptom seen in WBS patients. The results are in line with existing literature on *Gtf2i* gene family.

Canine developmental disorder maps to the critical region of human 22q11.2 deletion syndrome. *M. Hytönen[1,2], A. Lappalainen[3], H. Lohi[1,2].* 1) Molecular Neurology, Research Programs Unit and Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland; 2) Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Equine and Small Animal Medicine, Faculty of Veterinary Medicine, University of Helsinki, Helsinki, Finland.

Dogs have emerged as clinically and genetically relevant large animal models for human inherited disorders. We present here a genetic study of a congenital canine syndrome characterized by typical craniofacial features, patellar subluxation, microphthalmia and mental disturbances. We have performed genome wide association study to map the disease to canine chromosome 26. The associated locus overlaps human DiGeorge syndrome region characterized by a 22q11.2 deletion. Our ongoing targeted resequencing efforts aim to discover the causative mutation in the critical region. Comparative phenotypic analyses reveal similarities in canine and human phenotypes and genetic characterization of the canine locus may assist in the genetic dissection and understanding of the DiGeorge syndrome in both species. This study also enables the development of a genetic test for breeding purposes in dogs.

2876M

A transgenic zebrafish model for facioscapulohumeral dystrophy. *A. Lek[1,2], H. Mitsuhashi[1,2], F. Rahimov[1,2], C. Mosimann[1,2], L. Zon[1,2], L. Kunkel[1,2].* 1) Genetics, Boston Children's Hospital, Boston, MA; 2) Pediatrics and Genetics, Harvard Medical School, MA.

Facioscapulohumeral muscular dystrophy (FSHD) is one of the most common forms of muscular dystrophy, characterized by asymmetric weakness of the facial, shoulder and upper arm muscles, accompanied by hearing loss and retinal vasculopathy. Although the causative gene for FSHD remains controversial, the primate specific retrogene, DUX4, is a leading candidate. There is currently no mammalian model that recapitulates the human FSHD pathology. Previously, our lab has shown that misexpression of very low levels of human DUX4 in zebrafish development recapitulates the phenotypes seen in FSHD patients. It was demonstrated that microinjection of human DUX4 mRNA into zebrafish eggs caused asymmetric abnormalities of the eyes and ears, and disorganization of fin and trunk muscles. Using a tamoxifen-controlled CreER^{t2}-loxP system, we have now generated a transgenic DUX4 line that successfully reproduces the mosaic, low-level expression of DUX4. We show that activating DUX4 expression during development results in a degenerative muscle phenotype by day 7 post-fertilization. This stable line will enable us to control when, where and how much DUX4 is expressed to best model FSHD pathogenesis in zebrafish, allowing for better functional studies.

2877T

Role of palmitoylation in alopecia and skin abnormality in genetic deficiency of Zdhhc13 in Mice. *K. Liu[1,2], Y. Chen[3], L. Shen[1], A. Saleem[1], I. Song[1,5], L. Chen[1], Y. Chen[3], J. Wu[1], J. Yen[1], Y. Chen[1,2,4].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Clinical Medicine, National Yang-Ming University, Taipei, Taiwan; 3) Institute of Chemistry, Academia Sinica, Taipei, Taiwan; 4) Department of Pediatrics, Duke University Medical Center, Durham, NC, USA; 5) Graduate Institute of Life Sciences, National Defence Medical Center, Taipei, Taiwan.

Palmitoylation, a post-translational modification of 16-carbon of palmitic acid, regulates protein folding, trafficking, stability, and protein-protein interactions. Defects of palmitoylation are associated with certain human neurological disorders and cancers. We previously reported mice with genetic deficiency in palmitoyl acyl transferase, Zdhhc13, had alopecia and hyperkeratosis, amyloidosis and osteoporosis. Here we investigated the pathogenic mechanism of hair and skin abnormalities. Mutant mice had hair loss prematurely occurred in each of Catagen of hair cycle, instead of Telogen and resulted in cyclic alopecia phenotype. Scanning electron microscope showed the broken and dilapidated hair cuticle structure. Furthermore, immunohistology showed hyperproliferation of the epidermis, and enhanced and delayed terminal differentiation of the keratinocytes (also known as cornification or keratinization). Biochemically, we found a palmitoylation substrate, cornifelin, was not present in the epidermis and hair cuticle. We also identified the 5 palmitoylation sites of cysteine on cornifelin. Interestingly, overexpression of cornifelin in XB2 cell, a mouse teratoma keratinocyte cell line, resulted in reduced amount of cornifelin protein when each of 2 predicted palmitolyated-cysteines of C-terminal was mutated to serine. Our data suggested that 1. Cornifelin is a specific substrate of ZDHHC13. 2. Defective palmitoylation causes loss of cornifelin protein. 3. Because of unique localization of cornifelin in hair cuticle and in skin cornified layer, it is likely that absence of cornifelin in hair and skin of mice causes the defective hair cuticle structure and disruption of cornification which results in cyclic alopecia and hyperkeratosis.

Mouse Models: Effective Therapeutics Development and Comparative Genomics. *C.L. Smith, S.M. Bello, J.T. Eppig, Mouse Genome Informatics Staff.* Mouse Genome Informatics, Jackson Laboratory, Bar Harbor, ME.

Advances in genome sequencing technology have revolutionized human molecular genetics. Coupling sequence, phenotypes, pathogenicity variant calls, copy number variation, and other biological evidence with use of mouse model data can accelerate the identification and testing of therapeutic candidates. Examples include use of losartan to treat aortic aneurysms in Marfan syndrome and other heritable conditions, enzyme replacement therapy in Pompe Disease and ipilimumab, an antibody therapy that extends life in patients with metastatic melanoma. Other potential therapies developed using mouse model data and awaiting clinical trials include progesterone antagonist therapy (Lonaprisan) in Pelizaeus-Merzbacher hypomyelinating disease and C-type natriuretic peptide (CNP) analog (BMN 111) in the treatment of Achondroplasia.

Exome sequence data from patients with diseases with unknown etiology have provided several hundred new candidate genes for many diseases, and targeted re-sequencing technologies have provided gene variation information on dozens of these candidate genes in tens of thousands of individuals with high specificity and sensitivity. Comparison of gene, phenotype and genetic disease data provided by mouse models aids in the refinement of potential therapeutic targets. Mouse Genome Informatics (MGI, www.informatics.jax.org) provides data sets to correlate mouse phenotype with human clinical signs and symptoms. MGI catalogs all mouse mutant alleles with genotypes annotated to phenotype and OMIM disease model descriptions, and includes links to other supporting gene information including sequence, polymorphism, spatiotemporal expression, genomic location, biochemical function and process, sub-cellular topology, and mammalian gene homology. Standardization of nomenclature and application of bio-ontologies, including the Mammalian Phenotype (MP) Ontology, ensure that data are consistently annotated, making robust data mining possible. The model data at MGI aids in understanding biochemical pathways and pathological processes, and thus assists in determining the underlying mechanisms of human genetic disease. We will show MGI query results utilizing comparative human and mouse data that assist in finding novel candidate genes for human disease, and we will provide examples of therapeutic targets identified using data generated from mouse models. Supported by NIH grant HG000330.

2879M

Rapid Approaches in Functional Validation of Candidate Disease Genes Identified from Structural Rearrangements and Next-Generation Sequencing. *R. Greenlees[1,2], S. Yousoof[1,2], E. Semina[3], R.V. Jamieson[1,2].* 1) Eye Genetics Research Group, Children's Medical Research Institute, The Children's Hospital at Westmead, Save Sight Institute, Sydney, Australia; 2) Sydney Medical School, University of Sydney, Australia; 3) Medical College of Wisconsin, Milwaukee, US.

The application of next-generation sequencing (NGS) has provided unparalleled opportunities for gene discovery; however, there is a bottleneck in functional validation of the candidate disease genes. This study presents functional approaches that can be utilized to elucidate the role of candidates using the example of a novel candidate disease gene in eye disease. The candidate disease gene was identified in a patient presenting with anterior eye and lens abnormalities, and a de novo balanced chromosomal translocation disrupting the candidate disease gene. NGS in an extended cohort of patients with genetic eye disease has identified other patients with likely pathogenic variants in this gene. The candidate disease gene contains domains with predicted roles in cell adhesion. 2-dimensional epithelial cell assays showed colocalisation of the candidate with markers of adherens and tight junction proteins, as well as cytoskeletal filamentous actin (F-actin). In another patient with anterior segment eye disease, NGS led to a predicted pathogenic missense variant in this gene, and transfection of a construct with this variant led to abnormal F-actin localisation in the 2D assay. A 3-dimensional assay using Caco2 cells resulted in formation of epithelial cysts and shRNA knockdown of the candidate disease gene resulted in abnormal cysts with multilayering and aberrant expression of polarity markers. Animal models, including zebrafish and mouse, were utilised to investigate the function of the candidate disease gene in vivo. Decreased expression of the candidate disease gene in both these models produced abnormal lens development. The knockout mice exhibited a cataract phenotype and demonstrated abnormalities in the expression of cell adhesion and polarity markers at both embryonic and postnatal ages. The cell-based assays we have utilised provide a rapid, inexpensive model system for functional validation of novel candidate disease genes and variants affecting the lens, identified from NGS discovery projects. The animal-based approaches have provided more detailed mechanistic understanding of the role of this gene in epithelial morphogenesis.

Natural genetic modifiers of autosomal dominant retinitis pigmentosa and ER stress. *C.Y. Chow, M.F. Wolfner, A.G. Clark.* Dept Molec Biol & Gen, Cornell Univ, Ithaca, NY.

Retinitis pigmentosa (RP) is a hereditary disease characterized by progressive loss of vision due to degeneration of rods and cones in the retina. Autosomal dominant retinitis pigmentosa (ADRP) makes up 30-40% of all RP cases. Dominant mutations in the *rhodopsin* gene (*RHO*) comprise 25% of all ADRP cases and represent the most common cause of RP. Dominant mutations in the *Drosophila melanogaster* ortholog of *RHO*, *Rh1* (or *ninE*), provide an important model for dissecting the pathophysiology of ADRP. The $Rh1^{G69D}$ mutation in *Drosophila* closely resembles many human mutations in *RHO*. This mutation results in a misfolded Rh1 protein that is retained in the endoplasmic reticulum (ER), and induces the ER stress response, leading to apoptotic cell death and retinal degeneration. Previous studies demonstrated that mutations in genes in the ER stress and apoptosis pathways can alter the phenotypic presentation of $Rh1^{G69D}$. However, these previous genetic screens relied entirely on loss-of-function (LOF) mutations. In the human population, it is unlikely that severe LOF mutations contribute appreciably to variability in ADRP phenotypes. We take advantage of natural genetic variation in *Drosophila* to identify dominant modifiers of $Rh1^{G69D}$ induced retinal degeneration. We crossed the $Rh1^{G69D}$ mutation into ~200 strains from the *Drosophila* Genetic Reference Panel (DGRP). The DGRP is a collection of wild-derived *Drosophila* strains that harbor genetic polymorphisms present in a natural population. To assess the effect of DGRP backgrounds in modulating the phenotypic impact of $Rh1^{G69D}$, we measured eye size to quantify the extent of degeneration and apoptosis. We found that eye size varied by more than ten phenotypic standard deviations, presenting a more than two-fold difference in eye size due to background modifiers. This dramatic phenotype allowed us to perform an association study to identify natural genetic polymorphisms that enhance or suppress the $Rh1^{G69D}$ retinal degeneration. We used functional studies to validate the novel candidate genes found through this approach. The candidate polymorphisms and genes nominated from this study may more accurately identify potential human modifiers of ADRP, as they are drawn from existing natural variation. These results have important implications for identifying modifiers of the ER stress response and identifying loci that modify human ADRP.

***AIPL1* mutation in Persian cats defines a new model for Leber's Congential Amaurosis.** *B. Gandolfi[1], H. Alhaddad[2], R.A. Grahn[3], D.J. Maggs[4], H-C. Rah[5], N.C. Pedersen[6], L.A. Lyons[1].* 1) Department of Veterinary Medicine & Surgery, University of Missouri - Columbia, Columbia, MO; 2) College of Science, Kuwait University, Safat, Kuwait; 3) Veterinary Genetics Laboratory, School of Veterinary Medicine, University of California - Davis, Davis, CA USA; 4) Department of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California - Davis, Davis, CA USA; 5) College of Medicine, Chungbuk National University, Chongju, Chungbuk Province, South Korea; 6) Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California - Davis, Davis, CA USA.

Leber's Congential Amaurosis (LCA) is a rare inherited eye disease that has onset at birth or early in life. LCA Type 4 (LCA4, MIM: 604393) is caused by mutations in the gene, *aryl-hydrocarbon-interacting protein-like 1 (AIPL1)* and is considered the severe end of the spectrum for LCA. Newborns with *AIPL1* mutations generally have severely impaired vision or blindness, nystagmus, and an abnormal or flat electroretinogram. A variety of mutations in *AIPL1* have been identified to cause LCA in humans, presenting with varying ages of onset and degree of cone - rod dystrophies. Persian cats have been demonstrated to have an autosomal recessive progressive retinal atrophy (PRA) similar to LCA. Onset of photoreceptor loss is approximately 5 weeks of age with severe loss by 16 weeks of age. The cats often have divergent strabismus but do not suffer from bilateral ectasia with central thinning of the cornea as the cat ages. A series of association studies, including linkage analysis and transmission distortion tests suggested that the casual gene for Persian PRA was localized to cat chromosome E1, which is homologous to human chromosome 17. A partial analysis of *AIPL1*, did not readily identify a mutation, as the cat genome assembly was in complete for *AIPL1*. Whole genome sequence to 30x coverage of a trio of cats, including one carrier and affected parent and one affected offspring, was performed using 350 and 550 bp PCR-free libraries and HiSeq 100bp paired end reads. Variant calling was performed using Freebayes by Maverix Biomics. A stop gain was identified at in *AIPL1* at c.577C>T producing a p.Arg193*, as predicted by the human sequence and knocking out approximately 33% of the normal protein. Data from the sequencing reads and an improved cat genome assembly supported the confirmation of the mutation in the extended pedigree of Persians with PRA. Two mouse models of *AIPL1* deficiency include the Aipl1-hypomorphic (h/h) mouse (with reduced Aipl1 levels and a relatively slow degeneration), and the Aipl1-null mouse (with no functional Aipl1 and a very rapid retinal degeneration). Gene therapies using the sc-Y733F-AAV2/8 viral vector have shown rescue vision loss in the null mouse model. Cats have a longer life span than mice and can be evaluated for repeated and longer term gene and stem cell therapy trials. The cat can now become an efficient and effective model for gene and stem therapies for LCA.

2882M

Genome-wide linkage analysis in conjunction with whole exome sequencing for identification of deafness-causing genes in multi-generational families. *M. Grati[1], R. Mittal[1], J. Qing[1,3], DH. Xie[3], Q. Ma[1], LL. Du[1], Q. Liu[1,4], QJ. Wang[4], SM. Yang[4], P. Dai[4], Y. Feng[5], D. Yan[1], S. Masmoudi[6], S. Blanton[2], XZ. Liu[1,2].* 1) Departments of Otolaryngology-Head and Neck Surgery, University of Miami Miller School of Medicine, Miami, Florida 33136, USA; 2) Dr. John T. Macdonald, Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL 33136, USA; 3) Department of Otolaryngology- Head and Neck surgery, Institute of Otology, the Second Xiangya Hospital, Central South University, Changsha, Hunan, 410011, China; 4) Department of Otolaryngology, Head and Neck Surgery, Chinese PLA, Beijing, 100853, China; 5) Department of Otolaryngology, Xiangya Hospital, Central South University, Changsha, Hunan, 410008, China; 6) Microorganisms and Biomolecules Laboratory, Centre of Biotechnology of Sfax, Sfax University, Sfax, Tunisia.

Hearing loss (HL) is the most common sensory defect, affecting 1 in every 500 newborns around the world which half of it is due to genetic causes. Nonsyndromic HL (NSHL) accounts for more than 70% of all hereditary HL. Gene isolation for NSHL has been successful in isolated populations and consanguineous families. However, even after the gene has been localized to a region on a chromosome, the process of positional cloning by Sanger sequencing to analyze each selected gene in the linked interval, is costly and time consuming and can be impractical, in the case of large candidate intervals. Now whole exome sequencing (WES) offers a valuable tool for the many challenges in the identification of mutations in heterogenic diseases such as deafness. In this study we report the genome-wide linkage in conjunction with WES analyses of a collection of 14 multi-generational families including 10 Chinese families with autosomal dominant NSHL and 4 consanguineous Tunisian families with autosomal recessive NSHL for finding deafness causative genes. The SureSelect human all exon 50Mb kit (Agilent Technologies) and the Hisq2000 instrument (Illumina) were used for WES and the Genomes Management Application (GEMapp; (https://secureforms.med.miami.edu/hihg/gem-app) was applied for data filtering. Computational functional prediction algorithms and conservation scores were also applied to evaluate the possible impact on protein function of the detected variations. By linkage analysis, we determined the chromosomal location of the disease to prioritize candidate genes for mutation screening. On average, 97% of RefSeq exons were captured and approximately, each exome in the 14 families had 97%, 85% and 70% of mappable bases of the Gencode defined exome represented by coverage of at least 2, 10 and 20 reads, respectively. By our filtering strategy under the autosomal dominant or recessive model, we have rapidly identified novel genes with homozygous or heterozygous missense variants common to affected siblings subjected to WES. Co-segregation of the variants with the disease phenotype is validated using Sanger sequencing in each family and In vitro studies to establish the pathogenetic nature of the variants are being performed. Our study shows that combination of genome wide linkage analysis with WES is a powerful strategy for identification of causative mutations in genetically heterogeneous condition such as deafness.

***ILDR1*: Novel mutation and a rare cause of congenital deafness in the Saudi Arabian population.** *K. Ramzan[1], K. Taibah[2], A. Tahir[1], N. Al-Tassan[1], A. Berhan[1], A. Khater[2], S. Al-Hazzaa[3], M. Al-Owain[4], F. Imtiaz[1].* 1) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Riyadh, Saudi Arabia; 2) ENT Medical Centre, Riyadh 11333, Saudi Arabia; 3) Department of Ophthalmology, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 4) Department of Medical Genetics, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Hearing impairment is the common human sensorineural disorder and is a genetically heterogeneous phenotype for which more than 100 genomic loci have been mapped so far. *ILDR1* located on chromosome 3q13.33, encodes a putative transmembrane receptor containing an immunoglobulin-like domain. We used a combination of autozygosity mapping and candidate gene sequencing to identify a novel mutation in *ILDR1*, as a causative gene for autosomal-recessive non-syndromic hearing loss (arNSHL) in a consanguineous Saudi family with three affected children. Autozygosity mapping identified a shared region between the affected individuals encompassing *ILDR1* on chromosome 3q13.12-3q22.1. Sequencing revealed homozygous 9 base pair duplication, resulting in an in-frame duplication of three amino acids p.(Asn109_Pro111dup). The mutation was segregating with the disease phenotype and is predicted to be pathogenic by SIFT and PROVEAN. The identified mutation is located in the immunoglobulin-type domain of the ILDR1 protein. In silico analysis using I-TASSER server and PyMOL offers the first predictions on the structural and functional consequences of this mutation. To our knowledge, this is the first ILDR1 mutation identified in a Saudi family. Identification of *ILDR1* mutation in only one of 100 Saudi familial and sporadic individuals with hearing loss suggests that this mutation is unique to this family and that *ILDR1* should be considered as a rare cause of congenital deafness among Saudi Arabian population. Our data also confirms the evidence for *ILDR1* allelic heterogeneity and expands the number of familial arNSHL-associated *ILDR1* gene mutations.

2884S

Homozygosity mapping of families with autosomal recessive intellectual disability and examination of WWOX, GFRA3, and PTBP1 genes. *A. Alkhateeb[1,2], S. Aburahma[2], W. Habbab[1].* 1) Qatar Biomedical Research Institute, Doha, Qatar; 2) Jordan University of Science and Technology, Irbid, Jordan.

Intellectual disability is a relatively common disorder affecting all populations. In Arab countries, where consanguinity has a high prevalence, there is an increase in autosomal recessive intellectual disability. We tried to identify the genetic causes of intellectual disability in four consanguineous local Arab families. Families were recruited in the study after giving informed consent and obtaining institutional review board approval. All families had multiple affecteds, at least one of the affecteds was a female. Samples were genotyped by high-density HumanOmniExpress (700K, Illumina Inc). Genotypes were analyzed by HomozygosityMapper and multiple regions of homozygosity were found in the four families. No copy number variants were found. A single overlap between two families harbored WWOX (WW domain-containing oxidoreductase) gene. Woxx was found previously to be mutated in mice with seizures and epilepsy and the two families had seizures and epilepsy as part of their phenotype. Sequencing WWOX gene detected three commons SNPs with no indication of pathogenicity. In the third family, two other candidate genes (GFRA3 and PTBP1) localized within the homozygosity interval were sequenced; no variants were found in the coding region. In conclusion, we recruited four local consanguineous families with multiple affecteds of intellectual disability. Those families showed different homozygosity intervals illustrating the heterogeneity of the phenotype. We examined the candidacy of WWOX, GFRA3, and PTPP1 genes within the homozygosity intervals but no pathologic variants were found. We are now in the process of doing whole exome sequencing for one patient of each family.

2885M

Santos syndrome is caused by homozygous mutation in *WNT7A*. *L.U. Alves[1], S. Santos[2], R.S. Thiele-Aguiar[1], P.A. Otto[1], R.C. Mingroni-Netto[1].* 1) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, São Paulo, SP, Brazil; 2) Departamento de Biologia, Universidade Estadual da Paraíba, Campina Grande, PB, Brazil.

Santos et al. (Am J Med Genet 2008) described a new syndrome in six relatives living in a remote area in Northeastern Brazil. This syndrome is characterized by fibular agenesis/hypoplasia, hypoplastic femora and grossly malformed/deformed clubfeet with severe oligodactyly, upper limbs with severe ungual hypoplasia/anonychia sometimes associated with mild bractactyly and occasionally pre-axial polydactyly. This syndrome, named as "Santos syndrome" (OMIM 613005), was classified as a distinct syndrome from other previously described conditions exhibiting fibular agenesis/hypoplasia. An autosomal dominant inheritance model with incomplete penetrance was suggested to be more likely by Santos et al. (2008), but autosomal recessive inheritance was not discharged. Linkage analysis was performed based on results of genotyping by SNP-array (500 K - Illumina/Agilent) in samples from the six affected individuals. After multiple point LOD score calculations, two candidate regions on chromosome 3 were found to be statistically significant under the dominant (k=0,324) and recessive model hypothesis, in 3p26.1-p25.2 and in 3p13-q12.3. The maximum values of LOD score calculated under recessive model hypothesis were 2,856 and 3,235 for these two regions, respectively. Under the dominant model, positive LOD scores were observed in the same regions, but with smaller values than in the recessive model. The best candidate gene in the mapped regions was *WNT7A*, in which homozygous mutations had already been associated with two other limb defect syndromes (Fuhrmann syndrome, #228930 and AARRS, #276820). Sequencing of *WNT7A* revealed a novel homozygous c.934G>A (p.Gly312Ser) mutation, in five of six affected individuals; the remaining affected individual in heterozygous as to the mutation, and his phenotype is accordingly much less severe than his relatives. The glycine 312 at WNT7A protein is highly conserved (Uniprot) and the mutation was predicted to be probably damaging with score of 1,0 by PolyPhen-2. Thus, Santos syndrome can be explained by mutation in the *WNT7A* gene. We hypothesize that the affected heterozygous individual either has a different condition or his phenotype results from a mild clinical manifestation of Santos syndrome.

Mutation Screening in *PRPF31* in an Autosomal Dominant Retinitis Pigmentosa (ADRP) Family with Incomplete Penetrance. *S. Bhatia[1], S. Goyal[1], I.R. Singh[2], V. Vanita[1].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Dr. Daljit Singh Eye Hospital, Amritsar.

Purpose: The objective of present study was to perform mutation screening in *PRPF31* in a four generation ADRP family with incomplete penetrance. **Material and Methods:** Present study involved a large four generation ADRP family with incomplete penetrance which was diagnosed and collected at the Dr. Daljit Singh Eye Hospital, Amritsar with six affected individuals and few asymptomatic carriers. Asymptomatic carrier passed the disease to next generations. Age of onset of the disease in this family was by birth. Ophthalmic examinations included visual acuity testing, intraocular pressure, fundus testing alongwith fundus photography and Optical Coherence Tomography (OCT) after pupil dilation and Electroretinography (ERG) testing. We undertook mutation screening in the *PRPF31* gene that is well reported to be linked with ADRP with incomplete penetrance. Bi-directional sequence analysis of amplified products of all the 14 *PRPF31* exonic regions including splice sites, was performed in this family. **Results:** Mutation screening revealed identification of a novel missense mutation in one of the exonic region of *PRPF31* in this family. The identified missense mutation segregated completely with the disease in all the six affected members of this family as well as carriers of the disease. However, 19 tested unaffected members of this family and 100 control samples from the same population didn't carry the identified *PRPF31* substitution, excluding its possibility as a polymorphism. **Conclusions:** Present study identifies a previously unreported mutation in *PRPF31*. These findings further demonstrate the role of *PRPF31* in relation to ADRP with incomplete penetrance.

Molecular Genetic Analysis in an Autosomal Recessive Retinitis Pigmentosa Family of Indian origin. *S. Goyal, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: Present study aimed to identify underlying genetic defect in a nonsyndromal retinitis pigmentosa family (arRP) of Indian origin by whole genome homozygosity mapping. **Material and Methods:** It was a large 4 generation arRP family with 3 affected individuals and their parents being first cousins. Age of onset of the disease varied from 2 to 17 years. Ophthalmic examinations that included visual acuity, intra ocular pressure testing, electroretinography (ERG), ocular coherence tomography (OCT), fundus testing and fundus photography after pupil dilation, confirmed status of 3 individuals being affected by non-syndromic typical RP. Whole genome homozygosity mapping was conducted on 7 members (3 affected and 4 unaffected) using 8-sample HumanOmniExome Beadchip, consisting of >2,40,000 functional exonic markers. Genotyping data was subsequently used to identify the identical homozygous regions present in affected individuals using the online homozygosity mapping tool Homozygosity Mapper. Further, mutation screening in candidate genes at mapped homozygous region was done by bi-directional sequence analysis of the amplified products on an automated DNA sequencer. Sequences were assembled with SeqA6 sequencing analysis software (ver.6.0) and analyzed. **Results:** The homozygous region at 14q31.3 was identified that harbored the *SPATA7* and Tetracopeptide domain 8 gene (*TTC8*). Sequencing of all the coding regions of *SPATA7* indicated c.913-23T>G an already known SNP in all the 3 affected members as well as unaffected members of the family. However, mutation screening in all the 15 coding exonic regions including splice donor and acceptor sites of *TTC8* revealed a novel missense substitution. This novel substitution segregated in all the three tested affected members in homozygous form whereas unaffected members of this family were either heterozygous or homozygous for the wild-type allele. Further, 50 tested control samples (100 chromosomes) from the same population did not carry the identified substitution, excluding its possibility as a polymorphism. **Conclusion:** We identified a novel disease-linked missense mutation in *TTC8* in an arRP family of India origin with nonsyndromic RP. *TTC8* is previously reported to be linked with Bardet-Biedl syndrome (BBS) as well as with nonsyndromic RP. Our findings thus further expand the mutation spectrum of *TTC8* and inherent genetic and phenotypic heterogeneity for arRP.

Achromatopsia Genetic Determinants in Palestinian Families. *H. Shahin[1], F. Sheibat[1], Y. Ashhab[2].* 1) Dept Life Sci, Bethlehem Univ, Bethlehem, Palestinian Territory; 2) Biotechnology Research Center, Palestinian Polytechnic University, Hebron, Palestine.

Achromatopsia is a rare autosomal recessive disorder that leads to color blindness, and can include photophobia, nystagmus, cataracts, reduced visual acuity and eccentric fixation. Achromatopsia can result from mutations in any of four genes: CNGB3, CNGA3, GNAT2, and PDE6C. The purpose of our study was to discover the genetic causes in consanguineous Palestinian families with achromatopsia. In four multiply affected families, where affected individuals had complete color blindness, reduced vision, photophobia and nystagmus, we first tested linkage to each of the four known genes, then fully screened any linked gene by Sanger sequencing. The first family evaluated includes 7 individuals with achromatopsia and 11 unaffected sibs from 3 generations. Parents of the affected individuals are members of the same extended kindred. CNGA3, which codes for the cyclic nucleotide-gated cation channel alpha-3 cone photoreceptor, is most likely responsible for achromatopsia in this family. Markers flanking CNGA3 were homozygous in affected family members. Sequencing of all 8 coding exons of CNGA3 revealed an in-frame 3 bp deletion at chr2:99,012,573-99,012,576 delATC, resulting in CNGA3 c.1357delATC (p.Ile312del). Deletion of isoleucine at residue 312 is predicted by bioinformatics tools to perturb the transmembrane structure of this photoreceptor. Genotyping this mutation in the four families revealed that all 17 affected family members were homozygous for the deletion and all 25 unaffected family members tested were either heterozygous or wildtype at this site. Multiple mutations in CNGA3, including single amino acid deletions, have been identified in persons with achromatopsia in the Middle East and elsewhere.

2889T

Mutations in ALDH1A3, FOXE3 and VSX2 cause ocular abnormalities in consanguineous Pakistani families. *E. Ullah[1,2], MA. Saqib[2], N. Shah[2], S. Sajid[2], R. Lao[3], E. Wan[3], PL. Tang[3], P. Kwok[3], M. Ansar[2], A. Slavotinek[1].* 1) Department of Pediatrics, University of California San Francisco, San Francisco, CA; 2) Department of Biochemistry, Quaid-i-Azam University, Islamabad, Pakistan; 3) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA.

Anophthalmia/microphthalmia (A/M) is a genetically heterogeneous birth defect for which the etiology remains poorly understood, with less than 50% patients receiving a molecular genetic diagnosis. We hypothesized that exome sequencing in A/M patients would be an efficient method to provide data to find novel candidate genes. We have collected 6 families with A/M but without any other phenotypic abnormalities from Pakistan. All families had multiple affected members and evidence of consanguinity, suggestive of autosomal recessive (AR) inheritance. We therefore performed Sanger sequencing to exclude mutations in known A/M genes with AR inheritance (ALDH1A3, RAX, VSX2, FOXE3) and two genes with autosomal dominant (AD) inheritance (SOX2, OTX2). In the first family with non-syndromic bilateral anophthalmia, we found a novel frameshift mutation c.1310_1311delAT, p.Tyr437Trpfs*44 in ALDH1A3, which segregates in the family with disease phenotype. The Mutation Taster predicted this mutation as disease causing. In a second family with non-syndromic bilateral anophthalmia, we found a nonsense mutation c.598C>T, p.Arg200* in VSX2, that has been published in a family with bilateral anophthalmia in the medical literature. In a third family with bilateral microphthalmia, corneal opacity and anterior segment dysgenesis, we found a novel missense mutation c.289A>G, p.Ile97Val in FOXE3. This mutation is predicted as disease causing mutation by SIFT, PolyPhen-2 and Mutation Taster. In a fourth family with bilateral microphthalmia, corneal opacity and anterior segment dysgenesis we found a frameshift mutation c.21_24delGGAT, p.Met7Ilefs*216 in FOXE3. This mutation has previously been reported in a Pakistani family with bilateral microphthalmia, sclerocornea, corneal opacity, buphthalmosis and primary aphakia. The remaining two families were negative for the aforementioned disease genes and therefore were subjected to whole exome sequencing. We selected several autosomal recessive sequence variants as potential candidates that were predicted to be deleterious after exome data analysis by Ingenuity Variant Analysis. Although none of the candidate sequence variants segregated with the disease phenotype, we are currently analyzing whole exome data of both families to identify disease causing variant.

2890S

Two novel mutations in *ABCG5* and *ABCG8* genes in a Mexican family with sitosterolemia. *A. COLIMA[1, 2], E. WONG[3, 4], M. MAGAÑA[1].* 1) LABORATORIO DE BIOQUIMICA I, DIVISION DE GENETICA, CIBO, IMSS, guadalajara, JA., Mexico; 2) DOCTORADO EN GENETICA, CENTRO UNIVERSITARIO DE CIENCIAS DE LA SALUD, UNIVERSIDAD DE GUADALAJARA; 3) HOSPITAL GENERAL DE TEPIC; 4) UNIVERSIDAD AUTONOMA DE NAYARIT.

Sitosterolemia (STSL[MIM 210250]) is an autosomal recessive inherited disorder characterized by enhanced intestinal absorption of vegetal sterols and cholesterol and a slow removal of them through the liver. Clinical features include xanthomas, arthralgias, arthritis, thrombocytopenia, accelerated atherosclerosis and premature coronary heart disease. Sitosterolemia is caused by mutations in *ABCG5* and *ABCG8* genes. We studied a 12 years old girl from Nayarit, Mexico with biochemical and clinical characteristics of sitosterolemia. She showed slightly high total cholesterol values (295mg/dL), levels extremely high of sitosterol 681 µg/ml (normal range: 2.16±2.20 µg/ml) and campesterol 324 µg/ml (normal range: 3.09±1.65 µg/ml). She also had soft lumps on elbows and knees, thickening of the Achilles tendon and thrombocytopenia. Her treatment consisted of pravastatin (40 mg) and cholestyramine. One of the two patient's brothers had thrombocytopenia and high values of sitosterol (192µg/ml) and campesterol (125µg/ml). DNA was obtained with the CTAB-DTAB method for a molecular analysis. The primer pairs to PCR were design using the Oligo 6 software. Mutational screening of the *ABCG5* and *ABCG8* genes was performed by direct sequencing using an ABI PRISM310 genetic analyzer. . In *ABCG5* gene was detected a heterozygous mutation c.1523 delC, rendering an amino acid change H510T and L511X, resulting in a truncated protein. This mutation was also present in the mother and in the two brothers of the patient. In addition, deletion of exon 2 of the *ABCG8* gene in the index case and in her mildly affected brother was detected, in homozygous state. We found no information in the literature about the two mutations observed so that they could be considered as new mutations related to sitosterolemia.

2891M

Identification of hemizygous loss-of-function mutations in *OFD1* in two unrelated male patients with a clinical phenotype of primary ciliary dyskinesia (PCD). *W.B. Hannah[1,2], A.S. Rali[1], S. Strausbaugh[1,3], B. Gaston[3], M. Rosenfeld[4], W.E. Wolf[5], M.R. Knowles[5], M.A. Zariwala[6].* 1) Department Internal Medicine, University Hospitals Case Medical Center, Cleveland, OH; 2) Department of Genetics, University Hospitals Case Medical Center, Cleveland, OH; 3) Department of Pediatrics, University Hospitals Case Medical Center, Cleveland, OH; 4) Seattle Children's Hospital, School of Medicine, University of Washington, Seattle, WA; 5) Department of Medicine, University of North Carolina School of Medicine, Chapel Hill, NC; 6) Department of Pathology & Laboratory Medicine, University of North Carolina School of Medicine, Chapel Hill, NC.

This report describes two male patients with hemizygous *OFD1* variants and typical symptoms of primary ciliary dyskinesia (PCD). PCD is a rare, genetically heterogeneous, usually recessive disorder characterized by ciliary dysfunction and sino-pulmonary disease, otitis media, bronchiectasis, situs abnormalities, and male infertility. Rarely, PCD can be present in the setting of other syndromes such as X-linked mental retardation (XLMR). Usually, mutations in *OFD1* are observed in patients presenting with X-linked oral-facial-digital type 1 syndrome; however, in one family an *OFD1* mutation has been reported in male subjects presenting with recurrent respiratory tract infections, macrocephaly, intellectual disability, and ciliary dysfunction (PMID# 16783569). We outline the clinical presentation and genetic profile of two male individuals with *OFD1* variants and concurrent PCD symptoms.

Case 1 was a 32 year old male with chronic cough, sinus disease, bronchitis/pneumonia, and bronchiectasis. His nasal nitric oxide was low (54.7nl/min versus ~300nl/min for unaffected control subjects), consistent with PCD. Nasal ciliary biopsy showed normal ultrastructure. Whole exome sequencing followed by the analysis of 30 genes associated with PCD (including *OFD1* and *RPGR*, mutations in which have been seen in PCD associated with other syndromes) revealed a hemizygous frameshift mutation (c.2868delT [p.Pro957Leufs*2]) in *OFD1* predicted to result in premature translation termination signal. Case 2 was a 30 year old male who presented with a history of recurrent sinusitis and pneumonias, bronchiectasis, intellectual delay, and polydactyly. His nasal ciliary biopsy showed normal ultrastructure. Whole exome sequencing revealed a hemizygous *OFD1* deletion (c.2789_2793del5 [p.Ile930Lysfs*8]) resulting in a frameshift followed by a premature stop codon.

In summary, mutations in *OFD1* were identified in two unrelated male subjects who presented with a phenotype that resembles PCD and in one case also presented with intellectual delay and polydactyly.

A Novel Homozygous LRP5 Splice-site Deletion Mutation Causes Syndromic Autosomal Recessive Familial Exudative Vitreoretinopathy. *V. Chini[1], Y. Al-Sarraj[1], MT. Trese[2], H. El-Shanti[1,3], M. Kambouris[1,4].* 1) Qatar Biomedical Research Institute, Medical Genetics Center, Doha, Qatar; 2) Associated Retinal Consultants, Royal Oak, MI, USA; 3) University of Iowa, Pediatrics, Iowa City, IA, USA; 4) Yale University School of Medicine, Genetics, New Haven, CT, USA.

A consanguineous Saudi Arabian family with two female siblings affected by an autosomal recessive condition resembling Familial Exudative Vitreoretinopathy [FEVR], but also with short stature, bone fragility with thin and wasted appearance was studied by homozygosity mapping and positional candidate gene screening to identify the offending gene and mutation. The gene was mapped to three possible homozygous genomic regions [[2q, 4q, 11q], as the family structure did not allow identification of a single interval with a significant LOD score. Mutations in three genes (FZD4, TSPAN12, NDP and LRP5) have been associated with FEVR. The LRP5 gene localizes within the 11q13.2 homozygosity interval in this family rendering it the positional candidate of choice. Screening by Sanger sequencing identified a novel homozygous one-base splice-site deletion mutation c.3236+1 delG in exon 14. LRP5 is a low-density lipoprotein receptor (LDLR) a transmembrane protein that binds and internalizes ligands in the process of receptor-mediated endocytosis. The cDNA encodes a 1,615-amino acid protein containing conserved modules including a putative signal peptide, four epidermal growth factor (EGF) repeats with associated spacer domains, three LDLR repeats, a single transmembrane-spanning domain, and a cytoplasmic domain. The extracellular domain contains 6 potential N-linked glycosylation sites. LRP5 has a unique organization of EGF and LDLR repeats compared to other LDLR family members and in addition to FEVR, mutations in the gene have been associated with Hyperostosis corticalis OMIM 144750; Osteopetrosis, autosomal dominant 1 OMIM 607634; Osteoporosis-pseudoglioma syndrome OMIM 259770; Osteosclerosis OMIM144750; van Buchem disease, type 2 OMIM 607636; Bone mineral density variability 1 OMIM 601884; Osteoporosis OMIM 166710. Only missense mutations and splice site substitutions in LRP5 have been associated with autosomal dominant and recessive FEVR. This is the first report of an autosomal recessive LRP5 splice-site deletion mutation causing a syndromic form of FEVR.

2893S

A Mutation in SORBS2 Actin filament Adapter, Cell Adhesion, Migration & Intracellular Signaling Protein Causes Autosomal Recessive Hand & Foot Malformation Syndrome. *H. El-Shanti[1,2], Y. Al-Sarraj[1], H. Shaath[1], F. Alshaban[1], RI. Thompson[1], V. Chini[1], M. Kambouris[1,3].* 1) Qatar Biomedical Research Institute, Medical Genetics Center, Doha, Qatar; 2) University of Iowa, Pediatrics, Iowa City, IA, USA; 3) Yale University School of Medicine, Genetics, New Haven CT, USA.

A consanguineous family of Qatari ethnicity with two male siblings, 24 and 6 year old, affected by possibly an autosomal recessive disorder of hand and foot malformations and dysmorphic facial features, was studied by homozygosity mapping and whole Exome Next Generation Sequencing [NGS] of the two affected siblings and one parent to identify the responsible gene and mutation. The right foot of the younger patient was split with preaxial polydactyly and the left foot showed syndactyly between the 3rd and 4th toes and the 5th and 6th toes with postaxial polydactyly. Both feet showed nail hypoplasia and malpositioned halluces. The hands showed scars of the removed postaxial polydactyly. In addition, there is ptosis, hypertelorism, thin and tented upper lip with a smooth filtrum. The older brother had similar facial features and similar hand and foot malformations. The offending gene was mapped to three possible genomic intervals [4q, 19p, 21q]. Comparative analyses of the NGS data for autosomal recessive as well as X-linked inheritance and data mining for damaging variants within the homozygosity intervals and the shared X-chromosome genomic regions identified a homozygous single nucleotide frame shift deletion mutation c.143delC / p.Pro48fs in the SORBS2 gene, at 4q35.1. The mutation co-segregates with the disease phenotype within the family and it is absent in 400 ethnically matched control chromosomes. SORBS2 [sorbin and SH3 domain containing 2] an 824 amino acid protein is involved in actin filament organization, cell adhesion, cell migration and intracellular signaling. It has three C-terminal SH3 domains and an N-terminal sorbin homology (SoHo) domain that interacts with lipid raft proteins. It functions as an adapter protein to assemble signaling complexes in stress fibers, acting as link between Abl family kinases and the actin cytoskeleton and it binds the synapse-associated protein 90 / postsynaptic density-95-associated protein (SAPAP). The frame shift deletion mutation is in exon 1 at amino acid 48 and results in incorporation of 18 erroneous amino acids before a stop codon is encountered. It affects one of the nine possible isoforms [isoform 6] as it is the only isoform containing exon 1. No data on SORBS2 isoform 6 expression or role during embryonic development exists but it appears the isoform is essential for normal fetal development. This is the first association of SORBS2 to a human malformation disease.

A Mutation in MYO1A Causes Autosomal Recessive Autism Spectrum Disease. *M. Kambouris[1,2], V. Ilyin[3], Y. Al-Sarraj[1], H. Shaath[1], F. Alshaban[1], M. Tolefat[4], V. Chini[1], H. El-Shanti[1,5].* 1) Qatar Biomedical Research Institute, Medical Genetics Center, Doha, Qatar; 2) Yale University School of Medicine, Genetics, New Haven, CT, USA; 3) Carnegie Mellon University-Qatar, Doha, Qatar; 4) Shafallah Center for Children with Special Needs; 5) University of Iowa, Pediatrics, Iowa City, IA, USA.

A consanguineous family of Pakistani ethnicity with two female siblings (22 and 19 years of age), affected by a possibly novel autosomal recessive disorder, was studied by homozygosity mapping and whole Exome Next Generation Sequencing [NGS] of the two affected siblings and one parent to identify the responsible gene and mutation. The disorder is marked by intellectual disability, speech and motor delay, congenital malformations and possibly autism spectrum disorder (ASD). The malformations include microcephaly, microphthalmia, micrognathia and arachnodactyly with hyperextensibility and persistent fetal pads in fingers and toes. The offending gene was mapped to five possible homozygous genomic regions [[6q, 12q, 17p, 20p, 22q], as the family structure did not allow identification of a single interval with a significant LOD score. Comparative analyses of the NGS data for autosomal recessive inheritance and data mining for damaging variants within the homozygosity intervals identified a damaging homozygous c.C1675T / p.R559C mutation in the MYO1A gene, at 12q13.3. The mutation co-segregates with the disease phenotype within the family, is absent in known polymorphism databases and in 400 ethnically matched control chromosomes. Myosins are molecular motors that, upon interaction with actin filaments, utilize energy from ATP hydrolysis to generate mechanical force. The N-terminal motor domain contains both ATP-binding and actin-binding sequences. Following the motor domain is a light-chain-binding 'neck' region containing 1-6 copies of a repeat element, the IQ motif that serves as a binding site for calmodulin and other members of the EF-hand superfamily of calcium-binding proteins. The C terminus has a distinct tail domain that serves in dimerization, membrane binding, protein binding, and/or enzymatic activities and targets each myosin to its particular subcellular location. Heterozygous mutations in MYO1A have been found in patients with sensorineural hearing loss, speculated to cause autosomal dominant sensorineural hearing loss but co-segregation to the phenotype has never been demonstrated. Two rare heterozygous MYO1A mutations [c.G2021A / p.G674D and one in the 3'UTR] have been found in patients with autism but their clinical significance is unknown. The association of MYO1A to autosomal recessive ASD without deafness in this family, elevates the importance of MYO1A both as causative and contributive gene for Autism Spectrum Disease.

2895T

Linkage Analysis and Gene Identification in Consanguineous Pakistani Families with Autosomal Recessive Retinal Dystrophy. *M. Ansar[1,2], K. Lee[1], RL. Santos-Cortez[1], E. Ullah[2], Z. Ravesh[2], MA. Saqib[2], X. Wang[1], JD. Smith[3], J. Shendure[3], MJ. Bamshad[3], DA. Nickerson[3], W. Ahmad[2], SM. Leal[1], University of Washington Center for Mendelian Genomics.* 1) Center for Statistical Genetics, Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Biochemistry, Faculty of Biological Sciences, Quaid-i-Azam University, Islamabad 45320, Pakistan; 3) Department of Genome Sciences, University of Washington, Seattle, Washington 98195, USA.

Retinal dystrophy constitutes a phenotypically and genetically heterogeneous group of inherited diseases. Retinal dystrophies can be grouped into different categories depending on age of onset, disease progression, additional clinical features and mode of inheritance. The clinical signs and symptoms of retinal dystrophies are complex and overlapping, which challenges clinicians to make accurate diagnoses. The Pakistani population provides an opportunity to document large families with multiple affected individuals and has been used to extensively study many inherited disorders in the last two decades. In this study, we performed homozygosity mapping, linkage analysis and DNA sequencing using samples from seven consanguineous Pakistani families with autosomal recessive retinal dystrophy. Seven multiplex autosomal recessive retinal dystrophy families were ascertained from different regions of Pakistan. DNA samples from these families were genotyped using 500,000 SNP markers which were analyzed using homozygosity mapping and linkage analysis. Two families are linked to regions containing known autosomal recessive retinal dystrophy genes; FAM161A and RDH12; one family mapped to a region with the autosomal dominant retinal dystrophy gene, PRCD; two families map to regions with syndromic genes e.g. CDH3 which include an eye phenotype and two families mapped to novel regions. For the FAM161A gene a novel variant c.782delA (p.Asp261ValfsX39) was found. No potentially pathogenic variants were identified in either PRCD or CDH3. One of the families for which the autosomal recessive retinal dystrophy locus is linked to a novel region, a DNA sample from a single affected family member underwent exome sequencing and a novel gene which segregates with the RD phenotype was identified on chromosome 1q. The variant was not found in 360 Pakistani control chromosomes. The identified gene was also screened in samples from 24 Pakistani probands with autosomal recessive retinal dystrophy, but no putatively causal variants were found. Functional studies and a search for additional families with a variant in the same gene are ongoing. The five families for which the causal variant has not been identified will undergo exome sequencing.

2896S

Genetic linkage analysis of familial PFAPA in Finland. *E. Einarsdottir[1], U. Lantto[2], J. Kere[1,3,4,5], M. Uhari[2], T. Tapiainen[2], P. Koivunen[2], M. Renko[2].* 1) Department of Biosciences and Nutrition, Karolinska Institute, SE-14183 Huddinge, Sweden; 2) Departments of Pediatrics and Otorhinolaryngology, Institute of Clinical Medicine, University of Oulu, FI-90014 Oulu, Finland; 3) Folkhälsan Institute of Genetics, Helsinki, Finland; 4) Haartman Institute, Medical Genetics, University of Helsinki, FI-00014 Helsinki, Finland; 5) Research Programs Unit, Molecular Neurology, University of Helsinki, FI-00014 Helsinki, Finland.

We report on six multi-case families from Finland with Periodic Fever, Aphthous Stomatitis, Pharyngitis, Adenitis Syndrome (PFAPA). PFAPA is characterized by recurrent spontaneous fevers lasting of up to a week, followed by 3-6 weeks of no apparent symptoms.

PFAPA has previously been considered mainly a sporadic disease, but we have identified six families from the Oulu region of Finland with 2-4 confirmed cases and available DNA samples. We performed a genome-wide linkage analysis of PFAPA in these families, assuming a highly penetrant recessive model and a very rare mutation. We followed up interesting linkage peaks through haplotype analysis and studying potential candidate genes in the regions of interest. We also looked for indications of shared founder risk haplotypes between the different families.

We found a linkage peak with a parametric lodscore of 2,811 (using all families), contributed to mainly by three of the families. This region contains a plausible candidate gene for PFAPA, involved in innate immunity, and we are currently searching this gene for possible causative mutations. We find no indications that previously described possible PFAPA genes might contribute to the disease in the Finnish population.

2897M

Haploinsufficiency of a novel gene on 3p26.1, SMDD1, cause autosomal-dominant dentin dysplasia type I. *F. Xiong[1], Y. Liu[2], Z. Ji[1], Z. Yu[1], L. Hu[1], Z. Liu[3], Z. Tian[4], Q. Qiu[1], D. Chen[5], L. Zhang[4], X. Shang[1], W. Zhang[6], H. Yuan[7], X. Xu[1].* 1) Department of Medical Genetics, Southern Medical University, Guangzhou, China; 2) Department of Prenatal Diagnosis Center, Dongguan Maternal and Child Health Hospital, Dongguan, Guangdong, China; 3) Department of Stomatology, Dongguan Donghua Hospital, Dongguan, Guangdong, China; 4) Department of Stomatology, Nanfang Hospital, Southern Medical University, Guangzhou, Guangdong, China; 5) Department of Stomatology, Fourth affiliated Hospital of Zhengzhou University, Zhengzhou, Henan, China; 6) Department of Cell Biology, School of Basic Medical Sciences, Southern Medical University, Guangzhou, Guangdong, China; 7) Institute of Otolaryngology, Chinese PLA General Hospital, Beijing, China.

The hereditary dentin defects, dentinogenesis imperfecta (DGI) and dentin dysplasia (DD) comprise a group of autosomal-dominant genetic conditions and the molecular basis of such dental disorders in all sub-groups except for DD Type I (DDI) is linked to mutations in dentin sialophospho-protein gene (DSPP). DDI shows an exclusive character in phenotypes featuring late-onset missing teeth with short dental roots and unknown genetic etiology, thus providing a useful model to unravel the mechanism for dentin formation involved in tooth development. Here we study the gene mapping and the molecular pathogenic mechanism of DDI. Using a cohort of a large Chinese family with 20 normal members and 14 DDI patients, we mapped the gene locus responsible for DDI to 3p26.2-3p24.3 by combining use of whole genome-wide SNP array and STR linkage analysis. We further identified a novel missense mutation, c.353 C>A (P118Q) in SMDD1 gene on 3p26.1 through targeted sequencing of 125 candidate genes by capture-based next-generation sequencing, and followed by Sanger sequencing and co-segregation analysis for confirmation. We showed that the mutant P118Q in dental pulb stem cells expressed at 50% of wild-type levels with exhibiting haploinsufficiency. In vivo zebrafish functional assay of a homology of human SMDD1, we determined that missing teeth similar to that of the index case phenotypes were replicated in the RNAi knock-down zebrafish and could be partially rescued by injection of normal human SMDD1 mRNA to the mutant zebrafish. We also observed that SMDD1 depletion in the zebrafish negatively regulates the expression of two major genes (bmp2 and pitx2) involved in odontogenesis. In addition, we generated the P118Q mutant knock-in transgenic (TG) mice and investigated the role of the P118Q mutation in heterozygous and homozygous TG mice. We found that dentin defects were radiographically evident in all teeth with homozygotes, to show incomplete obliteration of the nonmineralized pulp in TG mice, consistent with clinical characteristics in those patients with DDI. Moreover, high-resolution radiography, micro-computed tomography and scanning electron microscopy revealed a reduced zone of mineralized dentin with anomalies in the number and organization of dentinal tubules in TG mice. Our observations demonstrate that haploinsufficiency of SMDD1 disrupts dental formation and that this novel gene, together with other odontogenesis genes are involved in tooth development.

2898T

Mutations in *CCNO* identified in patients with a clinical phenotype consistent with primary ciliary dyskinesia (PCD) and defective mucociliary clearance reflecting reduced motile cilia generation. *M.A. Zariwala[1], M.W. Leigh[2], J.E. Pittman[2, 5], J.L. Carson[2], M.J. Hazucha[3], J. Wallmeier[4], N.T. Loges[4], H. Olbrich[4], H. Omran[4], M.R. Knowles[3].* 1) Department of Pathology and Laboratory Medicine, University of North Carolina School of Medicine, Chapel Hill, NC, USA; 2) Department of Pediatrics, University of North Carolina School of Medicine, Chapel Hill, NC, USA; 3) Department of Medicine, University of North Carolina School of Medicine, Chapel Hill, NC, USA; 4) Department of General Pediatrics and Adolescent Medicine, University Hospital Muenster, Muenster, Germany; 5) Pediatric Pulmonology, Washington University School of Medicine, St. Louis, MO, USA.

Primary ciliary dyskinesia (PCD) is clinically manifested by oto-sino-pulmonary symptoms, situs abnormalities and male infertility. It is a rare, recessive, genetically heterogeneous disorder caused by defective ciliary structure, function and/or biogenesis. Diagnosis has traditionally relied on documenting defective ciliary motility or ciliary ultrastructure, either using electron microscopy, or immunofluorescence analysis. Not all subjects with PCD present with defective cilia; thus, defining biallelic mutations in one of the 30 known or novel cilia-associated genes has become a useful diagnostic approach in challenging cases. A subset of patients with a clinical phenotype consistent with PCD have reduced generation of multiple motile cilia (RGMC). Indeed, mutations in *CCNO* that affect centriole amplification and migration have been recently reported in such cohort (PMID# 24747639). We have accrued four unrelated families with a clinical phenotype consistent with PCD and low levels of nasal nitric oxide (an adjunct marker for PCD) and ciliary "aplasia and/or oligoplasia" on multiple nasal/bronchial biopsies. Mutation screening of all three coding exons of *CCNO* revealed biallelic mutations in all four unrelated affected probands. Segregation analysis revealed that mutations were inherited in trans. Briefly, an affected male (UNC-79) harbored a novel homozygous frameshift mutation (c.875_897del23 [p.Asp292Alafs*71]). In another family (UNC-178), an affected female presented with a novel, evolutionarily conserved, missense variant (c.851C>T [p.Ala284Val]) and a previously known frameshift mutation (c.248_252dupTGCCC [p.Gly85Cysfs*11]). An affected sib-pair (UNC-136) harbored a previously known homozygous frameshift mutation (c.248_252dupTGCCC [p.Gly85Cysfs*11]), and an affected identical twin-pair (UNC-468) harbored previously known compound heterozygous (c.248_252dupTGCCC [p.Gly85Cysfs*11]) and (c.258_262dupGGCCC [p.Gln88Argfs*8]) mutations. To conclude, mutations in *CCNO* appear to be a common cause of a clinical phenotype indistinguishable from PCD, reflecting RGMC. Large scale screening will be carried out in subjects suspected to suffer from PCD without a known genetic diagnosis to decipher the prevalence of *CCNO* in a large cohort. Identification of New Genes and Pathways for Rare Infantile Forms of Spinal Muscular Atrophy and Neuromuscular Disorders. *J.M. Hunter[1,2], C.D. Balak[1,2], J. Kiefer[2], M.E. Ahearn[1], G. Lambert[3], D. Duggan[3], B. Wirth[4], W. Tembe[5], C. Legendre[5], W. Liang[6], L. Cuyugan[6], J. McDonald[6], J. Adkins[6], A. Kudoglu[7], J. Corneveaux[7], M. Russell[7], M. Huentelman[7], D. Craig[7], J. Carpten[1], S.M. Bernes[8], J. Hall[9], L. Baumbach-Reardon[1,2].* 1) Integrated Cancer Genomics, TGen, Phoenix, AZ; 2) Pharmaceutical Genomics, TGen, Phoenix, AZ; 3) Genetic Basis of Human Disease, TGen, Phoenix, AZ; 4) Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany; 5) Center for Bioinfomatics, TGen, Phoenix, AZ; 6) Collaborative Sequencing Center, TGen, Phoenix, AZ; 7) Neurogenomics, TGen, Phoenix, AZ; 8) Division of Neurology, Phoenix Children's Hospital, Phoenix, Az; 9) Departments of Pediatrics and Medical Genetics, University of British Columbia, Vancouver, Canada.

Spinal muscular atrophy (SMA) (MIM# 600354) is the leading genetic cause of infantile death. Mutations in the SMN1 gene account for a large percentage of SMA. However, numerous cases with SMA or related disorders do not have mutations in SMN1. Our goal is to use next-generation sequencing to identify the genetic cause of undiagnosed cases of motor neuron disease and muscular dystrophies in infants and children. Our journey began many years ago with the study of a rare form of X-linked (XL) form of SMA. In 2008 Dr. Lisa Baumbach-Reardon's group discovered mutations in UBA1 as the cause of XL-SMA (MIM# 3018300). Since that discovery, we have developed a custom sequencing panel for all coding regions of UBA1. Using Ion-torrent sequencing we have screened 10 affected cases and 18 relatives in our cohort. As expected, UBA1 sequencing revealed common variants in each individual, but surprisingly no new disease associated variants were identified. The molecular etiology of disease in these cases has remained undiagnosed for many years. At TGen, we have now been able to performed whole exome sequencing on these individuals as well as numerous other cases. We are excited to report that in many of these cases we have identified novel probable pathogenic mutations in genes known to cause disease as well as in genes not previously associated with disease. We highlight results from four cases. First, a family with two affected boys revealed novel compound heterozygous deleterious CHRND mutations that cause a form of lethal congenital myasthenic syndrome (MIM# 100720). Second, a novel start loss M1V mutation in SCML2 (MIM# 300208) was detected in the proband and mother of a family with an X-linked history of fetal and neonatal deaths. SCML2 encodes a component of the polycomb transcriptional repressor complex, and has not been previously associated with any human disease. In a second large family with X-linked infantile deaths, we identified another novel missense mutation in SCML2 in obligate carriers. Lastly, we identified a novel de novo mutation in DYNC1H1 known to cause autosomal dominant SMA lower extremity predominance (SMA-LED MIM#158600). These results, along with identification of unique and interesting variants in other families, shed light on new mechanisms and pathways associated with SMA and related diseases. We are privileged to be part of the effort to translate next-generation sequencing into answers for these rare and devastating diseases.

2900M

GeneSEARCH - Diagnostic testing and a tool for research in the Iranian Population. *E.G. Ozkan[1], B. Chioza[2], J. Aragon-Martin[1], G. Harlalka[2], M. Patton[1], K. Everett[1], R. Sharifi[1].* 1) St. George's University of London, London, UK; 2) University of Exeter Medical School, Devon, UK.

The GeneSEARCH programme is a collaboration between Iranian research centres and St George's University of London. The aim is to identify genetic causes of inherited diseases in the Iranian communities. Here we report the identification of one previously reported and three novel mutations in genes causing retinopathies in consanguineous Iranian families. Homozygosity mapping was performed using data generated from the Cyto12 SNP array pertaining to affected individuals from each family. Candidate genes were screened using massively parallel sequencing and/or Sanger sequencing. Validation of putative causal variants and segregation analysis was performed using Sanger sequencing. All described variants segregated with disease. In silico tools demonstrated that all segregating variants were likely to be damaging. All described variants were absent from 100 ethnically matched controls. Family 1: a 3 generation family with 4 individuals presenting with retinitis pigmentosa (RP) and polydactyly. The largest region of homozygosity (ROH) was on chromosome 2q23.3-2q31.1 and contains the Bardet-Biedl syndrome (BBS [MIM 209900) gene, BBS5 (MIM 603650). RP and polydactyly are key diagnostic features of BBS. Screening of BBS5 identified a novel substitution in exon 5; c.382C>G (p.H128D). Family 2: a 6 generation family in which 3 males have been diagnosed with Leber Congenital Amaurosis (LCA [MIM 204000).The largest ROH was on chromosome 17p13. This region contains a known gene for LCA: GUCY2D (MIM 600179). Screening of this gene identified a novel variant in exon 12; c.2348T>C (p.L783P). Family 3: a 4 generation family with 7 individuals affected by RP. The largest ROH was on chromosome 1q31.3. This region contains a known gene for LCA: CRB1 (MIM 604210). Screening of this gene identified a novel frameshift mutation in exon 2 (c.361delC). Family 4: a 6 generation family with 18 individuals affected by RP. The largest ROH was on chromosome 15q23-q25.1. The segregating variant rs28937873 (c.932G>A, p.R311Q) in NR2E3 (MIM 604485) has been previously reported in a Jewish family with RP. GeneSearch is a unique opportunity to diagnose rare genetic disorders within the Iranian community. The initial aim of this work is diagnostic and will benefit families and the community for genetic and carrier testing. This study provides the first example of this work. Genetic diagnosis is a crucial component of treatment and counselling for heterogeneous disorders such as these.

***HIVEP2*: A New Causative Gene for Intellectual Disability?** *A.M. Zink[1,2], S. Srivastava[3,4], K. Cremer[1], M. Menzel[6], T. Wieland[7], M. Schuhbach[6], S. Biskup[6,8], M. Kreiß-Nachtsheim[1], S. Endele[9], D. Wieczorek[10], T.M. Strom[7], M. Zenker[5], J. Cohen[3], H. Engels[1], I. Schanze[5], S. Naidu[3,4].* 1) Institue of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life and Brain Center, Rheinische Friedrich-Wilhelms-University, Bonn, Germany; 3) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, Maryland, USA; 4) Departments of Neurology and Pediatrics, The Johns Hopkins Hospital, Baltimore, Maryland, USA; 5) Institute of Human Genetics, University Hospital Magdeburg, Magdeburg, Germany; 6) CeGaT GmbH, Tuebingen, Germany; 7) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 8) Hertie Institute for Clinical Brain Research, German Center for Neurodegenerative Diseases, Tuebingen, Germany; 9) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany; 10) Institute of Human Genetics, Universitätsklinikum Essen, Essen, Germany.

Intellectual disability (ID) has an estimated prevalence of 2-3%. Due to its extreme heterogeneity, the genetic basis of ID remains elusive in many cases. Recently, whole exome sequencing (WES) studies revealed that a large proportion of sporadic cases are caused by *de novo* gene mutations. Applying WES to ID patients at different centers, we identified three patients carrying *de novo* mutations in *HIVEP2* (human immunodeficiency virus type I enhancer binding protein 2). Two of the mutations are nonsense mutations and one is a 1 bp deletion resulting in a premature stop codon. In silico prediction programs (SIFT/ Mutation Taster) predict nonsense mediated mRNA decay as the consequence of all three mutations, pointing to a loss of function and haploinsufficiency as the common disease-causing mechanism of the three *HIVEP2* mutations. None of the three mutations was present in the Exome Variant Server or in 2500 in-house exomes. All three patients presented with moderate ID, muscular hypotonia, mild dysmorphic signs and variable mild structural brain anomalies. Growth parameters were in the normal range except for slight microcephaly at birth in one patient. Two of the patients presented with behavioral anomalies including hyperactivity and aggression. *HIVEP2*, also known as *Schnurri-2*, belongs to a family of zinc finger-containing transcriptional proteins involved in growth and development. Many of the genes regulated by *HIVEP2* are implicated in brain development, e.g. *SSTR-2*, *c-Myc* and several genes of the NF-κB pathway. *HIVEP2*- knockout mice have been shown to exhibit several behavioral features suggestive of schizophrenia such as working memory deficits, as well as increased anxiety and hyperactivity. Based on the genotype-phenotype correlation and the previously published functional data we propose *HIVEP2* as a novel causative ID gene.

2902S

DUX4 induces FRG2 expression by directly activating its promoter in facioscapulohumeral muscular dystrophy. *P.E. Thijssen[1], J. Balog[1], Z. Yao[2], T.P. Pham[1], R. Tawil[3], S.J. Tapscott[2], S.M. Van der Maarel[1].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, Washington, United States of America; 3) Neuromuscular Disease Unit, Department of Neurology, University of Rochester Medical Center, Rochester, New York, United States of America.

Facioscapulohumeral muscular dystrophy (FSHD) is the third most common muscular dystrophy and the major form is associated with a genetic contraction of the polymorphic D4Z4 macrosatellite repeat on chromosome 4q35. Several candidate genes have been proposed as pathogenic entities in FSHD, including *FRG2* located proximal to the D4Z4 macrosatellite repeat. For long it has been known that expression of *FRG2* is induced specifically in differentiating myoblast cultures derived from FSHD patients, which was explained by a position effect emanating from the contracted D4Z4 repeat array. However, a contribution of FRG2 upregulation to FSHD pathology was never shown and the function of FRG2 remains unclear at this time. More recently, sporadic activation of the *DUX4* retrogene, encoded within the D4Z4 unit, has emerged as the most prominent disease model. DUX4 is a double homeobox transcription factor and its expression has been shown to be toxic in myogenic cultures. We now show that FRG2 expression in FSHD derived differentiated myoblasts is a direct consequence of DUX4 protein activity. Overexpression of DUX4 in proliferating myoblasts and primary fibroblasts results in a steep upregulation of FRG2 transcription. Moreover, we identified DUX4 binding at the *FRG2* promoter by chromatin immunoprecipitation followed by deep sequencing. Next, we confirmed the transactivation effect of DUX4 on the *FRG2* promoter by luciferase reporter assays. Activation of luciferase was dependent on DUX4 expression and the presence of the DUX4 consensus binding sites identified in the *FRG2* promoter. In conclusion we show that the FSHD specific upregulation of *FRG2* can be explained by the protein activity of DUX4, confirming its central role in FSHD pathogenesis.

2903M

Expansion of the spectrum of nuclear envelopathies: mutation in TOR1AIP1 associated with muscular dystrophy. *P. Dincer[1], G. Kayman-Kurekci[1], B. Talim[1], P. Korkusuz[1], N. Sayar[2], T. Sarioglu[3], I. Oncel[1], P. Sharafi[1], H. Gundesli[1], B. Balci-Hayta[1], N. Purali[1], P. Serdaroglu-Oflazer[3], H. Topaloglu[1].* 1) Hacettepe University, Ankara, Turkey; 2) Bilkent University, Ankara, Turkey; 3) Istanbul University, Ankara, Turkey.

A consanguineous family with three individuals affected by a myopathic phenotype with joint contractures, proximal and distal weakness and atrophy with cardiomyopathy and respiratory involvement was analyzed by genome-wide homozygosity mapping using 250K NspI array. A single homozygous haplotype shared by the three affected individuals was detected. Homozygous c.186delG mutation in torsin A-interacting protein 1 (TOR1AIP1) gene encoding lamina-associated polypeptide 1B (LAP1B) was shown to cause a frameshift resulting in a premature stop codon (p.E62fsTer25). TOR1AIP1 mRNA level in the patient skeletal muscle was 5,88-fold lower than in the control sample. Expression of LAP1B protein was absent in the patient skeletal muscle fibres. Ultrastructural examination showed an intact sarcomeric organization but alterations of the nuclear envelope including nuclear fragmentation and degeneration, and altered chromatin condensation. LAP1B is an integral protein of the inner nuclear membrane that binds to A-type and B-type lamins, and is involved in the regulation of torsin A ATPase. Moreover, overexpression of luminal domain-like LAP1 (LULL1)-the endoplasmic reticulum-localized regulatory partner of torsin A-was overexpressed in the patient's muscle. This suggests a compensatory effect between LAP1 and LULL1. The absence of LAP1B in muscle might influence the structural and mechanical stability of the nuclear envelope due to the impaired binding to the nuclear lamina. The muscle-restricted phenotype underlies a critical role for LAP1B in striated muscle and this study expands the spectrum of nuclear envelopathy causing genes.

2904T

Association of IFRD1 gene polymorphisms with nasal polyposis in Cystic Fibrosis. *A. Baldan[1], F. Belpinati[1], A.R. Lo Presti[1], L. Xumerle[1], M.D. Bettin[1], C. Castellani[2], P.F. Pignatti[1], G. Malerba[1], C. Bombieri[1].* 1) Sec. of Biology and Genetics, Dpt of Life and Reproduction Sciences, University of Verona, Verona, Italy; 2) Veneto Regional CF Center, Verona Hospital, Verona, Italy.

Cystic fibrosis (CF), the most frequent autosomal recessive disease in the Caucasian population, is a lethal multi-system disorder caused by mutations in the CFTR gene. Severity of clinical manifestation, particularly the respiratory phenotype, is widely variable, even among patients with the same CFTR genotype or within the same family. This variability is only partially explained by allelic heterogeneity at the CFTR gene, therefore many genes have been investigated as possible CF phenotype modifier contributing to disease severity heterogeneity. Nasal polyposis (NP) is a manifestation of a chronic inflammatory disease of the upper nasal airways that affects 1-4% of the general population worldwide. In CF the prevalence of NP is reported between 6 to 48% of cases with no association with a particular CFTR gene mutation. Literature data reported the IFRD1 (Interferon-Related Developmental Regulator 1) gene as a possible modifier of cystic fibrosis lung disease severity (Nature 458:1039-42, 2009). The IFRD1 gene encodes for a histone-deacetylase-dependent transcriptional co-regulator, expressed during terminal neutrophil differentiation, that could act as CF phenotype modifier through the regulation of neutrophil effector function. In this study, we investigate a possible association with NP of three IFRD1-SNPs (rs7817, rs3807213, rs6968084), previously described in association with a more severe CF lung phenotype, in a cohort of 146 North-East Italian CF patients, diagnosed according to international criteria and clinically evaluated for respiratory and gastrointestinal parameters. An association study was performed by logistic regression analysis; a p value of less than 0.05 was considered to indicate statistical significance. All analysed IFRD1-SNPs were in Hardy-Weinberg equilibrium. No evidence of association between CFTR genotype and respiratory phenotype was observed. A logistic regression model showed a 4-fold higher probability of NP in patients with CT genotype (p=0.02), and a 7.3-fold higher in patients with TT genotype (p= 0.003) when compared to the homozygote wild-type CC patients for the SNP IFRD1-rs7817. In conclusion, these results show the association of IFRD1-rs7817 polymorphism with NP in CF. Further investigation may be accomplished to test IFRD1 polymorphism association in other population samples.

2905S

A missense mutation in hexokinase 1 (HK1) causes autosomal dominant retinitis pigmentosa (adRP). *S.P. Daiger[1,7], S.J. Bowne[1], L.S. Sullivan[1], D.C. Koboldt[2], D.G. Birch[3], D.K. Wheaton[3], S.H. Blanton[4], R.K. Koenekoop[5], C.F. Chakarova[6], R.S. Fulton[2], R.K. Wilson[2], G.M. Weinstock[2], C.A. Garcia[7], C.E. Avery[1], E.D. Cadena[1], R.A. Lewis[8].* 1) Human Genetics Center, Univ. of Texas Health Science Center, Houston, TX; 2) The Genome Institute, Washington Univ., St. Louis, MO; 3) The Retina Foundation of the Southwest, Dallas, TX; 4) Hussman Institute of Human Genomics, Univ. of Miami, Miami, FL; 5) McGill Ocular Genetics Laboratory, Depts of Paediatric Surgery, Human Genetics and Ophthalmology, McGill Univ. Health Center, Montreal, Quebec, Canada; 6) Institute of Ophthalmology, University College London, London, United Kingdom; 7) Dept. of Ophthalmology and Visual Sciences, Univ. of Texas Health Science Center, Houston,TX; 8) Depts of Ophthalmology and Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Whole-genome linkage mapping in a seven-generation family with autosomal dominant retinitis pigmentosa (adRP) identified a linkage region on chromosome 10q21.3-q22.1 with a maximum LOD score of 3.6 at 0% recombination. All known adRP genes and X-linked RP genes were excluded in the family by a combination of linkage exclusion, Sanger sequencing, and next-generation sequencing (NGS). Whole-exome NGS revealed a missense mutation in hexokinase 1, HK1 c.2539G>A, p.Glu847Lys, tracking with disease in all affected individuals. One severely-affected family member who was homozygous for this region by linkage analysis has two copies of the mutation. No other potential mutations were detected in the linkage region nor were any likely candidates identified elsewhere in the genome. Subsequent testing revealed the identical mutation in four additional, unrelated families with adRP, for a total of five mutations in 459 probands tested (1.1%). Taken together, the families have a combined maximum LOD score of over 8.0. No further instance of the mutation was found in publically-available databases or in control samples tested in our laboratory. Of the five families, three are from the Acadian population in Louisiana, one is French Canadian and one is Sicilian. Analysis of the affected chromosome in each family and in the homozygous individual revealed multiple haplotypes with a maximum possible overlap of 600 kb, suggesting either independent origins of the mutation or an ancient founder mutation. HK1 is a widely-expressed gene, with multiple, abundant retinal transcripts, coding for hexokinase 1. Hexokinase catalyzes phosphorylation of glucose to glucose-6-phospate, the first step in glycolysis. The Glu847Lys mutation is in a highly-conserved site, outside of the active site or known functional sites. Bioinformatic analysis of pathogenicity is inconclusive because of the large number of HK1 isoforms and homologs. Rare recessive null mutations in HK1 cause non-spherocytic hemolytic anemia, which was not observed in these families. However, a discrepancy between the phenotypes associated with dominant versus recessive mutations is common among inherited retinopathies. We conclude that a mutation, or mutations, in HK1 cause roughly 1% of adRP cases in these populations, revealing a novel retinal disease gene and possibly a common founder-effect mutation.

2906M

A novel disease-causing gene for Pelizaeus-Merzbacher disease. *M. Nafisinia[1], N. Sobreira[3], WA. Gold[1,2], L. Riley[1,2], R. Ouvrier[4,5], C. Boehm[3], J. Christodoulou[1,2,6].* 1) Genetic Metabolic Disorders Research Unit, Western Sydney Genetics Program, the Children's Hospital at Westmead, Sydney, NSW, Australia; 2) Discipline of Paediatrics & Child Health, Sydney Medical School, University of Sydney, Sydney, NSW, Australia; 3) Institute of Genetic Medicine, Johns Hopkins Univ School Med, Baltimore, MD, USA; 4) Neurosurgery, Children's Hospital at Westmead, Sydney, NSW, Australia; 5) Children's Hospital at Westmead, Sydney, NSW, Australia; 6) Discipline of Genetic Medicine, Sydney Medical School, University of Sydney, Sydney, NSW, Australia.

Background: Pelizaeus-Merzbacher disease (PMD) is a rare Mendelian disorder characterized by central nervous system hypomyelination. The disease is caused by mutations in several genes, which are associated with delay in motor abilities and intellectual function. Aim: To identify the genetic cause of disease in two siblings with a clinical picture of PMD but negative for mutations in the known PMD genes PLP1 and GJC2. Patients & Methods: Two sibs with a clinical diagnosis of PMD were born to non-consanguineous parents of Maltese background. The affected brother had motor and expressive delay, bilateral horizontal nystagmus, an action tremor, head titubation, an ataxic gait and cognitive impairment. When last examined at 17 years of age, he had normal muscle bulk with slightly reduced strength, brisk deep tendon reflexes, ankle clonus and upgoing plantar reflexes bilaterally. His brain MRI scan with fluid attenuated inversion recovery sequence confirmed a dys- or demyelinating process in the central and non-myelination in the peripheral white matter. His sister was less severely affected than her brother with mild nystagmus, ataxic gait and anxiety attacks. When last examined at age10, she had increased tone in her lower limbs, mild cerebellar signs, moderate cognitive impairment, truncal ataxia and pendular nystagmus. Whole exome sequencing (WES) was used to screen for likely pathogenic variants followed by western blotting, and temperature sensitivity and auxotrophic studies of patient fibroblasts to confirm pathogenicity. Results: WES uncovered a homozygous mutation in the arginyl-tRNA synthetase (RARS) gene (c.5A>G, p.Asp2Gly), which has recently been associated with a hypomyelination syndrome. Protein levels of RARS, and those of a binding partner, KARS (Lysyl-tRNA synthetase), were found to be significantly reduced by 80%; and 65%; respectively using western blotting of patient fibroblast extracts. As RARS is involved in protein synthesis where it attaches arginine to its cognate tRNA, patient cells were tested to determine their ability to function without this essential amino acid. Patient fibroblasts cultured in limited arginine at 30°C, showed a significant reduction ($p<0.001$) in viability compared to control cells indicating the inefficiency of protein synthesis in the patient cells. Conclusion: Here we provide evidence for a novel PMD-causing gene. Screening of a larger PMD cohort is in progress to further delineate the RARS phenotype.

2907T

Identification of a homozygous CLN5 mutation p.S312N in a family with adult-onset cerebellar ataxia. *A. Brusco[1,2], S. Nassani[3], Y. Guo[4], E. Giorgio[1], A. Calcia[1], X. Liu[5], E. Di Gregorio[2], S. Cavalieri[2], E. Pozzi[1], A. Brussino[1], Y. Xie[5], F. Wang[4], L. Tian[4], W. Chen[5], B. Nmezi[6], Q.S. Padiath[6], H. Jiang[5,7], A. Kyttala[8], N.R. Pizio[3], H. Hakonarson[4,9,10], C. Mancini[1].* 1) Department of Medical Sciences, University of Torino, Italy, Torino, Italy; 2) A.O. Città della Salute e della Scienza, S.C.D.U. The NCLs or Batten Diseases are a group of progressive neurodegenerative disorders characterized by rapid death of cortical neurons and intracellular accumulation of autofluorescent lipopigment material (lipofuscin) in the body's tissues. Fourteen genetically distinct human NCLs were identified. Clinically NCLs are characterized by a combination of cerebellar ataxia, visual impairment, and variable association of seizures, behavioral disturbances, and cognitive deterioration. CLN5 mutations (13q21.1-q32) are reported in severe autosomal recessive forms of variant Late Infantile Neuronal Ceroid Lipofuscinoses (vLINCL, OMIM*608102). The clinical course includes progressive intellectual and motor deterioration, seizures, and visual failure. Typical CLN5 forms have an onset between 4-7 yrs. Here, we describe two italian siblings affected by an adult form of ataxia, who presented with a homogeneous phenotype characterized by onset between 54-56 yrs, walk difficulties, dysarthria. Progressive cognitive decline associated to visual loss, ascribed to glaucoma, appeared only after few years of disease. Neurological evaluation at 61yrs. showed nystagmus and head/truncal tremor, and no sensory-motor neuropathy. MRI showed severe cerebellar atrophy and mild cortical atrophy of both hemispheres. Exome sequencing identified a homozygous c.935G>A (p.S312N) transition in CLN5 gene, never reported before nor present in Exome variant Server (http://evs.gs.washington.edu/). Alignment of orthologous sequences and in silico softwares predict the substitution Ser>Asn to be disease causing. We studied the subcellular localization of the mutated protein, transfecting the CLN5*S312N-pCMV plasmid in Hek293 cells: as reported for vLINCL mutations, p.S312N seemed to affect trafficking and maturation of the CLN5 protein, resulting in its accumulation in ER compartment and indicating that misfolding may be the major cause for its retention. We speculate this mutation acts as mild or modifier genes/epigenetics factors may contribute to this late clinical onset. Our results further demonstrated the power of exome sequencing in identifying genes disease causing, especially when linked to atypical phenotypes.

2908S

Search for missing regulatory region mutations at the DFNB1 locus in GJB2 heterozygotes with deafness. *J. Foster, G. Bademci, M. Tekin.* Dr. John T. Macdonald Foundation Department of Human Genetics and John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Approximately 30-40% of congenital profound hearing loss is attributed to autosomal recessive mutations in the DFNB1 locus that contains both GJB2 and GJB6 genes which code the proteins Cx26 and Cx30, respectively. Recent reports show that loss of GJB2 expression in deaf probands can result from a gross deletion in the DFNB1 locus upstream of GJB6 when in trans with heterozygous mutations in GJB2. These results support the existence of the putative cis-regulatory element upstream of GJB6. We identified 21 deaf probands who remained heterozygous for a single variant after sequencing both exons of GJB2 in our deafness repository that includes 957 families. In two large families with multiple affected and unaffected children, all affected children were heterozygous for a GJB2 mutation (family 1:c.35delG, family 2: c.-23+1G>A), suggesting that their deafness is related to the DFNB1 locus. We excluded previously reported gross deletions in the DFNB1 locus (GJB6-D13S1830 and D13S1845, chr13:19,837,343-19,968,698, and a >920kb deletion involving both GJB2 and GJB6) via CNV analysis with quantitative PCR. Here we propose these two families as strong candidates for the investigation of the putative cis-regulatory element predicted to be in the 100kb region upstream of GJB6. We are utilizing a custom enrichment in the DFNB1 locus upstream of GJB6 for targeted sequencing. We are also performing whole exome sequencing to rule out mutations in other genes. Our results will help to further characterize the regulatory mechanism through which GJB2 is expressed.

2909M

Identifying causative gene variants for hearing loss using a target enrichment/next generation strategy. *D. Tekin[1], D. Yan[1], S.H. Blanton[2], M. Tekin[2], X.Z. Liu[1,2].* 1) Department of Otolaryngology, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

The extensive genetic heterogeneity of hearing loss makes single gene testing inefficient, except for the most common gene GJB2. Therefore, target enrichment/next generation strategy is more time and cost-efficient considering the translation of research data into clinical care. We have developed a custom capture panel (Miami Hearing Genes) of 146 known deafness genes with a target size of approximately 1MB (Agilent Sure Select DNA Design). The genes were identified by searching databases including Hereditary Hearing Loss Homepage, RefSeq, Ensembl, The Human Genome Mutation Database (HGMD), Online Mendelian Inheritance in Man (OMIM) and recent peer-reviewed publications related to the genetics of deafness. The design covered all coding exons, 5' and 3' untranslated regions (UTRs) and 25 bases of intronic flanking sequences for each exon. The overall in silico coverage of the design was 97.47%. The mitochondrial genome with 16,520 kbp was also blended into the design. To validate our panel, we used a set of 16 DNA samples obtained from patients with hearing loss. There were 8 positive controls with known mutations and 8 unknown samples. Analysis detected all known variants in nuclear and mitochondrial genes. These results prove the accuracy and reliability of the custom capture experiment. The search for the causative variations in candidate genes for the 8 unsolved samples and the screen on additional 200 deaf probands from nonsyndromic hearing loss families are in progress.

2910T

Application of whole exome sequencing for identification of deafness causative genes in small families. *D. Yan[1], M. Grati[1], D. Tekin[1], R. Mittal[1], Q. Ma[1], LL. Du[1], Q. Liu[1,5], J. Qing[1,4], Z. Ahmed[3], XZ. Liu[1,2,4].* 1) Departments of Otolaryngology-Head and Neck Surgery, University of Miami Miller School of Medicine, Miami, Florida 33136, USA; 2) Dr. John T. Macdonald, Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL 33136, USA; 3) Abrahamson Pediatric Eye Institute, Otolaryngology Head & Neck Surgery, Cincinnati Children's Hospital Medical Center 3333 Burnet Avenue ML 7003, Cincinnati, OH 45229; 4) Department of Otolaryngology, Head and Neck Surgery, Institute of Otology, the Second Xiangya Hospital, Central South University, Changsha, Hunan, 410011, China; 5) Department of Otolaryngology, Head and Neck Surgery, Chinese PLA, Beijing, 100853, China.

Hereditary deafness is a genetically heterogeneous disorder, with wide range of symptoms through clinical variation, including difference in frequencies affected, hearing threshold changes and age of onset. The causes of hearing loss (HL) may be genetic, environmental, or multifactorial. Although tremendous progress has been made in our understanding of the molecular basis of hearing and HL, the identification of genes and gene defects that affect the process of hearing remains challenging. Up to date, there are more than 60 genes known to be involved in non syndromic HL (NSHL). Nevertheless, it is estimated that there are many more genes to be discovered. Furthermore, for countless families too small for the conventional linkage analysis, the genetic cause of their HL is still an unsolved problem. For those cases, now the availability of whole-exome sequencing (WES) involving the targeted sequencing of the protein-coding subset of the human genome, makes it possible to efficiently identify novel causative genes and mutations. In this study we perform WES on 4 families negative for common deafness genes mutations that are not amendable to conventional approaches. The SureSelect human all exon 50Mb kit (Agilent Technologies) was used for exons and flanking intronic sequences enrichment and the sequencing was performed on the Hisq2000 instrument (Illumina). The Genomes Management Application (GEMapp; https://secureforms.med.miami.edu/hihg/gem-app) was applied for data filtering. Computational functional prediction algorithms (PolyPhen, SIFT, MutationTaster) and conservation scores (PHASTCO, GERP, PHYLOP) were also applied. Aproximately, 92,000 single nucleotide variants and 9,206 INDELS per sample were obtained before variant filtering. Coverage of targeted exons for >10 reads were ranged from 90.3% to 93.5% and >20 reads from 80% to 83.5%. By our filtering strategy, we have rapidly identified homozygous and heterozygous missense variations in novel genes in families presenting autosomal recessive and dominant NSHL, respectively. Sanger sequencing confirmed cosegregation of the variants with the disease phenotype in each family. *In vitro* studies for confirmation of the pathological nature of the sequence changes are being performed and identification of new NSHL genes in multiplex families that are negative for all known deafness genes is in process. Our study shows the great potential of novel deafness gene discovery in small families utilizing WES.

2911S

Genetic analysis of Rubinstein-Taybi Syndrome. *S. de Boer[1], F. Rossello[2], S. White[1].* 1) MIMR-PHI Institute of Medical Research, Monash University, Clayton, Victoria, Australia; 2) Victorian Bioinformatics Consortium, Monash University, Clayton, Victoria, Australia.

Rubinstein-Taybi syndrome (RTS) is a rare congenital disorder. It affects ~1 in 100,000 individuals and is characterized by intellectual disability, growth delay, broad thumbs and big toes, organ malformations, behavioural problems, and specific facial features. Diagnosis of RTS is essentially based on clinical presentation and can be confirmed by genetic screening. Most cases are due to *de novo* mutations, and causative mutations can be identified in <60% of RTS patients, affecting a single copy of either *CREBBP* or *EP300*. The mutation distribution in RTS is uneven, with *CREBBP* mutations being significantly more frequent than *EP300* mutations (~50% and 5% of cases respectively). The significant percentage of RTS cases without a genetic diagnosis suggests that RTS is a genetically heterogeneous disorder, and that there are additional genes involved in RTS. There are other syndromes characterised by clinical features overlapping with RTS, and some are caused by mutations in genes encoding CBP and/or P300-interacting proteins. Next generation sequencing (NGS) on the HiSeq 1500 (Illumina) or the Ion Proton (Life Technologies) has been used to search for RTS-causing mutations by sequencing the entire protein-coding DNA sequence (exome) of six RTS patients. Data analysis showed one patient with a stop/gain SNV in *CREBBP*, which was confirmed by Sanger sequencing. No *EP300* mutations were found in our patient cohort, and analysis is ongoing to generate a candidate gene list based on the Interactome and genes involved in diseases with similar characteristics to RTS.

2912M

The utility of clinical exome sequencing in identifying the genetic origins of eight unclassified developmental disorders in unique Canadian populations. *S.M.K. Farhan[1, 2], J. Wang[1], J.F Robinson[1], V.M. Siu[2,3,4], C.A Rupar[2,3,4], R.A. Hegele[1,2] FORGE Canada Consortium.* 1) Robarts Research Institute, Schulich School of Medicine and Dentistry, Western University; 2) Department of Biochemistry, Schulich School of Medicine and Dentistry, Western University; 3) Medical Genetics Program, Department of Pediatrics, London Health Sciences Centre; 4) Children's Health Research Institute, London Health Sciences Centre.

We are a part of two large national rare disease initiatives: FORGE and Care for Rare Canada, in which >300 rare diseases have been ascertained and diagnosed. Specifically, our group is investigating the genetic etiology of 8 developmental disorders, namely: (1) infantile mitochondrial complex II and III deficiency (IMC23D), (2) seizures, delay, and unusual facies (SDUF) syndrome, (3) epilepsy with ataxia, (4) osteopetrosis, (5) Angelman-like syndrome, (6) ichthyosis-microcephaly, (7) ataxia, dystonia, and mental retardation, and (8) nocturnal seizures with developmental delay. Collectively, these affect 27 patients in 11 families from different Canadian communities. Their clinical presentations vary in severity, symptoms and tissues affected. Six disorders were found in communities with high rates of consanguinity; consequently, we applied homozygosity mapping to generate candidate loci. Next, whole exome sequencing (WES) was performed on DNA from 19 patients across the 8 disorders. Using a non-synonymous, rare variant analysis, WES with in silico analyses, was applied to identify mutations for each disorder. For some disorders, we performed population screening and functional studies to supplement the clinical description. Using our approach, we have identified the likely causative mutations of 6 disorders thus far. While each disorder is clinically distinct, the process used to identify the causative gene is the same. Importantly, we have identified 5 new genes, heretofore never implicated in a human disease, which when mutated, can lead to developmental disorders. These include: (1) NFS1, an iron-sulfur cluster protein, which causes IMC23D; (2) EXT2, a heparan sulfate biosynthesis enzyme and a tumour suppressor, which leads to SDUF syndrome; (3) TMTC3, a protein whose function is still unknown, is depleted in nocturnal seizures with developmental delay; (4) FSD1, a centrosome associated protein with specific brain tissue expression, is mutated in patients with Angelman-like syndrome; and (5) NUDCD2, which interacts with lissencephaly associated protein PAFAH1B1, is mutated in patients with ataxia, dystonia, and mental retardation. We have also identified a known disease causing gene, KCTD7 as the cause of progressive myoclonus epilepsy. These studies allow for an academic and a clinical focus by allowing us to better understand the dynamic function and mechanistic significance of these genes and importantly, how they can underlie human disease.

2913T

Protein-altering rare variants in candidate genes in patients with Biliary Atresia. *R. Rajagopalan[1], E.A. Tsai[2], C.M. Grochowski[1], A. Falsey[1], K.M. Loomes[3,4], M. Devoto[3,6,7,8], N.B. Spinner[1,5,9].* 1) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA., USA; 2) Genomics and Computational Biology Graduate Group, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, USA; 3) Department of Pediatrics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, USA; 4) Division of Gastroenterology, Hepatology and Nutrition, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 5) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Perelman School of Medicine, Philadelphia PA, USA; 6) Division of Human Genetics,; 7) Department of Biostatistics and Epidemiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 8) Department of Molecular Medicine, University La Sapienza, Rome, Italy; 9) Division of Genomic Diagnostics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA.

Biliary atresia (BA) is a pediatric liver disease resulting in necroinflammatory obliteration of the extrahepatic biliary tree,presenting within the first few months of life. The incidence of BA is 1 in 14,000 in Caucasians. The etiology of BA is unknown to date, with evidence for immunologic, infectious, environmental, and genetic factors described. We hypothesized that rare variants in key genes in hepatobiliary development would be present in infants with BA. METHODS: Using a well-characterized cohort of patients with isolated BA, enrolled in an IRB-approved protocol through the NIDDK-funded Childhood Liver Disease Research and Education Network (ChiLDREN), we performed whole-exome sequencing in 100 unrelated Caucasian patients and looked for rare variants in 21 candidate genes. These genes were chosen based on previous reports of mutations found in the syndromic form of BA, animal models with hepatobiliary defects, and/or genome-wide association studies. We hypothesized that genetic susceptibility would be caused by rare variants and we therefore filtered for rare protein-altering sequence variants (nonsense, splice, non-synonymous variants, and small insertions/deletions) that were present at a less than 1% frequency threshold in any of the public datasets (ESP6500 and 1000 Genomes). RESULTS: A total of 20 missense variants (4 novel) and 2 in-frame insertions were identified in 13 genes in a total of X patients. We found more than one variant in LGR4, ZEB2, DNMT1, INVS, JAG1 & PRICKLE4 and some of these variants were shared among more than one proband. CONCLUSIONS: This suggests that these candidate genes may be enriched for protein-altering variants in BA patients. We are currently in the process of validating the candidate variants with Sanger sequencing for both confirmation of their presence and the mode of inheritance. These findings suggest that the underlying etiology of BA is likely to be highly heterogeneous and a single variant or gene may not explain the phenotypic complexity of the disease.

2914S

Whole genome sequencing of mummy DNA shows significant association with human disease phenotype. *S. Bhattacharya[1], J. Li[2], H. Lam[2], R. Lachman[3], N. Asadi[2], A. Butte[1], G. Nolan[4].* 1) Division of Systems Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford, CA.,94305 USA; 2) Department of Bioinformatics, Bina Technologies, Redwood City, CA; 3) Stanford University Medical Center, CA; 4) Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford California 94305.

In 2012 an analysis was initiated of a mummified specimen (Ata) found in the Atacama Desert of Chile, South America. The 6-inch specimen with human or primate features manifested only 10 pairs of ribs (humans have 12), a skull shape that did not appear human, and apparently prematurely ossified growth plates suggesting a greater age at time of death than the size of the specimen would indicate. To determine possible genetic drivers of the observed morphology, DNA from the specimen was subjected to whole genome sequencing using the Illumina HiSeq platform-- 377,333,714 reads passed the set of filtering criteria. Using the BINA secondary analysis pipeline (ver 1.5.0-dev-217-ga8038cc), 97% reads successfully mapped; of these, 89.77% uniquely mapped to the human reference genome (GRCh37) with a set of decoy sequences; 7.03% mapped to multiple locations, and 3.20% were unmapped. The sequence reads were also aligned to the Chimpanzee genome (88.01% uniquely mapped). In total, 3,356,569 single nucleotide variations (SNVs) were found as compared to the human reference genome, 518,365 insertions and deletions (INDELs) detected, of which 81.5 % and 77.5% are in dbSNP, respectively. To identify putative causal variants associated with Ata's phenotype, the SNVs were run through ANNOVAR pipeline and confirmed by BINA's analytic platform. The SNV and INDEL mutations fell within the range of "human normal", ruling out a non-human primate origin for the specimen. A preliminary phenotype enrichment analysis of a subset of variants in genes that carry one or more deleterious mutations, using the hypergeometric test, showed a significant association with several phenotypes, including: proportionate short stature (adjP=9.5e-03), Aplasia involving forearm bones (adjP=3.15e-02), 11 pairs of ribs (adjP= 2.96e-02) and premature osteoarthritis (adjP=2.96e-02)—gene-disease phenotype knowledgebase information was obtained from Human Phenotype Ontology database. Disease enrichment analysis indicates that mutations in genes associated with dwarfism and bone diseases significantly enriched. These findings suggest there might be one or more Mendelian traits influencing the observed phenotype, strengthening the molecular basis for deriving understanding how genomic variations in this specimen lead to phenotypic consequences.

2915M

Excess of de novo variants in genes involved in chromatin remodeling and regulation of transcription in patients with marfanoid habitus and intellectual disability. *L. Faivre[1,2], F. Daoud[1], C. Jondeau[14], C. Thauvin-Robinet[1,2], Y. Duffourd[1,2], JB. Rivière[1,2].* 1) EA4271, Université de Bourgogne, Dijon, France; 2) FHU TRANSLAD, CHU Dijon, France; 3) Département de Génétique, CHU Bordeaux, France; 4) Institut Imagine, Hôpital Necker Enfants Malades, Paris, France; 5) Département de Génétique, CHU Lille, France; 6) Département de Génétique, CHU Nancy, France; 7) Département de Génétique, CHU Montpellier, France; 8) Département de Génétique, CHU Rennes, France; 9) Département de Génétique, CHU Grenoble, France; 10) Service de Génétique, CH Toulon, France; 11) Service de Génétique, CH Le Mans, France; 12) Institut Fédératif de Génétique, Hôpital Pitié Salpétrière, Paris, France; 13) INSERM UMR_S910, Faculté de Médecine Marseille, France; 14) Centre de Référence Maladie de Marfan, Hôpital Bichat, France.

Marfanoid habitus (MH) combined with intellectual disability (ID) is a genetically and clinically heterogeneous group of overlapping disorders. In 2013, we reported our genetic investigations of 100 patients with MH and ID. A custom 244K array CGH and targeted sequencing of 6 genes (MED12, ZDHHC9, UPF3B, FBN1, TGFBR1 and TGFBR2) led to identification of the underlying genetic cause in 20% of subjects, which included non-overlapping chromosomal anomalies, mutations of FBN1, and a mutation of MED12 in fourteen, three and one individuals, respectively. In addition, two subjects carried both a FBN1 mutation and a chromosomal rearrangement, thus suggesting digenic inheritance for at least a fraction of individuals with MH and ID. To further decipher the genetic basis of MH with ID, we performed exome sequencing in 35 affected individuals with a systemic score of at least seven, using a trio approach in 15 subjects, whereas the remaining 20 were sequenced without their parents. The trio-based analysis identified a higher than expected rate of non-synonymous de novo changes (32 mutations, average of 2.1 per trio), thus adding further support to the hypothesis of a polygenic inheritance for MH and ID. Searching for rare variants of genes identified by the trio-based analysis in the remaining 20 index cases combined with segregation analysis in available relatives led to identification of six genes with de novo mutations in at least two unrelated individuals. Overall, at least one likely pathogenic mutation was identified in ~50% of subjects (17/35), with mutations in eight genes previously associated with a Mendelian disease. Among them, two are known to be mutated overgrowth syndromes. Strikingly, a half of the identified mutated genes belong to a highly interconnected network of proteins involved in chromatin remodeling and regulation of transcription, thus highlighting molecular pathways that may be targets for future research efforts. In conclusion, these findings provide additional information about the genetic and molecular basis on MH and ID, with an increased de novo rate, an enrichment of de novo mutations in several genes, and the identification of chromatin remodeling and regulation of transcription as key cellular pathways in the pathogenesis of these phenotypes. Finally, our data demonstrate the added value of studying sub-phenotypes of ID for identifying genes associated with this extremely heterogeneous and complex group of disorders.

2916T

Exome analysis of 116 patients supposed to be autosomal recessive hereditary spastic paraplegia established molecular diagnoses of 49 patients with broad genetic heterogeneities. *H. Ishiura[1], K. Koh[2], H. Shimazaki[3], J. Mitsui[1], Y. Takahashi[4], J. Goto[1], K. Yoshimura[5], K. Doi[5], S. Morishita[5], H. Sasaki[6], Y. Takiyama[2], S. Tsuji[1,7], JASPAC (Japan Spastic Paraplegia Research Consortium).* 1) Department of Neurology, The University of Tokyo, Tokyo, Japan Tokyo, Tokyo, Japan; 2) Department of Neurology, Yamanashi University, Yamanashi, Japan; 3) Department of Neurology, Jichi Medical University, Tochigi, Japan; 4) Department of Neurology, National Center of Neurology and Psychiatry, Tokyo, Japan; 5) Department of Computational Science, Graduate School of Frontier Sciences, The University of Tokyo, Chiba, Japan; 6) Department of Neurology, Hokkaido University Graduate School of Medicine, Hokkaido, Japan; 7) Medical Genome Center, The University of Tokyo Hospital, The University of Tokyo, Tokyo, Japan.

[Background] Hereditary spastic paraplegia (HSP) is a clinically and genetically heterogeneous neurodegenerative disorder. To date, SPG1-72 was identified as the disease loci, of which 56 causative genes have been identified. Autosomal recessive HSP (AR-HSP) is more clinically heterogeneous than autosomal dominant HSP (AD-HSP). A previous study revealed that causative mutations were found in only 17.2 % of patients who was suspected to have autosomal recessive (AR) inheritance (Ishiura et al. 2014). [Methods] We recruited 116 HSP patients who were supposed to have AR inheritance because 1. they had parental consanguinity with or without affected sibling(s), 2. they had affected sibling(s) without affecteds in the previous generations, or 3. they were sporadic but had complicated form HSP. The previous analyses with resequencing microarray for 13 genes, aCGH for 16 genes, and Sanger sequencing for 3 genes were performed in 46 patients. Subsequently, one hundred and four patients underwent exome analysis. Variants with minor allele frequency of < 0.2 % in 56 causative genes for HSP and 203 causative/susceptibility genes for other neurodegenerative diseases were considered to be candidate mutations. Nonsense, insertion/deletion, splice site, and known missense mutations were considered to be pathogenic. In the case of novel missense mutations, we considered them as pathogenic if 1. more than one pathogenic missense mutations have been described. and 2. the identified mutations are located in the vicinity of the region in genes such as *SPAST* or *KIF5A* where pathogenic mutations have been described to be clustered. [Results] We found 33 patients and 5 patients with mutations in AR-HSP and AD-HSP genes, respectively. SPG11 (12.1 %), SPG28 (4.3 %), SPG46 (3.4 %), and SPG15 (2.6 %) were frequent subtypes of AR-HSP. In addition, 8 patients with AR neurodegenerative disease such as spinocerebellar ataxias and leukoencephalopathies and 3 patients with autosomal dominant neurodegenerative diseases were found. [Discussion] Exome analysis revealed pathogenic mutations in 42 % of patients suspected to have AR inheritance. Although exome sequencing is highly efficient for the molecular diagnosis of HSP, assessment of pathogenicity of missense mutations is still a challenging issue. Mutations were found in 23 genes, indicating clinical heterogeneity of these patients. The causative genes for the rest of the patients remain to be further elucidated.

2917S

New candidate genes associated with autosomal dominant partial epilepsy with auditory features identified by whole exome sequencing. *F.R. Torres[1,3], P.A. Oliveira[1,3], R. Secolin[1,3], C.V. Soler[1,3], M.G. Borges[1,3], A.C. Coan[2,3], M.E. Morita[2,3], B.S. Caravalho[1,3], F. Cendes[2,3], I. Lopes-Cendes[1,3].* 1) Department of Medical Genetics, Unicamp, Campinas, SP, Brazil; 2) Department of Neurology, Unicamp, Campinas, SP, Brazil; 3) The Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas, SP, Brazil.

Background: Epilepsy is a common chronic neurological disorder that affects approximately 1% of the population worldwide. Autosomal dominant partial epilepsy with auditory features (ADPEAF) is a clinically well characterized syndrome. Deleterious mutations in *LGI1* are present in about 50% of families segregating ADPEAF. Objective: To identify genes associated with ADPEAF in two large families with no mutations identified in *LGI1*. Methods: Whole exome sequencing was performed in nine individuals from two ADPEAF families (F- 1 and F- 2), including seven patients and two unaffected parents. Exome was targeted with Nextera Rapid Capture Expanded Exome kit (Illumina®) and sequenced in a high-performance Hiseq Illumina® 2500 sequencing machine (Illumina®) to obtain >50X average coverage per sample. Bioinformatics analysis was performed using the GATK software package. Sequences were aligned using the BWA algorithm. Variant calling and in silico functional prediction of mutations was performed using VariantAnnotator and SnpEff tools. We prioritized non-synonymous, frameshift, splicing, and indel variants according to novelty, quality score, and putative pathogenicity. Results: We found a total of 1,007,575 and 1,006,376 variants in F-1 and F-2 families, respectively. After bioinformatics analysis, we identified 54 variants in F-1 and 83 in F-2, which are shared by all patients and are absent in unaffected individuals. Among these we observed mutations in eight genes that are potentially associated with ADPEAF. Conclusions: Putative roles related to formation of axon connections, protein-protein interaction, neuronal differentiation and ionic channels make the eight candidate genes identified relevant for ADPEAF.

2918M

Hoyeraal Hreidarsson syndrome, a severe variant of dyskeratosis congenita, caused by biallelic mutations in TPP1. *B.J. Ballew[1], H. Kocak[2], K. Bisht[2], J.F. Boland[3], B.D. Hicks[3], L. Burdett[3], A. Vogt[3], A.A. Hutchinson[3], N. Giri[1], B.P. Alter[1], M. Yeager[3], C. Keegan[2], J. Nandakumar[2], S.A. Savage[1], NCI DCEG Cancer Sequencing Working Group.* 1) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), Rockville, MD, USA; 2) University of Michigan, Ann Arbor, MI, USA; 3) Cancer Genomics Research Laboratory, Leidos Biomedical Research, NCI-Frederick, Rockville, MD, USA.

Dyskeratosis congenita (DC) is an inherited telomere biology disorder resulting in heightened risk of bone marrow failure, cancer, pulmonary fibrosis, liver disease, and other complications. Leukocyte telomeres <1st percentile for age are diagnostic. Causative germline mutations in any of 9 telomere genes (*DKC1*, *TERC*, *TERT*, *TINF2*, *NOP10*, *NHP2*, *WRAP53*, *CTC1*, or *RTEL1*) are present in ~70% of DC. Gene discovery is complicated by incomplete penetrance, variable expressivity, and genetic anticipation, but is important to confirm diagnosis and for family planning. DC genes also provide insight into potential cancer susceptibility loci: polymorphisms in 6 DC genes are associated with cancer risk in the general population. We performed whole exome sequencing on mutation-negative DC families in our IRB-approved cohort study. Based on data from the NHLBI Exome Sequencing Project, 1000 Genomes, and an in-house database of 1400 exomes, we identified rare variants. We further filtered variants by family structure, examining all plausible inheritance models. We then combined our naïve analysis with a candidate-gene approach, highlighting variants in any of ~3000 genes associated with DC-related phenotypes. Finally, we analyzed variants' impact using in silico techniques. This led to the discovery of novel mutations in *TPP1* (*ACD*, MIM 609377), part of the telomeric shelterin complex, in a DC family. The proband of family NCI-275 is a 5 year-old boy with Hoyeraal Hreidarsson syndrome, a severe variant of DC that includes cerebellar hypoplasia, immunodeficiency and intrauterine growth retardation. The proband, his older sister, and father have telomeres <1st percentile; all three harbor a single-amino acid deletion in the TEL patch of TPP1. The proband also has a missense TPP1 mutation in the TIN2 binding domain; his mother is a silent carrier of this mutation. Functional analyses demonstrated that the deletion severely compromises both telomerase processivity and recruitment to telomeres. The missense mutation does not directly impact telomerase processivity or recruitment; however, it reduces TPP1-TIN2 binding, which may affect recruitment of TPP1 to telomeres. Modeling of the deletion using the crystal structure of TPP1-OB as a template suggests a structural mechanism for the defects. These data demonstrate that the compound heterozygous inheritance of these two alleles, each with defects in different aspects of TPP1 function, results in clinically severe DC.

2919T

Targeted next generation sequencing in DNA diagnostics for familial cancer. *A.H. van der Hout, Y.J. Vos, B. Raddatz, K. van Dijk-Bos, A. Knopperts, L.K. Leegte, J. ter Beest, H. Westers, R. Sinke, R. Sijmons.* Genetics, University Medical Center Groningen, Groningen, Netherlands.

Purpose Phenotypes of many hereditary tumour syndromes are known to overlap. In addition, different genes may underlie one syndrome. Therefore the number of genes to examine in a particular clinical case can be relatively large. Next generation sequencing (NGS) makes it is possible to analyze large numbers of genes in parallel at relatively low cost. We studied the expediency of a targeted NGS gene panel approach in DNA diagnostics for a group of 100 patients with either early-onset breast cancer or colorectal cancer in whom a pathogenic mutation in the *BRCA1/2* genes was already excluded by Sanger sequencing, or their tumours showed no signs of Lynch syndrome, respectively. Methods We developed and validated a sequencing panel based on Agilent Sure Select Target Enrichment® for mutation scanning in 71 genes known to be associated with tumour syndromes.. The samples were sequenced using 151 base pair paired-end reads on an Illumina MiSeq® sequencer and analyzed using Softgenetics' NextGENe® and Cartagenia's Benchlab NGS® software. The 71 genes are divided in three virtual, non-overlapping gene subpanels, based on the levels of preventive options and strength of risk information, in which for genes in subpanel 1 the most information is available about preventive options and specific tumour risks. In pre-test genetic counselling the genes to be tested were discussed as the 3 subpanels rather than individually. Patients can choose for any of the 3 subpanels to be tested and have the results returned to them. In addition, all 71 genes are tested in all patients for research purposes after de-identifying the patients. Results and Conclusion Approximately 65% of the patients chose to have results returned for all subpanels, 30% for subpanels 1 and 2 and 5% for subpanel 1 only. In 5 cases a pathogenic mutation was detected, 4 times a heterozygous mutation in *CHEK2* and one mutation in *RAD51D*. Heterozygosity for a pathogenic mutation in *MUTYH* was detected in 3 additional cases. In 13 cases one or two mutations classified as 'likely pathogenic' were detected in 13 different genes. Co-segregation and tumor analysis in the families may provide more information about pathogenicity of these mutations. In most cases the patient's phenotype does not match with the currently known tumour spectrum associated with the mutated gene. Analysis of large gene panels may broaden our knowledge of tumour spectra associated with mutations in certain genes.

2920S

Mutation screening of retinal dystrophy patients by targeted capture from tagged pooled DNAs and next generation sequencing. *M.E. Elasrag[1], C.M. Watson[3], D.A Parry[2], J.E Morgan[2], C.V Logan[1], I.M Carr[2], E. Sheridan[2], R. Charlton[3], C.A Johnson[1], G. Taylor[3], C. Toomes[1], M. McKibbin[1,4], C.F Inglehearn[1], M. Ali[1].* 1) Section of Ophthalmology & Neuroscience, Leeds Institute of Biomedical & Clinical Sciences, University of Leeds, UK; 2) Section of Genetics, Leeds Institute of Biomedical & Clinical Sciences, University of Leeds, UK; 3) Yorkshire Regional Genetics Service, St. James's University Hospital, Leeds, UK; 4) Department of Ophthalmology, St. James's University Hospital, Leeds, UK.

Retinal dystrophies are genetically heterogeneous, resulting from mutations in over 200 genes. Prior to the development of massively parallel sequencing, comprehensive genetic screening was unobtainable for most patients. Identifying the causative genetic mutation facilitates genetic counselling, carrier testing and prenatal/pre-implantation diagnosis, and often leads to a clearer prognosis. In addition, in a proportion of cases, when the mutation is known treatment can be optimised and patients are eligible for enrolment into clinical trials for gene-specific therapies. The genomic DNA of twenty patients each from a different family was sheared, tagged and pooled in batches of four samples, prior to targeted capture and next generation sequencing. The enrichment reagent was designed against genes listed on the RetNet database. Sequence data were aligned to the human genome, variants were filtered to identify potential pathogenic mutations, which were confirmed by Sanger sequencing. Molecular analysis identified likely pathogenic mutations in 12 cases, many of them known and/or confirmed by segregation. These included previously described mutations in ABCA4 (c.6088C>T,p.R2030*; c.5882G>A,p.G1961E), BBS2 (c.1895G>C,p.R632P), GUCY2D (c.2512C>T,p.R838C), PROM1 (c.1117C>T,p.R373C), RDH12 (c.601T>C,p.C201R; c.506G>A,p.R169Q), RPGRIP1 (c.3565C>T,p.R1189*) and SPATA7 (c.253C>T,p.R85*) and new mutations in ABCA4 (c.3328+1 G>C), CRB1 (c.2832_2842+23del), RP2 (c.884-1G>T) and USH2A (c.12874A>G,p.N4292D). We report here that tagging and pooling DNA prior to targeted capture of known retinal dystrophy genes identified mutations in 60% of cases. This relatively high success rate may reflect enrichment for consanguineous cases in the local Yorkshire population, and the use of multiplex families. Nevertheless this is a promising high throughput approach to retinal dystrophy diagnostics.

2921M

Homozygosity mapping and exome sequencing of a Faroese family with albinism. *K. Grønskov[1], K. Vilhelmsen[2], T. Rosenberg[3, 4].* 1) Clinical Genetic Clinic, Kennedy Center, Rigshospitalet, Glostrup, Denmark; 2) , Dept. of Ophthalmology, National Hospital of The Faroe Islands, FO-100 Torshavn, The Faroe Islands; 3) The National Eye Clinic for the Visually Impaired, Kennedy Center, Glostrup Hospital, Glostrup, Denmark; 4) Gordon Norrie Center for Genetic Eye Diseases, Copenhagen, Denmark.

Albinism is a genetically heterogeneous disorder characterized by a number of specific deficits in the visual system such as nystagmus, low vision, and crossed asymmetry of the visual pathway in association with a variable hypopigmentation phenotype. The lack or reduction of pigment might affect the eyes, skin and hair (oculocutaneous albinism, OCA [MIM 203100]), or the eyes only (ocular albinism, OA [MIM 300500]). In a lightly pigmented population such as the Faroese, it can be difficult to distinguish between OCA and OA. Mutations in six genes (*TYR* [MIM 606933], *OCA2* [MIM 611409], *TYRP1* [MIM 115501], *SLC45A2* [MIM 600202], *SLC24A5* [MIM 609802] and *C10orf11* [MIM 614537]) are known to cause autosomal recessive OCA and furthermore, one locus (OCA5 [MIM 615312]) has been identified. A founder mutation in *C10orf11* was found in six out of nine Faroese families with OCA/OA. Mutations in one gene, *GPR143* [MIM 300808], are known to cause X-linked OA. More genes are expected to be associated with OCA/OA. A consanguineous family from The Faroe Islands with two children affected with OCA/OA and two unaffected children were investigated. Mutation analysis of *TYR*, *OCA2*, *SLC45A2* and *C10orf11* in affected individuals showed no pathogenic changes. Homozygosity mapping showed 12 homozygous regions with approximately 100 genes. Exome sequencing will be performed.

2922T

Identifying novel genes that cause Rett syndrome by trio-based exome sequencing of MECP2-negative patients. *S.A. Sajan[1,2], S.N. Jhangiani[3], D.M. Munzy[3], R.A. Gibbs[3,4], J.R. Lupski[3,4,5], D. Glaze[1], W.E. Kaufmann[6], S.A. Skinner[7], M. Friez[7], A.K. Percy[8], J.L. Neul[1,2,4].* 1) Section of Child Neurology and Developmental Neuroscience, Department of Pediatrics, Baylor College of Medicine, Houston, TX; 2) Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics, Baylor College of Medicine and Texas Children's Hospital, Houston, TX; 6) Department of Neurology, Boston Children's Hospital, Boston, MA; 7) Greenwood Genetic Center, Greenwood, SC; 8) Department of Pediatrics, University of Alabama at Birmingham, Birmingham, AL.

Rett syndrome (RTT [MIM#312750]) is a neurodevelopmental disorder which in the majority of cases is caused by mutations in Methyl CpG binding protein 2 (*MECP2*) on the X chromosome. The disorder affects about 1 out of 10,000 live female births and is typified by apparently early normal development in the first 6-18 months of life followed by psychomotor regression involving loss of speech and hand use, the development of gait problems and characteristic repetitive hand stereotypies. While some clinical subtypes of RTT, referred to as atypical RTT, have been shown to be caused by mutations in *CDKL5* and *FOXG1*, classical/typical RTT still remains an essentially monogenic disorder with de novo *MECP2* mutations accounting for 95-97% of such cases. We sought to identify the molecular basis of some of the 3-5% of typical RTT cases that are *MECP2*-negative by trio-based exome sequencing. We used the Illumina platform to sequence the exomes of 10 trios with RTT probands who did not harbor mutations in *MECP2* as determined by Sanger sequencing of coding exons as well as by copy number variation analysis on a clinical array. Data analysis using the Genome Analysis Toolkit (GATK) revealed 8 heterozygous de novo protein altering mutations in 8 different genes in 7 patients, with one patient having de novo mutations in two different genes. These two genes were *MDMX* and *ZNF536* with missense and frameshift insertion mutations, respectively. Missense mutations were also identified and confirmed in *GABRB2*, *IMPDH2*, and *SAFB2* and were predicted to be damaging by at least 2 out of 6 mutation prediction algorithms. Two non-frameshift deletions were found in *GRIN2B* and *IQSEC2*, and a splice site mutation was found in *TCF4*. Other mutations in the two nervous system-expressed ion channel genes *GRIN2B* and *GABRB2*, as well as in *TCF4* and *IQSEC2*, have previously been reported to result in developmental delay and intellectual disability. Our results suggest that *MECP2*-negative RTT is heterogeneous and caused by mutations in genes that also result in other types of neurodevelopmental disorders. We recommend including these genes in a list of high-priority genes when exome or targeted sequencing is performed on *MECP2*-negative RTT patients.

2923S

Baratela Scott Syndrome is a recessive skeletal dysplasia syndrome caused by disruption of the XYLT1 gene. *K. Sol-Church[1], M. Kircher[2], D. Stabley[1], K. Gripp[1], M. Bober[1].* 1) Nemours AI duPont Hospital for Children, Wilmington, DE., USA; 2) Department of Genome Sciences, Seattle WA.

Baratela Scott Syndrome (OMIM 300881) is characterized by skeletal dysplasia, facial features, and developmental delay. Skeletal findings include patellar dislocation, short tubular bones, mild metaphyseal changes, brachymetacarpalia with stub thumbs, short femoral necks, shallow acetabular roofs, and platyspondyly. Facial features include: a flattened midface with broad nasal bridge, cleft palate or bifid uvula and synophrys. Though some of the cognitive delays are typically masked by a warm and engaging personality, all of the patients demonstrated preschool onset of a cognitive developmental delay with a shortened attention span. We previously described seven male patients from six different families with Baratela Scott Syndrome (BSS), and performed Whole Exome Sequencing on the patients and available unaffected family members. We identified in a single individual a homozygous c.1290 -1G>A splice variant in the Xylosyltranferase (XYLT1) gene located on chromosome 16p. Both parents were heterozygous for this splice variant. This mutation caused splicing out of exon 6 and premature termination. In 3 patients from 2 unrelated families we discovered a large 3 Mb deletion covering 16p13-11 to 16p12.3 which includes the XYLT1 gene. Because of poor capture performance for exon 1 of the XYLT1 gene, we used Sanger sequencing and identified other variants in exon 1 of XYLT1 in two additional patients: One patient carried a c.319 G>T. Gly107Ter mutation while the other carried a 26 bp deletion (c.281-306). We conclude that Baratela Scott Syndrome is a recessive disorder caused by disruption of the XYLT1 gene.

2924M

Whole exome sequencing a consanguineous family in search for a novel genetic cause of Charcot-Marie-Tooth (CMT) disease. *S. Tey[1], N. Shahrizaila[2], K.J. Goh[2], A.P. Drew[3], M.L. Kennerson[3,4], A. Ahmad Annuar[1].* 1) Department of Biomedical Science, Faculty of Medicine, University of Malaya, Malaysia; 2) Department of Medicine, Faculty of Medicine, University of Malaya, Malaysia; 3) Northcott Neuroscience Laboratory, ANZAC Research Institute, Sydney, Australia; 4) Molecular Medicine Laboratory, Concord Hospital, Sydney, Australia.

Charcot-Marie-Tooth (CMT) neuropathy is a clinically and genetically heterogeneous group of disorders affecting the motor and sensory neurons with an estimated prevalence of 1 in 2500 people [1]. Over eighty genes have been identified for CMT and related peripheral neuropathies however there are many cases yet to be resolved [2]. In this study, we have taken a whole exome sequencing (WES) approach to investigate the genetic aetiology of CMT in two affected brothers from a consanguineous marriage. The onset of symptoms was in their teens and clinical examination revealed bilateral pes cavus with weakness of dorsiflexion resulting in foot drop. The proband had associated brisk reflexes whereas in his brother, the reflexes were normal/reduced but there was evidence of mild intellectual impairment. Nerve conduction studies indicated a demyelinating form of CMT. The segregation of the disease in the family suggests either an autosomal recessive or X-linked inheritance. WES was performed on two affected brothers, the parents and an unaffected brother. Mutations in known genes associated with autosomal recessive and X-linked CMT were found to be negative after querying the WES data. This suggests that the family may present a novel genetic cause of CMT. By analysing the WES data of the family members, 152 candidate variants were identified in the affected brothers and are not present in the unaffected family members. To narrow down the number of variants, we analysed our WES data using MERLIN [3] and PLINK [4] for linkage analysis and homozygosity mapping. We were able to reduce the number of candidate variants to only five. Currently we are investigating the potential involvement of these candidate variants in disease pathology. References: 1. Deciphering the genetic basis of idiopathic short stature. *C.T. Thiel[1], N.H. Hauer[1], K. Kessler[1], U. Uebe[1], A.B. Ekici[1], H. Sticht[2], H.-G. Doerr[3], A. Reis[1].* 1) Institute of Human Gentics, Friedrich-Alexander-University of Erlangen-Nuremberg, Erlangen, Germany; 2) Institute of Biochemistry Friedrich-Alexander-University Erlangen-Nuremberg, Erlangen, Germany; 3) Department of Pediatrics and Adolescent Medicine Friedrich-Alexander-University Erlangen-Nuremberg, Erlangen, Germany.

Shortness of stature is one of the most common pediatric concerns and has an incidence of 3 % in the general population. In 80 % of patients with growth deficit the etiology remains elusive in the absence of morphological details. Uncovering the genetic basis of short stature is therefore not only important for clinical diagnosis, prognosis and genetic counseling of affected individuals and their families, but is also a prerequisite for future development of therapeutic approaches. While Genome-wide association studies identified hundreds of common single nucleotide polymorphisms and copy number variants (CNVs) contributing to the height variation in the healthy population, we confirmed a frequent disease - rare variant hypothesis by the identification of pathogenic CNVs in 10% of patients with short stature. Our results implied a heterogeneity with more than 200 genes involved in short stature by power analysis. To address this hypothesis we thoroughly build a study group of more than 500 families with idiopathic short stature and performed whole exome sequencing (WES) in 60 trios. Thoroughly filtering and validation of the identified variants resulted in the identification of potential pathogenic variants in genes involved in epigenetic modification, cell cycle regulation, ubiquitination and protein synthesis. We found compound heterozygous inherited and de novo variants to be associated with short stature. In addition, including CNV analysis from WES further identified compound heterozygous variants. Thus, we were able to identify novel candidate genes for short stature. Analysis of further individuals with short stature will lead to a more elaborate and detailed view on mechanisms involved in growth regulation.

2926S

Coffin-Siris syndrome is a BAF complex disorder. *Y. Tsurusaki, M. Nakashima, H. Saitsu, N. Miyake, N. Matsumoto.* Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Coffin-Siris syndrome (CSS; MIM 135900) is a congenital disorder characterized by intellectual disability, growth deficiency, microcephaly, coarse facial features, and hypoplastic or absent fifth fingernails and/or toenails. The majority of affected individuals represent sporadic cases, which is compatible with an autosomal dominant inheritance mechanism. The genetic cause for this syndrome has not been elucidated. We previously reported that five genes are mutated in CSS, all of which encode subunits of the Brahma-associated factor (BAF) (also known in yeast as the SWI/SNF) ATP-dependent chromatin-remodeling complex: *SMARCB1*, *SMARCA4*, *SMARCE1*, *ARID1A*, and *ARID1B*. In this study, we examined 49 newly recruited CSS-suspected patients, and re-examined three patients who did not show any mutations (using high-resolution melting analysis) in the previous study, by whole-exome sequencing or targeted resequencing. We found that *SMARCB1*, *SMARCA4*, or *ARID1B* were mutated in 20 patients. By examining available parental samples, we ascertained that 17 occurred *de novo*. All mutations in *SMARCB1* and *SMARCA4* were non-truncating (missense or in-frame deletion) whereas those in *ARID1B* were all truncating (nonsense or frameshift deletion/insertion) in this study as in our previous study. Our data further support that CSS is a BAF complex disorder. Aknowledgments: Drs. N Okamoto, H Ohashi, S Mizuno, N Matsumoto, Y Makita, M Fukuda, B Isidor, J Perrier, S Aggarwal, AB Dalal, A Al-Kindy, J Liebelt, and D Mowat are highly appreciated for contributing to this work.

Whole-Exome Sequencing and Linkage Analysis Reveal a Novel Genetic Locus for Autosomal Dominant Pattern Dystrophy of the Retinal Pigment Epithelium. *A. Vincent[1,2,3], N. Forster[2], J.T. Maynes[3,4], T.A. Paton[2,5], G. Billingsley[2], N. Roslin[2,5], A. Ali[2], J. Sutherland[1], T. Wright[1], C. Westall[1,3], A.D. Paterson[2,3,5], C.R. Marshall[2,5], . FORGE Canada Consortium[6], E. Heon[1,2,3].* 1) Department of Ophthalmology, Hospital for Sick Children, Toronto, Canada; 2) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Canada; 3) University of Toronto, Toronto, Canada; 4) Department of Anaesthesiology, Hospital for Sick Children, Toronto, Canada; 5) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Canada; 6) FORGE Canada Consortium: Finding of Rare Disease Genes in Canada.

Purpose: To identify the genetic cause of autosomal dominant pattern dystrophy (PD) of the retinal pigment epithelium (RPE) in two families. **Methods and Results:** Eight members of a two generation family with PD (Family 1, five affected) were genotyped using Illumina's Infinium Linkage-24 chip. Multipoint genome wide linkage analysis identified 7 regions of potential linkage; microsatellite markers were used to refine these regions in an extended version of Family 1 (n = 12, six affected) and a maximum LOD score of 2.09 was observed across regions of four chromosomes. Exome sequencing on two affected family members identified 15 shared non-synonymous coding sequence variants within the linked regions; candidate genes were prioritized and further analyzed. Sanger sequencing confirmed a novel heterozygous missense variant (E79K) in *OTX2* that segregated with the disease phenotype. A second family (Family 2) with PD harbored the same missense variant in *OTX2*. A shared haplotype of 20.62 cM and 1,211 single nucleotide polymorphisms between the two families (HumanCoreExome chip) encompassing the *OTX2* gene suggest a shared ancestry. All cases from both families had decrease in distance vision and myopia. All except one affected case across the two families (aged 13 years) had a "pattern" at the macula. In vivo structural retinal imaging showed discrete areas of RPE-photoreceptor separation at the macula in all cases across both families; photoreceptor outer segments appeared disrupted in these regions. Electroretinogram testing showed generalized photoreceptor degeneration in three cases. Developmental anomalies observed include optic dysplasia (n = 4), microcornea (n = 1) and Rathke's cleft cyst (n = 1). **Conclusion:** This is the first report implicating *OTX2* to underlie PD phenotype. This phenotype resembles conditional mice models that show slow photoreceptor degeneration secondary to loss of *Otx2* function in the adult RPE. This allelic *OTX2* variant appears to spare pituitary hormonal abnormalities.

Cardiomyopathy Pathology of a GSDIIIa Patient Revealed by Whole Genome Sequencing. *Q. Zhao, S. Song, N. Zheng, F. Li, J. Huang, S. Hu.* State Key Laboratory of Cardiovascular Disease, Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

Cardiac involvements have been recognized in glycogen storage disease type III (GSD III, OMIM 232400) and the severity varies among patients, however, up to now little is known about the pathology. The endeavor to link the genotypes of AGL (the causal gene of GSD III) to cardiac phenotypes didn't find any significant associations. In this case study, we sequenced the whole genome of a GSD IIIa patient with severe heart failure on Illumina HiSeq 2500 system. Generally, cardiac involvement is apparent only after age 30 and the common phenotypes are ventricular hypertrophy. Our case was very special as she showed ventricle dilation and rapid progression to end stage heart failure at her early 20s. On physical examination the case was assessed in NYHA class IV. Echocardiography showed the enlargement of the heart and wall thickening accompanied with the left ventricular diastolic and systolic dysfunction. She received intensive anti heart failure therapy but got very limited improvements and then underwent heart transplantation after discussion with hepatology experts and approved by the Medical Ethics Committee in Fuwai Hospital. In her DNA we identified two causal mutations (c.1735+1G>T and c.G3299A) in AGL genes. Besides we also found the case harbored four damaging mutations in two genes (3 in TTN and 1 in SGCD) implicated in cardiomyopathies. Taken the clinical symptoms and DNA analysis together we conclude that the severe cardiomyopathy in our case was at least partly attributed to gene mutations.

2929S

PNPLA6 mutations in Laurence-Moon Syndrome (LMS) illustrate its distinct genetic etiology from Bardet-Biedl syndrome (BBS) and suggest its classification as part of a newly described neurodegenerative spectrum. *H. Dollfus[1,2], M. Prasad[1], E. Schaefer[1], D. Bonneau[3], C. Mutter[4], C. Stoetzel[1].* 1) Laboratoire de Génétique Médicale, INSERM U1112, Strasbourg, France; 2) Centre de référence pour les Affections Rares en Génétique Ophtalmologique (CARGO), Hôpitaux Universitaires de Strasbourg, France; 3) Service de génétique, CHU d'Angers, Angers, France; 4) Centre d'Investigations Cliniques (CIC) Hôpitaux Universitaires de Strasbourg, France.

There has been a long-standing confusion concerning Bardet-Biedl Syndrome (BBS) and Laurence-Moon Syndrome (LMS) as, historically, their names were linked together because of overlapping features. We have been studying a large family, with 5 affected siblings, reported as having LMS (Chalvon-Demersay at al., 1993) because of early onset retinal dystrophy, obesity, hypogonadism and spastic paraplegia (the patients did not have polydactyly or kidney impairment). In-depth clinical exploration identified cerebellar vermis atrophy in two patients that were wheel chair bound with spastic paresis. Moreover, we show that the retinal phenotype is remarkably distinct compared to BBS retinal dystrophy. In order to identify the underlying molecular alteration we performed, in 2010, a next-generation sequencing exome scan, but failed to find any pathogenic mutations with the initial commercial analysis pipeline. In 2014, an in-house analysis pipeline revealed a novel (p.[Arg1031Glnfs*38]; c. [3088_3091insAGCC]) mutation in the PLNLA6 gene. Homozygous mutations in PNPLA6 were reported at the same time in Boucher-Neuhäuser and Gordon Holmes syndromes (Synofzik et al, 2013). Due to poor coverage of the gene by exome sequencing, Sanger sequencing was used to identify a second mutation, a novel missense mutation (p.[Gly726Arg]; c.[2176G>C]) in a residue that is highly conserved through C. elegans. Both mutations segregated in the family. We suggest that Laurence-Moon syndrome enters the Boucher-Neuhäuser and Gordon Holmes spectrum in a broad group of neurodegenerative diseases and should not be considered as a part of the BBS and ciliopathy spectrum.

2930M

Microdeletion in the PITX2 Upstream Region in a Family with Axenfeld-Rieger Syndrome. *M. Walter, T. Footz.* Dept Med Gen, Univ Alberta, Edmonton, AB, Canada.

Purpose: Axenfeld-Rieger Syndrome (ARS) is a genetically-heterogeneous autosomal dominant disorder that affects ocular development and puts patients at an elevated risk of acquiring glaucoma, a neurodegenerative blinding disorder. DNA variations that cause ARS have been discovered in two transcription factor-encoding genes, PITX2 and FOXC1, but only account for about half of the reported cases of ARS.

Methods: To investigate the missing heritability of the syndrome, we commissioned whole-exome sequencing (WES) for three members of a family with autosomal dominant inheritance of ARS who lack mutation of the coding regions of PITX2 and FOXC1. DNA variants detected by WES were analysed by PCR-based targeted sequencing of additional family members. Quantitative genomic PCR was used to examine gene dosage.

Results: No non-synonymous coding region mutations that fully segregated with the disease were discovered. However, the correct segregation of alleles of five DNA variants at the PITX2 locus (a missense single nucleotide polymorphism (SNP), three intronic SNPs and a nearby intergenic microsatellite marker), led us to examine PITX2 gene copy number in the family. As a result, we discovered half-dosage of a subset of conserved regulatory elements directly upstream of the PITX2 transcript, but normal dosage of PITX2 exons.

Conclusions: Our results suggest that these ARS patients harbour a deletion of no more than 360 kilobases, the smallest known deletion that is restricted to the PITX2 upstream region. Since deletion of the entire upstream region is sufficient to cause ARS, we conclude that this small upstream segment contains PITX2 regulatory elements essential for normal ocular development and function.

2931T

Mutations in DOCK7 in individuals with epileptic encephalopathy and cortical blindness. *F.F. Hamdan[1], I. Perrault[2, 3], M. Rio[4], J-M. Capo-Chichi[1], N. Boddaert[5], J-C. Décarie[6], B. Maranda[7], R. Nabbout[8], M. Sylvain[9], A. Lortie[1], P. Roux[10], E. Rossignol[1], X. Gérard[2, 3], G. Barcia[8], P. Berquin[11], A. Munnich[4], G. Rouleau[12], J. Kaplan[2,3], J. Michaud[1], J-M. Rozet[2,3].* 1) CHU Sainte-Justine Research Center, MONTREAL, Canada; 2) INSERM UMR 1163, Laboratory of Genetics in Ophthalmology, 75015 Paris, France; 3) Paris Descartes - Sorbonne Paris Cité University, Imagine Institute, 75015 Paris France; 4) Department of Genetics, Hôpital Necker Enfants Malades, 75015 Paris, France; 5) Department of Pediatric Radiology, Hôpital Necker-Enfants Malades, APHP, Paris, Descartes University, 75015 Paris, France; 6) Department of Medical Imaging, Sainte-Justine Hospital, Montreal, Canada, H3T 1C5; 7) Division of Genetics, Centre Hospitalier Universitaire de Sherbrooke, Sherbrooke, Canada, J1H 5N4; 8) Department of Pediatric Neurology, Centre de Reference Epilepsies Rares, Hôpital Necker-Enfants Malades, APHP, Paris, Descartes University, 75015 Paris, France; 9) Division of Neurology, Centre Hospitalier Universitaire de Québec, Québec, Canada, G1V 4G2; 10) Institute for Research in Immunology and Cancer, University of Montreal, Montreal, Canada, H3C 3J7; 11) Department of Pediatric Neurology, CHU Amiens, 80054 Amiens Cedex, France; 12) Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada, H3A 2B4.

Epileptic encephalopathies are increasingly thought to be of genetic origin, although the exact etiology remains uncertain in many cases. We describe here three girls from two non-consanguineous families showing a clinical entity characterized by dysmorphic features, early-onset intractable epilepsy, intellectual disability, and cortical blindness. Brain imaging also showed specific changes in individuals from each family, including an abnormally marked pontobulbar sulcus as well as abnormal signals (T2 hyperintensities) and atrophy in the occipital lobe. Exome sequencing performed in the first family did not reveal any gene with rare homozygous variants shared by both affected siblings. It did, however, show one gene, DOCK7, with two rare heterozygous variants (c.2510delA (p.Asp837Alafs*48) and c.3709C>T (p.Arg1237*)) found in both affected sisters. Exome sequencing performed in the proband of the second family also showed the presence of two rare heterozygous variants in DOCK7 (c.983C>G (p.Ser328*) and c.6232G>T (p.Glu2078*)). Sanger sequencing confirmed that all three individuals are compound heterozygotes for these truncating mutations in DOCK7. These mutations have not been observed in public SNP databases and are predicted to abolish critical domains for DOCK7 function. DOCK7 codes for a Rac guanine nucleotide exchange factor that has been implicated in the genesis and polarization of newborn pyramidal neurons as well as in the morphological differentiation of GABAergic interneurons in the developing cortex. All together, these observations suggest that loss of DOCK7 function causes a previously unrecognized syndrome by affecting multiple neuronal processes.

2932S

Nonsense mutation in coiled coil domain containing 151 gene (*CCDC151*) causes Primary ciliary dyskinesia. *M. Erzurumluoglu[1], M.M. Alsaadi[2], S. Rodriguez[1], T.R. Gaunt[1], A.C. Al-Rikabi[4], P.A.I. Guthrie[1], K.K. Alharbi[3], H.Z. Omar[2], M. Mubarak[2], I.N.M. Day[1].* 1) Bristol Genetic Epidemiology Laboratories, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 2) College of Medicine, King Saud University, Riyadh, Kingdom of Saudi Arabia; 3) College of Applied Medical Sciences, King Saud University, Riyadh, Kingdom of Saudi Arabia; 4) Department of Pathology, King Saud University, Riyadh, Kingdom of Saudi Arabia.

Primary ciliary dyskinesia (PCD, OMIM: #244400) is an autosomal recessive disorder characterised by impaired ciliary function and/or structure which leads to subsequent clinical phenotypes such as chronic sino-pulmonary disease. PCD is also a genetically heterogeneous disorder with many single gene mutations (with >20 genes identified so far) leading to similar clinical phenotypes. Here we present a novel PCD causal gene, coiled coil domain containing 151 (*CCDC151*), which has been shown to be essential in motile cilia of many animals and vertebrates but its nullizygous effects in humans was not observed previously. We observed a novel nonsense mutation in the *CCDC151* gene (c.925C>A, p.E309X) in a clinically diagnosed PCD patient from a consanguineous family of Arabic ancestry. We then directly assayed the variant using PCR-RFLP in 238 randomly selected individuals to find the prevalence of the variant in the local population. The variant was absent in all individuals indicating that the mutation is not a founder mutation and may have occurred relatively recently. *CCDC151* will be an addition to the already identified PCD causal genes (with six of them being coiled-coil domain containing genes: *CCDC39*, *CCDC40*, *CCDC65*, *CCDC103*, *CCDC114* and *CCDC164*) and facilitate our understanding of this complex disorder. Our finding also shows that given prior knowledge from model organisms, even a single whole-exome sequence (with high read depth, e.g. 50X) can be sufficient to discover a novel causal gene (i.e. once a strong candidate is pinpointed, the variant status can be confirmed in the other family members by amplifying the region of interest).

2933M

Combined exome and targeted gene NGS gene panel identifies mutations in *CCDC151* as a cause of Primary Ciliary Dyskinesia. *A. Onoufriadis[1,2,17], R. Hjeij[3,17], CM. Watson[4,5,17], N. Primary ciliary dyskinesia (PCD) is a heterogenous genetic disorder of ciliary/flagellar dysmotility characterized by chronic upper and lower respiratory infections and defects in laterality. The disease is recessively inherited and affects one per 15,000-30,000 births. So far, mutations in 27 genes have been identified to cause PCD including *DNAH5, DNAH11, DNAI1, DNAI2* and *DNAL1* which encode subunits of the axonemal outer dynein arm (ODA) components, *CCDC114* which encodes an ODA docking complex component and *ARMC4* which is essential for proper targeting and anchoring of ODAs. Resequencing of a panel of candidate ciliopathy genes was applied to an affected Bedouin-Arabic individual from a consanguineous marriage. Therefore, we focused on homozygous non-synonymous or splice-site substitutions or indels, that were novel or present in the 1000 Genomes Project with a frequency <0.01. This analysis revealed a homozygous protein truncating variant in *CCDC151* (c.925G>T; p.Glu308*). In parallel, exome sequencing combined with autozygosity mapping was applied to an affected offspring from a UK-based consanguineous Pakistani-origin family. This strategy highlighted a large autozygous region in chromosome 19p13 harbouring an additional homozygous protein-truncating variant in *CCDC151* (c.1256C>T; pSer419*). Sanger sequencing of the *CCDC151* coding exons and their associated splice-sites in a cohort of 150 cases affected with PCD resulting from ODA defects identified an individual carrying the c.925G>T nonsense variant. Segregation analysis of the c.925G>T and c.1256C>T substitutions in all available members of the pedigrees confirmed recessive inheritance of both variants. Transmission electron microscopy of respiratory cilia cross-sections from individuals carrying *CCDC151* mutations showed loss of ODA. Immunofluorescence analysis showed that *CCDC151* encodes an axonemal coiled coil protein, mutations in which abolish assembly of CCDC151 into respiratory cilia, and furthermore cause a failure in axonemal assembly of the ODA component DNAH5 and ODA-DC associated proteins CCDC114 and ARMC4. In summary, these data suggest that *CCDC151* mutations cause PCD by disruption of the ODA docking complex formation.

2934T

Defective core protein IFT81 as a rare cause of a ciliopathy with neurological involvement. *I. Perrault[1, 2], J. Halbritter[3], J. Porath[3], X. Gérard[1,2], H. Yung Gee[3], D. Braun[3], H. Bidirectional intraflagellar transport (IFT) consists of two major protein complexes, IFT-A and IFT-B. In contrast to IFT-B, all components of IFT-A have recently been linked to human ciliopathies when defective. By screening of 1,056 individuals with nephronophthisis-related ciliopathies for mutations in all genes encoding IFT-B, we identified one family with a homozygous obligatory splice site mutation in IFT81. Independently, by applying targeted ciliome resequencing of 572 individuals with early-onset severe retinal dystrophies or multisystemic ciliopathies, we found another family with a homozygous frameshift resulting in a loss-of-stop mutation with extension of the deduced protein by 10 amino acids. Both affected individuals presented with typical ciliopathy features, such as nephronophthisis, retinal dystrophy, cerebellar atrophy, and mild skeletal malformations. Cultured fibroblasts from one of the affected individuals showed no difference to control fibroblasts in regards of IFT81 localization to primary cilia or binding to IFT25. However, there was a statistically significant decrease in ciliated cell abundance compared to control fibroblasts. In addition, expression of GLI1 and PTCH1 appeared markedly increased, suggesting deranged sonic hedgehog signaling. Unlike the peripheral IFT-B members IFT172, and IFT80, IFT81 is only the second core protein found defective in humans. Our data further elucidate the role of IFT-B in human disease and show that defects in the IFT-B core are an exceedingly rare finding, probably due to its indispensable role for ciliary assembly in development.

2935S

Genetic study of patients with Joubert Syndrome and Related Disorders. *T. Vilboux[1], D. Yildirimli[1], M. Vemulapalli[2], A.R. Cullinane[1], M.C.V Malicdan[1], Y.M. Chang[1], J. Bryant[1], C. Sinclair[1], R. Fischer[1], B. Maskeri[2], A.C. Young[2], J. Mullikin[2], M. Huizing[1], W.A. Gahl[1,3,4], M. Gunay-Aygun[1,3], NISC Comparative Sequencing Program, NHGRI, NIH.* 1) MGB, NHGRI, NIH, Bethesda, MD; 2) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Rockville MD 20852, USA; 3) Office of the Clinical Director, NHGRI, National Institutes of Health, Bethesda, MD USA; 4) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, Maryland, USA.

Joubert Syndrome and Related Disorders (JSRD) is a clinically and genetically heterogenous group of ciliopathies defined based on a distinctive brain malformation (molar tooth sign) on brain imaging. Most JSRD patients display hypotonia, developmental delay, abnormal eye movements, and an abnormal respiratory pattern in infancy. Variable features include fibrocystic kidney disease, congenital hepatic fibrosis, retinal degeneration, retinal colobomas, and polydactyly. To date, twenty-two genes have been identified; they account for approximately 50% of JSRD. Over the past 10 years, we have evaluated over 100 JSRD patients at the NIH Clinical Center, under the NHGRI protocol "Clinical and Molecular Investigations into Ciliopathies" (www.clinicaltrials.gov, trial NCT00068224). The enrollment criterion was a clinical diagnosis of JSRD made based on brain MRI report describing the pathognomanic finding of "molar tooth sign" on brain MRI. In about fifty patients in whom we found no mutation in known JSRD genes using standard methods, we performed whole exome sequencing; to facilitate the analysis, family members were included. To date, the analysis has revealed that 2/3 of these patients have mutations in known ciliopathy genes. In the remaining 1/3, we have identified 4 novel genes; only 16% of families now lack a molecular basis for their JSRD. Identification of the underlying genetic causes of JSRD patients and further description of the full clinical spectrum of the related phenotypes will provide the groundwork for more focused studies. We are now assessing cilia integrity and function at the cellular level as well as at the level of the whole organism, using animal models such as zebrafish and C. *elegans*. This study will help to define genotype-phenotype correlations, improve diagnosis and prognosis, and stimulate development of improved supportive treatments as well as specific, novel and targeted therapies.

2936M

The Role of a Rare Variants in Genetic Predisposition to Statin-Induced Myopathy. *V. Stranecky[1], K. Hodanova[1], H. Hartmannova[1], L. Piherova[1], A. Pristoupilova[1], M. Neroldova[2], M. Vrablik[3], M. Jirsa[2], S. Kmoch[1].* 1) First Medical Faculty, Charles University of Prague, Prague, Czech Republic; 2) Laboratory of Experimental Hepatology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; 3) Third Medical Department, First Faculty of Medicine Charles University and General Faculty Hospital in Prague, Czech Republic.

Statin-induced myopathy is an important cause of statin intolerance and the most common cause of statin discontinuation. Statins exhibit a class-wide side effect of muscle toxicity and weakness, which has led regulators to impose both dosage limitations and a recall. This study focuses on the genetic factors associated with increased statin muscle concentrations, especially the genes encoding an influx transporter (SLCO1B1), efflux transporters (ABCB1 and ABCG2) and others, still unknown genes. We have analyzed gDNA of extreme cases of statin-induced myopathy. Patients had to fulfill the criteria: age over 18, clinically and biochemically determined myopathy, elevation of creatinin kinase and histological confirmation of muscle disease, no intake of inhibitors of OATP1B1 membrane transporters. We have performed exom sequencing, whole genome genotyping, analyzed CNV's and searched for large deletions. Here we present preliminary results of 11 patients. We found LOH (loss of heterozygosity) in *SLO1B* loci in 4 patients and a novel frameshift mutation c.209_210insATTGA (p.D70fs) in *SLCO1B3* in one individual. Heterozygous variant c.521T>C (p.V174A) dbSNP rs4149056 in *SLCO1B1* associated with station myopathy (Link et al, NEJM 2008), was found in 5 patients. In two cases this variation was combined with LOH in the *SLCO1B3* region. The incidence of this variant in our study is 5/22 alleles, which exceeds population frequency (MAF in 1000Genomes 0.123). No potential pathogenic variants in genes *SLCO1B1* and *SLCO1B3* was found in 3 of 11 patients. Furthermore we found null mutations in 823 genes. The most relevant for the study are *CYP3A43* (1 patient), *CYP3A5* (1 patient) a *AMPD1* (2 patients). Frequent occurrence of null mutations was found in *CYP* (*CYP2F1* 4x, *CYP4B1* 3x) gene family and transporters (*SLC7A13* 3x, *ABCB10* 2x). We found also null mutations in *APOB1* (1 patient) and *LPL* (1 patient) which contribute to hyperlipoproteinemia. Theoretical consequence of our project lies in detailed knowledge of genetic predisposition to toxicity of statins. Our results will help to predict pharmacodynamics and kinetics of statins and other drugs. Individual approach based on the assessment of the patient's genotype will improve the safety of the therapy.

2937T

Ocular developmental anomalies (ODA) such as Anophthalmia/Microphthalmia (AM) or anterior segment dysgenesis (ASD) have an estimated combined incidence of 3.7 in 10,000 births. Mutations in *SOX2* are the most frequent contributors to severe ODA, yet account for a minority of the genetic drivers. To identify novel ODA loci, we conducted targeted high-throughput sequencing of 407 candidate genes in an initial cohort of 22 sporadic ODA patients. Patched 1 (*PTCH1*), an inhibitor of sonic hedgehog (SHH) signaling, harbored an enrichment of rare heterozygous variants in comparison to either controls, or to the other candidate genes (four missense and one frameshift), and targeted resequencing of *PTCH1* in a second cohort of 48 ODA patients identified two additional rare nonsynonymous changes. Consistent with a role of *PTCH1* in ODA, functional analysis in a zebrafish *in vivo* complementation model showed that all six patient missense mutations affect SHH signaling. These results underline the SHH signaling pathway role during human ocular development, and demonstrate that PTCH1 contributes mutations to as much as 10% of ODA.

2938S

Deciphering the endothelin pathway in auriculocondylar syndrome and isolated question mark ears. *C. Gordon[1], F. Petit[2], P. Kroisel[3], L. Jakobsen[4], R. Zechi-Ceide[5], M. Oufadem[1], C. Bole-Feysot[1], P. Nitschke[1], A. Munnich[1], S. Lyonnet[1], M. Holder-Espinasse[6], J. Amiel[1].* 1) Institut Imagine, INSERM U-1163, Paris, France; 2) Hopital Jeanne de Flandre, Centre Hospitalier Regional Universitaire de Lille, Lille, France; 3) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 4) Copenhagen University Hospital, Herlev, Denmark; 5) Hospital for Rehabilitation of Craniofacial Anomalies, University of Sao Paulo, Bauru, Brazil; 6) Department of Clinical Genetics, Guy's Hospital, London, UK.

Auriculocondylar syndrome (ACS) is a rare craniofacial disorder involving micrognathia, condyle hypoplasia and question mark ear (QME). QME, which involves a defect in the fusion of the lobe and helix, can occur as an isolated anomaly. Recently, mutations in PLCB4 (encoding a phospholipase C enzyme) and GNAI3 (encoding a G alpha protein) were identified in ACS. Both genes are predicted to function in the endothelin 1 (EDN1)-endothelin receptor type A (EDNRA) signalling pathway during the development of the pharyngeal arches. Following exclusion of PLCB4 and GNAI3 in a series of ACS and QME patients, we performed exome sequencing in four unsolved families. We identified a mutation in EDN1 in three cases, and a mutation in a gene known to regulate intracellular calcium release downstream of phospholipase C activity, in the fourth. Another EDN1 mutation was subsequently identified by direct sequencing. Two of the four EDN1 mutations occurred in patients affected with ACS, born to consanguineous, healthy parents; these patients harboured homozygous missense mutations in EDN1, each predicted to interfere with enzymatic cleavage of the EDN1 proprotein. The other two EDN1 mutations occurred in patients with dominantly-inherited isolated QME; they harboured heterozygous EDN1 mutations - a premature stop in one case and a missense mutation affecting a highly conserved residue of the mature EDN1 peptide in the other. The nature of the mutations and the different modes of inheritance suggest that heterozygous loss of function mutations in EDN1 cause isolated QME and that homozygous hypomorphic mutations cause ACS. These are the first reported mutations of EDN1 in humans. Our studies have also identified a mutation in a regulator of intracellular calcium release not previously implicated in the EDN1 pathway or in craniofacial development. Our results suggest that ACS and QME are a phenotypic continuum resulting from impaired EDN1-EDNRA signaling.

Mutations in *COG2* Encoding a Subunit of the Conserved Oligomeric Golgi Complex Cause a Congenital Disorder of Glycosylation. *H. Kodera[1], N. Ando[2], I. Yuasa[3], Y. Wada[4], Y. Tsurusaki[1], M. Nakashima[1], N. Miyake[1], S. Saitoh[2], N. Matsumoto[1], H. Saitsu[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Kanagawa, Japan; 2) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Aichi, Japan; 3) Division of Legal Medicine, Faculty of Medicine, Tottori University, Tottori, Japan; 4) Department of Molecular Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan.

The conserved oligomeric Golgi (COG) complex is involved in intra-Golgi retrograde trafficking, and mutations in six of its eight subunits have been reported in congenital disorders of glycosylation (CDG). Here we report a patient showing severe acquired microcephaly, psychomotor retardation, seizures, liver dysfunction, hypocupremia, and hypoceruloplasminemia. Analysis of his serum glycoproteins revealed defects in both sialylation and galactosylation of glycan termini. Trio-based whole-exome sequencing identified two heterozygous mutations in *COG2*: a *de novo* frameshift mutation [c.701dup (p.Tyr234*)] and a missense mutation [c.1900T>G (p.Trp634Gly)]. Sequencing of cloned reverse-transcription polymerase chain reaction products revealed that both mutations were located on separate alleles, as expected, and that the mutant transcript harboring the frameshift mutation underwent degradation. The c.1900T>G (p.Trp634Gly) mutation is located in a domain highly conserved among vertebrates and was absent from both the public database and our control exomes. Protein expression of COG2, along with COG3 and COG4, was decreased in fibroblasts from the patient. Our data strongly suggest that these compound heterozygous mutations in *COG2* are causative of CDG.

2940T

De novo *SOX11* mutations cause Coffin-Siris syndrome. *N. Matsumoto[1], Y. Tsurusaki[1], E. Koshimizu[1], H. Ohashi[2], S. Phadke[3], N. Miyake[1].* 1) Yokohama City Univ Grad Sch Med, Yokohama, Japan; 2) Division of Medical Genetics, Saitama Children's Medical Center, Iwatsuki, Japan; 3) Department of Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Uttar Pradesh, India.

Coffin-Siris syndrome (CSS) is a congenital disorder characterized by growth deficiency, intellectual disability, microcephaly, characteristic facial features and hypoplastic nails of the fifth fingers and/or toes. We previously identified mutations in five genes encoding subunits of the BAF complex, in 55% of CSS patients. To further address genetic causation,Here we performed whole exome sequencing in additional CSS patients, identifying de novo SOX11 mutations in two CSS patients with mild intellectual disabilitya mild end of CSS phenotype. sox11a/b knockdown in zebrafish causes brain abnormalities, potentially explaining the brain phenotype of CSS. SOX11 is the downstream transcriptional factor of the PAX6-BAF complex, highlighting the importance of the BAF complex and SOX11 transcriptional network in brain development. Aknowledgment: Drs. Kou I, Shiina M, Suzuki T, Okamoto N, Imamura S, Ymashita M, Watanabe S, Yoshiura K-i, Kodera H, Miyatake S, Nakashima M, Saitsu H, Ogata K are highly appreciated for their contribution to this work.

Copy Number Variations detection for Congenital Absence of bilateral ACL and PCL ligaments. *Y. Liu[1], R. Golhar[1], ME. March[1], Y. Guo[1], Y. Li[1], ME. March[1], J. Li[2], J. Zhang[2], X. Xu[2], MA. Deardorff[1], B. Keating[1], H. Hakonarson[1].* 1) Center for Applied Genomics, The children's hospital of philadelphia, Philadelphia, PA; 2) BGI-Shenzhen, Shenzhen, China 518083.

Absence of the anterior (ACL) or posterior cruciate ligament (PCL) are rare congenital malformations that results in knee joint instability with a prevalence of 0.017 per 1,000 live births and can be associated with other lower limb abnormalities such as ACL agnesia and absence of menisci. While few cases of absence of ACL/PCL are reported in literature, a number of large familial case series of related conditions such as ACL agnesia suggest a potential underlying Mendelian etiology. We report a Copy Number Variation (CNV) deletion of exons in the gene CEP57L identified in a mother and daughter of the same family based on exome sequencing. CEP57L1 (centrosomal protein 57kDa-like 1) is a protein-coding gene that annotated as microtubule binding and molecular_function based on Gene Ontology (GO). Corresponding protein centrosomal protein may be required for microtubule attachment to centrosomes indicates the gene involved with mitosis processes. The deletion is validated through qPCR. The specificity of the CNV deletion has been check through ~700 exome sequencing data including 274 healthy individuals, and Database of Genomic Variations (DGV), a database contains large numbers of annotated CNVs from previous scientific reports. The CNV deletion we reported is a de novo variation that associated with ACL/PCL.

2942M

New standards in OMIM for gene-phenotype relationships in the era of whole genome/exome sequencing and a new way to follow disease gene discovery through MIMmatch. *J.S. Amberger, C.A. Bocchini, N. Sobreira, A.F. Scott, A. Hamosh.* Institute of Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD, USA.

For almost 50 years, OMIM has been cataloging phenotype-gene relationships. Over time, variants have been ascertained by a variety of technologies and the certainty of these relationships is highly variable. The use of whole-genome/exome sequencing has enabled rapid growth in the publication of causative variants, but still does not confirm the certainty of the relationships. Effective January 2013, OMIM has adopted the following criteria to establish a gene-phenotype relationship: (1) the existence of multiple, unrelated individuals with pathogenic variants in the same gene; (2) the variants segregate with the phenotype in multiplex families; and/or (3) the variants occur de novo in a statistically significant number of individuals. Functional data and/or animal models support the causality but are not required. A "qualified" gene-phenotype relationship is established based on the following: (1) only one multiplex family is reported to have variants in a single gene and the variants segregate with the phenotype in the family, and (2) there is supportive functional data such as in vitro enzyme activity, a comparable phenotype in a model organism experiment, or an animal model; in this case the gene-phenotype relationship is qualified by noting that the variant has been identified in only "1 family". In rare instances, a similar gene-phenotype relationship may be established on the basis of a single patient if there is robust supporting phenotype and functional data. The morbid map listing of a qualified phenotype is preceded by a "?". When other information is entered into OMIM that substantiates the phenotype-gene relationship, the qualifier is removed. No relationship is established if a report identifies only 1 patient or family and provides no supporting functional data; however, an allelic variant may be created as a "variant of unknown significance" with a discussion of a possible relationship with the phenotype. The same criteria is being applied retrospectively to all existing OMIM gene-phenotype relationships that are based on a single allelic variant. To help users follow OMIM entries, we have implemented a new service, MIMmatch. MIMmatch members can designate entries or Phenotypic Series to follow and receive email alerts when these are updated; find other researchers who share their interest in certain entries; and/or receive a daily update on new gene-phenotype relationships established in OMIM.

Using an Augmented Exome to Improve Diagnostic Yield: Case Studies in Retinal Disorders. *S. Garcia[1], J. Tirch[1], M.J. Clark[1], S. Strom[2], A. Martinez[3], G. Chandratillake[1], J. Harris[1], A. Patwardhan[1], S. Chervitz[1], M. Li[1], M. Pratt[1], G. Bartha[1], S. Luo[1], R. Chen[1], J. West[1], M.B. Gorin[3].* 1) Personalis, Inc., Menlo Park, CA; 2) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA; 3) Department of Ophthalmology and Jules Stein Eye Institute, UCLA, Los Angeles, CA.

Identifying the genetic etiology for retinal disorders is challenging because of allelic, phenotypic, and locus heterogeneity, as well as environmental toxicities resulting in phenocopies. Patients often endure long diagnostic odysseys involving many single gene and/or gene panel tests, with a genetic etiology remaining undetermined in a large percentage of cases (30-50%). Whole exome sequencing (WES) is a highly appealing alternative to panels which require frequent revision as new causative genes are discovered; however, incomplete coverage of relevant genes means standard WES is also non-ideal. To address these limitations, we developed an augmented exome (ACE Exome), which improves sensitivity to detect variants by enhancing coverage over genes of biomedical relevance. We conducted ACE Exome sequencing for members of eleven families with undiagnosed retinal disorders and used a novel automated system to rank variants by integrating family history and phenotypic information with the exome data. For ten of these families, we successfully identified the likely genetic basis of their retinal disorder. Several of these diagnoses would have been either missed completely or timely and expensive to pick-up via sequential gene testing protocols due to the involvement of genes that are thought to cause disease only rarely, e.g. variants in CRX, which is associated with only 1% of cases of retinitis pigmentosa (RP), were detected in three of our families. Three diagnoses involved genes not present on gene panels available in the US at the time of testing: one family has a novel homozygous variant in LEPREL1, a gene that has only been associated with retinal disorders in a single family in the literature; the second family has a variant in a new gene, previously considered a candidate gene for RP; and a third family was found with variation in NMNAT1, a recently described gene added to panels only very recently. Finally, one family has an X-linked genetic etiology that would have been missed by standard exome sequencing due to poor gene coverage of RPGR. These successes demonstrate the efficacy of enhanced exome sequencing to diagnose the genetic cause of retinal disorders.

2944S

Identifying genetic determinants of poor cochlear implantation outcomes using massively parallel DNA sequencing. *Y.H. Lin[1,2], C.C. Wu[2,3], T.C. Liu[2], W.S. Yang[3,4,5,6], C.J. Hsu[2,7], P.L Chen[1,3,5,6], C.M. Wu[8].* 1) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 2) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 4) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 5) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 6) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan; 7) Department of Otolaryngology, Taichung Tzu Chi Hospital, Buddhist Tzu Chi Medical Foundation; 8) Department of Otolaryngology, Chang Gung Memorial Hospital, Chang Gung University, Taoyuan, Taiwan.

Cochlear implantation, although extremely expensive, is currently the treatment of choice for children with severe to profound hearing impairment. However, the outcomes with cochlear implants (CIs) vary significantly among recipients. The purpose of the present study is to identify the genetic determinants of poor CI outcomes. Twelve children with poor CI outcomes (the "cases") and 30 "matched controls" with good CI outcomes were subjected to comprehensive genetic analyses using massively parallel sequencing, which targeted 129 known deafness genes. Audiological features, imaging findings, and auditory/speech performance with CIs were then correlated to the genetic diagnoses. We identified genetic mutations in 7 (58%) of the 12 cases; 4 cases had bi-allelic *PCDH15* mutations and 3 cases had bi-allelic *DFNB59* mutations. Mutations in the *WFS1*, *GJB3*, *ESRRB*, *LRTOMT*, *MYO3A*, and *POU3F4* genes were detected in 7 (23%) of the 30 matched controls. The allele frequencies of *PCDH15* and *DFNB59* mutations were significantly higher in the cases than in the matched controls (both $P < 0.001$). In the 7 CI recipients with *DFNB59* or *PCDH15* mutations, otoacoustic emissions were absent in both ears, and imaging findings were normal in all 7 implanted ears. *DFNB59* or *PCDH15* mutations are major genetic determinants of poor CI performance, probably because of their role in the pathology of spiral ganglion neurons and/or brainstem auditory nuclei. Because children with *DFNB59* or *PCDH15* mutations show clinical features indistinguishable from those of other typical pediatric CI recipients, genetic examination is indicated in all CI candidates prior to operation.

Exome sequencing reveals *TPO* mutations in Pseudo-Pendred syndrome. *A. DENOMME-PICHON[1], E. COLIN[1,2], S. MARLIN[3], L. JONARD[3], S. ROULEAU[4], S. KURY[5], S. DUMONT[5], D. GOUDENEGE[1], R. COUTANT[4], D. BONNEAU[1,2].* 1) Department of Biochemistry and Genetics, CHU Angers, Angers, France; 2) UMR CNRS 6214 INSERM 1083, Angers, France; 3) Department of Genetics, CHU Necker-Enfants-Malades, Paris, France; 4) Department of Pediatrics, CHU Angers, Angers, France; 5) Department of Genetics, CHU Nantes, Nantes, France.

Pseudo-Pendred syndrome (PPDS) is defined by the association of sensorineural deafness, hypothyroidism due to iodide organification defect, absence of inner ear malformation and absence of mutation in *SLC26A4* (MIM 605646), the gene responsible for classical PDS (MIM 274600).

In order to determine the cause of PPDS, we performed whole exome sequencing (WES) in a family with two children affected with hypothyroidism, developmental delay, positive perchlorate test and absence of inner ear malformation on CT-scan. Parents were healthy and non-consanguineous and direct sequencing of *SLC26A4* was normal in both patients.

WES was performed in both patients and their father. Variants were ranked by segregation, allele frequency, protein change and degree of conservation to assess likelihood of causation. Both patients were found to be compound heterozygous for missense mutations (c.T1357G,p.Y453D and c.G699C,p.W233C) in *TPO* (MIM 606765) and the father was heterozygous for the Y453D mutation.

In silico prediction tools determined a deleterious mutational impact of both variants on protein function. Sanger sequencing confirmed the mutation segregation and found that the mother was heterozygous W233C. The latter mutation was novel and both were absent in the control population.

TPO encodes thyroperoxidase which catalyzes key reactions in thyroid hormone synthesis and mutations in *TPO* are responsible for thyroid dyshormonogenesis 2A. Mutations in *TPO* have been reported in 4 patients with hypothyroidism and deafness in a series of Israeli patients with iodide organification defect (Tenenbaum-Rakover, 2007) but their phenotype was not described as PPDS. These cases together with the present report suggest that mutations in *TPO* can be responsible for pseudo-PDS.

2946T

Alleles of the reported deafness genes are major contributors to the etiology of moderate to severe hearing loss in Pakistani population. *A. Imtiaz[1,2], R. Bashir[2], G. Mubtaja[2], A. Maqsood[2], I. Bukhari[2], A. Rehman[1], R.J. Morell[1], T.B. Friedman[1], S. Naz[2].* 1) NIDCD, National institute of Health, Bethesda, MD; 2) School of Biological Sciences, University of the Punjab, Lahore, Pakistan.

Most of the genes that cause recessively inherited deafness are associated with profound, prelingual hearing loss, which occurs approximately 1/1,000 live births. The genetic causes of moderate, progressive, post-lingual hearing loss are not well understood, despite the fact that this type of hearing loss is much more prevalent in the general population. We studied the molecular genetic bases of recessively inherited, stable or progressive, moderate to severe hearing loss in 44 consanguineous Pakistani families. We used a stepwise experimental approach, starting with homozygosity mapping at reported DFNB loci, followed by targeted sequencing of the known deafness genes, and finally whole-exome sequencing (WES) to identify mutations in novel genes associated with this phenotype. 11 known and 17 novel mutations in the known deafness genes cosegregate with moderate to severe hearing loss in 68% of these families. The majority of these reported mutant alleles are thought to cause only profound deafness. Nevertheless, our finding of their association with less severe phenotype may suggest the presence of environmental or genetic modifiers (suppressors) that reduce phenotypic severity. *SLC26A4, TMC1* and *OTOF* are three of the major contributors in this cohort. In 14 of the families we did not find causative variants in known deafness genes. Our findings indicate that the same genes and alleles known to cause profound deafness are also major contributors to the genetic basis of moderate to severe hearing loss.

2947S

Mutations in a metabolic kinase gene lead to autosomal dominant retinitis pigmentosa. *F. Wang[1,2], Y. Wang[3], B. Zhang[1,2], H. Li[4], L. Zhao[1,5], K. Wang[1,2], M. Xu[1,2], Y. Li[1,2], F. Wu[6], C. Wen[6], P. Bernstein[7], H. Wang[1,2], R. Sui[4], K. Zhang[6,8], R. Chen[1,2,5,9,10].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030, USA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 3) Zhongshan Ophthalmic Center, Sun Yat-sen University, Guangzhou 510060, China; 4) Department of Ophthalmology, Peking Union Medical College Hospital, Peking Union Medical College, Beijing 100730, China; 5) Structural and Computational Biology and Molecular Biophysics Graduate Program, Houston, TX 77030, USA; 6) Shiley Eye Center and Institute for Genomic Medicine, University of California San Diego, La Jolla, CA 92093, USA; 7) Department of Ophthalmology and Visual Sciences, Moran Eye Center, University of Utah School of Medicine, Salt Lake City, Utah 84132, USA; 8) Veterans Administration Healthcare System, San Diego, CA 92161, USA; 9) The Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX 77030, USA; 10) Program in Developmental Biology, Baylor College of Medicine, Houston, TX 77030, USA.

Retinitis pigmentosa (RP) is a genetically heterogeneous disease with over 60 causative genes known to date. Nevertheless, approximately 40% of RP cases remain genetically unsolved, suggesting many novel disease-causing genes are yet to be identified. Here, we identified a glucose metabolism-related kinase gene as a novel causative gene for autosomal dominant RP (adRP). This is the first report that associates the glucose metabolic pathway with human retinal degenerative disease, suggesting a potential new disease mechanism. A large adRP family with negative result from known-retinal-disease-gene screening was recruited. Linkage analysis identified a minimal disease region of 8 Mb with a peak parametric LOD score of 3.500. Further whole-exome sequencing identified a heterozygous missense mutation that segregated with the disease phenotype in the family. Screening over 200 unsolved RP patients identified two unrelated simplex RP cases carrying an identical mutation which is only 11 amino acids away from the initial mutation identified in the adRP family, suggesting that both alleles may impact the same functional domain. Biochemical assays showed that the mutation does not affect kinase enzymatic activity or the protein stability, suggesting that the mutation may impact other uncharacterized function or result in a gain-of-function.

2948M

Expansion of the fibrosing poikiloderma phenotype caused by FAM111B to include cytopenia and pancreatic dysfunction. *A. Seo[1], T. Walsh[2], M.K. Lee[2], M-C. King[1,2], A. Shimamura[3].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Division of Medical Genetics, University of Washington, Seattle, WA; 3) Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, WA.

Poikiloderma, a dermatological disorder including telangiectasia, uneven pigmentation, and epidermal atrophy, can be inherited recessively as part of Rothmund-Thomson syndrome (RTS [MIM 268400]), Kindler Syndrome (MIM 173650), hereditary sclerosing poikiloderma of Weary [MIM 173700], and dyskeratosis congenita (DKCX [MIM 305000]). Recently, heterozygous missense mutations in FAM111B (MIM 615584) were shown to be responsible for a newly defined autosomal dominant condition including poikiloderma, tendon contraction, myopathy, pulmonary fibrosis, heat intolerance, hypohidrosis, eczematous lesions, and alopecia/sparse hair (POIKTMP [MIM 615704]). The critical FAM111B mutations all lie in the C-terminal trypsin-like cysteine/serine peptidase domain. Little is known about the function of FAM111B, and it remained unclear whether variants in other regions of FAM111B would result in the same or different clinical phenotype. We evaluated a large family of Northern European ancestry with a history of poikiloderma, eczema, heat intolerance, hypohidrosis, sparse hair, and elevated liver enzymes, apparently inherited in autosomal dominant fashion. The two youngest affected siblings also exhibited intermittent cytopenias, marrow hypocellularity, and exocrine pancreatic dysfunction, which are the characteristic features of Shwachman-Diamond Syndrome (SDS). A grandfather had a history of interstitial pulmonary disease, and several individuals had signs of tendon contracture. SBDS, the causative gene for SDS, was wildtype in the affected siblings. Whole exome sequencing of these two siblings, the affected father, and the unaffected mother revealed a heterozygous in-frame deletion FAM111B c.1261_1263delAAG (p.Lys421del) in the affected individuals. Genotyping the family revealed the mutation to be present in all 7 affected relatives genotyped and absent in all 3 unaffected relatives genotyped. The mutation does not appear on any public databases or among our in-house control exomes. In FAM111B, lysine at residue 421 lies outside the trypsin-like cysteine/serine peptidase domain, which may explain phenotypic differences between this family and those harboring mutations in the peptidase domain. Our study expands the phenotype caused by variants in FAM111B to include exocrine pancreatic dysfunction, cytopenias, and marrow failure. Our findings suggest FAM111B may play an important role in regulating fundamental processes of cellular maintenance, growth, and proliferation.

An atypical Bloom syndrome identified by exome sequencing in a ten year old girl with microcephaly. *C. Dupont[1], Y. Vial[2,3], I. Baatout[1], B. Diarra[1], S. Jacquier[3], B. Benzacken[1,3,4], A.C. Tabet[1], H. Cave[2,5], A. Baruchel[6], A. Verloes[7], M. Ouachee[6], S. Drunat[2,3].* 1) Unite de Cytogenetique, Departement de Genetique, APHP-Hopital Robert Debre, CHU Paris, Paris, France; 2) Unite de Biologie Moleculaire et Biochimie, Departement de Genetique, Hopital Robert Debre-AP-HP, CHU Paris, Paris, France; 3) Unite Inserm UMR1141- Universite Paris 7, France; 4) CHU Paris, Hopital Jean Verdier, Unite de Cytogenetique, Bondy, France, Universite Paris 13, Sorbonne Paris Cite; 5) Unite Inserm UMR1131- Universite Paris 7, France; 6) Service d'hemato-immunologie, Hopital Robert Debre-AP-HP, CHU Paris, Paris, France; 7) Unite de Genetique Clinique, Departement de Genetique, Hopital Robert Debre-AP-HP, CHU Paris, Paris, France.

Introduction: Bloom's syndrome (BSyn) is a very rare autosomal recessive chromosomal breakage disorder mainly characterized by pre-and post-natal growth retardation, cancer predisposition, facial sun-sensitivity and increased susceptibility to infections. BSyn is caused by mutations in the *RECQL3* gene, a DNA helicase, and is more common in the Ashkenazic jewish population where a founder mutation was identified. We report the unexpected diagnosis of Bloom syndrome in a Caribbean girl referred for microcephaly. Case report: The patient is a 10 year-old girl which presented with growth retardation of prenatal onset, severe microcephaly (-5SD) without intellectual disability, moderate thrombopenia, immune deficiency, and small café-au-lait spots on the trunk and limbs. Material and methods: Trio-based exome sequencing was performed in order to find new candidate genes for microcephaly in this patient. The data analysis searched for homozygous mutations found in the patient and not in her parents or compound heterozygous mutation inherited from one parent. Sister chromatid exchanges were BrDU induced on patient lymphocytes according to standard protocols and compared to an age-matched control to confirm the molecular diagnosis. Results: Exome sequencing identified compound heterozygous mutation in the *RECQL3* gene: NM_000057.2:c.c.2650_2651del (p.Lys884Alafs*5) and NM_000057.2:c.2809C>T (p.Gln937*) which both introduce a premature stop codon. The mutations and their de novo occurrence were confirmed by Sanger sequencing. BrDu-cytogenetic analysis showed a higher percentage of sister chromatid exchanges (five to eight times more exchanges) in patient's lymphocytes compared to the control. Discussion: In the reported case, the molecular diagnosis led to a retrospective clinical diagnosis in a patient with a phenotypic presentation not suggestive of Bloom syndrome. This result further illustrates that exome sequencing may be a comprehensive tool to detect genetic mutations, allowing for the identification of unexpected genetic causes in atypical clinical phenotypes.

2950S

Achieving genetic diagnosis in deaf patients with non-confirmative *GJB2* genotypes using massively parallel DNA sequencing. *C.J. Hsu[1,2], Y.H Lin[2,3], C.C. Wu[2,4], P.L. Chen[3,4,5].* 1) Department of Otolaryngology, Taichung Tzu Chi Hospital, Taichung, Taiwan; 2) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 3) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 5) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan.

Recessive mutations in the *GJB2* gene are the most common genetic cause of idiopathic sensorineural hearing impairment (SNHI). However, in about 10% to 50% of patients, only 1 recessive *GJB2* mutation can be detected, constituting a diagnostic dilemma. In these patients, we hypothesize that there might be undetected mutations in: (1) the non-coding region of *GJB2* (such as untranslated exons, introns, promoter or enhancer) leading to compound heterozygous inheritance; (2) other gap junction genes leading to digenic inheritance; or (3) other modulating deafness genes. Accordingly, we designed a massively parallel sequencing (MPS) panel which target the whole *GJB2* gene and the exons of 129 deafness genes (including all gap junction genes), and applied this panel to 12 patients with only 1 recessive *GJB2* mutation detected by conventional Sanger sequencing of the *GJB2* coding region. Causative mutations in other deafness genes were identified in 4 patients, including *SLC26A4* mutations in 2 patients (genotypes: p.K369X/p.T410M and p.P8T/p.P8T, respectively), *KCNQ4* mutation in 1 patient (genotype: p.F182L/wt), and *MYO15A* mutations in 1 patient (genotype: p.W58C/c.8596-1G>C). A splicing site mutation (IVS1+1G>A) in *GJB2* was detected in 1 patient, contributing to compound heterozygosity of *GJB2* mutations. Of note, we also found ~67% mosaicism of *GJB2* c.235delC in another patient which was difficult to be identified by Sanger sequencing alone. In total, our MPS panel achieved genetic diagnosis in 6 (50%) of 12 patients with only 1 recessive *GJB2* mutation detected by conventional Sanger sequencing, including 4 with SNHI attributable to mutations in other deafness genes and 2 with SNHI attributable to compound heterozygosity or mosaicism of *GJB2* mutations. Our results demonstrated the utility of MPS in achieving genetic diagnosis in deaf patients with non-confirmative *GJB2* genotypes on conventional genetic examinations.

Megacystis microcolon intestinal hypoperistalsis syndrome (MMIHS) is a heterogenous condition characterized by marked dilatation of the bladder without structural obstruction, microcolon and decreased or absent intestinal hypoperistalsis. The adverse prognosis is due to complications related mainly to parenteral nutrition and renal failure. Although more than 200 described cases are sporadic, the ocurrence of MMIHS associated with consanguinity and recurrence in siblings with asymptomatic parents gave support for many years to the hypothesis of autosomal recessive (AR) inheritance. Recently, the identification of a de novo mutation in the ACTG2 gene in patients with MMIHS changed this concept and highlighted the possibility of genetic heterogeneity. The ACTG2 gene was also associated with phenotypes related to the spectrum of visceral smooth muscle diseases [familial visceral myopathy and chronic intestinal pseudo-obstruction (CIP)] with autosomal dominant pattern. The objective of this presentation is to show the preliminary investigation of five new Brazilian patients with MMIHS and related phenotypes. So far, we have identified the following patients: three with the classical MMIHS, being two sibs with consanguineous parents [F= 1/16], one presenting CIP, and the last one with megacystis without a defined etiology. The investigation strategy is firstly to sequence the ACTG2 by the Sanger method and, if negative to study these cases by the whole-exome sequencing. The ACTG2 sequencing of three patients is ongoing (MMIHS, CIP and megacystis without etiology). In conclusion, we present five new cases of the MMIHS and related phenotypes with a strong evidence of AR inheritance in one family (two sibs with F= 1/16). The up coming results should confirm the genetic heterogenity of the MMIHS spectrum and can contribute to improve the knowledge about its genetic basis.

Prevalence of *EIF2AK4* gene mutations in patients with a clinical diagnosis of pulmonary arterial hypertension. *K.L. Sumner[1], K. Damjanovich[1], B. Smith[2], I. Nakayama[3], Y. Ha[1], E. Paul[1], A. Morris[1], L.M. Brown[4,5], P. Bayrak-Toydemir[1,6], C.G. Elliott[4,5], D.H. Best[1,6].* 1) ARUP Institute for Clinical & Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Division of Pulmonary and Critical Care Medicine, Maine Medical Center, Portland, ME; 3) Good Samaritan Hospital, Puyallup, WA; 4) Dept. of Medicine, Intermountain Medical Center and the University of Utah, Murray, UT; 5) Division of Pulmonary Medicine, University of Utah School of Medicine, Salt Lake City, UT; 6) Dept. of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Background: Pulmonary arterial hypertension (PAH) is a rare disorder that may be heritable (HPAH), idiopathic (IPAH), or associated with either drug-toxin exposures or other medical conditions. HPAH is caused by autosomal dominant (with reduced penetrance) mutations in *BMPR2*, and less frequently by mutations in *ACVRL1*, *ENG*, *CAV1*, or *KCNK3*. Recently, autosomal-recessive mutations in *EIF2AK4* have been associated with pulmonary capillary hemangiomatosis and pulmonary veno-occlusive disease. However, it is not clear whether *EIF2AK4* mutations also occur in patients diagnosed with PAH without pathologic examination of lung tissue.

Materials and Methods: Sixty patients with a clinical diagnosis of PAH (7 HPAH, 48 IPAH, 5 unknown) were evaluated for mutations in *BMPR2* by Sanger sequencing and deletion/duplication analysis. *BMPR2* mutation negative patients (n=47) were then tested for mutations in the other known PAH-associated genes (*ACVRL1*, *ENG*, *CAV1*, and *KCNK3*) by Sanger sequencing. The *ACVLR1* and *ENG* genes were also tested for large deletions and duplications. All remaining mutation negative patients (n=46) were then evaluated for mutations in *EIF2AK4* by Sanger sequencing.

Results: Gene mutations were identified in a total of 14 patients. As expected, mutations in *BMPR2* represented the bulk of mutation positive patients (n=13). Mutations were also identified in *ENG* (n=1) and variants of unknown significance were found in *ACVRL1* (n=1) and *KCNK3* (n=1). No mutations were identified in *CAV1* or *EIF2AK4*.

Conclusion: *EIF2AK4* mutations do not appear to be a common cause of disease in patients with a clinical diagnosis of PAH.

2953S

Comprehensive mutation analysis using Ion PGM in 95 patients with neonatal intrahepatic cholestasis. *T. Togawa[1], T. Sugiura[1], K. Ito[1], T. Endo[1], A. Kikuchi[2], N. Ichinoi[2], S. Kure[2], S. Saitoh[1].* 1) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 2) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan.

Next generation sequencing (NGS) technology has revolutionized genomic and genetic research. Neonatal intrahepatic cholestasis is a heterogeneous disorder and caused by mutations in a number of genes, making genetic diagnosis challenging. We developed a diagnostic custom panel of causative 19 genes for neonatal intrahepatic cholestasis using the Ion AmpliSeq™ (LifeTechnologies) and Ion Torrent PGM technology. gDNA samples were obtained from 95 patients divided into two groups. Group A; 50 patients with neonatal or infantile cholestasis, in whom conventional mutation screening was not successful. Group B; 45 patients suspected to have NICCD, and no variants in *SLC25A13* was found by a melting-curve analysis with adjacent hybridization probes (HybProbe, Roche) detecting 95% of mutations in Japanese patients with citrin deficiency. NGS workflow based on a custom AmpliSeq™ panel was designed for sequencing the 14 prevalent known causative genes and 5 unknown genes on Ion PGM™ Sequencer. A panel of genes included *JAG1*, *NOTCH2*, *SLC25A13*, *ATP8B1*, *ABCB11*, *ABCB4*, *AKR1D1*, *HSD3B7*, *CYP7B1*, *TJP2*, *BAAT*, *EPHX1*, *ABCC2*, *VPS33B*, *SLC10A1*, *LST1*, *ABCB1*, *SLCO1A2,* and *SLC4A2*. Number of amplicons, total targeted bases and exons were 551, 53.426kb, 355, respectively. Our AmpliSeq™ custom cholestasis panel allowed us to cover 98.4% of the targeted sequences. NGS was performed on Ion PGM™ with Ion 316™ or 318™ sequence chips. Average coverage of depth in the target region was 654, and 97.1% of sequenced region was covered over 100 coverage. Variant call and annotation were performed with CLC Genomics Workbench version 7.0 and IonReporter™ 4.0. Variants were filtered out by common dbSNP138 and in-house filtering data. Accordingly, we detected disease-causing mutations in 13 patients in group A; four *JAG1* mutations, 1 *NOTCH2*, 2 *ATP8B1*, 2 *ABCB11*, 3 *SLC25A13*, and 1 *ABCC2*. In group B, six patients were identified in 6 causative genes; one *JAG1* mutation, 1 *NOTCH2*, 1 *ABCB11*, 1 *SLC25A13*, 1 *ABCC2*, and 1 *TJP2*. This study shows clinical usefulness of comprehensive mutation analysis by NGS for neonatal intrahepatic cholestasis with unknown genetic etiology.

An update on the CMTX3 locus: using whole genome sequencing to search for the elusive mutation. *M.H. Brewer[1,2], J. Qi[1,3], R. Chaudhry[1,2], A. Drew[1], G. Nicholson[1,2,4], M. Kennerson[1,2,4].* 1) Northcott Neuroscience Laboratory, ANZAC Research Institute, Concord, NSW, Australia; 2) Sydney Medical School, University of Sydney, Camperdown, NSW, Australia; 3) Department of Pathology, University of Sydney, Camperdown, NSW, Australia; 4) Molecular Medicine Laboratory, Concord General Repatriation Hospital, Concord, NSW, Australia.

Charcot-Marie-Tooth (CMT) disease is the collective name given to a group of inherited peripheral neuropathies featuring both sensory and motor involvement. The disease is genetically heterogeneous, with over 1000 mutations identified in over 80 genes, and can be inherited in an autosomal dominant, autosomal recessive or X-linked fashion. Six X-linked CMT loci (CMTX1-6) have been reported, of which the gene mutations for four loci have been identified (GJB1, AIFM1, PRPS1 and PDK3). CMTX3 was first mapped to the q-arm of chromosome X in 1991 [1] and yet this locus remains genetically unsolved. The overarching aim of this project is to identify the genetic cause of CMTX3. Genetic linkage studies performed on two large families confirmed and refined the locus to a 5.7 Mb region at Xq26.3-q27.3 [2,3]. Interestingly, both families carry the same disease haplotype suggesting they share the same disease mutation inherited from a common founder [3]. Mutation scanning the coding exons, splice-sites and untranslated regions of all annotated genes within the disease locus did not reveal a causative mutation. Therefore we hypothesize that CMTX3 is caused by a mutation disrupting a non-coding regulatory element. To thoroughly investigate the CMTX3 locus for regulatory variants we have performed whole genome sequencing (WGS) on six individuals - two affected males and one related healthy male from each family. Analysis of the known CMT genes did not reveal any mutation segregating with the disease phenotype, confirming a known gene does not cause CMT in these two families. Under the assumption that these two families share a common founder disease mutation, WGS data was filtered for: a) novel variants; b) that map within the CMTX3 locus and; c) were found in all affected individuals across both families and absent from both controls. This identified 21 candidate variants (16 SNPs and five indels). Variants were either intronic or intergenic. Importantly, no novel coding variants were identified supporting our previous mutation scanning results. These variants will be assessed for pathogenicity by: a) testing for segregation with the disease phenotype in both CMTX3 families and; b) screening these variants in over 600 neurologically normal controls. PITUITARY HORMONE DEFICIENCY: HUNT FOR NOVEL CAUSATIVE GENES AND GENETIC CONTRIBUTIONS TO VARIABLE PENETRANCE AND EXPRESSIVITY. *Q. Fang[1], I.J.P. Arnhold[3], A.F. Benedetti[3], T. Brue[4], L.R.S. Carvalho[3], F. Castinetti[4], F.A. Correa[3], N. Foyouzi[2], M.M. Franca[3], J.Z. Li[1], Q. Ma[1], B.A. Ozel[1], B.B. Mendonça[3], M. Moreira[3], A.P. Otto[3], R. Reynaud[4], A. Sadeghi-Nejad[5], S.A. Camper[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Obstetrics and Gynecology, University of Michigan Medical School, Ann Arbor, MI; 3) University of São Paulo, Clinical Hospital, São Paulo, Brazil; 4) Aix-Marseille University, Center for Research in Neurobiology and Neurophysiology of Marseille (CRN2M) - CNRS UMR7286, Timone Hospital, Marseille, France; 5) Division of Pediatric Endocrinology, Tufts University School of Medicine, Boston, MA.

Pituitary hormone deficiency is genetically heterogeneous and fatal if hypoglycemia and adrenal insufficiency are untreated. The known causal genes explain a minority of the cases. Predicting patient outcomes is difficult because some genes exhibit dominant inheritance with incomplete penetrance, and most mutant genes have variable clinical presentations. Mutations in the transcription factors OTX2 and HESX1 cause defects in craniofacial development involving the eyes, pituitary gland, or both. To identify novel causal genes and to search for genes that influence penetrance we sequenced the exomes of 22 individuals with hypopituitarism. We found two cases of mutations in transcription factor HESX1. A familial case of pituitary aplasia with neonatal crisis is a novel compound heterozygote for HESX1, R159W/R160H, which disrupts the DNA sequence recognition helix. We found a previously reported p.I26T lesion that impairs HESX1 repressor function in a consanguineous case of multiple pituitary hormone deficiency. We discovered a homozygous, recurrent p.L144H mutation in the growth hormone releasing hormone receptor (GHRHR) gene in a consanguineous case of isolated growth hormone deficiency (IGHD). A proband with hypopituitarism, polydactyly, and normal eyes was ascertained in a large pedigree, has a novel heterozygous variant in OTX2 (p.H230L). This histidine is conserved across all vertebrate species, and the leucine variant acts as a dominant negative in both heterologous (293T) and homologous GnRH neuronal cell lines (GT1-7) transfected with either a consensus OTX2 binding site or a known target, the gonadotropin releasing hormone receptor promoter. The proband's mother is a p.H230L carrier with short stature, and several unaffected individuals in the pedigree are heterozygous for this variant. The presence of polydactyly in the father and the proband suggests the possibility of digenic disease. We found a few heterozygous variants shared by the father and the proband that are rare, likely damaging, and are associated with polydactyly or pituitary enriched expression. These genes are candidates for enhancing the effects of the OTX2 variant on hormone production and polydactyly. This exome sequencing pilot revealed that approximately 20% of probands have mutations in known genes, and nominates novel genes and pathways that affect normal pituitary function.

A Combined Exome sequencing and RNA-Seq Strategy Reveals a Novel Mutation in DOCK8 that Results in Immunodeficiency and Radiosensitivity. *S. Khan[1], M. Kuruvillas[1,2], B. Wakeland[1], C. Liang[1], K. Vishwanathan[1], R. Gatti[3], T. Torgersen[4], N. van Oers[1], E. Wakeland[1], M. Teresa de la Morena[1,2].* 1) UT Southwestern Medical Center, Dallas, TX; 2) Children's Medical Center, Dallas, TX; 3) University of California, Los Angeles, CA; 4) Seattle Children's Research Institute, Seattle, WA.

Primary immunodeficiency diseases (PIDs) are rare in the human population, with the causal genetic mutations difficult to identify. To date, more than 180 genes have been linked to diverse PIDs, with the vast majority due to monogenic defects. Recent strategies to identify the genetic causes of PIDs include exome and whole genome sequencing. We performed RNA sequencing and exome sequencing on RNA and DNA from two siblings with prominent manisfestations of warts and cryptosporidium sclerosing cholangitis, profound T cell lymphopenia and radiosensitivity. Comparative analyses including an unaffected sibling and parents using exome sequencing revealed a novel homozygous 2 bp insertion in the splice site region in intron (26-27) of dedicator of cytokinesis 8 (DOCK8) gene in the two affected siblings. RNA-SEQ analysis of their whole blood showed a significant reduction in mRNA levels of DOCK8 gene as well as a cluster of aberrant transcripts within the splice junction. The consequence was a significant loss in DOCK8 protein expression. Both affected siblings had an increased sensitivity to ionizing radiation. While mutations in the DOCK8 gene have been reported as causal to immune dysfunction, this is the first report that indicates a role in radiosensitivity . Also this is the first report identifying a causal mutation in an intronic site by combining RNA sequencing with exome sequencing.

Preliminary analysis of 14 Brazilian patients with Thyroid Dysgenesis using Whole Exome Sequencing. *M.M.L. Kizys[1], G.K. Furuzawa[1], M. Mitne-Neto[2], L.T. Cerdeira[2], M.C.C. Melo[1], M.G. Cardoso[3], S. Nesi-França[4], M.R. Dias-da-Silva[1], R.M.B. Maciel[1].* 1) Medicine, Universidade Federal de Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Fleury Group, Sao Paulo, Sao Paulo, Brazil; 3) Biochemistry, Universidade Federal de Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 4) Pediatrics, Universidade Federal de Parana, Curitiba, Parana, Brazil.

Thyroid dysgenesis (TD [MIM 218700]) is the main cause of congenital hypothyroidism. It is believed that TD result from alterations in specification, proliferation, migration and survival of thyroid cell precursors. The objective of this work was to perform Whole Exome Sequencing (WES) in patients with TD. Total DNA was isolated from 3 thyroid hemiagenesis, 3 hypoplasia, 3 ectopic, 5 agenesis cases and 14 controls for WES. Exons were captured using SeqCap EZ Human Exome v3 kit (Roche NimbleGen, Madison, WI, USA) and sequenced in Illumina HiSeq2000. Mapping and variant calling were performed using the CLC Genomic Workbench 6.5. Sequencing coverage was greater than 60x. The average number of mapped reads was 67 million per sample with about 7 billion aligned bases. The first step of the analysis focused on variants in thyroid embryogenesis related genes. The other variants were classified according to the gene function were they occurred based on Gene Ontology website (http://www.geneontology.org/), including their paralogs and their receptors. The average of variants found on these genes was 846 per patient. The majority of variants were placed in non-coding regions (introns, 5' and 3' UTR). We prioritized the non-synonymous exonic variants and those characterized by loss or gain of stop codon, deletion or insertion of codons, frameshift, loss or gain of splicing sites and variants with minor allele frequency (MAF) less than or equal to 0.01. Specifically for agenesis, a symptomatic condition, we filtered the variants which frequency in the 1000Genome population database (http://www.1000genomes.org/) was lower than 0.01%. Using those filters, we found 48 variants for agenesis, 47 for ectopic gland, 45 for hypoplasia and 29 for hemiagenesis. The analysis after comparing with 14 control samples resulted in 29 variants (26 in heterozygosis) for agenesis, 26 for ectopic (25 in heterozygosis), 23 (21 in heterozygosis) for hypoplasia and 14 (13 in heterozygosis) for hemiagenesis groups. The majority of variants were observed in transcription factors coding genes, allowing us to identify new candidate genes for TD development. Herein, we first report the preliminary analysis using WES and suggest a rather complex genomic mechanism in TD development. Financial support: FAPESP.

Whole-exome sequencing as a diagnostic tool reveals *POC1A* mutation in Primordial Dwarfism. *A. Koparir[1], H. Ulucan[1], O.F. Karatas[1,2], A. Gezdirici[1], B. Yuceturk[3], B. Yuksel[3], A.O. Bayrak[4], O.F. Gerdan[4], E. Fenercioglu[1], M. Seven[1], A. Yuksel[1], M. Ozen[1,5].* 1) Medical Genetics Department, Istanbul University, Istanbul, Turkey; 2) Molecular Biology and Genetics Department, Erzurum Technical University, Erzurum, Turkey; 3) Genetic Engineering and Biotechnology Institute, TUBITAK Marmara Research Center, Kocaeli, Turkey; 4) Information Technologies Institute, TUBITAK Marmara Research Center, Kocaeli, Turkey; 5) Department of Pathology & Immunology, Baylor College of Medicine, Houston, TX, 77030, USA.

Primordial dwarfism is a group of genetically heterogeneous disorders and the term is used for describing prenatal onset growth failure, which persists postnatally. Short stature, onychodysplasia, facial dysmorphism and hypotrichosis (SOFT) syndrome (MIM #614813), a recently described disorder, is characterized by prenatal onset growth retardation, brachydactyly, onychodysplasia, postpubertal onset hypotrichosis, normal psychomotor development, facial dysmorphisms, short long bones, femoral and vertebral body ossification delay. The only associated gene with this syndrome, *POC1A*, encodes POC1A protein which localizes to centrioles and spindle poles. In the current study, we report two patients from a family with primordial dwarfism. The clinical pictures of our patients resembled 3M syndrome particularly, because of short stature, facial dysmorphism and tall vertebral bodies. We utilized WES in our primordial dwarfism patients to screen all primordial dwarfism related genes and to define putative novel candidate genes. A novel homozygous missense mutation was detected in *POC1A* and was confirmed by using Sanger sequencing. Parents have also been demonstrated to be heterozygous carriers for this mutation. This result shows that the clinical pictures of the patients are more consistent with SOFT syndrome rather than 3M syndrome. There are two more reports associated with SOFT syndrome, therefore, here we report the third family and a novel mutation. Moreover, to confirm the pathogenicity of the detected mutation, punch biopsies from the patients and a control individual were used to culture fibroblasts and demonstrate the effects of the identified mutation through a series of functional studies.

2959S

Mutation of *CLPB*, a human homologue of bacterial ClpB /yeast Hsp104 mitochondrial molecular chaperone, causes a novel form of autosomal recessive 3-methylglutaconic aciduria. *C. Saunders[1,2], F. Wibrand[3], P. Bross[4], K. Ravn[3], L. Smith[1], I. Thiffault[1], A. Atherton[5], N. Miller[1], E. Farrow[1], S. Kingsmore[1,2], E. Østergaard[2].* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO; 2) Department of Pathology and Laboratory Medicine, Children's Mercy Hospital, Kansas City, MO; 3) Department of Clinical Genetics, Copenhagen University Hospital Rigshospitalet, Copenhagen, Denmark; 4) Research Unit for Molecular Medicine, Aarhus University Hospital, Aarhus, Denmark; 5) Department of Pediatrics, Section of Genetics,Children's Mercy Hospital, Kansas City, MO.

Methylglutaconic aciduria comprises a heterogeneous group of five different syndromes of inborn errors of metabolism characterized by mitochondrial dysfunction (3-MGA-uria: MIM#250950). The metabolic landmark is urinary excretion of 3-methylglutaconic acid and its derivative, 3-methylglutaric acid. Types I-III and V are caused by mutations in four different genes, however, the genetic cause of 3-MGA-uria type IV has not been established. Here we describe a novel, lethal 3-MGA-uria characterized by onset within the first nine months with severe hypotonia, myoclonus, bilateral cataracts, and lactic acidosis, associated with variants in the *CLPB* gene encoding the ClpB caseinolytic peptidase B homolog. Mutations were identified in five patients, including four Greenlandic individuals from three families not known to be related, and one from North America. Homozygosity mapping in the Greenlandic patients identified a single 4.5 Mb region of interest on chromosome 11, encompassing 62 genes. Sequencing of putative mitochondrial genes in this region yielded the same homozygous *CLPB* variant, c.803C>T (p.Thr268Met), in all four patients. The variant changes a highly conserved threonine to a methionine, located in the ankyrin-repeat domain. It is predicted to be pathogenic by SIFT, PolyPhen2 and MutationTaster. Screening of Greenland controls showed a carrier frequency of 3.3%, similar to other severe recessive diseases in this population. Trio exome sequencing of the North American family revealed two nonsense variants in *CLPB*, p.Lys321* and p.Arg417*. Western blot analysis showed absence of CLPB protein in fibroblasts from the Greenland patients and liver from the North American patient. *CLPB* encodes a mitochondrial chaperone important for mitochondrial protein biogenesis, and is required to maintain organelle function under stress conditions. CLPB has mainly been studied in bacterial ClpB /yeast Hsp104, and belongs to the Clp/Hsp104 family (Hsp100 family), a group of sequence-related AAA+ proteins containing two consensus ATP-binding sites. Our data indicate that recessive variants in *CLPB* result in a specific phenotype including a new form of 3-MGA-uria. Further studies in these patients may provide new insights into mammalian mitochondrial dysfunction through protein aggregation in neurodegenerative disorders.

Leveraging Population Structure to Improve Causal Variant Identification in Exome Sequencing Studies of Mendelian Diseases. *R. Brown[1], H. Lee[2], A. Eskin[3], G. Kichaev[1], K. Lohmueller[1,4], B. Reversade[5], S. Nelson[2,3], B. Pasaniuc[1,2,3].* 1) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, Geffen School of Medicine, UCLA, Los Angeles, CA; 3) Department of Human Genetics, Geffen School of Medicine, UCLA, Los Angeles, CA; 4) Department of Ecology and Evolutionary Biology, UCLA, Los Angeles, CA; 5) Institue of Medical Biology, A*STAR, Singapore.

Recent breakthroughs in whole exome sequencing technologies have made possible the identification of many causal variants of Mendelian (monogenic) diseases. Although extremely powerful when related individuals (e.g. family trios) are simultaneously sequenced, exome sequencing of unrelated individuals with Mendelian traits is often unsuccessful due to the large number of variants that need to be followed-up for validation. The standard approach for reducing the number of putatively causal variants is to filter out all common variants above a pre-specified frequency threshold (e.g. 1%), followed by prioritization of the remaining variants according to their predicted functionality. In this work, we present new methods that leverage population structure (e.g. the variability of allele frequencies across populations) to improve the variant filtering step. We show that the existing filtering approaches are susceptible to high false negative rates (i.e. probability of missing a true causal variant) when reference panel sizes are limited. We introduce a framework that takes into account the finite size of the reference panels while correctly accounting for the ancestry of the sequenced individuals. In simulations starting from 1000 Genomes data, we show that our methods reduce the number of variants to be followed-up from an average of 408.1 variants per exome when ancestry is ignored to 254.8 when ancestry is taken into account (a 38% reduction). Most importantly, our proposed approaches are well calibrated with respect to the false negative rate. We validate our findings using exome-sequencing data from 22 unrelated individuals with Mendelian diseases for which the true causal variants are known. In this real data our method is able to reduce the number of variants for follow-up by 42% without filtering the true causal variants.

Truncating Mutation in CIB2 causes DFNB48 and not USH1J. *K.T. Booth[1], K. Kahrizi[2], A.C. Simpson[1], A.E. Shearer[1], C.M. Sloan[1], H. Najmabadi[2], H. Azaiez[1], R.J.H. Smith[1].* 1) Otolaryngology - Head & Neck Surgery, University of Iowa, Iowa City, IA; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

Deafness is the most frequent sensory disorder worldwide affecting one of every five hundred newborns. Currently there are over 90 genes causally related to hearing loss and of those 55 are associated with autosomal recessive non syndromic hearing loss (ARNSHL) making deafness extremely heterogenous. Here we report a consanguineous family of Iranian origin segregating ARNSHL. Audiologic examination of affected individuals revealed bilateral profound hearing loss across all frequencies. Ophthalmological examination was normal. To identify the genetic cause of deafness in this family, we concurrently performed linkage analysis to identify segments of homozygosity-by-descent and whole exome sequencing (WES) in one affected individual. The deafness-causing gene in this family mapped to the DFNB48/USH1J locus and WES data revealed a novel homozygous large deletion encompassing exon 2 of CIB2 gene. Variants in CIB2 are known to cause ARNSHL. The deletion we identified leads to a frameshift and premature stop codon at amino acid 24; c.52_86del: p.Asp18Alafs*7, yielding a null allele. We used long-range PCR and Sanger sequencing to map the breakpoints to a 3.1 kb interval that spans CIB2 exon 2 and includes several repetitive elements (LINE, SINE...) on either side of the deletion. This type of sequence homology favors genomic rearrangement by non-allelic homologous recombination. CIB2 encodes the calcium- and integrin-binding protein 2 (CIB2), which is expressed in both the retina and inner ear, where it localizes to the tips of stereocilia. In the inner ear CIB2 interacts with MYO7A and WHRN, making it part of the USH1 interactome. To date only four missense mutations have been described in CIB2. Two of them represent a major cause of ARNSHL in the Pakistani population. This study is the first to report of a copy number variation associated with CIB2-related deafness and further uncovers the genetic spectrum of deafness in the Iranian population.

Cornelia de Lange syndrome (CdLS) is a genetically heterogeneous disorder manifesting extensive phenotypic variability. To date, mutations in *NIPBL*, *SMC1A*, *SMC3*, *RAD21* and *HDAC8*, which encode subunits or regulators of the cohesin complex, are found in about 65% of patients. Wiedemann-Steiner syndrome (WDSTS), caused by mutations in *KMT2A*, shares phenotypic features with CdLS. We utilized genomic approaches to determine additional molecular etiologies for CdLS-like phenotypes and investigate molecular underpinnings of shared clinical features. Whole exome sequencing (WES) of two male siblings clinically diagnosed with WDSTS revealed a hemizygous, predicted-deleterious, missense mutation in *SMC1A*. Extensive clinical evaluation and WES of a Turkish cohort of 30 patients clinically diagnosed with CdLS revealed a *de novo* heterozygous nonsense *KMT2A* mutation in one patient without characteristic WDSTS features. Moreover, a *de novo* heterozygous frameshift mutation in *SMC3* was identified in a patient with combined CdLS and WDSTS features. Furthermore, in families from two separate world populations segregating an autosomal recessive disorder with CdLS-like features, we identified homozygous mutations in *TAF6*, which encodes a core component in a transcriptional regulation pathway. Our findings suggest CdLS and related phenotypes may result from a "transcriptomopathy" rather than a cohesinopathy: a conclusion supported by recent transcriptomic studies.

2963M

Deep re-sequencing of *CFTR* bearing the common F508del mutation reveals a rare variant associating with variation in lung infection. *B. Vecchio-Pagán[1], M. Lee[1], M.R. Knowles[3], S.M. Blackman[2], G.R. Cutting[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Division of Pediatric Endocrinology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Cystic Fibrosis/Pulmonary Research and Treatment Center, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Common and rare intragenic variation has the potential to modify protein expression that may correlate with severity of disease phenotypes. Here we describe deep re-sequencing of a well-characterized locus, *CFTR*, in 482 patients homozygous for the most common disease mutation, F508del (rs113993960). Variants in *CFTR* cause the autosomal recessive disorder, cystic fibrosis (MIM #219700), in which the primary cause of mortality is lung disease complicated by infection. A custom designed capture of the 215kb region containing *CFTR* in 964 chromosomes harboring the F508del mutation revealed 272 common variants (MAF > 1%), and 307 rare variants. 301 rare SNPs and small INDELs present on 6 or more chromosomes were used to define linkage disequilibrium (LD) blocks and construct unique haplotypes in this population. Two major LD blocks were observed, and could be explained by a recombination event in intron 16. These results further refine previous reports of recombination occurring within intron 22. The most common haplotype in both of these blocks accounts for 63% of all F508del chromosomes, suggesting that this is the ancestral F508del background. The remaining 37% of F508del chromosomes are combinations of minor haplotypes from both blocks, indicating a wealth of genotypic diversity with the potential for modifying disease severity. Testing of 579 total variants (~32 independent tests due to LD) with cystic fibrosis disease-specific traits revealed association between the rs35453239 A allele and later age at first *Pseudomonas aeruginosa* infection (p=9.16e-5, Bonferroni p=2.93e-3). The A allele of rs35453239 was present on 3 haplotype backgrounds (frequencies: 1.6%, 1.0% 0.7%); two of which were associated with later infection (p=9.16e-5 and p=5.62e-6) and each differs from the third haplotype at a SNP within intron 21 (chr7:117259340A>G; MAF: 0.016). These findings indicate that rs35453239 modifies age at infection only in the presence of the major allele at chr7:117259340. Under this condition, each rs35453239 A allele associates with ~2.32 yrs later age at first lung infection. Of note, both variants are located near putative transcription factor binding sites (ENCODE), suggesting a transcriptional regulation mechanism of effect. These results demonstrate the value of re-sequencing a well-characterized disease locus in an affected population to elucidate origins of phenotypic variability.

2964T

Whole Exome Sequencing in Autosomal Recessive Non-syndromic Deafness: 4 years experience. *G. Bademci[1], O. Diaz-Horta[1], I. Menendez[1], D. Duman[2], J. Foster II[1], F.B. Cengiz[2], N. Mahdieh[3], M. Bonyadi[4], F. Huesca Hernandez[5], M. Arenas Sordo[5], J. Dominguez-Aburto[5], E. Hernandez-Zamora[5], P. Montenegro[6], R. Paredes[6], G. Moreta[6], R. Vinueza[6], F. Villegas[6], R. Alyazidi[7], S. Mendoza Benitez[8], S. Guo[1], S.H. Blanton[1], M. Tekin[1].* 1) John P. Identification of pathogenic mutations underlying autosomal recessive non-syndromic deafness (ARNSD) is difficult, since causative mutations in 55 genes have been reported. After excluding mutations in the most common gene, GJB2, we performed whole-exome sequencing (WES) in 109 unrelated multiplex families with ARNSD. Families in our sample set originated from Turkey, Iran, Saudi Arabia, Mexico, Ecuador, and Puerto Rico. Agilent SureSelect Human All Exon 50 Mb kits and an Illumina Hiseq2000 instrument were used. GATK (Genome Analysis Tool Kit) was used for detection of Single Nucleotide Variants (SNVs) and insertion/deletions (INDELs); CoNIFER (Copy Number Inference From Exome Reads) and XHMM (eXome-Hidden Markov Model) were used for Copy Number Variation (CNV) detection. Autozygous regions as extended runs of homozygous genotypes in the studied samples were sought via WES data with AgileGenotyper and AgileVariantMapper. Candidate variants were confirmed with Sanger sequencing and evaluated for co-segregation with deafness in all available family members. We identified causative variants in 65% of the families in our sample set. The 10 most common genes with either an SNV or an INDEL are MYO15A, SLC26A4, TMC1, TMPRSS3, ILDR1, LOXHD1, MYO7A, OTOF, PCDH15, and USH1C. Homozygous CNVs were detected in OTOA and STRC. Analysis of the WES data in the families remaining negative for causative variants in known deafness genes is used to identify novel deafness genes. In conclusion, comprehensive analysis of SNVs, INDELs and CNVs via WES allows us to identify causative variants in both known and novel genes thus improving our ability to explain the underlying etiology in more families.

2965S

Resolving clinical diagnoses for syndromic cleft lip and palate phenotypes using whole-exome sequencing. *A. Collins[1], L. Arias[2], J. Martinez[2], R. Upstill-Goddard[1], R. Pengelly[1], J. Gibson[1], S. Ennis[1], I. Briceno[2].* 1) Human Genetics, Univ Southampton, Southampton, United Kingdom; 2) Department of Biomedical Sciences, Medical School, Universidad de La Sabana, Bogota, Colombia.

Individuals from three families ascertained in Bogota, Colombia, showing unusual syndromic phenotypes which included cleft lip and/or palate were exome sequenced. In each case exome sequencing revealed the underlying causal variations confirming or establishing diagnoses. The findings include rare and novel variants which provide insights into genotype and phenotype relationships for the conditions. These include the molecular diagnosis of an individual with Nager syndrome and another family exhibiting an atypical Incontinentia Pigmenti phenotype for which we identified a previously reported missense mutation in the IKBKG gene. In this family this rare mutation is associated with a less severe phenotype in which affected male relatives, atypically, survive to full term. The third family exhibited unusual and variably penetrant phenotypic features suggesting the Pierre Robin Sequence (PRS). Affected individuals were found to share a novel mutation in the IRF6 gene which has not previously been associated with PRS. Exome sequencing is a powerful and increasingly cost-effective route to establishing molecular diagnoses for conditions showing phenotypic and/or genetic heterogeneity. It is particularly effective for conditions featuring cleft lip and/or palate for which a substantial proportion of underlying causal genes have not yet been identified.

2966M

Recurrent mutations cause Ablepharon-macrostomia syndrome and Barber-Say syndrome. *T. Davis[1], S. Marchegiani[1], F. Tessadori[2], C. Markello[1], H. Huang[3], D. Schanze[4], A. Hoischen[5], G. van Haaften[2], V. Maduro[1], F. Brancati[6], B. de Vries[5], C. Boerkoel[1], S. Lin[3], W. Gahl[1,7], M. Zenker[4], T. Markello[1], AMS/BSS Consortium.* 1) Undiagnosed Diseases Program, Office of the Director, National Institutes of Health, Bethesda, MD, USA; 2) Hubrecht Institute-KNAW, University Medical Center Utrecht, Utrecht, Netherlands; 3) Department of Molecular, Cell and Developmental Biology, University of California-Los Angeles, Los Angeles, CA, USA; 4) Medizinische Fakultat und Uniklinikum Magdeburg, Institute of Human Genetics, Magdeburg, Germany; 5) Radboud University Nijmegen Medical Centre, Department of Human Genetics, Nijmegen, Netherlands; 6) University of G. d'Annunzio Chieti and Pescara, Department of Medical, Oral and Biotechnological Sciences, Chieti, Italy; 7) Medical Genetics Branch, National Human Genome Research Institute, Bethesda, MD, USA.

Ablepharon-macrostomia syndrome (AMS, MIM 200110) and Barber-Say syndrome (BSS, MIM 209885) are rare congenital disorders characterized by a similar array of craniofacial and dermal features. In order to identify the genetic basis of these disorders, we performed exome and candidate gene sequencing. Seven independent families were found to have a recurrent missense mutation causing AMS, and nine other independent BSS families had a different recurrent missense mutation of the same amino acid. In all cases where unaffected parental DNA was available, we found that these mutations arose de novo. By detailed genetic and molecular analyses, we show that these mutations are neomorphic in nature.

2967T

Mutations in *MAB21L2* result in ocular coloboma, microcornea, and cataracts. *B. Deml[1,2], A. Kariminejad[3], R.H.R. Borujerdi[4], S. Muheisen[1], L. Reis[1], E.V. Semina[1,2].* 1) Department of Pediatrics and Children's Research Institute, Medical College of Wisconsin and Children's Hospital, Milwaukee, WI; 2) Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI; 3) Kariminejad-Najmabadi Pathology and Genetics Center, Tehran, Iran; 4) Qom Welfare Organization, Qom, Iran.

Ocular coloboma is a congenital defect defined as the incomplete closure of the optic fissure and is often associated with additional ocular and systemic defects. Numerous genetic mutations have been identified in coloboma, but many cases still remain to be explained. Whole exome sequencing was performed to identify the causative mutation in a three-generation family with coloboma, microcornea, cataracts and skeletal dysplasia. Sequencing of affected first cousins identified a shared heterozygous allele in *MAB21L2* [MIM 604357], c.151C>G, p.(Arg51Gly), as the most likely causative mutation. Confirmation and segregation analyses were performed by Sanger sequencing and revealed that the c.151C>G, p.(Arg51Gly) allele was present in all five affected individuals and absent in the unaffected grandparents. The mutation was predicted to be damaging by SIFT, Polyphen2, Mutation Taster and MutationAssessor, and demonstrated high conservation scores for the affected nucleotide. Function of MAB21L proteins is largely unknown. *In silico* analysis using I-TASSER predicted the MAB21L2 structure to most closely resemble human cyclic GMP-AMP synthase (cGAS), a protein involved in innate immunity and binding of cytosolic double stranded DNA. According to this model, the arginine at position 51 is predicted to be located only 4 amino acids downstream of the possible DNA binding helix and thus may play a role in this possible interaction. *In situ* hybridization in zebrafish identified *mab21l2* transcripts in the presumptive eye field and midbrain at 18-hours post fertilization with continued strong expression in the retina, lens, brain, spinal cord, pharyngeal arches and developing fins at later developmental stages. To further evaluate the role of *mab21l2* in development, the gene was disrupted using TALEN genome editing technology targeting the region of the human mutation. Zebrafish carrying either homozygous or compound heterozygous frameshift mutations demonstrated microphthalmia with small or absent lenses in 100% of embryos and ocular coloboma in 76%. Zebrafish homozygous for an in-frame deletion, p.(Arg51_Phe52del), developed ocular coloboma in 100% of embryos but had overall normal lens appearance and eye size. These findings support *MAB21L2* as a novel factor involved in human ocular disease. Further, this study demonstrates the power of TALEN technology for the rapid development of animal models to study candidate genes found in human whole exome sequencing studies.

2968S

Homozygous *LRRC10* Mutation in Sporadic Pediatric Dilated Cardiomyopathy. *P.A. Long[1], J.M. Evans[2], B.T. Larsen[3], A.C. Grimes[4], Y. Lee[5], R.C. Balijepalli[4], T.M. Olson[1,6].* 1) Cardiovascular Genetics Research Laboratory, Mayo Clinic, Rochester, MN; 2) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 4) Cellular and Molecular Arrhythmia Research Program, Department of Medicine, University of Wisconsin School of Medicine and Public Health, Madison, WI; 5) Department of Cell and Regenerative Biology, Department of Medicine, University of Wisconsin School of Medicine and Public Health, Madison, WI; 6) Division of Pediatric Cardiology, Mayo Clinic, Rochester, MN.

Idiopathic dilated cardiomyopathy (DCM) is a heritable, genetically heterogeneous disorder characterized by progressive heart failure. DCM typically exhibits an autosomal dominant mode of inheritance and remains clinically silent until adulthood. We sought to identify the genetic basis of severe, non-syndromic DCM diagnosed in a two-month-old girl who underwent cardiac transplantation two months later. Her non-consanguineous parents displayed no phenotypic evidence of DCM on screening echocardiography. Array comparative genomic hybridization detected no clinically reportable chromosomal aberrations. Whole exome sequencing of the family trio revealed approximately 40,000 variants per individual in the 50 megabase capture region. Ingenuity® Variant Analysis™ was utilized to filter for rare, functionally significant variants and model homozygous recessive, compound heterozygous, *de novo*, and uniparental disomy modes of inheritance, resulting in only 3 candidate variants. Homozygosity for c.584T>C, p.Ile195Thr in the leucine rich repeat containing 10 gene (*LRRC10* [MIM 610846]) was identified in the proband, the only variant predicted to be damaging by SIFT and PolyPhen2. Heterozygosity for I195T occurs at a frequency of 0.44% in the population. However, no instances of compound heterozygosity or homozygosity of missense, splice site, or frameshift variants in *LRRC10* were identified in 7,595 exomes in Exome Variant Server and 1000 Genomes. While the molecular function of LRRC10 remains unknown, it was shown previously to have cardiac-specific expression in zebrafish, mice, and humans, with markedly increased expression at birth that is maintained through adulthood in mice. Knockout of *Lrrc10* in mice was shown to cause prenatal systolic dysfunction and postnatal DCM. Preliminary immunohistochemical studies of explanted heart tissue revealed LRRC10-I195T expression in cardiomyocytes. The I195 residue is located in the 7th leucine rich repeat at the 2nd conserved Leu within the highly conserved segment LxxLxLxxNxL. We speculate that substituting this conserved hydrophobic isoleucine with a polar threonine may disrupt proper protein folding and/or interactions with critical cardiac protein(s). In conclusion, we have identified *LRRC10* as a novel gene associated with autosomal recessive, pediatric DCM. Functional studies are underway to clarify the mechanism by which genetic perturbation of this cardiac-specific gene leads to early-onset heart failure.

2969M

Mutation in ANKFY1 as a Cause of Charcot-Marie-Tooth Neuropathy. *M. Park[1], B. Choi[2], S. Choe[3], H. Woo[1], H. Jo[1], K. Chung[4], S. Koo[1].* 1) Division of Intractable Diseases, National Institute of Health, Chungcheongbuk-do, South Korea; 2) Department of Neurology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, South Korea; 3) Department of Microbiology, School of Medicine, Wonkwang University, Iksan, South Korea; 4) Department of Biological Science, Kongju National University, Gongju, South Korea.

Charcot-Marie-Tooth disease (CMT) is the most common inherited neuromuscular disorder involving motor and sensory peripheral neuropathies. We investigated the disease-causing mutation in a Korean CMT2 family with not linked to major genes, and examined the pathogenic effect of the mutation. We performed the whole-exome sequencing for two patients. After filtering out with known variants, we focused on linkage analysis, sharing between two individuals and co-segregating within the family. We identified the causative mutation in the ANKFY1 gene which has never been reported to be caused or associated with motor and sensory peripheral neuropathies yet. The identified mutation is located in the ankyrin-repeat domain. It is known to be a cause of neurological disorder when the repeat domain is disrupted by mutations. Knockdown of ANKFY1 in zebrafish resulted in frequently disconnected motor axons and disorganized neuromuscular junctions, supporting the pathogenic role of mutated ANKFY1 in peripheral neuropathy. Therefore, our data strongly suggest that ANKFY1 mutation is exposed as a novel cause of CMT2. Furthermore, this study may improve understanding of ankyrin-repeat domain-associated axonal CMT neuropathies and their debated pathologic mechanism.

2970T

Characterization of mutation negative autosomal dominant polycystic kidney disease families using whole exome sequencing. *B.M. Paul, K. Hopp, J.L. Sundsbak, C.M. Heyer, V.E. Torres, P.C. Harris.* Division of Nephrology and Hypertension, Mayo Clinic, Rochester, MN.

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is a common (frequency 1: 1000), adult onset nephropathy accounting for 4-10% of patients requiring dialysis or renal transplant worldwide, with an annual US cost of >$1 billion. Mutations to either *PKD1* or *PKD2* cause most ADPKD. However, the description of ADPKD families unlinked to either gene, and no mutations detected in ~8% of ADPKD families, suggests further genetic heterogeneity. We identified ~130 no-mutation detected (NMD) families out of ~1500 screened. Interestingly, they are characterized by milder kidney disease and more frequently have negative family history than is typical in ADPKD. Initially, we analyzed two families by whole exome sequencing (WES), P75 (3 affected, 2 unaffected) and M560 (3 affected). Library preparation and capture was done using the Agilent SureSelectXT Human All Exon V5+UTRs on the Agilent Bravo workstation and sequencing employed on Illumina HiSeq2000. Alignment was performed using Bowtie/BWA and GATK used for variant calling according to best standard practices. Data mining was performed using the Golden Helix SNP and Variation suite (SVS). Initial filtering was set by read depth (10X), genotype quality (≥20) and assignment of autosomal dominant inheritance according to the affected status of the individuals. The ESP6500 and 1000 Genomes databases were used to remove variants with a MAF of ≥ 0.1% and dbNSFP to characterize coding variants. Independent VAAST analysis was also employed. We found a *PKD1* nonsense mutation in M560, previously missed by Sanger sequencing. In P75, 15 candidate variants were detected by both SVS and VAAST and six by VAAST alone. Eleven variants were removed due to misalignment or because of poor consensus score in dbNSFP. Five variants were annotated as damaging by four prediction tools in dbNSFP and five others by two tools. We are prioritizing these ten candidates by their likely localization and involvement in processes and pathways associated with ADPKD. As a next step, we are analyzing six other multiplex NMD families by WES. Finding variants in the same protein, or related pathways/functions, in different families will help identify high-level candidates. Analysis of these candidates will be extended to simplex NMD families using Agilent HaloPlex enrichment. Our large and well characterized cohort of NMD ADPKD families and modern genomic screening methods are allowing rigorous testing for further genetic heterogeneity in ADPKD.

2971S

Whole Exome Sequencing to Uncover Causative Genes in Families with Inherited Autonomic Dysfunction. *J.E. Posey[1], T. Gambin[1], S.N. Jhangiani[2], D.M. Muzny[2], R. Martinez[3], J.E. Lankford[3], M.T. Numan[4], W. Wiszniewski[1], R.A. Gibbs[1,2], I.J. Butler[3], J.R. Lupski[1,2,5,6], Baylor Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030, USA; 3) Division of Child and Adolescent Neurology, Department of Pediatrics, The University of Texas Health Science Center, Houston, TX 77030, USA; 4) Division of Cardiology, Department of Pediatrics, The University of Texas Health Science Center, Houston, TX 77030, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030, USA; 6) Texas Children's Hospital, Houston, TX 77030, USA.

Autonomic dysfunction can be a crippling medical condition, and is characterized by a variety of symptoms including dizziness, palpitations, syncope, temperature dysregulation, increased pain sensitivity, and gastrointestinal distress. These clinical manifestations may be associated with several well-defined genetic syndromes, including Hereditary Sensory and Autonomic Neuropathy, Ehlers-Danlos Syndrome or Familial Dysautonomia [OMIM 223900]. Familial Dysautonomia, also known as Riley-Day Syndrome, is an autosomal recessive type 3 Hereditary Sensory and Autonomic Neuropathy in which patients suffer from cardiovascular instability, gastrointestinal dysfunction, and altered sensitivity to pain and temperature. We identified 14 families in which autonomic dysfunction is inherited in an autosomal dominant manner. Extensive clinical characterization has demonstrated a very specific phenotype that includes postural orthostatic tachycardia syndrome (POTS), atrial septal defect (ASD), headaches, and gastrointestinal distress. These patients do not have decreased or absent lingual fungiform papillae, a hallmark feature of Familial Dysautonomia, and they do not report Ashkenazi Jewish heritage. Given the distinct phenotype, ethnicity, and mode of inheritance seen in these families, we suspect that their autonomic dysfunction is caused by mutations in novel gene(s) playing a role in development and/or functioning of the nervous system. We have performed whole exome sequencing and cSNP analysis on affected members of these families. We are using a combination of cohort analysis, candidate gene analysis, copy number analysis, and individual variant review to identify potentially pathologic variants. Thus far, 17 potentially pathogenic variants have been identified, and we are actively recruiting additional affected family members to further investigate these variants. We are also continuing to enroll new families demonstrating mendelian inheritance of autonomic dysfunction.

2972M

Exome sequencing identifies a recurrent de novo mutation in *ZSWIM6* that causes Acromelic Frontonasal Dysostosis. *J. Smith[1], A. Hing[2,3,4], C. Clarke[4], N. Johnson[2], F. Perez[7], S. Park[4], J. Horst[5], B. Mecham[6], L. Maves[2,3], D. Nickerson[1], M. Cunningham[2,3,4], University of Washington Center for Mendelian Genomics.* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Center for Developmental Biology and Regenerative Medicine, Seattle Children's Research Institute, Seattle, WA; 3) Department of Pediatrics, University of Washington, Seattle, WA; 4) Craniofacial Center, Seattle Children's Hospital, WA; 5) Department of Biochemistry and Biophysics, UCSF, San Francisco, CA; 6) Trialomics Inc, Seattle, WA; 7) Department of Radiology, UW Medicine, Seattle, WA.

Acromelic Frontonasal Dysostosis (AFND MIM 603671) is a rare genetic disorder characterized by distinct craniofacial, brain and limb malformations including frontonasal dysplasia. We performed exome sequencing on one trio and two unrelated probands, and identified an identical missense variant (p. Arg1163Trp) in a highly conserved protein domain of ZSWIM6. Sanger validation of the three trios confirmed its de novo status in the three probands. A fourth case was Sanger sequenced and the identical variant was observed. *ZSWIM6* encodes a 133.5 kDa protein containing a zinc finger SWIM domain. Proteins with SWIM domains have been identified in a diverse number of species from bacteria to eukaryotes and are predicted to have DNA binding and protein-protein interacting properties, but little has been elucidated about their function in vivo. In an effort to understand the potential impact of the p.Arg1163Trp mutation, we conducted detailed structural in silico modeling of amino acid substitutions in ZSWIM6. Interestingly, in situ hybridization of early zebrafish embryos at 24 hours post fertilization (hpf) demonstrates telencephalic expression with onset of midbrain, hindbrain and retinal expression at 48 hpf. Immunohistochemistry of later stage mouse embryos demonstrates widespread expression in the derivatives of all three germ layers. Furthermore, gene expression analysis using qRT-PCR on osteoblast and fibroblast cell lines from two of the probands revealed evidence of Hedgehog pathway activation. Our analysis suggests the mutation in *ZSWIM6* leads to rare craniofacial, brain and limb malformations through disruption of Hedgehog signaling pathway.

2973T

The Gene Discovery Core: four years of experience in determining the genetic basis of orphan diseases. *M.C. Towne[1], C.A. Brownstein[1,2], D.M. Margulies[1,2], A.H. Beggs[1,2], P.B. Agrawal[1,2].* 1) The Manton Center for Orphan Disease Research, Division of Genetics and Genomics, Boston Children's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA.

The Gene Discovery Core (GDC) of The Manton Center for Orphan Disease Research at Boston Children's Hospital has been enrolling individuals and families with rare and unknown disorders in an IRB-approved protocol for the last four years. Goals of the GDC include: determination of the genetic and molecular bases of orphan diseases using various genomic technologies, evaluation of the functional effects of gene mutations using various models, and return of the results to participants in a research setting with independent clinical confirmation. Enrollment is open to any family with a rare or unknown diagnosis that has a suspected, yet unidentified, genetic etiology despite extensive clinical testing. Following identification of a new family with a rare condition, we often ascertain and enroll additional families with similar phenotypes to develop a cohort to create a critical mass for further study. To date, 550 families have participated, of which 57% represent single instances of unique and undiagnosed disorders. Genetic analysis has been initiated for 263 families: 234 of which received whole exomic/genomic sequencing and 30 of whom had targeted gene sequencing of candidate genes. Analysis has been completed for 139 families. Of those with completed analysis, 39% of the families were found to have a mutation in a known gene that fits their phenotype, and these results were returned to the participants after confirmation in a CLIA-certified laboratory. For 20 families, variants were identified in novel genes without prior reports of association with human disease, and suspected to be pathogenic based on *in silico* analysis, gene expression data and pathway involvement. Following review of the literature, we are performing various follow-up studies on these cases, including analysis of mouse and zebrafish models, as well as patient-derived cell or tissue samples, to evaluate causality. Whenever possible, functional assays are developed and tailored for each gene in question. We have successfully linked the phenotype to these novel genes in three of those 20 cases, and we are actively working on the remaining families.

2974S

Exome sequencing identifies the cause of a novel multiple pterygium syndrome and expands the spectrum of phenotypes caused by variants in *MYH3*. *A.E. Beck[1, 2], J.X. Chong[1], C.T. Marvin[1], M.J. McMillin[1], H.I.S. Gildersleeve[1], K.M. Shively[1], W. Best[1], J.C. Carey[3], J. Shendure[4], D.A. Nickerson[4], M.J. Bamshad[1,2,4], University of Washington Center for Mendelian Genomics.* 1) Dept Pediatrics, Div Genetic Med, Univ Washington, Seattle, WA; 2) Seattle Children's Hospital, Seattle, WA; 3) Dept Pediatrics, Div Med Genetics , Univ Utah, Salt Lake City, UT; 4) Dept Genome Sciences, Univ Washington, Seattle, WA.

Mutations in *MYH3*, encoding embryonic myosin, cause Distal Arthrogryposis type 1 (DA1), Sheldon-Hall syndrome (SHS or DA2B), and Freeman-Sheldon syndrome (FSS or DA2A). Each of these conditions is characterized by multiple congenital contractures (MCC) but have distinct clinical characteristics and natural histories that enable them to be distinguished from one another. Individuals with DA type 8 (DA8) likewise have MCC but also have short stature, severe scoliosis and multiple pterygia reminiscent of multiple pterygium syndrome (MPS). Sanger sequencing of candidate genes (*TNNI2*, *TNNT3*, *TPM2*, *CHRNG*, and *RAPSN*) that underlie DA1, DA2B, and MPS in a parent and two affected children with DA8 failed to identify a compelling causal variant. Subsequently exome sequencing revealed a novel 3-base pair duplication in exon 25 of *MYH3*, c.3214_3216dup predicted to lead to an in-frame duplication of a single amino acid residue, p.Asn1072dup. Pathogenic variants in *MYH3* were first identified in individuals with FSS, and subsequent screening of phenotypes with clinical characteristics overlapping FSS led to finding *MYH3* variants that cause SHS and DA1. While the phenotype of DA8 is similar to FSS and SHS, it was distinct enough for *MYH3* not to have been considered a compelling candidate gene. In contrast, exome sequencing (ES) offers the advantage of searching for causal variants with less bias, which can lead to the identification of variants in a single gene that cause new phenotypic features of known conditions (i.e., phenotypic expansion) as well as novel conditions. In large-scale ES efforts to find genes for Mendelian conditions, the identification of genes in which different variants can have very diverse phenotypic effects is becoming increasingly commonplace. We call this property of a gene, specifically the spectrum of phenotypes associated with variants in a given gene, phenotropy in contrast to pleiotropy, which is the spectrum of different effects of a given gene on the body. It also contrasts with allelic heterogeneity, in which variants in a given gene cause variable expression of the same phenotype. We suggest that one of the eventual major impacts of genotype-driven characterization of Mendelian conditions enabled by ES will be a more complete catalogue of phenotropy for virtually every human gene.

2975M

Exome sequencing to identify the genetic bases for lysosomal storage diseases of unknown etiology. *N. Wang[1,2], E. Gedvilaite[1], D. Kumar[3], R. Donnelly[4], J. Xing[1,2], D. Sleat[5,6], P. Lobel[5,6].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Human Genetics Institute of New Jersey, Rutgers University, Piscataway, NJ; 3) Waksman Institute of Microbiology, Rutgers University, Piscataway, NJ; 4) Molecular Resource Facility, Rutgers - New Jersey Medical School, Newark, NJ; 5) Center for Advanced Biotechnology and Medicine, Rutgers University, Piscataway, NJ; 6) Department of Biochemistry and Molecular Biology, Robert Wood Johnson Medical School, Rutgers University, Piscataway, NJ.

Lysosomes are membrane-bound, acidic eukaryotic cellular organelles. As an enzyme container, they play important roles in the degradation of macromolecules. Monogenic mutations resulting in the loss of enzyme activities in the lysosome may lead to severe health problem, such as neurodegeneration, early death, etc. These conditions are categorized as lysosome storage diseases (LSDs). The diagnosis of LSDs is typically straightforward, but in some cases, mutations that result in atypical clinical presentation or defects in previously undescribed lysosomal disease genes may complicate the identification of the underlying genetic defect. Here, we performed whole exome sequencing on 14 suspected LSD cases, with the goal of finding the causal mutations in each case. From the raw sequence data, we first identified DNA variants in each individual using three variant discovery pipelines: the Genome Analysis Toolkit, LifeScope and CLC Genomics Workbench. We then used the Variant Annotation Analysis Selection Tool (VAAST) to prioritize disease-causing mutations in 848 candidate LSD genes. As a probabilistic disease gene finder, VAAST integrates allele frequency, amino acid substitution severity and conservation information into a composite likelihood framework. Different from hard filtering methods, VAAST preserves all the candidates by listing them according to their disease-causing potential. So far a number of candidate variants have been identified, and we are performing downstream mutation validation and proteomic analyses to investigate the potential connection between our candidate variants and LSDs. Our project makes use of bioinformatics analyses to decode enormous exome sequencing data, narrowing down candidate lists and largely increasing the efficiency of downstream proteomic studies. Our results will shed light on the genetic basis of LSDs.

2976T

Clinically significant copy number variants (CNVs) in a cohort of retinal dystrophy probands inferred from whole exome sequence data. *G. Arno[1], S. Hull[1,2], P. Sergouniotis[1,2], E. Lenassi[1,2], A.R. Webster[1,2], V. Plagnol[3], A.T. Moore[1,2].* 1) Inherited Eye Diseases, ORBIT, UCL Institute of Ophthalmology, London, United Kingdom; 2) Moorfields Eye Hospital, London, United Kingdom; 3) University College London Genetics Institute, London, United Kingdom.

Introduction High throughput exome sequencing has enabled the detection of many, novel rare genes for Mendelian disorders. However, there is limited discussion of the inference of clinically meaningful CNVs from the same whole exome sequencing data. We sought to determine the frequency of detectable CNVs in a series of retinal dystrophy patients who had undergone exome sequencing. **Methods** Patients comprised 101 probands affected with a retinal dystrophy. Exome sequencing was carried out and reads were aligned to the hg19 human reference sequence. CNV analysis was carried out with ExomeDepth(1), based on read depth data. Exome data displayed using the Integrated Genomics Viewer (IGV - Broad Institute) was inspected directly over candidate genes to detect reads having an unusual orientation. **Results** 54/101 patients had likely disease causing homozygous or compound heterozygous mutations in known retinal dystrophy genes. Of these, 5 CNVs were detected by ExomeDepth. A homozygous deletion of exons 2-7 of *TRPM1* in a patient with congenital stationary night blindness (CSNB) and a heterozygous duplication of exons 2-9 of *TRPM1* in trans with a novel missense change (p.Y56C) was found in a second patient with CSNB. A heterozygous 42 exon deletion of *GPR98* was found in trans with a frameshift single nucleotide deletion in an Usher syndrome patient and a heterozygous single exon deletion of *GPR98* was found in trans with a frameshift single nucleotide insertion in a second Usher syndrome patient. Finally, a heterozygous 6 exon duplication was found in trans with a novel missense change (p.V1215A) in *PNPLA6* in a patient with an appropriate phenotype. One duplication was identified using IGV to inspect read orientation of candidate genes. A heterozygous single exon duplication characterised by clusters of everted read pairs flanking exon 4 of *NMNAT1* was found. This was in trans with the common missense mutation p.E257K. **Conclusions** CNV analysis based on read depth and close scrutiny of probable disease causing genes in this cohort revealed deletions or duplications in 6 patients. It is essential to incorporate CNV calling methods such as these in exome analysis since they form a significant proportion of clinically significant mutations, in this cohort 7/108 disease-causing alleles. **Reference** 1- Plagnol V, et al. Bioinformatics. 2012 1;28(21):2747-54.

2977S

Pathogenic mutation of coagulation factor X deficiency may prevent atypical hemolytic uremic syndrome. *F. Bu[1,2], N. Borsa[2], W. Tollefson[3], M. Schnieders[3], H. Azaiez[2], K. Wang[4], C. Thomas[2,5], C. Nester[2,5], R. Smith[1,2,5].* 1) Interdepartmental PhD Program in Genetics, University of Iowa, Iowa City, IA; 2) Molecular Otolaryngology and Renal Research Laboratories, University of Iowa, Iowa City, IA; 3) Department of Biochemistry, University of Iowa, Iowa City, IA, USA; 4) Department of Biostatistics, College of Public Health, University of Iowa, Iowa City, IA; 5) Rare Renal Disease Clinic, Departments of Pediatrics and Internal Medicine, Carver College of Medicine, University of Iowa, Iowa City, IA,.

Introduction: Atypical hemolytic uremic syndrome (aHUS) is an ultra-rare renal disease caused by uncontrolled activation of the alternative pathway of complement at the cell surface. Approximately 22% of patients carry pathogenic mutations in *CFH*, the penetrance of which ranges from 12.5% to 100% in familial studies. We hypothesized that genetic modifiers exist that impact the penetrance of aHUS. **Patients & Methods:** Five families carrying a well-recognized aHUS mutation - c.3644G>A, p.Arg1215Gln - in *CFH* were studied. Using targeted genomic enrichment and massively parallel sequencing, we screened subjects for variants in coding exons of all genes in the complement and coagulation cascades based on the recognized cross-talk between these two pathways. Data were analyzed using locally implemented Galaxy software. Pathogenic variants were annotated based on computational predictions and the literature. The functional impact of select variants was confirmed using in vitro assays. **Results:** We identified a reported factor VII deficiency variant ('Padua' variant; *F7* c.1091G>A, p.Arg364Gln) and a reported factor X deficiency variant (*F10* c.424G>A, p.Glu142Lys) in two families that may impact the penetrance of aHUS. The factor X variant segregated in a three-generation family in which two children under 5 years of age developed aHUS. Neither child carried the *F10* p.Glu142Lys mutation. All older family members, none of whom developed aHUS, segregated BOTH the *F10* p.Glu142Lys variant and the *CFH* p.Arg1215Gln variant. Protein structure simulations show the mutated positively charged Lys142 prefers to hydrogen bond with Ser146 instead of Cys129 (the hydrogen-bonding partner of Glu142), destabilizing an important intra-light-chain interaction between a two-stranded beta-sheet and a small alpha-helical secondary structure element. A conformation change is consistent with in vitro studies showing altered secretion of factor X Lys142. In addition, activity assays demonstrate a 30% reduction in activity of the factor X Lys142 variant. **Summary:** A deficiency mutation in coagulation factor X was identified in healthy carriers of known aHUS *CFH* mutation. The coagulation factor mutation causes hypo-coagulation that is predicted to counter-balance the aHUS phenotype. The consequence may explain some instances of incomplete penetrance. In addition, identification of 'protective' genetic modifiers may offer new therapeutic targets to treat this life-threating disease.

2978M

Genetic testing with targeted exon enrichment and massively parallel sequencing for 272 Chinese cases with hearing loss. *j. cheng[1], Y. Lu[1], Z. Jiang[2], C. Li[2], X. Zhang[1], H. Duan[1], D. Han[1], H. Yuan[1].* 1) Inst Otolaryngology, Chinese PLA Gen Hosp, beijing, China; 2) Center for Genetic & Genomic Analysis, Genesky Biotechnologies Inc., Shanghai, China.

Hereditary non-syndromic hearing loss (NSHL) is extremely heterogeneous. The large reservoir of known deafness genes precluded comprehensive genetic testing and population-scale sequencing. Until recently, the combination of targeted genomic capture and massive parallel sequencing (MPS) has become a promising tool for detecting novel and known mutations involved in hereditary hearing loss. In this study, we aimed to establish Chinese population-level frequencies of reported deafness-causing variants in known genes related hearing loss and to determine the genetic defects for 272 Chinese families and 170 congenital deafness cases. We performed a targeted enrichment that enables the capture of 484 genes included both known regions of the human genome associated with hearing loss and some candidate genes in some important pathways related to hearing. With a single reaction for high throughout mutation identification by massively parallel sequencing, the patient samples were barcoded individually and multiplexed. Mutations in 21 known DFNA genes are identified in 37 families with progressing sensorineural hearing loss, and 22 known DFNB genes are identified in 44 cases with congenital deafness. For the potential candidates, the confirmation by Sanger sequencing and co-segregation analysis has been done. Besides the frequency of mutations in known gene was dissolved, novel genes and mutations are described. Discovery of these new genes will continue to help define compelling mechanisms for deafness.

2979T

Prospecting genetic disorders in a highly inbred region of Brazil: two novel genes for AR intellectual deficiency. *T. Figueiredo[1,2,3], U. Souto[2], A. Pessoa[4], P. Ribeiro[5], A. Brandão[5], M. Zatz[2], F. Kok[2,5], S. Santos[1].* 1) Núcleo de Estudos em Genética e Educação, Universidade Estadual da Paraíba, Campina Grande, Brazil; 2) Centro de Pesquisas sobre o Genoma Humano e Células-Tronco, São Paulo, Brazil; 3) Rede Nordeste de Biotecnologia, RENORBIO, Universidade Federal da Paraíba, João Pessoa, Brazil; 4) Faculdade de Medicina, Universidade de Fortaleza, Fortaleza, Brazil; 5) Faculdade de Medicina, Departamento de Neurologia, Universidade de São Paulo, São Paulo, Brazil.

Intellectual deficiency (ID) is a highly heterogeneous condition affecting 3% of the population worldwide. In a field study conducted in a highly inbred area of Northeastern Brazil, we investigated two large consanguineous families with ID. Genome-Wide Human SNP Array 6.0 (Affymetrix) microarray was used to determine regions of homozygosity-by-descent from 3 affected and 3 normal individuals in each family. Whole exome sequencing (WES) was performed in one affected individual of each family using Nextera Rapid-Capture Exome and Illumina HiSeq2500. Potentially deleterious variants detected in regions of homozigosity-by-descent and not present among 8,000 controls (including 600 Brazilians) were subject to further scrutiny and segregation analysis by Sanger sequencing. **Family A** has 9 affected adults descending from four closely related first-cousin couples affected by severe non-syndromic ID associated to disruptive paranoid behavior. Homozigosity-by-descent analysis disclosed a 20.7 Mb region in 8q12.3-q21.2 (lod score: 3.11). WES identified a homozygous deleterious variant in inositol monophosphatase1 gene (*IMPA1*), consisting of a 5 bp duplication (c.489_493dupGGGCT) leading to frameshift (p.Ser165Trpfs*10). *IMPA1* gene product is responsible for the final step of biotransformation of the second messenger inositol-polyphosphate. Homozygous *Impa1* knockout mice die in utero, but can be rescued by supplementation of myo-inositol. Deficiency of IMPA1 might represent a new inborn error of metabolism, affecting inositol-phosphate biotransformation. **Family B** has 3 adult siblings with severe syndromic ID. Phenotype includes large forehead, prognatism, large cupped ears, mildly downslanted eyes and a very large nose. Additionally, affected male has macropenis. Homozigosity-by-descent analysis found a 4.0 Mb region in 19q13.32-q13.33 (lod score: 3.24). WES disclosed a homozygous variant (c.418C>T, p.Arg140Trp) in mediator complex subunit 25 (*MED25*), predicted as deleterious by Provean and SIFT. MED25 is a component of the Mediator complex, involved in regulation of transcription of nearly all RNA polymerase II-dependent genes. Deleterious mutations in *MED12*, *MED17* and *MED23* have been already associated with ID. These findings demonstrate that the combination of field investigation of large families in highly inbred regions with modern NGS technologies is an effective way to identify new genes and pathways which can be the target of future treatment.

2980S

Molecular Basis of Nieman-Pick A-B and Neimann-Pick C Diseases in the Aegean Region of Turkey: Identification of Three Novel Mutations in SMPD1 Gene. *H. Onay[1], A. Aykut[1], S. Kalkan[2], M. Çoker[2], F. Ozkinay[1,2].* 1) Ege University Faculty of Medicine, Department of Medical Genetics, İzmir, Turkey; 2) Ege University Faculty of Medicine, Department of Pediatrics, İzmir, Turkey.

The Niemann-Pick disease group consists of two different entities: (1) acid sphingomyelinase-deficient forms which are caused by SMPD1 gene mutations and encompasse type A and type B, as well as intermediate forms; (2) Niemann-Pick disease type C is a cellular lipid trafficking disorder caused by NPC1 or NPC2 gene mutations. Niemann-Pick Type A patients present with enlarged livers and spleens, a failure to thrive, and neurological manifestations in the first 6 months of life resuting in death before 3 years of age. Niemann-Pick type B patients have little or no neurological involvement , milder symptoms, and survive into adulthood. Niemann-Pick type C has a broad clinical spectrum ranging from a nonimmune hydrops fetalis to an adult-onset chronic neurodegenerative disease. The aim of this study is to investigate the spectrum of mutations detected in SMPD1, NPC1 and NPC2 genes, in either affected individulas or carriers, analysed in a reference center from the Aegean region of Turkey. Screening for the mutations was performed using the direct sequencing method. There were 42 mutant SMPD1 alleles found with nine different types detected amongst these.The most prevalent mutation was p.L137P with an allelic frequency of 47.6 %. Two mutations, namely p.L137P and p.P189PfsX65, accounted for 69% of the total mutated alleles. Three novel mutations (L161P, W176C, T397M) were detected in the group studied. Among these, L161P was found in 11.9% of the unrelated mutant alleles and was the third most common mutation. One of the patients was compound heterozygous for the novel mutation W176C and previously described I178N mutation. Another patient who had very mild symptoms and low enzyme levels was heterozygous for the novel T397 mutation. Four different mutations were detected in NPC1 gene from among 62 indivudals suspected of having NPC disease. One of the patients was homozygous for c.839delT(p.L280CfsX30) mutation, the other for p.N906Y mutation; and two were heterozygous for G992R and A558T mutations. No NPC2 mutation was detected. The results provided will be useful in genetic counseling and prenatal diagnostic services in our region.

2981M

Frataxin, a Fredrich's ataxia protein is defective in mitochondrial processing peptidase-alpha (*PMPCA*) mutations. *P.B. Agrawal[1], M. Joshi[1], I. Anselm[2], F. Giani[1], M. Towne[1], K. Schmitz-Abe[1], K. Markianos[1], V.G. Sankaran[1].* 1) Department of Medicine, Boston Children's Hospital and Harvard Medical School, Boston, MA; 2) Department of Neurology, Boston Children's Hospital and Harvard Medical School, Boston, MA.

A 4-year-old girl with an unknown mitochondrial disease (MD) had multisystem involvement including cardiomyopathy, hypotonia, respiratory insufficiency, myoclonic jerks and blindness. Her cousin (their fathers are brothers and mothers are first cousins), a boy died at 14 months age due to a similar presentation. A MD was suspected based on clinical and histopathological findings and electron microscopy with abnormally enlarged mitochondria. Respiratory chain enzyme analysis in skin fibroblasts revealed minor reduction in complexes I and II/III activities. Sequencing of the mitochondrial DNA, mitochondrial nuclear gene panel and microarray analysis for copy number variations revealed no abnormality. The family was enrolled in an IRB-approved study and to unveil the molecular basis, whole exome sequencing was performed on the trio. We identified compound heterozygous *PMPCA* (MIM 613036) mutations (c.G1066A; p.G356S and c.G1129A; p.A377T) in the proband. These mutations were also present in the affected cousin and they segregated appropriately in the proband's and cousin's parents. A majority of nuclear and mitochondrial DNA-encoded mitochondrial proteins have N-terminal targeting presequence which is cleaved off after import for optimum function. Mitochondrial processing protein alpha (PMPCA), encoded by *PMPCA*, along with the PMPCB (together called MPP) may play a critical role in this process. This may be especially true for frataxin, a protein altered in Fredrich's ataxia (FA) that needs to be cleaved twice, and studies have implicated MPP in FA. This is the first instance of MPP proteins linked to a human disease. PMPCA is highly conserved with homologs present in yeast and rice. The altered amino acids are highly conserved, with G356 present in yeast and rice, and A377 in drosophila and C. elegans. Polyphen-2, SIFT and Mutationtaster software indicated the mutations to be pathogenic. The amount of PMPCA protein was reduced in the patient compared to age-matched control skin fibroblasts. Further, mature frataxin was markedly reduced in the proband while unprocessed frataxin was increased. We overexpressed wild type *PMPCA* in the patient's fibroblasts using lentiviral transduction and rescued the amounts of processed frataxin thereby confirming that *PMPCA* mutations cause defects in frataxin. Currently, we are using morpholinos to evaluate the effects of PMPCA deficiency in zebrafish models and rescue attempts are underway using wild type and mutant *PMPCA*.

Genetic diagnosis of mitochondrial disorders in Finland by whole-exome sequencing. *C.J. Carroll[1], P. Isohanni[1,2], V. Brilhante[1], H. Tyynismaa[1,3], E. Palin[1], C. Vasilescu[1], T. Tyni[1], H. Almussa[4], P. Ellonen[4], T. Lönnqvist[2], H. Pihko[2], A. Suomalainen[1,5].* 1) Research Programs Unit, Molecular Neurology, Biomedicum-Helsinki, University of Helsinki, 00290 Helsinki, Finland; 2) Department of Pediatric Neurology, Children's Hospital, Helsinki. University Central Hospital, 00029 Helsinki, Finland; 3) Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland; 4) Finnish Institute for Molecular Medicine (FIMM), University of Helsinki, Finland; 5) Department of Neurology, Helsinki University Central Hospital, Helsinki, Finland.

Mitochondrial disorders comprise a heterogeneous group of genetic diseases that can manifest in any organ system and have any mode of inheritance. These diseases are caused by mutations in either the mitochondrial genome or in nuclear genes encoding mitochondrial proteins, which makes molecular diagnosis challenging. We report here the results of a whole-exome sequencing approach of a cohort of 68 Finnish patients suspected of having a recessively inherited mitochondrial disease and classified using Bernier criteria. The patient phenotypes included Leigh/Alpers or similar, encephalopathy, cardiomyopathy, infantile lactic acidosis or arPEO. We customized an analysis pipeline, and prioritized rare variants using a unique population variant data resource over 3300 Finnish exomes (Sequencing Initiative Suomi). We identified the genetic background in a total of 29 patients (42%), of whom 20 carried mutations in genes encoding mitochondrial proteins, and nine in non-mitochondrial protein encoding genes, emphasizing the advantageousness of a whole-exome approach instead of targeted sequencing of candidate genes. 24 patients had mutations in known disease genes, of which 15 (22%) presented with known phenotypes previously associated with the mutated gene, thereby enabling a straight forward diagnosis Surprisingly, we did not identify major founder alleles in the Finnish mitochondrial disease population, despite the country being a genetic isolate, but most families had their own specific compound heterozygous gene defects. The few families carrying same defects result in a requirement of extensive functional verification of identified variants, to establish pathogenicity. We conclude that whole-exome sequencing is an effective method for the molecular diagnosis of suspected mitochondrial disorders, with high potential to lead to specific diagnosis early in the diagnostic workup.

2983S

A comprehensive genomic analysis for mitochondrial respiratory chain disorder. *M. Kohda[1], Y. Tokuzawa[2], Y. Kishita[2], Y. Yamashita-Sugahara[2], Y. Mizuno[2], Y. Nakachi[1], Y. Moriyama[2,3], T. Hirata[1], Y. Kanesaki-Yatsuka[2], H. Harashima[4], M. Ajima[5], T. Yamazaki[4], M. Mori[6], K. Murayama[5], H. Kato[1], A. Ohtake[4], Y. Okazaki[1,2].* 1) Div Trans. Mitochondria are small organelles and serve as the powerhouse of the living cells because they generate vital energy in their respiratory chain system consisting of protein complexes I to V. Mitochondrial respiratory chain disorder (MRCD) is an intractable disease that develops in childhood. It is a highly frequent inborn errors of metabolism that occurs in at least one out of every 7,000 births. Prominent symptoms develop in such organs as the brain, heart, and muscles, where a great deal of energy is required. In most cases, effective treatment has not been established yet. It is known that various gene abnormalities cause defects of the protein complexes of the respiratory chain, which results in mitochondrial dysfunction. However, identification of the causative genes and the understanding of pathogenic mechanisms of MRCD remain largely unsolved. In this study, we applied long PCR based mtDNA sequencing, high density SNP arrays and whole exome sequencing for comprehensive genomic analysis. Exome sequencing data were filtered using three different criteria: (i) the presence of rare variants in known disease causing genes; (ii) rare variants in genes that code for mitochondrial proteins; (iii) unbiased genome-wide approach with strict filtering strategy. In this study, 144 unrelated individuals were chosen who display juvenile-onset mitochondrial disorders. In 24/144 cases, we identified novel mutations in known disease-causing genes (ACAD9, BOLA3, CO×10 etc). Currently we are validating the rare variants in mitochondria-related candidate genes. In addition, unbiased genome-wide analysis allows us to list up candidates for new disease causing genes thereby extending our understanding of genetic landscape of MRCD. The progress of our precisely controlled strategy will be presented at the meeting.

2984M

Diagnosing mitochondrial disease: Is there an added advantage of whole-exome sequencing? *S.J. Mosca[1], P.M. Gordon[2], L. Dimnik[4], S.T. Nakanishi[2,6], S. Hume[7], D.S. Sinasac[1,5], J.S. Parboosingh[1,2,4], A. Khan[1,2,3].* 1) Department of Medical Genetics, University of Calgary, Alberta, Canada; 2) Alberta Children's Hospital Research Institute, University of Calgary, Alberta, Canada; 3) Metabolic Diseases Clinic, Alberta Children's Hospital, Alberta, Canada; 4) Molecular Diagnostics Lab, Alberta Children's Hospital, Alberta, Canada; 5) Biochemical Genetics Laboratory, Alberta Children's Hospital, Alberta, Canada; 6) Department of Physiology and Pharmacology, University of Calgary, Alberta, Canada; 7) Department of Medical Genetics, University of Alberta, Alberta, Canada.

The diagnosis of mitochondrial disease currently involves multiple invasive procedures, which carry the risk of complications, and in many cases a diagnosis of mitochondrial disease cannot be made or excluded confidently. The Calgary Metabolic Clinic reviewed 292 patients with a clinical suspicion of mitochondrial disease, of which 35% had an eventual diagnosis of mitochondrial disease (MDx), 24% had a diagnosis of non-mitochondrial disease (OtherDx), and 41% had no final diagnosis (NoDx). When muscle-extracted mitochondrial DNA (mtDNA) analysis was performed, a diagnosis was made in 66.7% of cases in the MDx group and none in either of the other groups ($p<0.001$). mtDNA analysis showed the highest specificity compared to muscle histology and enzyme biochemistry. Whole-exome sequencing (WES) was performed on 12 unrelated patients from the NoDx group, who had no mtDNA mutations, and 1 case that had an mtDNA deletion and a suspected causative nuclear mutation. A systematic workflow for the evaluation of variants identified through WES was developed using the Illumina TruSight One gene list as well as a custom mitochondrial disease gene list as a first-line filter in an attempt to identify mutations in known disease-causing genes. Of the 13 patients, the variant prioritization workflow was able to identify the one known cause of mitochondrial disease, and putative disease-causing mutations were identified in five patients (compound heterozygous mutations in TRMU, ATP10A and DGUOK and heterozygous mutations in COL6A1 and NDUFS). Taken together, this data suggests that mtDNA analysis from muscle-extracted DNA produced the highest single diagnostic yield of cases with a mitochondrial disease, and that WES of nuclear DNA provided an answer in an additional 38% of previously unsolved cases of suspected mitochondrial disease with no mtDNA mutations. From this pilot data, we propose that the most efficient model for a genetic diagnosis of mitochondrial disease may be muscle-extracted mtDNA analysis followed by WES if the results are negative. With this approach, we expect to have higher confidence in not only confirming a diagnosis of mitochondrial disease, but also in excluding one and reduce the reliance on invasive procedures.

2985T

Realignment of whole-genome and exome sequencing reads supports novel potassium channel (Kir2.x) isoforms that were formerly identified by Sanger sequencing as polymorphisms of a single channel gene in thyrotoxic periodic paralysis locus. *M.R. Dias da Silva[1], R.M. Paninka[1], I.S. Kunii[1], G.K. Furuzawa[1], M.M.L. Kizys[1], R.M.B. Maciel[1,2], M. Mitne-Neto[2], L.T. Cerdeira[2], S. Pinto[3], H. Rodrigues[3], S. Tufik[3], D.R. Mazzotti[3].* 1) Laboratory of Molecular and Translational Endocrinology, Department of Medicine, Escola Paulista de Medicina, Universidade Federal de São Paulo, São Paulo, SP, Brazil; 2) Fleury Group, São Paulo, SP, Brazil; 3) Departament of Psychobiology, Escola Paulista de Medicina, Universidade Federal de São Paulo, São Paulo, SP, Brazil.

Thyrotoxic periodic paralysis (TPP [MIM 613239]) is the commonest cause of muscle weakness in adults suffering from hyperthyroidism, characterized by transient hypokalaemia and linked to mutations in the potassium channel *KCNJ18* (Kir2.6 [MIM 613236]) in 33% of patients. While searching for mutations in Kir2.x paralogues we verified that many SNPs have been mistakenly attributable to *KCNJ12* (Kir2.2 [MIM 602323]) due to high homology among family members (95-99% at protein level). The exact positions of *KCNJ17* (Kir2.5) and *KCNJ18* (Kir2.6) remain unclear. Although a BAC containing *KCNJ17* has not been found, both RP11-437N10 (*KCNJ18*) and RP11-728e14 (*KCNJ12*) have been mapped to 17p11.1-2. FISH originally localized *KCNJ12* and *KCNJ17* to 17p11.1. We aimed to identify possible misalignments of whole exome (WES) and whole genome sequencing (WGS) reads in the GRCh37/hg19 reference region of Kir2.2 by performing realignment of those reads to Kir2.2, Kir2.6 and Kir2.5 regions obtained by peripheral blood Sanger cDNA (direct and cloning) sequencing. WGS was performed with paired-end 100bp reads with the Illumina HiSeq2000 at target coverage of 30X. Alignment to the reference genome and variant calling was carried out with a standard BWA/GATK pipeline. We identified a single Kir2.2 and Kir2.5 cDNA, and 3 major Kir2.6 sequences named as RRAI, QHEV and QHAV haplotype based on the amino acid changes at 39, 40, 56 and 249 residue. After inspection of reads aligned to the GRCh37/hg19 genome reference assembly within the pericentromeric region of 17p11.1-2 spanning *KCNJ12* (chr17:21279699-21323179), a notable number of variants were detected, suggesting misalignment of reads due to low coverage of the reference assembly at that region. After realignment to the sequence identified by Sanger, we found 1992 and 613 reads aligned to that in the WES and WGS. Among WES reads, 706 (35.4%), 750 (37.6%) and 536 (26.9%) aligned to Kir2.6, Kir2.5 and Kir2.2, respectively. Similarly, in WGS, 158 (25.8%), 190 (31.0%) and 295 (43.2%) aligned to Kir2.6, Kir2.5 and Kir2.2. Taking together mapping and functional data, our findings support the presence of novel isoforms of Kir channels not adequately mapped to the reference genome. Although pericentromeric duplications are thought to contain heterochromatic DNA and have fewer expressed genes, we have presented several lines of evidence suggesting that Kir2.x paralogues are distinct and may play a role in muscle plasticity as observed in TPP.

2986S

Novel SLC29A3 mutation causing H Syndrome in an Indian Adolescent. *N. Kamath[1], R.D. Shenoy[2], M. Varma[3], R. Khubchandani[4], S. Babay[5], A. Zlotogorski[5,6], V. Molho Pessach[5,6].* 1) Department of Pediatrics, Kasturba Medical College, Manipal University, Mangalore, Karnataka, India; 2) Department of Pediatrics K.S. Hegde Medical Academy, Nitte University, Mangalore, India; 3) Private Rheumatology Clinic, Mumbai, India; 4) Pediatric Rheumatology Clinic, Jaslok Hospital and Research Center, Mumbai, India; 5) Center for Genetic Diseases of the Skin and Hair, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 6) Department of Dermatology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel.

Purpose: H syndrome (OMIM 6027828) is an autosomal recessive genodermatosis with systemic manifestations due to biallelic mutations in the SLC29A3 gene. The major clinical findings include hyperpigmentation, hypertrichosis, hearing loss, heart anomalies, hepatospleenomegaly, hypogonadism, low height (short stature), hallux valgus/flexion contractures and hyperglycemia/diabetes mellitus. It has recently been recognized as an inherited form of Histiocytosis. Genetic analysis of a case with clinical features consistent with H syndrome was performed in search for the causing mutation. **Methods**: A 16-year-old Indian adolescent, born out of non consanguinous parentage was referred due to short stature, sensorineural hearing loss, insulin dependent diabetes mellitus, delayed puberty and diffuse cutaneous hyperpigmentation. On physical examination she was noted to have height and weight below the third centile in the CDC 2000 growth charts, bilaterally symmetrical indurated sclerodermatous hyperpigmented patches with accompanying hypertrichosis overlying the trunk and lower extremities with sparing of the knees and buttocks, prepubertal sexual maturity rating, hepatosplenomegaly, dilated lateral scleral vessels, arcus senilis, infiltrated cheeks, lateral tibial torsion and hallux valgus. Laboratory evaluation revealed microcytic anemia, highly elevated ESR and hypogonadotropic hypogonadism. DNA was extracted from peripheral blood and analyzed for SLC29A3 mutations by Sanger sequencing. **Results**: We identified a novel misesnse homozygous mutation in the fifth exon of SLC29A3: c.677G>A (G209R). This variant was absent in dbSNP (http://www.ncbi.nlm.nih.gov/SNP), the 1000 Genomes project data (http://www.1000genomes.org/) and the Exome Variant Server (http://evs.gs.washington.edu/EVS). The mutation was predicted to be disease-causing by MutationTaster with a score of 0.99 (http://www.mutationtaster.org/). **Conclusions**: We demonstrated a novel homozygous mutation in the SLC29A3 gene in an adolescent female of Indian origin with clinical features consistent with H syndrome. Our patient emphasizes the pathognomonic cutaneous phenotype as well as the various extra cutaneous features of this autosomal recessive pleomorphic disorder.

2987M

An intergenic 9.4 kb microduplication at chromosome 5p13 as a cause of brachydactyly type A1. *L. Racacho[1], S.M. Nikkel[2], J. MacKenzie[3], C.M. Armour[2], M.E. McCready[4], Y. De Repentigny[5], R. Kothary[5], L.A. Pennacchio[6,7], D.E. Bulman[1,2,8].* 1) Department of Biochemistry, University of Ottawa, Ottawa, ON, Canada; 2) Department of Pediatrics, University of Ottawa, Department of Genetics, CHEO Research Institute, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 3) Department of Medical Genetics, Kingston General Hospital, Queen's University, Kingston, ON, Canada; 4) Pathology and Molecular Medicine, McMaster University, Hamilton, ON, Canada; 5) Regenerative Medicine Program, Ottawa Hospital Research Institute, Ottawa, ON, Canada; 6) Genomics Division, Lawrence Berkeley National Laboratories, Berkeley, CA, USA; 7) US Department of Energy Joint Genome Institute, Walnut Creek, CA, USA; 8) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

Brachydactyly type A1 (BDA1 [MIM 112500]) is an autosomal dominant brachymesophalangeal trait, primarily characterized by a hypoplastic and/or aplastic pattern of the middle phalanges of digits 2-5 in the hands and feet. Missense mutations in either *IHH* or *GDF5* have been associated with BDA1. We previously reported the linkage of a BDA1 locus to chromosome 5p13 (BDA1B [MIM 607004]) in a single large family. The PCR-based sequencing of all the protein coding genes within the 3 Mb critical region did not reveal a mutation. We did not identify any large genomic rearrangements spanning the critical region with either a 3-color FISH or a 500K SNP array. In order to provide a higher sensitivity of mutation detection, we performed a targeted hybridization enrichment of the BDA1B locus on two affected family members followed by high-throughput sequencing. The alignment of the sequence reads from both individuals to the reference genome revealed a novel and shared 9.4 kb intergenic tandem duplication. The microduplication falls within a 'gene desert' consisting of several vertebrate conserved sequence blocks. We were able to demonstrate the enhancer activity of these conserved blocks through the use of an *in-vivo* transgenic reporter assay. Relative quantitative PCR on the patient's fibroblast cDNA showed an up-regulation of distal genes when compared to unaffected controls. Our findings suggest that a *cis*-regulatory mutation is most likely involved in the pathology of BDA1 in these two individuals.

2988T

Novel molecular insights into severe congenital microcephaly through targeted next generation sequencing. *G. Mirzaa[1,2], V. Vasta[1], S. Christian[1], Q. Zhang[3], S. Eun[4], S. Collins[1], S. Hahn[1,2], W. Dobyns[1,2].* 1) Human Genetics, Seattle Children's Research Institute, Seattle, WA; 2) Department of Pediatrics, Division of Genetic Medicine, University of Washington, Seattle, WA; 3) Fred Hutchinson Cancer Research Center; 4) Department of Pediatrics, Korea University School of Medicine, Seoul, Korea.

Microcephaly (MIC) is a developmental brain growth disorder that accounts for a significant fraction of childhood intellectual disability, autism and epilepsy. It occurs in isolation (primary MIC) and as part of a broad range of neurodevelopmental syndromes with or without other cortical malformations. MIC is genetically very heterogeneous and the rate of identification of novel MIC genes has increased dramatically with the advent of next generation sequencing (NGS). The majority of MIC genes are key regulators of critical processes including mitotic spindle assembly and structure, centrosome function, and DNA repair and damage response (DDR) pathways. We screened a cohort of 93 individuals with MIC using a targeted NGS panel that contains 377 known and candidate MIC genes. Most individuals had severe congenital or postnatal MIC (head circumference 3 standard deviations or more below the mean) with or without otherstructural brain malformations, such as polymicrogyria, cerebellar and callosal abnormalities. We identified mutations in 26/93 (28%) of patients. Recessive mutations identified in known MIC genes include ASPM (N=7; 7.5%), CENPJ (N=1), CEP135 (N=1), CASC5 (N=1), WDR62 (N=1), ASNS (N=2), RBBP8 (N=1), ADSL (N=1) and RAB3GAP2 (N=1). Heterozygous de novo mutations were identified in TUBA1A (N=2), DYNC1H1 (N=2), TUBB2B (N=1), DYRK1A (N=1), FOXG1 (N=1), MLL2 (N=1), CASK (N=1), and HCCS (N=1). Our cohort expands a number of phenotypes including HCCS-associated features in males to include MIC, short stature and micropenis without severe eye defects, RBBP8-associated Jawad syndrome in a Pakistani family with MSG but without digital anomalies, adenylosuccincate lyase deficiency (ADSL) in a large sibship with MSG and increased extra-axial space, and Warburg Micro syndrome caused by mutations RAB3GAP to include postnatal MIC, hypotonia, and severe developmental encephalopathy without eye involvement. Our cohort also introduces new reports of rare phenotypes including asparagine synthetase (ASNS) mutations causative of congenital MIC and progressive epileptic encephalopathy with early childhood death, DYNC1H1 mutations causative of bilateral cortical dysplasia (specifically posterior-predominant pachygyria), CEP135 mutations with features of microcephalic osteodysplastic primordial dwarfism, CENPJ with MIC, seizures and growth deficiency, and DYRK1A associated primary microcephaly, epilepsy, severe intellectual disability and growth retardation.

2989S

Molecular genetic characterization of an autosomal recessive Familial Essential Tremor. *D. Monies[1], E. Naim[1], B. Al-Younes[1], M. Al-Breacan[1], M. Al-Saif[1], S. Wakil[1], K. Khabar[2], B. Meyer[1], S. Bohlega[3].* 1) Genetics, RC, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) Biomolecular Medicine, RC, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 3) Neurosciences, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia.

Despite the presence of strong family histories the underlying genetics of familial essential tremor (FET) is not well defined. Although several loci associated with FET have been described, there exists only relatively poor linkage data and no causative mutations having been identified to date. This far the mode of inheritance for FET is best described as autosomal dominant with incomplete penetrance. We describe the molecular genetic characterization of an autosomal recessive familial disorder characterized by tremor of juvenile onset, dystonia and myoclonus with preserved cognitive, cerebellar and peripheral nervous system functions. Mild spasticity appeared with disease progression and some white matter changes were evident upon MRI. Linkage analysis of a consanguineous family with five affected individuals identified a locus on chromosome 17 with a LOD score >4.0. Homozygozity mapping confirmed a single homozygous region shared by all affected individuals only and consistent with the locus identified by linkage analysis. Whole exome sequencing was performed on 1 affected individual with variants being filtered based upon the linkage interval, absence in variant databases at a frequency >0.1%, presence in coding/flanking regions and homozygozity. A single candidate causative variant segregating with disease in the family was identified. We describe further the functional validation of this variant. This is the first description of FET inherited in an autosomal recessive manner and offers opportunities for the further investigation of tremor associated with other disorders including Parkinsons disease.

2990M

Denovo mutations in a novel disease causing gene cause Temple-Baraitser syndrome and non-syndromic epilepsy. *C. Simons[1], L. Rash[1], J. Crawford[1], K. Ru[1], S.M. Grimmond[1,2], D. Miller[2], G. King[1], J. McGaughran[3,4], M. Gabbett[3,4], R.J. Taft[1,5,6].* 1) Institute for Molecular Bioscience, University of Queensland, Jindalee, QLD, Australia; 2) Institute of Cancer Sciences, Translational Research Centre, University of Glasgow, Scotland; 3) Genetic Health Queensland, Royal Brisbane & Women's Hospital, Australia; 4) School of Medicine, The University of Queensland, Australia; 5) School of Medicine and Health Services, Departments of Integrated Systems Biology and of Pediatrics, George Washington University, USA; 6) Illumina, Inc., San Diego, CA USA.

Temple-Baraitser syndrome (TBS) is a multi-system developmental disorder characterized by intellectual disability, epilepsy and hypo- or aplasia of the nails of the thumb and great toe. TBS is rare, with only five cases reported to date, although it is possible that that TBS is largely unrecognized and therefore under-reported. We recruited six unrelated TBS individuals and their parents for analysis by whole exome sequencing. Here we report damaging de novo mutations in a novel disease causing gene that is predominantly expressed in the central nervous system, in six TBS individuals. Functional characterization of two variants revealed that TBS-associated mutations lead to deleterious gain-of-function. Consistent with this result, we found that two TBS mothers with epilepsy, but who were otherwise healthy, were low level (12% and 30%, respectively) mosaic carriers of pathogenic mutations. This suggests that the etiology in some cases of non-syndromic epilepsy may be explained by low level mosaicism for mutations in this gene.

2991T

High diagnostic success rate in a cohort of unresolved leukoencephalopathy patients investigated by whole exome sequencing. *R.J. Taft[1,2,3], G. Helman[4], A. Pizzino[4], A. Vanderver[4], C. Simons[1].* 1) Illumina Inc., San Diego, CA; 2) Institute for Molecular Bioscience, University of Queensland, St Lucia, Australia; 3) School of Medicine and Health Services, The George Washington University, Washington DC, USA; 4) Children's National Medical Center, Washington DC, USA.

Leukoencephalopathies are a heterogeneous group of heritable central-nervous system white matter disorders that are primarily characterized by abnormal signal on brain magnetic resonance imaging. Leukoencephalopathies remain a diagnostic challenge for medical practitioners, with nearly 50% of cases remaining unresolved despite recent advances in both radiological and biochemical testing. We performed whole exome sequencing (WES) on a cohort of 85 patients with unsolved leukoencephalopathies, who were prospectively collected by the Myelin Disorders Bioregistry Project, with non-specific radiologic findings or previously negative diagnostic testing. WES and downstream bioinformatics analysis was performed on trio or greater family groups in all cases, and Sanger sequencing was used to validate and confirm segregation of all candidate pathogenic mutations. Resolution of more than 40% of cases was achieved and included mutations in a wide variety of known and novel disease genes including those associated with mitochondrial cytopathy, epileptic encephalopathy, hypomyelinating leukodystrophies and, unexpectedly, ataxia telangiectasia and dyskeratosis congenita. Overall, fewer than a quarter of the cases solved were due to mutations in genes classically associated with leukoencephalopathies. This study strongly suggests that clinical deployment of agnostic and untargeted high-throughput genomic screening approaches in the leukoencephalopathies will substantially reduce the number of unresolved cases and reduce the burden of the diagnostic odyssey.

Causal mutations and unique variants identified by exome analysis of Pakistani pedigrees with retinal degeneration. *R. Ayyagari[1], B. Maranhao[1,2], P. Biswas[1], M. Navani[1], J.J. Suk[1], F. Kabir[3], M.A. Naeem[4], J. Chu[1,2], S.N. Khan[4], S. Riazuddin[4], P. Lee[1], S.A. Riazuddin[3,4].* 1) Ophthalmology, University of California, San Diego, La Jolla, CA; 2) Department of Bioengineering, University of California, San Diego, 9500 Gilman Drive, La Jolla, CA 92093, USA; 3) The Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, 21287, USA; 4) National Centre of Excellence in Molecular Biology, University of the Punjab, Lahore 53700 Pakistan.

Purpose: To define the molecular basis of retinal degeneration in consanguineous Pakistani pedigrees and identify variants unique to the Pakistani population. Methods: A cohort of 26 pedigrees with 269 individuals of Pakistani origin was enrolled. Exomes of selected individuals were captured with Agilent or Nimblegen kits and sequenced on an Illumina HiSeq 2500. Variant call format (VCF) files were generated using standard protocol and subsequently analyzed with exomeSuite to identify candidate variants. Selected variants were examined for segregation with the disease phenotype in their respective pedigrees and their population frequency was investigated in ethnicity matched control chromosomes. All single nucleotide changes displaying no strand bias during sequencing, exhibiting a read depth greater than 10, and mapping quality greater than 30 were further tabulated by pedigree. Results: We identified six novel homozygous mutations in USH2A, CNGB1, FAM161A, CERKL and GUCY2D along with three previously reported causative mutations in RPE65, GUCY2D and LCA5 as the underlying cause of RD in 13 pedigrees. Additionally, we identified more than 2000 single nucleotide variants in the Pakistani cohort that are absent in the HapMap, 1000 Genome and NHLBI ESP6500 databases. Of these, 612 variants present in five or more pedigrees were not reported in the dbSNP database. Conclusions: Here, we identify six novel and three previously reported causative mutations in genes known to be associated with retinal degeneration in 13 of 26 consanguineous pedigrees of Pakistani origin. Additionally, we detected 612 single nucleotide variants that occur in multiple Pakistani pedigrees but are not present in the dbSNP database, thus suggesting that these variants are unique to Pakistani population.

2993M

Identifying the underlying cause of Retinal Degeneration by Exome Sequencing in seven unrelated pedigrees. *P. Biswas[1], B. Maranhao[1], I. Kozak[2], M. Parke[3], K. Branham[4], L. Ganriel[5], J. Heckenlively[4], A. S. Riazuddin[6], J. Duncan[7], R. Ayyagari[1].* 1) Ophthalmology, University of California San Diego, San Diego, CA; 2) Ophthalmology, King Khaled Eye Specialist Hospital, Umm Al Hamam Algharbi, Riyadh, Saudi Arabia; 3) Cornell University, Ithaca, NY, United States; 4) Ophthalmology & Visual Sciences, University of Michigan Kellogg Eye Center, Ann Arbor, MI, United States; 5) Genetics and Ophthalmology, Genelabor , GOIANIA, Brazil; 6) Ophthalmology, Johns Hopkins University School of Medicine, Baltimore, MD, United States; 7) Ophthalmology, University of California San Francisco, San Francisco, CA, United States.

Purpose: To determine the molecular basis of disease in patients with autosomal recessive retinal degeneration. Methods: Ophthalmic evaluation was performed on all affected members and some unaffected relatives. Family history, medical history and blood samples were collected from all the available members and DNA was isolated using standard protocols. Exomes of probands were captured using Nimblegen V3/V2 or Agilent V5+UTR kits, and sequencing was performed on Illumina HiSeq. Reads were mapped against hg19, and analyzed using GATK algorithms. Variants were analyzed by exomeSuite using an autosomal recessive model. Segregation and ethnicity matched control sample analyses were carried out by dideoxy sequencing. Result: Seven unrelated pedigrees with a total of 4-10 individuals and 1-3 affected members were recruited for the study. Analyzing variants using exomeSuite along with stringent filtering criteria revealed 7 novel and 4 reported mutations. A novel homozygous missense mutation was found in *ARL6* in a Middle Eastern family. A novel homozygous frame shift mutation causing premature truncation of the *CERKL* protein was found in a pedigree of Indian origin. A previously reported homozygous mutation was detected in the *ABCA4* gene in a Pakistani pedigree. Recessive compound heterozygous causative variants were observed in the remaining four Caucasian pedigrees. One of these had a novel damaging missense and a novel frame shift variant in the *RPE65* gene. In a second Caucasian pedigree, two heterozygous nonsense changes (novel and reported) in *PDE6B* were detected. In two additional pedigrees causative changes were detected in the *USH2A* and *ABCA4* genes. A novel nonsense and a novel damaging missense variants were detected in the *USH2A*. A missense mutation and a second intronic variant reported to be associated with RD were detected in the *ABCA4* gene in a Caucasian pedigree. All these variants segregated with disease and the novel variants were not detected in ethnicity-matched controls. Conclusions: Exome capture and sequencing revealed seven novel and four known variants as the underlying cause of retinal degeneration in seven unrelated pedigrees.

2994T

Trio-based exome sequencing approach to identify candidate genes for phenotypic variability of Incontinentia pigmenti. *F. Fusco[1], M.I. Conte[1], M. Paciolla[1], M.B. Lioi[2], M.G. Miano[1], M.V. Ursini[1].* 1) Institute of Genetics and Biophysics 'Adriano Buzzati-Traverso', IGB-CNR, Naples, Italy; 2) University of Basilicata, Potenza 85100, Italy.

Incontinentia pigmenti (IP, MIM308300, 1/10.000) is an X-linked dominant neuroectodermal disorder. The skin defects are always present, while the extracutaneous manifestation (ocular, dental, hair, nail and central nervous system-CNS- defects) may occur at variable frequency. In 30% of IP patients CNS anomalies (seizures, encephalopathy, encephalomyelitis, ischemic stroke) are reported. IP patients carry a mutation in the IKBKG/NEMO gene (IKBKG/Nuclear Factor kappaB, Essential MOdulator) that encodes for NEMO/IKKgamma regulatory protein of the IKK complex, required for the activation of the canonical NF-kappaB pathway. We collected a large cohort of IP patients with an high variability of clinical phenotype. A variable CNS defect was observed, even in IP patients with an identical NEMO mutation. The NEMOdel4_10 deletion, identified in 72% of IP patients, can be associated with a wide range of CNS symptoms also in the same IP family. The skewed X-chromosome inactivation could only partially explain this variability thus modifier loci may contribute to the severity of IP phenotype. Here we present a trios-based exome sequencing approach to identify candidate genes for phenotypic variability of IP. We selected three severe IP cases carrying the NEMOdel4_10 deletion, one case with extreme intra-familial phenotypic variability: in the mother only skin defects were present, in the children also a severe mental retardation with neuromuscular defects were reported; and two sporadic cases. We performed whole exome-sequencing of trios samples. From sequencing of an exome-enriched library a list of single nucleotide/indels variants was produced. By applying combined filtering method we select SS/I variants and NS variants predicted to be damaging by polyphen software. We sorted all variants by two model of inheritance: de novo dominant, and recessive (homozygous, compound heterozygous). We will present a list of candidate genes and their associated pathways prioritizing variants fitting to recessive model of inheritance.The most representative category of alterated genes is the methabolic pathway in which we identified two genes acting as modifiers in known diseases. Trio-based exome sequencing has proven to be a powerful approach for identifying candidate genes that may contribute to the phenotypic variability of IP. The identification of modifier genes of IP will be useful to anticipate the outcome of the IP disease in order to apply an early targeted therapy.

2995S

NEMO Deficiency: Mutation in 5' leader sequence of *IKBKG* causes adult onset mycobacterial skin disease. *A.P. Hsu, G. Uzel, S.M. Holland.* Laboratory of Clinical Infectious Diseases, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD.

Uniallelic hypomorphic mutations of X-linked *IKBKG*, encoding the nuclear factor-κB essential modulator (NEMO), lead to ecdodermal dysplasia with immunodeficiency (MIM 300248). Onset of infections in affected males is typically in infancy or childhood, with *Pneumocystis jirovecii*, pyogenic bacteria and mycobacteria. Severe systemic infections cause high mortality during the first decades of life. We identified 3 patients who presented as adults with disseminated *Mycobacterium avium* complex (MAC) and granulomatous skin disease, but limited prior infectious histories. Patient A.I.1 had *Haemophilus influenzae* pericarditis at age 5 then diffuse cutaneous MAC at age 34. Full-length cDNA analysis of the major isoform showed a 110 base pair (bp) deletion in the 5' leader sequence due to a G>C transversion at the last base of the first exon, c.1-16G>C, weakening the consensus splice site and leading to utilization of a cryptic site 110 bases 5' to the end of the exon. Patient B.II.1 had the same change (c.1-16G>C) in *IKBKG* with similar consequence. He had *Mycobacterium marinum* at age 6 and then disseminated MAC at age 27. His maternal cousin, B.II.3 had recurrent respiratory infections in childhood and then developed disseminated MAC at 31 years. Intracellular staining of patient lymphocytes showed <50% of normal NEMO protein. Patients A.I.1 and B.II.1 were lymphopenic (total lymphocyte counts <800), with low naïve CD4+ and CD8+ cells as well as few CD20+/CD27+ memory B cells. Stimulation of PBMCs from patient A.I.1 showed decreased production of TNFα in response to LPS. Bioinformatic analysis revealed the deletion is wholly contained within a conserved 153 bp upstream open reading frame (uORF). This deletion causes a frameshift of the uORF leading to 8 original and 5 missense codons in frame with the initial coding ATG. The uORF ATG has a stronger predicted Kozak sequence than the canonical ATG, possibly leading to a 13 residue N-terminal extension of the protein. Luciferase constructs are being used to determine whether reduced NEMO protein is due to a shortened 5' leader sequence, loss of the uORF, or the 13 additional residues. These late onset mycobacterial infections are caused by mutations in *IKBKG* that affect NEMO protein levels. The identification of similar mutations in 2 unrelated kindreds suggests that 5'UTR *IKBKG* mutations should be sought in late onset MAC infections.

2996M

Inherited UNC13D or PRF1 Mutations in patients with PTLD and severe HHV viremia after HSCT. *H. Liu[1], Y. Zhang[1], F. Wang[1], W. Teng[1], X. Chen[2], P. Zhu[2], C. Tong[1], T. Wu[1], Y. Zhao[1], J. Zhang[1], D. Lu[1].* 1) Medical Laboratory Division, Ludaopei Hematology & Oncology Center, Beijing, China; 2) Department of Hematology, Peking University First Hospital, China.

Background: Post-transplant lymphoproliferative disorder (PTLD) is a rare but life-threatening disease after hematopoietic stem cell transplantation (HSCT) and 90%are EBV positive. Severe human herpes virus (HHV) viremia is the more common form of HHV activation after HSCT. Familial hemophagocytic lymphohistocytosis (FHL) is a mainly autosomal recessive inherited disorder and always triggered by HHV (esp. EBV), the most common mutated genes are UNC13D and PRF1. **Methods and Cases:** To identify the association of genetic defects and HHV disease after HSCT, 32 acute myeloid or lymphoblastic leukemia patients underwent HSCT were enrolled, including 7 PTLD cases and 25 suffered from severe HHV viremia. Genomic DNA was obtained from peripheral blood of the patients before and after HSCT and their donors. Qualitative and quantitative analysis of HHV in peripheral blood was performed by PCR. Molecular genetic studies were performed by direct sequencing of all coding exons and flanking sequences of UNC13D and PRF1. **Results:** 6 paired cases carried UNC13D or PRF1 mutations. Including 4 cases with monoallelic mutations in the recipients' blood sample after HSCT and their donors, one with PRF1 p.P22RfsX29, one with UNC13D p.L202M and two with UNC13D c.2553+5C>G mutations. In the other 2 cases, mutations were inherited carried by the patients' own somatic cells, one with UNC13D p.T1045M/c.2553+5C>G biallelic mutations, and the other with UNC13D c.2553+5C>G mutation.**Conclusion:** UNC13D and PRF1 mutations might be the inherited predisposing factors of severe HHV viremia or PTLD after HSCT.

2997T

Exome sequencing of a family with Wiskot-Aldrich syndrome reveals a mutation in the WIPF1 gene. *A. Hawwari[1], M. Dasouki[1], L. Al Baik[1], S. Al-Hiss[1], O. Khier[1], H. Al-Mousa[1, 2, 3], R. Arnaout[2].* 1) Department of Genetics, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 2) Department of Pediatrics, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; 3) Al-Faisal University, Riyadh, Saudi Arabia.

This Family we are reporting in this abstract is the first family with WIP deficiency in Saudi Arabia and it would be the second WIP deficiency case reported in the literature. This family originates from the south province of Saudi Arabia, highly consanguineous, with more than fourteen members reported to have clinical presentation suggestive of WIP deficiency. Most of whom had fatal courses. We had the opportunity to evaluate five of these patients from this family. The first case was a boy which presented more than 10 years ago with low platelets, recurrent infection and eczema. He was initially diagnosed as Wiskot-Aldrich case, except that his platelets were of normal size (normal MPV). The Patient underwent stem cell transplantation successfully. Two years later, a second degree female cousin of the first case presented to our hospital with low platelets also normal MPV, and fungal brain infection. Being a female, we started questioning the diagnosis of WAS and WIP deficiency, theoretically, was a logical alternative diagnosis. However, there were no reported human cases of WIP deficiency then. Over the following years, 3 more members of the family all females presented to us soon after birth all with low normal sized platelets, and severe CMV infection in the first months of life. All underwent stem cell transplantations, two survived transplant and the third, who is a sister of our second case, died post transplantation from CMV infection and post transplant complications. We decided to perform Whole Exome Sequencing of two sisters along with their parents which revealed a nonsense mutation (Q237X) in the WIPF1 gene. Full molecular evaluation of many of members of this family confirmed our long suspected diagnosis of WIP deficiency.

2998S

Erythroid Krüppel-like factor mutations are relatively more common in a thalassemia endemic region and ameliorate the clinical and hematological severity of β-thalassemia. *X. Xu[1], D. Liu[1], X. Zhang[2], L. Yu[1], R. Cai[3], X. Ma[1], C. Zheng[4], Y. Zhou[5], Q. Liu[6], X. Wei[1], L. Lin[1], T. Yan[3], J. Huang[1], N. Mohandas[7], X. An[7].* 1) Southern Medical University, Guangzhou, Guangdong, China; 2) Department of Hematology, 303rd Hospital of the People's Liberation Army, Nanning, China; 3) Department of Birth Health and Heredity, Liuzhou Women and Children Care Hospital, Liuzhou, China; 4) Prenatal Diagnostic Center, Guangxi Zhuang Autonomous Region Women and Children Care Hospital, Nanning, China; 5) Department of Birth Health and Heredity, Zhuhai Women and Children Care Hospital, Zhuhai, China; 6) Key Lab for Experimental Teratology of the Ministry of Education and Department of Medical Genetics, School of Medicine, Shandong University, Jinan, China; 7) Red Cell Physiology Laboratory, New York Blood Center, New York City, NY, United States.

The erythroid transcriptional factor 1 (KLF1) has recently emerged as one of the key regulators of the γ- to β-globin gene switching. Mutations in human KLF1 have recently been reported to be responsible for increased fetal hemoglobin (HbF) and hemoglobin A2 (HbA_2). As increased HbF and HbA_2 levels are important features of β-thalassemia, we examined whether there is any relationship between KLF1 mutation and β-thalassemia in China. For this, we first studied the incidence of *KLF1* mutations in two Chinese populations: 3839 individuals from a thalassemia endemic region in south China and 1190 individuals from a non-thalassemia endemic region in north China. Interestingly we found that the prevalence of *KLF1* mutations is significantly higher in thalassemia endemic region than that in non-thalassemia endemic region (1.25% versus 0.08%). Furthermore, a total of 64 mutant alleles were documented in the present study, of which 41 are *KLF1* heterozygotes alone, 11 are *KLF1* mutations co-inherited with β-thalassemia heterozygotes, and 12 are *KLF1* mutations co-inherited with β-thalassemia homozygotes or compound heterozygotes. We identified seven functional variants including four previously reported (p.Gly176AlafsX179, p.Ala298-Pro, p.Thr334Arg and c.913+1G>A) and three novel ones (p.His299Asp, p.Cys341Tyr and p.Glu5Lys) in southern China. The two most common mutations, p.Gly176AlafsX179 and p.His299Asp, accounted for 90.6% of the total. This study also provides an overview of the important hematological features of individuals with *KLF1* heterozygous mutations. In addition, we found it surprising that two KLF1 zinc-finger mutations were selectively represented in 12 β-thalassemia intermedia patients, who were identified from 922 β-thalassemia patients with known β-globin genotypes and various modifier genes. Both multivariate and univariate analysis showed that the modifier of *KLF1* mutations had an effect on amelioration of the severity in β-thalassemia. Our findings suggest that *KLF1* mutations occur selectively in the presence of β-thalassemia to increase the production of HbF which in turn ameliorates the clinical severity of β-thalassemia. The knowledge gained from this study should help in clinical accurate diagnoses and genetic counseling, as well as enable designing of appropriate and personalized transfusion program for thalassemia patients with *KLF1* mutations.

2999M

Homozygous loss of *DIAPH1* causes a rare, complex syndrome with epilepsy, blindness, immune deficiency and lymphoma. *M. Kaustio[1], R. Hinttala[2,3,4], H. Almusa[1], M. Renko[2,3], H. Tuominen[5], R. Herva[5], J. Uusimaa[2,3,4], J. Saarela[1].* 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) Institute of Clinical Medicine, Department of Pediatrics, University of Oulu, Oulu, Finland; 3) Department of Pediatrics, Oulu University Hospital, Oulu, Finland; 4) Medical Research Center, University of Oulu and Oulu University Hospital, Oulu, Finland; 5) Department of Pathology, Oulu University Hospital and University of Oulu, Oulu, Finland.

Using whole-exome sequencing (WES), we investigated a Finnish family with two affected male siblings, who presented with a novel, complex syndrome including an early-onset intractable epilepsy, blindness, severe mental retardation, deficiency in cellular immunity and B-cell lymphoma. Muscle biopsy showed atrophy, mild increase of fat, a few SDH-COX negative muscle fibres, and an increased number of mitochondria suggesting a mitochondrial disease. Brain MRI and spectroscopy revealed focal occipital leukoencephalopathy. The disease course was progressive leading to death in both siblings at the age of 5 and 18 years. The neuropathologic examination showed severe gliosis, atrophy and vascular abnormality affecting the primary visual cortex. Through WES we identified a rare, homozygous splice donor variant (NM_005219: c.684+1G>A) in the gene *DIAPH1*, which encodes for the mammalian diaphanous-related formin mDia1. Capillary sequencing of reverse transcribed patient RNA with amplicons spanning the mutated site showed that the mutation results in the use of several different cryptic splice sites, all of which ultimately result in the introduction of a premature stop codon in the Drf/GBD domain and likely cause lack of any functional protein. The absence of a protein product in patient cells or tissues was confirmed by western blotting and immunostaining for mDia1. mDia1 acts downstream of Rho GTPases promoting actin polymerization and microtubule stabilization, and it is known to play a role in various processes such as cell migration and tumour metastasis, neuronal development, mitochondrial trafficking and the function of several types of immune cells. Hence, the several aspects of mDia1 function seem to explain most if not all of the features of the phenotype observed in the affected individuals. The *DIAPH1* splice donor variant is not present in databases such as the 1000 Genomes, the Exome Variant Server or dbSNP, but instead was found in the Sequencing Project Suomi (SISu) database with exome sequencing data from about 3300 Finnish individuals with a frequency of 0.075%. This led us to hypothesize that this variant may be enriched in the Finnish population and hence, we will further assess the prevalence and distribution of this putative novel disease variant in Finland by using genotyping data from ~11400 Finns. Furthermore, functional studies addressing the effect of this mutation on mitochondrial function are also ongoing.

3000T

Copy number variations in a cohort of Brazilian sickle cell anemia patients with and without cerebrovascular accident. *P.RS. Cruz[1], G. Ananina[1], F. Menaa[1], A.S. Araujo[2], G.P. Gil[1], W.M. Avelar[3], F. Cendes[3], F.F. Costa[4], M.B. Melo[1].* 1) Genetics and Molecular Biology, University of Campinas, Campinas, São Paulo, Brazil; 2) Hematology and Hemotherapy Center of Pernambuco/HEMOPE, Recife, Pernambuco, Brazil; 3) Neuroimaging Laboratory, Department of Neurology, University of Campinas, Campinas, São Paulo, Brazil; 4) Hematology and Hemotherapy Center/HEMOCENTRO, University of Campinas, Campinas, São Paulo, Brazil.

Although sickle cell anemia (SCA) results from homozygosity for a single mutation at position 6 of gamma-hemoglobin locus, this disease presents high heterogeneity in phenotype, so that different patients may have significantly different clinical outcomes. Virtually all organs may be affected by vascular occlusion, with emphasis on the Central Nervous System, where are observed transient ischemic attacks, stroke and cerebral hemorrhage, which affect approximately 25% of patients with SCA. Early identification of patients with sickle cell anemia, susceptible to stroke (CVA) could reduce the risk, possibly preventing the recurrence of infracts and potentially reducing their incidence. Thus, we propose to investigate the presence of copy number variation in alleles or "Copy Number Variation" (CNV), using high density microarray (Genome-Wide Human SNP Array 6.0) in order to identify genomic regions potentially involved in the increased risk of stroke in sickle cell patients. Among individuals evaluated by microarray so far, 32 are categorized as non-affected by stroke, while 39 have reported at least one episode in their medical history. An exploratory analysis of distribution of copy number events was performed to compare all autosomal CN events larger than 1 kb between groups. Distribution of CN events per individual in the affected and non-affect cohorts, respectively, was: max. number - 499/511; min. number - 62/51; median - 159/147 for losses; while for gains we observed max. number - 1437/ 1166; min. number - 54/56; median - 160/213. Further, by means of permutation analysis using PLINK software, we found a CNV on chromosome 22 to differ between cases and controls (0.15% vs. 0 for deletions, and 38% vs. 10% for duplications, respectively; p-value=$9e^{-9}$).

HLA confer the risk of familial Mediterranean fever in Japanese population. *M. Yasunami[1], H. Nakamura[1], K. Agematsu[2], M. Yazaki[3], K. Migita[4].* 1) Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 2) Department of Infection and Host Defense, Shinshu University Graduate School of Medicine, Matsumoto, Japan; 3) Department of Medicine, Shinshu University School of Medicine, Matsumoto, Japan; 4) Clinical Research Center, National Hospital Organization Nagasaki Medical Center, Omura, Japan.

BACKGROUND Familial Mediterranean fever (FMF) has been considered to be an autosomal recessive trait which is characterized by self-limiting recurrent fever and serositis (OMIM #249100) and classified into a category of autoinflammatory disease. *MEFV*, identified as the responsible gene for FMF, encodes cytosolic protein pyrin (also known as marenostrin) which regulates the activity of NLRP3 inflammasome. Mutations in MEFV gene have been registered to “Infevers” database (http://fmf.igh.cnrs.fr/ISSAID/infevers/); 296 *MEFV* sequence variants have been reported so far (as of June 4th, 2014) including hot spots for pathogenic amino acid substitutions in the C-terminus region of the protein. Recently, dominant form (OMIM #134610) of the disease was reported (Koné-Paut I, *et al.*, *Rheumatology* 2009), and overlapping and continuum to other autoinflammatory diseases were proposed (Touitou I, *et al.*, *J Med Genet* 2013). We performed a nationwide surveillance of FMF in Japan and found that only M694I is commonly identified among hot spot mutations in the exon 10, homozygotes of which comprise as many as 10 % of Japanese FMF (Migita K, *et al.*, *Medicine* 2012). It is possible that the weak genotype-phenotype correlation observed in Japanese FMF is under the strong influence of modifier gene(s). *HLA* is one of the candidates for such modifiers because it is involved in many immune-related and inflammatory diseases. METHODS Genotypes of *HLA-B* and *-DRB1* loci were determined for 267 probands of FMF pedigree, who satisfied modified Tel-Hashomer criteria, by WAKFlow HLA-B and HLA-DR typing reagent kits (Wakunaga Pharmaceutical, Japan) after obtaining written informed consent. Frequencies of allele carriers in the patients were compared with those of the controls to obtain odds ratio for the evaluation of risk/protective effects of *HLA* alleles. RESULTS Carriers of *B*39:01* were increased (10.5% vs. 3.3%, OR=3.39, $p=7.1\times10^{-4} < 0.05/13=3.8\times10^{-3}$) in the patients, whereas those of *B*52:01* were decreased (15.7% vs. 25.4%, OR=0.55, $p=4.7\times10^{-3}$, not significant after Bonferroni’s correction). The decrease of *B*52:01* appeared secondary to the decrease of *DRB1*15:02* (12.8% vs. 24.1%, OR=0.46, $p=6.5\times10^{-4}$, $< 0.05/14=3.6\times10^{-3}$), which is in tight linkage with *B*52:01* in Japanese population. CONCLUSION The *HLA class I*-associated genetic risk and the *HLA class II*-associated genetic resistance were identified for Japanese FMF.

3002M

A pathogenic haplotypes of the g6pd gene correlating with enzyme activity. *D. Nantakomol[1], M. Chaowanathikhom[1], P. Nuchnoi[2].* 1) Department of Clinical Microscopy, Faculty of Allied Health Sciences, Chulalongkorn University, Bangkok, Thailand; 2) Department of Clinical Microscopy, Faculty of Medical Technology, Mahidol University.

The single nucleotide polymorphisms (SNP) in glucose-6-phosphate dehydrogenase (G6PD) gene caused enzyme deficiency leading to acute hemolytic anemia and neonatal jaundice. Over 400 SNPs in G6PD have been deposited in G6PD database. Most of the G6PD SNP showing clinical significance caused amino acid substitution. However, the association of G6PD SNP and enzyme activity could not be well established. Molecular characterization of 107 Thai adults revealed 11 reported mutations and 2 novel mutations (IVS-12: G+50A and 3’UTR: A*99G) of G6PD gene were detected. Mostly four SNPs consisted of IVS-11 (T93C) 50.5%, 3’UTR (A*357G) 50.5%, silent mutation-2 (C1311T) 49.5%, following by Viangchan variant (G871A) 21.5%. Haplotype analysis using Haploview software revealed the haplotype block of G6PD gene that consisted of four haplotypes (G1: GCTA, G2: GTCG, G3: ATCG and G4: GCCG). Only Viangchan variant (G871A) and haplotype G3 (ATCG) showed significance by association test and was found in G6PD deficient group more than normal group. Moreover, it showed high odds ratio (OR 7.90, 95% CI: 3.15-19.81) and affected G6PD mRNA secondary structure changing and microRNA binding that were predicted by CLC Main Workbench 6.9 and RegRNA 2.0 program, respectively. Altogether, this is the first report of haplotype association with reduction of G6PD enzyme expression. Thus, not only a single variation but also haplotype of G6PD gene should considered for the severity of G6PD deficiency.

3003T

Defective Dimerization of STAT3 causes Autosomal Dominant Hyper-IgE Syndrome. *M. Dasouki[1], S. Keles[2], T. Chatila[2].* 1) Neurology, Univ Kansas Med Ctr, Kansas City, KS; 2) Pediatric Immunlogy, Harvard University School of Medicine.

Background: Autosomal dominant and autosomal recessive hyper-IgE syndromes are primary immune deficiency syndromes caused by heterozygous mutations in STAT3 (Signal Transducer and Activator of Transcription 3) and homozygous mutations in DOCK8 & PGM3 respectively. STAT3 is involved in IL6 and related cytokines induced signal transduction by JAK kinases and represses macroautophagy. STAT3 forms a homodimer or a heterodimer with a related family member (at least STAT1) and mediates cellular responses to interleukins, KITLG/SCF and other growth factors. It also binds to (IL-6)-responsive elements identified in the promoters of various acute-phase protein genes. Upon tyrosine phosphorylation and dimerization, and in response to signaling by activated FGFR(1-4) it is translocated into the nucleus. Most previously reported STAT3 mutations involve its SH2 domain. Aim: To characterize the causal mutation and its functional effects in a 40 year old Dutch man with AD-HIES (severe chronic eczema, onychomycosis, asthma and bilateral cataract, lymphopenia, hypereosinophilia and hyper IgE). Methods: STAT3 mutation analysis by DNA sequencing. Activation of STAT3 by IL-6 and IL-21 and STAT1 by IFN-α was assessed by intracellular staining with anti-phospho (p)STAT3 and -pSTAT1 antibodies. TH17 and TH1 cell differentiation was assessed by measuring the production of IL-17 and IFN-γ, respectively. Results: Patient had normal B&T cell flow cytometry profiles and normal TREC count. A novel heterozygous STAT3 mutation (c.491G>A; p.R84Q) which is predicted to impair its dimerization was identified. Lymphocytes functional studies showed reduced phosphorylation of STAT3 in response to cytokine stimulation, whereas pSTAT1 activation was unaffected. Also, impaired TH17 responses and (early steps) in TH17 differentiation was found. Conclusion: This novel amino terminal domain STAT3 mutation causes defective dimerization and impaired TH17 responses indicating a novel mechanism for AD-HIES.

3004S

WES detects disease causing SNVs and CNVs in Primary immunodeficiencies. *H.S. Sorte[2], A. Stray-Pedersen[1,2,3], T. Gambin[1], P.S. Samarakoon[2], M.D. Vigeland[2], O.K. Rodningen[2], I.C. Hanson[4], L.R. Forbes[3,4], J.S. Orange[3,4], R. Lyle[2], J.R. Lupski[1,5,6], Baylor-Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 3) Center for Human Immunobiology, Texas Children's Hospital, Houston, TX; 4) Department of Pediatrics, Section of Immunology, Allergy, and Rheumatology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Human Genome Sequencing Center of Baylor College of Medicine, Houston, TX.

Primary immunodeficiencies (PIDDs) constitute a heterogeneous group of genetic diseases affecting the immune system. Depending on the genetic etiology, symptoms range from mild to severe and life threatening. Knowledge of the molecular genetic cause and disease mechanism is important and can direct targeted and curative therapy. However, subtype classification is difficult as patients often have overlapping phenotypes. In addition, more than 250 PIDD genes have been reported, and few are offered for diagnostic genetic testing. We examined the utility of whole-exome sequencing (WES) to detect single nucleotide variants (SNVs) and copy number variations (CNVs) in the diagnosis of PIDDs. As of June 2014, 275 patients with extensive immunological and genetic testing from 241 families have been recruited from Texas Children Hospital (Houston, USA) and Oslo University Hospital (Norway). Strategies for genetic analysis were tailored based on clinical data, immunophenotyping and family history, in 25 families more than one person WES tested, but for most families only the proband was subjected to WES. Initially, WES data were systematically screened for variants in reported and potential PIDD genes. In addition, a computational CNV prediction pipeline was applied to enable identification of potential disease-causing CNVs from the WES data. Analysis of the first 126 families identified PIDD relevant variants in 60 percent of the cases; half of these attaining a definitive molecular PIDD diagnosis. The other half had previously reported PIDD-causing variants, but with an unexpected or extended clinical phenotype, or heterozygote, potential deleterious variants in recessively inherited PIDD genes. In two families the patients had co-existing disease causing and modifying variants in two genes (*ZAP70/RNF168* and *SH2D1A/FANCB*, respectively). In one family two different PIDDs occurred (RAG1 SCID and DOCK8 related Hyper IgE syndrome). Other interesting findings include PIDD-causing CNVs in 7 families, somatic revertant mosaicism (*IL7R, FANCA, IL2RG*), de novo AK2 lymphocyte mosaicism, and 13 novel disease genes (5 definitive *NUDCD3, PGM3, COPA, MCM10, SIGIRR*, and 8 potential).

Human phosphoglucomutase 3 (PGM3) catalyzes the conversion of N-acetyl-glucosamine (GlcNAc)-6-phosphate into GlcNAc-1-phosphate during the synthesis of uridine diphosphate (UDP)-GlcNAc, a sugar nucleotide critical to multiple glycosylation pathways. We identified three unrelated children with recurrent infections, congenital leukopenia including neutropenia, B and T cell lymphopenia, and progression to bone marrow failure. Whole-exome sequencing demonstrated deleterious mutations in *PGM3* in all three subjects, delineating their disease to be due to an unsuspected congenital disorder of glycosylation (CDG). Functional studies of the disease-associated PGM3 variants in E. coli cells demonstrated reduced PGM3 activity for all mutants tested. Two of the three children had skeletal anomalies resembling Desbuquois dysplasia: short stature, brachydactyly, dysmorphic facial features, and intellectual disability. However, these additional features were absent in the third child, showing the clinical variability of the disease. Two children received hematopoietic stem cell transplantation of cord blood and bone marrow from matched related donors; both had successful engraftment and correction of neutropenia and lymphopenia. We define PGM3-CDG as a treatable immunodeficiency, document the power of whole-exome sequencing in gene discoveries for rare disorders, and illustrate the utility of genomic analyses in studying combined and variable phenotypes.

3006T

IPEX and IPEX-like syndromes: *FOXP3* and *FOXP3*-pathway related genes. *M. Vignoli[1,2], S. Ciullini Mannurita[1,2], G. Colarusso[3], F. Barzaghi[4], R. Bacchetta[4], M. Cecconi[5], A. Tommasini[6], A. Gennery[7], S.M. Holland[8], A.J. Cant[7], E. Gambineri[1,2].* 1) Dept of NEUROFARBA, section of Child's Health, University of Florence; 2) "Anna Meyer" Children's Hospital, Florence, Italy; 3) Santo Stefano Hospital, Paediatric Unit, Prato, Italy; 4) San Raffaele Telethon Institute for Gene Therapy (HSR-TIGET), Milan, Italy; 5) Human Genetic Laboratories, Ospedale Galliera, Genoa, Italy; 6) IRCCS Burlo Garofalo, Paediatric Immunology Laboratory, Trieste, Italy; 7) Department of Paediatric Immunology, Newcastle upon Tyne Hospitals, Newcastle upon Tyne, UK; 8) Laboratory of Clinical Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda.

IPEX (MIM #304790) is characterized by severe early-onset enteropathy, endocrinopathy, dermatitis and other autoimmune phenomena. It is due to *FOXP3* (Xp11.23) gene mutations. Interestingly an increasing number of patients show a phenotype consistent with IPEX but do not harbour *FOXP3* mutations. *IL2Rα* (10p15.1) and *STAT5b* (17q11.2) are two genes involved in *FOXP3* pathway whose mutations have been associated with IPEX-like penotype, nevertheless many patients remain without a molecular diagnosis. Our cohort of patients is composed of 76 cases with a phenotype compatible with IPEX syndrome, that were referred to us during the past 10 years for molecular analysis. We decided to perform a retrospective study evaluating clinical and laboratory findings to better delineate the clinical spectrum of multiple autoimmune diseases and identify different subgroups of patients to be addressed to specific molecular investigations. We analyzed the clinical history, T regulatory cells (Tregs) and FOXP3 expression by flow cytometry and the gene sequencing results of *FOXP3*, *IL2Rα*, *STAT5b*, *STAT1*, *IL10*, *IL10Ra*, *IL10Rb*. In 16 cases we identified *FOXP3* mutations confirming IPEX syndrome diagnosis. The 60 IPEX-like patients were divided in three distinct groups. The first group includes 31 cases with a phenotype very similar to IPEX, they showed enteropathy with onset within six months of life, growth retardation, eczema and at least one autoimmune phenomena. The second group comprises 22 cases with a later onset of the clinical symptoms (mainly diarrhoea and at least two autoimmune signs). The third group includes 7 cases with severe early-onset diarrhea together with perianal abscesses or enteric fistulae, these cases are more similirar to Inflammatory Bowel Disease manifestation. Autoimmune enteropathy is the key clinical sign for IPEX-like patients of all groups, while in subjects without enteropathy, endocrinopathy and cytopenias are the main clinical symptoms. High IgE levels is often reported. In the first group the molecular analysis resulted in 3 patients harboring *IL2Rα* mutations leading to the absence of CD25 expression, a patient with a *STAT5b* variation and one *STAT1* deficiency case, confirming the association between mutations in *FOXP3*-related genes and clinical features very similar to IPEX. Therefore the clusterization in distinct subgroups can help to address the molecular analysis of different genes and to select patients for whole exome sequencing analysis.

3007S

Aicardi-Goutières syndrome is caused by IFIH1 mutations. *H. Oda[1,2], K. Nakagawa[1], J. Abe[1,3], T. Awaya[1], M. Funabiki[4], A. Hijikata[5], R. Nishikomori[1], M. Funatsuka[6], Y. Oshima[7], Y. Sugawara[8], T. Yasumi[1], H. Kato[4,9], T. Shirai[5], O. Ohara[2,10], T. Fujita[4], T. Heike[1].* 1) Department of Pediatrics, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Integrative genomics, RIKEN-Institution for Integrative Medical Sciences, Yokohama, Japan; 3) Pediatric Department, Kitano Hospital, Osaka, Japan; 4) Laboratory of Molecular Genetics, Institute for Virus Research, Kyoto University, Kyoto, Japan; 5) Department of Biosciences, Nagahama Institute of Bio-Science and Technology, Nagahama, Japan; 6) Pediatric Department, Tokyo Women's Medical University, Tokyo, Japan; 7) Pediatric Department, Faculty of Medical Sciences, University of Fukui, Fukui, Japan; 8) Pediatrics and Developmental Biology Department, Tokyo Medical and Dental University, Tokyo, Japan; 9) PRESTO, JST, Kawaguchi, Japan; 10) Human Genome Research Department, Kazusa DNA Research Institute, Kisarazu, Japan.

Aicardi-Goutières syndrome (AGS) is a rare, genetically determined early-onset progressive encephalopathy. Individuals affected with AGS typically exhibit severe neurological symptoms associated with basal ganglia calcification and type I interferon elevation in the cerebrospinal fluid. To date, mutations in six genes (TREX1, RNASEH2A, RNASEH2B, RNASEH2C, SAMHD1, and ADAR1) have been identified as etiologic for AGS. However, our previous Japanese nationwide AGS survey (Abe, 2013) as well as other reports showed a group of AGS individuals without mutations in the six genes above, suggesting the existence of additional AGS associated genes. We performed trio-based whole exome sequencing in three AGS individuals without molecular diagnosis. After the removal of common polymorphisms, de novo missense mutations in IFIH1 were identified in all three. IFIH1 encodes MDA5, one of the cytosolic pattern recognition receptors that recognize double-stranded RNA (dsRNA). MDA5 activation by its oligomerization on dsRNA results in the enhancement of type I interferon transcription, leading to the activation of a large number of interferon-stimulated genes (ISGs). Indeed, transfection of IFIH1 plasmids containing the mutations in the AGS individuals into Huh7 cells showed significantly stronger promoter activities of IFNB1 as well as downstream IFIT1 transcription, suggesting that these IFIH1 mutations induce activation of type I interferon pathway and are responsible for the phenotypes of AGS. Furthermore, we retrovirally reconstituted Ifih1-null mouse embryonic fibroblasts (MEFs) with the IFIH1 mutants, and subsequently infected these MEFs with encephalomyocarditis virus (EMCV), an MDA5-specific ligand. Interestingly, these MDA5 mutants lacked ligand-specific responsiveness, which was similar to the lack of ligand responsiveness of p.Gly821Ser mouse MDA5 mutant, previously reported in the SLE mouse model (Funabiki, 2014). Our results, currently under revision, showed that AGS is caused by the mutations in IFIH1, which has also been recently reported by Rice et al (Rice, 2014). Further analysis remains to elucidate the precise mechanism how these IFIH1 mutations cause the type I interferon overproduction.

3008M

The comprehensive genetic analysis of congenital anomalies of kidney and urinary tract (CAKUT) in Japan. *N. Morisada[1], M. Taniguchi-Ikeda[1], K. Nozu[1], A. Shono[1], K. Kamei[2], S. Ito[2], R. Tanaka[3], K. Iijima[1].* 1) Pediatrics, Kobe University Graduate School of Medicine, Kobe, Hyogo, Japan; 2) Nephrology and Rheumatology, National Center for Child Health and Development, Tokyo, Japan; 3) Nephrology, Hyogo Prefectural Children's Hospital, Kobe, Japan.

Purpose: Congenital anomalies of kidney and urinary tract (CAKUT) are the most common cause of pediatric end-stage renal disease over the world. The detailed mechanisms of development of CAKUT were still unclear; however genetic mutations in various genes may play pivotal roles. We have conducted the comprehensive genetic analyses of CAKUT in Japan. Methods: This study was approved by the Institutional Review Board of Kobe University Graduate School of Medicine. Genomic DNA samples of patients were provided from peripheral blood mononuclear cells. We performed direct sequencing, multiplex ligation-dependent probe amplification (MLPA) analysis, array comparative genome hybridization (aCGH) analysis and/or next-generation sequencing (NGS). Results: We examined 206 patients from 187 families. Ninety-one patients out of 82 families were non-syndromic CAKUT (NSC) and 115 patients out of 105 families were syndromic CAKUT (SC). We identified the responsible genes in 62 patients from 44 families. The detection rates in NSC and SC families were 14.6% and 30.5%, respectively. The most common responsible gene found in this cohort was *PAX2* (11 families). Other responsible genes were *EYA1* (9), *HNF1B* (7), *UMOD* (1), *OFD1* (1), *SALL1* (1) and *CHD7* (1). MLPA analysis enabled us to identify *TSC2-PKD1* contiguous gene deletions in a patient in our cohort. aCGH is useful to reveal the responsible chromosomal lesion in CAKUT with intellectual disability (ID), and we have identified copy number variations in 9 patients with CAKUT and ID such as 22q11.2 microdeletion, 16q microdeletion and 1q21.1 microdeletion. We identified several responsible genes in the patients by NGS. Conclusions: This is the first nation-wide study for the genetic approach of CAKUT in Japan.

3009T

Deciphering Molecular Etiology of the Mayer-Rokitansky-Küster-Hauser (MRKH) Syndrome. *A.B. Ekici[1], C. Büttner[1], J. Pschirer[1], P. Strissel[2], P. Oppelt[2], S. Renner[2], M. Beckmann[2], R. Strick[2].* 1) Institute of Human Genetics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany; 2) Department of Gynecology and Obstetrics, Laboratory for Molecular Medicine, University-Clinic Erlangen, Germany.

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome describes women with congenital aplasia of the uterus, cervix and the upper two-thirds of the vagina due to absent paramesonephric (Müllerian) ducts. Women with MRKH have a normal female karyotype (46, XX), normal female external development, internal normally regressed mesonephric (Wolffian) ducts and have correctly timed pubarche and thelarche. The incidence of the MRKH syndrome is one in 4,500 female newborns. MRKH patients represent the second most frequent cause of primary amenorrhea after Turner syndrome and commonly have associated malformations, like skeletal and renal abnormalities. The MRKH syndrome occurs isolated as a genital malformation (type 1), but also with associated malformations (especially malformations of the kidneys and urinary tract (type 2) and MURCS association (Müllerian renal and cervicothoracic somite abnormalities; partial or complete absence of the spinal column, ribs, or arms; asymmetric or improperly developed ribs or arms). To date the genetic or molecular etiology of the MRKH syndrome is completely unknown. We performed copy number variation analysis with high density SNP microarrays, whole exome sequencing and sequenced the enriched methylome from two pairs of discordant monozygotic twins and their family members. Since the results of this integrative analysis of these three high-throughput analysis data sets did not resulted in clear causative variants even with a combined genetic-epigenetic disease model for the data analysis, we now made the next step in the extent of data depth. We now used two in depth analysis methods: sequencing whole genomes and bisulfite converted whole genomes in parallel. The first method enables in addition to comprehensive SNV and small InDel analysis also a thoroughly analysis for structural variants like large InDels, inversions, translocations etc. The latter method is the gold standard for DNA methylation analysis and provides single nucleotide resolution map of 5-mC of the genome. So far the first tier of data analysis is very promising and a complete comparative analysis is ongoing. We believe that the methods in the present application will help to unravel the genetic or molecular causes of MRKH and be of clinical relevance in order to help clinicians for an accurate molecular diagnosis and council patients and their families in order to understand the syndrome.

3010S

Utility of whole exome sequencing in diagnosis of individuals with congenital anomalies of kidney and urinary tract. *M. Bekheirnia, N. Bekheirnia, M. Bainbridge, N. Janzen, S. Jhangiani, D. Muzny, M. Michael, E. Brewer, E. Elenberg, A. Kale, A. Riley, S. Swartz, P. Srivaths, S. Wenderfer, R. Alan Lewis, E. Gonzales, R. Gibbs, J. Lupski, J. Belmont, D. Roth, M. Braun, D. Lamb.* Baylor College of Medicine, Houston, TX.

Introduction: Congenital Anomalies of Kidney and Urinary Tract (CAKUT) are the most common cause of pediatric end stage renal disease (ESRD). The discovery of underlying genetic etiologies would not only improve diagnostic precision for non-syndromic forms, optimize management of affected patients, prevent disease recurrence by PGD (preimplantation genetic diagnosis), but also aid prenatal diagnosis in forms that result in early-onset ESRD. Here, we show the utility of whole exome sequencing (WES) in a diagnostic setting and in the genomic research of CAKUT. Methods: We completed research WES in 65 families with CAKUT. Approximately 25% of the cases were familial and 10% were syndromic. We used the ACMG (American College of Medical Genetics and Genomics) standards to classify genetic variants. We focused on analysis of the cases with mutations in 20 genes that are known to cause CAKUT and are central to development of the kidney and urinary tract. Results: Mutational analysis was performed and the following deleterious or possibly deleterious mutations were identified: *PAX2* (G24fs, S171P), *HNF1B* (Q378fs), *RET* (S401C), *EYA1* (c.867+5G>A), *SIX2* (P241L), and *DSTYK* (R592Q, D120N). No mutation was identified in *GDNF, SIX1, SOX17*, or *GATA3*. Benign variants or variants of unknown significance were identified in *BMP7, CDC5L, CHD1L, SALL1, SIX5, ROBO2, UPK3A, BMP4, KAL1*, and *TNXB*. The G24fs mutation occurs in a family with multiplex renal dysplasia and membranous nephropathy that has not been reported previously with *PAX2* mutations. Q378fs is a novel mutation in *HNF1B*. Phenotypes of some of these families expand our current knowledge about the corresponding genes. Conclusion: This is the first report utilizing WES for diagnosis in patients with CAKUT. At least 12% of individuals with CAKUT have deleterious mutations in known genes that can be identified by WES. Therefore, WES should be considered as a diagnostic tool in such patients, especially in the families with complex medical histories. Identification of novel mutations and expansion of the phenotypes are additional important benefits of WES as a diagnostic tool. Focal segmental glomerulosclerosis exomes reveal candidate variants highly enriched in cell movement and cell adhesion related genes. *J. Suh[1], G. Genovese[1,2], V. Charoonratana[1], A. Knob[1], M. Pollak[1,2].* 1) Beth Israel Deaconess Medical Center, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA.

The findings of focal segmental glomerulosclerosis (FSGS)-causing genes established that genetic components contribute to the development of FSGS during recent two decades. However, in majority of families even with the evidence of strong inheritance, underlying genetic cause is unknown. Here, we analyzed exome of families and sporadics which are unexplained by known FSGS genes in an extended effort to find the gene responsible for the development of FSGS. We performed exome sequencing of 403 probands from 311 familial and sporadic cases of FSGS. We also sequenced 96 unaffected family members. After variants calling, variants are filtered against common variants from the 1,000 Genomes Project, dbSNP, and Exome Sequencing Project except known FSGS-causing variants, and then novel non-synonymous or splice variants are kept. Exome analysis revealed that 30.3 percent of all cases contain known FSGS-causing variants with 47.9 percent of familial cases and 16.0 percent of sporadic cases, respectively. After excluding explained cases, we filtered genes showing more than 4 novel non-synonymous and splice variants, and grouped genes according to 1) their cellular component, molecular function, and biological process using gene ontology service, AmiGO2, and 2) their protein-protein interaction using DAPPLE. GO terms of genes from unexplained cases were significant enriched in cellular component movement and cell adhesion both with p-value less than 0.0001. DAPPLE results consistently showed two big protein-protein interactions each involving cell movement and cell adhesion, respectively. Here we show sporadic FSGS cases are less explained by known FSGS-causing genes compared to familial cases. These data show that novel non-synonymous or splice variants are highly enriched in cell movement- and cell adhesion-involved genes in the exome of FSGS patient samples, suggesting the importance of podocyte movement and interaction with neighboring cells and extracellular matrix.

The role of *MAZ* in the regulation of genitourinary development via modulation of WNT signaling. *M. Haller, D.J. Lamb.* Baylor College of Medicine, Department of Molecular and Cellular Biology, Center for Reproductive Medicine, Houston, TX.

Genitourinary (GU) birth defects comprise some of the most common yet least studied congenital malformations and range in severity from conditions such as undescended testes (cryptorchidism) and ventrally misplaced urethral meatus (hypospadias) to highly complex malformations such as bladder exstrophy epispadias complex (BEEC) and ambiguous genitalia. Congenital anomalies of the kidney & urinary tract are also common and include phenotypes such as duplicated tract components, kidney agenesis, congenital hydronephrosis, horseshoe kidney, and cystic kidneys. Genomic aberrations such as copy number gains and losses can result in congenital malformations of the GU tract, among other organ systems. Genome wide array comparative genomic hybridization (aCGH) together with an extensive literature review allowed identification of genomic hotspots of GU development and delineated the smallest CNV regions of maximum overlap. CNV mapping revealed over 30 patients with GU defects harboring duplications or deletions in the syndromic genomic region, 16p11.2 - the most common known pathogenic gene dosage region in humans. The only gene covered collectively by all the mapped CNVs in patients with GU defects was MYC-associated zinc finger (*MAZ*). *MAZ* encodes a transcription factor with a similar consensus sequence to that of *WT1*, and is implicated in WNT signaling. *In situ* hybridization on mouse embryos and isolated mouse GU tracts defined the expression profile of *Maz* during development. *In situ* experiments showed robust staining of the GU tract including the kidneys, ureters, testes, bladder and genital tubercle. Immunohistochemistry confirmed this expression pattern at the protein level. Analysis of the lab's cohort of genomic DNA from GU-abnormal patients and GU-normal fertile controls via CNV qPCR determined the frequency of *MAZ* CNVs in these groups. Validated by two independent probe sets, 6% of our GU abnormal cohort displayed CNVs in *MAZ* (n=258) compared to 0% in controls (n=57). As predicted based on its consensus sequence, knockdown or overexpression of *MAZ* in human embryonic kidney (HEK293) cells results in differential expression of several WNT pathway genes including *DKK1/2/4, LRP5/6, FZD1/9/10, DACT1, SFRP4/5, WNT4, WNT11* and *GSK3A*. *MAZ*, once thought to be simply a housekeeping gene, encodes a dosage sensitive transcription factor that may play a key role in urogenital development and contribute to the congenital malformations of the 16p11.2 phenotype.

3013S

Functional Characterization of Renin Variants Identified in African Americans in Exome Sequencing Project. *S. Kmoch[1], M. Zivna[1], K. Hodanova[1], P. Vyletal[1], V. Stranecky[1], B.I. Freedman[2], A.J. Bleyer[2].* 1) First Medical Faculty, Charles University of Prague, Prague, Czech Republic; 2) Section of Nephrology, Wake Forest School of Medicine, Winston-Salem, North Carolina, USA.

Renin is a key component of blood pressure regulation. It is encoded by the *REN* gene and produced in juxtaglomerular cells in kidney. Its primary structure consists of a 23 amino acid N-terminal signal sequence, 43 amino acid "pro" domain, and the mature renin comprising 340 amino acids. The *REN* mutations lead to two different human diseases. Dominant mutations located within the signal sequence of *REN* cause familial juvenile hyperuricemic nephropathy type 2 (HNFJ2; OMIM 613092), characterized by early onset hyperuricemia, anemia and chronic kidney disease. Recessive mutations, mostly nonsense, affecting synthesis or the activity of renin cause renal tubular dysgenesis (RTD; OMIM 267430). To further study *REN* variation, we interrogated the Exome Variant Server (http://evs.gs.washington.edu/EVS/) and identified three nonsynonymous variants P8A, R33W and G217R. These variants are present exclusively in African-Americans with 0.005; 0.001 and 0.062 allele frequencies, respectively. Localization of these variants in the context of *REN* mutations associated with HNFJ2 and RTD suggested, that if causal, the P8A variant may lead to symptoms of HNFJ2 in 1.17 % and R33W and G217R variants to RTD in 0.35 % of African Americans. To asses functional impact of these variants, we cloned individual cDNAs and transiently expressed wild-type and corresponding mutant proteins in HEK293 cells. We studied proteolytic processing and glycosylation patterns of expressed proteins, measured renin activities in cell lysates and cultured media and investigated cellular localization of expressed proteins. Our analysis revealed, that the P8A variant does not affect biosynthesis and activity of prorenin and renin but reduces their secretion rate by ~ 50 % compare to wild-type protein. The R33W variant reduces biosynthesis of prorenin and renin to ~ 25 % of the wild-type protein and also affects formation of characteristic intracellular renin secretory granules. The G217R variant had no effect on prorenin and renin properties. The results of the analysis suggest that P8A and R33W variants significantly affect renin biosynthesis and secretion and may thus contribute to low plasma renin activity and a higher incidence of kidney diseases in populations of African origin. Exact population frequencies and clinical effects of these two variants should be therefore further studied using association studies in appropriate population cohorts and by detailed phenotyping of individual carriers.

3014M

Detection of genes causing polycystic kidney in Saudi Arabian Fetuses and Neonates. *M.H. Al-Hamed[1], W. Kurdi[2], Z. Abdullah[3], M. Tulbah[2], M. Al-Nemer[2], R. Khan[2], N. Al-Sahan[2], M. Albaqumi[1,4].* 1) Department of Genetics, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; 2) Department of Obstetrics and Gynecology, KFSHRC, Riyadh, Saudi Arabia; 3) Obstetrics and Gynaecology Dept, PSMMC, Riyadh, Saudi Arabia; 4) Department of Medicine, KFSHRC, Riyadh, Saudi Arabia.

Polycystic kidney disease (PKD) is common in the Saudi population and is associated with significant morbidity and mortality. Recent reports estimated the prevalence of PKD in Saudi population to be 0.57 per 1000 births. The majority of polycystic disease in fetuses arises from recessively inherited mutations of genes expressed in the primary cilium of renal epithelial cells. To investigate the genetic basis of polycystic disease in Saudi families, we recruited forty fetuses presenting with PKD diagnosed by ultrasound. Molecular karyotype to exclude aneuploidy was negative for all cases. Sequencing of the following genes (PKHD1, NPHP1, INVS, NPHP3, NPHP4, IQCB1, CEP290, GLIS2, RPGRIP1L, AHI1, CC2D2A, MKS1, TCTN2, TMEM67, and TMEM216) resulted in identification of molecular causes of PKD in 16 cases (40%). Mutations of the CC2D2A gene are most common and account for 44% of mutations detected. Mutations in the CC2D2A gene are always associated with cystic kidneys and Encephaloceles indicating Meckel-Gruber syndrome diagnosis. Novel mutations in INVS and TCTN2 genes were detected. Oligogenic inheritance has been observed in two families. A third family had homozygous mutation in TMEM67 gene and another homozygous mutation in the RPGRIP1L gene. These types of inheritance (Oligogenic and homozygosity in two Cilia genes) are likely aggravating the phenotype.

Loss of *Zeb2* Causes Glomerulocystic Kidney Disease in Mice. *H. Milo Rasouly, S. Chan, A. Pisarek-Horowitz, W. Lu.* Renal, Boston University, Boston, MA.

BACKGROUND: ZEB2 is a zinc finger E-box-binding homeobox transcription factor. Mutations in *ZEB2* cause the Mowat-Wilson syndrome (MIM #235730), an autosomal dominant disorder characterized by multiple congenital anomalies including kidney anomalies. However, the role of ZEB2 during kidney development is unknown. **METHODS**: ZEB2 expression was analyzed by immunostaining of the embryonic kidneys during mouse development. Kidney specific *Zeb2* conditional knockout mice were generated by crossing the *Zeb2* floxed allele ($Zeb2^{flox/flox}$) with the *Pax2-cre* and *Six2-cre* alleles. The conditional knockout mice were analyzed from embryonic stage E14.5 to postnatal 8 weeks old. The mouse kidneys were analyzed by H&E staining and immunostaining for apoptosis. Gene expression analysis was performed by TaqMan assays. Kidney function was assessed by measuring urine protein levels, serum creatinine and blood urea nitrogen. **RESULTS**: ZEB2 is highly expressed during mouse kidney development. Both $Zeb2^{flox/flox}$*;Pax2-cre* and $Zeb2^{flox/flox}$*;Six2-cre* conditional knockout mice developed kidney glomerular cysts starting at E16.5 days. $Zeb2^{flox/flox}$*;Pax2-cre* mice died at birth and $Zeb2^{flox/flox}$*;Six2-cre* mice developed abnormal kidney function at 5 weeks old. The cysts originate from glomeruli with dilated Bowman's capsules and collapsed glomerular tufts. Reduced apoptosis was detected in the S-shaped and C-shaped bodies of *Zeb2* knockout mice compared to the wild type controls. Gene expression analysis revealed increased levels of *Pkd1* mRNA in the developing kidney of both *Zeb2* conditional knockout mice compared to the wild-type controls. Interestingly, overexpression of *Pkd1* has been reported to cause glomerular cysts in mice. **CONCLUSIONS**: Loss of *Zeb2* causes glomerulocystic kidney disease in mice with increased expression of the *Pkd1* transcript.

Whole exome sequencing identifies a homozygous mutation in *SOHLH1* in two sisters with non-syndromic hypergonadotropic hypogonadism. *Y. Bayram[1], T. Guran[2], G. Yesil[3], Z. Atay[2], E. Karaca[1], T. Gambin[1], S. Turan[2], D. Pehlivan[1], S.N. Jhangiani[4], D. Muzny[4], B. Halioglu[2], A. Bereket[2], R.A. Gibbs[4], J.R. Lupski[1,5,6].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Department of Pediatric Endocrinology and Diabetes, Marmara University Hospital, Istanbul, Turkey; 3) Department of Medical Genetics, Bezmialem University, Istanbul, Turkey; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 6) Texas Children's Hospital, Houston, TX, USA.

Patients with hypergonadotropic hypogonadism (HH) present with primary or secondary amenorrhea or delayed puberty secondary to primary gonadal dysfunction and characterized by elevated gonadotropins and low sex steroids. HH is always a pathological state; therefore, assessment should include history of surgery, irradiation and chemotherapy, examination for features of the Turner syndrome and consideration of a karyotype. Several genetic defects have been shown to cause HH including genes having a role in gonadal development or maintenance and defects in sex steroid synthesis, or end organ resistance to gonadotropins. However, elucidation of novel genetic defects causing HH will provide major insights into the biology of this condition - especially knowledge of the regulation of human reproductive function. Here we report two sisters who were born to a first degree cousin marriage presenting with HH. Both of them were referred to a pediatric endocrinology clinic because of primary amenorrhea and lack of secondary sex characteristics at 16 and 14 years of age, respectively. Further hormonal investigations revealed elevated FSH and LH and decreased estradiol concentrations. On the pelvic ultrasound imaging both patients had hypoplastic ovaries and prepubertal-sized uteri. Karyotype analyses were normal and no other significant clinical or dysmorphic features were identified; the patients were diagnosed with non-syndromic HH. We performed whole exome sequencing (WES) for both affected patients which identified a homozygous frame-shift deletion (c.705delT; p.Lys236Argfs*3) in the *SOHLH1* gene. Segregation analysis within the family revealed that both parents were heterozygous carriers while the unaffected sister was wild type for the same variant consistent with Mendelian expectations. *SOHLH1* encodes a basic helix-loop-helix transcription factor with homologues in humans and other placental mammals. Previous mouse studies revealed that *Sohlh1* is preferentially expressed in mouse oocytes during early folliculogenesis and required for oogenesis. In a *Sohlh1* knock-out mouse model, *Sohlh1* -/- female mice have been observed to be infertile with atrophic ovaries that lacked oocytes while the *Sohlh1* +/- females were normal. In conclusion; we describe the first homozygous *SOHLH1* mutation in humans and clinical features in our patients together with findings observed in a mouse model strongly suggest that homozygous mutations in *SOHLH1* cause ovarian dysfunction.

3017M

IMAGe syndrome mutations in the PCNA-binding site of *CDKN1C* cause in increased protein stability and inhibition of the cell cycle. *V.A. Arboleda[1,2], K.S. Borges[3], E. Vilain[1,4,5].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Department of Genetics, Ribeirão Preto Medical School, University of São, Ribeirão Preto, Brazil; 4) Department of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 5) Department of Urology, David Geffen School of Medicine at UCLA, Los Angeles, CA.

Mutations in CDKN1C (a.k.a. P57KIP2) can cause opposing genetic syndromes: the undergrowth syndromes IMAGe Syndrome (Intrauterine growth retardation, Metaphyseal dysplasia, Adrenal hypoplasia and Genital anomalies) and Russell Silver Syndrome (RSS) and the overgrowth syndrome Beckwith-Wiedemann syndrome (BWS). Gain-of-function mutations located in the PCNA-binding domain of CDKN1C result in a spectrum of undergrowth disorders ranging from IMAGe Syndrome and RSS, while loss-of-function mutations in CDKN1C cause BWS. CDKN1C is a cyclin-dependent kinase inhibitor that functions as a negative regulator of cell proliferation. Here, we investigate the effects of gain-of-function CDKN1C mutations on protein stability during cell cycle progression and on cell proliferation to understand the molecular mechanisms underlying IMAGe syndrome. 293T cells transfected with wild type and IMAGe-mutant (p.K278E or p.F276V) and treated with de novo protein synthesis inhibitor, cyclohexamide (CHX), were subject to immunoblotting and demonstrated an increased stability of IMAGe-mutant CDKN1C compared to wild-type CDKN1C. To demonstrate that IMAGe-mutant CDKN1C resulted in impaired progression through the cell-cycle, we transfected them with wild-type, IMAGe-mutant (p.K278E), or BWS-mutant (p.L42P), synchronized the cells, and then assessed the levels of CDKN1C protein over a 24-hour period. Both the wild-type and BWS-mutant cells showed peak levels of CDKN1C at 3- and 15- hours post thymidine release while the IMAGe-mutant showed stable CDKN1C protein expression over 24-hours, indicating a lack of progression through the cell cycle. Cell-cycle phase distribution at the time T0 showed that in IMAGe-mutant transfected cells, a larger proportion of cells were in the G1 phase (36.94%) compared to wild-type CDKN1C, empty plasmid, and BWS-mutant (32.31%, 14.88% and 19.85 respectively). Finally, clonogenic assays demonstrated that cells transfected with IMAGe-mutant CDKN1C had smaller and fewer colonies than cells transfected with wildtype CDKN1C plasmids. In conclusion, gain-of-function mutations in the PCNA-binding site of CDKN1C increase protein stability by inhibiting degradation of CDKN1C during cell-cycle progression. Therefore, cells are stalled in G1-phase and have decreased clonogenic potential. Our findings shed light on the molecular mechanism behind IMAGe mutations on cell cycle, proliferation, and undergrowth disorders in humans.

3018T

Hypopituitarism caused by dysregulation of pituitary progenitors and epithelial to mesenchymal transition. *M.Ines. Perez Millan, A.H. Mortensen, M.L. Brinkmeier, S.A. Camper.* Human Genetics, University of Michigan, Ann Arbor, MI.

Mutations in PROP1 and several other transcription factors, including POU1F1 (PIT1), HESX1, and OTX2, cause Multiple Pituitary Hormone Deficiency (MPHD) in humans and mice. PROP1 is co-expressed with stem cell markers including the growth factor receptor, GFRA2 and transcription factors SOX2, SOX9, and OCT4 (1, 2). In mouse fetal development *Prop1* expression coincides spatially and temporally with the delamination, migration, and differentiation of progenitor cells in Rathke's Pouch (RP) into hormone producing cells of the adenohypophysis. *Prop1* mutant progenitors fail to undergo these processes, leading to organ dysmorphology, poor vascularization, and postnatal pituitary hypoplasia (3). *Prop1* is necessary for regulating expression of two other MPHD genes; repressing *Hesx1* and activating *Pou1f1*. Mutations in *PROP1* are the most common known cause of MPHD, but most of the patients have no molecular diagnosis. The aim of this work is to identify additional downstream target genes of *Prop1* to reveal new candidate genes for the cases of hypopituitarism that remain unexplained and to better understand the pathophysiology of MPHD. We chose an in vitro approach of identifying DNA sequences bound by PROP1 in an immortalized pituitary cell line by ChIP-Seq technology. Because the efficiency and specificity of ChIP depends on the quality of the antibody, we developed a biotin-tagged PROP1 system that permits precipitation of PROP1 with an avidin based detection assay. We identified enrichment of PROP1 binding at the *Pou1f1* gene and in genes that encode components of the pathways of cell junction signaling and regulation of epithelial to mesenchymal transition (EMT). We examined expression of several candidate genes in *Prop1* mutant mice and confirmed that their expression was altered. These data suggest that *Prop1* promotes the transition of progenitors to differentiation by suppressing expression of progenitor markers like SOX genes and repressing claudin gene expression, in order to release tight junctions and permit EMT. In addition, *Prop1* activates expression of cyclin E, a marker of the transition state, and *Pou1f1*, a marker of the differentiation state. This study establishes new mechanisms underlying PROP1's role in pituitary progenitor cell regulation and offers new candidate genes for MPHD. References 1. Fauquier et al. Proc Natl Acad Sci 105:2907-12, 2008. 2. Garcia-Lavandeira et al. PLoS One 4:e4815, 2009. 3. Ward et al. Mol Endo 20:1378-1390, 2006.

3019S

Cell Specific Biochemical Changes in Snyder Robinson Syndrome. *J. Albert[1,2], L. Wolfe[1,2], W. Bone[1], T. Markello[1,2], D. Adams[1,2], C. Schwartz[3], R. Gafni[4], M. Collins[4], L. Tosi[5,6], N. Bhattacharyya[4], W. Gahl[1,2], C. Boerkoel[1].* 1) Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, MD, USA; 2) Medical Genetics Branch, National Human Genome Research Institute, Bethesda, MD, USA; 3) J.C. Self Research Institute, Greenwood Genetics Center, Greenwood, SC 29646, USA; 4) Skeletal Clinical Studies Unit, Craniofacial and Skeletal Disease Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, MD 20892, USA; 5) George Washington University School of Medicine, Washington, DC, USA; 6) Children's National Medical Center, Washington, DC, USA.

Spermidine and spermine are simple positively charged ubiquitous molecules synthesized by spermidine synthase and spermine synthase (SMS), respectively. Spermine and spermidine homeostasis is crucial for ion channel regulation, transcription and translation. Deficiency of the SMS enzyme disturbs this homeostasis in Snyder-Robinson syndrome (SRS), a form of X-linked intellectual disability. Individuals with SRS have developmental delay, dysmorphic facies, osteoporosis, seizures, and hypotonia. A major cause of morbidity in these individuals is bone disease. To elucidate the mechanism of osteoporosis, we obtained osteoblasts from an individual with SRS and our results demonstrate that there is an osteoblast specific effect of deficient SMS enzyme activity and/or aberrant polyamine homeostasis. SMS fibroblasts and osteoblasts have similar decreases in SMS protein compared with normal controls. However, normal control osteoblasts have less SMS protein compared with normal control fibroblasts suggesting that osteoblasts may be more sensitive to more subtle changes in SMS protein. In both cell lines, we observed a slight decrease in both cytoplasmic and nuclear SMS protein as detected by cellular fractionation and western blot. Furthermore, the differences in spermine and spermidine levels were significantly lower and higher, respectively in the osteoblasts. These osteoblast specific changes in polyamine metabolism may exemplify the mechanism underlying the cellular specificity of disease in SRS.

Genetic and enzymatic characterization of the anti-oxidant enzyme GPx1 in sickle cell disease patients. *M. Beaudoin[1], G. Galarneau[1], A. Binding[2], M. Reid[3], I. Hambleton[4], C. McKenzie[3], J.N. Hirscchorn[5,6], M. Warner[2], G. Lettre[1].* 1) Montreal Heart Institute and Université de Montréal, Montreal, Quebec, Canada; 2) McGill University, Montreal, Quebec, Canada; 3) Tropical Medicine Research Institute, The University of the West Indies, Mona, Jamaica; 4) The University of the West Indies, Cave Hill, Barbados; 5) Children's Hospital Boston, Boston, MA, USA; 6) Broad Institute, Cambridge, MA, USA.

Introduction: Sickle cell disease (SCD) is a genetic blood disorder characterized by anemia, pain crises, strokes and early death. Affected individuals inherit two copies of a mutation in the gene encoding β-globin, one of the two subunits of hemoglobin. Despite of this simple mode of inheritance, SCD is characterized by patient-to-patient clinical heterogeneity. Alpha-thalassemia and fetal hemoglobin levels are two known modifiers of SCD severity. The goal of our study was to identify new genetic modifiers of SCD using whole-exome sequencing followed by functional characterization. Methods: We sequenced the whole-exome of 19 patients selected from the Jamaican SCD birth cohort. Over 18 years of follow-up observations, these patients presented with few severe SCD-related complications when compared to the rest of the cohort (0.07 vs. 0.57 severe events per year, $p<0.001$). Analysis of the whole-exome sequence data identified a common missense variant in GPX1 (Pro200Leu, rs1050450) that is enriched in Jamaican patients with mild SCD. We obtained DNA and red blood cell (RBC) membranes from 40 SCD patients recruited at the Royal Victoria Hospital in Montreal, Canada. We genotyped GPX1 Pro200Leu using a high resolution melting protocol. We measured GPx1 protein level and enzymatic activity with ELISA and absorbance assays, respectively. Results: The GPX1 Leu200 allele is enriched in 19 “mild” Jamaican SCD patients when compared to populations of African ancestry from the 1000 Genomes Project (47% vs. 25-34%). In 95 patients from the Jamaican SCD birth cohort, GPX1 Pro200Leu is associated with a composite score that summarizes severe SCD-related events collected from birth until adulthood ($p=0.02$). In RBC membranes from SCD patients, GPX1 Pro200Leu is not associated with GPx1 protein amount ($p=0.95$), but is correlated with GPx1 enzymatic activity ($p=0.049$). Conclusion: GPX1 encodes glutathione peroxidase, an enzyme that protects RBC from free radical damages. Previous studies have implicated free radical production in SCD severity, and in particular in the etiology of vaso-occlusive crises. Our results indicate that a common missense variant in SCD patients regulates the activity of an important enzyme implicated in the RBC defense against oxidation. Larger studies are required to determine how this enzymatic variation may impact clinical heterogeneity in SCD.

3021T

Structural, molecular and cellular impact of the Ogden syndrome Ser3-7Pro mutant N-terminal acetyltransferase Naa10. *G.J. Lyon[1], L. Myklebust[2], P. Van Damme[3], S. Stove[2], N. Reuter[2], M. Doerfel[1], Y. Wu[1], G. Liszczak[4], A. Abboud[2], T. Kalvik[2], C. Grauffel[2], V. Jonckheere[3], H. Kaasa[2], R. Marmorstein[4], K. Gevaert[3], T. Arnesen[2].* 1) Cold Spring Harbor Laboratory, New York City, NY; 2) Department of Molecular Biology, University of Bergen, N-5020 Bergen, Norway; 3) Department of Medical Protein Research, VIB, B-9000 Ghent, Belgium; 4) Department of Chemistry, University of Pennsylvania, Philadelphia, PA 19104, USA.

The infantile X-linked lethal Ogden syndrome was the first reported human genetic disorder associated with a mutation in an N-terminal acetyltransferase (NAT) gene. The eight affected and now deceased males in two unrelated families had a Ser37Pro mutation in the gene encoding Naa10, the catalytic subunit of NatA, the major human NAT. NATs transfer an acetyl moiety from acetyl coenzyme A (Ac-CoA) to the primary α-amino group of nascent polypeptides as they emerge from ribosomes, and proteomic analyses have revealed that 50-90% of yeast, plant, fruit fly and human proteins are Nt-acetylated. In order to understand the detrimental impact of Naa10 Ser37Pro in humans, we performed structural, molecular and cellular investigations. Structural modeling and molecular dynamics simulations of the human NatA and its Ser37Pro mutant suggest differences in regions involved in catalysis and at the interface between Naa10 and the auxiliary subunit Naa15. In agreement, biochemical data demonstrate a reduced catalytic capacity and a reduced complex formation of Naa10 Ser37Pro with Naa15 and Naa50, indicating a disruption of the NatA complex. Patient derived Naa10 mutant cells show reduced Nt-acetylation for a subset of NatA-type substrates compared to wild type Naa10 cells. More specifically, N-terminal acetylome analyses of B-cells and fibroblasts reveal an in vivo perturbation of Naa10 (NatA) mediated Nt-acetylation in Ogden syndrome males as some NatA-type substrates are less Nt-acetylated, with some of these substrates previously found to be affected in their Nt-acetylation status by siNatA-mediated knockdown. Ogden syndrome fibroblasts displayed reduced cell proliferation and migration capacity as well as abnormal growth patterns. Introduction of human NatA into yeast that lack endogenous NatA could rescue a specific heat stress phenotype, whereas NatA Ser37P failed to. Additionally, proteomic analyses of these strains revealed a reduced expression of ribosomal proteins in the Ogden strains. The impaired NatA S37P complex formation and catalytic capacity, together with reduced in vivo Nt-acetylation and abnormal cellular phenotypes provide new insights into the underlying molecular and cellular mechanisms of Ogden syndrome. More broadly, these studies broaden our understanding of the role of N-terminal acetylation of proteins, which is a vastly understudied but very prevalent co- and post-translational modification.

3022S

Analyzing KMT2D/MLL2 missense mutations as causative in Kabuki syndrome and testing U1snRNAs-based approaches to revert KMT2D/MLL2 splicing defects. *L. Micale[1], B. Mandriani[1], P. De Nittis[1], B. Augello[1], C. Fusco[1], A. Romano[2], B. Piccini[2], M.T. Pellico[1], C. Rinaldi[1], A. Di Lauro[1], T. Verri[3], G. Merla[1].* 1) Medical Genetics Unit, IRCCS Casa Sollievo Della Sofferenza Hospital, San Giovanni Rotondo, Italy; 2) Institute of Experimental Neurology, Division of Neuroscience, San Raffaele Scientific Institute, Milan, Italy; 3) Department of Biological and Environmental Sciences and Technologies, University of Salento, Lecce, Italy.

Histone methylation is an epigenetic mechanism by which spatial and temporal expression of distinct genes and pathways are regulated at precise developmental stages. The discovery of histone methyltransferase KMT2D and demethylase KDM6A genetic alterations in Kabuki syndrome patients expanded and highlighted the role of histone modifiers in causing congenital anomalies and intellectual disability syndromes. Kabuki syndrome is a multiple congenital malformation syndrome characterized by facial features, skeletal anomalies, dermatoglyphic abnormalities, mental retardation, and postnatal growth deficiency. KMT2D and KDM6A, play important roles in the epigenetic control of active chromatin states modulating the expression of genes essential for embryogenesis and development. We performed a mutational screening on about 400 Kabuki patients by sequencing, MLPA, and qPCR. Among the KMT2D mutations we identified 49 missense variants across the entire length of the KMT2D gene and 9 splicing site variants that result in a frameshift with the generation of premature stop codons. In this study we ascertain the pathogenicity of KMT2D missense mutations through an integrative analysis of bioinformatics tools and biochemical and cellular assays. We used an innovative in silico approach that combines comparative analysis and motif/domain search tools with threading/homology modeling protocols to predict functional/structural effect of KMT2D missense variants. Due to the huge size of KMT2D gene, we devised a strategy where minigenes carrying KMT2D missense variants were generated. Their biological effects were evaluated by measuring KMT2D methyltransferase activity and KMT2D-mediated target genes expression during neuronal differentiation in NT2/D1 cells silenced for KMT2D. In this study we also used U1 small RiboNuclearProteins (U1snRNAs)-based approaches to restore normal splicing process of KMT2D 5' splice site. This strategy, exploited using minigenes and adapted U1snRNAs complementar to the mutated splice site, allowed us to revert the splicing defects for all the analysed mutations. The experimental approaches proposed offer a valuable support to estimate the real deleterious effect of KMT2D missense variants, a main issue in diagnostic counseling, and evaluate the effectiveness of modified U1snRNAs in reverting KMT2D splicing defects as therapeutic tool.

Infantile myofibromatosis: Gene discovery leads to novel treatment paradigm based on *PDGFRB* gain-of-function mutations. *K. Oishi[1,2], B.R. Evans[1], T. Silvers[1], J.A. Martignetti[1].* 1) Dept Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Dept Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY.

Background: Infantile myofibromatosis (IMF; MIM 228550) is an autosomal dominant disorder characterized by solitary or multicentric fibrous tumors of skin, muscles, viscera and bones. Tumor growth may begin during fetal development and can be present throughout adult life. Occasionally, these tumors may spontaneously regress without treatment. Recently, our group and another identified germline missense mutations in the platelet-derived growth factor receptor beta gene (*PDGFRB*) as causing the majority of IMF cases. The effect of IMF mutations on PDGFRB signaling and the molecular pathway(s) which are dysregulated and result in IMF tumors are unknown but will need to be understood if a targeted therapy is to be devised. **Objective**: To characterize the molecular functions of the IMF-causative mutant PDGFRB. **Design/methods**: Wild-type (WT) human *PDGFRB* cDNA was cloned into pcDNA3.1 expression vector. Two IMF-causing mutations, R561C and P660T, were introduced using site-directed mutagenesis. Mutant proteins were transiently expressed in COS-7 cells, which lack PDGFRB, and the resultant cell lines were stimulated with PDGF-BB for 30 min after serum starvation. Phospho-PDGFRB and phospho-AKT antibodies were used for western blot. **Results**: Cells expressing mutant PDGFRB proteins had an increase in basal phosphorylation of PDGFRB at Y751 and Y857, compared to cells expressing WT protein. Following PDGF-BB stimulation, all cells demonstrated an increased phosphorylation of PDGFRB, but the IMF mutant cells still maintained markedly higher phosphorylation than controls. While basal AKT phosphorylation was minimal in all cell lines, IMF mutant PDGFRB-expressing cells had increased activation of AKT following PDGF-BB stimulation. Levels of phospho-PDGFRB and phospho-AKT were both consistently higher in P660T than R561C. Imatinib, a tyrosine-kinase inhibitor, suppressed the PDGFRB activation. **Conclusions**: IMF-causing *PDGFRB* mutations result in constitutive gain-of-function (GOF). It was suggested that the mutations induce excessive kinase activity and binding capacities with other signaling molecules through increased phosphorylation of Y857 and Y751, respectively. Of note, there was a ligand-dependent increased AKT activation in the cells expressing mutant PDGFRB. There was GOF strength difference between the two mutations, P660T and R561C. Suppression of PDGFRB activation by imatinib suggests a new therapeutic approach for IMF.

Biochemistry of UBA1 Mutations that Cause Infantile X-Linked Spinal Muscular Atrophy. *C.D. Balak[1], J.M. Hunter[1], G. D'Urso[2], D. Wiley[2], L. Baumbach-Reardon[1].* 1) Translational Genomics Research Institute, Phoenix, AZ; 2) University of Miami, Miller School of Medicine, Miami, Florida.

Spinal muscular atrophy (SMA) is the leading genetic cause of infantile death. Mutations in the SMN1 gene account for a large percentage of SMA. However, in 2008, Dr. Lisa Baumbach-Reardon's group discovered that a rare and lethal form of X-linked SMA can be caused by mutations in the UBA1 gene. UBA1 is an essential non-redundant gene found highly conserved in all organisms from yeast to man; coding for the Ubiquitin Activating Enzyme-1 (Uba1). Uba1 is the pinnacle enzyme in the Ubiquitin Proteasome System (UPS) that is responsible for the turnover and degradation of most proteins in every living cell. The role of Uba1 in the UPS is to activate and transfer a Ubiquitin (Ub) molecule to an E2 Ubiquitin-conjugating enzyme. These Ubiquitin-E2 complexes, in conjunction with E3 ubiquitin ligases, transfer the activated Ub to targeted proteins "tagging" them for degradation by the proteasome. This process of tagging and degrading proteins is essential for the survival of every cell. Our goal is to understand how mutations in Uba1 alter its biochemical function. This is fundamental in understanding the disease mechanism in XL-SMA and developing treatments for XL-SMA. Uba1 activates Ub in a 2 step process. First, Uba1 adenylates Ub in a reaction that transfers the energy of ATP to Ub. The activated Ub is then covalently bound to a cysteine residue of Uba1 to form a thiolester bond in the second step. The Ub is then transferred to a cysteine residue of an E2 enzyme. To date, all of the mutations that have been found in UBA1 cluster in one domain of Uba1 thought to be important for ATP and Mg2+ binding and adenylation, or for protein-protein interactions. Therefore we have developed a continuous kinetic assay to measure the adenylation activity of wild type (WT) and mutant (MT) forms of Uba1. Our initial experiments demonstrate Uba1 mutants retain adenylation activity, thus suggesting alterations in other catalytic activities or protein-protein interactions. We are investigating the rate of thiolester bond formation between Ub and Uba1, and transthiolation of activated Ub to E2 enzymes. Finally we are measuring interactions between mutant forms of Uba1 and key SMA proteins, Smn and gigaxonin. The results of our studies will identify the causal biochemical defect in XL-SMA and pave the way forward for identifying pharmaceutical targets and treatments for XL-SMA.

Comparative proteomic analysis of different fragile X syndrome cell lines. *S. Lanni[1], F. Palumbo[1], M. Goracci[1], G. Mancano[1], A. Vitali[2], V. Marzano[3], F. Iavarone[3], F. Vincenzoni[3], M. Castagnola[3], P. Chiurazzi[1], E. Tabolacci[1], G. Neri[1].* 1) Institute of Medical Genetics, Catholic University, Rome, Italy; 2) Institute of Chemistry of Molecular Recognition-UOS Rome, CNR, Rome, Italy; 3) Institute of Biochemistry and Clinical Biochemistry, Catholic University, Rome, Italy.

Fragile X syndrome (FXS), the leading cause of inherited intellectual disability, is caused by absence of the FMRP protein due to expansion over 200 repeats of the CGG tract at the 5' UTR of the FMR1 gene and subsequent DNA methylation. We have already characterized rare individuals of normal intelligence with CGG expansion over 200 repeats without DNA methylation (unmethylated full mutation, UFM), which have relatively normal transcription and translation, and represent the status of FXS cell lines prior to gene silencing. We have compared the three types of cell lines (normal control WT, FXS and UFM fibroblasts) with a proteomic approach in order to demonstrate possible differences that might clarify the mechanisms through which the rare UFM cells remain unmethylated and transcriptionally active. Protein extracts were compared by LC-ESI LTQ Orbitrap MS/MS analysis after mono-dimensional SDS-PAGE and trypsin digestion. Interrogation of the dataset for differential protein expression shows that some metabolic pathways are deregulated in UFM cells when compared to FXS cells. Among these pathways, mitochondrial metabolism (oxidative stress) is of particular interest considering its role in neurodegenerative diseases (like FXTAS) and particularly in epigenetic regulation. The deregulated proteins, specifically mitochondrial SOD (SOD2), were validated by Western blot. The interaction of target mRNAs with FMRP was assessed by RNA immunoprecipitation. Preliminary data suggest that mitochondrial metabolism is likely to have a role in DNA hypomethylation of UFM cell lines. Supported by Telethon Onlus, FRAXA Foundation, Italian Association for fragile X syndrome and Novartis Institute for Biomedical Research.

Utilization of Cas9/CRISPR to understand the genetic disease mechanism: dissecting the functions of NIPBL in the pathogenesis of Cornelia de Lange syndrome. *K. Izumi[1], M. Bando[1], I. Krantz[2], K. Shirahige[1].* 1) Research Center for Epigenetic Disease, The University of Tokyo, Tokyo, Japan; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, PA, USA.

Cornelia de Lange syndrome (CdLS) is a multisystem developmental disorder characterized by craniofacial dysmorphisms, intellectual disabilities, growth retardation, limb anomalies and several other systemic abnormalities. Heterozygous germline mutations in cohesin structural and regulatory components cause CdLS, and mutations in NIPBL, a cohesin regulatory component, have been identified in nearly 60% of CdLS probands. The cohesin complex possesses multiple roles such as maintaining sister chromatid cohesion during cell division and transcriptional control. Given the absence of premature sister chromatid separation in CdLS patient cell lines, the pathogenesis of CdLS is considered to be associated with abnormal gene expression. To reveal the underlying transcriptome abnormality of CdLS, we have previously performed transcriptome analysis using patient-derived cell lines, however, the influence of genetic background difference cannot be eliminated. To overcome this problem, we created 293FT cell line, a common cell line originating from human embryonic kidney, with NIPBL frameshift mutations using Cas9/CRSPR system. Among the clones screened, we discovered a 293FT clone with bi-allelic NIPBL frameshift mutation in exon 3 (NIPBL null clone). Western blot with N-terminus NIPBL antibody demonstrated the complete absence of full length NIPBL. Interestingly, sister chromatid separation defects were not obvious in this clone, suggesting that for the prevention of premature sister chromatid separation, full length NIPBL is not required. RNA-seq using this clone discovered 3732 genes (out of 35636) whose expression was significantly altered from wild type 293FT line. The expression of many HOX genes was altered in the NIPBL null clone. Since abnormal expression of HOX genes were often seen in CdLS patient samples, this NIPBL null clone recapitulates the some features of transcriptome alteration seen in CdLS. Surprisingly, RNA-seq demonstrated the normal expression level of NIPBL transcript, suggesting the presence of hitherto un-described shorter NIPBL isoform(s). These data suggests that full length NIPBL primarily possesses gene expression regulatory role, however, the full length NIPBL appears not to be required for the maintenance of sister chromatids cohesion during cell division. Our results suggest the differential functional roles of NIPBL isoforms, and full-length NIPBL plays a cardinal role in transcriptional regulation, whose disruption causes CdLS.

3027T

Incontinetia pigmenti: identification of IKBKG/NEMO mutation revealing a novel mechanism of cell death acting as major triggering of the disease. *A. Pescatore[1], E. Esposito[1], G. Calculli[1], G. Courtois[2], M.V. Ursini[1].* 1) Institute of Genetics and Biophysics "A. Buzzati-Traverso" CNR, Via P. Castellino, 111 80125 Naples, Italy; 2) Institut de Recherches en Technologies et Sciences pour le Vivant (iRTSV) CEA Grenoble 17 avenue des Martyrs 38054 Grenoble, France.

Incontinentia pigmenti (IP, MIM#308300) is an inherited neuroectodermal disorder lethal in male and caused in heterozygous female by mutation in the X-linked NEMO/IKBKG, which encodes for a key regulatory protein of the NF-kappaB pathway. Such pathway is involved in many fundamental biological functions regulating the expression of essential proteins for innate and adaptive immunity, inflammation and cell survival. In agreement with the crucial function of NEMO/IKBKG, the embrionic lethality in hemizigous male is considered to be due to massive liver apoptosis. Instead, IP females survive thanks to the skewed X-inactivation that produced counter selection of NEMO mutated cells. Currently it is thought that the sensitivity to apoptosis observed in NEMO-lacking cells in response to TNF is mainly a consequence of impaired transcription of NF-kappaB-dependent anti-apoptotic genes. We will present data on a novel NEMO/IKBKG mutation found in a female affected by a classical although severe form of IP associated to microcephaly, brain atrophy and mental retardation. In vitro analysis of Nemo (-) complemented with the NEMO/IKBKG mutation revealed that these cells prevented NF-kappaB activation upon TNF treatment. Unexpectedly, NEMO-mutant cells were only poorly sensitive to TNF-induced cell death when compared to Nemo (-) cells, while they were very sensitive to TNF-induced necroptosis. We will illustrate how the presence of mutated-NEMO could affect the molecular mechanisms governing the balance between apoptosis and necroptosis, following TNF-receptor stimulation, paying a special attention to the role of NEMO to this regard. These findings open new avenues for future treatment of IP severe form.

3028S

The *cblX* gene, *HCFC1*, regulates craniofacial development by modulating *MMACHC* expression. *T.H. Shaikh, E.A Geiger, B. Appel, A.M. Quintana.* Dept. of Pediatrics, University of Colorado School of Medicine, Aurora, CO.

Mutations in *HCFC1* (MIM300019), which encodes a transcriptional co-regulator, have been recently associated with methylmalonic acidemia and homocysteinemia *cblX* type (MIM309541), an X-linked, recessive disorder characterized by defects in cobalamin metabolism. The metabolic imbalance results from the aberrant transcriptional regulation of *MMACHC* (MIM609831) expression, a downstream target of HCFC1 known to be involved in cobalamin metabolism. Mutations in *MMACHC* cause a highly related disorder, commonly referred to as *cblC*. Both *cblX* and *cblC* have overlapping clinical manifestations including developmental delay, microcephaly, and failure to thrive, but individuals with *cblX* are additionally characterized by severe neurological defects that primarily include intractable epilepsy. According to global ChIP-seq analysis there are over 5000 genes, including *MMACHC*, whose expression is potentially regulated by HCFC1. Thus, it is unclear if all of the clinical manifestations observed in *cblX* are mediated by aberrant expression of *MMACHC* or if some of them result from the dysregulation of other target genes. To begin to elucidate the mechanism by which HCFC1 modulates disease phenotypes, we have carried out loss of function analyses in the developing zebrafish. Of the two *HCFC1* orthologs in zebrafish, *hcfc1a* and *hcfc1b*, the loss of *hcfc1b* specifically led to defects in craniofacial development. Subsequent analysis revealed that *hcfc1b* is essential for the expression of *col2a1* and *sox9a*, two genes that are essential for neural crest cell differentiation into chondrocyte progenitors. Further, the *hcfc1b*-mediated craniofacial abnormalities were rescued by expression of exogenous human *MMACHC*. These data raise the possibility that HCFC1 regulates craniofacial development by modulating expression of *MMACHC*. Furthermore, distinct *HCFC1* mutations demonstrated variable effects on *MMACHC* expression in humans and craniofacial development in zebrafish. Notably, several individuals with mutations in either *HCFC1* or *MMACHC* have been reported to have mild to moderate facial dysmorphia. Thus, our data demonstrate that *HCFC1* plays a role in craniofacial development, which is in part mediated through the regulation of *MMACHC* expression. Further, these observations highlight facial dysmorphism, a previously under-reported phenotype, as a potential outcome of mutations in both *HCFC1* and its downstream target, *MMACHC*.

Disruption of *FMR1*, *RAI1*, *MBD5*, and *TCF4* results in abnormal expression of circadian rhythm genes and sleep disturbances in fragile X, Smith-Magenis, 2q23.1 deletion, and Pitt-Hopkins syndromes. *S.V. Mullegama[1], L. Pugliesi[2,3], B. Burns[2], R. Tahir[2], Z. Shah[2], Y. Gu[2], D.L Nelson[1], W-H. Tan[4], S.H. Elsea[1,2].* 1) Department of Human and Molecular Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Human and Molecular Genetics, Virginia Commonwealth University School of Medicine, Richmond, VA; 3) St. Joseph's Regional Medical Center, Paterson, NJ; 4) Division of Genetics, Boston Children's Hospital; Harvard Medical School, Boston, MA USA.

Sleep disturbance is prevalent in neurodevelopmental disorders such as fragile X syndrome (FXS, *FMR1*), Smith-Magenis syndrome (SMS, *RAI1*), 2q23.1 deletion syndrome (del 2q23.1, *MBD5*), and Pitt-Hopkins syndrome (PTHS, *TCF4*). The frequent comorbidity of sleep disturbance with neurodevelopmental disorders implies overlapping pathways exist that lead to shared sleep phenotypes. We hypothesize that sleep phenotypes in FXS, SMS, del 2q23.1, and PTHS have common etiologies and that FMRP, RAI1, MBD5, and TCF4 function in overlapping circadian pathways that lead to these sleep disturbances. While sleep disturbance is well described in SMS and FXS, we sought to delineate the sleep anomalies in del 2q23.1 and PTHS. Through caregiver surveys and review of the literature, we found that difficulty maintaining sleep was a feature of both disorders. Furthermore, del 2q23.1 patients have difficulty falling asleep and experience night or early awakenings, while PTHS patients have frequent night awakenings. Thus, common sleep issues in these 4 disorders include reduced total sleep time and frequent nighttime and early morning awakenings. We then evaluated expression of the causative genes for these 4 neurodevelopmental disorders in patient lymphoblastoid cell lines (LCLs), which revealed altered levels of *MBD5*, *TCF4*, *RAI1*, and *FMR1* across each of the 4 syndrome cell lines, suggesting a possible common etiology in all four syndromes. To support involvement of these genes in circadian gene expression, we identified putative E-boxes in *MBD5*, *RAI1*, and *FMR1*, while TCF4 regulates gene expression at E-box containing promoters. Expression levels of circadian genes (*NR1D2* and *CRY2*) were reduced in patient LCLs, suggesting key roles for MBD5, TCF4, RAI1, and FMRP in the regulation of circadian gene expression. *MBD5*, *RAI1*, and *TCF4* siRNA knockdown in SH-SY5Y cell lines showed that levels of *CLOCK*, *PER1*, *CRY2*, *ATF2*, and *ATF4* were altered, supporting a role for *MBD5*, *RAI1*, and *TCF4* in circadian gene expression. Pathway analysis of *MBD5*, *RAI1*, and *TCF4* knockdown microarray data show dysregulation of pathways associated with sleep disturbance, including circadian rhythm signaling and mTOR signaling pathways, corroborating published *FMR1* studies, while *mTOR* expression was altered in LCLs from all 4 disorders. These data demonstrate that MBD5, TCF4, RAI1, and FMRP function in overlapping circadian rhythm pathways and point to a common etiology for sleep disturbance in these disorders.

3030T

ITM2B implicated in familial dementias and retinal dystrophy associates with ciliary-centrosomal protein TOPORS. *B. Czub, A.Z. Shah, P. Kruczek, G. Alfano, C. Chakarova, S.S. Bhattacharya.* Institute of Ophthalmology, University College London, London, United Kingdom.

Purpose: *TOPORS* (MIM 609507) is a ubiquitously expressed gene implicated in autosomal dominant retinitis pigmentosa (RP [MIM 268000]); mutations are known to cause only RP with no systemic symptoms. We performed yeast two-hybrid (Y2H) screens of human retinal cDNA libraries to identify proteins interacting with TOPORS, which could explain the restricted phenotype. This led to the isolation of a soluble fragment of integral membrane protein 2B (*ITM2B* [MIM 603904]), mutations in which are associated with inherited forms of dementia and, most recently, a dominant form of retinal dystrophy. **Methods**: Matchmaker™ Gold Y2H System (Clontech) was used for library screening and testing direct protein-protein interactions (PPIs). Results were validated in HeLa and hTERT-RPE1 (RPE1) cell extracts by co-immunoprecipitation. Immunofluorescence methods were used for co-localisation studies in RPE1 cells and mouse retina cryo-sections. ProteoExtract® Subcellular Proteome Extraction Kit (Merck) was used to prepare cellular fractions (HeLa). **Results**: The TOPORS-ITM2B PPI, identified by screening, was selected for further study due to the role of *ITM2B* in retinopathy. It was detected in complexes with TOPORS precipitated from HeLa and RPE1 extracts, and both proteins co-localised at the centrosome in RPE1 cells. In mouse retina sections the strongest ITM2B signal was observed in rod photoreceptor inner segment, with a weaker signal in the ganglion cell layer. Direct PPI experiments in yeast with artificial TOPORS fragments (corresponding to different protein domains) implied that its mutation hotspot region may be required for association with ITM2B. Interaction with the TOPORS' RING finger region was also consistently observed, suggesting ITM2B could be modified by ubiquitination. Preliminary Western blot results suggest differential expression of proteolytically cleaved ITM2B peptides in cellular fractions. **Conclusions**: ITM2B is a novel interacting partner of TOPORS; defining the cellular processes in which they both associate could explain their roles and the phenotypes resulting from their mutations. Furthermore, evaluation of their relationship could lead to a better understanding of neurodegeneration mechanisms overall. Subsequent work will aim to delineate the roles of the various ITM2B peptides, generated by physiological proteolytic cleavage of the membrane-bound precursor protein, which could clarify the centrosomal co-localisation with TOPORS.

3031S

Disruption of the basal body protein POC1B results in autosomal recessive cone-rod dystrophy. *S. Roosing[1,2,3,7], I.J.C. Lamers[2,3,7], E. de Vrieze[2,4,7], L.I. van den Born[5,7], S. Lambertus[6], H.H. Arts[2,3], T.A. Peters[4], C.B. Hoyng[6], H. Kremer[2,3,4], L. Hetterschijt[2], S.J.F Letteboer[2,3], E. van Wijk[4,8], R. Roepman[2,3,8], A.I. den Hollander[2,3,6,8], F.P.M. Cremers[2,3,8], Study group.* 1) Department of Neurosciences, University of California San Diego, La Jolla, San Diego, CA; 2) Department of Human Genetics, Radboud university medical center, Nijmegen, The Netherlands; 3) Radboud Institute for Molecular Life sciences, Radboud University Nijmegen, Nijmegen, The Netherlands; 4) Department of Otorhinolaryngology, Radboud university medical center, Nijmegen, The Netherlands; 5) The Rotterdam Eye Hospital, Rotterdam, The Netherlands;; 6) Department of Ophthalmology, Radboud university medical center, Nijmegen, The Netherlands; 7) Shared first author; 8) Shared last author.

Exome sequencing revealed a homozygous missense mutation (c.317C>G, p.Arg106Pro) in *POC1B*, encoding POC1 centriolar protein B, in three siblings with autosomal recessive cone dystrophy or cone-rod dystrophy, and compound heterozygous *POC1B* mutations (c.199_201del [p.Gln67del] and c.810+1G>T) in an isolated case with cone-rod dystrophy. Upon overexpression of POC1B in human TERT-immortalized retinal pigment epithelium 1 cells, the encoded wild-type protein localized to the basal body of the primary cilium, while this localization was lost for p.Arg106Pro and p.Gln67del variant POC1B proteins. Morpholino oligonucleotide induced knock-down of poc1b translation in zebrafish resulted in a dose-dependent small eye phenotype, impaired optokinetic responses and decreased photoreceptor outer segment length. These ocular phenotypes could partially be rescued by wild-type human *POC1B* mRNA, but not by c.199_201del and c.317C>G mutant human *POC1B* mRNAs. Yeast two-hybrid screening of a human retinal cDNA library revealed FAM161A as a binary interaction partner of POC1B. This was confirmed in coimmunoprecipitation and co-localization assays, which both showed loss of FAM161A interaction of p.Arg106Pro and p.Gln67del variant POC1B. FAM161A was previously implicated in autosomal recessive retinitis pigmentosa and shown to be located at the base of the photoreceptor connecting cilium where it interacts with several other ciliopathy-associated proteins. Taken together, this study demonstrates that *POC1B* mutations result in a defect of the photoreceptor sensory cilium affecting the cone and rod photoreceptors.

3032M

TOPORS, a centrosomal and ciliary protein implicated in Retinitis Pigmentosa, associates with the actin cytoskeleton. *A.Z Shah, B. Czub, P.M. Kruczek, G. Alfano, C.F. Chakarova, S.S. Bhattacharya.* Department of Genetics, Institute Ophthalmology, UCL, London, United Kingdom.

Purpose: *TOPORS* (MIM 609507) is a ubiquitously expressed gene, encoding a protein localising to the nucleus and centrosome of dividing cells, and to the basal body of ciliated cells (including connecting cilium of photoreceptor cells in the retina). Interestingly, mutations in *TOPORS* are only implicated in dominant retinitis pigmentosa (MIM 268000). This study was undertaken to better understand the role of TOPORS in the cell. **Methods:** Subcellular localisation of TOPORS was examined in hTERT-RPE1 (RPE1) cell line by confocal immunofluorescence in cultures of increasing confluence. Stress experiments were performed to test observations. Co-immunoprecipitation was performed on RPE1 total cell extract; cellular fractions were prepared using ProteoExtract® Subcellular Proteome Extraction Kit (Merck); both analysed by Western blotting. RT-PCR on cDNA from human cell lines and retina was performed to identify alternatively spliced variants. TOPORS antibody was validated using RNAi knockdown. All experiments were performed on endogenous proteins. **Results:** Confluence studies showed TOPORS localises primarily to the nucleus but is found in the cytoplasm, centrosome and close to the cell membrane with increasing cell density. Furthermore it localises along actin filaments. Stress conditions (such as changes in osmolarity) do not appear to effect TOPORS localisation. Results suggest TOPORS could interact with actin and other cytoskeletal components. There is one alternatively spliced isoform reported for TOPORS. The commercially available TOPORS antibody is able to detect both long and short isoforms, as confirmed by RNAi knockdown experiments. The short isoform for TOPORS was detected in all cell lines tested and in human lymphocytes, and could account for the cytoplasmic localisation observed. However, to date it has not been detected in human retina. Preliminary evidence suggests differential expression of both TOPORS isoforms in different cellular compartments. **Conclusions:** In addition to being a nuclear and centrosomal protein, TOPORS is a novel component of the actin cytoskeleton. This could be due to the short TOPORS isoform. Our findings suggest a potential role of TOPORS in mediating actin-related cellular changes through its E3 ubiquitin- and/or SUMO-1 ligase activities and could indicate a role in cell signalling. This work highlights the increasing complexity of protein function and the importance of understanding their role(s) in health and disease.

3033T

Loss of the ribosome-associated factor Sbds in murine models of Shwachman-Diamond syndrome leads to aberrant polysome profiles. *H. Liu[1, 2], M.E. Tourlakis[1, 2], R. Gandhi[1], P. Hu[3], J.M. Rommens[1, 2].* 1) Program in Genetics & Genome Biology, SickKids Research Institute, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Department of Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada.

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disease characterized by growth retardation, exocrine pancreatic dysfunction, skeletal dysplasia, cognitive impairment and hematological abnormalities with increased susceptibility for leukemia. SDS is caused by mutations in *SBDS*. A current model proposes that SBDS/Sbds functions together with EFTUD1/Eftud1 and is involved in the release of EIF6/Eif6 from the pre-60S complex, enabling translation initiation. Mouse embryos deficient for Sbds ($Sbds^{R126T/R126T}$) show notable growth retardation and cell culture models reveal reduced protein synthesis. To assess translation deficiency, polysome profiles of fetal organs from this SDS murine model (E18.5) were examined and found to show anomalies compared to matched controls (*Sbds*+/+ and $Sbds^{+/R126T}$), with reduction in 80S peaks as well as preservation of polysomes. The low 80S peak suggested impairment of translation initiation; however the prominent polysomes were unexpected and appeared inconsistent with deficiency in protein synthesis. To investigate how the translatome is affected in SDS, total and polysomal mRNAs of mutant and control fetal liver samples were studied using cDNA microarray analyses. By comparing individual polysomal transcript to respective total transcript level, we could establish which genes were being actively translated and/or retained by the polysomes with loss of Sbds function. With normalization, 173 genes showed reduced association with polysomes, while 664 showed increased association. Typically, long transcripts with lower GC content were favored for polysome association. However, the changes of polysome association did not correspond to respective steady state protein levels, as shown by western immunoblotting and label-free mass spectrometry. Further, the proteome revealed that relative levels of ribosomal proteins and translation factors are unaltered in SDS fetal livers. The observations of prominent polysomes and the large number of transcripts with high polysome association in absence of corresponding increase in the protein levels suggest that loss of Sbds function leads to the formation of ribosomes which may be deficient in elongation or ribosome recycling, possibly due to impaired removal of Eif6 prior to subunit joining.

3034S

Examining the Molecular Mechanisms Underlying SRCAP Mutations in Floating-Harbor Syndrome. *R.L. Hood[1,2], K.M Boycott[2,3,4], W.L. Stanford[1,5,6], D.E Bulman[2,4].* 1) Department of Biochemistry, Microbiology and Immunology, University of Ottawa, Ottawa, Ontario, Canada; 2) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa; 3) Department of Genetics, Children's Hospital of Eastern Ontario; 4) Department of Pediatrics, University of Ottawa; 5) The Sprott Centre for Stem Cell Research, Regenerative Medicine Program, Ottawa Hospital Research Institute; 6) Department of Cellular and Molecular Medicine, University of Ottawa.

Floating-Harbor Syndrome (FHS; OMIM# 136140) is a rare genetic disorder which is characterized by short stature, delayed osseous maturation, language deficits, and unique dysmorphic facial features. FHS typically occurs sporadically; however a few instances of autosomal dominant transmission have been reported. Since our first report of mutations in SRCAP as the cause of FHS, we have identified a total of 50 mutation positive patients. The mutations identified were shown to be de novo in all cases where parental DNA was available. SRCAP encodes a SNF2-related chromatin-remodeling factor which is known to be a coactivator of CREB-binding protein (CREBBP or CBP) and CBP-mediated transcription. Additionally SRCAP is part of a large complex which catalyzes ATP-dependent substitution of the variant histone H2A.Z into nucleosomes. Based on the existence of patients with deletions encompassing all of SRCAP who do not have FHS, we postulate that the mechanism of disease is not due to haploinsufficiency. Furthermore we expect that FHS mutations result in widespread gene dysregulation; however the mechanisms and biological pathways underlying the FHS phenotype are currently unknown. We are directing our efforts at determining the mechanism by which truncating mutations of SRCAP cause disease. Sequencing of FHS patient cDNA indicated the presence of SRCAP mutant transcript and the relative abundance of this transcript was found at relatively comparable levels to the wild type. RNAseq analyses were used to compare expression differences in FHS patients compared to non-patient controls. Initial findings support the hypothesis that FHS is not caused by a haploinsufficient mutation mechanism. To more specifically examine the growth deficiency phenotype of FHS we reprogrammed FHS patient and gender matched control fibroblast samples into induced pluripotent stem cells (iPSCs) using an episomal vector approach. iPSCs were subsequently characterized by pluripotency cell surface marker expression, in vitro embryoid body differentiation, and in vivo teratoma formation assays. We plan on differentiating these clones into chondroprogenitors so we can begin elucidating the molecular mechanisms underlying the bone pathogenesis of FHS. Taken together these studies will increase our understanding of how truncating mutations of SRCAP alter its function and gain insight into the pathways which contribute to the development of Floating-Harbor syndrome.

3035M

Functional characterization and pharmacological correction of eleven novel mutations identified in Indian CF population. *R. Prasad[1], H. Sharma[1,2], M. Jollivet Souchet[2], F. Becq[2].* 1) Department of Biochemistry, PGIMER, Chandigarh, Chandigarh, India; 2) Laboratoire Signalisation et Transports Ioniques Membranaires, Université de Poitiers, CNRS, Poitiers, France.

Cystic Fibrosis an autosomal recessive disorder is usually considered as rare disease for Indian population hence much less is known about this disease in context with Indian sub continent. Recently we have established a spectrum of mutations in CFTR gene from classical Cystic Fibrosis as well as from infertile male patients with CBAVD/CUAVD in Indian populations. Among them S549N, L69H in classical CF and G126S, F87I, S118P, H139Q, F157C, F494L, E543A, Y852F, D1270E in CBAVD males were among the rare missense mutations (Sharma et al ., 2009). In this study we have attempted to conduct in vitro gene expression analysis to well establish genotype and phenotype correlation and to characterize these four rare missense mutations according to the mechanism that disrupt CFTR protein function. All four mutations from Indian population were characterized by expressing pEGFP-CFTR constructs in BHK-21 cells via 3 step technique viz; CFTR cellular localization was determined by confocal microscopy, where as Western blot analysis and automated iodide efflux assays was used to determine CFTR maturation processes and its channel activity respectively. In Western blot analysis only b-band is obtained for L69H substitution as for F508del whereas in the case of other mutants both b and c bands were found, indicating L69H mutation impair CFTR maturation process, the finding was again confirmed by confocal imaging. Iodide Efflux assay revealed significant decrease in channel activity for L69H and S549N mutants CFTR expressing cells in comparison to WT, although this decrease in channel activity was rescued when cells were incubated at 27 C. When the effect of CFTR correctors was checked on different mutants, it was found that VX809 significantly ameliorate the defect caused by L69H mutation. Mutations G126S, F87I, S118P, H139Q, F157C, F494L, E543A, Y852F, D1270E have no impact on CFTR maturation and function. Thus we can conclude that L69H mutation is a class II CF mutation causing impaired maturation leading to protein degradation and Cl^-ions impermeability as observed in F508del mutation. This defect is rescued by the corrector VX 809. Whereas S549N mutation can be categorized into a class II/III mutation causing impaired maturation and reduced channel activity.

3036T

Understanding the role of EYS by identification and characterisation of its retinal interacting partners. *P.M. Kruczek[1], G. Alfano[1], B. Czub[1], A.Z. Shah[1], A.C. Zelhof[2], S.S. Bhattacharya[1].* 1) Department of Genetics, UCL Institute of Ophthalmology, London, United Kingdom; 2) Department of Biology, Indiana University, 1001 East Third St, Bloomington, IN 47405, USA.

Purpose: The eyes shut homolog (Drosophila) gene (*EYS* [MIM 612424]) is one of the largest genes known to be expressed in the human retina. Mutations in *EYS* are the most common cause of autosomal recessive retinitis pigmentosa (arRP) (RP25 [MIM 602772]; RP [MIM 268000]). *EYS* encodes a protein named EYS whose biological role in humans is presently unclear, however, a *Drosophila* ortholog of EYS has been shown to be essential for the organization of *Drosophila* photoreceptors. In addition, *Drosophila* EYS interacts with Prominin, a transmembrane protein associated with microvilli of the *Drosophila* photoreceptor rhabdomere. Prominin is highly conserved throughout evolution and interestingly, mutations in human Prominin-1 (*PROM1* [MIM 604365]) cause retinopathies. This study was undertaken to investigate the relationship of EYS and Prominin-1 in humans, and to identify novel interacting partners for EYS in the retina. **Methods:** Putative interaction of EYS and Prominin-1 was examined by immunochemistry in cultured Y79 and ARPE19 cell lines. Novel potential binding partners of EYS were identified using Yeast 2-hybrid technology (Y2H) - baits, consisting of full-length EYS and three fragments covering N-terminal, middle and C-terminal parts of the protein, were screened against human retinal cDNA libraries. **Results:** Preliminary data suggest that EYS and Prominin-1 may co-localise in Y79 cell line. Furthermore, exogenous expression of EYS and Prominin-1 in ARPE19 cell line suggests that Prominin-1 might be required for proper localisation of EYS. Y2H screens revealed six proteins that potentially interact with EYS: AIPL1, SERF2, FBN1, PPT2, UBA52 and COX7C. **Conclusions:** Investigation of interaction between EYS and Prominin-1 suggests that these proteins may possess similar functions to their *Drosophila* orthologs and could play a role in maintaining the integrity of human photoreceptors. Y2H screens have identified six potential interactors of EYS which may help us elucidate its role in the retina. Additional investigation is required to validate and further analyse the aforementioned results. This will include verification using direct interaction in the Y2H system as well as experiments such as co-immunoprecipitation and immunocytochemistry. Not only is this crucial to the understanding of the role of EYS in health and disease, but it will also shed light on physiology and maintenance of human photoreceptors.

3037S

A pathologic genomic rearrangement in Incontinentia Pigmenti locus reveals a transcriptional regulation of NEMO gene by p63 family proteins. *M.I. Conte[1], M. Paciolla[1], E. Candi[2], A. Lena[2], G. Melino[2], M.V. Ursini[1], F. Fusco[1].* 1) Institute of Genetics and Biophysics, Naples, Italy; 2) Universita' di Tor Vergata, Rome, Italy.

Incontinentia pigmenti (IP, MIM308300, 1/10.000) is an X-linked dominant neuroectodermal disorder, lethal in males and caused in female by a mutation in the IKBKG/NEMO gene that encodes for NEMO/IKKgamma regulatory protein required for the activation of the NF-kappaB pathway. The typical IP skin defects, always present in IP patients, are due to the mosaic expression of NEMO/IKBKG mutation related to X-chromosome inactivation in heterozygous females. NEMO/IKBKG is transcribed by the bidirectional promoterB, shared by the two overlapping IKBKG/NEMO and G6PD genes and promoterA, unidirectional for NEMO expression. We recently described an IP de novo case due to a genomic deletion, named IKBKGdel, that eliminates the NEMO principal promoterB and preserves its expression by the secondary promoterA. The patient with IKBKGdel, showed only skin abnormalities suggesting that an early X-inactivation of mutated allele occurred in the other extracutaneous tissues, or the promoterA activity of NEMO prevented the IP alterations. We analysed promoterA transcription in vivo on RNA from different layers of the skin from healthy donors and in vitro on RNA from differentiated and proliferating HaCat keratinocyte to obtain a better insight into its role in the skin. Bioinformatic sequence comparison using the multiple alignment software m-Vista of the 5' of the NEMO promoter A in different species predicted several p53-like binding sites in the highly conserved regions. Here, we present our findings by in vivo and in vitro assays on the different role of p53-related proteins, p63 and p73, on promoterA-driven NEMO expression. Our data suggest that members of p63 family, DNp63alpha and TAp63alpha, which are key transcription factors in epithelial development and differentiation, are able to regulate the expression of promoter A of NEMO during the skin differentiation. Moreover, we found that the isoform TAp73alpha while regulating G6PD expression has not effects on NEMO transcription. The differential effects of p53-related proteins, p63 and p73 on NEMO and G6PD will be illustrated.

3038M

Chinese family segregating isolated diffuse oesophageal leiomyomatosis: a new COL4A5/COL4A6 deletion and a case of gonosomal mosaicism. *K.L. Wong[2], W. Liu[1], H.E. Qiuming[1], H.M. Wong[2], S.T. Tang[2,3], R. Zhang[3], M.T. So[3], K.Y. Wong[3], J. Nicholls[4], S. Cherny[2,5], P.C. Sham[2,5], P.K. Tam[3,5], M.M. Carcia-Barcelo[3,5], H. Xia[1].* 1) Guangzhou Women and Children's Medical Center, Guangzhou, China; 2) Department of Psychiatry, The University of Hong Kong, Hong Kong SAR, China; 3) Department of Surgery,The University of Hong Kong, Hong Kong SAR, China; 4) Department of Pathology,The University of Hong Kong, Hong Kong SAR, China; 5) Center for Genomic Sciences,The University of Hong Kong, Hong Kong SAR, China.

Diffuse oesophageal leiomyomatosis (DOL) is a rare disorder characterized by tumorous overgrowth of the muscular wall of the oesophagus. DOL is present in 5% of Alport syndrome (AS) patients. AS is a rare hereditary disease that involves varying degrees of hearing impairment, ocular changes and progressive glomerulonephritis leading to renal failure. In DOL-AS patients, the genetic defect consists of a deletion involving the COL4A5 and COL4A6 genes on the X chromosome. We present a two-generation family with two members (mother and son) affected with DOL and none of the features of AS. Exome sequencing and Copy Number Analyses revealed a new 40kb deletion encompassing from intron 2 of COL4A5 to intron 1 of COL4A6 at Xq22.3. The breakpoints were also identified. Possible confounding pathogenic exonic variants in genes known to be involved in other extracellular matrices disorders were also shared by the two affected individuals. Meticulous analysis of the maternal DNA revealed a case of gonosomal mosaicism. This is the first case where a "classic" DOL-AS COL4A6 deletion is described in patients with no AS and the first report of gonadosomal mosaicism associated to this condition. COL4A5/COL4A6 genes should also be investigated in cases of isolated DOL.

3039T

Atypical Microvillous Inclusion Disease (MVID) in a newborn with intractable diarrhea: clinical, pathological and molecular characterization. *A. Iglesias[1], D. Ball[1], S. Wontakal[2], V. Aggarwal[2].* 1) Division of Medical Genetics, Department of Pediatrics, Columbia University Medical Center, New York, NY; 2) Department of Pathology & Cell Biology, College of Physicians & Surgeons of Columbia University, New York, NY.

Microvillus inclusion disease (MVID) is characterized by intractable life-threatening watery diarrhea. Treatment includes total parental nutrition (TPN) or small bowel transplantation, both associated with high morbidity and mortality. Electron microscopy (EM) of the small bowel typically displays characteristic loss of microvilli as well as pathognomonic microvillus inclusion bodies in intestinal epithelial cells. Mutations in the *MYO5B* gene, which encodes a type Vb myosin motor protein, are associated with MVID. We report an 8 month-old male that presented at birth with intractable watery diarrhea. He was born prematurely at 35 weeks to a 30 year old mother by NSVD with APGARS of 6/8. Birth weight was 2850 grams. Diarrhea started on day 1 of life. Despite being properly fed since birth his weight on day 7 was 1900 grams. He was found to be severely dehydrated and in renal failure with a hyperchloremic metabolic acidosis with a normal anion gap. Metabolic evaluation and newborn screening were normal. An initial endoscopic intestinal biopsy revealed non-diagnostic alterations, however, based on clinical presentation, a primary intestinal disorder was strongly suspected. An immunological evaluation with normal results was done. To determine a possible molecular etiology for the intractable congenital diarrhea, whole exome sequencing (WES) was performed. WES identified a paternally inherited variant (c.4168C>T;p.Q1390X) and a maternally inherited alteration (c.4852+3A>T) in the *MYO5B* gene. These variants have not been previously reported in patients with MVID; however, given this intriguing finding, EM biopsy samples were re-examined. Re-evaluation of the EM images identified rare atypical findings in the small intestine, but unexpectedly, atypical findings in the colon were also noted. These findings were interpreted as consistent with the clinical presentation and therefore likely represent an atypical case of MVID. Currently we are conducting RNA studies to confirm the pathogenicity of these changes. The patient is currently on TPN and trophic enteral feedings. He is thriving and doing well, however, long-term prognosis is uncertain and the possibility of small bowel transplant has been already discussed with the family. In summary, we are presenting clinical, pathological and molecular characterization of an atypical case of MVID. This case expands the phenotype of this rare disorder and highlights the utility of WES in clinical practice.

3040S

Mutations in ACTG2 are associated with sporadic congenital chronic intestinal pseudo-obstruction and megacystis-microcolon-intestinal hypoperistalsis syndrome. *M. Yourshaw, A. Sicolo, R. Venick, L. Reyen, D. Farmer, J. Vargas, S. Nelson, M. Martín.* Pediatrics, UCLA Geffen School of Medicine, Los Angeles, CA.

Chronic intestinal pseudo-obstruction (CIPO) is a serious motility dysfunction syndrome characterized by symptoms of intestinal obstruction in the absence of any mechanical blockage. It is a major cause of intestinal failure. With whole-exome sequencing in a cohort of 20 patients with congenital CIPO or MMIH, we identified a subset of 10 cases with potentially damaging de-novo mutations at highly conserved loci in the ACTG2 gene, which encodes actin, gamma-enteric smooth muscle precursor. We conclude that ACTG2 governs a significant proportion of cases of sporadic congenital CIPO and MMIH.

3041M

Functional analysis of genes carrying de novo mutations in 24 sporadic Hirschsprung cases revealed 7 unexpected genes relevant to ENS development. *R. Hofstra[1,2], D. Schriemer[3], H. Gui[4], W. Cheng[4], P. Griseri[5], A. Pelet[6], M. Ruiz-Ferrer[7], C. Berrios[8], W. van Ijcken[9], M. van den Hout[9], Y. Sribudiani[1], R. Chaudan[1], P. Tam[4], C. Tang[4], I. Matera[5], I. Antinolo[7], A. Chakravarti[8], S. Borrego[7], S. Lyonnet[6], I. Ceccherini[5], B. Eggen[3], J. Amiel[6], M. Garcia-Barcelo[4].* 1) Clinical Genetics, ErasmusMC, Rotterdam, Netherlands; 2) Institute of Child Health, UCL LOndon UK; 3) University Medical Centre Groningen, Netherlands; 4) University of Hong Kong, China; 5) Instituto G. Gaslini, Genoa, Italy; 6) Universite Paris5-Descartes, Paris France; 7) Hospital Universptario, Virgen del Rocio, Sevilla, Spain; 8) Johns Hopkins University, Baltimore MD USA; 9) Biomics, EramusMC, Rotterdam, Netherlands.

Hirschsprung disease (HSCR) is a complex genetic disorder, characterized by the absence of the enteric neurvous system (ENS) of the distal part of the gastrointestinal-tract. HSCR most commonly presents sporadically, however it can be familial (~20% of the patients). The sporadic form of the disorder is believed to be genetically complex. To assess the role of de novo variations in sporadic HSCR, we performed exome sequencing on DNA of 24 sporadic HSCR patients and their unaffected parents. In total we confirmed 26 de novo variations (23 SNV, 3 Indels) in 19 genes. Eight variants were present in RET, the major HSCR gene. The remaining 18 genes all carried one de novo variant and none of the genes could directly be linked to any of the known HSCR associated gene network. Knockdown experiments in zebrafish, by both splice- and translation-blocking morpholino's, resulted in a HSCR like phenotype for 7 of these 18 genes (CKAP2L, DENND3, NCLN, NUP98, TBATA, MED26, MAP40). The zebrafish work is complimented by proliferation, migration and differentiation assays using stable, siRNA expressing neural crest derived cell lines. Our data show that de novo, as well as inherited mutations, contribute to the development of the ENS and thereby to HSCR. Moreover, as the identified 7 novel HSCR genes are all unrelated to the previous gene networks, our study suggests that functional analysis of all genes carrying de novo mutations, is warranted to genetically delineate the genetic architecture of a genetically complex diseases.

3042T

Identification of a novel gene causing a recognizable and distinct autosomal recessive cerebellar ataxia and intellectual disability syndrome, associated with early onset cerebellar atrophy and relative macrocephaly. *P. Stanier[1], A.C. Thomas[1], H. Williams[1], N. Setó-Salvia[1], C. Bacchelli[1], M. O'Sullivan[1], L. Ocaka[1], K. Mengrelis[1], M. Ishida[1], G. Anderson[2], D. Morough[2], M. Rytan[3], J.M. Saraiva[4], F. Ramos[4], B. Farren[2], D. Saunders[2], P. Gissen[1], A. Straatmaam-Iwanowska[1], F. Baas[5], N. Wood[3], R. Robinson[2], J. Hersheson[3], H. Houlden[3], R. Hennekam[5], J. Hurst[2], R. Scott[2], M. Bitner-Glindzicz[1,2], G. Moore[1], S.B. Sousa[1,4].* 1) University College London, Institute of Child Health, London, United Kingdom; 2) Great Ormond Street Hospital, London, United Kingdom; 3) University College London, Institute of Neurology, London, United Kingdom; 4) Hospital Pediátrico de Coimbra, Portugal; 5) University of Amsterdam, Holland.

A large number of conditions have been described where severe intellectual disability and ataxia are found in patients with cerebellar hypotrophy. Individually, most types are rare and without known molecular pathology. Here we describe three similar but unrelated consanguineous families with presumed autosomal recessive inheritance from Turkey and Portugal. The seven affected individuals share overlapping phenotypes, including severe intellectual disability, ataxia, early onset cerebellar atrophy, relative macrocephaly, coarse face, hearing loss, absent speech and 5th finger clinobrachydactyly and camptodactyly. To facilitate gene identification, two families with multiple affected individuals were selected for homozygosity mapping followed by exome sequencing. In family 1, a unique homozygous nonsense variant was identified in a novel gene contained within a large region of shared homozygosity. The variant was not subject to nonsense-mediated decay but produced reduced transcript levels and a truncated protein. The same gene was also found to contain a homozygous, multiexon deletion within the largest region of homozygosity in family 2. Compared to controls, this mutation resulted in normal transcript levels in patient fibroblasts, although a correspondingly truncated protein was predicted. The third case was selected from a large cohort of patients purely based on the phenotypic characteristics of the two index families. Sanger sequencing in this patient for the novel gene revealed a homozygous splice site mutation, which was demonstrated to result in an in-frame skipping of an exon that was present in all isoforms. Transcript levels were similar to those found in controls and a truncated protein was predicted to be present. This third family supports the proposal that the phenotype is sufficiently distinct to identify this condition as a novel and recognizable syndrome. Patient fibroblasts from each family were found to contain unusual vesicular inclusions supporting a likely role for the mutant protein in endosomal trafficking. Further characterization of the cellular function of the novel protein is ongoing.

3043S

The role of SRSF10 in *SMN1/2* splicing. *S. Brøner[1], Y. Hua[2], T.K Doktor[1], G.H. Bruun[1], M.R. Larsen[1], A.R Krainer[2], B.S. Andresen[1].* 1) Department of Biochemistry and Molecular Biology, University of Southern Denmark, 5230 Odense M, Denmark; 2) Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, NY 11724, USA.

SR-proteins are important regulators of pre-mRNA splicing through sequence specific binding to motifs in splicing silencers and enhancers, but their *in vivo* binding motifs are still insufficiently characterized. The intronic splicing silencer, ISS-N1, located in intron 7 of the *SMN* genes is the target of splicing correction by Antisense Oligonucleotide blocking, which is currently in clinical trials for treatment of the neurodegenerative disease Spinal Muscular Atrophy (SMA). Until now, only members of the heterogeneous nuclear ribonucleoprotein family, like hnRNPA1, are known to bind to the ISS-N1 silencer and inhibit splicing. We have performed RNA affinity binding assays combined with iTRAQ labelling and LC-MS/MS analyses in order to elucidate the binding of different splicing factors to this ISS-N1 motif. One new candidate is the splicing factor SRSF10, which belongs to the well characterized SR-protein family. SRSF10 was found to bind significantly stronger to the wild type ISS-N1 motif compared to a mutant motif in which two A>C substitutions destroys the two hnRNP A1 motifs. Our preliminary data using over expression of SRSF10 and SMN minigenes have shown that the long isoform of SRSF10 binds to the ISS-N1 motif and can affect the splicing of exon 7 in the *SMN2* gene similar to hnRNP A1. Interestingly, the presumed SRSF10 binding site overlaps the hnRNP A1 binding sites located in the ISS-N1 silencer. Whereas the hnRNP A1 is more constitutively expressed in all tissues SRSF10 shows a more neuronal tissue specific expression pattern. Thus, SRSF10 could be an important factor affecting the splicing of the *SMN* genes in a neuronal context. We are currently trying to elucidate the role of SRSF10 in determining SMN splicing efficiency and we employ a more genome-wide approach in order to characterize the role and the binding motifs of SRSF10 in other disease genes.

3044M

A functional role for BDNF in Familial Dysautonomia. *M. Nilbratt[1], M. Salani[1], E. Morini[1], F. Urbina[1], G. Lee[2], S. Haggarty[1], S. Slaugenhaupt[1].* 1) Neurology, Massachusetts General Hospital, Boston, MA; 2) Institute for Cell Engineering, John Hopkins University, Baltimore, MD.

Familial Dysautonomia (FD), or Riley-Day syndrome, is an autosomal recessive disorder with extensive sensory and autonomic nervous system involvement present at birth. FD is characterized by recurrent episodes of hypertension with tachycardia, impaired thermoregulation, and deceased sensitivity to pain and temperature. Neuropathological studies show a marked reduction of neurons in the sympathetic and sensory ganglia. All FD patients have an intronic splice site mutation in the *IKBKAP* gene, the scaffolding member of the Elongator protein complex involved in transcriptional elongation. This mutation results in tissue-specific skipping of exon 20 in the mRNA with aberrant splicing most pronounced in neuronal tissues. The alternative splicing defect leads to reduced production of IKAP protein. Complete embryonic loss of *Ikbkap* in mice causes early embryonic lethality, proving that this gene is required for effective transcription of genes involved in early neural development. The molecular mechanisms leading to FD are poorly understood. Neurotrophic factors are implicated in the survival and differentiation of several neuronal populations. Although there is evidence for a role of neurotrophins in various human neuropathies, their relevance to the disease process is not fully understood. Previous *in vitro* studies have indicated reduced neurotrophic activity in human fibroblasts from FD patients and defective expression of genes encoding neurotrophic factors in mice leads to similar neuronal phenotypes to those observed in FD patients. Here we show that reduced IKAP expression impacts brain-derived neurotrophic factor (BDNF) transcription in FD patient fibroblast cells, and we demonstrate a functional consequence of BDNF misregulation using our induced pluripotent stem (iPS) cell model system of human neural development. We found insufficient neurotrophic support from FD cells on the development of human iPS cell-derived neurons. Compromised development of human neurons was also observed by inhibition of neurotrophic activity from normal fibroblasts by neurotrophin antagonists. Interestingly, the reduced biological activity from FD patient cells was rescued pharmacologically using the plant cytokinin kinetin, which corrected aberrant mRNA splicing of *IKBKAP* and restored BDNF protein expression. Our data suggest that aberrant regulation of BDNF due to IKAP reduction may contribute to the developmental defects in neural development observed in FD patients.

3045T

Mutations in LAMA1 cause cerebellar dysplasia and cysts with and without retinal dystrophy in Poretti-Boltshauser syndrome. *K.A. Aldinger[1,2], S.J. Mosca[3], M. Tétreault[4], J.C. Dempsey[2], G.E. Ishak[9], T. Hartley[5], I. Phelps[2], R.E. Lamont[3], D. Basel[6], K.W. Gripp[7], J.S. Hogue[8], M.J. Stephan[8], F.P. Bernier[3], K.M. Boycott[5], J. Majewski[4], J.S. Parboosingh[4], A.M. Innes[3], D. Doherty[1,2].* 1) Seattle Children's Research Institute, Seattle, WA; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Department of Medical Genetics, University of Calgary, Alberta; 4) Department of Human Genetics, McGill Univeristy, Montréal, Quebec.Montréal, Quebec; 5) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa, Ontario. Care4Rare, Canada; 6) Division of Genetics, Medical College of Wisconsin, Milwaukee, WI; 7) Division of Medical Genetics, A.I. duPont Hospital for Children, Wilmington, DE; 8) Department of Pediatrics, Madigan Army Medical Center, Tacoma, WA; 9) Department of Radiology, Seattle Children's Hospital, University of Washington, Seattle, WA.

Cerebellar dysplasia with cysts (CDC) is an imaging finding typically seen in combination with cobblestone cortex and congenital muscular dystrophy in patients with dystroglycanopathies. More recently, CDC was reported in a series of seven children without neuromuscular involvement (Poretti-Boltshauser syndrome). Using a combination of homozygosity mapping and whole exome sequencing, we identified biallelic LAMA1 mutations as the cause of CDC in seven additional affected individuals from five families. Most of these patients also have high myopia, and some have retinal dystrophy and patchy increased T2/FLAIR signal in the cortical white matter. Two siblings with truncating LAMA1 mutations have retinal dystrophy and mild cerebellar dysplasia without cysts, further expanding the phenotype associated with LAMA1 mutations. This work adds another phenotype to the spectrum of laminopathy disorders and highlights the tissue-specific roles played by different laminin genes.

3046S

Whole genome sequencing of a balanced translocation reveals new gene candidates for epilepsy, learning difficulties and risk of acute myeloid leukaemia. *S-K. Chung[1,2], S. Ali[1], W.O. Pickrell[1,2], J.G. Mullins[1], A. Fry[3], D.T. Pilz[2,3], M. Kerr[2,4], M.I. Rees[1,2].* 1) Neurology and Molecular Neuroscience, College of Medicine, Swansea University, Swansea, UK; 2) Wales Epilepsy Research Network, College of Medicine, Swansea University, UK; 3) Institute of Medical Genetics, University Hospital Wales, Cardiff, UK; 4) Institute of Psychological Medicine and Clinical Neurosciences, School of Medicine, Cardiff University, UK.

Whole-genome sequencing (WGS) was commissioned in a patient with generalised epilepsy, learning difficulties (LD), a familial history of treatment-resistant acute myeloid leukaemia (AML) and a constitutional balanced translocation t(1;14) (q32;q31). WGS revealed the exact translocation coordinates and confirmed breakpoints on 1q32 and 14q31 that were validated by Sanger sequencing. On chromosome 1 the breakpoint interrupts a gene of undetermined function (TAT protein family) which is poorly-documented in the literature. Pathway analysis indicates a 'DNase domain-containing protein' function with important endonuclease role in chromosome segregation and eye development in zebrafish. On chromosome 14, a more familiar gene was interrupted (*FOX* gene family) whose function includes neurodevelopmental regulation of the cell cycle and protein synthesis. Other FOX family genes have been linked to seizure disorders, cognition and haematological malignancies. Further mutation screening of these genes in unrelated epilepsy and LD cohorts (n=60) has revealed 4 non-synonymous variants that are not in controls or control dataset websites. Structure / function assays are underway to confirm pathogenic status of these variants as well as gene-fusion studies in the original index-case and screening these genes in cytogenetic-negative AML. These findings have predictive value for the at-risk members of the family and have further neuro-genetic impact in LD and genetic generalised epilepsy.

3047M

The complexity of *KDM5C* transcription: an XLID gene under the control of disease-related transcription factors. *A. Padula[1], L. Poeta[1], C. Shoubridge[2], F. Fusco[1], A. Ranieri[1], K. Helin[3], J. Gecz[2], C.E. Schwartz[4], M.V. Ursini[1], M.G. Miano[1].* 1) Institute of Genetics and Biophysics "Adriano Buzzati Traverso" CNR, Naples, Italy; 2) Department of Paediatrics, University of Adelaide, South Australia 5006, Australia; 3) Centre for Epigenetics, University of Copenhagen, Copenhagen DK-2200, Denmark; 4) J.C. Self Research Institute, Greenwood Genetic Center, Greenwood, SC, USA.

Lysine-specific demethylase 5C (*KDM5C*) is a chromatin remodelling regulator with histone demethylase activity for di- and trimethylated histone 3 lysine 4 (H3K4me2 and H3K4me3), acting as transcriptional repressor during brain development and neuronal maturation. Mutations in *KDM5C* are emerging as frequent causes of a spectrum of X-linked intellectual disorders (XLID), with cognitive handicap alone or in association with Epilepsy (XLID/Epilepsy). With Regulatory Element-1-Silencing Transcription factor (REST), a critical regulator of the spatio-temporal transition of neural progenitors to neurons, KDM5C co-occupies the promoters of a subset of REST target genes. We recently identified an epileptogenesis path, linking functionally *KDM5C* to another XLID/Epilepsy gene, encoding the homeotic transcription factor ARX, whose mutations severely impair *KDM5C* transcript regulation. Expanding our study, we analysed two additional XLID proteins that also bind the *KDM5C* promoter. They are PHD Finger Protein 8 (PHF8), a H3K9 demethylase belonging to JmjC protein family, and Zinc Finger Protein 711 (ZNF711), a transcriptional factor, whose role is unclear. We observed that PHF8 and ZNF711, which co-occupy the target promoter, cooperatively induce *KDM5C* stimulation. We therefore tested the impact of *ZNF711* mutants on *KDM5C* trans-activation in order to establish their functional effects. This activity seems to be ARX-independent and we propose that the transcriptional induction by ARX does not synergize with the action of the PHF8/ZNF711 complex and consequently they represent distinct levels in *KDM5C* regulation. Starting from these data, we are now able to break up a unique epigenetic road involved in ID and epilepsy. However, the framework of this complex regulation may become more clear once we will decode the role of other key elements, such as ncRNAs, chromatin modifiers and cofactors. Ongoing efforts to define this transcriptional path may help to identify useful tools towards research and drug discovery for XLID/Epilepsy phenotypes and many other companion disorders with malignant seizure.

3048T

Genetics of Joubert syndrome in the French Canadian population. *M. Srour[1], F.F. Hamdan[1], J. Schwartzentruber[2], L. Patry[1], C. Nassif[1], L.H. Ospina[3], E. Lemyre[1], C. Massicotte[1], D. Joubert syndrome (JBTS) is a primarily autosomal recessive disorder characterized by a distinctive mid-hindbrain/cerebellum malformation, oculomotor apraxia, irregular breathing, developmental delay, hypotonia and ataxia. JBTS is considered a ciliopathy; most of the known 21 causal genes are implicated in ciliary structure or function. We sought to characterize the genetic landscape associated with JBTS in the French Canadian (FC) population. We performed mutation analysis in 40 FC JBTS patients from 32 families using a stepwise approach, combining screening of recurrent FC mutations by Sanger sequencing and exome sequencing. We identified causal mutations in 28 families. Twelve families had mutations in *C5ORF42*, 9 in *CC2D2A*, 2 in *TMEM231*, 2 in *NPHP1*, one in *TCTN1*, one in *TMEM67*. Interestingly, we documented a complex founder effect with multiple recurrent mutations in 3 genes (*C5ORF42*, *CC2D2A*, *TMEM231*). In the remaining families, we identified potentially pathogenic mutations in known JBTS genes (*CEP290*, *OFD1*) and in cilia genes, which are therefore strong candidates for JBTS. We conclude that JBTS has substantial locus and allelic heterogeneity in FC populations.

Hereditary diffuse leukoencephalopathy with spheroids (HDLS): Novel CSF1R mutations and locus heterogeneity. *C. Toro[1], H. Cheung[1], M. Tzeng[1], D. Landis[1], A. Vanderver[3], R. Godfrey[1], M. Nehrebecky[1], C. Boerkoel[1], W. Gahl[1, 2].* 1) NIH Undiagnosed Diseases Program, National Institutes of Health, Bethesda, MD; 2) Office of the Clinical Director, NHGRI, National Institutes of Health, Bethesda, MD; 3) Children's National Medical Center, Washington, DC.

Hereditary diffuse leukoencephalopathy with spheroids (HDLS [MIM 164770]) is an uncommon, dominantly inherited, adult-onset neurological disorder with characteristic clinical and MRI features. Most often, patients present in their third to fifth decade of life with progressive personality changes, dementia, spasticity, gait difficulties and depression. For decades, the diagnosis was only possible by brain biopsy or autopsy. Recently, however, mutations in the protein tyrosine kinase (PTK) domain (exons 13 thru 19) of the colony stimulating factor receptor 1 (*CSF1R*) gene have been associated with this disorder. As part of the NIH Undiagnosed Diseases Program, we evaluated 8 patients in 5 families with typical clinical and imaging features of HDLS. All patients underwent clinical phenotyping, brain and spinal cord MRI and CSF examination. One patient had undergone a brain biopsy and subsequent autopsy brain examination, which confirmed the clinical diagnosis of HDLS. All patients underwent whole exome sequencing or direct Sanger sequencing of all *CSF1R* coding exons. Previously unreported, predicted damaging mutations in exons 13 and 19 of *CSF1R* were identified in 2 families. One family with documented vertical transmission and autopsy-proven HDLS did not harbor mutations in *CSF1R*, indicating locus heterogeneity for HDLS. Another patient harboring a novel predicted damaging mutation in exon 19 *(NM_005211.3:c.2512G>T:p.V838F),* with disease onset at age 35 years, shared the variant with his father, who at age 75 was reported to be clinically unaffected, indicating incomplete penetrance. Our study enhances understanding of the genetic basis of this devastating disorder and highlights the need to continue searching for additional causative genes; this could be aided by and improved insight into the cell biological mechanisms responsible for the emergence of signs and symptoms.

3050M

A variant in *DCTN2* causes intermediate Charcot-Marie-Tooth disease. A new Charcot-Marie-Tooth disease gene? *G.J. Braathen[1,2,3], H. Høyer[1,2,3], O.L. Busk[1], C.F. Skjelbred[1], M.B. Russell[2,3].* 1) Section of Medical Genetics, Department of Laboratory Medicine, Telemark Hospital, Skien, Norway; 2) Head and Neck Research Group, Research Centre, Akershus University Hospital, Lørenskog, Norway; 3) Institute of Clinical Medicine, Campus Akershus University Hospital, University of Oslo, Nordbyhagen, Oslo, Norway.

Introduction: Charcot-Marie-Tooth disease (CMT) is a heterogeneous inherited neuropathy. The number of known CMT genes is rapidly increasing mainly due to next generation sequencing technology, at present more than 60 CMT-associated genes are known. We investigated whether variants in the *DCTN2* could cause CMT. **Material and methods:** Fifty-nine Norwegian CMT families from the general population with unknown genotype were tested by targeted next-generation sequencing (NGS) for variants in *DCTN2* along with 33 CMT genes and 18 other genes causing other inherited neuropathies or neuronopathies, due to phenotypic overlap. **Results:** Targeted NGS identified in one family a variant of *DCTN2*, c.337C>T, segregating with the phenotype in five affected while it was not present in the three unaffected members. The *DCTN2* variant c.337C>T; *p.(His113Tyr)* was neither found in in-house controls nor in SNP databases. The result is further strengthened by the fact that 33 known CMT genes and 18 other peripheral neuropathy genes did not harbor pathogenic mutations. **Conclusions:** This is the first time a *DCTN2* variant has been linked to an inherited neuropathy in man.

Asymmetric cell division is essential for normal human brain development. Mutations in several genes encoding centrosomal proteins that participate in accurate cell division have been reported to cause autosomal recessive primary microcephaly (MCPH). By homozygosity mapping including three affected individuals from a consanguineous MCPH family from Pakistan, we delineated a critical region of 18.53Mb on chromosome 1p21.3-1p13.1. This region contains the gene encoding HsSAS-6, a centrosomal protein primordial for seeding the formation of new centrioles during the cell cycle. Both next-generation and Sanger sequencing revealed a homozygous c.185T>C missense mutation in the *HsSAS-6* gene, resulting in a p.Ile62Thr substitution within a highly conserved region of the PISA domain of HsSAS-6. This variant is neither present in any single nucleotide polymorphism or exome sequencing databases nor in a Pakistani control cohort. Experiments in tissue culture cells revealed that the p.Ile62Thr mutant of HsSAS-6 is substantially less efficient than the wild-type protein in sustaining centriole formation. Together, our findings demonstrate a dramatic impact of the mutation p.Ile62Thr on HsSAS-6 function and add this component to the list of genes mutated in primary microcephaly.

Consulsive seizures and SUDEP in a mouse model of SCN8A epileptic encephalopathy. *J.L. Wagnon[1], M.J. Korn[2], R. Parent[3], J.M. Jones[1], M.F. Hammer[4], G.G. Murphy[3,5], J.M. Parent[2,6], M.H. Meisler[1,2].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Neurology, University of Michigan, Ann Arbor, MI; 3) Molecular and Integrative Physiology, University of Michigan, Ann Arbor, MI; 4) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, Tuscon AZ; 5) Molecular and Behavioral Neuroscience Institute, University of Michigan, Ann Arbor MI; 6) VA Ann Arbor Healthcare System, Ann Arbor, MI.

Mutations of the voltage-gated sodium channel gene SCN8A have recently been recognized as a cause of epileptic encephalopathy, which is characterized by refractory seizures with developmental delay and cognitive disability. We previously described the heterozygous SCN8A missense mutation p.Asn1768Asp in a child with epileptic encephalopathy that included seizures, ataxia, autism, and sudden unexpected death in epilepsy (SUDEP). This mutation results in increased persistent sodium current and hyperactivity of transfected neurons. We introduced the gain-of-function mutation into the mouse genome to investigate the pathology of the altered channel in vivo using TALEN technology with a targeting construct. Heterozygous Scn8aN1768D/+ mice exhibit seizures and SUDEP, confirming the causality of the de novo mutation in the proband. Using video/EEG analysis, we detected ictal discharges that coincide with tonic seizures, generalized tonic-clonic seizures, and myoclonic jerks. Prior to seizure onset, heterozygous mutants were not defective in motor learning or fear conditioning, but did exhibit mild impairment of motor coordination and social discrimination. Homozygous mutant mice exhibit earlier seizure onset than heterozygotes and more rapid progression to SUDEP. Analysis of the intermediate phenotype of functionally hemizygous Scn8aN1768D/- mice indicates that severity is increased by a double dose of mutant protein and reduced by the presence of wildtype protein. Scn8aN1768D mutant mice provide a model of epileptic encephalopathy that will be valuable for studying the in vivo effects of hyperactive Nav1.6 and the response to therapeutic interventions. (Support from NIH R01 NS34509).

FAR1 loss of function impairs the reduction of fatty acids in individuals with intellectual disability. *R. Abou Jamra[1], R. Buchert[1], H. Tawamie[1], J. Parboosingh[2], S. Uebe[1], B. Hallak[3], I. Micheil[2], C. Smitz[2], A.B. Ekici[1], H. Sticht[4], B. Schwarze[5], F. Bernier[2], A. Reis[1].* 1) Institute of Human Genetics, FAU Erlangen-Nürnberg, Erlangen, Bavaria, Germany; 2) Department of Medical Genetics, University of Calgary, Calgary, Canada; 3) Practice for Pediatrics, Kefrenbel, Syria; 4) Institute of Biochemistry, FAU Erlangen-Nürnberg, Erlangen, Germany; 5) Institute for Forensic Medicine, FAU Erlangen-Nürnberg, Erlangen, Germany.

Homozygosity mapping and exome sequencing in two Syrian siblings with severe intellectual disability, early onset epilepsy, congenital cataracts (in one patient), spasticity, microcephaly, and growth retardation revealed a homozygous mutation in the fatty acyl-CoA reductase 1 gene (FAR1: p.E165_P169delinsD). In addition, exome sequencing identified compound heterozygous mutations in FAR1 (p.Arg263X; p.Asp365Gly) in an unrelated 19 year old Canadian male with severe intellectual disability, congenital cataracts, microcephaly, spasticity and severe growth failure. In silico prediction programs and protein molecular modeling suggested a pathogenic effect for all identified variants. To further prove protein function impairment, we transfected HEK293 with either wild type or mutant FAR1 and performed gas-chromatography and mass-spectrometry on lipid extracts of cell cultures. All three variants abolished protein function since cells transfected with mutant FAR1 could not metabolize palmitic acid and stearic acid to hexadecanol and octadecanol, respectively. FAR1 is essential for the synthesis of plasmalogens, which are essential membrane components, especially in the nervous system, in the protection against reactive oxygen species. Mutations in other genes of the plasmalogen synthesis pathway in peroxisomes, PEX7, GNPAT and AGPS, cause rhizomelic chondrodysplasia punctata 1, 2 and 3, respectively. Our patients show overlapping features with rhizomelic chondrodysplasia punctata including severe intellectual disability, early onset epilepsy, cataracts, spasticity, microcephaly, and growth retardation. But they do not show chondrodysplasia. Altogether, we consider the identified mutations as causing for the phenotype in our patients and suggest FAR1 as a novel autosomal recessive peroxisomal disorder gene involved in plasmalogen synthesis.

3054T

Ten years apart: the second family with non-syndromic autosomal recessive intellectual disability due to a CRBN gene mutation. *B. Popp[1], F. Radwan[1], A. Muhammed[2], S. Uebe[1], A. Ekici[1], A. Reis[1], R. Abou Jamra[1].* 1) Institute of Human Genetics; FAU Erlangen-Nürnberg, Erlangen, Germany; 2) Practice for Pediatrics and Children with Special Needs, Lattakia, Syria.

In 2004 CRBN (cereblon) was only the second gene ever to be implicated in non-syndromic autosomal recessive intellectual disability (ARID). CRBN is part of the Cullin 4-Ring ubiquitin ligase complex CUL4 and functions as a substrate receptor which recruits proteins for ubiquitination. Extensive functional analyses of the nonsense mutation identified in single kindred with mild ARID showed altered CRBN degradation as the likely pathomechanism. Nevertheless, despite the broad application of whole-exome sequencing in ARID families no second mutation was reported to date, which would have confirmed its relevance beyond the initial family reported. Now, 10 years later we report this second CRBN mutation. We performed homozygosity mapping and exome sequencing in a family with two affected siblings of a consanguineous family with mild non-syndromic intellectual disability. Both affected individuals show a similar phenotype to the previously described cases with an estimated IQ of 50 to 70 and without dysmorphic or autistic features. We identified a homozygous splice-donor mutation in intron 8 of CRBN (c.835+1G>A) co-segregating with the phenotype in the family. In silico analysis using multiple splice site programs predicted disruption of the splice donor. Through cDNA analysis we could exclude the existence of full length CRBN transcript and characterize three aberrant transcripts in the affected individuals. One transcript leads to a frame-shift and a premature stop-codon before the last exon and thus is most likely subject to degradation through NMD. Two of these transcripts lead to an in-frame deletion and to an abruption of a C-terminal ubiquitination site. Thus this mutation likely interferes with the normal regulation of CRBN and leads to an altered formation or activity of the complex. The identification of this new mutation confirms the implication of the CRBN gene in autosomal recessive non-syndromic intellectual disability, possibly due to CRBN deficiency caused by altered autoubiquitination. The rareness of CRBN mutations underlines the heterogeneity in ARID and emphasizes that, although a second mutation is still needed to confirm pathogenicity, a gene implicated in ARID may not be discarded only because of pending replication studies. Pathway enrichment methods along with large scale collaborations may offer an opportunity to accelerate this confirmation process.

3055S

De novo mutations in _NALCN_ cause a new syndrome with congenital contractures, hypotonia, and early death. *K.M. Shively[1], J.X. Chong[1], M.J. McMillin[1], A.E. Beck[1,2], C.T. Marvin[1], K.J. Buckingham[1], J.R Armenteros[1], A. Monteil[3], J. Shendure[4], D.A. Nickerson[4], M.J. Bamshad[1,2,4], University of Washington Center for Mendelian Genomics.* 1) Department of Pediatrics, University of Washington, Seattle, WA, USA; 2) Seattle Children's Hospital, Seattle, WA, USA; 3) Department of Physiology, Institute for Functional Genomics, Montpellier, France; 4) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

Mutations in multiple genes, including *TPM2*, *TNNI2*, *TNNT3*, and *MYH3*, cause distal arthrogryposis (DA) but ~60% of cases remain unexplained. Analysis of exome sequencing data from six kindreds with an atypical form of DA with neurological abnormalities including hypotonia and developmental delay identified six different missense mutations in the gene sodium leak channel, non-selective, or *NALCN*. All six mutations were confirmed by Sanger sequencing to be *de novo*. Recently, it has been reported that mutations in *NALCN* cause autosomal recessive infantile hypotonia with psychomotor retardation and characteristic facies (IHPRF) and infantile neuroaxonal dystrophy (INAD) with facial dysmorphism in consanguineous Turkish and Saudi Arabian families. Two of these mutations were predicted to result in a truncated protein (or no protein if subject to nonsense-mediated decay), while the third mutation was a missense variant located in the 3rd helix of domain IV. In contrast, all six of the mutations we discovered are in the helices of the pore-forming regions of *NALCN*. These findings demonstrate that mutations in *NALCN* cause both recessive and dominant conditions, perhaps depending on the domain(s) affected by the mutations. Moreover, while there is some phenotypic overlap between the individuals with INAD with facial dysmorphism or IHPRF and the individuals with atypical DA, there are unique clinical features that distinguish the individuals with *de novo* mutations including congenital contractures of the hands, mouth, and feet. Last, the widely varied severity of developmental delay and contractures in the six kindreds we studied suggests that *NALCN* mutations could account for individuals with other congenital contracture disorders and/or unexplained developmental delay.

3056M

Application of array painting and next generation mate-pair sequencing (MPS) for improved mapping of chromosomal breakpoints in a familial translocation segregating with a particular phenotype. *P.M. Kroisel[1], M. Auer[1], K.M. Roetzer[2], R. Birnbacher[3], K. Wagner[1], M.R. Speicher[1], M.M. Mehrjouy[4], M. Bak[4], J.B. Geigl[1], N. Tommerup[4].* 1) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 2) Hanusch-Krankenhaus, Vienna, Austria; 3) Department of Pediatrics, Regional Hospital Villach, Villach, Austria; 4) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, Faculty of Health Science, University of Copenhagen, Copenhagen, Denmark.

In a familial translocation t(1;6)(p36.3;p21.2) identified in a mother and one of her two sons as well as in the maternal grandmother we previously confirmed by array CGH that no genomic unbalance is present. The translocation cosegregates with distinct phenotypic features including a mild to moderate intellectual disability and microcephaly. No other genetic disorders have been reported in this family. Array painting performed by using laser micro dissected and amplified chromosomal fragments carrying the translocation breakpoints followed by hybridization to standard 60k CGH arrays allowed the characterization of both chromosomal breakpoints at an achieved resolution that made it possible to identify genes potentially affected by the translocation. A number of less than ten chromosomal fragments was sufficient to obtain an adequate signal to noise ratio for this analysis. The CAMTA1-gene (Calmodulin binding transcription activator 1) at 1p36.31 and the BTBD9 or KIAA1880 gene at 6p21.2 were found to be located very close to or at the chromosomal breakpoints. Next generation mate-pair sequencing (MPS) will further improve the resolution of the breakpoint mapping by pin-pointing the location of the breakpoints at base pair level, allowing a detailed characterization of the genotype-phenotype relationship and of the DNA repair mechanism involved in the rearrangement. This approach might also allow a more immediate and better interpretation of the molecular and functional effects of particular structural genomic aberrations.

3057T

Deletion of the 5' exons of the TCF4 gene in patients without classical Pitt-Hopkins syndrome. *S. YU[1,3], D. GAI[2], N. Jillian[1].* 1) GENETIC Medicine, SA Pathology, North Adelaide, South Australia, Australia; 2) Royal Melbourne Hospital, Parkville, Victoria, Australia; 3) School of Paeddiatrics and Reproductive Health, University of Adelaide, South Australia, Australai.

Pitt-Hopkins syndrome (PHS) is characterised by severe intellectual disability (ID) and typical facial features. Other features include episodic hyperventilation, seizures, eye abnormalities and constipation. The TCF4 gene was identified as disease-causing. Haplo-insufficiency of TCF4 has been reported to cause classical PHS. We describe two patients with deletions of the first two 5' exons of TCF4 without classical PHS. The first patient is a 16 year old boy with high functioning autism spectrum disorder and constipation. Array CGH identified a 128 kb deletion [chr18: 53,278,787-53,526,749 (hg19)]. He also has a 227kb duplication of 11p15.5 (chr15:1,448,960 -1,222,378) with unknown clinical significance. His mother does not carry the TCF4 deletion but the father is not available for testing. The second patient is a 14 year old girl who had mild ID with perceptual reasoning problems. She had a similar deletion (chr18: 51,429,785-51,677,747). Parents are not available for testing. No dysmorphism was reported in either patient. DECIPHER database recorded at least four cases with a deletion only involving the 5' exons of the TCF4 gene without classical PHS. Two cases (269234 and 269230) had mild intellectual disability. The third (250498) had ID, microcephaly, constipation, and seizures. The fourth (1024) had ID, microcephaly, delayed speech and other features. In addition, disruption of the TCF4 gene proximal to exon 4 by a translocation was reported in a girl with ID but without classic PHS (Kalscheuer et al). TCF4 has 20 exons with multiple isoforms using alternative 5' exons. Mutations and deletions causing classical PHS have been reported in most coding exons sparing the 5' exons (exons 1-3) (Whalen et al). TCF4 mRNA expression study showed that the isoforms containing the 5'exons were restricted to testis, prostate and placenta, and not expressed in brain, while other isoforms expressed in multiple brain regions (Sepp et al). It is possible that deletions of the 5' exons of the TCF4 gene only affect isoforms not expressed in brain and therefore lead to a less severe phenotype. This is the first report to suggest that deletion of the 5' exons of the TCF4 gene may not cause classical PHS. Tissue specific expression of particular isoforms may contribute to the milder phenotype. 1.Kalscheuer VM et al. (2008) Am J Med Genet Part A 146A:2053-2059. 2.Sepp M et al. (2011) PLoS ONE 6:e22138 3.Whalen S et al. (2011) Human Mutation 33:64-72.

3058S

A genetic dosage study of DYT1 Dystonia using an inducible knock-in ΔE-Tor1a mouse model. *C. Weisheit[1], W. Dauer[1,2,3].* 1) Graduate Program in Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI; 2) Department of Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI; 3) Department of Neurology, University of Michigan Medical School, Ann Arbor, MI.

DYT1 dystonia is a common inherited form of primary dystonia caused by a dominant mutation in TOR1A that removes a single glutamic acid ("ΔE") residue from torsinA, the encoded protein. We generated a novel line of inducible knock-in (I-KI) ΔE-Tor1a knock-in mice to evaluate whether the ΔE mutation acts via a gain- or loss-of-function mechanism. The ΔE mutation is located in the last exon (exon 5) of Tor1a. I-KI mice contain a floxed exon 5, and an additional downstream exon 5 containing the ΔE mutation; this allele is converted from a wild type to DYT1 allele following Cre deletion, allowing spatial and temporal induction of the pathogenic protein from the endogenous locus. We intercrossed these mice with mice carrying a floxed Tor1a gene to generate a gene dosage series, hypothesizing that if the ΔE mutation causes a gain of toxic function, animals harboring two mutant alleles would fare worse than littermates with one mutant and one null allele. We evaluated Nestin Cre Tor1aI-KI/Flx and Tor1aI-KI/I-KI littermates for viability, motor phenotype, and neuropathology. We found that Nestin Cre Tor1aI-KI/I-KI mice do not experience a worsening phenotype compared to Nestin Cre Tor1aI-KI/Flx mice. Both Nestin Cre Tor1aI-KI/I-KI and Tor1aI-KI/Flx mice exhibit abnormal motor behavior and histological investigations show increased reactive gliosis, ubiquitin accumulation, and neurodegeneration in several motor brain regions recapitulating pathology observed in conditional knockout mouse models. To this end, we developed a primary cortical culture model that successfully recapitulates torsin LOF abnormalities observed in mice. With this tool, we are addressing the hypothesis that layer 5 projection neurons are distinctly susceptible to torsinA LOF. In addition, we aim to further characterize the implications of gene dosage by comparing cultures from Nestin Cre Tor1aI-KI/I-KI and Tor1aI-KI/Flx mice. This project will provide an essential cell culture model that recapitulates specific phenotypes observed in a disease-manifesting mouse. These are necessary tools currently lacking in the field that will undoubtedly lead to a better understanding of torsinA dysfunction and DYT1 pathogenesis.

3059M

Whole exome sequencing identified the first STRADA point mutation in a patient with polyhydramnios, megalencephaly, and symptomatic epilepsy syndrome (PMSE). *W. Bi[1], I. Glass[2], A. Sun[2], D.M. Muzny[3], A.L. Beaudet[1], R.A. Gibbs[1,3], C.M. Eng[1], Y. Yang[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Polyhydramnios, megalencephaly and symptomatic epilepsy syndrome (PMSE) is an ultra rare neurodevelopmental disorder characterized by severe, infantile-onset intractable epilepsy, neurocognitive delay, macrocephaly and craniofacial dysmorphism. The molecular diagnoses of this condition had only been made in 16 Old Order Mennonites who carry a homozygous 7-kb founder deletion mutation affecting exons 9 to 13 of the STRADA gene, which encodes an upstream inhibitor of mammalian target of rapamycin complex 1 (mTORC1). We recently performed clinical whole exome sequencing (WES) on a 4-year-old South Asian male with global developmental delay, a history of failure to thrive, infantile spasms, seizures, repetitive behaviors, hypotonia, low muscle mass, marked joint laxity in large and small joints, and dysmorphic facial features including tall forehead, long face, arched eyebrows, small chin, and carp shaped mouth. Concurrent cSNP array and WES genotype data revealed absence of heterozygosity (AOH) in multiple chromosomal regions (total AOH ~186 Mb) consistent with the fact that parents are first cousins. A homozygous single nucleotide duplication, c.842dupA (p.D281fs), in exon 10 of the STRADA gene of this patient was identified by WES. The frameshift change is located within one of the AOH regions on 17q23.3. Sanger sequencing confirmed the mutation in the individual and identified both parents as carriers. In light of the molecular discoveries, the patient's clinical phenotype was considered to be a good fit for PMSE. In addition, his unique features expand the spectrum of clinical findings associated with STRADA mutations. Because of the non-specific nature of the PMSE phenotype and the fact that the molecular basis of the disorder had only been previously reported once in the Old Order Mennonites, PMSE was not considered as a possible diagnosis during clinical evaluations. The previously reported mutation in STRADA is limited to the 7-kb founder deletion mutation in the Old Order Mennonites. We identified for the first time a homozygous point mutation in the STRADA gene causing PMSE in a patient of South Asian origin. Additional bi-allelic mutations related to PMSE are not seen in other WGL data, supporting the rarity of this disorder. Our findings may also have treatment implications for the patient since previous studies have shown rapamycin as a potential treatment for the seizures and cognitive problems in PMSE patients (PMID 23616120).

3060T

The expanding role for chromatin remodeling in epilepsy: Gene discovery to pathogenic mechanisms. *G.L. Carvill[1], J.M McMahon[2], H. Wang[3], J. Stamatoyannopoulos[3], I.E. Scheffer[2], H.C. Mefford[1].* 1) Pediatrics, University of Washington, Seattle, WA; 2) Epilepsy Research Center and Department of Medicine, University of Melbourne, Austin Health, Australia; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

Epilepsy is one of the most common neurological disorders, with a lifetime incidence of 3%. The epileptic encephalopathies (EEs) are the most severe of all the epilepsies. Patients typically present with refractory epilepsy with multiple seizure types, cognitive arrest or regression, and have a poor prognosis. *De novo* mutations have been increasingly recognized as causative for these disorders, and mutations in over 30 genes have been described. These gene discovery efforts have highlighted a role for genes involved in chromatin regulation in the pathogenesis of EE, including *CHD2, MBD5*, *MEF2C*, *FOXG1* and *ARX*. We aim to identify novel causes of epilepsy in genes that are chromatin regulators. We selected 26 known and candidate genes that act in this process and will perform targeted resequencing in a cohort of 868 patients to identify novel *de novo* mutations. To date we have completed mutation detection in 703 patients in 21 genes. Thus far we have identified 17 pathogenic mutations in seven genes with at least one novel gene for this disorder. Overall, mutations in chromatin regulator genes account for ~2% of cases in our cohort, and about 14% of all mutation positive patients. Our results illustrate the importance of this biological process in the pathogenesis of epilepsy and highlight the need for studies of the pathogenic mechanisms that underlie these conditions. To this end, we are using the chromatin remodeler, CHD2, as a model to develop novel epigenomic approaches to studying disease mechanisms. By performing ChIP-seq in four fetal tissues, we will identify those target genes that are brain-specific and integrating this data with chromatin state maps from fetal brain we will determine the likely function of CHD2. This experimental paradigm could be expanded to include other epilepsy genes. The role of chromatin remodeling is largely unexplored in epilepsy, but it is a dynamic process with many therapeutic targets, and presents a novel opportunity to develop new treatments for patients.

3061S

Processing of double-R-loops (RNA:DNA hybrids) in (CAG)•(CTG) and *C9orf72* (GGGGCC)•(GGCCCC) repeats causes instability. *M.H.M. Schmidt[1,2], K. Reddy[1,2], J. Geist[3], G.B. Panigrahi[1], T. Zu[4], L.W. Ranum[4], Y.H. Wang[5], C.E. Pearson[1,2].* 1) The Hospital for Sick Children, Canada; 2) University of Toronto; 3) Laurentian University; 4) University of Florida; 5) University of Virginia.

Expansion of gene-specific repeat sequences causes at least 40 neuromuscular and neurodegenerative diseases, 14 of which are associated with CAG/CTG repeats. Recently amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) was shown to be caused by an expanded hexanucleotide repeat. Continued somatic repeat expansions can contribute to disease onset and progression, thereby highlighting a need to understand the expansion process or processes that inhibit this. R-loops, transcriptionally-induced RNA:DNA hybrids, can occur at various trinucleotide repeat sequences including (CAG)n, (CTG)n, (CGG)n, (CCG)n, and (GAA)n, that are associated with diseases such as myotonic dystrophy, Huntington's disease, spinocerebellar ataxia, fragile X and Friedreich's ataxia. Many of these repeats are bidirectionally transcribed, allowing for single- and double-R-loop configurations, where either or both DNA strands of the repeat may be bound by RNA. R-loops can trigger repeat length instability at transcribed (CTG)/(CAG) repeat tracts, but the mechanism of how this occurs remains unclear. We demonstrate R-loop-mediated instability through direct processing of R-loops by human cell extracts (HeLa and the neuron-like SH-SY5Y). We find that double R-loops, derived from simultaneous convergent transcription across the repeats can trigger greater levels of repeat instability than single R-loops derived from transcription in either direction alone. Pretreatment with RNase H only partially suppresses R-loop-mediated instability, supporting a model in which R-loops may directly generate instability through their aberrant processing, or through formation of slipped-DNAs upon RNA removal from the R-loop and their subsequent aberrant processing. Removal of the RNA from R-loops can lead to slipped-DNA formation, as evidenced by electron microscopy. Since transcriptionally-induced R-loops can occur in the absence of DNA replication, R-loop processing, possibly involving a slipped-DNA intermediate, may be a source of repeat instability in non-proliferating tissues. Double-R-loop formation and processing to instability was extended to the expanded *C9orf72* (GGGGCC)•(GGCCCC) repeats, known to cause ALS and FTD, providing the first suggesting through which these repeats may become unstable. These findings extend our understanding of the mechanistic basis for R-loop-mediated instability at disease-associated repeat tracts.

Glutathione-S-transferase gene polymorphisms (GSTM1,GSTT1, GSTM3 &GSTP1) and and its correlation with GST enzyme activity in DM1. *A. Kumar, S. Agrawla, S. Pradhan, S. Phadke.* Sanjay Gandhi Post-Graduate Institute of Medical Sciences (SGPGIMS) Raebareli Road, Lucknow, Uttar Pradesh, India.

Background: Myotonic dystrophy type 1 (DM1) is due to trinucleotide sequence (CTG) in the 3' UTR region of DMPK gene located at 19q13.3 chromosome. Glutathione S-transferases (GSTs) activity involved in the pathogenesis of DM1 is because it contains polymorphic triplet repeat and GSTs belong to a super family of phase II detoxification enzymes and play an important role in protecting cells from damage. Aim: The intention of the present study is to assess the association of GST gene polymorphisms (GSTT1, GSTM1, GSTP1 and GSTM3) and its enzyme activity in DM1 affected Indian population Material and Methods: Clinically diagnosed 20 DM1 patients (16 men and 4 women; median age 32.8 years±9.3, range 17-52) and 75 age-sex matched controls (median age 31.0 years±8.6, range 16-54) were included in the study. DNA isolation (standard phenol chloroform method) and serum separation were performed. Serum GST level was assessed by using Glutathine-S-Transferase assay kit (Cat. No. 703302-96) of Cayman Chemical Company, USA. GSTM1 (null or present) & GSTT1 (null or present), GSTM3 (AA, AB and BB) & GSTP1 (Ile/Ile, Ile/Val and Val/Val -105) were analysed by PCR and PCR-RFLP method respectively. Results: Serum GST was reduced significantly in the patient group compared to the control group and were significantly correlated with diabetes only. Patients had significantly higher (except GSTM3A/B) GSTM1*0 (GSTM1 null genotype), GSTT1*0 and GSTP1 (ile/val) frequency than controls. The deletion frequencies (GSTM1 and GSTT1) and GSTP1 (ile/val) were not associated with higher risk while heterozygous frequency of GSTM3 (A/B) increased the risk ratio up to three fold. The GSTM1, GSTT1 and GSTM3 genotypes correlated with dyspepsia, age at presentation and duration of disease respectively. The group of combination genotype frequency had no impact on higher risk of disease. There was no correlation between GST activity and GST polymorphisms. Conclusion: Our data supports that a significant association occurs between DM1 and GSTT1 & GSTM1 polymorphism in Indian population. Further study of GST polymorphisms or other antioxidant enzymes are required to clarify the relationship between increased oxidative stress and DM1.

3063T

The whole genome sequences from a Rottweiler and Black Russian Terrier with overlapping neurological syndromes contain the same RAB3GAP1 frame shift mutation. *T. Mhlanga-Mutangadura[1], G.S. Johnson[1], G.C. Johnson[1], L. Hansen[1], G.V. Tamassia[1], J.F. Taylor[2], R.D. Schnabel[2], D.P. O'Brien[1].* 1) College of Veterinary Medicine, University of Missouri, Columbia, MO; 2) College of Agriculture, Food and Natural Resources, University of Missouri, Columbia, MO.

We generated whole-genome sequences (WGSs) with DNA from a 5-month-old male Rottweiler diagnosed with neuronal vacuolation and laryngeal paralysis and a 3-month-old female Black Russian Terrier diagnosed with juvenile laryngeal paralysis, polyneuropathy, microphthalmia, persistent pupillary membranes and cataracts. Initially we thought these two dogs had overlapping but distinct disease syndromes; however, both of their WGSs contained the same homozygous single base pair deletion: RAB3GAP1:c.743delC. The frame shift produced by this deletion predicts a premature stop codon and a truncated gene product RAB3GAP1:p.P248Lfs3* missing 730 C-terminal amino acids. In addition to the Rottweiler and Black Russian Terrier with the WGSs, the DNA samples from all 3 other affected Rottweilers and all 4 other Black Russian Terriers in our collection were homozygous for the c.743delC allele; whereas, 85 clinically normal Rottweilers and 41 clinically normal Black Russian Terriers tested either heterozygous (n = 18) or homozygous for the ancestral allele (n = 108). Truncating mutations in human RAB3GAP1 have been found in patients with Warburg micro syndrome. This severely debilitating developmental disorder is characterized by microcephaly, microphthalmia, microcornea, congenital cataracts, optic atrophy, cortical dysplasia, mental retardation, and hypogonadism. In contrast, Rab3gap1 knockout mice have exhibited only subtle abnormalities. The disease phenotype produced by the frame shift mutation in canine RAB3GAP1 appears to be less severe than that in the children with Warburg micro syndrome but much more severe than that of Rab3gap1 knockout mice. We are currently re-evaluating the disease phenotypes from affected dogs from the two breeds to see if they are, in fact, identical and to determine if they have other clinical signs in common with the Warburg micro syndrome patients.

3064S

The missing factors influencing spinal and bulbar muscular atrophy: evaluation of genetic polymorphisms. *C. Bertolin[1], G. Querin[1], M. Pennuto[2], E. Pegoraro[1], C. Gellera[3], D. Pareyson[3], C. Mariotti[3], G. Sorarù[1].* 1) Biology, University of Padova, Padova, Padova, Italy; 2) 2Dulbecco Telethon Institute Laboratory of Neurodegenerative Diseases, Centre for Integrative Biology (CIBIO), University of Trento, Italy; 3) 3Unit of Genetics of Neurodegenerative and Metabolic Diseases, Fondazione IRCCS Istituto Neurologico "Carlo Besta", Milan, Italy.

Spinal and bulbar muscular atrophy (SBMA) is caused by a pathological expansion over 38 of a CAG repeat in the first exon of the androgen receptor (AR) gene on chromosome X, coding for a polyQ tract (La Spada et al, 1991). SBMA is an androgen-dependent disorder, with males with full disease manifestations, and females showing only mild symptoms even if homozygous for the mutation. While a correlation between expansion size of polyQ tract and disease severity has been reported, patients with the same number of CAG repeats have different age at onset and disease progression even if relatives. This study aims to find AR gene polymorphisms that can explain the genotype-phenotype correlation of spinal bulbar muscular atrophy (SBMA) in an Italian cohort of patients. In order to do that, we evaluated polymorphism (SNPs and trinucleotide repeats) of the human AR gene. The effect of these sequences on SBMA phenotype has not been studied yet. To characterize the effect of AR coding repeated sequences on SBMA phenotype, we genotyped AR polymorphisms in 132 molecularly defined Italian SBMA patients, referring to the Motor Neuron Clinic of the University of Padua and to Fondazione IRCCS Istituto Neurologico "Carlo Besta", Milan. Age of onset was considered as the marker of disease severity. Among candidate AR polymorphisms, only a GGN sequence coding polyG is polymorphic in our cohort. Interestingly, the genotyping of polyG stretch highlights that patients belonging to different polyG allele classes showed different levels of correlation between polyQ lenght and disease's severity. Our study confirms that the size of SBMA-causing polyQ tract does not fully explain the disease phenotype and point to a polyG strech within AR exon 1 as a modifier in SBMA phenotype.

3065M

Abnormalities in neuronal architecture and synaptic activity impairment in mice heterozygous for different deletions of the Williams-Beuren syndrome locus. *C. Borralleras[1, 3], M. Bosch-Morató[2], B. Guivernau[2], M. Bravo-Garmendia[2], LA. Pérez-Jurado[1, 2, 3], FJ. Muñoz[2], V. Campuzano[1, 2, 3].* 1) Hospital del Mar Research Institute (IMIM), Barcelona, Barcelona, Spain; 2) Universitat Pompeu Fabra, Barcelona, Spain; 3) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain.

Williams-Beuren syndrome (WBS, [MIM 194050]) is a neurodevelopmental disorder caused by a spontaneous 1.55-1.83 Mb deletion at chromosal band 7q11.23 containing between 26-28 genes, including 2-3 TFII-I family members. WBS is characterized by distinctive dysmorphic features, mild growth retardation, cardiovascular abnormalities, and a specific cognitive profile with mild intellectual disability, visuospatial deficits, hypersensitivity to sounds and hypersociability. Neurologic examination and brain imaging in patients have shown changes in brain function and brain anatomy. Haploinsufficiency at *GTF2I* has been shown to play a major role in the neurodevelopmental abnormalities of WBS. To clarify the involvement of *GTF2I* in neurocognitive features we characterized four WBS mouse models deleting *Gtf2i* with and without additional genes: PD (proximal deletion, from *Gtf2i* to *Limk1*), CD (complete deletion, from *Gtf2i* to *Fkbp6*), *ΔGtf2i* +/- and *ΔGtf2i* -/-. We examined the morphology of a transgenically labeled subset of cortical and hippocampal pyramidal neurons in YFP-H mice crossed with the different mutant lines. The number of YFP+ cells was decreased by up to 87% in WBS mouse models in various cortical regions. Lower number of YFP+ cells was present as early as P12-14 developmental stages. Spine density of apical dendrites in the CA1 area of the hippocampus was reduced in *ΔGtf2i* -/-, PD and CD mice by 14%, 15% and 17%, respectively. Moreover, spines in all animals were shorter, pointing to a more immature type of spine. Calcium imaging experiments in primary cultures of hippocampal neurons showed alterations in glutamatergic synaptic activity. As GTF2I has a role in PI3K/AKT pathway (involved in synaptic plasticity) and is a regulator of *Dlx* genes (involved in the differentiation of GABAergic projection neurons), we analyzed the expression of these genes in our mutant mice. Mutant mice showed deregulation of these genes, suggesting impairment in synaptic plasticity and inhibitory synaptic activity. These findings suggest that *GTF2I* plays an important role in neurodevelopmental abnormalities in WBS. Abnormalities in neuronal architecture and perturbations in synaptic activity could be associated with the cognitive impairment seen in WBS patients.

3066T

A Homozygous PIGN Missense Mutation in Soft Coated Wheaten Terriers with Paroxysmal Dyskinesia. *A. Kolicheski[1], G.S. Johnson[1], D. Gilliam[1], T. Mhlanga-Mutangadura[1], J.F. Taylor[2], R.D Schnabel[2], D.P. O'Brien[1].* 1) College of Veterinary Medicine, University of Missouri-Columbia, Columbia, MO; 2) College of Agriculture, Food and Natural Resources, University of Missouri, Columbia, MO.

The paroxysmal dyskinesia (PD) we studied is a previously undescribed Soft Coated Wheaten Terrier (SCWT) movement disorder characterized by multiple episodes of dyskinesia that sometimes last for only a few minutes and other times last for over an hour. Episodes begin in young adult SCWTs and include hyperextension or hyperflexion primarily of the pelvic limbs with difficulty moving forward and arrhythmic hopping. Between episodes the dogs move normally. We generated a whole genome sequence (WGS) with 21-fold average coverage and 6.9 million sequence variants (differences from the reference canine genome sequence) with DNA from a PD-affected SCWT and another WGS with 18-fold average coverage and 5.5 million sequence variants with DNA from a second PD-affected SCWT that had no known relationship to the first. We filtered the sequence variants to identify those that were homozygous in both case WGSs, predicted to alter the amino acid sequence of the gene product, and absent from 100 other canid WGSs. The only variant that met these criteria was a *PIGN*:c.398C>T transition that predicts a *PIGN*:p.T133I substitution. All 13 PD-affected SCWT (including the 2 with WGSs) were homozygous for the *PIGN*:c.398T allele. The genotyping of archived SCWT DNA samples of unknown phenotype identified 469 *PIGN*:c.398C homozygotes, 7 heterozygotes and no *PIGN*:c.398T homozygotes. Samples of 505 dogs of varied breeds were also genotyped and all were homozygous wild type. *PIGN* encodes an enzyme in the biosynthetic pathway for glycosylphosphatidylinositol anchors that attach many different proteins to cell surfaces. Mutations in human *PIGN*, cause multiple congenital anomalies-hypotonia-seizures syndrome 1 (MCASH1 [MIM 614080]), with characteristic neonatal hypotonia, facial dysmorphism, and psychomotor underdevelopment. A minority of MCASH1 patients have exhibited choreoathetosis which may be related to the PD in the SCWTs. Nonetheless, the canine *PIGN* mutation reported here causes disease phenotype that is very different than that of the human MCASH1 patients.

Congenital hypotonia: Two rare diseases in one family. *T. Falik-Zaccai[1,2], M. Baydany[1,2], L. Kalfon[1], N. Nasser Samra[1,2], Y. Shoval[1], D. Savitzki[3], S. Ivry[4], Z. Zonis[5], H. Mandel[6].* 1) Institute of Human Genetics, The Galilee Medical Center, Nahariya, Israel; 2) The Galilee Faculty of Medicine, Bar Ilan University, Safed, Israel; 3) Department of Pediatric Neurology, The Galilee Medical Center, Nahariya, Israel; 4) Department of Anesthesiology, The Galilee Medical Center, Nahariya, Israel; 5) Pediatric Intensive Care Unit, The Galilee Medical Center, Nahariya, Israel; 6) Meyer Children's Hospital, Metabolic Unit, Rambam Medical Center, Haifa, and Rappaport Faculty of Medicine, Technion, Haifa, Israel.

Background: Congenital hypotonia is a non specific physical finding, common to a heterogeneous group of diseases. We present an extended highly consanguineous family of Druze origin, with multiple affected children born with severe congenital hypotonia. We hypothesize that congenital hypotonia in this family is a monogenic autosomal recessive disorder. We aim to determine its causative gene and mutation, and to characterize its molecular and biochemical basis. Methods: Clinical investigations, homozygosity mapping of patients and their parents, linkage analyses and whole exome sequencing, were performed to find the novel sequence variation segregating with the disease in two nuclear families within the extended pedigree. mRNA and protein levels were further determined. Results: We have identified 4 novel sequence variations within two genes in the two nuclear families that present both with multiple affected children with congenital hypotonia. In the first family we have identified a novel nonsense mutation in the gene NGLY1. A recently reported gene with only 8 patients described worldwide. RNA levels were significantly reduced among the patients compared to controls in both fibroblasts and leukocytes. In the second nuclear family which is closely related to the first, we have identified compound heterozygosity for three novel RYR1 mutations in two affected sisters. Two mutations inherited from the father in cis and a third mutation inherited from the mother. We screened 100 healthy ethnically matched individuals from the same village and found 1:30 carriers for the mutation in NGLY1, 1:100 carriers' frequency for the allele presenting two mutations in cis, and 1:33 carriers' frequency for the third mutation in the gene RYR1. No healthy individual in this village was found to be homozygous or compound heterozygous for any of the mutations. Conclusions: We have identified a genetic isolate for two extremely rare forms of congenital hypotonia presenting to our surprise in one extended highly consanguineous family. Revealing the causative gene and mutation will enable us to provide credible genetic counseling and pre-natal diagnosis to the extended family, and genetic screening for this high risk population. The family presented here demonstrates the critical role of comprehensive clinical evaluation along with whole exome sequencing for accurate determination of the genetic basis of congenital hypotonia and other rare genetic disorders.

3068M

Identification of a novel autophagy-related gene mutation in a canine storage disease. *K. Kyöstilä[1,2,3,4], V. Jagannathan[5], P. Syrjä[1], T. Jokinen[6], G. Chandrasekar[7], J. Kere[2,4,7,8], E.H. Seppälä[1,2,3,4], D. Becker[5], M. Drögemüller[5], E. Dietschi[5], C. Drögemüller[5], J. Lang[9], F. Steffen[10], C. Rohdin[11], P. Wohlsein[12], D. Henke[13], A. Oevermann[13], H. Lohi[1,2,3,4], T. Leeb[5].* 1) Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland; 2) Research Programs Unit, Molecular Medicine, University of Helsinki, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) Department of Molecular Genetics, Folkhälsan Institute of Genetics, Helsinki, Finland; 5) Institute of Genetics, Vetsuisse Faculty, University of Bern, Bern, Switzerland; 6) Department of Equine and Small Animal Medicine, University of Helsinki, Helsinki, Finland; 7) Center for Biosciences, Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 8) Science for Life Laboratory, Karolinska Institutet, Solna, Sweden; 9) Department of Clinical Veterinary Medicine, Division of Clinical Radiology, Vetsuisse Faculty, University of Bern, Bern, Switzerland; 10) Neurology Service, Department of Small Animals, Vetsuisse Faculty, University of Zurich, Zurich, Switzerland; 11) University Animal Hospital, Swedish University of Agricultural Sciences, Uppsala, Sweden; 12) Department of Pathology, University of Veterinary Medicine Hannover, Hannover, Germany; 13) Division of Neurological Sciences, Vetsuisse Faculty, University of Bern, Bern, Switzerland.

Purebred dogs suffer from different types of inherited neurodegenerative diseases similar to humans. As a large animal, the dog is physiologically closer to human than traditional model organisms and therefore a better replicate for human phenotypes. We have studied clinical, pathological and genetic aspects of a storage disease in the Lagotto Romagnolo dog that predominantly affects the nervous system. The affected dogs suffer primarily from progressive ataxia but show also other symptoms, such as episodic nystagmus and behavioral changes. The onset of clinical signs varies from 4 months to 4 years of age. The main histological findings in the central and peripheral nervous system are profound cytoplasmic vacuolization in neurons along with granular spheroid formation. Cytoplasmic vacuolization of several secretory epithelia is also present. To identify the genetic cause of the disease, we genotyped three pathologically confirmed cases and four control dogs using Illumina's canine 170K SNP arrays. In addition, we performed low-coverage whole genome sequencing (WGS) in one affected dog. Genotyping data was analyzed by performing homozygosity mapping and parametric linkage analysis. WGS data was filtered against the genomes of 46 dogs from different breeds. Combining of results from genome-wide analyses and the WGS data revealed a single non-synonymous variant in an autophagy-related gene on canine chromosome 20. Genotyping of this variant in a cohort of nearly 2,000 Lagotto Romagnolo dogs, including 17 clinically confirmed affected dogs, indicated a highly significant association with the disease ($p=3.8 \times 10^{-108}$). Furthermore, the variant was absent in 642 dogs from 40 other breeds. The gene has not been previously associated with inherited diseases in any species. The encoded protein is poorly characterized but proposed to function in a macroautophagy pathway, which has been implicated in neurodegenerative diseases. We are currently performing experiments to further delineate the function of the gene in the zebrafish model. In conclusion, our study identifies a novel mutation associated with a previously uncharacterized canine storage disorder. This animal model may be useful to further characterize the interplay between dysfunctional autophagy and neural degeneration, and to explore possible therapeutic options. Meanwhile, dog breeders will benefit from genetic testing.

3069T

Mutations in the neurofilament heavy chain gene (NEFH) trigger pathological aggregates in Charcot-Marie-Tooth disease. *A. Rebelo[1], A. Abrams[2], A. Horgha[3], M. Gonzalez[1], H. Houlden[3], E. Cottenie[3], M. Sweeney[3], M. Hanna[3], M. Auer-Grumbach[4], M. Reilly[3], S. Zuchner[1].* 1) HIHG, University of Miami, Miami, FL; 2) Neurology, University of Miami, Miami, FL; 3) University College London, London, England; 4) Medical University of Graz, Graz, Austria.

Charcot-Marie-Tooth disease (CMT) comprises a group of heterogeneous motor and sensory neuropathies caused by mutations in several genes. Abnormal accumulation of neurofilaments and disruption of neurofilament network is a common cause of motor neuron degeneration in CMT. In particular, mutations in the neurofilament light chain (NEFL) and heat shock protein, HSPB1, leads to neurofilaments pathological aggregates. Neurofilament aggregation is also the hallmark of neuronal dysfunctional associated with other neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS), Parkinson and Alzheimer. Applying exome sequencing, we have identified 2 novel dominantly inherited CMT mutations in the neurofilament heavy (NEFH) subunit. Both mutations caused frameshifts in the conserved c-terminal domain, resulting in the loss of the stop codon and consequently producing an extra 40 amino acid long extension at the c-terminal tail. NEFH mutations identified in the patients were also evaluated at the functional level, where we observed prominent abnormal aggregates in neuro2a cells transfected with the mutant protein. Therefore, we concluded that abnormal aggregation of the mutant NEFH suggests a possible toxic gain of function effect that leads to the progression of CMT in patients. Moreover, zebrafish eggs injected with mRNA encoding the mutant NEFH resulted in embryos with significantly decreased motor neuron lengths. Our studies support the hypothesis of neurofilament aggregation and dysfunction as a disease mechanism for axonopathies.

3070S

MUTATIONS IN THE TRICARBOXYLIC ACID CYCLE ENZYME, ACONITASE 2, CAUSE EITHER ISOLATED OR SYNDROMIC OPTIC NEUROPATHY WITH ENCEPHALOPATHY AND CEREBELLAR ATROPHY. *JM. Rozet[1], M. Metodiev[1], S. Gerber[1], L. Hubert[1], D. Chretien[1], X. Gerard[1], P. Amati-Bonneau[2], MC. Jacomoto[3], N. Boddaert[4], A. Kaminska[4], I. Desguerre[4], M. Rio[4], J. Kaplan[4], A. Munnich[1,4], A. Rotig[1], C. Besmond[1].* 1) Inserm UMR1163, UPD - Sorbonne Paris Cité, Imagine-Institute of genetic diseases, Paris, France; 2) Department of Biochemistry and Genetics, CHU d'Angers, Angers, France; 3) Department of Ophthalmology, Polyclinique du Maine, Laval, France; 4) Departments of Pediatrics, Radiology and Genetics, Hôpital Necker-Enfants Malades, Paris, France.

Inherited optic neuropathy has been ascribed to mutations in mitochondrial fusion/fission dynamic genes, nuclear and mitochondrial DNA-encoded respiratory enzyme genes or nuclear genes of poorly known mitochondrial function. On the other hand, enzymopathies of the tricarboxylic acid cycle (TCA) have been reported to cause severe encephalopathies or isolated retinitis pigmentosa, but no TCA-cycle enzyme deficiency has been hitherto reported in isolated optic neuropathy. Studying a series of five patients with optic atrophy, we found homozygous or compound heterozygous missense and frameshift mutations in the gene encoding mitochondrial aconitase (ACO2), a TCA-cycle enzyme, catalyzing interconversion of citrate into isocitrate. Retrospective studies using patient-derived cultured skin fibroblasts revealed various degrees of deficiency in ACO2 activity but also in ACO1 cytosolic activity. Our study shows that autosomal recessive ACO2 mutations can cause either isolated or syndromic optic neuropathy. This observation identifies ACO2 as the second gene responsible for non syndromic autosomal recessive optic neuropathies and provides evidence for a genetic overlap between isolated and syndromic forms, giving further support to the view that optic atrophy is a hallmark of defective mitochondrial energy supply.

3071M

UBE3B Deficiency in Kaufman oculocerebrofacial syndrome. *R. Yilmaz[1], L. Basel-Vanagaite[2,3,4], S. Tang[5], M.S. Reuter[6], N. Rahner[7], D.K. Grange[8], M. Mortenson[9], P. Koty[9], H. Blepharophimosis-mental retardation (BMR) syndromes are clinically and genetically heterogeneous group of disorders characterized by intellectual disability and typical facial features. Mutations in *KAT6B* and *MED12* were reported to cause autosomal dominant Say-Barber-Biesecker-Young-Simpson syndrome and X-linked Maat-Kievit-Brunner type BMR syndrome, respectively. We have previously identified biallelic *UBE3B* mutations by exome sequencing in patients affected by Kaufman oculocerebrofacial syndrome (KOS) (Basel-Vanagaite et al., 2012), a syndrome with clinical overlap with BMR syndromes. KOS is characterized by developmental delay, growth retardation with a small head circumference, congenital anomalies, low cholesterol levels and characteristic facial dysmorphisms. Here, we have screened 24 patients with clinical overlap to KOS by Sanger or exome sequencing. We have identified *UBE3B* mutations in six additional patients from five unrelated families. Two of the patients who were siblings had previously been reported as having Toriello-Carey syndrome and one patient had been reported as having a "new" syndrome by Buntinx and Majewski in 1990. In patients with no *UBE3B* mutation, we sequenced *KAT6B* and *MED12*. None of the patients carried mutations in either of the gene. As the clinical heterogeneity could also suggest the involvement of another gene, we performed exome sequencing in a sibling pair and our filters identified *PROM2* as candidate gene. We did not however find any rare or unreported variants in *PROM2* in the patients whom were screened by capillary sequencing. Although *UBE3B* is reported to be highly expressed in adult tissues, we found it has low- to medium- abundance expression based on PCR on various tissue cDNAs. Moreover, different cell lines such as U2OS, 293T, MCF-7 and H4 contain very low or undetectable UBE3B protein levels as shown by Western blot. We did not detect any difference in protein mobility on SDS-PAGE between phosphorylated and dephosphorylated forms of UBE3B. *oxi-1* is a *UBE3B* homolog in C. elegans and was shown to be involved in protein degradation under oxidative stress. However, in preliminary tests, we did not observe increased UBE3B protein levels upon H_2O_2 induced oxidative stress. Overexpression studies revealed that UBE3B is predominantly localized in the cytoplasm. We will also present the results of localization studies of *UBE3B* constructs containing KOS-associated missense variants.

3072T

Whole genome sequences from two individual dogs with neuronal ceroid lipofuscinosis contain novel truncating mutations: one in CLN8 and the other MFSD8. *J. Guo[1], M.L. Katz[2], H.A. Brown[3], T. Mhlanga-Mutangadura[1], J.F. Taylor[4], R.D. Schnabel[4], D.P. O'Brien[5], G.S. Johnson[1].* 1) Veterinary Pathobiology, University of Missouri-Columbia, columbia, MO; 2) Mason Eye Institute, University of Missouri School of Medicine, Columbia, MO; 3) Metz Petz Veterinary Clinic at Shawnee, Lima, OH, USA; 4) Division of Animal Science, University of Missouri College of Agriculture, Food and Natural Resources, Columbia, MO; 5) Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri Columbia, MO.

We generated separate whole genome sequences (WGSs) with DNA from 2 different young adult female dogs that were diagnosed with neuronal ceroid lipofuscinosis (NCL) based on a clinical history of neurodegeneration and the presence of CNS neurons with autofluorescent cytoplasmic storage granules containing material with characteristic multilamellar ultrastructures. One of the dogs had both Australian Shepherd and Blue Heeler ancestry. She was euthanized at approximately 22 months of age due to intractable seizures. For about a year prior to euthanasia, she had shown signs of progressive neurodegeneration that included visual loss, cognitive decline and MRIs indicative of diffuse brain atrophy. Among the homozygous sequence variants in the WGS from this dog was a CLN8:c.585G>A transition that predicts a CLN8:p.W95* nonsense mutation. This variant was considered most likely to be causal because it was the only rare variant in a canine ortholog of a gene associated with human NCL and because it was predicted to encode a truncated protein missing the 93 C-terminal amino acids. By genotyping archived DNA samples from 1488 Australian Shepherds and 133 Blue Heelers at CLN8:c.585, we identified a pair of purebred Australian Shepherd siblings that were homozygous for CLN8:c.585A. These siblings had been previously diagnosed with NCL of unknown cause. The other dog was a purebred Chinese Crested. This dog was euthanized at approximately 19 months of age due to a 5-month history of progressive neurological decline that included blindness, anxiety, and cognitive impairment. Among the homozygous sequence variants in the WGS from this dog was MFSD8:c.843delT. This single base deletion is predicted to cause a frame shift and premature stop codon resulting in a truncated protein, MFSD8:p.F282Lfs13*, missing its 239 C-terminal amino acids. All but one of our archived DNA samples from 1477 Chinese Cresteds tested homozygous for the ancestral MFSD8:c.843T allele. The exception was a sample from a 10-year-old Chinese Crested that lived in Sweden and tested heterozygous for the c.843delT allele. MFSD8 mutations have been identified in human patients with a form of variant late infantile NCL known as CLN7. These examples indicate that the likely molecular genetic causes of canine Mendelian diseases can be identified by generating WGSs from individual affected dogs.

Mice with combined deficiencies of β-Hexosaminidase A and Sialidase Neu3 mimic the fundamental aspects of the neurological abnormalities of Tay-Sachs disease due to accumulation of ganglioside: New hope for Tay-Sachs patients and families. *V. Seyrantepe[1], S. Akyildiz Demir[1], Y. Calhan[1], Z. Timur[1], C. Marsching[2], R. Sandhoff[2], T. Miyagi[3].* 1) Dept Molecular Biology and Genetics, Izmir Institute of Technology, Urla Izmir, Turkey; 2) DKFZ Heidelberg Zelluläre und Molekulare Pathologie AG Lipidpathobiochemie Heidelberg Germany; 3) 6Division of Cancer Glycosylation Research, Institute of Molecular Biomembrane and Glycobiology, Tohoku Pharmaceutical University, Sendai, Japan.

Tay-Sachs disease is a severe lysosomal storage disorder caused by mutations in the HEXA gene coding for α subunit of lysosomal β-Hexosaminidase A enzyme, which converts GM2 to GM3 ganglioside. HexA-/- mice, depleted of β-Hexosaminidase A enzyme, remains asymptomatic to 1 year of age, owing to the ability of these mice to catabolise stored GM2 ganglioside via sialidase (s) removing sialic acid into glycolipid GA2 which further processed by β-Hexosaminidase B, thereby bypassing the HexA defect. Previously we showed that mice with targeted distruption of both HexA and Neu4 genes (HexA-/-Neu4-/-) have epileptic seizures and accumulating GM2 ganglioside in brain. To elucidate whether plasma membrane associated sialidase Neu3 can also contribute to GM2 ganglioside degradation, we generated a double deficient mouse model by crossing previously generated HexA-/- mouse model and Neu3-/- mouse model. HexA-/-Neu3-/- were health at birth but lost weight gradually and died at 4 months of age. Thin layer chromatography analysis of double deficient mice showed increased GM2 ganglioside level and altered ganglioside pattern in brain as well as liver, kidney and lung. Mass spectrometry analysis confirmed accumulation of GM2 and other gangliosides such as LacCer, GA2 and GM3. Immunohistochemical analysis using anti-GM2 antibodies indicated massive accumulation of GM2 in hippocamous and cortex of mice brain Slow movement, ataxia and tremor were among neurological abnormalities. The unexpected severe phenotype of HexA-/- mice appeared to be influence by the status of Neu3 gene. HexA-/-Neu3-/- mice mimic the fundamental aspects of the neurological abnormalities of Tay-Sachs disease. Our data suggests potential therapy of Tay-Sachs disease based on the upregulation of human sialidase Neu3 by drug treatment and give new hope to patients and families.

Mutation of NUP50 in a consanguineous family with intellectual disability. *JM. Capo-chichi, C. Nassif, ME. Samuels, FF. Hamdan, JL. Michaud.* Centre de Recherche du CHU Sainte-Justine, 3175 Chemin Côte Ste-Catherine Montréal, Québec, Canada.

We studied the case of two sisters from a consanguineous North-African family that presented with intellectual disability (ID). We first performed whole-genome SNP genotyping and homozygosity mapping on both affected siblings and identified 6 regions of shared homozygosity (HR) of ≥ 25 consecutives SNPs and extending over 1 Mb. The largest HRs identified were of ~ 10 Mb (chr22:37,650,774-47,938,048) and ~7 Mb (chr7:116,156,423-123,007,208). Next, we performed exome sequencing on one of the affected siblings and identified 55 rare homozygous amino acid-altering or splicing variants in the exome. Only one variant, a non-synonymous change in NUP50 (NM_007172:exon5:c.502C>T (p.R168W)) was found in an HR (the 10Mb one) shared by the two probands. Sanger sequencing showed that this variant segregates with a recessive mode of inheritance in the family. The 502C>T (p.R168W) variant was absent from all public SNP databases (1000 Genomes, Exome Variant Server (EVS), dbSNP138), and from our in-house exome dataset (>1000). The R168 residue in NUP50 is highly conserved among various species and the p.R168W mutation is predicted to be damaging by Polyphen-2, SIFT and Provean. NUP50 (or NPAP60) encodes for a component of the nuclear pore complex that plays a role in nucleocytoplasmic transport of proteins through direct interaction with importin-alpha. Nup50 is expressed in various mouse tissues, particularly in the brain with high signals in cerebellum and hippocampus. Nup50 has been shown to play a role in development as mice homozygous for a targeted null mutation in Nup50 die embryonically and present neural tube abnormalities and intrauterine growth retardation. Humans express two functional isoforms of NUP50 (NUP50-S and NUP50-L), both of which are affected by the p.R168W mutation. NUP50-S has been shown to stabilize the binding of importin-alpha to classical NLS-cargo, whereas NUP50-L rather promotes the release of importin-alpha from the NLS-cargo. The antagonizing roles of NUP50 isoforms suggest that changes in NUP50 levels might perturb the efficiency of nucleocytoplasmic transport in humans. Our findings suggest that the homozygous p.R168W mutation in NUP50 might be responsible for the ID phenotype in the studied family. Identification of additional similarly affected families with mutations NUP50 will be necessary to establish the role of NUP50 as a neurodevelopmental disease gene. Collaborations towards this effort are welcome.

3075T

Phenotype of 21 novel autosomal recessive cognitive disorders. *K. Kahrizi[1], A. Tzschach[2,3], H. Hu[2], Z. Fattahi[1], M. Hosseini[1], S. Abedini[1], T. Wienker[2], H.H. Ropers[2], H. Najmabadi[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany; 3) Institut für Human Genetik Universitäts Klinikum Tübingen Calwerstr, Tübingen, Germany.

After releasing 52 novel intellectual disability genes by Najmabadi et al in 2011, most of researchers working on cognitive pathway in human and animal models were interested in phenotypically aspect of some of these genes to reach the function of changes in mouse, drosophila and human brain. From 52 novel candidate genes of Intellectual Disability (ID) that have been reported, 21 families had additional features that some of them could have been related to the effect of these genes on neuronal networking. Ten out of 21 syndromic families with microcehaly or neurological symptoms were selected and MRI was performed for one or two affected siblings in each family. In the previous study, homozygosity mapping, coupled by conventional sequencing or next generation sequencing (NGS) were used to define underlying genetic defects. From total of 10 families, eight families showed different types of abnormalities as periventricular leukoencephalopathy, reduced cerebral cortex, pachygyria, polymicrogyria, small corpus callosum and cerebellar hypoplasia on MRI including subjects with mutations in CAPN10, TAF2, CNKSR1, WDR45L, ERLIN2, PARP1 and SLC31A1 genes. Three syndromic families had normal brain architecture (ZBTB40, KIF7 and TMEM135).

3076S

An emerging role for the Rho-GEF Collybistin in neuropathological mTORC1-mediated protein translation. *A. Sertie[1], C.O.F. Machado[1], K. Griesi-Oliveira[2], C. Rosenberg[2], F. Kok[2,3], S. Martins[1], M.R. Passos Bueno[2].* 1) Hospital Israelita Albert Einstein, Centro de Pesquisa Experimental. Av. Albert Einstein, 627/701 - Morumbi - São Paulo, Brasil; 2) Centro de Estudos do Genoma Humano, Instituto de Biociências, Universidade de São Paulo, Brasil; 3) Faculdade de Medicina, Universidade de São Paulo, Brasil.

Protein synthesis regulation via the mammalian target of rapamycin (mTOR) signaling pathway plays key roles in neural development and function, and its dysregulation is involved in neurodevelopmental disorders associated with autism and intellectual disability. mTOR regulates assembly of the translation initiation machinery by interacting with the eukaryotic initiation factor eIF3 complex and controlling phosphorylation of key translational regulators. Collybistin (CB), a neuron-specific Rho-GEF responsible for X-linked mental retardation with epilepsy, also interacts with eIF3 and its binding partner gephyrin associates with mTOR. However, studies addressing whether CB also binds mTOR and affects mTORC1-signaling activity are not yet available. To test these hypotheses, we used two model systems: heterologous expression in HEK293T cells and induced pluripotent stem cells (iPSC)-derived neural progenitor cells (iNPCs) from a patient with a CB gene deletion and from normal subjects. Our results suggest that CB forms a complex with mTOR both in 293T cells and in control iNPCs. We also show that CB inhibits mTORC1-signaling pathway and protein synthesis. We suggest a model whereby CB forms a complex with mTOR and eIF3 and by sequestering these proteins down-regulates mTORC1 signaling and protein synthesis. These findings also suggest that disinhibited mTORC1 signaling mays also contribute to the pathological process in patients with loss-of-function mutations in CB. Elucidation of the signaling network regulating protein synthesis in neuronal cells is essential for understanding the pathological process of several neurological disorders and further studies on the involvement of CB in translation control will likely prove highly fruitful. Support: FAPESP, CNPq, Autismo & Realidade.

De novo dominant mutations in the kinesin motor protein KIF1A cause a severe static or progressive encephalopathy with cerebral and cerebellar atrophy. *S. Esmaeeli Nieh[1], M. Madou[1], B. Fregeau[1], A.J. Barkovich[2], J.G. Pappas[3], B. Hallinan[4], C.G. Spaeth[5], J.B. Strober[1], N. Smaoui[6], E.H. Sherr[1].* 1) Neurology, University of California, San Francisco, San Francisco, CA; 2) Department of Radiology, University of California, San Francisco CA; 3) 3Department of Pediatrics, Clinical Genetic Services, NYU School of Medicine, New York, NY; 4) Division of Pediatric Neurology, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 5) Division of Human Genetics, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 6) GeneDx, Gaithersburg, MD.

The causes of developmental encephalopathies are complex and often remain poorly understood. Arriving at a diagnosis can have important implications for clinical management and prognosis. Clinically indicated whole exome sequencing was performed on 750 trios in which the proband had a range of neurologic conditions including encephalopathy and global developmental delay. Four individuals were identified with de novo missense mutations in KIF1A, the major plus-end directed microtubule motor in neuronal axons. Two patients had the same mutation (T99M) in the ATP binding domain; two patients had additional novel mutations (pR216C, E253K) in the motor domain. All four patients had microcephaly, cortical visual impairment, global hypotonia with spasticity and severely impaired development. Movement disorders and epilepsy were also observed. Three patients had evidence of progressive neurologic disease both clinically and radiologically, with supratentorial and cerebellar white matter and grey matter volume loss seen on sequential MRI scans. To predict the effect of KIF1A motor domain mutations, we performed protein-structure-based prediction using Schrödinger, and compared all de novo mutations with the previously reported recessive mutations as well as reported population polymorphisms. Results showed that dominant mutations were located within 5 Å of the ATP binding site recessive mutations were along the interface with tubulin. All 8 reported polymorphisms from the exome variant server database were located at neither of these sites. To address the functional consequences of these mutations, we are performing a gliding assay of tubulin over kinesin using the KIF1A motor-domain with wild type and both dominant and recessive mutant constructs. Recessive mutations in KIF1A were previously demonstrated to cause hereditary motor and sensory neuropathies. We describe a novel and consistent clinical phenotype resulting from de novo dominant highly penetrant mutations in the ATP and microtubule binding domains of KIF1A, the most severe form leading to a rapidly progressive early childhood onset neurodegenerative disease. Given the severity of these dominant mutations in comparison to silent recessive mutations, it is critical that we develop tools to predict clinical severity for family-based anticipatory guidance. Early data from prediction algorithms suggest that this is possible and ongoing in vitro and cell-based assays will address these directly.

3078T

Clinical and molecular characterization of progressive encephalopathies in children. *J.R. Helle[1], D. Misceo[1], T. Barøy[1], C. Ramane[1], A. Holmgren[1], T. Hughes[1], M.D. Vigeland[1], S. Thirukeswaran[1], S.S. Amundsen[1], T.H. Gamage[1], A. Torgersbråten[1], N. Skauli[1], I. Akkouh[1], E.O. Carlsen[1], M. Fannemel[1], P. Strømme[2], E. Frengen[1].* 1) Department of Medical Genetics, Oslo University Hospital and University of Oslo, Oslo, Norway; 2) Women and Children's Division, Department of Clinical Neurosciences for Children, Oslo University Hospital, Ullevaal, Oslo, Norway.

BACKGROUND AND OBJECTIVES: Progressive encephalopathies (PE) in children consist of clinically and genetically heterogeneous disorders.They often affect brain morphology or signaling intensity visualized on cerebral MRI and lead to developmental arrest before subsequent regression of acquired skills. Metabolic defects or other neurodegenerative mechanisms result in atrophy of already existing neural cells. Neural tissues, such as spinal cord, peripheral nerves, and retina may also be involved. Intellectual disability, epilepsy, ataxia, spasticity and dystonia frequently accompany PE. Mortality is high. Approximately 20% of PE lack a diagnosis, and this gap in knowledge about etiology impairs genetic counseling and treatment. Once a causative gene is identified, clinical data suggesting time and focus of the incipient PE may also provide valuable insight on this gene's implication in normal brain functioning. Our objectives were to characterize mutations in a series of undiagnosed cases of PE and to perform functional analyses in novel disease genes. METHODS: We have collected more than 70 patients in 50 families presumed to have a genetic etiology, and where extensive medical work up had been negative. We ruled out CNS infection, trauma, vascular accidents and sequelae after asphyxia and prematurity. Cerebral MRI examinations revealed cortical atrophy, subcortical white matter changes, cerebellar degeneration, or basal ganglia abnormalities in the majority of the patients. Congenital anomalies, also those outside the nervous system, were evaluated using the London Medical Database for syndrome identification. After karyotyping, aCGH and analysis of candidate genes by MLPA and/or sequencing, we have so far performed Whole Exome Sequencing (WES) in 50 family trios and continued with data filtering, alignment, variant calling and selection based on population frequency, estimated severity of variants and inheritance pattern. RESULTS: Among the 20 WES trios finalized through the bioinformatics pipeline, a putative disease causing mutation has been identified in ten. Functional studies are currently being performed in two novel disease genes and in one novel disease entity affecting peroxisomal functioning. CONCLUSION: Clinical and molecular characterization, particularly via WES, provides additional etiologic and pathogenic criteria to classical clinical criteria in childhood PE taxonomy.

3079S

Low levels of CHIP in fibroblasts derived from patients with autosomal recessive cerebellar ataxia caused by mutations in *STUB1*. *S. Johansson[1], K. Heimdal[2], M. Sanchez-Guixé[1], I. Aukrust[3], J. Bollerslev[4], A.K. Erichsen[5], E. Gude[6], J.A. Koht[7], S. Erdahl[3], T. Fiskerstrand[1], B.I. Haukanes[3], L.G. Bjorkhaug[1], C.M.E. Tallaksen[8], P.M. Knappskog[3].* 1) Department of Clinical Science, University of Bergen, Bergen, Bergen, Norway; 2) Department of medical genetics, Oslo University hospital, Oslo, Norway,; 3) Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway; 4) Section of Specialized Endocrinology, Medical Clinic B, Oslo University Hospital; 5) Department of ophthalmology, Oslo University Hospital; 6) Department of Cardiology, Oslo University Hospital Rikshospitalet, Oslo, Norway; 7) Department of Neurology, Vestre Viken Hospital, Drammen; 8) Department of Neurology, Oslo University Hospital, Norway.

A subset of hereditary cerebellar ataxias is inherited as autosomal recessive traits (ARCAs). Recently, reports have linked mutations in genes involved in ubiquitination (*RNF216, OTUD4, STUB1*) to ARCA with hypogonadism. We used homozygozity mapping and exome sequencing, to identify a homozygous missense variant (c.194A>G, p.Asn65Ser) in STUB1 in three consanguineous siblings with ARCA and cognitive impairment, and a missense change (c.82G>A, p.Glu28Lys) which was inherited in trans with a nonsense mutation (c.430A>T, p.Lys144Ter) in another patient. *STUB1* encodes CHIP (C-terminus of Heat Shock protein 70 - interacting protein), a dual function protein with a role in ubiquitination as a co-chaperone with heat shock proteins, and as an E3 ligase. We show that the p.Asn65Ser substitution impairs CHIPs ability to ubiquitinate HSC70 in vitro, despite being able to self-ubiquitinate. These results are consistent with previous in vitro studies highlighting this as a critical residue for the interaction between CHIP and its co-chaperones. Furthermore, we show that the levels of CHIP are strongly reduced in vivo in patients' fibroblasts compared to controls. These results suggest that STUB1 mutations might cause disease by impacting not only the E3 ligase function, but also its protein interaction properties and protein amount. Whether the clinical heterogeneity seen in *STUB1* ARCA can be related to the location of the mutations remains to be understood, but interestingly, all siblings with the p.Asn65Ser substitution showed a marked appearance of accelerated aging not previously described in *STUB1* related ARCA, none display hormonal aberrations / clinical hypogonadism while some affected family members had diabetes, alopecia, uveitis and ulcerative colitis, further refining the spectrum of *STUB1* related disease.

3080M

Truncating mutations in the negative feed-back regulator of interferon 1 signalling, *USP18* gene causes pseudo-TORCH syndrome. *G.M.S. Mancini[1], M.E.C.M. Meuwissen[1], R. Schot[1], S. Tinschert[5], L. van Unen[1], D. Heijsman[2], W.F.J. van IJcken[3], J.M. Kros[4], R. Willemsen[1], F.W. Verheijen[1].* 1) Clinical Genetics, Erasmus University Medical Center, Rotterdam, Netherlands; 2) Bioinformatics, Erasmus University Medical Center, Rotterdam, Netherlands; 3) Biomics core, Erasmus University Medical Center, Rotterdam, Netherlands; 4) Pathology, Erasmus University Medical Center, Rotterdam, Netherlands; 5) Medical genetics, University of Innsbruck, Austria.

Inappropriate stimulation of the type 1 interferon (IFN1) response pathway has been proposed as the disease mechanism in autoimmune disorders such as systemic lupus erythematosus. Also disorders resembling congenital viral infections such as pseudo-TORCH and Aicardi-Goutières syndrome have been ascribed to mutations in receptors and enzymes that lead to cytosolic accumulation of nucleic acids as triggers, indirectly linking these disorders to the IFN1 pathway. The general term “type 1 interferonopathies” is now used to indicate these disorders. We report on two unrelated families with five affected individuals with a pseudo-TORCH-like phenotype, presenting in the perinatal period with severe brain hemorrhage, destruction of ependymal layer and early demise.In the first consanguineous family including 3 affected sibs we used linkage analysis, whole exome sequencing and Sanger sequencing of the non-covered exons in the linkage area and identified a homozygous truncating mutation in *USP18* causing total absence of *USP18* transcript in cultured fibroblasts. In the second family including two sibs the same truncating mutation in heterozygous form was found. However, no transcript was amplified from cells of the two patients, suggesting that a second pathogenic mutation is present in areas not covered by Sanger sequencing. *Usp18* knockout mice have cerebral hemorrhage and hydrocephalus with ependymal necrosis. Microscopy of patient brain tissues shows severe ependymal abnormalities, similar to the mouse. *USP18* encodes UBP43, a protein with a dual independent function in cleavage of ubiquitin-like protein 15 (ISG15) conjugates, through its carboxypeptidase domain, and, through its SH2 domain, a function as negative feed back regulator of the intracellular interferon-dependent JAK-STAT signalling pathway. *USP18* mutations therefore result in a sustained, deleterious and deregulated interferon response. *USP18* mutations are a novel genetic cause of pseudo-TORCH syndrome and severe cerebral hemorrhage. While the other interferonopathies are linked to inappropriate stimulation of the IFN1 response pathways, this is the first example of defective negative feed-back regulation of the IFN1 pathway, which might have consequences for the design of future therapies.

3081T

The Expanding Phenotype of TRPV4 Related Neuropathies With Notable Intrafamilial Variability. *L. Medne[1], C. Bonnemann[2], S. Scherer[3, 4], R. Finkel[5], X. Ortiz-Gonzalez[1], A. Glanzman[6], T. Estilow[7], A. Moll[7], R. Leshner[8], Y. Wang[9], T. Winder[9], S. Yum[1, 4].* 1) Division of Neurology, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) NINDS, NIH, Bethesda, MD; 3) Division of Neurology, The Hospital of the University of Pennsylvania; 4) School of Medicine, The University of Pennsylvania; 5) Nemours Children's Hospital, Orlando, FL; 6) Department of Physical Therapy, The Children's Hospital of Philadelphia, Philadelphia, PA; 7) Department of Occupational Therapy, The Children's Hospital of Philadelphia, Philadelphia, PA; 8) Division of Neurology, Rady Children's Hospital, San Diego, CA; 9) Prevention Genetics Laboratory, Marshfield, WI.

TRPV4 gene mutations are known to cause 5 skeletal dysplasias, 1 arthropathy and 3 forms of neuropathies: congenital distal spinal muscular atrophy (CDSMA), scapuloperoneal spinal muscular atrophy (SPSMA) and Charcot-Marie-Tooth disease type 2C (CMT2C). We report 5 patients with TRPV4 related neuropathies, three of whom have positive family histories. Three patients share the common p.Arg269His mutation but have varied phenotypes. Patients 1 and 2 presented with arthrogryposis multiplex congenital (AMC), hip dysplasia, scoliosis, distal>proximal weakness in lower extremities (LE) with limited walking, and weakness of proximal upper extremities (UE). Patient 3 with the p.Arg269His has CMT2 with pure axonal neuropathy, which she inherited from her subclinically affected mother with evidence of mild chronic denervation on EMG. Her maternal uncle and cousin, also with p.Arg269His, had AMC, motor axonal neuropathy and severe course: uncle lost ambulation in his 40s; her cousin never walked. Patient 4 has AMC with limited walking since 2.5 years, distal>proximal weakness in LE, mild proximal UE weakness and prominent scapulae. He has 2 mutations: p.Val620Ile - seen in CMT2C and brachyolmia type 3, but not in CDSMA; and p.Arg151Trp seen with low frequency in dbSNP. Patient 5 is a 3 y/o with gait abnormalities and axonal neuropathy with a similarly affected father and grandmother. His p.Arg186Gln is a known CMT2C mutation. All five probands reported here had clear motor axonal neuropathies on nerve conduction and EMG studies. All had muscle fasciculations noted during their muscle ultrasound examinations that showed an overall neurogenic pattern of echogenicity The broad phenotypic spectrum of TRPV4 neuropathies represents both a diagnostic and clinical management dilemmas. There is no definitive genotype : phenotype correlation, particularly as demonstrated by the presence of both CMT2C and CDSMA phenotypes in the same family (patient 3) reported here. All three patients with congenital arthrogryposis presentation also had proximal upper extremity weakness and patients 2 and 4 had scapular winging, showing an overlap between CDSMA and SPSMA phenotypes rather than completely distinct clinical entities. TRPV4 gene mutations should be considered in all cases of AMC presentation with evidence of axonal neuropathy.

3082S

WWOX and severe early onset epileptic encephalopathies: description of two additional patients and new clinical insights. *C. Philippe[1, 2], C. Mignot[3], L. Pasquier[4], I. lambert[5], L. Allou[2], J.L. Guéant[2], P. Jonveaux[1, 2].* 1) Laboratory of Medical Genetics, Centre Hospitalier Universitaire, Vandoeuvre les Nancy, France; 2) Laboratoire INSERM-U954-NGERE-Nutrition Génétique et Exposition aux Risques Environnementaux, Faculté de Médecine, Université de Lorraine, Vandoeuvre les Nancy, France; 3) Département de Génétique, Centre de Référence "Déficiences Intellectuelles de Causes Rares"; APHP; Groupe Hospitalier Pitié Slapêtrière, Paris, France; 4) Service de Génétique Clinique, Centre de Référence CLAD Ouest, CHU Rennes, Rennes, France; 5) Unité de Génétique Clinique, Médecine Néonatale, Maternité Régionale Universitaire, Rue du Dr Heydenreich, Nancy, France.

WWOX on chromosome 16q was initially identified as a putative tumor suppressor gene considering that it is frequently altered by deletions or translocations in many neoplastic lesions. The 46-kDa WWOX protein contains two N-terminal WW domains and a central short-chain dehydrogenase/reductase domain. It has been implicated in many biological processes including tumor suppression, metabolic disorders, immune defects, bone tumors, neurodegenerative diseases, and early onset severe epileptic encephalopathies. The description of individuals carrying germline WWOX mutations or deletions is recent. The first germline rearrangement of WWOX in a heterozygous state was reported in a child with ambiguous genitalia (White et al. Eur J Hum Genet 2012). Recently, WWOX was implicated in autosomal recessive spinocerebellar ataxia-12 (SCAR12) in two consanguineous families with homozygous missense mutations (Mallaret et al., Brain 2014). In another consanguineous family, a homozygous early stop codon was identified in an Egyptian girl affected by a severe lethal neurologic phenotype resulting in death at age 16 months (Abdel-Salam, Orphanet J Rare Dis 2014). Early onset severe epileptic encephalopathies (EOEE) are genetically heterogeneous disorders. By comparative genomic hybridization, we initially identified a heterozygous composite genotype consisting of two large deletions in WWOX in a female with EOEE. We subsequently screened the WWOX locus for point mutations in patients with EOEE and heterozygous for an inherited copy number variation affecting the WWOX locus. We characterized a second patient positive for WWOX alterations affecting both alleles. Our study confirms that biallelic WWOX mutations are a (not so rare?) cause of autosomal recessive early onset epileptic encephalopathies with clinical heterogeneity depending on the mutation(s) type(s). WWOX-related severe encephalopathy is characterized by 1) normal pregnancy and delivery or mild intrauterine growth retardation 2) severe developmental delay, poor spontaneous motility and absent eye contact from birth, little if any acquisitions thereafter 3) early-onset pharmacoresistant epilepsy starting in the first two months of life 4) compromised survival during the first years. This study also demonstrates the need for combining data from array comparative genomic hybridisation and next generation sequencing for the identification of genes responsible for rare autosomal recessive disorders.

Mechanisms leading to brain malformations in tubulinopathies. *M.I. Rees[1,2], T.D. Cusion[1], S-K. Chung[1,2], R. Oegema[3], A. Paciorkowski[4], W.B. Dobyns[5], D. Doherty[5], D.T. Pilz[2,6].* 1) Neurology & Molecular Neuroscience Research, College of Medicine, Swansea University, UK; 2) Wales Epilepsy Research Network, College of Medicine, Swansea University, UK; 3) Department of Clinical Genetics and Expertise Centre for Neurodevelopmental Disorders, Erasmus University Medical Center, Rotterdam, The Netherlands; 4) Departments of Pediatrics and Biomedical Genetics, University of Rochester Medical Center, Rochester, NY, USA; 5) Center for Integrative Brain Research, Seattle Children's Hospital and Department of Pediatrics, University of Washington, Seattle, USA; 6) Institute of Medical Genetics, University Hospital Wales, Cardiff University, UK.

The tubulinopathy spectrum of overlapping brain malformations, including lissencephaly, atypical polymicrogyria and mildly disorganized gyral patterning, arise from tubulin gene variations affecting neuronal proliferation, migration and post-migrational organisation during cerebral cortex development. We ascertained a series of children with these cortical malformations, and/or characteristic basal ganglia and cerebellar malformations, and screened them for gene-variations in four human brain-expressed tubulin genes (*TUBA1A, TUBB2B, TUBB2A* and *TUBB3*). Although many variants in these genes have been reported by us and other groups, the in vitro functional consequences for the putatively causative mutations have only partially revealed cellular mechanisms. Here we present data where 3 different mechanisms are becoming apparent. These include intracellular tubulin disorganisation as detected by immunocytochemistry and functional domain specificity; neurite-length defects as detected in outgrowth assays; and possible cell-cycle delays in the G2/M phase as indicated by flow cytometry. This varied collection of mechanisms may underlie the clinical and structural heterogeneity observed in individuals with tubulinopathies, and provides contextual detail before the design of in vivo models for interventional research.

3084T

A novel pathogenic mechanism in Hereditary Spastic Paraplegia. *R. Schüle[1,2,3], A. Rebelo[1], M. Bonin[4], E. Battaloglu[5], G. Woehlke[6], L. Schöls[2,3], S. Zuchner[1], A. Caballero Oteyza[2,3].* 1) Hussman Institute for Human Genomics, Miami, FL; 2) Hertie Institute for Clinical Brain Research, Tubingen, Germany; 3) German Center for Neurodegenerative Disease, Tubingen, Germany; 4) Institute of Medical Genetics and Applied Genomics, Tübingen, Germany; 5) Bogazici University, Department of Molecular Biology and Genetics, Istanbul, Turkey; 6) Department of Physics E22 (Biophysics), Technical University Munich, Garching, Germany.

Hereditary Spastic Paraplegias (HSP) are characterized by a length dependent axonopathy of corticospinal tract motor neurons. With more than 70 genetic subtypes described, HSPs are among the most heterogeneous Mendelian disorders. Known HSP genes are involved in numerous cellular processes including membrane shaping, intracellular membrane transport, metabolism of complex lipids and mitochondrial function. Here we describe the discovery and functional characterization of a novel autosomal recessive HSP disease gene. The gene was identified via whole exome sequencing in a family with spastic ataxia and confirmed in a second family with a similar phenotype. Missense mutations observed in our family lead to reduced protein stability and dramatic subcellular misslocalization. The novel disease gene has been poorly studied so far. Using mass spectrometry we identified binding partners of this novel HSP-associated protein. Interaction was later confirmed using immunoprecipitation with two known RNA binding proteins: Polyadenylate-binding protein 1 (PABP-1) and Insulin-like growth factor 2 mRNA-binding protein 1 (IMP-1). PABP-1 and IMP-1 are known to be part of a multisubunit autoregulatory ribonucleoprotein complex that is involved in regulation of mRNA translation and nonsense mediated decay. To confirm the interaction of the novel HSP protein with RNA we performed RNA immunoprecipitation and were indeed able to precipitate mRNA using antibodies directed against the novel HSP protein. Further studies to reveal the identity of the bound mRNA and further functional consequences of pathogenic mutations are underway. To our knowledge this is the first report linking HSP to RNA metabolism. Disturbances of RNA metabolism with formation of RNA stress granules and potentially more widespread alteration of RNA metabolism are however increasingly recognized as a key pathogenic factors of motor neuron death in Amyotrophic Lateral Sclerosis, a related motor neuron disease.

DNM3; a genetic modifier of LRRK2 parkinsonism. *J. Trinh[1], E. Gustavsson[1], I. Guella[1], C. Vilarino-Guell[1], C. Thompson[1], H. Han[1], S. Bortnick[1], H. Sherman[1], D.M. Evans[1], M. Toft[2], M. Petersen[3], J. Aasly[4], F. Hentati[5], M.J. Farrer[1].* 1) Djavad Mowafaghian Centre for Brain Health, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada, V6T 2B5; 2) Department of Neurology, Oslo University Hospital, Oslo, Norway; 3) Department of Occupational Medicine and Public Health, The Faroese Hospital System, Tórshavn, Faroe Islands; 4) Department of Neuroscience, Norwegian University of Science and Technology, Trondheim, Norway; 5) Service de Neurologie, Institut National Mongi Ben Hamida de Neurologie, La Rabta, Tunis, Tunisia.

Background: *LRRK2* p.G2019S accounts for 30-40% Parkinson disease (PD) in North African Arab Berbers, 18-30% in Ashkenazi Jews and 1-3% in Caucasians. Disease penetrance of *LRRK2* p.G2019S is variable, may result in early-onset parkinsonism or elderly asymptomatic carriers, and we hypothesize additional genetic factors are responsible.

Methods: Genome-wide STR linkage analysis for age-of-onset (AAO) of disease was evaluated in multi-incident *LRRK2* p.G2019S families (126 affected and 71 asymptomatic carriers). Case-only haplotype association of AAO was performed with Plink, Snipsnip and Beagle in 266 *LRRK2* p.G2019S Arab-Berber patients. Analysis of gene expression and transcript isoforms in striatum was evaluated using Taqman RT-PCR and Ion Torrent PGM. Sanger and next-generation sequencing were performed for *DNM3* (n=400 PD and controls), with subsequent Sequenom iPLEX MassArray genotyping of coding substitutions in a Caucasian case-control series (n= 1999).

Results: Linkage of *LRRK2* p.G2019S AAO gave a LOD=2.9 on chromosome 1, and suggested regions on 11, 21 and X (LOD>2.0). A significant haplotype association for AAO was only observed on chromosome 1 ($p<0.00001$), spanning *DNM3*. The SNPs responsible appear to regulate gene transcription. Subsequent sequencing in Caucasian subjects showed a 2-fold increase in *DNM3* substitutions in PD compared to control subjects, of which *DNM3* p.M664V segregates with parkinsonism within 5 families, albeit with reduced penetrance.

Conclusions: *DNM3* is a penetrance modifier of *LRRK2* parkinsonism, as shown by linkage, association and sequencing analyses, and highlights how a homogeneous population may yield genetic modifiers of Mendelian disease. Importantly, chromosome 1 linkage for AAO was previously reported in Ashkenazi Jewish *LRRK2* p.G2019S carriers, whereas co-immunoprecipitation/co-localization has shown a biological interaction between LRRK2 and DNM1-3. Findings suggest the regulation of protein sorting and trafficking in neurons is central to the etiology of PD.

Novel de novo sequence variation in *HNRNPU* gene is associated with generalized epilepsy responsive to ketogenic diet. *R. Veith[1], L. Carey[1], D. Helbling[2], M. Tschannen[2], J. Wendt-Andrae[2], M. Waknitz[2], G. Scharer[1,2].* 1) Pediatrics-Genetics, Children's Hospital of Wisconsin, Milwaukee, WI, United States; 2) HMGC, DNL-Seq Laboratory, Dept. of Pediatrics, Medical College of Wisconsin, Milwaukee, WI, United States.

Infantile and childhood onset seizure disorders and epileptic encephalopathies (EE) are a heterogeneous group of disorders for which there is established evidence of genetic contribution. Novel or de-novo sequence changes play an important role in seizure disorders and have been described in several known and new genes through the use of whole exome sequencing (WES). Our patient is a 27 month old Caucasian female with onset of generalized seizures between 10-12 months of age, which initially appeared to be single febrile events. Mild developmental regression was noted following the second and third seizure. At 12 months the patient experienced her first cluster (afebrile) seizures, was admitted with report of “normal” MRI and EEG (with diffuse slowing), and at that time was started on Phenobarbital. Several antiepileptic drugs were administered, but did not control seizures adequately. During the next 12 months she developed a severe EE and at peak experienced 20-25 seizures per day. The patient empirically began a ketogenic diet at 22 months of age and experienced significant relief of seizures within a month of initiation. This has dramatically improved her clinical course and she now has only 3-4 seizures per day; and has gone for up to 10 days without seizures. Extensive genetic evaluation (including comprehensive epilepsy gene panel), and metabolic work-up did not reveal a diagnosis. WES (SureSelect® v4) was pursued and identified a novel deleterious sequence variant in HNRNPU (p.ARG770TER). This de-novo variant was not detected in both parents or the healthy sister. The variant was also not identified in 10,000 reference exomes or control chromosomes. HNRNPU has been recently published in association with EE via point mutation and microdeletions. Individuals with deletions of chromosome 1q44 have been documented with significant seizure disorder. It has been suspected that an EE gene resides in this region. HNRNPU would be a likely candidate. The known predisposition genes for the EE work in a complex network and HNRNPU directly interacts with other well documented EE genes including PNKP. Interestingly, none of the previously documented cases of HNRNPU associated EE patients have achieved adequate seizure control or significant improvement with traditional pharmacologic management. Based on our patient’s symptomatic relief, ketogenic diet may be a reasonable alternative management for epileptic encephalopathy resulting from HNRNPU deficiency.

3087T

Modifiers of age at onset in spinocerebellar ataxia type 2: a preliminary study in a Brazilian population. *F.dosS. Pereira[1,10], T.L. Monte[4], L.D. Locks-Coelho[1], A.S.P. Silva[1], A.L. Silva[1], O. Barsottini[6], J.L. Pedroso[6], F.R. Vargas[7,8], M.A.F.D. Lima[7], H.V.D. Linden Jr[9], R.M. Castilhos[1,5], M.L. Saraiva-Pereira[1,2,5,10], L.B. Jardim[1,3,4,5,10] on behalf of Rede Neurogenetica.* 1) Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil; 2) Department of Biochemistry, Universidade Federal do Rio Grande do Sul, Brazil; 3) Department of Internal Medicine, Universidade Federal do Rio Grande do Sul, Brazil; 4) Post-Graduation Program in Medical Sciences, Universidade Federal do Rio Grande do Sul, Brazil; 5) Post-Graduation Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Brazil; 6) Department of General Neurology and Ataxias- Discipline of Clinical Neurology of UNIFESP - Escola Paulista de Medicina, Universidade Federal de São Paulo, Brazil; 7) Laboratory of Epidemiology of Congenital Malformations, Fundação Oswaldo Cruz, Rio de Janeiro, Brazil; 8) Departament of Genetic and Molecular Biology, Universidade Federal do Estado do Rio de Janeiro, Brazil; 9) Rehabilitation Centre Dr. Henrique Santillo, Goiânia, Goiás, Brazil; 10) Instituto Nacional de Genética Médica Populacional, Brazil.

The spinocerebellar ataxia type 2 (SCA2) is caused by a CAGn expansion at *ATXN2* gene, and ATXN2 expansions account for 50% of the variability in age at onset (AO). Former reports pointed to CAGn variations and polymorphisms at other genes as responsible for the remaining AO variance. Aims: to address a confirmation study of other polyglutamine tracts and of a mitochondrial DNA polymorphism as modifiers of AO in SCA2 patients. Methods: symptomatic individuals with a molecular SCA2 diagnosis were recruited from Brazil. Capillary electrophoresis was performed to detect CAG lengths at SCA1, SCA2, SCA3/MJD, SCA6 and RAI1 associated genes; the mitochondrial complex I gene polymorphism (10398G>A) was determined by PCR followed by capillary electrophoresis analysis. Pearson correlations with AO were tested against each CAGn for all individuals; the 10398G>A polymorphism of one person per maternal lineage was analysed by t test; all followed by a step-wise linear regression. Results: 83 individuals (33 families and 42 maternal lineages) were studied. Mean (range) AO and CAGn at normal and expanded ATXN2 alleles were 32.45 (3-76) years and 22 (22-33) and 42 (34-67) repeats. At first, AO correlated with the large alleles at *ATXN2* with the short allele of *ATXN2*, and with short allele at *RAI1*. 10398G>A polymorphism was not associated with AO. On step-wise regression, only the correlation with *ATXN2* expanded allele was maintained ($r = -0.78$; $r2 = 0.61$; $p < 0.0001$). Discussion: This data confirms the link between the expanded allele of the ATXN2 and antecipation of AO of symptoms and reveals conflicting results to those previously reported for both the mitochoondrial polymorphism 10398G>A and for the small allele of the *RAI1* gene. Preliminar data should be confirmed by an outlier sampling strategy, in the future.

3088S

Defining the presence of GTF2IRD1 in epigenetic complexes as a means to understand features of Williams-Beuren syndrome. *P. Carmona-Mora[1], F. Tomasetig[1], C.P. Canales[1], A. Alshawaf[2], M. Dottori[2], E.C. Hardeman[1], S.J. Palmer[1].* 1) Cellular and Genetic Medicine Unit, School of Medical Sciences, UNSW Australia, Sydney, New South Wales 2052, Australia; 2) Centre for Neural Engineering, The University of Melbourne, Melbourne, VIC 3010, Australia.

GTF2IRD1 is a member of the *GTF2I* gene family, which lies on chromosome 7 within a 1.8 Mb region that is prone to duplications and deletions leading to a series of physical and neurobehavioural abnormalities. Hemizygous deletions cause Williams-Beuren syndrome (WBS) and duplications cause WBS duplication syndrome. Genotype-phenotype correlations of patients with atypical deletions and knockout mouse models show *GTF2IRD1* as responsible for the craniofacial abnormalities, mental retardation, visuospatial construction deficits and hypersociability of WBS. In order to understand the basis of the phenotypes related to GTF2IRD1, we have studied its molecular function *in vitro*. We evaluated its expression in human ES cell-derived neurons, to correlate it with specific neuronal types and stages of differentiation. Furthermore, a detailed analysis in cell lines of endogenous GTF2IRD1 shows a specific nuclear speckled pattern of expression, colocalizing with markers of gene silencing complexes. To define GTF2IRD1 functional relationships, we used a yeast two-hybrid approach to isolate interaction partners and validated many interactions in mammalian cells. Most of the proteins are involved in chromatin modification and transcriptional regulation in agreement with the nuclear localization data. In addition, several of these partners, such as ZMYM2, ZMYM3, ZC4H2 and DCAF6, were shown to occupy the same nuclear compartment as GTF2IRD1 at the endogenous level. Some of these proteins are involved in histone deacetylase (HDAC) complexes related to neuron-specific gene regulation and others are directly linked to mental retardation through mutations in their encoding gene. We have demonstrated the presence of GTF2IRD1 in chromatin modifier complexes and identified direct associations with HDACs, allowing us to expand its interactional network and propose functional links with specific transcription factors and epigenetic silencing complexes. Within the same context, we also explored GTF2IRD1 capability to bind nucleic acids and tested the dependence of relevant protein-protein interactions upon such binding. Our data indicates that GTF2IRD1 forms complexes with DNA binding and chromatin modifying proteins that direct gene regulation through epigenetic mechanisms. For the first time, we provide an empirical account of the molecular basis of GTF2IRD1 function and permit the construction of testable hypotheses regarding its role in WBS and 7q11.23 duplication syndrome.

Generation of a comprehensive panel of patient-derived pluripotent stem cells to dissect oligodendrocyte dysfunction in the pediatric myelin disorder Pelizaeus-Merzbacher Disease. *Z. Nevin[1], R. Karl[1], G. Hobson[2], P. Tesar[1,3].* 1) Genetics and Genome Sciences, Case Western Reserve University School of Medicine, Cleveland, OH; 2) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 3) New York Stem Cell Foundation, New York, NY.

Patient-derived induced pluripotent stem cells (iPSCs) have become integral tools for parsing the molecular biology of complex human genetic disorders. Pelizaeus-Merzbacher Disease (PMD [MIM 312080]) is a pediatric leukodystrophy affecting central nervous system myelin that results in severe motor impairment, intellectual delay, and premature death and has no available treatment. Though PMD is a single-gene disorder, it exhibits a spectrum of phenotypes and clinical severities attributed to over 200 different mutations in the essential myelin gene *PLP1* (MIM 300401), which encodes for two protein isoforms, proteolipid protein 1 (PLP1) and DM20. Protein misfolding and endoplasmic reticulum stress have been implicated in the pathogenesis of PMD in transgenic animal models overexpressing PLP1, but this may not hold true for the many various point mutations and gene deletions identified in patients. Detailed investigations of PLP1's normal function and the etiology of PMD are further complicated by a lack of access to primary human oligodendrocytes, the only cell type in which PLP1 protein is known to be expressed. To address this need, we have generated a large panel of patient-derived iPSCs from children with unique duplication, triplication, deletion, and point mutations in *PLP1* that encompass the genotypic and phenotypic variation seen in patients. Using new methods optimized in our lab, we have derived pure populations of oligodendrocytes and oligodendrocyte progenitors from these iPSCs in order to dissect individual patient phenotypes at a cellular level. Access to this unique resource is now allowing us to identify the cellular pathways and processes disrupted by particular *PLP1* mutations, which in turn will inform the pursuit of patient-specific chemical and genetic therapies.

The NINDS Repository collection of patient-derived fibroblasts and induced pluripotent stem cells for neurodegenerative disease research. *C.A. Pérez[1,4], S. Heil[1,4], J. Santana[1,4], C. Grandizio[2,4], S. Gandre-Babbe[2,4], K. Hodges[3,4], M. Sutherland[5], R.A. Corriveau[5], C. Tarn[1,4].* 1) NINDS Repository; 2) Stem Cell Biobank; 3) Cell Culture Laboratory; 4) Coriell Institute for Medical Research, Camden, NJ; 5) National Institute of Neurological Disorders and Stroke - NIH, Bethesda, MD.

Induced pluripotent stem cells (iPSCs) reprogrammed from patient-derived primary fibroblasts have become an increasingly utilized and needed resource for the study of human disease and have proven especially valuable in studying neurodegenerative disorders for which disease models are difficult to establish. The National Institute of Neurological Disorders and Stroke (NINDS) Repository is a public resource established in 2002 aiming to provide a centralized and open collection of biological samples (DNA, lymphoblastoid cell lines, fibroblasts, iPSCs, biofluids such as plasma, serum, cerebrospinal fluids, and urine) and associated de-identified clinical data from a diverse population of patients and normal controls. Since 2011, the NINDS Repository has added to its web-based catalog (http://ccr.coriell.org/NINDS) close to 50 iPSC and 165 fibroblast lines. Most iPSC lines are contributed by Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS) or Huntington's disease (HD) investigators from NINDS-sponsored Stem Cell Consortia. By making available to the research community neurodegenerative disease iPSCs and fibroblasts, the NINDS Repository continues to fulfill the NINDS mission of reducing the burden of neurological disease - a burden borne by every age group, by every segment of society, by people all over the world. To ensure the quality of these valuable resources, all iPSCs and fibroblasts submitted to the NINDS Repository by iPSC Consortia and other investigators undergo rigorous quality assessments (viability, pluripotency, karyotyping, differentiation status, gene expression analysis, sterility) prior to distribution by the NINDS repository. The results are summarized in a Certificate of Analysis and/or displayed on the web-based catalog along with the recommended culturing protocol. The NINDS Repository fibroblast and iPSC collections include mostly cell lines bearing specific genetic mutations associated with PD, ALS, HD, frontotemporal degeneration, or Alzheimer's disease, as well as samples derived from neurologically normal controls. For certain affected individuals, the parental fibroblast, corresponding iPSC line, and whole blood DNA are available. The NINDS Repository serves as a unique and effective centralized resource where these iPSCs, fibroblasts and their de-identified phenotypic data, are available to basic and applied research investigators worldwide.

3091S

Human iPSC model of the Ras/MAPK pathway role in neurodevelopmental disorders. *E. Yeh[1], Z.Y. Wu[1], C. Tom[1], B. Adviento[1], K.A. Rauen[2], L.A. Weiss[1].* 1) Department of Psychiatry, UCSF, San Francisco, CA; 2) Department of Pediatrics, UC Davis, Sacramento, CA.

Germline mutations in the primordial Ras/MAPK pathway cause a class of human genetic syndromes termed RASopathies characterized by overactivation of this pathway. Cardiofaciocutaneous syndrome (CFC) is a rare RASopathy characterized by heart defects, a distinctive facial appearance, and ectodermal abnormalities. Neurological abnormalities include low IQ, learning disability, and speech delay. Autistic traits are present in 54-64% of the CFC patients, the highest percentage among RASopathies. To better understand the role of the Ras/MAPK signaling pathway in neurodevelopment, we established induced pluripotent stem cell (iPSC) lines from skin fibroblasts from 3 CFC patients carrying the most common mutation ($BRAF^{Q257R}$, present in 29% of the patients) and 3 sex- and age-matched controls. Next, we submitted the iPSC lines to neural differentiation and generated neural progenitor cells (NPC). Finally, we induced NPC to differentiate into neurons for characterization. $BRAF^{Q257R}$ NPC showed higher proliferation rates compared to wild-type (WT) NPC, as evidenced by higher percentage of KI67 positive cells (74.9±6.6% vs 50.7±7.5%, p=0.028) and shorter doubling time (41.9±7.8 vs 85.6±20.8 h, p=0.038). Seven days after induction, $BRAF^{Q257R}$ and WT cultures expressed similar levels of the neuron-specific markers Beta III tubulin, MAP2 and Tau protein. However, image analysis revealed that $BRAF^{Q257R}$ neurons had more neurites (3.5±0.1 vs 2.9±0.1 neurites/cell, p=0.0047) and longer neurites (156.2±17.6 vs 79.8±9.5 μm, p=0.0096). The early maturation in $BRAF^{Q257R}$ neurons was further evidenced by a higher number of cells positive for TBR1, a layer 5/6 cortical marker (44.07±5.8% vs 16.33±5.3%, p=0.0105). The higher NPC proliferation rate we observe is particularly interesting as >50% of CFC patients have macrocephaly. Previous literature shows that *Braf* null mice have shorter neurites and kinase-activated *Braf* mice have longer neurites, which are consistent with our observations. In addition, increased numbers of neurites and longer neurites are indicators of neuronal differentiation and maturation, which was supported by increased presence of a cortical layer 5/6 marker. Thus, we showed for the first time in human cells that a CFC mutation in *BRAF* is associated with early neuronal maturation. This study will help us obtain insight not only into the pathophysiology of CFC, but also into the role of Ras/MAPK pathway in common disorders, like Autism Spectrum Disorders.

3092M

New insights into the biological role of VAX2 in human, in health and disease. *G. Alfano[1], A.Z Shah[1], N.H. Waseem[1], A.R. Webster[1,2], S.S. Bhattacharya[1]*. 1) Institute of Ophthalmology, UCL, London EC1V 9EL, UK; 2) Moorfields Eye Hospital, London EC1V 2PD, UK.

Purpose: VAX2 (MIM 604295) is a transcription factor expressed in the ventral region of the prospective neural retina in vertebrates and is required for ventral eye specification. Its genetic inactivation in mouse leads to an incompletely penetrant ocular coloboma. Based on the similarities between the mutant mouse phenotype and the clinical features of isolated coloboma in human, VAX2 represents a good candidate gene for this human condition. Thus far, however, no mutations affecting VAX2 in coloboma patients have been reported. Interestingly, recently it has been shown that Vax2 in mouse plays a key role in ensuring appropriate gene expression in cone photoreceptor cells. Despite a wide range of studies in vertebrates its function in human is still poorly understood. This study was undertaken to better elucidate the role of VAX2 in human in health and disease. Methods: VAX2 transcripts were obtained by RT-PCR on cDNA from human tissues and cultured cells. These transcripts were sub-cloned into mammalian expression vectors for in vitro analysis. Variant proteins were generated by site-directed mutagenesis. A cohort of cone-rod dystrophy patients was screened for variant identification using Sanger sequencing. Results: It was observed that VAX2 is highly expressed in neuronal tissues and cultured cell lines. Two spliced variants were detected: isoform-1 (NM_012476), and a novel transcript (isoform-2), mainly expressed in retina and predicted to encode a shorter protein of 150 amino acids. In vitro exogenous expression of tagged protein isoforms showed differential localization potentially underlying distinct biological roles. Isoform-1 localizes to the nucleus while isoform-2 is widespread throughout the cell. The involvement of Vax2 in cone specific gene expression suggested screening of patients with cone-rod dystrophy. Sequence analysis revealed a heterozygous change c.416T>G (p.Leu139Arg) in one patient. Characterization of this variant showed damaging effects on protein localisation and is therefore suggestive of a functional defect, with potential involvement in the disease phenotype. Conclusions: Our data suggest that in addition to being a transcription factor VAX2 could be involved in other molecular pathways due to the short isoform in the human. Moreover, VAX2 may be involved in cone photoreceptor cell biology. In summary, our findings raise new questions about the VAX2 gene and its biological role in health and disease.

3093T

Digital gene expression differences in the OVT73 ovine model of Huntington's Disease. *S.J. Reid[1], R. Brauning[2], P. Maclean[3], S. Patassini[1], R.R. Handley[1], P. Tsai[4], H.J. Waldvogel[4], J.F. Gusella[5], M.E. MacDonald[5], R.L.M. Faull[1], R.G. Snell[1], and.the H.D.S.C.R.G[6]*. 1) Centre for Brain Research, The University of Auckland, Auckland, Auckland, New Zealand; 2) AgResearch, Invermay Agricultural Centre, Mosgiel, New Zealand; 3) AgResearch, Ruakura Research Centre, Hamilton, New Zealand; 4) School of Biological Sciences, The University of Auckland, Auckland; 5) Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston; 6) Huntington's Disease Sheep Collaborative Research Group (10.3233/jhd-130067).

In order to better understand the early molecular mechanisms of Huntington's Disease, we examine the OVT73 transgenic sheep for progressive histopathological and molecular changes. These animals express at modest levels the full length human huntingtin protein with 73 glutamine repeats [1], demonstrate reduced striatum levels of $GABA_A$ α1 receptor, cortical huntingtin aggregates [2] and an early circadian abnormality [3]. The sheep are healthy and visibly indistinguishable from control South Australian Merino. They present an opportunity to better understand and utilise the pre-symptomatic phase of Huntington's Disease.

To identify genome-wide gene expression differences, Illumina RNA-seq data (2.3×10^9 50bp PE reads) was collected from ribosomal depleted total RNA isolated from anterior striatum tissue of twelve 5-year old OVT73 sheep (6 transgenic, 6 control). For assembly of a *de-novo* transcriptome, further reads (1.3×10^9 100bp PE) were collected from brain and liver total RNA from fetal and neonate sheep. Differentially expressed transcripts in OVT73 were identified using both genome based approaches and the assembled transcriptome. A selection of these annotated transcript findings will be presented, including OXTR and AVPR1A which may relate to the circadian abnormality seen in the OVT73 animals.

De Novo mutations in TEAD1 and OCEL1 in non-X linked Aicardi Syndrome. *I. Schrauwen[1,2,3], S. Szelinger[1,2], A.L. Siniard[1,2], J.J. Corneveaux[1,2], A. Kurdoglu[1,2], R. Richholt[1,2], M. De Both[1,2], I. Malenica[1,2], S. Swaminathan[1,2], S. Rangasamy[1,2], N. Kulkarni[4], S. Bernes[4,5], J. Buchhalter[6], K. Ramsey[1,2], D.W. Craig[1,2], V. Narayanan[1,2], M.J. Huentelman[1,2]*. 1) Dorrance Center for Rare Childhood Disorders, Translational Genomics Research Institute, Phoenix, AZ; 2) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 4) Phoenix Children's Hospital, Phoenix, AZ; 5) MIHs integrated program, Phoenix, AZ; 6) Alberta Children's Hospital , Calgary, Alberta, Canada.

Aicardi syndrome (AIC) is a congenital neurodevelopmental disorder characterized by infantile spasms, agenesis of the corpus callosum and chorioretinal lacunae. There is a wide range in severity of these classic symptoms however, with chorioretinal lacunae as the most constant feature of the disease. Although cytogenetic studies have linked AIC to the X-chromosome, no gene has been identified to date, and little is known about the pathogenic mechanisms underlying the disease. Recently, XY males with the disease have been described as well, suggesting the presence of genetic heterogeneity. In this study, we investigated 10 female children diagnosed with AIC, and their parents, by exome/genome sequencing. In two cases, we identified de novo mutations in the autosomal genes TEAD1 and OCEL1, both expressed and important in the retina and brain. The mutation in TEAD1 is a nonsense mutation (p.Trp206Ter; CADD score = 40), and the mutation in OCEL1 is a non-synonymous mutation (p.Ala167Thr; CADD score = 15.3), which is predicted damaging according to MutationTaster, LTR, Polyphen2, and affects a highly conserved residue (PhyloP = 2.1). A missense mutation in TEAD1 has previously been associated with Sveinsson's chorioretinal atrophy, which is characterized by chorioretinal degeneration. In a second part of this study, we performed RNA-sequencing on RNA extracted from blood from 9 of these cases, their parents and unrelated controls. We found that altered expression of genes associated with neuronal synaptic plasticity is an important underlying potential pathogenic mechanism shared among cases, in addition to several seizure-associated genes and retinal developmental genes. Last, we found 1 case with skewed X-inactivation (XCI), supporting the idea that non-random XCI might be important in AIC, as previously reported. In conclusion, this is the first report of genes mutated in AIC, and proposal of putative pathogenic mechanisms underlying AIC. Our data suggest that AIC is a genetically heterogeneous disease and is not entirely restricted to the X-chromosome. This raises the important possibility that mutations in the genes detailed here may be present in male patients with similar phenotypic presentations. Investigation of the pathological mechanisms that lead to disease (retinal and neuronal) through OCEL1 and TEAD1 dysfunction might reveal novel therapeutic avenues for treatment and symptomatic management of the disease.

3095M

Absence of ER cation channel *TMEM38B*/TRIC-B causes recessive osteogenesis imperfecta by dysregulation of collagen post-translational modification. *W.A. Cabral[1], E.N. Makareeva[2], M. Ishikawa[3], A.M. Barnes[1], M.A. Weis[4], F. Lacbawan[5], D.R. Eyre[4], Y. Yamada[3], S. Leikin[2], J.C. Marini[1].* 1) Bone & Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD, USA; 2) Section on Physical Biochemistry, NICHD, NIH, Bethesda, MD, USA; 3) Molecular Biology Section, NIDCR, NIH, Bethesda, MD, USA; 4) Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA; 5) Department of Medical Genetics, Children's National Medical Center, Washington DC, USA.

A novel form of recessive osteogenesis imperfecta (OI) has been reported in Israeli and Saudi Bedouins, caused by homozygous deletion of exon 4 and surrounding intronic sequence of *TMEM38B*. *TMEM38B* encodes TRIC-B, an integral ER membrane protein proposed to facilitate Ca^{++} release from intracellular stores. However, the molecular mechanisms through which this founder mutation causes OI are unknown. We identified a 20 month-old girl with moderately severe OI who is the offspring of consanguineous parents from Saudi Arabia, and is homozygous for the *TMEM38B* founder mutation. The proband presented with growth deficiency, osteopenia, recurring long bone fractures and blue sclerae. Proband *TMEM38B* transcripts are 25% of normal control level and include six spliced forms. Although one minor transcript is in-frame, absence of TRIC-B protein was confirmed by immunoblot. Consequently, proband cells have decreased intracellular and ER luminal Ca^{++} concentrations, which were more rapidly depleted upon ATP-induced Ca^{++} efflux from the ER. The lower Ca^{++} level does not involve changes in expression or stability of SERCA2b or IP3R, the ion channels involved in ER Ca^{++} loading and release, respectively. Furthermore, depletion of Ca^{++} is associated with ER stress, activation of ATF4 translation, and dysregulation of type I collagen synthesis. Although proband cells have normal PDI levels, the 20-minute delay in procollagen chain assembly into heterotrimeric molecules is consistent with sequestration of PDI by calreticulin in low Ca^{++} conditions. Abnormal modification of proband collagen is evident by increased electrophoretic migration of alpha chains on SDS-Urea PAGE, consistent with a 30% reduction in collagen lysine hydroxylation, despite increased LH1 expression. The presence of lower stability species (30-40% of secreted collagen) on DSC, decreased procollagen processing and increased intracellular accumulation of BiP, indicate abnormal procollagen conformation. However, extracellular matrix deposited by proband fibroblasts contained only collagen with normal thermal stability, and was associated with 30% reduction of crosslinked collagen in matrix. These data support a role for TRIC-B in maintaining intracellular Ca^{++}, and demonstrate that absence of TRIC-B causes OI by dysregulation of multiple Ca^{++}-regulated collagen-specific chaperones and modifying enzymes in the ER. Therefore, the mechanism of TRIC-B absence falls within the collagen-related paradigm of OI.

Exome sequencing identifies locus heterogeneity in multiple epiphyseal dysplasia. *K. Balasubramanian[1], M.J. Bamshad[2,3], D.A. Nickerson[3], R.S. Lachman[5], D.H. Cohn[1,2,4], University of Washington Center for Mendelian Genomics.* 1) Department of Molecular, Cell, and Developmental Biology, University of California, Los Angeles, Los Angeles, CA; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) Department of Orthopaedic Surgery and Orthopaedic Hospital Research Center, University of California, Los Angeles, Los Angeles, CA; 5) International Skeletal Dysplasia Registry, University of California, Los Angeles, Los Angeles, CA.

Multiple Epiphyseal Dysplasia (MED) is a relatively common skeletal dysplasia associated with mild short stature and early-onset osteoarthritis. Mutations in five genes have been associated with dominant forms of the disease: cartilage oligomeric matrix protein (*COMP*), matrilin-3 (*MATN3*), and the three type IX procollagen genes (*COL9A1*, *COL9A2*, and *COL9A3*). All of these genes are selectively expressed in cartilage and encode structural molecules of the cartilage extracellular matrix. A clinically distinct recessive form of MED results from mutations in a widely expressed gene, Solute Carrier Family 26 Member 2 (*SLC26A2*), which encodes a protein required for post-translational sulfation. In about 15% of MED cases the molecular basis of disease remains unknown, implying further genetic heterogeneity.

To identify additional disease loci, exome sequencing of eight MED families was conducted. This cohort included four sporadic cases hypothesized to represent dominant MED, two recurrent cases thought to represent recessive MED, and two large families with clear dominant inheritance. In three cases, mutations in the known genes were identified. A novel de novo c.949C>T mutation in *COMP* that results in the protein change p.Asp317Asn in the calmodulin-like repeats was identified in one sporadic case. A recurrent c.518G>T mutation resulting in the p.Ala173Asp amino acid change and a novel c.326A>T mutation resulting in the p.Ile109Lys protein change in *MATN3*, both of which target the Von Willebrand Factor-A domain in which all previous *MATN3* MED mutations have been found, were identified in the two large families with dominant MED.

The remaining five cases were negative for mutations in the known genes, but heterozygosity for two novel de novo variants was identified in one case: a c.871G>T missense variant resulting in a p.Val291Phe protein change in *PTH2R*, a G protein-coupled receptor expressed in the endochondral growth plate, and a c.734delT frameshift variant in *PRICKLE1*, a protein involved in the WNT5A noncanonical planar cell polarity pathway. Screening of 32 additional MED cases did not detect mutations in either *PTH2R* or *PRICKLE1*, suggesting that mutations in one of these genes may be a rare cause of MED. Causative variants were not found in the remaining 4 cases, demonstrating further locus heterogeneity in MED.

Girisha[1].* 1) Department of Medical Genetics, Kasturba Medical College, Manipal University, Manipal, India; 2) Pediatric Orthopedics services, Department of Orthopedics, Kasturba Medical College, Manipal University, Manipal, India; 3) Clinical Genetics Unit, Christian Medical College, Vellore, India; 4) Department of Medical Genetics, Childs Trust Medical Resaerch Foundation, Kanchi Kamakoti childs Trust Hospital Chennai, India; 5) Department of Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India; 6) Department of Pediatric Genetics, Amrita Institute of Medical Sciences and Research Center, AIMS Ponekkara, Cochin, India; 7) Centre for Human Genetics, Bangalore, India; 8) Division of Genetics, Department of Pediatrics, AIIMS, New Delhi, India; 9) Centre of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, India; 10) Department of Pediatrics, JJM Medical College, Davanagere, India; 11) Department of Pediatrics, PGIMER, Chandigarh, India; 12) Vivekananda Institute of Medical Sciences, Kolkata, India; 13) Department of Medical Genetics, Nizam's Institute of Medical Sciences, Hyderabad, India; 14) Department of Rheumatology, Madras Medical College, Chennai, India; 15) Department of Pediatrics, SAT Hospital, Government Medical College, Trivandrum, India; 16) Diagnostics Division, Centre for DNA Fingerprinting and Diagnostics, Hyderabad, India.

A small subset of arthropathies is monogenic. We aimed to analyze the mutations underlying all the conditions with arthropathy listed under the different groups in the Nosology and Classification of Genetic Skeletal Disorders (2010). The list includes progressive pseudorheumatoid dysplasia; chronic infantile neurologic cutaneous articular syndrome; sterile multifocal osteomyelitis, periostitis, and pustulosis; familial hyperphosphatemic tumoral calcinosis; infantile systemic hyalinosis; familial digital arthropathy with brachydactyly; multicentric osteolysis, nodulosis and arthropathy; multicentric carpal-tarsal osteolysis with and without nephropathy; stickler syndrome type 1, 2, 3 and type 4. The clinical and molecular spectrum of these syndromes is being studied. We recruited 43 families with progressive pseudorheumatoid dysplasia; 11 families with multicentric osteolysis nodulosis and arthropathy; 2 families with familial hyperphosphatemic tumoral calcinosis; one family each with chronic infantile neurologic cutaneous articular syndrome and infantile systemic hyalinosis. We identified 13 mutations (6 novel: c.49-1G>A, p.S177*, p.C209Mfs*21, p.C247Lfs*31, p.I260Nfs*17, p.Q269Nfs*44 and 5 known: p.C52*, p.C78Y, p.G226V, p.R230Lfs*4, p.C247Lfs*31, p.C337Y) in *WISP3* gene. In *MMP2* gene we identified 6 mutations: 5 are novel (p.S304Pfs*115 and p.N430Tfs*68, p.R101C and p. G410V, p.E231*) and one known (p.R101H). These are the preliminary results of our cohort of patients with inherited arthropathies. We wish to extend this study by collaborating with national and international investigators and hope to explore the genetic bases of Mendelian arthropathies.

3098M

XYLT1 mutations impact on cellular proteoglycan biosynthesis leading to Desbuquois dysplasia type 2. *C. Huber[1], C. Bui[1], B. Tuysuz[2], Y. Alanay[3], C. Bole-Feysot[4], J. Leroy[5], G. Mortier[6], P. Nitschke[7], A. Munnich[1], V. Cormier-Daire[1].* 1) Department of Genetics, INSERM U781, Université Paris Descartes- Sorbonne Paris Cité, Institut Imagine, Hôpital Necker Enfants Malades (AP-HP), Paris, 75015, France; 2) Istanbul University, Cerrahpasa Medical Faculty, Department of Pediatric Genetics, Istanbul, 34098, Turkey; 3) Acibadem University, School of Medicine, Department of Pediatrics, Pediatric Genetics Unit, Istanbul, 34457, Turkey; 4) Plateforme de Génomique, Fondation IMAGINE, Paris, 75015, France; 5) Greenwood Genetic Center, Greenwood, South Carolina 29646, USA; 6) Department of Medical Genetics, Antwerp University Hospital and University of Antwerp, Edegem, 2650, Belgium; 7) Plateforme de Bioinformatique, Université Paris Descartes, Paris, 75015, France.

Desbuquois dysplasia (DBQD) is a severe chondrodysplasia belonging to the multiple dislocation group and characterized by short stature, joint laxity and advanced carpal ossification. Based on the presence of additional hand anomalies, we have previously distinguished DBQD type 1 and identified CANT1 (calcium activated nucleotidase 1) mutations as responsible for DBQD type 1. We report here the identification of 5 distinct homozygous xylosyltransferase 1 (XYLT1) mutations in 7 DBQD type 2 cases from 6 consanguineous families. Among the 5 mutations, 4 were expected to result in loss of function and a drastic reduction of XYLT1 cDNA level was demonstrated in 2 cultured individual fibroblasts. No significant clinical or radiological differences could be found with the remaining 14 DBQD type 2 cases with unknown molecular bases. However, long term follow up of XYLT1 mutated individuals emphasizes the severity of the short stature (< -6 SD) contrasting with obesity, lower limb and foot deformities requiring often repeated surgeries and intellectual disability (5/7). Interestingly, respiratory distress was present at birth in 4/7 cases and spontaneously resolved in the first years of life but thorax narrowness persisted in the eldest children. Since xylosyltransferase 1 (XT-I) catalyzes the very first step in proteoglycan (PG) biosynthesis, we further demonstrated in the two individual fibroblasts a significant reduction of cellular PG content, as well as an important reduction of secreted and large chondroitin sulphate PG production. A recent study published by Mis et al., describe the phenotype of the pug mouse mutant carrying a homozygous missense mutation in Xylt1 and characterized by a disproportionate dwarfism. They observed only 20% Xylt1 activity leading to a reduction of PG processing sufficient to disrupt premature chondrocyte maturation. Finally, our findings of XYLT1 mutations in DBQD type 2 further support a common physiological basis involving PG synthesis in the multiple dislocation group of disorders. This observation sheds light on the key role of the XT-I during the ossification process.

3099T

LOX, among the LOX family proteins, plays a key role in osteoblast differentiation. *Y. Kim, M. Salahuddin.* Dept Biochem, Wonkwang Univ Sch Med, Iksan, Jeonbuk, South Korea.

The lysyl oxidase (LOX) family is an emerging family of amine oxidases that play an essential role in the formation of collagen fibrils in the extracellular matrix. So far, five *LOX* family genes have been identified in humans, encoding LOX and LOX-like proteins (LOXL, LOXL2, LOXL3, and LOXL4). During osteoblastogenesis, LOX regulates the formation of collagen fibrils that function as a three-dimensional scaffold for mineralization. To assess the functional roles of the LOX family members in osteoblastogenesis, we investigated the temporal expression of this gene family as a function of phenotypic development during osteoblastic differentiation of primarily cultured mouse calvaria cells. Among the *LOX* family members, only *LOX* showed prominent expression during osteoblast differentiation. During osteoblast differentiation of the mouse calvaria cells, *LOX* showed the highest level of expression on day 9 in both RT-PCR and Western blot analyses. *COL1A2* that encodes the 2-chain of human collagen type I showed a similar expression pattern to that of LOX, reaching the highest level on day 9. The total amine oxidase activity of the differentiating osteoblast cells also reached the greatest level on day 9. Presence of BAPN, a well-known specific inhibitor of LOX-derived amine oxidase activity, significantly inhibited both mineral nodule formation and expression of osteoblastic marker genes during the differentiation. These findings suggest that the LOX-mediated organization of collagen fibrils in extracellular matrices of differentiating osteoblasts is an important regulator of osteoblastogenesis. Further studies on the functional regulation of LOX in osteoblastogenesis will provide valuable information for better understanding the molecular mechanisms associated with aberrant formation of bone matrix.

Identification of mutations in patients with osteogenesis imperfecta from Russia. *D.D. Nadyrshina[1], R.I. Khusainova[2], E.K. Khusnutdinova[1,2].* 1) Biological Department, Bashkir State University, Ufa, RE., Russian Federation; 2) Laboratory of human molecular genetics, Institute of Biochemistry and Genetics, Ufa, Russian Federation.

Osteogenesis imperfecta (OI) is a clinically and genetically heterogeneous brittle bone disorder. Whereas dominant OI is mostly due to heterozygous mutations in either *COL1A1* or *COL1A2* encoding type I procollagen, recessive OI is caused by mutations in genes encoding proteins involved in type I procollagen processing or chaperoning. The aim of our study was to identify mutations in *COL1A1, COL1A2, CRTAP, LEPRE1, PPIB* and *SERPINF1* genes in Russian OI patients. We examined 78 patients with OI and 100 healthy controls corresponding by age, gender, ethnicity and place of residence. We sequenced the coding and exon-flanking regions of *COL1A1, COL1A2, CRTAP, LEPRE1, PPIB* and *SERPINF1* genes. We identified five distinct mutations, undescribed before. For the first time previously unreported nonsense mutation c.967G>T (p.Gly323X) in *COL1A1* gene was identified in heterozygous state in two Russian patients, the novel frameshift mutation c.3541insC (p.Gly1181ArgfsX38) in *COL1A1* gene was observed in Yakut patient, the splicing mutation c.1724+4G>A in *LEPRE1* gene was identified in two patients from Tatar population. And novel compound heterozygous mutations (c.913C>G (p.Leu305Val) of *SERPINF1* gene and c.641T>C (p.Val214Ala) of *CRTAP* gene) was observed in three patients from Bashkir population. We also detected three previously described nonsense mutations in five Russian patients: c.1081C>T (p.Arg361X), c.1243C>T (p.Arg415X) and c.2869C>T (p.Gln957X), two frameshift mutations in two Tatar patients: c.579delT (p.Gly194ValfsX71) and c.2444delG (p.Gly815AlafsX293) and one splicing mutation in one Yakut patient: c.4005+1G>T. One frameshift mutation (c.579delT (p.Gly194ValfsX71), three nonsense mutations (c.967G>T (p.Gly323X), c.1081C>T (p.Arg361X), c.2869C>T (p.Gln957X)) and one splice mutation (c.4005+1G>T) were identified in patients with OI type I. Two mutations (c.2444delG (p.Gly815AlafsX293) and c.3540_3541insC (p.Gly1181AlafsX38)) occurred in sporadic cases of OI type I, whereas c.1243C>T (p.Arg415X) mutation - of OI type III. The mutation c.1724+4G>A were identified in patients with OI type VIII. In conclusion, the present study revealed 8 mutations in *COL1A1* gene, 1 mutation in *SERPINF1* gene, 1 mutation in *LEPRE1*, 1 mutation in *CRTAP* gene, five of them was not observed before and no mutations in *COL1A2* and *PPIB* genes in Russian patients with OI. Future research will focus on other genes responsible for OI development in Russian patients.

3101M

Two Distinct Mutations in *IFITM5* Causing Different Forms of Osteogenesis Imperfecta Using Reciprocal Mechanisms. *A. Reich[1], AM. Barnes[1], CR. Farber[2, 3], P. Becerra[4], F. Rauch[5], WA. Cabral[1], A. Bae[1], FH. Glorieux[5], TL. Clemens[6], JC. Marini[1].* 1) NICHD, NIH, Bethesda, MD; 2) Center for Public Health Genomics, Univ Virginia, Charlottesville, VA; 3) Depts Public Health Sciences, Biochemistry & Mol Genet, UVA, Charlottesville, VA; 4) Section on Protein Structure and Function, LRCMB, NEI, NIH, Bethesda, MD; 5) Shriners Hosp for Children and McGill Univ, Montreal, Canada; 6) Dept Orthopaedic Surgery, Johns Hopkins Sch Med, Baltimore, MD.

Osteogenesis imperfecta (OI) type V is caused by a recurrent dominant mutation (c.-14C>T) in *IFITM5*, which encodes BRIL, a transmembrane ifitm-like protein most strongly expressed in osteoblasts, whose expression coordinates with mineralization. Patients with type V OI have distinctive clinical manifestations with overactive bone mineralization and include mesh-like lamellation on bone histology. Recessive null mutations in *SERPINF1* cause OI type VI, which impairs mineralization. Type VI OI patients have absence of serum PEDF, elevated alkaline phosphatase (ALPL) as children, and bone histology with broad unmineralized osteoid and fish-scale pattern. We identified a 25-year-old woman with severe OI, who had multiple features of type VI OI. Her dermal fibroblasts (FB) and cultured osteoblasts (OB) displayed minimal secretion of PEDF, but her serum PEDF was normal. *SERPINF1* sequences were normal despite bone histomorphometry typical of type VI OI, and elevated childhood serum ALPL. Exome sequencing yielded a de novo mutation in IFITM5 in one allele of the proband, causing a p.S40L substitution in the BRIL intracellular domain, despite her not having type V OI characteristics. In OB with the *IFITM5* p.S40L mutation, *IFITM5* expression was normal, as was BRIL protein level on western blot and in permeabilized OB by microscopy. Notably, *SERPINF1* expression was decreased in p.S40L OB, and PEDF was barely detectable in conditioned media of S40L cells. OB with the S40L mutation also had decreased expression of ALPL and osteocalcin (OCN), as seen in primary PEDF defects. Conversely, OB from type V OI, with 5 residues added to the N-terminus of BRIL, have increased *SERPINF1* expression and PEDF secretion during differentiation, and increased ALPL and OCN expression. The *IFITM5* mutations also have opposite effects on OB mineralization in culture - OB with the 5'-terminal mutation have increased mineralization during differentiation, while mineralization was decreased in S40L OB. OB from both mutations share a collagen related defect, with decreased expression and secretion of COL1A1. Together, these data show that 2 distinct mutations in *IFITM5* generated different forms of OI with distinctive phenotypes using reciprocal mechanisms; the type V OI and p.S40L BRIL are gain- and loss-of-function mutations, respectively. Furthermore, BRIL and PEDF have a relationship that connects the genes for types V and VI OI and their roles in bone mineralization.

3102T

Identification and Genetic Characterization of a Mysterious Crippling Disorder of Arai Village, J&K, India. *S. Sharma[1], A. Mahajan[2], P. Kumar[3], M.K. Dhar[2], S. Razdan[4], K. Thangaraj[5], C. Wise[6], S. Ikegawa[7], K.K. Pandita[4], E. Rai[1].* 1) School of Biotechnology, Shri Mata Vaishno Devi University, Katra, J&, India; 2) School of Biotechnology, University of Jammu, Jammu, J&, India; 3) Human Genetic Research cum Counselling Centre, University of Jammu, Jammu, J&, India; 4) Acharya Shri Chander College of Medical Sciences, Jammu, J&, India; 5) Centre for Cellular and Molecular Biology, Hyderabad, A.P, India; 6) Texas Scottish Rite Hospital for Children, Dallas, Texas, USA; 7) Laboratory for Bone and Joint Diseases, RIKEN Center for Integrative Medical Sciences,Tokyo, Japan.

Clinical features of rare disorders are very often poorly understood due to their low prevalence. Quite a few times, these rare disorders remain uncharacterized, or patients are misdiagnosed and get poor medical attention. A mysterious skeletal disorder that remained unidentified for decades and rendered many people physically challenged and disabled for life has been reported in an isolated remote village 'Arai' of Poonch district of Jammu and Kashmir state, India. The typical phenotypic characteristics shared among the affected included: pain, kyphoscoliosis, fatigability, muscular weakness, progressive restriction of joint movement, stiffness and swelling at several joints, including the proximal and distal interphalangeal joints. This village is located deep in mountains, and the population residing in the region is highly consanguineous. Combining multiple lines of evidence (familial histories and genetic data, clinical features, radiological and biochemical data and phenotypic features), we identified the disorder as a recessive hereditary skeletal disease "Progressive Pseudorheumatoid Arthropathy of Childhood" (PPAC) also known as "Spondyloepiphyseal Dysplasia Tarda with Progressive Arthropathy" (SEDT-PA). Typically a very rare disorder [for example, with an estimated frequency one per million in UK], in our survey, of this village with a total population of approximately 5000 individuals, we observed about 70 affected people. Mutations in one reported gene "** WISP3**" are known to be responsible for causing of PPAC. Therefore, we sequenced coding and UTR regions of this gene of two multigenerational extended families from the village. We found a novel splice site mutation at position c.643+1G>A that perfectly segregated with the disease in one pedigree and is most plausibly the cause of disease in this family. Interestingly, the affected in second family also shared identical clinical characteristics and disorder showed similar recessive inheritance. However, *WISP3* was negative for co-segregating mutations in the second family suggesting the existence of a different candidate gene for SEDT-PA. Therefore, we are using Next Generation (exome) Sequencing as a promising option and pursuing it. This genetic characterization will aid in molecular diagnosis and genetic counseling, critically required to curb the disorder and to prevent its appearance in future generations in the population.

3103S

Novel mutation in *RUNX2/CBF-alpha-1* with alanine tract expansion from Japanese cleidocranial dysplasia patient. *A. Shibata[1, 2], J. Machida[1, 3], S. Yamaguchi[1, 4], M. Kimura[1, 5], T. Tatematu[1, 2], H. Miyachi[1], Y. Higashi[2], A. Nakayama[6], K. Shimozato[1], Y. Tokita[1, 2].* 1) Oral and Maxillofacial Surgery, school of Dentistry, Aichi-Gakuin University, Nagoya, Japan; 2) Department of Perinatology, Institute of Developmental Research, Aichi Human Service Center, Kasugai, Japan; 3) Department of Oral and Maxillofacial Surgery, Toyota Memorial Hospital, Toyota, Japan; 4) Department of Dentistry and Oral surgery, Aichi Children's Health and Medical Center, Obu, Japan; 5) Department of Dentistry Oral and Maxillofacial Surgery, Ogaki Municipal Hospital, Ogaki, Japan; 6) Department of Embryology, Institute of Developmental Research, Aichi Human Service Center, Kasugai, Japan.

Cleidocranial dysplasia (CCD [MIM 119600]) is an autosomal-dominant skeletal disease with high penetrance and variable expressivity caused by heterozygous mutations in the osteoblast-specific transcription factor known as runt related transcription factor 2 or core-binding factor subunit alpha-1 (*RUNX2/CBF-alpha-1*). Molecular analysis of the *RUNX2* gene in a 29-year-old woman with a diagnosis of CCD demonstrated a heterozygous in-frame 9-bp duplication between codon 181 and 189 (c.181_189dupGGCGGCTGC), corresponding to 3-alanine expansion in the polyalnine tract (17Ala>20Ala). To date, only one case has been reported with alanine tract expansion of Runx2 (27Ala) as a cause of CCD. To investigate the role of this short alanine expansion in the CCD pathologies, we investigated the transcription activity of the 20Ala and 27Ala tract expansion variants of RUNX2 with the p6OSE2-luciferase reporter gene, which contains six tandem copies of osteoblast-specific element-2, the RUNX2-binding promoter sequence. Then we studied the protein aggregates formation in the gene-transfected cells, since it has been demonstrated that alanine tract stretch of RUNX2 with 27Ala variants induces cytoplasmic protein aggregation. Although we detected minor effect of the alanine stretches on the transactivation function at 24 hours after gene transfection, we observed large amorphous aggregates of the 20Ala and 27Ala variants of RUNX2 in the cytoplasm of transfected cultured COS7 cells at 48 hours after gene transfection. These findings indicate that the 20Ala allele, as well as 27Ala variant, is a biologically relevant polymorphism that influences osteoblast differentiation. Furthermore, our results suggested that the lengths of alanine expansion correlated with aggregation severity, while there is no relation between the alanine expansion lengths and clinical severity.

3104M

Rapid Turnover Skeletal Disease Caused By A Multiple-Exon Duplication of *TNFRSF11A* Encoding RANK. *S. Mumm[1], F. Collins[2,3], S. Duan[1], M. Huskey[1], D. Sillence[3], M. Whyte[4].* 1) Bone/Mineral Div, Box 8301, Washington Univ Sch Med, St Louis, MO; 2) The Children's Hospital at Westmead, Australia; 3) Sydney University Medical School, Australia; 4) Shriners Hospital for Children, St. Louis MO.

Mendelian disorders of constitutive RANK activation are caused by in-frame 12, 15, 18, or 27-bp duplications in exon 1 of *TNFRSF11A* encoding the signal peptide of RANK. The similar rapid bone turnover disorder juvenile Paget's disease (JPD) is due to deactivating mutations in *TNFRSF11B* encoding OPG. We report a rapid turnover skeletal disease in a mother and fetus from a novel RANK defect. The 38-year-old proposita is the child of nonconsanguineous parents. Family history was negative for fractures or deafness. She wore hearing aids for deafness at age 15 months. Brittle teeth were noted at age 3 years. Secondary tooth loss began at age 9 years. At age 10 years, she was non-dysmorphic and without bone pain or fractures. Bone scintigraphy showed increased uptake in the long bones, and CT revealed hypoplastic ossicles and semicircular canals and no cochleas. A skeletal survey revealed thickened cortices of tubular bones, but a normal skull. Biopsy of a tibia and ileum showed unremarkable lamellar bone, slightly increased vascularity, numerous osteoblasts, and normal marrow. Serum alkaline and acid phosphatase were elevated. An atypical form of JPD was diagnosed. At age 14 years, she had normal stature, slight knock-knee deformity, and fractured major limb bones. She received calcitonin and then a bisphosphonate. At age 16 years, biopsy of the maxilla and jaw showed areas resembling cementifying fibroma, irregular woven bone, and marked osteoblastic and osteoclastic activity in a highly cellular fibrovascular stroma resembling osteolytic Paget's disease. Teeth were eroded and replaced by osteocementum and fibrous tissue. She was edentulous by age 27 years. At age 30 years, she had a prominent forehead and nasal bridge, deep set eyes, and anterior tibial bowing. Then, ultrasound of her first pregnancy at 18 weeks showed abnormal fetal bones with angulated femurs. Sequencing of coding exons and adjacent mRNA splice sites of the RANK and OPG genes of the mother and abortus was negative. However, in both, microarray-based copy number analysis showed amplification of exons 4-9 of the RANK gene. Confirmatory qPCR showed 3 copies of exons 4-9 in the mother, and >3 in the fetus. An in-frame tandem duplication of exons 4-9 creates a RANK fusion protein of one extracellular RANKL-binding domain combined with double intracellular activation domains. Thus, we have identified a new genetic basis within the family of disorders featuring constitutive RANK activation.

3105T

Asynchronous remodelling is a driver of failed regeneration in Duchenne Muscular Dystrophy. *S. Dadgar, Z. Wang, H. Johnston, K. Nagaraju, A. Hill, T. Partridge, E. Hoffman.* Children's National Medical Center- George Washington University, Washington, DC.

The molecular mechanisms underlying the progressive fibrosis and failure of regeneration in Duchenne muscular dystrophy have remained elusive. Analysis of 166 patient muscle biopsy mRNA profiles (test and validation sets) identified a 56 member network centered on TGFβ associated with severe pathology (fibrosis and failed regeneration). Superimposing this pathology-related network on a 27 time point murine normal muscle regeneration series showed stage-specific regulation of each network member during normal staged regeneration, but at distinct time points (temporal parsing into subnetworks). From this, we developed an asynchronous remodeling model for fibrosis and failed regeneration. This model predicted that the normal 2 week regeneration cycle of muscle is disrupted through inappropriate crosstalk between neighboring cells in different time points of the 2 week-cycle. To test this hypothesis, we developed an experimental model of focal asynchronous bouts of muscle regeneration, with laser capture microscopy of marked tissue regions (first bout, second bout, and in between [crosstalk] areas). mRNA profiling and immunohistochemical validations showed that the crosstalk areas in between staged bouts of regeneration became inappropriately fixed in the developmental time point by which the initial bouts were separated. This led to a chronic inflammatory state and mitochondrial insufficiency in bouts separated by 4 days, and a chronic profibrotic state in bouts separated by 10 days. Molecular networks associated with these localized areas of pro-inflammatory states were suppressed by treatment with glucocorticoids and VBP15. In summary, synchronous regeneration of muscle is successful, whereas neighboring asynchronous bouts create inappropriate crosstalk between cells in different stages of the regenerative process that results in failed regeneration and the pro-fibrotic and pro-inflammatory state. Our data provide a unifying model for failed regeneration and pathological fibrosis in muscular dystrophies that is likely generalizable to chronic inflammatory states in other regenerative tissues. This model also provides a novel mechanism of action for glucocorticoids in many of these disorders: they serve to re-synchronize remodeling, much as diurnal cortisol fluctuations do in most animals.

3106S

Novel mutations in *GNAI3* associated with Auriculocondylar Syndrome strengthen a common dominant negative effect. *V.L.R. Tavares[1], C.T. Gordon[2], R.M. Zechi-Ceide[3], N.M. Kokitsu-Nakata[3], N. Auriculocondylar syndrome is a rare craniofacial disorder comprising core features of micrognathia, condyle dysplasia and question mark ear. Causative variants have been identified in *PLCB4*, *GNAI3* and *EDN1*, which are predicted to function within the EDN1-EDNRA pathway during early pharyngeal arch patterning. To date, two *GNAI3* variants in three families have been reported. Here we report three novel *GNAI3* variants, one segregating with affected members in a family previously linked to 1p21.1-q23.3 and two *de novo* variants in simplex cases. Two variants occur in known functional motifs, the G1 and G4 boxes, and the third variant is one amino acid outside of the G1 box. Structural modeling shows that all five altered GNAI3 residues identified to date cluster in a region involved in GDP/GTP binding. We hypothesize that all *GNAI3* variants lead to dominant negative effects.

3107M

Mouse Model with Mutant Type I Collagen C-propeptide Cleavage Site has Brittle Bones and Increased Osteoblast Mineralization. *A.M. Barnes[1], J.E. Perosky[2], M.H. Rajpar[1], K.M. Kozloff[2], J.C. Marini[1].* 1) BEMB, NICHD/NIH, Bethesda, MD; 2) Orthopedic Surgery and Biomedical Engineering, University of Michigan, Ann Arbor, MI.

Classical dominant osteogenesis imperfecta (OI) is caused by mutations in type I collagen. Mutations in the C-propeptide cleavage site of both *COL1A1* and *COL1A2* were shown to cause high bone mass OI, characterized by bone hypermineralization and normal to increased DXA Z-scores. We generated a mouse with a heterozygous C-propeptide cleavage site defect (high bone mass, HBM) in which the Ala-Asp residues of the proα1(I) cleavage site were mutated to Thr-Asn to prevent cleavage by BMP1. We utilized this mouse to investigate the role of proα1(I) C-propeptide processing in bone formation. Collagen from HBM calvarial osteoblasts (OB) had normal biochemistry and the collagen was incorporated normally into trimers. Conditioned media from HBM fibroblasts showed decreased processing of the C-propeptide. HBM OB deposited only about 50% of WT matrix. An *in vitro* mineralization assay showed that HBM calvarial OB had a 15% increase in mineralization ($p=0.006$), ± BMP2. Dermal fibril diameters were smaller and more homogeneous in HBM than WT, with a loss of large fibrils. HBM mice are growth deficient, remaining smaller than WT from 4-16 weeks. At 2 months, male HBM mice are significantly smaller in weight (77%) and length (92%) and have shorter femurs (92%). Femoral areal BMD in HBM mice is decreased 25% ($p<0.001$); vertebral BMD is normal. All 2 month HBM mice have pelvic deformities, and 40% have kyphosis. On μCT, HBM femora have a thinner cortex with decreased cortical area; the distal femoral metaphysis is notably thinner. Cortical TMD is modestly reduced, while trabecular TMD, trabecular bone volume and trabecular number and thickness are decreased. Four point bending revealed an extremely brittle phenotype; post-yield displacement is only ~10% of WT ($p<0.001$). HBM femoral stiffness, yield load, and ultimate load are also significantly decreased. The bone phenotype of HBM mice is similar to *Bmp1*$^{-/-}$/*Tll1*$^{-/-}$ mice (Muir, et al, *HMG*, 2014, 23:3085-3101), in which cleavage of multiple procollagens as well as bone-related factors is defective. *Bmp1*$^{-/-}$/*Tll1*$^{-/-}$ mice have small size, thin cortices, reduced failure energy and maximum load and a dramatic decrease in post-yield displacement. The HBM mouse demonstrates that the essential elements of the broader BMP1 enzyme deficiency are reproduced by a substrate defect in type I C-propeptide cleavage. These data show the importance of the proα1(I) C-propeptide to both collagenous and mineral properties of bone.

Spliceosomopathies: an emerging link between the spliceosome and disorders of craniofacial and skeletal development. *D.C. Lynch[1], A.M. Innes[1, 2], R.L. Lamont[1, 2, 3], J.S. Parboosingh[1, 2, 3], F.P. Bernier[1, 2].* 1) Medical Genetics, University of Calgary, Calgary, Canada; 2) Alberta Children's Hospital Research Institute, Calgary, Canada; 3) Genetic Laboratory Services, Alberta Health Services, Calgary, Canada.

Recently a group of craniofacial and skeletal disorders caused by dominant mutations in spliceosomal genes has emerged. The first of these to be identified is mandibulofacial dysostosis type Guion-Almeida (MFDGA), caused by haploinsufficiency of the U5 snRNP component EFTUD2. We recently identified haploinsufficiency of SF3B4 as the cause of Nager syndrome, an acrofacial dysostosis (AFD). Mutation of SF3B4 was subsequently reported in AFD Rodriquez type (AFDR). SF3B4 is part of the U2 snRNP of the major spliceosome. Herein we also present heterozygous mutations in a highly conserved regulatory exon of SNRPB as the cause of cerebrocosto-mandibular syndrome (CCMS). Our experimental data show that these mutations disturb highly conserved exonic splicing silencer sequences crucial to the regulation of the gene's expression. SNRPB encodes a component of the Sm complex of the spliceosome, which is present in all snRNPs. Pierre Robin sequence and ear anomalies are present in all four syndromes. However, malar hypoplasia is present only in Nager, MFDGA and AFDR. Microcephaly is typically present only in MFDGA. Other disease-specific features include posterior rib gaps in CCMS, tracheoesophageal fistula in MFDGA, pre-axial anomalies in Nager and severe limb defects in AFDR. Together, these findings invite questions on the sensitivity of craniofacial and in particular pharyngeal arch development to spliceosomal defects, and on the role of the spliceosome in the regulation of development. We propose a comprehensive review of the clinical and molecular features of this emerging group of disorders with a particular emphasis on the role of SF3B4, EFTUD2 and SNRPB in disorders of craniofacial and skeletal development.

3109S

Novel COL1A2 Gene Mutation in Czech Osteogenesis Imperfecta Patient: Case report. *S. Mazurova[1], L. Hruskova[1], I. Marik[2], P. Martasek[1], I. Mazura[1].* 1) Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University in Prague, Ke Karlovu 2, 12100 Prague 2, Czech Republic; 2) Ambulant Centre for Defects of Locomotor Apparatus, Olšanská 7, 13000 Prague 3.

Osteogenesis imperfecta /OI/ is an inherited disorder of connective tissue. About 90% of affected patients with OI type I-IV show causative mutation in one of the two genes, COL1A1 and COL1A2, coding 2 alpha 1 chains and 1 alpha 2 chain of collagen type I protein. Clinical effect of these mutations results in mild to lethal phenotype regard on type of osteogenesis imperfecta and position of the nucleotide change. We continue with analyses of the Czech patients with OI type I-IV and COL1A1 and COL1A2 genes some of which have already been described earlier. This paper is focused on one mutation of COL1A2 gene and correlation of genotype-phenotype parameters in Czech osteogenesis imperfecta patient. Mutation observed in the COL1A2 gene is localized in exon 40 and we describe clinical symptoms of patient correlating with Gly814Trp substitution. We used molecular genetic analysis of genomic DNA extracted from peripheral blood leucocyte. DNA quality and quantity were confirmed by spectrophotometry and horizontal electrophoresis and subsequently target amplification and two-directional sequencing was performed. We demonstrate a case of 25 year old woman affected by OI type III which is clinically followed from 3 years and 4 months of life. Last clinical examination was performed in 17 years of life. This woman was born from second gravidity of unaffected parents and perinatal fractures of both low extremities were described. This work was supported by following grants: grant no.: SVV-2014-260034 supported by Charles University Prague, grant no.: UNCE 204011 supported by Ministry of Education, Youth and Sport, Czech Republic, grant no.: PRVOUK P24/1LF/3 supported by Ministry of Education, Youth and Sport, Czech Republic.

3110M

Expending the phenotypic spectrum of *PDE4D* and *PRKAR1A* mutations : from acrodysostosis to acroscyphodysplasia. *C. Michot[1], C. Le Goff[1], G. Baujat[1], K. Piquant[1], E. Blair[2], O. Acrodysostosis (MIM101800) is a dominantly inherited condition associating 1) a skeletal dysplasia characterized by short stature, facial dysostosis and severe brachydactyly with cone-shaped epiphyses 2) resistance to mutiple hormones 3) moderate to mild intellectual disability. Acroscyphodysplasia (MIM250215) is rare and characterized by lower femoral and upper tibial epiphyses embedded in cup-shaped, large metaphyses, associated to severe growth retardation and brachydactyly. We and others have identified *PDE4D* or *PRKAR1A* mutations in acrodysostosis cases. More recently, *PDE4D* mutation has been reported in one case of acroscyphodysplasia. The aim of our study was to review the clinical and molecular findings of 27 acrodysostosis and 5 acroscyphodysplasia cases to further establish genotype-phenotype correlation. Among the 27 unrelated acrodysostosis cases, we identified heterozygous de novo *PRKAR1A* mutations in 9 and heterozygous de novo *PDE4D* mutations in 10 cases. Neither *PDE4D* nor *PRKAR1A* mutations were found in 8 patients. These 8 patients presented with features highly evocative of acrodysostosis (short hands and cone-shaped epiphyses), but none had the canonical facial features and 2 presented with a less severe and atypical brachydactyly (not affecting the five digits). In the 5 cases of acroscyphodysplasia, we identified *PDE4D* mutations in 2. For 3 negative cases, the review of medical records revealed early and severe infection, which has already been described in some cases of acroscyphodysplasia. Splitting our series of acrodysostosis cases based on the disease causing gene confirmed genotype-phenotype correlations. Hormone resistance was consistently observed in the patients carrying *PRKAR1A* mutations while no hormone resistance was observed in at least 6 patients with *PDE4D* mutations. Moreover, all patients with *PDE4D* mutations shared characteristic facial features (midface hypoplasia with the canonical nasal hypoplasia) and some degree of intellectual disability. Finally, our findings of *PDE4D* mutations in 2 cases of acroscyphodysplasia support also that *PDE4D* is responsible for a severe skeletal dysplasia, with major epiphyseo-metaphyseal changes.

3111T

Transcriptional Dysregulation Associated with Somatic Neurofibromin Deficiency in Tibial Pseudoarthrosis with Neurofibromatosis Type 1.

J.J. Rios[1], N. Paria[1], T-J. Cho[2], IH. Choi[2], N. Kamiya[1], K. Kayembe[3], R. Mao[4], RL. Margraf[4], G. Obermosser[3], I. Oxendine[1], DW. Sant[4], MH. Song[6], DA. Stevenson[5], DH. Viskochil[5], CA. Wise[1], HKW. Kim[1]. 1) Research, Texas Scottish Rite Hospital for Children, Dallas, TX; 2) Division of Pediatric Orthopaedics, Seoul National University Children's Hospital, Seoul, Republic of Korea; 3) Baylor Institute for Immunology Research, Dallas, Texas; 4) ARUP Laboratories, Salt Lake City, Utah; 5) Department of Pediatrics, University of Utah, Salt Lake City, Utah; 6) Department of Orthopaedic Surgery, Jeju National University Hospital, Jeju, Republic of Korea.

NF1 haploinsufficiency causes neurofibromatosis type 1 (NF1) and results in constitutive Ras activation, predisposing individuals to neurofibroma and malignant peripheral nerve sheath tumor (MPNST) formation. Children with NF1 are also predisposed to tibial dysplasia with high risk of fracture, pseudoarthrosis and chronic nonunion. Previous studies described somatic loss-of-heterozygosity (LOH) at the NF1 locus in tibial pseudoarthrosis tissue. This study sought to confirm and expand this observation by characterizing the somatic mutation spectrum and transcriptional dysregulation in pseudoarthroses from 16 individuals with NF1. Genomic microarray analysis and whole-exome sequencing identified somatic variants in the NF1 gene in 12 samples, and unlike neurofibromas and MPNSTs, no other recurring somatic variants were identified. Somatic NF1 variants included a single large deletion, six individuals with sequence variants and five individuals with LOH encompassing the entire long-arm of chromosome 17. We did not identify somatic variants for four individuals. Whole-transcriptome sequencing (RNA-seq) was performed using cells cultured from pseudoarthrosis tissue from five individuals, and somatic variants were confirmed in the mosaic cell cultures. RNAseq analysis identified significant upregulation of a tumor-promoting transcriptional pattern in pseudoarthrosis samples, as compared to iliac crest cells from two affected individuals and control samples from three individuals without NF1. Upregulated genes included EGFR (2.5-fold, p=4.8e-4), KITLG/SCF (3.4-fold, p=1.9e-4) and EREG (55.7-fold, p=2.49e-11). Because NF1 haploinsufficiency results in activation of the ERK signaling pathway, we investigated whether pseudoarthrosis cells with neurofibromin deficiency had higher levels of ERK activation compared to haploinsufficient iliac crest cells. Flow cytometry identified no difference in the levels of ERK activation, suggesting upregulation is associated with neurofibromin deficiency rather than quantitative differences in pathway activation. Despite the transcriptional dysregulation, NF1 pseudoarthroses lacked other obvious oncogenic variants, and tumor formation from pseudoarthrosis tissue was not observed nor previously reported in the literature. Results from this study suggest receptor tyrosine kinase inhibitors should be investigated as a non-surgical treatment for tibial pseudoarthrosis to promote bone union in individuals with NF1.

3112S

Compound heterozygosity for a frameshift mutation and an upstream deletion that reduces expression of *SERPINH1* in siblings with a moderate form of osteogenesis imperfecta.

U. Schwarze[1], T. Cundy[2], Y.J. Liu[1], P.L. Hofman[3], J. Schleit[1], M.L. Murray[1,4], P.H. Byers[1,4]. 1) Department of Pathology, University of Washington, Seattle, WA; 2) Department of Medicine, Faculty of Medical & Health Sciences, University of Auckland, New Zealand; 3) Liggins Institute, Faculty of Medical & Health Sciences, University of Auckland, New Zealand; 4) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA.

Osteogenesis imperfecta (OI) is a heritable disorder characterized primarily by bone fragility and increased fracture risk, ranging in severity from mild to perinatal lethal. Currently mutations in 17 genes have been implicated in this disorder; more than 90% of cases of OI are caused by heterozygous mutations in *COL1A1* or *COL1A2*. Most of the remainder are recessively inherited and result from mutations in genes that encode proteins involved in the synthesis of type I collagen. *SERPINH1* encodes the collagen chaperone HSP47 that binds to arginine rich sequences in the type I procollagen trimers and provides the final steps in the folding and stabilization of the triple helical domain. Loss of both alleles in mice results in early embryonic lethality. Homozygous missense mutations in dachshunds and in one child resulted in a moderately severe form of OI with continuing fracture in the face of bisphosphonate treatment in the child. In both instances the identified missense mutations resulted in substitution of different interacting leucine residues by proline. We identified an additional family with non-consanguineous unaffected parents who have two children with moderate short stature, low bone density, fractures, and no evidence of dentinogenesis imperfecta. Both children are heterozygous for two mutations (allele 1; allele 2); one of each was derived from each parent. Initial study identified only a frameshift mutation in the last exon that did not lead to nonsense-mediated mRNA decay (c.1233dupT, p.Asp412*). Analysis of the expression of the two alleles in cultured cells indicated that the other allele was expressed, but was only about half as abundant as the frameshift containing allele. High density CGH identified a 5.3kb deletion upstream from the translation start site that removed a region of DNase sensitivity identified in the ENCODE data set. This allele was inherited from the father, and the mRNA in his cells was also expressed at a low level, which confirmed that this domain has a regulatory function for *SERPINH1*. This class of mutation is currently rarely found in individuals with genetically determined disorders and would not be detected by whole exome sequence analysis. While whole genome sequence analysis could identify it, targeted gene studies may be the more efficient way of identification, especially in families such as this one in which only one mutant allele is found, and appropriate cells are available to measure expression levels.

3113M

Rare TBX6 null mutations in congenital scoliosis. *N. Wu[1], Z. Wu[1], X. Ming[2], J. Xiao[2], X. Chen[4], J. Liu[1], S. Liu[1], Y. Ming[5], L. Jin[2,3], X. Zhang[6], G. Qiu[1], F. Zhang[2,3].* 1) Department of Orthopedic Surgery, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences, Beijing, Beijing, China; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China; 3) Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, Shanghai, China; 4) Beijing Municipal Key Laboratory of Child Development and Nutriomics, Capital Institute of Pediatrics, Beijing, China; 5) PET-CT Center, Cancer Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing, China; 6) McKusick-Zhang Center for Genetic Medicine and State Key Laboratory of Medical Molecular Biology, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, China.

Introduction: Congenital scoliosis (CS) is a common disorder with an estimated incidence of around 0.5-1 in 1000 live births. Genetic mutations have been implicated in CS pathogenesis, but the genetic basis of sporadic CS remains unclear. Human 16p11.2 deletions are rare but recurrent mutations. The CS conditions have been recently observed in a small portion of 16p11.2 deletion carriers, suggesting a potential involvement of 16p11.2 in CS. Methods: Subject Information. We enrolled 161 unrelated sporadic CS patients of Han Chinese from PUMCH between October 2010 and November 2012. Their CS conditions were confirmed by radiological imaging. The patients with known syndromes were excluded. A total of 166 unrelated healthy participants were used as population controls. High-density Oligonucleotide Comparative Genomic Hybridization Microarray. A high-density genome-wide copy number variation (CNV) analysis was performed in 20 trios. The genomic DNA was extracted from peripheral blood leukocytes. Quantitative Polymerase Chain Reaction (qPCR) Analysis. qPCR analysis was conducted to screen for 16p11.2/TBX6 deletion in additional 141 sporadic CS patients. Any 16p11.2 deletion candidate suggested by qPCR was further confirmed by the CGH microarrays. DNA Sequencing of the TBX6 gene. The entire TBX6 gene and its approximately 1-kb upstream region were amplified using long-range PCR in both CS patients and healthy controls. The PCR products were analyzed by Sanger DNA sequencing. Statistical analysis. The Fisher's exact test (two-sided) was used to investigate the potential significant difference in TBX6 mutation/variant frequencies between the CS patients and controls. The differences with $P<0.05$ were considered as statistically significant. Results: We identified recurrent deletions in proximal 16p11.2 in two patients (2/20). Furthermore, both deletions were de novo. Notably, ten more sporadic CS patients were found to have this recurrent 16p11.2 deletion. However, we did not observe any 16p11.2 deletion in 166 Han Chinese controls (12/161 vs. 0/166; $P<0.0002$). The DNA sequencing of the TBX6 gene revealed additional one nonsense and four frameshift mutations of TBX6 in these group of CS patients. Conclusions: Up to our knowledge, we reported the largest genetic study of sporadic CS, suggesting that the TBX6 null mutation is responsible for CS (approximately 10% of sporadic CS). Our findings will facilitate molecular diagnostics of CS.

3114T

Alteration of conserved alternative splicing in AMELX causes enamel defects. *J. Kim[1], K.-J. Kim[1], E.-J. Lee[1], K.-E. Lee[1], C.-Y. Yun[2], E.-S. Cho[2].* 1) Pediatric Dentistry, Seoul National University School of Dentistry, Seoul, South Korea; 2) Cluster for Craniofacial Development and Regeneration Research, Institute of Oral Biosciences, School of Dentistry, Chonbuk National University, Jeonju, Korea.

Tooth enamel is the most highly mineralized tissue in vertebrates, and its mineralization should be well-controlled under strict and harmonious enamel crystal formation and elongation to achieve exceptional hardness and a compact microstructure. Enamel matrix calcification occurs with several matrix proteins, such as amelogenin, enamelin and ameloblastin. Among them, amelogenin is the most abundant enamel matrix protein and multiple isoforms resulting from extensive but well-conserved alternative splicing and post-secretional processing have been identified. In this report, we recruited a family with unique enamel defect and identified a silent mutation in exon 4 of the AMELX gene. We show that the mutation caused the inclusion of exon 4, which is almost always skipped, in the mRNA transcript. We further show by generating and characterizing transgenic animal model that the alteration of the ratio and quantity of the developmentally conserved alternative splicing repertoire of AMELX caused defects in enamel matrix mineralization. This work was supported by grants from the Bio & Medical Technology Development Program (2013037491), the Science Research Center grant to Bone Metabolism Research Center (2008-0062614), and Basic Science Research Program (2013R1A2A1A01007642) through the National Research Foundation of Korea (NRF).

3115S

Loss of function mutations reveal that *DGAT1* is essential for gastrointestinal homoeostasis, lipid absorption and triglyceride deposition in humans and cows, but not rodents. *K. Lehnert[1,2], H. Ward[2], S.D. Berry[2], A. Ankersmit-Udy[2], A. Burrett[2], E.M. Beattie[2], N.L. Thomas[2], B. Harris[2], C.A. Ford[2], S.R. Browning[4], P. Rawson[7], G.A. Verkerk[5], Y. van der Does[6], L.F. Adams[2], S.R. Davis[2], T.W. Jordan[7], A.K.H. MacGibbon[6], R.J. Spelman[3], R.G. Snell[1,2].* 1) University of Auckland, Auckland, New Zealand; 2) ViaLactia Biosciences (NZ) Ltd., Auckland, New Zealand; 3) LIC, Hamilton, New Zealand; 4) Department of Biostatistics, University of Washington, Seattle, WA 98195, USA; 5) DairyNZ Ltd, Hamilton, New Zealand; 6) Fonterra Research Centre, Palmerston North, New Zealand; 7) Centre for Biodiscovery, Victoria University of Wellington, Wellington, New Zealand.

Diacylglycerol O-acyltransferase 1 (DGAT1) catalyzes the transfer of fatty acid-CoA to diacylglycerol in the terminal step in triglyceride synthesis. Dgat1-/- mice exhibit increased longevity, decreased body fat, resistance to diet-induced obesity and a failure to lactate. The absence of detectable negative effects outside the mammary gland in Dgat1-deficient mice, and the enzyme's role in human storage lipid synthesis, have made pharmacological inhibition of DGAT1 an attractive approach to the management of obesity. Interestingly, a family has been reported with a contrary phenotype of growth retardation and diarrhoea due to homozygosity for a splice site mutation in *DGAT1*, abolishing the production of active enzyme [Haas et al., 2012, PMID: 23114594]. In an endeavour to select for altered milk production in dairy cows we have screened 2.5 million cows and identified an extremely unusual animal producing milk with a 40% reduction of saturated fat (4 SD below breed mean). To identify the genetic basis of this extreme phenotype, we bred a three-generation pedigree from the unique founder. Linkage mapping and genome sequencing revealed a *de novo* heterozygous A>C transversion in a previously unidentified, conserved splice enhancer motif in exon 16 of the DGAT1 gene [g.8078>C; p.M435L]. The mutation caused skipping of exon 16 in 90-95% of mutant mRNA molecules, and the mutant enzyme was unable to transfer fatty acids from CoA to diglyceride. Growth, development, weight, and life span of heterozygous cows were normal. However, calves homozygous for the mutation developed severe, non-bloody diarrhoea within 2-3 days after being apparently born healthy and with normal birth weights. The animals failed to thrive despite normal food intake, and serum triglyceride and cholesterol levels were extremely low. Gastrointestinal function normalized on isoenergetic low-fat diets. Bi-weekly intravenous supplementation of essential and unsaturated lipids was required to restore growth, albeit at slower rates compared to unrelated calves of similar weights. Our discovery of the mutation in animals supports the identification of the causal mutation in the family above and a potential role for DGAT1 in malabsorption and diarrhoeal disorders. Finally, our observations underscore concerns for DGAT1 inhibition as a strategy to combat obesity in humans, and suggest the use of a large animal model to understand the role of *DGAT1* in the intestine.

3116M

Hennekam syndrome can be caused by FAT4 mutations and be allelic to Van Maldergem syndrome. *M. Alders[1], L. Al-Gazali[2], I. Cordeiro[3], B. Dallapiccola[4], L. Garavelli[5], B. Tuysuz[6], F. Salehi[1], M. Haagmans[1], O. Mook[1], C. Majoie[1], M. Mannens[1], R. Hennekam[1].* 1) Academic Medical Center, Amsterdam, The Netherlands; 2) United Arab Emirates University, Al-Ain, United Arab Emirates; 3) Hospital Santa Maria. Lisboa, Portugal; 4) Ospedale Pediatrico Bambino Gesù, IRCCS, Rome, Italy; 5) Arcispedale S. Maria Nuova, Reggio Emilia, Italy; 6) Cerrahpasa Medical School, Istanbul University, Istanbul, Turkey.

The Hennekam lymphangiectasia-lymphedema syndrome is a genetically heterogeneous disorder. It can be caused by mutations in CCBE1 which are found in approximately 25% of cases. We used homozygosity mapping and whole exome sequencing in a family with multiple affected individuals in whom no CCBE1 mutation had been detected, and identified a homozygous mutation in the FAT4 gene. Subsequent targeted mutation analysis of FAT4 in a cohort of 24 CCBE1 mutation negative Hennekam syndrome patients identified homozygous or compound heterozygous mutations in 4 additional families. Mutations in FAT4 have been previously associated with Van Maldergem syndrome. Detailed clinical comparison between van Maldergem syndrome and Hennekam syndrome patients shows that there is a substantial overlap in phenotype, especially in facial appearance. We conclude that Hennekam syndrome can be caused by mutations in FAT4 and be allelic to Van Maldergem syndrome.

3117T

Novel variant of *TNNI2* causes an atypical Distal Arthrogryposis syndrome. *C.T. Marvin[1], J.X. Chong[1], K.J. Buckingham[1], K.M. Shively[1], A.E. Beck[1,2], H.I.S. Gildersleeve[1], M.J. McMillin[1], D.A. Nickerson[3], J. Shendure[3], R.E. Stevenson[4], M.J. Bamshad[1,2,3], University of Washington Center for Mendelian Genomics.* 1) Dept. of Pediatrics, University of Washington, Seattle, WA, USA; 2) Seattle Children's Hospital, Seattle, WA, USA; 3) Dept. of Genome Sciences, University of Washington, Seattle, WA, USA; 4) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC, USA.

Distal arthrogryposis (DA) type 2B, or Sheldon-Hall syndrome, can be caused by pathogenic variants in any one of several genes that encode proteins of the contractile apparatus of skeletal muscles. Causal variants in four genes (*MYH3*, *TNNI2*, *TPM2* and *TNNT3*) each explain approximately 10% of families, so the genetic basis remains unknown in most circumstances. We were referred a single affected male who presented as a newborn with a history of reduced fetal movement accompanied by polyhydramnios, severe contractures of the upper and lower limbs, multiple dysmorphic facial characteristics, hyperelastic skin, multiple rib and long-bone fractures, and hypotonia born to apparently unaffected parents. Despite an exhaustive clinical evaluation, no specific diagnosis could be confirmed. However, evaluation by a group of expert dysmorphologists considered atypical DA2B to be one possible diagnosis. We screened exons of each gene known to underlie DA2B including exon 8 of *TNNI2*, exon 10 of *TNNT3,* and all coding exons of *MYH3* and *TPM2* without finding a compelling candidate variant. Subsequently, we performed exome sequencing of the proband and his parents and identified a *de novo* missense variant (c.337C>T, predicted p.Arg113Trp) in exon 7 of *TNNI2*. To date, variants causing DA2B have been reported only in exon 8 of *TNNI2*. Additionally, we identified a rare (MAF 0.024%) in-frame deletion (c.272_274del, predicted p.Glu92del) in exon 6 of *TNNI2*. This variant was also found in the mother of the proband who in retrospect was noted to also have somewhat hyperelastic skin. No candidate functional variants were found in genes potentially associated with hyperelastic skin. These results suggest that the atypical DA phenotype and in particular, the hyperelastic skin, may be caused by the occurrence of more than one disruptive variant in *TNNI2*, either on the same allele or affecting both alleles. Exome sequencing of additional atypical cases of DA2B is underway to determine whether causal variants exist in regions other than those encoded by exon 8 and whether the phenotype in some individuals is caused by multiple disruptive variants in *TNNI2*.

3118S

MTHFR and CBS: A risk factor for Down syndrome. *A. kaur, A. kaur.* Department of Human Genetics, Guru Nanak Dev University,., Amritsar, Punjab, India.

The mutations in metabolic pathway has been observed to be associated with higher birth frequency of Down syndrome. The most common mutations include MTHFR C677T (1p36.3) and CBS 844ins68 (21q22.3). MTHFR helps in converting homocystein to methionine while cystathionine beta synthase (CBS) helps in converting homocystein and serine to cystathionine, thus regulating the homocystein concentration. Mutations in MTHFR and CBS gene impair the activity of enzymes, leading to increased homocystein concentration, which has been reported to be the possible risk factor for Down syndrome. The present study investigated 126 mothers of DS children and 58 mothers having normal children for CBS 844ins68 polymorphism whereas 110 case mothers and 111 control mothers for MTHFR C677T polymorphism. Peripheral blood from mothers was collected in EDTA-coated vials for DNA extraction after taking informed consent. Genotyping was done using polymerase chain reaction. Products were electrophoresed in 2% agarose gel using ethidium bromide. In CBS 844ins68, presence of 68bp insertion produced 242bp band while wild type produced 174bp band. Among cases, 88.9% (112) were having -/- genotype and 11.11% (14) were having +/- genotype. However, +/+ genotype was not observed among any case or control mothers. The chi square value (χ^2- 0.065, p-0.79) suggested non-significant association between birth of DS child and presence of CBS 844ins68 polymorphism. In case of MTHFR C677T polymorphism, homozygous wild genotype (CC) was observed in 78.2%, heterozygous mutant (CT) in 20% and homozygous mutant (TT) in 1.8% mothers of DS children. On the other hand, control mothers had 80.2% CC and 19.8% CT genotype. The chi-square value (χ^2- 2.064) revealed non-significant association between cases and controls. We are working on larger sample size to understand the complex mechanism behind the presence of maternal polymorphisms and maternal risk of having DS child.

3119M

Investigation of a missense in NOTCH4 in autosomal dominant scleroderma. *C.J. Cardinale[1], D. Li[1], R.M. Chiavacci[1], L. Tian[1], S.J. Burnham[2], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

We encountered an 8-year-old girl presenting with systemic sclerosis (SSc), i.e., scleroderma, and a positive family history. This patient had an affected maternal aunt and a maternal grandfather who died of SSc. The pedigree suggests an autosomal dominant inheritance model with incomplete pentrance. We performed whole-exome sequencing on the proband and aunt as well as the unaffected maternal grandmother. We examined missense, nonsense, splice-altering, and coding indels matching the inheritance model. Results were filtered to exclude synonymous variants, variants with minor allele frequency (MAF) greater than 0.5%, and variants previously identified in controls by our in-house exome variant database. Relevant candidates were taken forward for manual curation. A p.Met1415Ile substitution in *NOTCH4*, previously implicated in the pathways by which TGF-β induces pulmonary fibrosis—one of the most severe clinical manifestations of SSc—was identified as the most likely candidate. We have cloned an expressed an AcGFP1-tagged clone of full-length NOTCH4 in HEK 293T cells and examined the impact of the mutation through immunoprecipitation and luciferase reporter assays.

3120T

Molecular Spectrum of Mutations in CFTR gene: First Report from the Aegean region of Turkey and definition of three novel mutations. *A. Aykut[1], H. Onay[1], I.M. Tekin[1], F. Gulen[2], F. Ozkinay[1].* 1) Ege University Faculty of Medicine, Department Medical Genetics, Izmir,Turkey; 2) Ege University Faculty of Medicine, Department of Pediatric Allergy and Respiratory Diseases, Izmir,Turkey.

Cystic fibrosis (CF) is an autosomal recessive disease caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. Up to date, more than 1900 different mutations in the CFTR gene have been reported. The aim of this study was to evaluate the spectrum of CFTR gene mutations in the Aegean region of Turkey. In this study, a total of 251 mutated CF alleles were identified in 194 individuals referred to our center for CFTR molecular analysis between January 2005 and May 2014. Among 251 mutant CFTR alleles, 55 different mutations, 3 of them being novel, were detected. The most common five mutations were F508del (32.8%), I148T (8%), 2183AA>G (7%), N1303K (4.7%) and G542X (4.7%). The novel mutations identified were p. S10N, c.2338delG and p.R1283G. The frequencies of CFTR mutations found in our region were slightly different from the frequencies found in general Turkish population.

3121S

Molecular Analysis of Dystrophic Epidermolysis Bullosa in Iran. *H. Vahidnezhad[1,2,3], L. Youssefian[2,3], M. Barzgar[4], S. Sotoudeh[2], Q. Li[3], N. Mozaffari[4], A. Isaian[2], M. Daneshpazhoh[2], M. Tabrizi[2], S. Zeinali[1], J. Uitto[3].* 1) Biotechnology Research Center, Department of Molecular Medicine, Pasteur Institute of Iran, Tehran, Iran; 2) Tehran University of Medical Sciences, Tehran, Tehran, Iran; 3) Department of Dermatology and Cutaneous Biology, Thomas Jefferson University, Philadelphia, Pennsylvania, USA; 4) Shahid Beheshti University of Medical Sciences, Tehran, Tehran, Iran;.

Epidermolysis bullosa (EB) is a clinically and genetically heterogeneous group of genodermatoses characterized by trauma induced mucocutaneous blistering and chronic epithelial fragility caused by mutations in at least 18 genes. The international consensus classification defines four types of EB based on the ultrastructural level of tissue separation: EB simplex (EBS), junctional EB (JEB), dystrophic EB (DEB) , and the Kindler syndrome. Numerous studies, mainly performed in European and US families with EB, have revealed a number of characteristic epidemiological and genetic features, which form the basis for current diagnostic and counseling strategies. However, there is currently no comprehensive study about the molecular epidemiology of EB in Iranian populations. In this study, we registered 250 EB families and here we report the evaluation of 150 EB families with ~ 200 affected individuals in Iran. Clinical examination and immunofluorescence mapping showed that EBS, JEB, and DEB represented 13, 15, and 66% of the cohort, respectively. Due to high rate of consanguineous marriages this ratio is different from EB patients in Europe and the USA in which EBS, JEB, and DEB were reported to represent 67, 27, and 33%, respectively. We have assessed a cohort of 67 DEB families for pathogenic sequence alterations in the *COL7A1* gene. Our results from 13 families show recurrent and novel mutations, including p.Gly2040Val, p.Arg2069Cys, p.Arg2063Trp , p.Gly2031Ser, c.6265delC, c.4958-4959delAA and IVS84+2 T>G (c.6714+2 T>G). Our data indicate the need for population-specific diagnostic and management approaches. Identification of specific mutations in the candidate genes and elucidation of the consequences of such mutations can provide a basis for the development of novel therapeutic approaches, including gene therapy, protein replacement, or cell based therapies, some of which are in early clinical trials for EB. Finally, DNA-based prenatal testing and preimplantation genetic diagnosis can be applied to families at risk for recurrence of this, currently intractable disease.

3122M

Genome-wide association meta-analysis of 6,365 subjects replicate EHF-APIP and identifies new modifier loci of lung disease severity in Cystic Fibrosis. *H. Corvol[1], G.R. Cutting[2], M.L. Drumm[3], M.R. Knowles[4], J.M. Rommens[5] on behalf of the International CF Gene Modifier Consortium.* 1) AP-HP, Hôpital Trousseau, Pediatric Pulmonary Department; Inserm U938, Paris, France; 2) Institute of Genetic Medicine, Johns Hopkins University, Baltimore MD; 3) Dept of Pediatrics, Case Western Reserve University, Cleveland, OH; 4) Dept of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC; 5) Program in Genetics & Genome Biology, SickKids Research Institute and Univ of Toronto, Toronto, ON, Canada.

Lung disease is responsible for 80% of mortality in cystic fibrosis (CF). Genetic modifiers play a prominent role in variation in lung function measurements (H^2~0.54). The North American Cystic Fibrosis (CF) Modifier Consortium had previously reported genome-wide significant association with lung function measures for SNPs positioned between *APIP* and *EHF* on chromosome 11p13 (GWAS1; *n* = 3,444; Wright *et al, Nat Genetics*, 2011). We now report replication of the *EHF-APIP* locus and identification of new modifier loci for lung disease severity in CF. Genome-wide SNP typing was performed on a second cohort of CF subjects from North America and the French CF Gene Modifier Consortium (GWAS2; *n*=2,921). Imputation using an admixed 1000 Genomes reference population generated a common set of 8,520,458 SNPs that were screened for association using linear mixed effects modeling with meta-analysis across patient groups and genotype platforms. Support for the chromosome 11p13 region was evident in a meta-analysis of GWAS1 and GWAS 2 (*P* = 4.8 x 10-9; GWAS1+2) and in the subgroup homozygous for the common CF mutation (*P* = 1.9 x 10-10; GWAS1+2 p.Phe508del p.Phe508del). Regions on chromosomes 5, 6 and X that previously indicated suggestive evidence for associations (GWAS1) met the genome-wide significance criterion (*P* = 6.8 x 10-12, 1.7 x 10-9 and 1.8 x 10-9, respectively; GWAS1+2) in the meta-analysis. Two new loci showed significant evidence for association, chromosome 3 (*P* = 3.3 x 10-11; GWAS1+2) and chromosome 17 (*P* = 1.8 x 10-7, GWAS2; and *P* = 2.4 x 10-9, GWAS2 p.Phe508del/p.Phe508del). The intervals of the six identified loci that contribute to lung function in CF patients suggest a series of biologically compelling genes that include *EHF* and *APIP*, the solute carrier *SLC9A3,* the mucins *MUC4* and *MUC20*, class II *MHC* genes, the lncRNA CASC17 and an angiotensin receptor *AGTR2* that is proximal to another solute carrier *SLC6A14.* Pleiotropic effects are evident as *SLC9A3* and *SLC6A14* have been observed to be modifiers of a different CF phenotype, neonatal intestinal obstruction. Together, these loci provide new molecular targets for therapeutic intervention of the major cause of mortality in CF.

3123T

A Homozygous NIPAL4 Mutation In A Case With Ichthyosis And Deafness. *E. Arslan Ates[1], H. Onay[2], I. Ertam[3], B. Senturk[3], F. Ozkinay[2].* 1) Medical Genetics, Sevket Yilmaz Training and Research Hospital, Bursa, Turkey; 2) Medical Genetics, Ege University Faculty of Medicine, Izmir, Turkey; 3) Dermatology, Ege University Faculty of Medicine, Izmir, Turkey.

Hereditary ichthyosis is a a group of keratinization disorder characterized by skin scaling and dryness. It is classified as syndromic and nonsyndromic ichthyosis depending on the presence of systemic findings. Keratitits-Ichthyosis-Deafness (KID, OMIM ID#148210) syndrome is one of the syndromic Ichthyosis disorders. Its cardinal features are ichthyosis, sensorineural deafness and ophthalmological findings. Heterozygous Connexin 26 (GJB2) gene mutations have been described as the underlying defects of KID. Autosomal Recessive Congenital Ichyhosis (ARCI) is a nonsyndromic ichthyosis form, without any systemic involvement. TGM1, NIPAL4, ALOX12B, ALOXE3, CYP4F22, ABCA12, PNPLA1 and LIPN genes have been described associated with ARCI. Here, we present a 6 year-old girl with ichthyosis and deafness. She was born to consanguineous parents. Scaling and redness of skin were recognised at birth. On physical examination she had typical skin findings of ichthyosis. Histopathological evaluation of skin biopsy was compatible with vulgar icthyosis. She had sensoryneural deafness. Ophthalmologic examination was normal. Because she was considered to have KID Syndrome, CX26 gene was sequenced and no mutation was found. Subsequently, TGM1 gene which have been known to be the most common cause of ARCI has been sequnced but no mutation was found in this gene as well. The second most common cause of ARCI are the defects found in NIPAL4 gene. Therefore NIPAL 4 gene was sequenced as the third gene and a homozygous c.527C>A (p.A176D) mutation was detected. To date there have been no reported ARCI case having deafness and NIPAL4 mutations in the literature. Althoug there may be a coincidence in this patient, NIPAL4 mutation analysis should be considered in patients with KID syndrome or in patients having both ichthyosis and deafness.

3124S

The *ALK1* IVS3-35A>G polymorphism is associated with arteriovenous malformations in hereditary hemorrhagic telangiectasia patients with *ENG* mutations, but not in patients with *ALK1* mutations. *L. Pawlikowska[1,2], J. Nelson[1], D.E. Guo[1], C.E. McCulloch[3], M.T. Lawton[4], W.L. Young[1,4], H. Kim[1,2,3], M.E. Faughnan[5,6], Brain Vascular Malformation Consortium HHT Investigator Group.* 1) Center for Cerebrovascular Research, Dept of Anesthesia and Perioperative Care, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Dept of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 4) Dept of Neurological Surgery, University of California, San Francisco, San Francisco, CA; 5) Division of Respirology, Department of Medicine, University of Toronto, Toronto, Canada; 6) Division of Respirology, Dept of Medicine and Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, Canada.

Background. Hereditary hemorrhagic telangiectasia (HHT) is caused by mutations in several TGFβ signaling pathway genes. Most HHT patients have a mutation in *ENG* or *ALK1* (*ACVRL1*) and have diverse phenotypes including chronic bleeding, hemorrhage, stroke, heart failure and other complications related to skin and mucosal telangiectases and organ arteriovenous malformations (AVM). The phenotypic heterogeneity of HHT suggests a possible role for genetic modifier effects. The common polymorphisms *ALK1* IVS3-35A>G and *ENG* 207G>A have been reported to be associated with sporadic brain AVM (BAVM); the *ALK1* IVS3-35A>G association has been replicated in 2 independent cohorts. We hypothesized that these polymorphisms are also associated with AVM in HHT patients. **Methods.** We genotyped *ALK1* IVS3-35A>G and *ENG* 207G>A in 716 HHT patients (95.9% Caucasian) recruited by the Brain Vascular Malformation Consortium. We evaluated association of genotype with AVM, defined as presence of any BAVM, liver AVM (LAVM) or pulmonary AVM (PAVM), and separately with each AVM type. Logistic regression analyses were adjusted for age, gender and family structure and further stratified by HHT mutation status (*ALK1* or *ENG*). **Results.** Among HHT patients with complete clinical data, 71% had at least one AVM, 50% had PAVM, 20% had BAVM and 20% had LAVM. Among 436 (61%) patients with mutation status available, 48% had *ENG* mutations and 43% had *ALK1* mutations. Among all 716 HHT patients, neither polymorphism was significantly associated with AVM, although *ALK1* IVS3-35A>G showed a trend toward association with PAVM (OR=1.48, 95%CI=0.90-2.22, p=0.062). When stratifying by HHT mutation, *ALK1* IVS3-35A>G was significantly associated with AVM among *ENG* mutation carriers (OR=2.66, 95%CI=1.15-6.13, p=0.022), but not among *ALK1* mutation carriers (OR=0.79, CI=0.38-1.63, p=0.52). *ALK1* IVS3-35A>G was also significantly associated with PAVM (OR=2.45, p=0.016) and LAVM (p<0.05, all 42 LAVM-positive patients carried the A risk allele) among *ENG* mutation carriers. There were no significant associations between *ENG* 207G>A and AVM, but a trend toward association with BAVM (OR=3.09, p=0.16) was observed among *ALK1* mutation carriers. **Conclusions.** *ALK1* IVS3-35A>G was associated with AVM in HHT patients bearing *ENG* but not *ALK1* mutations. These results suggest that common polymorphisms in TGFβ pathway genes other than the mutated HHT gene act as genetic modifiers and contribute to HHT phenotypic heterogeneity.

3125M

Neutral Lipid Storage Disease with Myopathy: disease modeling using patients' hiPSc. *D.A. Coviello[1], S. Missaglia[2], M. Castagnetta[1], E.M. Pennisi[3], M. Mogni[1], D. Tavian[2,4].* 1) Laboratory of Human Genetics, E.O. Ospedali Galliera, Genoa, GE, Italy; 2) Laboratory of Cellular Biochemistry and Molecular Biology, CRIBENS, Catholic University of the Sacred Heart, Milan, MI, Italy; 3) UOC Neurologia, A.C.O. San Filippo Neri, Rome, RM, Italy; 4) Psychology Department, Catholic University of the Sacred Heart, Milan, MI, Italy.

Mutations in the PNPLA2 gene cause the onset of Neutral Lipid Storage Disease with Myopathy (NLSD-M), a rare autosomal recessive disorder characterized by an abnormal accumulation of triacylglycerol into cytoplasmic lipid droplets (LDs). In most tissues the LDs are cellular organelles for the triacylglycerol storage. LDs metabolic functions are mediated by proteins bound to their surface. In particular, the lipase that catalyzes the removal of the first acyl chain from triacylglycerol is the adipose triglyceride lipase (ATGL), also known as patatin-like phospholipase domain-containing protein 2 (PNPLA2). To our best knowledge, twenty six different PNPLA2 mutations have been described in thirty two NLSD-M patients. NLSD-M patients are mainly affected by progressive myopathy, cardiomyopathy and hepatomegaly. However, their clinical severity appears to be highly variable. Other clinical symptoms may include diabetes, chronic pancreatitis and short stature. NLSD-M has, at present, no specific therapy. We have previously reported clinical and genetic findings of some NLSD-M patients obtaining dermal biopsies from them. Here we report the development of hiPSc (human induced pluripotent stem cell) from patients' fibroblasts harboring different PNPLA2 mutations. The first patient was found to be homozygous for a deletion at nucleotide 542 (c.542delAC). This deletion caused a premature stop codon at position 212. The molecular analysis of patient 2 showed a homozygous missense mutation, c.662G>C (p.R221P). Initial hiPSc colony selection was based on morphologic evaluation and on detection of pluripotency surface markers (SSEA-4 and TRA-1-81). HiPSc also expressed undifferentiated ES cell markers (NANOG, SOX2 and OCT4). Moreover, embryoid bodies (EBs) have been generated from NLSD-M-iPSCs to assess the pluripotent properties of these cells. Karyotypic analysis of hiPSc lines indicated a normal complement of chromosomes. Immunohystochemical evaluations of LDs on hiPSc revealed that they recapitulate pathological hallmark of the disease. We propose use of inherently patients- and disease specific hiPSc to study the pathogenetic mechanisms leading to NLSD-M and as a potential model for therapeutic evaluation. Communications to: daniela.tavian@unicatt.it.

British Ectopia Lentis (EL) patients with novel *ADAMTSL4* mutations: 2 homozygotes, 1 compound heterozygote & 1 compound heterozygote involving a splice site. *J.A. Aragon-Martin[1], Y.B.A. Wan[1], L. Collins[1], P. Mazadza[1], G. Arno[2], A. Chandra[3], D.G. Charteris[4], A. Saggar[5], A.H. Child[1].* 1) Cardiovascular Sciences Research Centre, St George's University of London, London, England, United Kingdom; 2) Institute of Ophthalmology, University College London, London, United Kingdom; 3) Vitreoretinal Unit, Royal Victorian Eye and Ear Hospital, Melbourne, Australia; 4) Vitreoretinal Surgery, Moorfields Eye Hospital, London, United Kingdom; 5) Clinical Developmental Sciences, St George's University of London, London, United Kingdom.

Background: Ectopia Lentis (EL) is clinically & genetically heterogeneous (autosomal dominant - MIM 129600; autosomal recessive - MIM 225100). The dominant form can arise through mutations in *FBN1* (Comeglio et al. 2007), at the milder end of the type-1 fibrillinopathy spectrum. The recessive form has been shown to be caused by *ADAMTSL4* mutations (Aragon et al. 2010). EL is characterized by the disruption of the zonular fibers. In time, the lens moves out of place causing lens subluxation.

Methods: Seventy-five UK patients with isolated EL were bidirectionally Sanger sequenced for mutations in the coding exons including intron/exon boundaries of *ADAMTSL4* gene. The patients did not fulfill the Ghent criteria for Marfan syndrome & 73% were *FBN1* negative. When possible, compound heterozygotes were confirmed by family screening. Mutations were based on the transcript NM_019032. Genome databases (1000Genome & EVS) & in-silico tools (GVGD, Mutation T@ster, Polyphene-2, SIFT, BDGP & ESE_finder) were used to help with the analysis of the mutations.

Results: Mutations in *ADAMTSL4* were found in 51/75 (68%) samples. Genetic Carriers - 19/75 (25%). Compound Heterozygotes - 12/75 (16%). Homozygotes - 20/75 (27%). Novel mutations: 2 homozygotes - [**c.963dupG/p.T322Dfs*10**] & [**c.2574_2580dupTGGGACG/p.G861Wfs*41**]; 1 compound heterozygote - [**c.888delG/p.R297Dfs*46** & **c.2594G>A/p.R865H**]; & 1 compound heterozygote involving a splice site - [**c.2270dupG/p.G758Wfs*59** & **c.2383-1G>C/splice site**]. The mutation p.R865H has been found so far as compound heterozygote in 4 patients; & once in an unaffected genetic carrier, parent of a compound heterozygote proband in our cohort.

Conclusions: This study supports the evidence that homozygous & compound heterozygous mutations in *ADAMTSL4* cause autosomal recessive EL, therefore demonstrating that *ADAMTSL4* could play a key role in the development &/or integrity of the zonular fibers. The identification of a causative mutation in *ADAMTSL4* will exclude Marfan syndrome in EL patients & guide clinical management, of particular relevance in young children affected with EL. In our EL population we screen first for *FBN1* mutations in marfanoid patients with autosomal dominant pedigrees, & first for *ADAMTSL4* in apparently autosomal recessive pedigrees. **Corresponding author**: jaragon@sgul.ac.uk.

3127S

Xeroderma Pigmentosum diagnosed in adulthood; atypical clinical presentation associated with a novel genetic defect in XPC gene. *C. Badenas[1,2], M. Meneses[1], M. Chavez-Bourgeois[1], S. Villablanca[1], P. Aguilera[1,2], A. Bennassar[1], Ll. Alos[1], S. Puig[1,2,3], J. Malvehy[1,2], C. Carrera[1,2].* 1) Hospital Clinic, Barcelona, Barcelona, Spain; 2) CIBER de Enfermedades Raras, Instituto de Salud Carlos III, Barcelona, Spain; 3) Universitat de Barcelona, Spain.

Importance: A case of Xeroderma Pigmentosum (XP) with a novel mutation in the XPC gene was diagnosed in a patient aged 42 after diagnosing multiple primary melanomas but none cutaneous carcinoma. XP is a rare genodermatosis caused by abnormal DNA-repair. XP complementation group C (XPC) is the most frequent type in Mediterranean countries. Early marked photoaging and non-melanoma skin cancers are the common clinical presentation from childhood. Observations: A phototype III otherwise healthy Caucasian male patient was referred to our Unit presenting sporadic melanoma. Initially another 4 melanomas were detected. Molecular studies did not identify mutations in CDKN2A, CDK4 or MITF genes. Two mutations in the XPC gene were detected: a c.2287delC (p.Leu763Cysfs*4) frameshift and a c.2212A>G (p.Thr738Ala) missense mutations. After digital follow-up, another 5 additional primary melanomas were diagnosed. Conclusions and Relevance: The p.Thr738Ala missense mutation has not been previously described. It may be the case that missense mutations in the XPC gene allow a partial functionality that could explain this unusual late onset XP. Atypical clinical presentation of XPC could be misdiagnosed as marked photoaging when genetic aberrations allow partial DNA repair capacity. Digital follow-up is the best strategy to ensure melanoma-early detection in these high-risk settings.

3128M

Mutation spectrum of the *ABCA4* Gene in Greek patients with Stargardt disease: Identification of two novel mutations and evidence of three prevalent mutated alleles. *S. KAMAKARI[1,2], G. KOUTSODONTIS[1], P. STAMATIOU[2], T. PANAGIOTOGLOU[3], I. DATSERIS[1], M. TSILIMBARIS[3].* 1) OPHTHALMIC GENETICS UNIT, OMMA OPHTHALMOLOGICAL INSTITUTE OF ATHENS, ATHENS, GREECE; 2) SCHOOL OF MEDICINE, UNIVERSITY OF ATHENS, GREECE; 3) DEPARTMENT OF OPHTHALMOLOGY, SCHOOL OF MEDICINE, IRAKLION, GREECE.

Purpose: Mutations in the *ABCA4*, photoreceptor-specific ATP-binding cassette transporter 4 gene (MIM 601691) have been associated with autosomal recessive Stargardt disease (STGD; MIM 248200) characterized by central vision impairment. This is the first systematic study investigating the frequency and pattern of disease-associated mutations among Greek STGD patients, never previously genetically characterized for sequence variations in the *ABCA4* gene. Methods: 34 unrelated and 2 related STGD patients were analyzed using the combined methodology of ABCR400 microarray analysis and direct sequencing of 4 selected or all 50 exons and flanking intronic regions of the *ABCA4* gene. Results: Disease-associated mutations, including two novel splice defects, c.4352+1G>A and c.5714+1G>C in introns 29 and 40, respectively, were detected in 28/34 unrelated patients analyzed (82.35%). Both mutant alleles were found in 16/28 cases (57.14%), whereas in 12/28 (42.85%) only one allele was identified. The major pathogenic allele c.5714+5G>A accounted for 28.57% of the mutant alleles. Other frequently mutant alleles were c.1622T>C/p.(Leu541Pro) alone or as a complex c.1622T>C, c.3113C>T /p.(Leu541Pro), p.(Ala1038Val) allele and c.5882G>A/p.(Gly1961Glu), each accounting for 23.8% of the mutated alleles. Notably, a young patient with unaffected parents whose paternal aunts were unexpectedly affected, were found homozygous for the p.(Leu541Pro)/p.(Ala1038Val) and compound heterozygous for the p.(Leu541Pro)/p.(Ala1038Val) and p.(Gly1961Glu) alleles, respectively thus resolving the atypical inheritance pattern and different disease severity. Conclusions: This first report of the *ABCA4* mutation spectrum underlying STGD disease in Greece further elucidates the distribution of *ABCA4* mutations in European populations. The detection rate by the combined methodology was 82.35%. We identified two novel, potentially pathogenic *ABCA4* splice mutations and 3 prevalent disease-causing alleles. Further evaluation of the genotype-phenotype correlations will advance our knowledge of STGD 's etiology in Greek patients.

The formation of cilia is a fundamental developmental process affecting diverse functions such as intracellular signaling, mechanotransduction, tissue morphogenesis and body patterning. Defects in ciliogenesis result in a diverse spectrum of human diseases, known as ciliopathies. However, the precise mechanisms of ciliogensis during vertebrate development are not fully understood. In this report we describe a novel role of the Nlz1 protein in ciliogenesis. We demonstrate morpholino-mediated knockdown of nlz1 in zebrafish caused abnormal specification of the cells of Kupffer's vesicle (KV, similar to the mammalian node); a severe reduction of the number of cilia in KV, the pronephros, and the neural floorplate; as well as a spectrum of later phenotypes reminiscent of human ciliopathies. nlz1 is expressed in KV and in the nucleus of dividing cells. In vitro and in vivo data indicate that Nlz1 acts downstream of the ciliary "master transcription factor", Foxj1a and, Nlz1, is upregulated by canonical Wnt signaling. Mutation screening of NLZ1 in humans with a variety of ciliopathies and left-right patterning defects are underway. Together, our data suggest a novel role of nlz1 in ciliogenesis and the morphogenesis of multiple tissues.

A primary ciliopathy protein plays an extra-ciliary role in neurodevelopmental disease. *N. Nuangchamnong[1], C.S. Carter[2,3], Q. Zhang[2,3], T. Vogel[4], V.C. Sheffield[2,3].* 1) Obstetrics and Gynecology, University of Iowa, Iowa City, IA; 2) Pediatrics, University of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA; 4) Neurosurgery, University of Cincinnati, Cincinnati, OH.

Hydrocephalus affects 1 to 3 of every 1000 live births and is a significant cause of perinatal and pediatric morbidity and mortality despite current surgical interventions. The majority of congenital cases are idiopathic, but hydrocephalus is increasingly considered to be a neurodevelopmental disorder. Bardet-Biedl Syndrome (BBS) is an autosomal recessive human ciliopathy in which neurological defects are common findings, and in which ventriculomegaly occurs at a higher incidence than in the general population. Primary cilia are now recognized for playing a critical role in development of the central nervous system. We have previously shown that a mouse model with a mutated component of the BBSome complex (BBS1) has aberrant cell signaling at primary cilia that causes decreased survival and proliferation of a specific class of neural progenitor cells and leads to mild communicating neonatal hydrocephalus that can be partially rescued with lithium. Further exploration of the molecular mechanisms underlying hydrocephalus has the potential to make noninvasive pharmacologic treatments possible. In this study, we use a hydrocephalic mouse model that lacks BBS3, a GTPase that is necessary for localization of the BBSome to the ciliary gate, but that, unlike BBS1, is not a component of the BBSome complex. We compare the development of hydrocephalus in the BBS3 knockout mouse to wild type littermate controls and to mice with a mutated component of the BBSome complex (such as BBS1). We find late fetal onset of hydrocephalus in the BBS3 knockout mouse model with ventriculomegaly as early as embryonic day 17 (E17). We also find decreased apoptosis along the cerebellar ventricular zones and increased apoptosis at the midbrain tectum overlying the Sylvian aqueduct of BBS3 knockout mice at E17. Similar to the BBS1 mouse model, there is increased apoptosis and decreased proliferation of cells in the subventricular zone of the lateral ventricles in the neonatal period. Unlike the BBS1 model, however, there is fetal rather than neonatal onset of ventricular dilation and postnatal progression to severe disease that is consistent with a non-communicating (obstructive) type of hydrocephalus. The knockout BBS3 mouse is a useful model of obstructive congenital hydrocephalus, as BBS3 may have an extra-ciliary function that prevents progression of hydrocephalus from mild to severe.

Congenital heart disease associated to PCD. *J. Wallmeier[1], H. Olbrich[1], P. Pennekamp[1], C. Edelbusch[1], N.T. Loges[1], C. Werner[1], D. Kececioglu[2], B. Stiller[3], H. Omran[1].* 1) Department of Pediatrics, University Hospital Muenster, Muenster, Germany. , Muenster, NRW, Germany; 2) Klinik fuer Angeborene Herzfehler; Herz- und Diabeteszentrum NRW; Georgstraβe 11; 32545 Bad Oeynhausen,Germany; 3) Department of Pediatric Cardiology, University Hospital Freiburg, Freiburg, Germany.

Primary ciliary dyskinesia (PCD) is a rare genetic disorder, that is characterized by recurrent infections of the upper and lower respiratory airways, sinusitis and otitis media, and is often associated with reduced fertility of males. In 50% of PCD-patients laterality defects occur, mostly *situs inversus totalis* (Kartagener's syndrome). About 6% of all patients show heterotaxy. There are certain organ abnormalities that are associated with heterotaxy such as asplenia and polysplenia. An important consequence associated with heterotaxy are complex cardiac defects. Dysfunction of motile cilia and flagella explains the complex PCD phenotype involving various organ systems. Respiratory epithelia covered with cilia move extracellular mucus towards the throat with a coordinated beating (mucociliary clearance). Loss of this mucociliary clearance causes recurrent respiratory infections. Dysfunction of nodal cilia during early embryogenesis causes randomization of left/right body asymmetry. So far 28 genes have been identified to cause PCD either coding for axonemal proteins or ciliary assembly factors. One of the first identified and most often mutated genes *DNAH5* causes an outer dynein arm defect leading to cilia with just residual ciliary beating. We sequenced all coding exons of *DNAH5*, by sanger sequencing including the exon-/intron boundaries in a cohort of 101 patients. All patients were followed up in cardiologic centres, suffered from heterotaxy and/or congenital heart defects, and had not been further evaluated for PCD. We refer to heterotaxy as the instance of *situs inversus totalis*, which means a mirror image of the common situs (*situs solitus*) as well as the instance of *situs ambiguous*, an abnormal arrangement of the thoracic or abdominal organs. Interestingly, two loss-of-function mutations in *DNAH5* (deletion-/stop-mutation) were identified. The results of these genetic analyses established the diagnosis of PCD. Even though PCD is a rare disorder 1% of our cohort with heterotaxy showed a mutation in one of the most common PCD causing genes. Because *DNAH5* only accounts for ~25% of PCD cases possibly some more patients of the analysed heterotaxia cohort will suffer from PCD. Therefore we like to emphasize the importance of the differential diagnosis of PCD in patients with CHD and respiratory disease.

Ductal plate malformations (DPM) present with a wide phenotypic spectrum comprising Von Meyenburg complexes (VMC), Caroli disease (CD), Caroli syndrome (CS), and autosomal recessive polycystic kidney disease (ARPKD). Familial forms of CD have been rarely described. In a family of 3 siblings presenting with the whole spectrum of severity of DPM (CS with renal cysts, CD and VMC), we performed whole exome sequencing and identified 2 compound heterozygous mutations of PKHD1, including in cis c.10444G>A; p.Arg3482Cys and in trans c.5521C>T; p.Glu1841Lys, segregating with the symptoms. Thereafter, we screened two other familial cases of DPM with at least one patient presenting with CD, and identified 2 compound heterozygous PKHD1 variants in each case, including one hypomorphic mutation. PKHD1 gene encodes fibrocystin, which is expressed in the primary cilium of renal epithelial cells and bile ducts. Mutations in PKHD1 are responsible for ARPKD, with an inconstant liver phenotype that could remain asymptomatic. Only few patients are diagnosed at the adult age with liver-related complications that could be related to CS in association with mild kidney disease. Exceptional cases of CD are associated with PKHD1 mutations. This report, together with the recent literature, confirmed that PKHD1 is a major gene responsible for isolated Caroli disease, and also expands the clinical manifestations associated with mutations of PKHD1 to VMC and thus to the whole spectrum of DPM. In such mild phenotypes, systematic hepatic and renal screening appears mandatory in asymptomatic siblings of affected patients, in order to determine at risk patients that should beneficiate from regular follow-up. These results give another example of the major inter- and intra-familial phenotypic variability associated with PKHD1 mutations. Whereas truncating mutations of PKHD1 are associated with the more severe phenotype, the pathogenicity of missense mutation remains unclear and the association of missense / hypomorphic mutations could explain mild phenotypes. Finally, this work adds an example of the contribution of exome sequencing, not only in the discovery of new genes but also in expanding the phenotypic spectrum of well-known disease-associated genes, using reverse phenotyping.

Stem Cells from Offspring of Mothers Demonstrate Evidence for Developmental Programming in Obesity. *P.R. Baker, K.E. Boyle, A.L. Butti, D. Dabelea, L.A. Barbour, J.E. Friedman.* University of Colorado, Aroura, CO.

Background: Developmental programming is a major contributor to obesity. Although there is strong evidence for the long-term effects of in utero exposure to maternal diabetes and obesity, and potential fetal overnutrition, the exact mechanisms by which these effects are transmitted from human mother to offspring remain poorly understood. Skeletal muscle of obese adults shows alterations in key mitochondrial energy pathways (including branched chain amino acid (BCAA) dependent intermediary metabolism and compromised fatty acid oxidation (FAO)). Myocytes derived from multipotent MSC populations have the potential to reveal early changes that may predispose infants to obesity. Here we test the hypothesis that umbilical cord-derived MSCs from infants of obese (Ob) vs normal weight (NW) mothers differentiated into myocytes (skMSC) manifest impaired mitochondrial metabolism when challenged with lipid exposure. Design/Methods: We used data from the Healthy Start Study. This pre-birth cohort study of maternal-infant pairs provides detailed maternal data, including pre-pregnant body mass index (BMI), and cord tissue samples. MSCs derived from full term infants born to NW (BMI<25, n=5) and Ob mothers (BMI>30, n=5) were grown and differentiated into myocytes under control and lipid exposed conditions. On day 21 of differentiation media from all cells was tested for amino acid concentrations using the Biochrom 30 Amino Acid Analyzer. Two-way Analysis of Variance compared the effects of maternal pre-pregnant BMI, treatment, and their interaction. Results: SkMSC from infants of Ob mothers had elevations in BCAA (leucine and isoleucine), Alanine, and Citrulline versus skMSC from infants of NW mothers (p=0.05, 0.04, 0.01, and 0.05). All of these increased with exposure to lipid. Only 2-aminobutyric acid, an under-recognized methionine and threonine intermediary metabolite, decreased with lipid exposure in Ob but increased in NW samples (p= 0.02 interaction). Conclusions: Differential handling of amino acids suggest differences in mitochondrial energy metabolism in offspring of Ob mothers. More data is needed to demonstrate use in intermediary metabolism rather than differences in cell transport or anabolism, however our data is consistent with amino acid findings in obese adult serum. This MSC model will further be valuable in the targeted study of energy metabolomics, transcriptomics, and epigenomics in fetal programming and obesity.

3134S

Aberrant activation of the sex-determining gene in early embryonic development results in postnatal growth retardation and lethality in transgenic mice. *T. Kido, Z. Sun, Y. Li, Y. Lau.* Dept Med, VA Med Ctr 111C5, Univ California, San Francisco, San Francisco, CA.

Sexual dimorphisms are prevalent between the sexes, particularly in neurodevelopment. Currently, the role of the Y chromosome in such phenomena has not been clearly defined. Among the Y chromosome genes, the sex-determining gene, *SRY*, could be a significant candidate capable of exerting male-specific effects on sexual dimorphisms. *SRY* is the founder of the SRY-box (*SOX*) genes, which are key regulators for various developmental processes. SRY and SOX proteins harbor a conserved HMG box DNA-binding domain. An ectopically expressed SRY could compete with the SOX factors in regulating the respective SOX targets, thereby disrupting the corresponding developmental processes. To test this hypothesis, we have established a transgene activation mouse system, in which a *SRY* transgene could be activated by a tissue-specific Cre. The Ddx4-Cre transgenic line expresses the Cre recombinase exclusively in the germ lines of both sexes. When a female Ddx4-Cre is crossed with a male SRY responder, the Cre recombinase is transferred to the single-cell embryo from the fertilized oocyte, thereby activating the SRY transgene in all tissues. However, when a male Ddx4-Cre is crossed with a female SRY responder, the *SRY* transgene could not be activated till later in germ cells. Hence, *SRY* transgene could be activated differentially with the respective sex of the Ddx4-Cre mice. Our results show that early activation of *SRY* transgene during embryonic development results in significant postnatal growth retardation of the offspring, which do not survive beyond two weeks of age while late and male germ cell activation of *SRY* transgene result in normal postnatal development. Characterizations of pups with early *SRY* transgene activation show significant abnormalities in heart, liver and brain development. Comparative transcriptome analysis of the brains between mutant and control pups show increases in functions of organismal death, hypoplasia, abnormalities in head and cerebrum, and lack of dentate gyrus development but significant decreases in functions of transcription, cell quantity, dendritic cell migration, long-term potentiation, neuritogenesis, behavior, learning, cognition, and dendritic growth/branching. Our results suggest that ectopic activation of *SRY* in non-gonadal tissues could have significant disruptive effects in embryonic development, including neurodevelopment while a mild *SRY* activation could be responsible for dimorphisms observed between the sexes.

3135S

Autophagy retards inflammatory mRNA decay and elicits a white phenotype during adipocyte maturation. *J. Shan, A. Worschech, R. Thomas, L. Chouchane.* Laboratory of Genetic Medicine and Immunology, Weill Cornell Medical College in Qatar - Qatar Foundation, Doha, Qatar.

Background: Recently, the role of autophagy in glucose and lipid metabolism has been emerging. Mice experiments showed that autophagy deficiency could prevent diet-induced obesity, characterized by less fat and a browning phenotype of white adipocyte (WAT). However, the underlying molecular mechanism is not well explored and the data from human are limited. Method: The mRNA sequencing data of undifferentiated and differentiated human adipocyte cell lines, including two white adipocyte (WAT) and one brown adipocyte (BAT) were included in our analysis. Gene expression was reduced by RNA interference in human adipocyte and was enhanced by glucocorticoid, respectively. Qualifying the lipid droplet content and quantifying the adipolysis and differentiation marker expression were applied to evaluate WAT differentiation. LC3 was used as a marker to examine autophagy function of adipocyte. Result: We found a remarkable feature of adipocyte differentiation that inflammation signaling was significantly strengthened during WAT maturation, but not during BAT maturation. The alteration of Zinc Finger protein 36 (ZFP36), which mediates the decay of mRNA transcripts of inflammation molecules, obviously affected the phenotype of mature WAT: silencing of ZFP36 gene resulted in a more whitening phenotype and induction of ZFP36 resulted in a browning phenotype. ZFP36 activity was associated with p38 MAPK signaling that was regulated by autophagy. Conclusion: ZFP36 links autophagy to the determination of mature adipocyte phenotype. Therefore, ZFP36 is a potential target to prevent obesity and improve glucose and lipid metabolism.

RNA-Seq to identify novel markers for neural tissue differentiation. *Y. Sun[1], K. Giorda[1], E. Frey[2], M. Taylor[1], T. Barron[2], C. Davidson[1], D. Piper[2], G. Meredith[1].* 1) Thermo Fisher Scientific, South San Francisco, CA; 2) Thermo Fisher Scientific, Madison, WI.

Neural tissue differentiated and cultured from patient-derived stem cells is expected to revolutionize treatment of patients with brain and spinal injuries and diseases. Critical for these cellular therapies is accurate control and monitoring of differentiation but current methods for such cell typing are limited to qPCR and immunocytochemisty (ICC) which is not sufficient to discriminate between the numerous (likely >100,000) possible neural cell-types. RNA-Seq profiling using next-generation sequencing systems permits characterization and discovery of much-needed novel markers. RNA was isolated over a time course from human embryonic stem cells (H9) and induced neural stem cells (NSCs) in triplicate. ICC was performed on the putative NSC pools at d7 and d14 for markers of pluripotency (Oct4) and neural differentiation (nestin, Sox1, and Pax6) and H9 cells were stained on d14 for markers of pluripotency (Oct4 and SSEA4). Ion Torrent semiconductor sequencing libraries were created to profile expression of miRNAs and whole transcriptomes for each of the 15 cell populations. We generated ≥1.5 million small RNA reads and ≥29 million whole transcriptome reads per sample. Cluster analysis of the RNA-Seq profiles indicates that the cell populations have characteristic molecular signatures. Among genes that are decreased in induced cells are OCT4 (POU5F1), JARID2, NANOG , consistent with the differentiation of iPSCs into neurons. Among genes that showed increased expressions are NTRK2, POU3F2, and a number of HOX family genes. We also find lincRNA are involved in cell differentiation. For Research Use Only. Not for use in diagnostic procedures.

A conserved role for IRF6 in neurulation. *Y.A. Kousa[1], H. Zhu[2], W. Fakhouri[3], Y. Lei[2], A. Kinoshita[4], R.R. Roushangar[1], E.J. Leslie[5], T.D. Busch[6], T.J. Williams[7], Y. Chai[8], B.A. Amendt[9], J.C. Murray[6], G.M. Shaw[10], A.G. Bassuk[6], A. Ashley-Koch[11], S. Gregory[11], R.H. Finnell[2], B.C. Schutte[12].* 1) Biochemistry and Molecular Biology Department, Michigan State University, 48824 East Lansing, Michigan, USA; 2) Dell Pediatric Research Institute, Department of Nutritional Sciences, University of Texas at Austin, 78723 Austin, Texas, USA; 3) Department of Diagnostic & Biomedical Sciences, School of Dentistry, University of Texas at Houston, 77054 Houston, Texas, USA; 4) Department of Human Genetics, Nagasaki University, Nagasaki, Japan; 5) Center for Craniofacial and Dental Genetics, Department of Oral Biology, University of Pittsburgh; 6) Department of Pediatrics, University of Iowa, 52242 Iowa City, Iowa, USA; 7) Department of Craniofacial Biology, University of Colorado Denver at Anschutz Medical Campus, 80045 Aurora, Colorado, USA; 8) Center for Craniofacial Molecular Biology, Ostrow School of Dentistry, University of Southern California, 90033 Los Angeles, California, USA; 9) Department of Anatomy and Cell Biology, University of Iowa, 52242 Iowa City, Iowa, USA; 10) Department of Pediatrics, Stanford University School of Medicine, 94305 Stanford, California, USA; 11) Duke Molecular Physiology Institute, Department of Medicine and Molecular Genetics and Microbiology, Duke University, 27701 Durham, NC, USA; 12) Department of Microbiology and Molecular Genetics, Michigan State University, 48824 East Lansing, Michigan, USA.

IRF6, TFAP2A and GRHL3 are part of a gene regulatory network that is required for development of the lip and palate in humans and mice. However, in mice, Tfap2a and Grhl3 are also required for neurulation. To test the hypothesis that Irf6 is also required for neurulation, we evaluated an allelic series of Irf6 mutant mice for neural tube defects. We found that overexpressing Irf6 led to anencephaly by directly repressing Tfap2a transcription. Reducing Irf6 expression led to the mouse equivalent of spina bifida by regulating Tfap2a and Grhl3. In addition, we observed Irf6 expression in neural and non-neural ectoderm and early migrating neural crest cells. Moreover, we observed that MCS9.7, an enhancer for IRF6, was active in pre-migratory neural crest during neurulation. Considering these data in mice, we asked if rare or common IRF6 variants are associated with human spina bifida. To find rare variants, we sequenced all IRF6 exons in 92 individuals with spina bifida. In one individual, we identified a rare nonsynonymous substitution previously reported in dominantly inherited orofacial clefting. In the 3'UTR, we identified a conserved region that regulated Irf6 stability in a cell culture assay. Within this element, we found a common SNP (rs17317411 T/C) whose derived allele (C) is predicted to create a new miRNA-binding site. Genotyping in 735 trios with spina bifida showed a significant association between the derived allele of rs17317411 and lipomyelomeningocele (N = 68 trios; p value = 0.04), but was not statistically significant for other types of spina bifida. To date, we have also sequenced MCS9.7 in 158 cases and 171 controls. We observed a significant association between the derived allele of rs76145088 and spina bifida (p=0.016). Interestingly, the derived allele at rs76145088 is predicted to abrogate a highly conserved cis-regulatory motif for the TEAD/TEF family of transcription factors. The TEAD family members mediate Hippo signaling in the neural plate border and pre-migratory neural crest cells and regulate neural progeniter cell number. In sum, we identified a conserved role for IRF6 in neurulation between mouse and humans that is in addition to its role in orofacial clefting. This is a rare example of two common variants, located in the same enhancer element, that contribute risk for more than one common, complex human disease.

3138S

Analysis of *CAPZB* function in cleft pathogenesis and lower jaw extension. *K. Mukherjee[1,4], M. Grimaldi[1], M. Talkowski[2,4], J. Gusella[2,4], R. Maas[3,4], C. Morton[3,4], E. Liao[1,4].* 1) Center for Regenerative Medicine, Massachusetts General Hospital; 2) Center for Human Genetic Research, Massachusetts General Hospital; 3) Brigham and Women's Hospital; 4) Harvard Medical School, Boston, MA.

Purpose: Orofacial clefts are among the most common congenital birth anomalies worldwide. Clefts and other craniofacial anomalies arise due to defects in craniofacial morphogenesis. In an ongoing gene discovery effort, the Developmental Genome Anatomy Project (DGAP) has developed whole genome sequencing strategies to characterize genes contributing to such human congenital anomalies. Through DGAP, we discovered a new candidate gene for cleft palate (CP), *CAPZB* that encodes an actin-capping protein. The isolated disruption of *CAPZB* was identified in a 6-month old female presenting cleft palate, micrognathia and hypotonia. We have exploited the zebrafish model to determine the function of *capzb* in craniofacial morphogenesis. **Methods:** The zebrafish embryonic Meckel's cartilage and ethmoid plate are analogous to the mammalian mandible and primary palate respectively, making it an ideal model system to study palate and lower jaw morphogenesis. The spatiotemporal gene expression of *capzb* was determined by whole mount *in situ* hybridization (WISH) during embryogenesis. Craniofacial cartilaginous structures and muscles were examined in the *capzb* mutant, identified from an insertional mutagenesis screen. **Results:** WISH analysis shows that *capzb* is ubiquitously expressed, demonstrating its potential requirement in the function of many tissue types. Moreover, preliminary analysis of the *capzb* mutants show that the lower jaw elements are smaller and retrusive and the palate is only partially fused with a cleft in the anterior palate. The actin cytoskeleton is in disarray without capzb, with loss of cell morphology in the palate chondrocytes and highly disorganized myofibrils, leading to atrophied muscles. **Conclusion:** We have identified *CAPZB* to be important in craniofacial and muscle morphogenesis, disruption of which is pathologic for palate development. Preliminary results from characterization of the *capzb* mutants suggest that *capzb* plays a role in palate fusion and lower jaw extension, and affects tissue types where actin organization is critical to cell morphology and higher order organ morphogenesis. Experiments are under way to delineate the mechanisms of *capzb* function in craniofacial morphogenesis and in regulation of fundamental cellular mechanisms where actin dynamics and cell signaling pathways intersect. This study illustrates how clinically based studies can uncover fundamental mechanisms that govern cell biology and tissue morphogenesis.

3139S

A novel transcriptional regulatory pathway in cardiac and skeletal muscle. *J. Bharj[1], D. Osborn[1], D. Zheng[1], M. Uysaloglu[1], J. Ross[2], F. Conti[2], Y. Jamshidi[1].* 1) Cardiogenetics Lab, St George's University of London, London, London, United Kingdom; 2) Dubowitz Neuromuscular Centre, Institute of Child Health, London, United Kingdom.

Gene expression can be regulated at the level of transcript elongation, when RNA polymerase pauses along the partially transcribed mRNA. Following the recruitment of transcription elongation factors (TEFs), RNA polymerase resumes transciption allowing for gene expression. Our aim was to determine the role of trancriptional elongation in the development of cardiac and skeletal muscle. Using zebrafish as a model organism, we confirm the expression of a cardiac and skeletal muscle specific elongation factor in these tissues. Morpholino-mediated knockdown of of this TEF leads to severe defects in development of the heart and somites, including aberrant looping, reduced circulation and detachment of somites from myosepta. Interestingly, these defects resemble those seen in zebrafish models of cardiomyopathy and muscular dystrophy, suggesting that defects in transciptional elongation may underlie these conditions. Analysis of gene expression shows deregulation of a large number of genes, including *titin* and *MEF2,* which are involved in heart and somite development. Strikingly, no known proteins involved in somite attachment appeared deregulated. This suggests either that TEFs regulate the expression of yet unkown effectors, or that the detachment of fibres is caused by small changes in the expression of a number of proteins. Our zebrafish model will be useful to further study transcriptional elongation, and may also lead to the identification of viable drug targets for cardiomyopathies and muscular dystrophies.

3140S

The Role of *RERE* in Cardiovascular Development. *H.P. Zaveri[1], B.J. Kim[1], A. Hernandez-Garcia[1], D.A. Scott[1,2].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX.

Deletions of chromosome 1p36 affect 1:5000 newborns. Over 70% of these infants have cardiovascular malformations. The arginine-glutamic acid dipeptide (RE) repeats gene (*RERE*) is located in one of five critical regions for cardiovascular malformations we have delineated on chromosome 1p36. *RERE* encodes a nuclear receptor coregulator that positively regulates retinoic acid signaling. In some tissues, this regulation involves the formation of a transcriptional complex that includes RERE and NR2F2, a nuclear receptor implicated in the development of cardiovascular malformations. Since perturbations in retinoic acid signaling can cause cardiovascular malformations, we hypothesized that RERE deficiency contributes to the development of cardiovascular malformations in children with 1p36 deletions. To test this hypothesis, we generated an allelic series of RERE-deficient mice using an *Rere* null-allele and an *Rere* hypomorphic allele (*eyes3*). *Rere*$^{-/-}$ embryos die of cardiac failure around E9.5 with enlarged midline hearts that have failed to undergo rightward looping. *Rere*$^{-/eyes3}$ embryos escape early embryonic lethality but have cardiovascular malformations—outflow tract, septal and valve abnormalities—that are similar to those seen in individuals with 1p36 deletions. Using these mouse models, we identified *in vivo* genetic interactions between *Rere* and *Raldh2*—which encodes the main enzyme that catalyzes retinoic acid production in the heart—and *Gata4*—which encodes a retinoic acid-responsive transcription factor that causes outflow tract and septal defects in humans. Further experiments revealed that the cardiac expression patterns of RERE and NR2F2 overlap in the atrioventricular canal and that *Nr2f2* interacts genetically with *Gata4* during septal development. We also found that manipulation of *in utero* retinoic acid levels was insufficient to rescue RERE-related cardiovascular malformations. These results suggest that RERE and NR2F2 may form a complex during heart development that acts downstream of RALDH2 to modulate the transcription of retinoic acid responsive genes—like *GATA4*—that play a critical role in the development of atrioventricular septum and its associated valves. We conclude that *RERE* contributes not only to the development of cardiovascular malformation caused by 1p36 deletions, but may also modulate the penetrance of cardiovascular malformations caused by mutations in *GATA4* and *NR2F2* and deletions of 8p23.1 and 15q26.2 where these genes reside.

3141S

Characterization of a knock-in mouse model expressing the Stormorken syndrome mutation. *T.H. Gamage[1], S.S. Amundsen[1], G. Gunnes[2], W.E. Louch[3], T.M. Pedersen[4], P.A. Holme[5,6], A. Holmgren[1], G.E. Tjønnfjord[5,6], A. Klungland[7], D. Misceo[1], E. Frengen[1].* 1) Department of Medical Genetics, Oslo University Hospital and University of Oslo, Oslo, Norway; 2) Faculty of veterinary medicine and biosciences, Norwegian University of Life Sciences, Norway; 3) Institute for Experimental Medical Research, Oslo University Hospital and University of Oslo, Norway; 4) Research Institute of Internal Medicine, Oslo University Hospital and University of Oslo, Norway; 5) Department of Hematology, Oslo University Hospital, Norway; 6) Institute of Clinical Medicine, University of Oslo, Norway; 7) Department of Molecular Medicine, Oslo University Hospital, Norway.

The *STIM1* [MIM *605921] R304W mutation was recently identified as the cause of Stormorken syndrome [MIM 185070] in patients from 8 independent families. STIM1 encodes the stromal interacting molecule 1, which is required for activation of the calcium release-activated calcium (CRAC) channel in the plasma membrane of most cell types. Previously, patients with complete STIM1 deficiency were described with combined immunodeficiency (CID), and patients with heterozygous missense mutations in the *STIM1* EF-hand present with tubular aggregate myopathy (TAM [MIM #160565]). Stormorken syndrome patients, however, present with a muscle phenotype (spasms, muscle weakness, lack of endurance capacity and TAM) as well as hematological defects (mild bleeding tendency, mild anemia, thrombocytopathy, thrombocytopenia), miosis, ichthyosis and asplenia. This wide range of clinical features indicates the importance of the *STIM1* function in several organs.

Our aim is to study the functional effects of the *Stim1* R304W mutation in a knock-in mouse model. We have established the knock-in mouse model on a CBA c57bl/6 background using Zinc finger technology. We compare the hematological aspects of knock-in vs wild-type mice to assess the functional consequences of the mutation. General behavior of mice is being observed and endurance testing is being performed to study the muscle phenotype. We are also presently performing a complete pathological and histological examination of the mouse. We expect that studying the biological consequences of the *STIM1* R304W mutation will provide new insight into STIM1 function, and reveal its role in the etiology and pathogenesis of Stormorken syndrome.

Haploinsufficiency of *RERE* contributes to the development of cleft palate in 1p36 deletion syndrome. *B. Kim[1], H.P. Zaveri[1], V. Jordan[2], D.A. Scott[1,2].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX.

Orofacial clefts—cleft palate and cleft lip with or without cleft palate—affect 1.7:1000 newborns and can lead to long-lasting adverse outcomes for health and social integration. Deletions of chromosome 1p36 are the most common telomeric deletions in humans and carry a high risk of orofacial clefts. The arginine-glutamic acid dipeptide (RE) repeats gene (*RERE*) is located in one of three non-overlapping critical regions for orofacial clefts we have defined on chromosome 1p36. *RERE* encodes a nuclear receptor coregulator that positively regulates vitamin A/retinoic acid signaling in the developing embryo. Since cleft palate can be caused by abnormalities in retinoic acid signaling, we hypothesized that haploinsufficiency of *RERE* may contribute to the development of cleft palate in children with 1p36 deletions. To test this hypothesis, we generated an allelic series of RERE-deficient mice using an *Rere* null-allele and an *Rere* hypomorphic allele (*eyes3*) identified in our laboratory. On a C57BL/6 background, cleft palate was seen in 80% (4/5) of $Rere^{-/eyes3}$ embryos at E15.5. When we ablated *Rere* in neural crest cells using a transgenic Wnt1-Cre, we found that $Rere^{flox/flox}$;Wnt1-Cre embryos and mice also developed cleft palates in which the opposing palatal shelves elevated into the normal horizontal position but failed to make contact in the midline. Further studies revealed that RERE is expressed in the bend region of the developing palate; a region where retinoic acid signaling controls cell proliferation and the expression of key palatal genes including *TBX1* that causes cleft palate associated with 22q11.2 microdeletions. We conclude that *RERE* plays a critical, cell-autonomous role in the neural crest cells during palatal development and that deletion of *RERE* contributes to the development of cleft palate in children with 1p36 deletions.

3143S

An animal model to investigate genetic variants in patients with 46,XY Disorders of Sex Development. *H. Barseghyan, V. Arboleda, R. Baxter, A. Eskin, S. Nelson, E. Délot, E. Vilain.* Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California.

Disorders of Sex Development (DSD) are defined as congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical. These conditions have a frequency of 0.5-1% of live births and encompass a wide variety of urogenital abnormalities ranging from mild hypospadias to sex reversal. At present, a specific molecular diagnosis is identified in only a minority of DSD cases. We used whole exome sequencing (WES) with gene list approach specific to DSD to identify the underlying genetic etiology for 46,XY DSD cases with a range of phenotypes. In 35% of these cases, exome sequencing identified mutations in genes, classified as pathogenic or likely pathogenic, that could explain the given phenotype. In the unexplained 65% of the cases, we identified a large number of variants of uncertain clinical significance (VUS). In order to investigate these variants, we utilized a powerful mouse model for studying undervirilization in 46,XY individuals. In this model, the presence of a Y chromosome originating from an M. domesticus strain (YPOS) in C57BL/6J (B6) background results in XY sex reversal and severe hypovirilization. We hypothesized that abnormal gonadal expression of specific genes in the B6-YPOS mouse model will correlate with VUS in genes of 46,XY DSD patients identified through WES. Thus, we isolated gonadal tissue at embryonic day 11.5 and performed RNA sequencing in order to assess the differential gene expression levels in the bipotential gonads of wild type (WT) B6 and undervirilized B6-YPOS males. The obtained differential expression data from the mouse model was analyzed in conjunction with WES data. We identified 12 genes in which the differential expression between WT and B6-YPOS males was significantly lower in B6-YPOS gonads, and in which a missense variant with an alternate allele frequency of less than 1% was identified in 46,XY DSD cases. Among these genes, four (FBLN2, SMTNL2, ADAMTS16, COL9A2) were predicted to be damaging by in silico tools. Additional studies and validation techniques are necessary to investigate the role of these new candidate genes for 46,XY DSD.

3144S

An Allelic Series Reveals Novel Roles of Fgf Ligands in Skeletogenesis. *I.H. Hung[1,2], G.C. Schoenwolf[1], M. Lewandoski[2], D.M. Ornitz[3].* 1) University of Utah, Salt Lake City, UT; 2) National Cancer Institute, Frederick, MD; 3) Washington University School of Medicine, St. Louis, MO.

Chondrodysplasia and craniosynostosis syndromes are caused by activating mutations in fibroblast growth factor (FGF) receptors. Although the roles of the FGFRs in bone development have been relatively well-characterized, only two FGF ligands, FGF9 and FGF18, have been identified to regulate embryonic skeletogenesis. We have generated an Fgf allelic series to further elucidate the functions of these growth factors during skeletal development. Mice lacking both Fgf9 and Fgf18 exhibit severe defects in endochondral and intramembranous ossification, demonstrating partial functional redundancy between these ligands. We provide evidence that FGF signaling is required at early developmental stages to prevent an arrest in chondrocyte differentiation of the proximal limb and to promote calvarial osteogenesis .

Phenotypic and functional characterization of $Bst^{+/-}$ mouse retina. *G. Sun[1,5], H. Riazifar[2,5], X. Wang[1], F.N. Ross-Cisneros[3], V. Carelli[4], A.A. Sadun[3], T. Huang[1,2].* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Pediatrics, Division of Human Genetics; University of California, Irvine, CA; 3) Doheny Eye Institute, Department of Ophthalmology, University of Southern California, Los Angeles, CA; 4) Dipartimento di Science Neurologiche, Universita di Bologna, Bologna, Italy; 5) Equal Contributor.

Current animal models for subretinal neovascularization (SRN) depend on using chemistry or physics methods to stimulate subretinal vessels grow. The animal model for retinal degenerative disease is also very limited. Genetic animal model for retinal disease is needed. The Belly spot and tail (Bst) mouse phenotype is caused by mutations of the ribosomal protein L24. $Bst^{+/-}$ mouse has striking ocular phenotypes, with the feature of delayed closure of choroid fissures, decreased ganglion cells, and subretinal vascularization. In seeking mouse model for stem cell therapy for retinal degenerative disease due to retinal ganglion cell (RGC) loss, we further characterized the $Bst^{+/-}$ mice and investigated the underlying molecular mechanisms. We found that although RGC was significantly reduced in retinal ganglion cell layer in $Bst^{+/-}$ mouse, melanopsin-positive RGC, also called ipRGCs seemed preserved. Pupillary light reflex is complete absent in $Bst^{+/-}$ mouse, while circadian rhythm is normal. In order to examine the pathological abnormalities in $Bst^{+/-}$ mice, we performed electronic microscope test and found mitochondria morphology was deformed with irregular borders and lacking cristae. The complex activities of mitochondrial electron transport chain were decreased significantly. Finally, for subretinal vascularization, the delay of angiogenesis was observed in $Bst^{+/-}$ mice associated with delayed haloid regression. Our characterization of $Bst^{+/-}$ mouse retina suggests that $Bst^{+/-}$ mouse could be a useful model for stem cell therapy.

3146S

Osteoblast development is driven by trans-acting regulations. *K. Choi[1], K. Shultz[1], D. Godfrey[1], M. Hibbs[2], C. Ackert-Bicknell[1], G. Churchill[1].* 1) The Jackson Laboratory, Bar Harbor, ME; 2) Trinity University, San Antonio, TX.

Understanding the genetic and molecular bases of normal osteoblast development is a key to new anabolic treatments for osteoporosis. To investigate development process of osteoblast, we generated time course RNA-seq data (Illumina HiSeq 2000) covering 9 time points from pre-osteoblast stage to mature osteoblast. The similar sets of data were derived from three different genetic backgrounds of C57BL/6J (B6) inbred, B6xCAST/EiJ, and B6x129S1/SvImJ hybrid mice.

We found that over 5,000 genes have either monotonically increasing or decreasing temporal expression patterns using Weighted Gene Co-expression Network Analysis tool version 1.34. For each strain, we ordered these monotone-patterned genes *temporally* with respect to their maximal change time by fitting to a four-parameter logistic growth model. We observed the temporal order of maximal expression change is largely preserved across the three mouse strains. We applied these time order to generate causality hypotheses in the MouseMap, a publicly available tissue-specific functional networks. For example, MouseMap provides the neighboring genes of Col3a1 but we do not know whether Col3a1 is triggering its neighboring genes or any of its neighbors is causing it to transcribe. But when we introduce temporal orders to the subnetwork, we can see Col3a1 is a requirement for its neighboring genes to function. Volk and colleagues reported that Col3$^{-/-}$ mice showed a significantly reduced mineralization capacity. We have found hundreds of interesting causal relationships, many of which are novel.

Time course transcriptome analysis of F1 hybrid coupled with its founder inbred strains is a great resource for identifying modes of gene regulation: whether a certain gene is regulated by cis- and/or trans-acting elements. Suppose a gene's total expression in F1 hybrid has different temporal pattern from those of its founder strains. If the two alleles are expressing similarly in the F1, then the gene has to be under trans-regulation since we know (1) local structural variations in those alleles do not influence their expression levels but (2) what is different between F1 and its founder strains is the trans-acting environment regulating this gene's transcription. We identified over 1,000 genes that are in trans-regulation in the process of osteoblast development using a statistically conservative filtering process.

3147S

The Role of SOX7 and SOX17 in Cardiovascular Development. *A. Hernandez-Garcia[1], M. Wat[1], R. Udan[2], A. Renwick[1], M. Garcia[2], Z. Yu[1], C.A. Shaw[1], M. Dickinson[2], D.A. Scott[1,2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX.

SOX7 is located on chromosome 8p23.1—a region that is commonly deleted in individuals with complex cardiovascular malformations. *SOX7* encodes a transcription factor that is highly expressed in the endocardium and in endothelial cells but its role in these cells remains unclear. To determine if SOX7 plays a critical role in cardiovascular development, we targeted the second exon of *Sox7* to create standard and conditional *Sox7* knockout mice. Although *Sox7*$^{+/-}$ mice were viable and fertile, *Sox7*$^{-/-}$ embryos died around E10.5 with signs of cardiac failure including pericardial edema and failure of yolk sac vasculature remodeling. The same phenotype was observed when *Sox7* was ablated in endothelial cells using a Tie2-Cre. Rare *Sox7*$^{-/flox}$;Tie2-Cre embryos that were recovered at E15.5 had pericardial effusions, vascular hemorrhage, ventricular septal defects, aberrant liver histology and evidence of developmental arrest. Using these mouse models, we also found that *Sox7* interacts genetically with *Sox17*—a known regulator of vascular sub-type specification—during vascular development with *Sox7*$^{+/-}$;*Sox17*$^{+/-}$ embryos dying around E10 with signs of cardiac failure. At E8.5—a time point prior to the onset of cardiac failure—*Sox7*$^{-/-}$ and *Sox7*$^{+/-}$;*Sox17*$^{+/-}$ embryos had abnormally high levels of endothelial cell proliferation when compared to wild-type littermate controls. Transcriptome and gene expression analyses carried out at E8.5 and E9.5, revealed several genes involved in cardiac, liver and vascular development—including *Tbx2* and *Vegfa*—that were dysregulated in the absence of SOX7. These results suggest that *Sox7* interacts genetically with *Sox17* during vascular development and that *Sox7* acts in a cell-autonomous fashion to modulate the transcription of genes that regulate endothelial cell proliferation. SOX7-deficiency leads to abnormal vascular development and may contribute to the development of cardiovascular malformations associated with recurrent 8p23.1 microdeletions.

3148S

Unraveling the genetic architecture of anencephaly: Identification and analysis of coding variants in *Cecr2* and candidate modifier genes of *Cecr2* in mice and humans. *R.Y.M. Leduc[1], D.R. Krupp[2], A.E. Ashley-Koch[3], S.G. Gregory[2], N. Mola[3], E.E. Davis[3], N. Katsanis[3], H.E. McDermid[1].* 1) Department of Biological Sciences, University of Alberta, Edmonton, Alberta, Canada; 2) Duke Molecular Physiology Institute, Duke University, Durham, North Carolina, USA; 3) Center for Human Disease Modeling, Duke University, Durham, North Carolina, USA.

Anencephaly, the failure of the cranial portion of the neural tube to close during early embryonic development, is an invariably lethal birth defect in humans. To investigate the mechanistic underpinnings of neural tube closure, we have examined genetic variants in mice and humans. In mice, a homozygous loss-of-function mutation of the gene *Cecr2* causes exencephaly (equivalent to the human anencephaly phenotype) in a strain-dependent manner. Approximately 54% of BALB/c *Cecr2* mutant mice develop exencephaly compared to 0% of FVB/N *Cecr2* mutant mice. This suggests the presence of DNA sequence variants that modify the penetrance of the exencephaly phenotype. Linkage analysis previously identified a modifier region on mouse chromosome 19. Microarray analysis was performed to identify genes differentially expressed between BALB/c and FVB/N within this region, and expression differences for prioritized candidate genes were confirmed with qRT-PCR. To detect possible functional variants, whole exome sequencing (WES) was also performed on Balb/c and FVB/N, and prioritized candidate genes were confirmed with Sanger sequencing. A combination of microarray and WES analyses yielded a list of 24 candidate modifier genes. It is not known whether *Cecr2* or any of the 24 candidate genes identified in mice are involved in the etiology of anencephaly in humans. Therefore, we performed custom capture sequencing of the coding regions of the human homologues of *Cecr2* and the 24 candidate modifier genes in a human anencephaly cohort of 157 probands. Fifty coding variants of interest (minor allele frequency (MAF) ≤ 3) were identified in 18 genes, including *CECR2*. All fifty variants were Sanger sequence verified in the probands and in available parental DNA samples. As the mutation in *Cecr2* is homozygous recessive in mice, we were also interested in looking for compound heterozygosity in the probands. To do this, nonsynonymous variants with a European MAF > 0.03 were also Sanger sequenced in proband and parental DNA samples if the proband contained more than one coding variant in the same gene. Six probands were identified as compound heterozygotes, three of which are in *CECR2*. These data demonstrate the utility of comparative genomics in dissecting the mechanisms of neural tube closure. Future functional assays will be necessary to determine causality of the identified variants.

3149S

Rapid identification of kidney cyst mutations by whole exome sequencing in zebrafish. *J.R. Willer[1,2], S. Ryan[2], L. Marjoram[2], J. Bagwell[2], J. Mankiewicz[2], I. Leshchiner[3], W. Goessling[3,4,5], M. Bagnat[2], N. Katsanis[1,2].* 1) Center for Human Disease Modeling, Duke University, Durham, NC; 2) Department of Cell Biology, Duke University; 3) Genetics Division, Brigham and Women's Hospital, Harvard Medical School, Boston; 4) Genetics and Gastroenterology Divisions, Brigham and Women's Hospital, Harvard Medical School, Boston; 5) Harvard Stem Cell Institute, Cambridge.

Forward genetic approaches in zebrafish have provided invaluable information about developmental processes. However, the relative difficulty of mapping and isolating mutations has limited the number of new genetic screens. Recent improvements in the annotation of the zebrafish genome coupled to a reduction in sequencing costs prompted the development of whole genome and RNA sequencing approaches for gene discovery. Here we describe a whole exome sequencing (WES) approach that allows rapid and costeffective identification of mutations. We used our WES methodology to isolate four mutations that cause kidney cysts; we identified novel alleles in two ciliary genes as well as two novel mutants. The WES approach described here does not require specialized infrastructure or training and is therefore widely accessible. This methodology should thus help facilitate genetic screens and expedite the identification of mutants that can inform basic biological processes and the causality of genetic disorders in humans.

3150S

A *Tgds* mutation in a novel mouse model of Pierre-Robin sequence-type clefting. *B.C. Bjork[1], I. Saadi[2], L. Pitstick[1], S. Docksey[1], D.R. Beier[3].* 1) Department of Biochemistry, Midwestern University, Downers Grove, IL; 2) Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS; 3) Center for Developmental Biology and Regenerative Medicine, Seattle Children's Research Institute, Seattle, WA.

Non-syndromic orofacial clefting is one of the most common human birth defects with both multigenic and environmental influences that contribute to its etiology. Pierre Robin sequence (PRS)-type clefting is a "palate-extrinsic" mechanism of cleft secondary palate (CP) that results as an indirect consequence of an abnormally small mandible and ankyloglossia. We identified the *little chin (lc)* mutant in a three-generation ENU-mutagenesis screen designed to identify autosomal recessive mouse mutants that model human congenital birth defects. *lc* mutants die shortly after birth due to respiratory distress and PRS-type CP, as evidenced by mandibular hypoplasia. *lc* mutant palate shelves fail to elevate above the tongue. Mutants also exhibit a shortened snout and a bifid xyphoid process. We initially mapped the *lc* mutation to a 1.1 Mb critical region on chromosome 14 by positional cloning. The region contains six genes, at least two of which, *Sox21* and *Gpc6*, represented attractive candidates for involvement in craniofacial development. However, initial sequencing of coding exons and highly conserved genomic sequences within the critical region failed to reveal any causative mutation.

Recently, we performed Next Generation whole-exome sequencing of genomic DNA from *lc* and *wild type* embryonic tissues and identified a homozygous point mutation in the *Tgds* gene that encodes the dTDP-glucose 4, 6-dehydratase enzyme. The C to T missense mutation creates a non-conservative Alanine to Valine substitution at amino acid 26 (A26V) of TGDS that is predicted to be damaging via PolyPhen. This is the only homozygous damaging sequence variant identified from this study. The exact function of TGDS and its relationship to craniofacial development is unknown. It has primarily been studied for its role in in cell wall integrity in plant species and Candida albicans. TGDS also plays an important role in NAD+/NADH shuttling, and the A26V mutation in *lc* mutants alters its highly conserved NAD binding motif (GGAGFIG). We are validating the mechanism of *Tgds* mutation in the etiology of clefting in *lc* mutants. Impaired TGDS function in *lc* mutants represents a novel mechanism to be explored as a contributing factor in the incidence of PRS-type clefting in humans.

3151S

The transcriptional co-regulator Jab1 is required for skeletogenesis. *G. Zhou, L. Bashur, Z. Chen, S. Murakami.* Orthopaedics, Case Western Reserve University, Cleveland, OH.

Skeletogenesis is a finely-tuned process governed by a spatiotemporal-specific transcriptional circuit. RUNX2 is a master transcription factor required for BMP signaling-mediated chondrocyte maturation and osteoblast differentiation. RUNX2 haploinsufficiency results in cleidocranial dysplasia, while mutations in various BMP signaling components lead to a spectrum of human skeletal developmental defects. Through analyzing a novel mouse model of lethal chondrodysplasia (Jab1flox/flox; Col2a1-Cre), we have recently shown that Jab1, a highly conserved transcriptional co-regulator, is a novel factor crucial for chondrocyte maturation, likely by inhibiting Runx2 and BMP signaling. To further dissect the role of Jab1 at successive steps of osteogenesis, we first generated Jab1flox/flox; Prx1-Cre conditional knockout (Prx1-Cre/cKO) mutant mice in which Jab1 was deleted in the osteochondral progenitor cells of the limb buds. At E18.5, Prx1-Cre/cKO mutants exhibited significantly shorter limbs with: very few hypertrophic chondrocytes, much smaller primary ossification centers with reduced von Kossa staining, decreased expression of Runx2 and Col1a1, and reduced BMP signaling response. Thus, Jab1 is required for early osteoblast differentiation of osteochondral progenitor cells. Next, we generated Jab1flox/flox; Osx-Cre conditional knockout (Osx-Cre/cKO) mutant mice in which Jab1 was deleted in the osteoblast precursor cells. Osx-Cre/cKO mutants appeared grossly normal in size at birth. However, histological study revealed reduced trabecular thickness and fewer trabecular areas in newborn Osx-Cre/cKO mutant long bones. Osx-Cre/cKO mutant long bones grew less after birth and all the mutants died before weaning age. Thus, Jab1 is likely to be required for the proliferation and function of osteoblast precursor cells. Finally, to specifically target differentiating osteoblasts, we generated Jab1-flox/flox; Col1a1-Cre conditional knockout (Col1a1-Cre/cKO) mutant mice, using a 2.3 Col1a1-Cre driver. Col1a1-Cre/cKO mice were viable, fertile, and showed no gross phenotype until 12-month age, indicating that Jab1 plays a less prominent role at later stage of osteoblast differentiation. We are further characterizing these novel Jab1 mutant models to study the stage-specific effect of Jab1 on Runx2 and BMP signaling during skeletogenesis. Our study will provide novel insights into the pathogenesis of skeletal disorders caused by dysregulated RUNX2 and BMP signaling.

3152S

SPECC1L modulation of adherens junctions and PI3K-AKT signaling is required for collective cell migration in facial morphogenesis. *N. Wilson[1], A. Olm-Shipman[1], E. Kosa[1], D. Acevedo[1], K. Stumpff[1], G. Smith[1], L. Pitstick[2], B. Bjork[2], A. Czirok[1], I. Saadi[1].* 1) Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS; 2) Department of Biochemistry, Midwestern University, Downers Grove, IL.

Orofacial clefts are among the most frequent birth defects, with cleft lip and palate (CL/P) alone affecting 1/800 live-births. While a number of contributory genes have been identified, there is continued need to understand underlying pathogenetic mechanisms. Previously, we identified *SPECC1L* as the first gene mutated in a severe cleft that extends from the oral cavity to the eye, termed Oblique Facial Cleft (ObFC). We proposed that mechanisms underlying ObFC and SPECC1L function are directly related to common CL/P malformations. Indeed, new heterozygous missense *SPECC1L* mutations have been identified in two patients with nonsyndromic CL/P (Dr. Murray, U. Iowa) and in two families with hypertelorism and bilateral CL/P (Dr. Zackai, CHOP), underscoring the significance of this novel cytoskeletal protein. Thus, we have created severe and hypomorphic mouse models of *Specc1l* deficiency. Hypomorphic homozygous mutants exhibit perinatal lethality with incompletely penetrant micrognathia, cleft palate, and subepidermal blebbing phenotypes. Severe homozygous *Specc1l* gene-trap mutants die during early embryogenesis with defects in neural tube closure and delamination/migration of neural crest cells (NCCs). Severe *Specc1l* mutant embryos show increased apoptosis and reduced AKT signaling. SPECC1L protein is stabilized at cell-cell boundaries upon confluence and interacts with both β-catenin and E-cadherin, two canonical components of adherens junctions (AJs). Further, SPECC1L-deficient cells (kd) show altered AJ staining predicted to reflect *more dense* AJs, which leads to *poor* cell migration. Electron micrographs of kd cells indicate jagged cell-cell boundaries and loss of apical-basal distinct electron-dense regions of AJs, consistent with increased AJ density. Interestingly, live-imaging analysis indicates that the migration defect is not due to slower individual speed, but rather due to *poor collective movement*. A significant proportion of kd cells show misoriented cell divisions along the long axis, suggesting a defect in cell polarity and directional cell division - two important considerations in collective migration of epithelial sheets. Modulation of cell-cell contacts is important not only for NCC delamination from the neural folds, but also for collective migration of NCCs to their defined destinations. Thus, SPECC1L is an entirely novel modulator of AJ density and of AKT signaling, affecting collective cell movement in facial morphogenesis.

3153S

Retinoic acid induced-1 (Rai1) regulates craniofacial and brain development in *Xenopus*. *R. Tahir[1], A. Kennedy[2], A.J. Dickinson[2], S.H. Elsea[3,4].* 1) Center of the Study of Biological Complexity, Virginia Commonwealth University, Richmond, VA; 2) Department of Biology, Virginia Commonwealth University, Richmond, VA; 3) Department of Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Retinoic acid induced-1 (RAI1 [MIM 607642]) is an important yet understudied histone code reader that when mutated in humans results in Smith-Magenis syndrome (SMS [MIM 182290]), a complex neurobehavioral disorder accompanied by signature craniofacial abnormalities, including a broad square-shaped face, a flat nasal bridge, a tented upper lip, and midface hypoplasia. Despite previous studies in mouse and human cell models, very little is known about the function of RAI1 during embryonic development. Here, we have utilized *Xenopus laevis* and *Xenopus tropicalis* to better understand the developmental roles of Rai1. Protein sequence analysis shows that frog Rai1 is conserved, especially in known functional domains. By *in situ* hybridization, we revealed expression of *rai1* in the developing craniofacial tissues and the nervous system, including the developing neural crest, eye, otic vesicles, branchial arches, and brain, and that excess retinoic acid enriched *rai1* in the developing embryo. Knockdown of Rai1 using antisense morpholinos resulted in defects in the developing brain and face, and in particular, Rai1 morphants displayed midface hypoplasia and malformed mouth shape analogous to defects in humans with SMS. These craniofacial defects were accompanied by aberrant neural crest migration and reduction in the size of facial cartilage elements. Rai1 morphants also had defects in axon patterns and decreased forebrain ventricle size. Such brain defects correlated with a decrease in the neurotrophic factor, *bdnf*, and an approximately 3-fold increase in forebrain apoptosis. These results emphasize a critical role of Rai1 for normal neural and craniofacial development, and further the current understanding of potential developmental mechanisms that cause Smith-Magenis syndrome.

3154S

The chromosome 3p22.3 region is a potential novel locus for complex heart disease, anorectal malformation and intellectual disability. *G. Akler[1], RA. Denchy[2], A. Anguiano[3], S. Sharma[2], MK. Geiger[1], L. Mehta[1].* 1) Icahn School of Medicine at Mount Sinai, New York, NY; 2) Elmhurst Hospital Center, Elmhurst, NY; 3) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Deletions in the 3p22.3 chromosomal region are rarely reported. Here we describe a female infant, currently 11 months old, with a de novo 1.5 Mb deletion encompassing 14 genes in the 3p22.3 region (no deletion of the 22q11 region detected). Significant phenotypic findings present included tetralogy of Fallot with absent pulmonary valve and a variant imperforate anus (rectoperineal fistula). A small extrarenal pelvis was reported in early renal sonograms. The association of these anomalies in the otherwise non dysmorphic child is suggestive of incomplete VACTERL association [MIM 192350]. Currently the patient is status-post repair of the heart defect, but has had motor delays, recurrent respiratory infections and failure to thrive prior to the repair. During embryologic development, aortopulmonary outflow tract septation, and down-growth of the urorectal septum with disintegration of the anal canal occurs between 5-8 weeks suggesting that these birth defects may result from factors disrupting development at this time. There are two previously reported interstitial deletions of this region: deletion 3p22.2-p24.2 in a patient with a small perimembranous ventricular septal defect, global developmental delay and short stature, and deletion 3p22.3p22.2 encompassing the ARPP21 [MIM 605488] and CLASP2 [MIM 605853] genes in a family with intellectual disability and dysmorphic facial features. The CLASP2 gene found in the overlapping region of all three cases may be a potential candidate gene for intellectual disability, given recent evidence of CLASP2 functioning as a key regulator of neuronal polarity and synaptic activity function. Of the other genes deleted in our patient, TRIM71 has been shown to be evolutionarily conserved and its regulation has been shown to play an important role in development. Recent literature has identified several CNV's and SNV's in patients with VACTERL/ VACTERL-like association. However, currently no consistent candidate regions or genes have emerged. This report adds to the literature on potential genetic etiologies for congenital heart defects and associated birth defects as in the VACTERL spectrum.

The sex-determining factor SRY is involved in numerous early events of testis differentiation including testis cord formation. *Y. Lau[1], Y. Li[1], M. Zheng[2].* 1) Dept Medicine/ VAMC-111C5, Univ California, San Francisco, San Francisco, CA; 2) Dept Anesthesia, Stanford Univ, Palo Alto, CA.

The Y-located sex-determining region Y (*Sry*) gene encodes the testis-determining factor, which plays a critical role in male sex determination during embryogenesis. A current hypothesis suggests that SRY collaborates with steroidogenic factor 1 (SF1) and activates a related transcription factor gene, SRY-box 9 (*Sox9*), the essential mediator for testis differentiation. SOX9, in turn, interacts with SF1 and propagates its own expression and testis differentiation. Using the ChIP-Chip strategy, we have identified large numbers of targets for both SRY and SOX9 in the fetal gonads of mouse embryos at the time of sex determination. Subsequent studies indicate that SRY or SOX9 bindings could be confirmed independently to about 90% of respective targets, which could be regulated by SRY or SOX9 in various reporter and transient gene transfection assays. SRY and SOX9 share about half of the respective targets, suggesting that these two transcription factors regulate a significant number of common target genes. Importantly, SRY, but not SOX9, binds to numerous ovarian differentiating genes and represses their activation by the WNT/β-catenin signaling. Among the SRY and SOX9 targets, numerous ones have been demonstrated to play critical roles in early events of testis differentiation. Notable ones include *Ptgds* (prostaglandin D2 synthase), critical in Sertoli cell recruitment; *Cyp26b1* (cytochrome P450, family 26, subfamily B, polypeptide 1), important for determining male lineage of the germ cells; and *Fgf9* (fibroblast growth factor 9) and *Gdnf* (glial cell derived neurotrophic factor), vital for Sertoli cell proliferation and male germ cell niche development. Gene ontology analysis identifies the Sertoli cell-Sertoli cell junction signaling, important for testis cord formation, as the top canonical pathway among the SRY and SOX9 targets. Our findings challenge the current paradigm and suggest that SRY is involved in regulating genes critical in early events of testis differentiation. Hence SRY determines the Sertoli cell fate by repressing ovarian and activating testicular differentiating genes, promotes Sertoli cell proliferation and recruitment, establishes the male germ cell lineage, and induces the early Sertoli cells to form testis cord. It then passes on its functions to SOX9, which regulates a set of common targets and activates its own gene regulatory program, beyond SRY action, in mammalian sex determination.

New insights in holoprosencephaly inheritance : Exome sequencing in families reveals new double-hit and recessive cases. *C. MOUDEN[1], C. DUBOURG[1,2], S. ROSE[1], G. VIOT[4], B. HERON[5], W. CARRE[2], M. DE TAYRAC[2,6], V. DUPE[1], S. ODENT[1,3], V. DAVID[1,2].* 1) Genetics of pathologies related to development, IGDR UMR 6290 CNRS, Rennes, France; 2) Laboratory of molecular genetics and genomics, CHU Pontchaillou, Rennes, France; 3) Service de Génétique médicale, CHU Hôspital Sud, Rennes, France; 4) Service de gynécologie-obstétrique 1 GHU Cochin - Saint Vincent de Paul, Paris, France; 5) Service de neuropédiatrie, Hôpital Jean Verdier, Bondy, France; 6) Génomique Fonctionnelle Intégrée et Biomarqueurs, IGDR, UMR6290 CNRS, Rennes, France.

Holoprosencephaly (HPE) is an anomaly of early development resulting from cleavage default of prosencephalon. It represents the most frequent cerebral malformation, with an occurrence of approximately 1 in 250 embryos and 1 in 10,000 births. About 60% of HPE cases are due to chromosomal defaults, to environmental causes like maternal alcoholism or diabetes, or are part of a polymalformative syndrome. A part of the remaining 40% of HPE cases, called genetic cases, are due to genetic alterations involving four main genes: SHH, ZIC2, SIX3 and TGIF. About 10 other minor genes are also implicated. But all these genic alterations explain only 30% of HPE genetic cases. Although these genes are formally involved, their penetrance is usually incomplete and mutations are often inherited from a healthy parent. Thus the outbreak of HPE should be due to a second event, like the implication of another gene. In this context, two high-throughput sequencing strategies (NGS) were used to identify new HPE genes. On one hand, we sequenced the whole exome in 15 families, in which known mutations were inherited from one of the two parents asymptomatic or presenting a microform of the disease, in order to point a potential inherited or de novo mutation in a new candidate gene. Analysis of one family with a known SHH mutation, revealed a second mutation in DISP1 in the HPE fetus. The screening for these two mutations in the entire family showed a co-segregation with HPE. This suggests for the first time a double hit involving SHH and DISP1. On the other hand, recessive inheritance of HPE can also be suspected in consanguineous families with intrafamilial recurrence. Homozygosity mapping was undertaken in eight families with history of consanguineous marriage to search for regions harboring mutations that are identical by descent. Exome sequencing in these consanguineous families revealed a homozygous mutation in two HPE children in a new candidate gene, involved in centrosome duplication. The KO of this gene in mouse leads to HPE phenotype. Functional tests are in progress to validate the deleterious role of this mutation in this good candidate gene. The discovery of new genes by these different strategies should permit to improve the prenatal diagnostic, and more generally the knowledge on early brain development.

3157S

Whole Exome Sequencing (WES) to Analyze the Genetic Basis of Non Syndromic Cleft Lip and Palate. *M. BASHA[1], M. QUENTRIC[1], R. HELAERS[1], N. REVENCU[2], B. BAYET[3].* 1) Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Europe, Belgium; 2) Center for Human Genetics, Cliniques universitaires St Luc, Université catholique de Louvain, Brussels, Belgium; 3) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St Luc, Université catholique de Louvain, Brussels, Belgium.

Cleft lip with or without cleft palate (CL/P) is the most common craniofacial birth defect with an incidence of ~ 1/700 live births, varying with ethnicity and cleft type. It is a debilitating condition requiring an expensive and lifelong treatment. We performed whole exome sequencing (WES) on 20 CL/P subjects, by using True Seq enrichment kit capture on Hiseq2000 (illumina) (38x mean coverage, 100bp 2x paired-end reads). Our pilot WES cohort predominantly consisted of familial cases (n=15) and a few isolated syndromic CL/P subjects (n=5). We WESed 1 affected subject per family. Their sub-phenotypes ranged from a full- blown bilateral CL/P to a subtler velopharyngeal insufficiency (VPI). After bioinformatic processing of raw data with an in-house developed pipeline, we analyzed our samples on Highlander (a software developed in our group by R. Helaers). Each sample had on an average ≈50,000 detected variants. We retained variants for further analysis if they met the following criteria: (i) passed the GATK filter (≈49,000), (ii) reported allele count of ≤10 in the population from the 1000 genomes project (≈40,000), (iii) not reported in the population from the GO-NL (genome Netherlands) project (≈6,000), (iv) occurrence in our in-house WES variant list in CL/P samples that passed GATK and at most 2 subjects afflicted with a different condition than CL/P that did not pass GATK (≈957). As “likely pathogenic“ variants, we considered those with a high impact (stops) or a moderate impact (non synonymous-NS), as predicted by SnpEff software. On average, a sample harbored 12 stops and 78 NS variants. All NS variants were predicted as damaging by at least 3 softwares. To identify causative gene(s) shared by multiple subjects, we used the following combinatorial filtering: {a} ≥2 samples with high impact variants in the same gene: 2 variants in 1 gene retained; {b} ≥2 samples with high or moderate-impact variants: 37 variants in 16 genes retained ; and {c} ≥2 samples with moderate-impact variants: 267 variants in 122 genes retained. Our results demonstrate important locus heterogeneity for familial CL/P. To be able to distill out the causal gene from the aforementioned data, we will WES additional affected subjects from multiplex families, for which continued collection is also ongoing.

CHROMOSOME ABERRATIONS IN A MEXICAN PEDIATRIC HOSPITAL. RING CHROMOSOMES 4, 13 AND 18. *I. Hurtado-Hernadez[1], J.M. Aparicio Rodríguez[2, 5], M.P. Barrientos[3], S. Chatelain Mercado[4].* 1) Cytogenetics,; 2) Genetics; 3) Endocrinology, Hosp para el Nino Poblano, Puebla; 4) Biotechnology, Universidad Autónoma Metropolitana; 5) Estomatology Benemérita Universidad Autónoma de Puebla, México.

he chromosome alteration due to a ring formation, is rare associated to chromosomes 4, 13 and 18 which is in relation to phenotypic malformations, neurologic problems and genital abnormalities. To clinical poly malformed case with treboliform skull, dimorphism with early seizures and malformed genitals with micropenis is presented. Among chromosome alterations, the ring of autosomic chromosome 4, 13 and 18 are not frequent, the main phonotypical alterations in this study are in relation to neurological, genital and craniofacial malformations. Taking in consideration that mutations or chromosome aberrations are considered alterations in the chromosome number or structure. They are mainly considered due to gametogenesis inborn error (meiosis) or during the zygote first cellular divisions. All these alterations might be observed during metaphase from the cellular cycle, where DNA loses are seen due to DNA repair processes deficiency o total absence, among others. Almost 5000 chromosomal studies were performed at Hospital Para El Niño Poblano (Pediatric Hospital) in Mexico (1n 19 years) were 34.6% (1596 patients) showed different chromosomal alterations and only two patients showed ring chromosome aberrations. These chromosome changes are classified as structural alterations. All pediatric patients with these genetic diseases are described in this study analyzing their clinical characteristics, medical or surgical treatments according to the phenotypic alterations.

Use of MLPA of buccal smear for Pallister-Killian diagnosis. *L.S.A. Costa, M. Moreira, A. Zandona-Teixeira, A. Dias, L. Kulikowski, R. Honjo, D. Bertola, C. Kim.* Dept Pediatrics, Universidade de São Paulo , São Paulo , Brazil.

Pallister-Killian syndrome (PKS) is a sporadic genetic disorder caused by the presence of a tissue-specific mosaicism for isochromosome 12p - i(12p) and is characterized by facial dysmorphism including coarse facies, upslanting palpebral fissures; bitemporal alopecia, pigmentary skin anomalies, developmental delay, hypotonia and seizures. Karyotype of skin, amniotic fluid, buccal smear or others tissues are essential for PKS diagnosis because cytogenetic analysis of peripheral lymphocytes usually fails to detect the mosaicism of isochromosome 12p - i(12p). We reviewed the medical records of patients with confirmed PKS followed in our service (since 1981 to 2014) and performed MLPA (Multiplex Ligation-dependent Probe Amplification) for diagnosis and confirmation in two of them. In this study we propose a new methodology for PKS diagnosis: MLPA of buccal smear. We describe eight patients with PKS. Clinical features of all patients were consistent with those described in the literature. Age at diagnosis varied from prenatal to 3 years. In all patients, peripheral blood karyotypes were normal. Seven patients were diagnosed by a skin fibroblast karyotype with i(12p) in 50% to 100% of cells. Recently, it was performed in two patients MLPA tecnique of buccal smear, showing 4 copies of 12p. Two patients have been lost during follow up and one patient died from pneumonia at 14 years old. The current age of five patients ranges from 9 months to 18 years, all of them with severe mental retardation. A precocious PKS diagnosis is important to optimally manage the disease and to provide genetic counseling. MLPA on buccal smears is a good and non-invasive method to detect extra copies of 12p and should be considered at the first exam, before a skin biopsy for a fibroblast karyotype is performed.

Cytogenetic characterization of 2 patients with supernumerary marker chromosomes (sSMCs) derived from complex genetic rearrangements. *A.L. Penton, R.D. Burnside, I. Gadi, V. Jaswaney, S. Schwartz, K. Phillips, J.B. Schleede, J.H. Tepperberg, J. Whiley, P. Papenhausen.* Cytogenetics, Laboratory Corporation of America, Durham, NC.

Small supernumerary marker chromosomes (sSMCs) that cannot be identified with standard cytogenetic G-banding techniques are estimated to occur in approximately 0.04% of live births potentially causing congenital abnormalities if associated with copy number gains in regions of clinically significant genes. We present cytogenetic findings from two newborn patients referred for cytogenetic analysis . Patient 1: Clinical indications for patient 1 included respiratory distress and suspected sepsis. G-banded chromosome analysis of lymphocytes collected from this patient showed the variable presence of 4 to 6 marker chromosomes in 20 cells counted . Whole genome SNP microarray analysis revealed a total copy number gain of 51.14 MB consisting of the pericentric regions of chromosomes 1, 6 and 9, as well an interstitial region of chromosome 17, suggesting the possibility of at least one composite marker. Subsequent FISH studies confirmed that these genomic regions were present in three distinct sSMCs . Patient 2: This patient was born at 29 weeks with congenital anomalies including a ventricular septal defect (VSD), patent ductus arteriosus (PDA), low set ears and widely spaced nipples. Whole genome SNP microarray analysis detected a total copy number gain of 15.80 MB originating from the pericentromeric regions of chromosomes 1, 8 and 13, and interstitial regions of chromosomes 6, 16 and X. A consistent percentage of mosaicism was detected for most of these regions, again suggesting the presence of several mitotically unstable composite marker chromosomes. Chromosome studies confirmed the variable presence of 3 to 6 supernumerary marker chromosomes in 30 cells counted . These results indicate that sSMCs can originate from complex genetic rearrangements and illustrate the necessity and efficacy of whole genome microarray analysis to precisely identify the overall genomic imbalance. Designation of the specific integration of the additional interstitial segments in each marker will entail numerous FISH studies which can be facilitated by multiprobe painting cocktails.

Double translocations in individuals and multiple family members. *D.H. Zaleski, K.J. Anderson, A.Z. Van Dyke, S.D. Nielsen, J.N. Sanmann, R.T. Hagelstrom, B.J. Dave, W.G. Sanger.* Human Genetics Laboratory, UNMC/ Munroe Meyer Institute, Omaha, NE.

The incidence of multiple, apparently balanced translocations in the general population is rare. Our lab has identified five families with multiple translocations, two of which have been previously reported. This study details the cytogenetic findings in the remaining three families. Family 1: Chromosome studies on a proband with cerebral palsy and intellectual disabilities revealed a balanced translocation: t(5;6)(p15.2;q23). Parental studies showed the father to be a carrier of a double balanced translocation: 46,XY,t(1;18)(p34.2;q11.2), t(5;6)(p15.2;q23). Two other siblings were also carriers of either one or both balanced translocations. Family 2: Karyotypic analysis of a newborn with osteogenesis imperfecta revealed two balanced translocations : 46,XX,t(2;6)(p11.2;p21.1),t(3;7)(q25;q11.2). The mother had a normal karyotype and the father was unavailable for study. Family 3: Cytogenetic analysis of a product of conception (POC) specimen on an individual with a history of multiple miscarriages showed the presence of an abnormal karyotype: 46,XY,der(17)t(6;17)(p21.3;p11.2),t(14;18)(q24.1;q23). Chromosome studies on peripheral blood of the patient revealed that she was a carrier of two balanced translocations: 46,XX,t(6;17)(p21.3;p11.2), t(14;18)(q24.1;q23). Typically, balanced translocations do not affect the health of the carrier. However, they are at an increased risk for miscarriages and/or children with chromosomal imbalances associated with clinical involvement. This risk is greater for individuals with two balanced translocations. For example in family 3, a translocation risk specialist calculated that at the given breakpoints, the t(6;17) poses a 38% risk of miscarriage and a 2.5% chance of having a live born with an unbalanced translocation. The t(14;18) results in a 31% risk of miscarriage and 2-4.5% chance of a live born with an unbalanced translocation. Considering the additional background risk of 20%, the calculated theoretical risk for miscarriage in this patient is ~89% and the theoretical risk for live birth with an unbalanced translocation is 4.5-7%. This leaves only 4-6.5% chance of having a child with normal or balanced chromosomes. For individuals with double translocations the risk of miscarriage/abnormal live born is much higher due to the cumulative effect of both translocations. Familial studies are important to derive accurate recurrence risk and appropriate genetic counseling.

3162T

Reversing differences in chromatin accessibility that distinguish homologous mitotic metaphase chromosomes. *W.A. Khan[1], P.K. Rogan[2,3,4], J.H.M. Knoll[1,4].* 1) Department of Pathology, London, ON; 2) Department of Biochemistry, London, ON; 3) Department of Computer Science, London, ON; 4) Cytognomix, London, ON Canada.

Treatment with agents that alter histone modifications, DNA conformation or its sequence are well established strategies for cancer chemotherapy. Apart from their effects on interphase chromatin (G1, S), little is known about how these compounds act during and preceding metaphase. We have previously demonstrated that most individual single copy (SC) FISH probes (1.5-5 kb) exhibit equivalent fluorescence hybridization intensities to allelic metaphase targets. A subset of these probes show reproducible, non-random hybridization intensity differences between homologous targets. Atomic and super-resolution microscopy analyses indicate that the differences correspond to 'differential accessibility' (DA) at these genomic loci. We investigated epigenetic characteristics of DA with agents that inhibit histone deacetylation, phosphorylation, cytosine methylation, and alter superhelicity in lymphoblastoid cell lines. Compared to controls, DA was impervious to chemical treatments targeting histone modifying enzymes or cytosine methylation from five distinct genomic regions (*RGS7*, 1q43; *CACNA1B*, 9q34.3; *ADORA2B*:IVS1, 17p12; *PMP22*:IVS3, 17p12 and *ACR*, 22q13.33). We also hybridized etoposide-treated metaphase cells with probes to the same genomic regions that exhibited DA in untreated cells. DA was reversed at all of these loci at various physiological etoposide concentrations ($p < 0.05$, two-proportion z-test, n = 30-40 cells/region). Differences in fluorescent probe intensity ratios measured between homologs from etoposide-treated cells were also 4 to 5-fold lower relative to untreated controls. With 3-D structured illumination microscopy, we demonstrated that the mean differences in hybridized probe volume between allelic targets significantly decreased ($p < 0.05$, two-tailed t-test) in treated cells ($\Delta\mu = 0.237\mu m^3$) compared to untreated controls in which one allele was less accessible ($\Delta\mu = 0.730\ \mu m^3$). Inhibition of the topoisomerase IIα-DNA cleavage complex decreased DNA supercoiling and axial metaphase chromosome condensation. Our findings suggest that allelic differences in metaphase chromosome accessibility represent a stable chromatin mark that is largely maintained on mitotic metaphase chromosomes; and that the local differences in condensation are due to topoisomerase activity, which result in DA.

3163T

Longitudinal shortening in telomere length as a biomarker for dementia status of adults with Down syndrome. *E.C. Jenkins[1], L. Ye[1], S.J. Krinsky-McHale[1], W.B. Zigman[1], N. Schupf[1,2], W.P. Silverman[3].* 1) Department of Human Genetics, NYS Institute for Basic Research in Human Genetics, Staten Island, NY; 2) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 3) The Kennedy Krieger Institute and The Johns Hopkins University School of Medicine, Baltimore, MD.

We have previously reported shorter telomeres in T-lymphocytes from participants in a cross-sectional study of 11 people with Down syndrome (DS) and mild cognitive impairment (MCI) or dementia versus those with DS only, using PNA (peptide nucleic acid) probes for telomeres and the chromosome 2 centromere (cen (2) PNA probe was a gift from DAKO for our research studies) (Jenkins et al., 2012). When measuring individual metaphase chromosomes, the length and/or light intensity of the cen (2) probe can be used to generate an "internal standard" to normalize telomere data. To calculate such a ratio (see Jenkins et al. 2012), the fluorescent light intensity of the chromosome 1 telomeres, for example, becomes the numerator while the denominator becomes the light intensity for the cen (2) PNA probe. The intensity/length for the cen (2) PNA probe should remain stable, while the light intensity/length of the telomeres is expected to shorten with each successive cell division. Multiple methods comparing telomere lengths of individuals with and without MCI revealed clear and consistent effects of clinical status in preparations using an FITC-labeled PNA telomere probe (DAKO) but longitudinal data were needed to verify that the effects reflect true accelerated telomere loss. Preliminary results from our first longitudinal study (N = 6; 4F, 2M) have now shown that interphase and metaphase chromosomes from T-lymphocytes of repeat samples from people who did not have MCI/dementia at Time 1 but who had converted to MCI (N = 5) or dementia (N = 1) by the time a second sample was obtained, all had substantially shorter telomeres after conversion to MCI/dementia. Compared to our previous cross-sectional results, group means prior to MCI/dementia onset were (0.12 - 0.17)[Note: 0.12 is the ratio obtained when chromosome 1 telomere length in microns is divided by chromosome 1 length minus chromosome 1 telomere length.] versus the "non-MCI/demented" cross-sectional group (0.19 - 0.23), while the MCI group telomere lengths following transition to MCI were 0.08 - 0.1 comparable to the cross-sectional MCI/demented group (0.08 - 0.13). We are anxious to extend this study with additional prospective follow-up of a larger sample of individuals with Down syndrome who have not yet converted to MCI/dementia. Supported in part by NYS OPWDD, Alz. Assoc. IIRG-96-077, IIRG-07-60558; NIH PO1-HD035897, RO1-HD037425, RO1-AG014673, and P30-HD024061.

3164T

The role of copy number variation in non-syndromic cleft lip and palate. *L.A. Harney[1,3], B.W. Darbro[1,3], A. Long[2], J. Standley[1], J.C. Murray[1,3], J.R. Manak[1,2,3].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Department of Biology, University of Iowa, Iowa City, IA; 3) Interdisciplinary Genetics Program, University of Iowa, Iowa City, IA.

Clefts of the lip and/or palate (CLP) are common congenital abnormalities affecting approximately 1 in 700 live births. It is estimated that 70% of CLP cases are non-syndromic (NS) which excludes individuals with CLP who exhibit cognitive or multiple congenital abnormalities. A variety of candidate gene, genome-wide association studies, and animal models have been used to study CLP, but no large-scale studies have explored the role of copy number variation (CNV) in clefting. We performed array-based comparative genomic hybridization on a NSCLP cohort from the Philippines to identify CNVs associated with clefting. After quality controls minimized false-positives, we processed 84 NSCLP cases and a replication cohort of 854 NSCLP cases for further analysis. Specifically focusing on deletions for this study, we used an analysis pipeline which identified CNV losses that overlapped with exons of genes in regions sharing 50% or less overlap with segmental duplications and common CNVs. Analysis of CNVs in the 84 NSCLP cases identified 33 deletions containing 53 genes, 1 of which overlapped with a previously identified clefting locus *CDH1* (MIM 192090). We also investigated the GWAS region significantly associated with NSCLP, *8q24* (MIM 612858). Analysis of *8q24* revealed three small deletions within a 1.4Mb region containing the most associated SNP *rs987525* (MIM 612858) and a recently reported murine medionasal enhancer of *MYC* (MIM 190080). Characterization of these deletions is underway. Seventeen regions from the small cohort, containing 23 genes, replicated in the larger cohort. In total, 178 regions appeared in two or more individuals in the large cohort, including six previously identified clefting loci *XRCC3* (MIM 600675), *JAG2* (MIM 602570), *8q24*, *NTN1* (MIM 601614), *DLG1* (MIM 601014), and *LPL* (MIM 609708). To elucidate the role of these CNVs in CLP, we are performing expression analysis of genes within the altered copy number regions, as well as altering their dose in zebrafish. In addition, we are conducting a trio study using the loci identified in the small cohort to determine if the CNVs are *de novo* or familial. Since this large dataset provides immense potential for the identification of novel CLP loci, we plan to extend the analysis to intronic and intergenic CNVs. It is our hope to define how CNVs contribute to NSCLP and identify novel causative variants for the disease.

Characterization of a fusion gene involving the leptin gene generated by a *de novo* 7q32.1 duplication associated with severe anorexia. *J. Lévy[1,2,3], E. Pipiras[1,4,5], L. de Pontual[5,6,7], V. El Ghouzzi[1,3], N. de Roux[1], AC. Tabet[2], P. Gressens[1,3], B. Benzacken[1,2,4,5], S. Lebon[1,3], A. Delahaye[1,4,5].* 1) Inserm U1141, Hôpital Robert Debré, Paris, France; 2) AP-HP, Service de Génétique et de Cytogénétique, Hôpital Robert Debré, Paris, France; 3) Université Paris Diderot, Sorbonne Paris Cité, Paris, France; 4) AP-HP, Service d'Histologie, Embryologie, et Cytogénétique, Hôpital Jean Verdier, Bondy, France; 5) Université Paris 13, Sorbonne Paris Cité, UFR SMBH, Bobigny, France; 6) AP-HP, Service de Pédiatrie, Hôpital Jean Verdier, Bondy, France; 7) Inserm, U781, Université Paris Descartes, Paris-Sorbonne Cité, Institut IMAGINE, Paris, France.

Leptin is a polypeptide hormone secreted by white adipocytes which plays a major role in the regulation of appetite and weight. Leptin action is mediated by receptors that are located in the arcuate nucleus of the hypothalamus and in many peripheral tissues. Homozygous mutations in either the leptin or leptin receptor genes cause extreme obesity in mice and humans. Here we describe a *de novo* 7q32.1 duplication spanning the *LEP* gene discovered in a 2-year-old boy referred for unexplained precocious anorexia associated with postnatal ponderal growth retardation.

Whole-genome sequencing revealed that the duplication was a direct tandem duplication. This duplication generated a fusion between a potential pseudogene paralogous to the *TLK2* gene (thereafter referred as *TLK2P3*) and the *LEP* gene. Several fusion transcripts generated by alternative splicing of *TLK2P3* were detected by RT-PCR on patient's fibroblasts and lymphocytes. They contained the complete coding sequence of the *LEP* gene. Constructions of expression vectors encoding HA-tagged leptin, TLK2P3 and TLK2P3-LEP were performed to characterize the potential fusion proteins. The expression of TLK2P3-LEP, LEP and TLK2P3 were analyzed by immunoblotting and western blot after transfection of human HeLa cells.

The first results of the fusion gene expressed in HeLa cells showed the production of a protein with the same size and the same cellular localization as leptin. Additional alternative fusion transcripts expressions in HeLa cells are ongoing. ENCODE analysis showed a highly active promoter regulating *TLK2P3*, predicted by a chromatin state segmentation for each of nine human cell types. This highly active promoter may induce deregulated and ectopic expression of leptin.

Several hypotheses of the mechanisms by which this 7q32.1 duplication affect the phenotype of the patient will be discussed. Although our results are preliminary, this study suggests that fusion genes can be a mechanism by which CNVs contribute to Human diseases.

Automated Dicentric Chromosome Identification by Machine Learning-Based Image Processing. *P.K. Rogan[1,2], Y. Li[1], A. Subasinghe[1], J. Samarabandu[1], R. Wilkins[3], J.H. Knoll[1,2].* 1) University of Western Ontario, London ON; 2) Cytognomix, London ON; 3) Health Canada, Ottawa CA.

Accurate detection of chromosome centromeres is a critical element of cytogenetic diagnostic techniques, including chromosome enumeration, karyotyping and radiation biodosimetry. We present an approach for identification of normal and dicentric chromosomes (DC) in either Giemsa- or DAPI-stained metaphase cells. Existing centromere segmentation methods perform poorly in the presence of irregular chromosome boundaries, shape variations and sister chromatid separation. Different sample preparation protocols can produce inconsistent centromere localizations. We apply a profile thickness measurement technique to chromosome structures of intensity-integrated Laplacian segmented images. A set of centromere candidates is generated, evaluated by a support vector machine (SVM) based on a set of image measurements, ie. features. We partition the chromosome contours to isolate telomere regions, then detect and correct for sister chromatid separation. This algorithm accurately localized 1220 of 1400 centromeres (87%). Distinction of true from false centromeres was enhanced by adding new features to the SVM. The new features incorporated pixel intensity, angular deviation from the projected centerline of each chromosome, and fitted a curve to the chromosome width. The original and new versions of the SVM were evaluated and assessed for correct assignments of both centromeres in known DCs. Candidate centromeres in 247 DCs were assessed based on their respective distances to the SVM hyperplane. The original and new SVMs were 89% and 92% accurate, respectively, for the identification of both centromeres among the 4 closest candidates to the hyperplane. For the true centromeres, ie. the 2 closest candidates to the hyperplane, accuracy was reduced (58% and 57%). SVMs based on predominantly monocentric chromosomes detected individual centromeres in these chromosomes and prioritized candidates in DCs, but did not reliably identify DCs de novo. This is caused by weak feature combinations in the SVMs for some DCs. A set of 158 DCs was used exclusively to train and test the SVMs by cross-validation. Accuracy was unchanged for the original SVM (59%), but the new SVM showed considerable improvement (75%). The SVMs are also more likely to miss candidate centromeres in normal acrocentric chromosomes or acrocentric-derived DCs. Expansion of the DC training set and custom segmentation of acrocentric-derived DCs are promising approaches to further improve performance.

3167T

Detectable mosaic 13q14 deletions in non-hematologic cancers and healthy controls. *M. Yeager[1,2], M. Machiela[2], W. Zhou[1,2], M. Dean[3], S.J. Chanock[1].* 1) Cancer Genomics Research Laboratory, Leidos Biomed, FNLCR,, Frederick, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, Bethesda, MD; 3) Center for Cancer Research, NCI, Frederick, MD.

Mosaic loss of 13q14.3 is a common chromosomal event found in approximately 50 percent of B-cell chronic lymphocytic leukemia (CLL) cases. Studies suggest 13q14.3 loss may be evident in somatic DNA of other non-hematologic tumor types, but to date no comprehensive study has been performed on the frequency of 13q14.3 mosaic loss in lymphocyte-derived DNA of solid tumor cases and healthy controls. Based on preliminary findings indicating an excess of 13q14.3 mosaic loss in our previous studies of detectable clonal mosaicism, we performed a comprehensive scan of chromosome 13 from 46,254 non-hematologic cancer cases and 36,229 controls using modified B-allele frequency and log R ratio based detection algorithms. We detected a total of 60 individuals with 13q14.3 mosaic loss, 1 occurrence of mosaic copy neutral uniparental disomy, and 13 individuals with stretches of homozygosity that spanned the 13q14.3 region. While detected 13q14.3 mosaic losses were variable in size, the minimally deleted region (MDR) in our analysis (chr13:49,590,000-49,983,100, NCBI36/hg18) closely resembled that seen in CLL and included transcripts of DLEU1 and DLEU2. A breakpoint analysis on 13q14.3 loss boundaries indicates a clustering of breakpoints with statistically significant enrichment for breakpoints around gene rich regions and areas of open chromatin when compared to random permutations of same-sized events spanning the chromosome 13 MDR. Our analysis indicated the frequency of 13q14.3 loss significantly increases with increasing age (p-value=0.028). The frequency of 13q14.3 mosaic loss did not significantly differ between non-hematological cancer cases (0.084%, 95% CI: 0.058-0.111%) and controls (0.058%, 95% CI: 0.033-0.083) nor did frequency estimates differ from age and sex standardized SEER estimates. While 13q14.3 deletions may serve as early biomarkers for CLL, our study indicates such events are present and potentially tolerated in peripheral blood lymphocytes of disease free controls and non-hematologic cancer cases.

Microdeletions and Microduplications in Brazilian Children with intellectual disability from a public health service. *A.D. da Cruz[1,2,3,4,5], I.P. Pinto[1,2], L.B. Minasi[1,2], A.V Melo[1,3], D.M.C. Cunha[1,2], A.S. da Cruz[1,5], C.L. Ribeiro[1], D.M. e Silva[1,2,6], C.C. da Silva[1,2,3,4].* 1) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group; 2) Pontifical Catholic University of Goias, Genetics Master's Program; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program; 4) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health; 5) Federal University of Goias, Biology Master's and PhD Programs; 6) Federal University of Goias, Genetics and Molecular Biology Master's and PhD Programs.

Intellectual disability is a complex, variable, and heterogeneous disorder, representing a disabling condition diagnosed worldwide and the etiologies are multiple and highly heterogeneous. Microscopic chromosomal abnormalities and well-characterized genetic conditions are the most common causes of intellectual disability. Here, we report 15 probands with undiagnosable intellectual disabilities referred by doctors from the public health system in Central Brazil. For all probands, G-banding karyotypes showed no visible alterations (46 XX or 46XY). Chromosomal Microarray Analysis (CMA) using Affymetrix CytoScanTM HD Array showed a total of 18 CNVs that were identified in 9/15 (60%) patients and no chromosome rearrangement was observed in 6/15 (40%) cases. Moreover, molecular karyotyping of all 30 progenitors included in our study showed no evidence of chromosome rearrangements. Pathogenic and likely pathogenic CNVs were classified based on their size, gene content and diversity, and previously reported cases of potential involvement with pathogenic mechanism in human and animal models. In our cohort, pathogenic CNVs represented about 22% of all observed rearrangements and were associated with chromosomes 17, 18, and X, involving genes that were related to the formation and/or maintenance of the central nervous system. Also, pathogenic CNVs included morbid genes from OMIM. Moreover, all pathogenic CNVs in this study had a de novo origin. 22% CNVs were classified as likely pathogenic and 56% CNVs were classified as of unknown clinical significance because they overlapped by more than 90% of the CNVs observed in the databases of normal control groups. CMA technology is a relatively new strategy useful as an additional tool for genetic diagnosis. The method has been recommended as the first-tier diagnostic test for patients with global developmental delay, intellectual disability, autism spectrum disorders, and multiple congenital anomalies. Furthermore, the correct diagnosis of a neurological disorder is crucial for predicting the probands' clinical follow up, to establish accurate prognostic, and to provide adequate genetic counseling.

3169T

First case of homozygous deletion in the ABAT gene leading to GABA-T deficiency and severe neonatal neurologic disease. *A. Mosca-Boidron[1,2], G.S. Salomons[3], E.A. Struys[3], C. Vianey-Saban[4], L. Faivre[2,5], M. Lefebvre[5], N. Marle[1,2], F. Feillet[6], M. Payet[1], C. Ragon[1], F. Mugneret[1], A. Masurel-Paulet[5], J. Thevenon[2,5], M.G. Mourot de Rougemont[7], C. Thauvin-Robinet[2,5], P. Callier[1,2], S. El Chehadeh[2,5].* 1) Laboratoire de cytogénétique, Plateau technique de biologie, CHU de Dijon, France; 2) GAD, EA4271, Génétique et Anomalies du Développement, Université de Bourgogne, Dijon, France; 3) Metabolic Unit, clinical chemistry, VUmc Medical center, de Boelelaan, Amsterdam, the Netherlands; 4) Service des maladies héréditaires du métabolisme et dépistage néonatal, Groupement hospitalier EST, Bron, France; 5) FHU TRANSLAD, Centre de référence maladies rares « anomalies du développement et syndromes malformatifs » de l'Est, Centre de Génétique, CHU de Dijon, France; 6) Service de médecine infantile, Hôpital d'Enfants de Brabois, CHU de Nancy, Vandoeuvre-les-Nancy, France; 7) Service de radiologie, Hôpital d'Enfants, CHU de Dijon, France.

Background 4-gamma-aminobutyrate transaminase (GABA-T) catalyzes the conversion of gamma-aminobutyric acid (GABA), one of the most important inhibitory neurotransmitters in the central nervous system of mammalians, into succinic semialdehyde and is encoded by the ABAT gene. GABA-T deficiency is a very rare autosomal recessive disorder characterized by severe psychomotor retardation, hypotonia, hyperreflexia, seizures, associated with early infantile death. It has been reported in only 3 patients to date, 2 of whom were siblings. Electroencephalographic and brain magnetic resonance imaging (MRI) abnormalities including respectively burst suppression pattern, cerebellar hypoplasia, posterior fossa cyst, corpus callosum agenesis and abnormal gyration, have been previously described. We report here on a fourth male patient born to consanguineous healthy Moroccan parents who presented with neonatal epileptic encephalopathy including major axial hypotonia, lethargy with hypomotility and intractable seizures, without any dysmorphic features. He died at 15 days of life. Methods Investigations that were done in the first week after birth included array-CGH, brain MRI, and wide metabolic screening. Results Brain MRI showed atrophy of the cerebellar vermis and hemispheres with a cerebellar cyst aspect, reduced white matter, very thin corpus callosum and diffuse thickening of the cortex leading to the suspicion of pachygyria. Electroencephalograms were abnormal showing burst suppression patterns. Array-CGH (Agilent 180 K) showed a homozygous 28 kb intragenic deletion of the 16p13.2 region encompassing exons 3 to 10 of the ABAT gene. This deletion was inherited from both parents who carried the deletion at a heterozygous state. Chromatography of urinary aminoacids showed an increased level of GABA (197 μMol/mmol creat; normal < 10 μMol/mmol creat) while GABA concentration was normal in blood and cerebrospinal fluid. Conclusion This observation is the first reported case of a homozygous deletion in the ABAT gene with clinical, imaging and biochemical features consistent with a diagnosis of GABA-T deficiency. It confirms the power of array-CGH in identifying intragenic rearrangements in genes implicated in rare diseases, in particular when there is no clinical clue leading to diagnosis, as is the case in many inborn errors of metabolism.

3170T

Manifestations of Xp22.2-22.13 and Xp21.3 microduplications. *M. Goto[1,2], A. Matsumoto[1], K. Kojima[1], E.F. Jimbo[1], M. Mori[1,3], H. Osaka[1], T. Yamagata[1].* 1) Pediatrics Dept, Jichi Medical University, Shimotsuke, Tochigi, Japan; 2) Pediatrics Dept, Kitaibaraki Municipal General Hospital, Kitaibaraki, Japan; 3) Pediatrics Dept, Matsudo City Hospital, Matsudo, Chiba, Japan.

Three Japanese patients with intellectual disability (ID) were reported to have two duplications on chromosome Xp. One was at Xp22.2-22.13 including exons 2-18 of REPS2 (MIM 300317) and exons 1-3 of NHS (MIM 300457). The other was at Xp21.3 including exon 2 of IL1RAPL1 (MIM 300206). Although the mechanisms underlying these duplications and their contributions to ID were not fully understood, they were strongly considered to be responsible for ID because they were not detected in unaffected males. Here we report on a boy with the same duplication showing ID, involuntary movements, and epilepsy to delineate the phenotype associated with this duplication. Case Report: The patient was a 7-year-old boy born to non-consanguineous healthy parents. He was bedridden because of severe ID and hypotonia. His clinical phenotype included epilepsy, athetoid movements, strabismus, hypodontia, delayed myelination, and cerebral atrophy. Array CGH analysis using an Agilent Human Genome CGH 180K detected a 728- and 95-kb duplication at Xp22.2-22.13 and Xp21.3, respectively. FISH analysis using two probes that were designed for Xp21.3 and Xp22.2-22.13 showed that the duplicated sequence at Xp21.3 was adjacent to the duplicated sequence at Xp22.2. His mother had the same duplication. Discussion: The duplications detected in our patient were identical to those detected in three previously reported Japanese patients (Honda, et al. J Hum Genet. 2010). One of these patients had West syndrome, severe ID, epilepsy, aphasia, and hippocampal atrophy; the other two were dizygotic twins with moderate ID, speech delays, and autism. Moderate to severe ID, epilepsy, athetoid movements, cerebral atrophy, delayed myelination and hypodontia were candidates for the phenotypes of this syndrome. In addition to these patients, females from a Korean family were found to be carriers for identical double duplications (Kondo, et al. J Hum Genet. 2012). This suggests that these chromosomal rearrangements could have been transmitted from a common ancestor in eastern Asia. The presence of excess genes localized in these duplicated regions was not pathogenic because these genes were partially duplicated. Inverse PCR analyses reported by Kondo et al. suggested that these duplications were related to each other and that they had occurred simultaneously. It was considered that complex genomic rearrangements including NHS and IL1RAPL1 had occurred and that they had consequences on neuronal development.

3171T

Comparison of de novo and inherited copy number variants of unknown clinical significance. *L. Matyakhina, S. Aradhya, D. Pineda, A. Janze, J. Nieto, G. Richard, J. Meck.* GeneDx, Gaithersburg, MD.

Variants of uncertain/unknown clinical significance (VUS), defined as a variation in copy number whose association with disease risk is unknown, comprise a significant percentage of the reports generated by a clinical microarray laboratory. Inheritance of the aberration from a parent is often used as a means of determining whether or not an aberration classified as VUS has clinical significance. If the aberration is de novo or is inherited from a similarly affected parent, then the aberration is most likely pathogenic in nature. By contrast, those VUS aberrations, which are found in a phenotypically normal parent, are more likely to be benign. We reviewed our VUS data from a custom-designed 180K whole genome microarray to determine patterns characteristic of inherited versus de novo VUS calls. Two hundred fifty six cases were tested for inheritance: 203 aberrations (79%) were inherited, 34 (13%) cases were de novo, and the remainder was inconclusive since only a single parent was tested. Of the 203 inherited cases, 134 were maternally inherited and 69 were paternally inherited (maternal: paternal ratio was 1.9). Duplications were inherited three times more frequently than deletions. In contrast to the inherited VUS aberrations, de novo deletions and duplications were represented in roughly equal proportion, with a slightly higher percentage of deletions (58%). Comparison of de novo versus inherited aberrations showed that the majority of the de novo variants contained significantly more genes, with a maximum of 35 genes, versus a maximum of 12 genes for the inherited aberrations. In addition, although there is overlap in aberration size, de novo and inherited VUS copy number variants differed with respect to overall size with 38% of de novo deletions and duplications being over 1 Mb versus 11% for inherited. For many de novo cases, parental testing was helpful to reclassify a VUS call to likely pathogenic. These data demonstrate the value of parental testing for better classification of copy number variants identified by chromosomal microarray and underscore the need for collaborative efforts to better resolve and understand the significance of inherited copy number variants.

Whole Genome Characterization of Copy Number Variation Regions in 2000 Phenotypically Normal Individuals. *A. Roter[1], J. Sampathkumar[1], C. Du[1], S. Schwartz[2], S. Scherer[3,4], M. Uddin[3], B. Thiruvahindrapuram[3], C. Marshall[3], R. Fpundt[5], T. Jonson[6], A.C. Thuresson[7], I. Quintela[8], F. Barros[8], J. Cuevas[1].* 1) Informatics, Affymetrix, Inc., Santa Clara, CA; 2) Cytogenetics Laboratory, Laboratory Corporation of America, Research Triangle Park, NC; 3) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 5) Radboud University Medical Centre, Nijmegen, Netherlands; 6) Department of Clinical Genetics Skåne University Hospital - 221 85 Lund, Sweden; 7) Department of Immunology, Genetics and Pathology, Rudbeck and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 8) Grupo de Medicina Xenómica, UdC, CeGen- CIBERER, Santiago de Compostela, Spain.

A large cohort of 2,321 genomic DNA samples from phenotypically normal individuals was characterized for genomic copy number variations to understand the frequency and genomic distribution of non-pathogenic CNVs in the population. DNA samples were extracted from blood samples obtained at 6 sites in 6 countries, including Sweden, the Netherlands, Norway, Spain, Canada and the United States. Samples were processed with the Affymetrix CytoScan® HD Microarray Kit and the data analyzed for copy number calls using Affymetrix Power Tools. Copy number calls were extracted from the output files and compiled into a large dataset, including only CNVs that exceeded a minimal size threshold, 25 markers and 25 kbp for copy number losses or 50 markers and 50 kbp for copy number gains, using a composite profile from 100 blood and 280 cell line samples as a reference. The CNV data set was evaluated for the frequency of finding a loss or gain at every genomic location. Frequencies of adjacent genomic locations were smoothed using an exponential decay window-smoothing algorithm and the data were segmented to reconstruct common regions of CNVs. We found less than 5.5Mb of the human genome to be associated with CNV regions having population frequencies of 10% or more. These common CNV regions were analyzed for genomic structure, such as segmental duplications and chromosomal position to help understand the genomic attributes associated with regions with frequent CNV polymorphisms.

3173T

Familial transmission of 5p13.2 duplication due to maternal der(X)ins(X;5). *L.C. Walters-Sen[1], K. Windemuth[1], J. Nandhlal[1,2], J.M. Milunsky[1].* 1) Center for Human Genetics, Inc., Cambridge, MA; 2) Boston Medical Center, Boston, MA.

Submicroscopic duplications of 5p13 have been recently reported in a number of cases, warranting the description of a new clinical entity (Chromosome 5p13 Duplication Syndrome, MIM 613174). These microduplications, while variable in size, all contain at least part of the *NIPBL* gene (MIM:608667). Patients with duplications in this region present with intellectual disability/developmental delay (ID/DD) and dysmorphic facies. In addition, skeletal and brain abnormalities have been variably reported, as well as propensity for obesity and hypotonia. We report a family with two affected sons, each carrying a duplication at 5p13.2 encompassing the 5' portion of *SLC1A3* (MIM:600111) and the 5' portion of *NIPBL*. The proband was originally referred for a SNP microarray analysis, which identified the 341 kb 5p13.2 duplication, also found in his brother by a different laboratory. Both brothers had delays in speech development and diagnoses of possible autism and ADHD. The proband's weight was in the 95-97th percentile, while that of his brother was in the 75-90th percentile. In addition, the brothers shared facial dysmorphisms, including long eyelashes, long palpebral fissures, a broad nasal tip with anteverted nares, and a small chin. Other anomalies included a high palate, pes planus, and prominent breast tissue. Upon confirming the SNP microarray finding by FISH in the proband, it was discovered that the 5p13.2 duplication was located on the short arm of the X chromosome. Further FISH studies on the mother demonstrated that both she and the proband carried a derivative X chromosome with insertion of material from 5p13.2 into the intermediate region of Xp [der(X)ins(X;5)(p2?2.1;p13.2p13.2)]. As the mother did not share facial dysmorphism or ID/DD with her sons, X-inactivation studies were performed. The mother showed skewed inactivation (82:18), providing a mechanism for suppression of expression of the duplicated 5p13.2 material. To our knowledge, this is the first report of an inherited duplication of 5p13.2 with multiple affected family members. This family underscores the need to confirm array findings by FISH, both in the proband and family members, to discern implications for pathogenicity and more accurately define the recurrence risk.

3174T

Submicroscopic chromosomal imbalances in patients with intrauterine growth retardation and features of Silver-Russell syndrome. *A. Bonaldi[1], A.C.S. Fonseca[1], D.R. Bertola[2], C.A. Kim[2], P.A. Otto[1], A.M. Vianna-Morgante[1].* 1) Department of Genetics and Evolutionary Biology, University of São Paulo, São Paulo, São Paulo, Brazi; 2) Genetics Unit, Children's Institute, Clinics Hospital, Faculty of Medicine, University of São Paulo, São Paulo, Brazil.

Silver-Russell syndrome (SRS, MIM 180860) is characterized by severe intrauterine and postnatal growth retardation associated with typical small triangular face and other variable features. Most frequently, SRS is caused by altered gene expression on chromosome 11p15 due to hypomethylation of the telomeric imprinting center (ICR1) (40%). Maternal uniparental disomy of chromosome 7 (matUPD7) is less frequent (5-10%). Thus, about half of SRS patients remain without a genetic diagnosis. Analysis of the known SRS genetic causes in a cohort of 70 patients, whose clinical picture included growth retardation and SRS features, revealed hypomethylation of ICR1 in 28 (39.4%), and matUPD7 in four patients (5.6%). Two patients (2.8%) had maternally inherited microduplications at 11p15. One of them carried a microduplication of the centromeric imprinting center, ICR2 (Bonaldi et al., AJMG 155A:2479,2011); in addition to the ICR1 and ICR2 microduplication, the other patient had a 4p microdeletion due to a cryptic unbalanced translocation, der(4)t(4;11)(p16.3;p15.4)mat, as documented by aCGH. Among the 36 patients (51.4%) without a causative diagnosis, 21 were submitted to aCGH analysis (CytoSure 180K/UPD180K, OGT). We found 32 rare variations in 14 patients: one probably pathogenic, 11 of unknown significance (VOUS) and 20 probably benign. One patient carried a paternally inherited Yp11.32 microdeletion, encompassing ~40 Kb of SHOX downstream regulatory region. Four VOUS identified in different patients were particularly interesting: (1) a paternally inherited ~365 Kb 2p23.3 microdeletion encompassing eight protein-coding genes; (2) a de novo ~1.4 Kb Xp11.23 microduplication in a male patient with intellectual disability (ID), partially comprising the 5'UTR and first exon of the FTSJ1 gene, which has been associated with ID in men; (3) a de novo ~28 Kb 11p15.2 microduplication at SOX6 intron 4, which contains highly conserved segments. SOX6 is involved with skeletal growth and chondrogenesis, and its dysregulation might explain the patient's phenotype. A boy has been described with a similar phenotype and a balanced de novo t(9;11) translocation, the chromosome 11 breakpoint mapping to SOX6 intron 4 (Tagariello et al., JMG 43:534,2006); (4) a ~544 Kb 1p36.32 microduplication, encompassing three potein-coding genes; inheritance could not be tested. Potentially pathogenic microimbalances were found among patients with atypical SRS phenotypes. Financial support: FAPESP.

3175T

Multiple homozygosity regions in a girl with unexplained intellectual disability. *C.C. da Silva[1,2,3,5,6], F.G. Reis[1,4], L.B. Minasi[1,2], I.P. Pinto[1,2], A.V. Melo[1,3], D.M.C. Cunha[1,2], C.L. Ribeiro[1], T.C. Vieira[5,6], D.M. e Silva[1,2,4], A.D. da Cruz[1,2,3,5].* 1) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Brazil; 2) Pontifical Catholic University of Goias, Genetics Master's Program, Brazil; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Brazil; 4) Federal University of Goias, Genetics and Molecular Biology Master's and PhD Programs, Brazil; 5) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Brazil; 6) State University of Goias, UnU Eseffego, Brazil.

Intellectual Disability (ID) is a complex disorder characterized by significant limitations in both intellectual functioning and adaptive behavior that begin before the age of 18 years. The detection of excessive long continuous stretches of homozygosity (LCSH) on multiple chromosomes may suggest consanguinity, and could be useful in determining candidate genes for further testing for autosomal recessive Mendelian disorders. Herein, we report a first case of a Brazilian girl who presented moderate intellectual disability and LCSH detected by Chromosomal Microarray Analysis (CMA). A 9 years old girl born of first-cousin parents, at 40 weeks gestation to a 27-year-old mother and 25-year-old father, her birth weight was 1210g and crown-heel length 42 cm, and she presented mild facial dysmorphism, highly arched eyebrows, congnitive impairment, and divergent strabismus. Affymetrix's CytoScan™ HD SNP array revealed several LCSH in 9 chromosomes (2p25.3; 2p13.2; 7q32.3; 8q24.23; 10q26.12; 11q24.1; 14q24.3; 14q32.2; 15q13.1; 21q11.2 e Xp21.1) and none pathogenic CNVs. The morbid genes included *TMEM18, SNTG2, COLEC11, MYT1L, TSSC1, SOX11, RNF144; DCTN1, PCGF1, LRRTM4; CASP2, CNTNAP2; KCNK9, TRAPPC9, BAI1; FGFR2; BSX, SCN3B, NRGN, KIRREL3; NGB, NRXN3, KCNK10, TDP1, CCDC88C, ATXN3; DYNC1H1; CHRFAM7A, CHRNA7, SLC12A6, TTBK2, MAP1A, GATM, UBR1; BTG3; TSPAN7,* respectively. NCBI database analyses showed that mutations in *COLEC11* gene are related to Malpuech-Michels-Mingarelli-Carnevale Syndrome (3MC Syndrome [MIM265050]) which has autosomal recessive inheritance. The results suggest that LCSH involving the *COLEC11* gene may be responsible for the intellectual disability of a child. Although the several LCSH not diagnostic a specific condition, it indicate a causative gene located within of these regions. Thus, further studies require Exome Next Generation Sequencing to identify the mutations for candidate genes and confirm the pathogenicity of such changes. Homozygous segments increase the likelihood the proband has inherited two copies of a deleterious allele for an autosomal recessive disorder. Therefore, the genetic counseling is recommended for families to help to understand that autosomal recessive disorders are strongly associated with consanguinity and that sporadic undiagnosed case of intellectual disability, congenital anomalies and dysmorphism may have an autosomal recessive etiology with risks of recurrence in future pregnancies.

3176T

Mate-pair sequencing analysis of karyotypically balanced chromosomal rearrangements associated with cryptic imbalances reveals additional structural variants and complex genomic reorganization typical of chromothripsis or replication mechanisms. *A.C.S. Fonseca[1,2], A. Bonaldi[2], M. Bak[1], K.T. Abe[3], A.M. Vianna-Morgante[2], N. Tommerup[1].* 1) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, University of Copenhagen, Denmark; 2) Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, São Paulo, Brazil; 3) Sarah Network of Rehabilitation Hospitals, Brasilia, DF, Brazil.

About 7% of karyotypically balanced chromosomal rearrangements (BCR) are associated with intellectual disability (ID), developmental delay (DD) and/or congenital malformations (CM). Cryptic imbalances on the rearranged chromosomes appear as an important cause of the clinical phenotypes, being detected in about 27% of the BCRs analyzed by aCGH (Feenstra et al. Eur J Hum Genet 19:1152, 2011). Aiming at investigating if structural variants (SVs) undetected by aCGH co-occur with such imbalances, we applied mate-pair sequencing (MPS) to characterize eight sporadic BCRs (four translocations and four complex rearrangements) carried by patients with ID, DD and CM. Previously performed aCGH (180K, OGT) had revealed one or more imbalances (2.2kb to 5.8Mb) at or in cis to the BCR breakpoints. Mate-pair libraries were prepared using the Nextera kit (Illumina), and paired-end sequenced (2×100 bp) on HiSeq2000. Filtering strategies and cluster analysis of discordant mate pairs were performed using an in-house script. SVDetect and Delly were used for SV prediction. In total 109 breakpoints (BPs; resolution <1kb) were identified, which resulted in 60 balanced and 29 unbalanced SVs. The number of BPs and SVs varied among the 8 BCRs (n=BP/SV; n1=4/2, n2=20/18, n3=18/17, n4=10/7, n5=17/17, n6=6/5, n7=12/11; n8=22/12). Among the 89 SVs identified by MPS, 25 unbalanced and 14 balanced SVs had been detected, respectively, by aCGH or karyotyping. The rate of SVs detected exclusively by MPS varied among the different SVs: deletions (4/23), duplications (0/6), inversions (2/2), intrachromosomal direct (15/16) and inverted insertions (10/11), translocations (2/12), interchromosomal direct (7/8) and inverted insertions (10/11). All but one BCR had SVs identified only by MPS (n1=0; n2=10; n3=12; n4=4; n5=10; n6=1; n7=9; n8=4). Our findings indicate that karyotypically balanced rearrangements carrying imbalances are likely associated with inter/intra chromosomal SVs, particularly insertions, which remain cryptic to aCGH, thus deserving reinvestigation by MPS. The chromosome shattering with clustered double-strand breaks we observed in three BCRs carrying deletions suggest they arose via chromothripsis, an evidence that this mechanism can result in gross DNA losses (>1kb) in the germline. A fourth BCR with complex reorganization contained several duplications, a hallmark of rearrangements involving replication mechanisms (Liu et al. Cell 146:889, 2011). (Financial support: FAPESP).

Novel H3K4me3 marks are enriched at human- and chimpanzee-specific cytogenetic structures. *G. Giannuzzi, E. Migliavacca, A. Reymond.* Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

Human and chimpanzee genomes are 98.8% identical within comparable sequence. They however differ structurally in nine pericentric inversions, one fusion that originated human chromosome 2 and content and localization of heterochromatin and lineage-specific segmental duplications. The possible functional consequences of these cytogenetic and structural differences are not fully understood and their possible involvement in speciation remains unclear. We show that subtelomeric regions—that have a species-specific organization, are more divergent in sequence, and are enriched in genes and recombination hotspots—are significantly enriched for species-specific histone modifications that decorate transcription start sites in different tissues in both human and chimpanzee. Human lineage-specific chromosome 2 fusion point and ancestral centromere locus as well as chromosome 1 and 18 pericentric inversion breakpoints showed enrichments of human-specific H3K4me3 peaks in prefrontal cortex. Our results reveal an association between plastic regions and potential novel regulatory elements.

Detection of copy number variation in single cells by next generation sequencing. *F. Kaper[1], C. April[1], X. Cai[1], H.Y. Chuang[1], T. Royce[1], H. Joshi[2], C.E. Michel[2], P. Burns[2], J.B. Fan[1].* 1) Illumina Inc, San Diego, CA; 2) Illumina Inc, Cambridge, UK.

The detection of copy number variations (CNVs) in single cells has many applications, including cell lineage mapping, cancer heterogeneity research, neuronal mosaicism research and preimplantation genetic screening (PGS). Current protocols employ an upfront whole genome amplification (WGA) step such as multiple displacement amplification (MDA), primer extension preamplification PCR (PEP-PCR) or degenerate oligonucleotide-primed PCR (DOP-PCR) followed by a next generation sequencing (NGS) library preparation. Here we describe results obtained with a novel protocol that combines NGS library preparation and WGA into one robust and rapid protocol. Single, three and five cell samples were isolated through FACS sorting or narrow-bore cell transfer pipetting from commercially available human lymphoblastoid cell lines with well-described subchromosomal abnormalities. NGS libraries were sequenced on a MiSeq® or a HiSeq® 2000 sequencing system. After alignment using Bowtie, only perfectly and uniquely aligning reads were kept for tag counting. The reference genome was divided into non-overlapping bins such that each bin is expected to contain 100 uniquely mapping reads. Deviations from this expectation are correlated with copy number. Unlike MDA-based methods, the protocol does not result in overamplification pile ups, resulting in increased signal to noise. Furthermore, the library fragments are generated in a random, uniform fashion across the entire genome unlike the reproducible bias of PCR-based WGA methods. Therefore genome coverage is correlated with increasing cell number. Using 1 million reads per NGS library, confirmed CNVs of 4Mb were reproducibly detectable at single, three and five cell input levels. The entire work flow from the start of sample preparation to available sequencing data takes 9 hours when using a MiSeq sequencing system. For the detection of smaller events, NGS libraries were sequenced to greater depth on a HiSeq 2000 system. In conclusion, this technique provides a simple and rapid protocol to detect CNVs in single cells by NGS; experiments to further validate the method are currently ongoing.

3179T

Mosaicism in a Mosaic: Reduced capacity of female X chromosomes to resist age-related structural erosion. *M.J. Machiela[1], W. Zhou[1,2], M. Dean[3], J.N. Sampson[1], N. Rothman[1], N.D. Freedman[1], S. Wacholder[1], M.A. Tucker[1], F.X. Real[4,5], L.A. Perez-Jurado[5,6], M. Yeager[1,2], S.J. Chanock[1], NCI GWAS Mosaicism Consortium.* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD, USA; 2) Cancer Genomics Research Laboratory, Leidos Biomedical Research Inc., Frederick, Maryland, USA; 3) Laboratory of Experimental Immunology, Center for Cancer Research, NCI-Frederick, Frederick, Maryland, USA; 4) Spanish National Cancer Research Centre (CNIO), Madrid, Spain; 5) Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Barcelona, Spain; 6) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain.

Previous studies characterizing large clonal mosaic events have not focused on the X chromosome. Therefore, we analyzed deviations in $\log_2$ intensity ratio and B allele frequency on the X chromosome using existing genome-wide association data of 38,581 female participants from cancer association studies. We detected 131 mosaic events ≥2 Mb in size on the X chromosome of 104 females (0.27%). The rate of mosaicism per base-pair was approximately 5 fold higher for the X chromosome than the autosomes (1.10 vs 0.22 events per 100,000 Mb). Similar to autosomal events, most detected X events were mosaic copy neutral losses of heterozygosity (53%) followed by mosaic losses (34%) and mosaic gains (14%). Contrary to autosomal observations, mosaic X events tend to be larger in size (mean 86.1 vs 44.6 Mb) and far more likely to involve the whole chromosome (49% vs 5%). Interestingly, when compared to individuals with no X mosaicism, individuals with detected X events were observed to have a 15 times increased odds of additionally harboring an autosomal event (p-value= 2.20×10^{-8}). Frequency of X mosaicism ranged from 0.1% in 50 year old women to 0.4% in women 75 years or older (trend p-value=0.0066). While no overall cancer association was observed (p-value=0.30), subtype analyses suggest an association of X mosaicism with increased lung cancer risk (p-value=0.04), an association also observed for autosomal mosaicism, but further studies are required to confirm this finding. Methylation arrays were hybridized for a subset of 10 samples in an attempt to localize events to either the active (X_a) or inactive (X_i) X chromosome. Initial results indicate 8 out of 10 events have a shift in methylation profile favoring more copies of X_i and fewer copies of X_a; however, the observed trend was not significant in our limited sample (p-value=0.11). Our results indicate a higher per base pair rate of mosaicism on female X chromosomes than on autosomes and show that age-related erosion of the genome, previously observed in studies as mosaic events on the autosomes, also occurs on female X chromosomes.

3180T

Array-based analysis reveals partial 11q14 duplication in a familial case with intellectual disability, short stature and mild dysmorphic features. *R. Satomi[1], M. Ohta[1], K. Matsumoto[1], T. Miyashita[1], M. Hayata[1], H. Shiraku[1], N. Matsuda[1], K. Kurosawa[2], K. Enomoto[1].* 1) Department of Pediatrics, JA Toride medical center, Toride, Ibaraki, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan.

Partial chromosomal duplications of 11q without additional imbalances are rare. A total of seven cases associated with 11q14 duplication without any other chromosomal involvement have been reported. The phenotypes in these previous cases were characterized by a wide variety of clinical findings and variable intellectual disability or psychomotor delay with facial dysmorphic features. This may be due in part to varying size of the duplicated segments. Herein, we report a new case with a 9.6Mb duplication involving 11q14.1 to q14.3 defined by array-based comparative genomic hybridization analysis: arr 11q14.1q14.3(79,131,430-88,758,610)x3 (hg19). The patient is a 9-year-old boy who exhibits developmental delay, intellectual disability, minor dysmorphic features, and short stature. He was born at 32-week gestation. His birth weight and length are 1854g (25-50th percentile) and 45cm (75-90th percentile), respectively. He was healthy and uncomplicated in infancy. Initial visit to our hospital was at age 9, complaining short stature. His height was 119.5cm (below -2.5SD). Physical examinations found that he also had mildly upslanting palpebral fissures and cryptorchidism. Subsequent examinations reveal that his intelligence quotient is 50 and ADHD Rating Scale based on DSM IV criteria is 26. His brother also has intellectual disability, learning disorder, and short stature. Furthermore, we have discovered that he has some relatives presenting similar features on his mother's side. Though, this family history strongly shows as if they have the X-linked recessive inheritance, the copy-number change is even in the autosome. Our observations delineate the phenotypic spectrum associated with a clearly defined duplication of chromosome 11q14. Phenotype-genotype correlation will be discussed in view of all the reported cases and our case's family members.

3181T

15q11.2 duplication encompassing only the *UBE3A* gene is associated with developmental delay and neuro-psychiatric phenotypes. *A. Noor[1], L. Dupuis[2], K. Mittal[3], T. Stockley[1,4], J.B. Vincent[3], R. Mendoza-Londono[2], D.J. Stavropoulos[1,4].* 1) The Hospital for Sick Children, Department of Paediatric Laboratory Medicine, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Department of Pediatrics, Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Molecular Neuropsychiatry & Development Lab, Neurogenetics Section, The Campbell Family Brain Research Institute, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 4) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada.

Due to the presence of low copy repeats (LCRs) in chromosome 15q11-q13 region is prone to recurrent structural rearrangements including deletions, duplications and inversions. This region is also subject to genomic imprinting, thus associated phenotypes show parent-of-origin specific effect. Interstitial duplications of the 15q11-q13 region with maternal imprints are associated with a wide spectrum of neuro-psychiatric disorders including, autism spectrum disorders (ASD), developmental delay, learning difficulties, schizophrenia and seizures. On the other hand, individuals with duplications of the same region with paternal imprints are often phenotypically normal or in rare instances mildly affected. These observations suggest that a dosage sensitive imprinted gene or genes within this region that underline the risk for neuro-psychiatric phenotypes. Recent studies have shown that *UBE3A* is the only gene within this region that is solely expressed from the maternal allele in mature neurons. To date, no case with duplication of only *UBE3A* has been reported, therefore the contributions of this gene to the 15q11-q13 duplication phenotypes remains unclear. We present a female patient with developmental delay in whom we identified a 129 Kb duplication in chromosome region 15q11.2 encompassing only the *UBE3A* gene. The duplication was found to be maternally inherited in the proband. We further tested the segregation of this duplication and it was found to be segregating with a neuro-psychiatric phenotype in four generations. Expression analysis in cultured fibroblast confirmed the over-expression of the *UBE3A* in the proband compared to age-matched controls. Our study shows for the first time the clinical features associated with over-expression of *UBE3A* in humans, and underscores the significance of this gene in the phenotype of individuals with 15q11-q13 duplication.

3182T

A duplication of the *CDKL5* gene identified in a boy with developmental delay with autistic behavior, short stature and microcephaly. *K. Takano[1], T. Nishimura[2], K. Wakui[1], S. Takahashi[3], Y. Inaba[2], T. Kosho[1], Y. Fukushima[1].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 2) Department of Pediatrics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Department of Pediatrics, Asahikawa Medical University, Asahikawa, Japan.

Mutations in the X-linked cyclin-dependent kinase-like 5 (*CDKL5*) gene [MIM#300203] cause neurological developmental disorders involving early infantile epileptic encephalopathy, atypical Rett syndrome, severe intellectual disability (ID), infantile spasms and epilepsy. Chromosomal microdeletions including *CDKL5* also cause similar neurodevelopmental disorders. Although duplications of the short arm of X chromosome including *CDKL5* have been reported in patients with ID, dysmorphic features and/or epilepsy, the effect of *CDKL5* copy number gains on neurological development remains unclear because of those duplications encompassing other X-linked ID genes. Here, we present a boy with developmental delay and autistic behavior having a microduplication including the only gene *CDKL5* that could affect developmental brain. The patient is a 3-year-old boy, born at 38 weeks of gestation with the weight as 2,226 g (-2.1 SD), length as 46 cm (-1.0 SD), and OFC as 29 cm (-2.8 SD). His mother has normal intelligence and short stature with the height as 145 cm. He had surgical repair of inguinal hernia at the age of 9 month. His motor development was delayed with sitting alone at 7 months and walking independently at 2 years and 1 month. His DQ was 51 at 1 year and 8 months and he presented autistic behavior. He began to refuse food at 2 years and 8 months, and nasogastric tube feeding was started. At 3 years, he showed growth impairment with the height as 84.0 cm (-3.1 SD), weight as 11.5 kg (-1.6 SD), and OFC as 46.5 cm (-2.1 SD). G-banded chromosomes were 46,XY. Chromosomal microarray analysis revealed a 200-kb duplication in Xp22.13 spanning along the most of the genomic region of *CDKL5* which was derived from his mother. This is the first report on a microduplication of *CDKL5*, implying neurodevelopmental effects of increased gene dosage of *CDKL5*.

3183T

Apparent fetal developmental correction of partial monosomy 4 secondary to possible inheritance of a single translocation derivative. *V. Potluri[1], R. Burnside[2], R. Pasion[2], P. Papenhausen[2].* 1) Dynagene, Div Lab Corp America, 3701, Kirby Drive, Houston, TX 77098; 2) Labcorp, 1904 Alexander Drive, Research Triangle Park, NC 27709.

A 13-year-old female was referred for chromosome microarray analysis due to multiple abnormalities which includes scoliosis, hepatomegaly, chronic lymphocytic thyroiditis, oliguria and anuria among others. The whole genome SNP microarray analysis detected an 88 Mb terminal chromosome 4q gain [arr [hg19](4q24q35.2)(103,160,816-190,195,071)x3]. In addition, there was a complete allele homozygosity of the 103 Mb remainder of the chromosome 4 (4pter to q24)(46,691-103,160,815). The large duplicated region of 4q includes numerous OMIM annotated genes (proximal OMIM gene SLC39A8). Chromosome analysis identified the duplicated portion of the terminal 4q fused to Xpter with no DNA lost from Xp by array analysis. The original genomic imbalance could be due to unbalanced meiotic segregation of a parental translocation involving chromosomes 4 and X with subsequent single derivative (3:1) segregation leaving the zygote monosomic for chromosome 4. The observed homozygosity contiguous with the translocated gain of 4q is a strong indication that the single chromosome 4 normal homolog duplicated creating UPD for all of chromosome 4, although the partial monosomy apparently was corrected by this probable pathway, it results in trisomy for the distal half of chromosome 4 that was fused to the X chromosome. Since there is no apparent loss of DNA at Xpter, selective inactivation of the derivative X chromosome (and subsequently the 4q) may not be 100% or may be slow to select against, allowing early gestational effects of the partial trisomy 4. In addition, the 4q segment may not be completely inactivated . Recessive mutations in the homozygotic region of 4 cannot be excluded as also contributing to the abnormal phenotype. Although corrections through trisomy and monosomy rescue are well documented in literature, this apparent correction which results in imbalance is highly unusual, demonstrating the apparent selective disadvantage of monosomy over trisomy.

3184T

Complex mosaic chromosome rearrangement in a patient with Phelan-McDermid Syndrome. *C. Purmann[1,2], W. Froehlich[1,3], J. Bernstein[3], R. Dolmetsch[4,5], J. Hallmayer[1], A.E. Urban[1,2].* 1) Department of Psychiatry & Behavioral Sciences, Stanford University, Palo Alto, CA; 2) Department of Genetics, Stanford University, Palo Alto, CA; 3) Department of Pediatrics, Stanford University, Palo Alto, CA; 4) Department of Neurobiology, Stanford University, Palo Alto, CA; 5) current address: Novartis Institutes for Biomedical Research, Cambridge, MA.

Phelan-McDermid Syndrome is caused by deletions or unbalanced translocations of chromosome band 22q13, for which few mosaic cases have been described. Here, we report a detailed genetic analysis of a patient with a 22q13 terminal deletion showing a complex rearrangement containing three different breakpoints. The affected patient exhibits global developmental delay, moderate intellectual disability, autism, and severely impaired speech. She was initially diagnosed with Phelan-McDermid Syndrome using multiplex ligation-dependent probe amplification (MLPA). Molecular karyotyping of a fibroblast sample using a high-density Illumina HumanOmni5Exome array revealed a complex rearrangement of a 1 Mb region missed by the MLPA assay pointing to two or possibly three different cell populations in the sample. This finding was followed up by digital droplet PCR and microsatellite analysis. Subsequent analyses include Fluorescence in situ hybridization (FISH) as well as targeted chr22 capture followed by deep sequencing for fine-mapping of the breakpoints. The combined approach revealed a complex rearrangement consisting of two different breakpoints of the 22q13 terminal deletion (BP1 and BP2). Furthermore, the patient showed an additional rearrangement between BP2 and a third breakpoint (BP3) pointing to a possible third cell population. To the best of our knowledge, this case represents the first mosaic chromosome rearrangement of this kind in Phelan-McDermid Syndrome. This case also highlights the effective use of established and new laboratory technologies for studying complex chromosomal rearrangements.

CMIP, a Strong Candidate Gene Involved in the Autism Spectrum Disorder. *M. Luo[1], S. Mulchandani[1], M. Harr[2], T. Wenger[3], E. Zackai[2], R. Schultz[3], N. Spinner[1], L. Conlin[1].* 1) Dept of Pathology & Lab Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Dept of Clinical Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Center for Autism Research, The Children's Hospital of Philadelphia, Philadelphia, PA.

Autism spectrum disorder (ASD) is a group of conditions that involve severe deficiency in language and social communication, along with inappropriate repetitive behaviors. Despite the evidence of high heritability, a clear genetic diagnosis can only be established in a minority of patients. Genetic heterogeneity has been appreciated, and both chromosomal aberrations and monogenic causes have been found. We report two patients with deletions involving the CMIP gene, identified by genome-wide SNP array analysis. Both patients presented with ASD, specifically with pervasive developmental delay and attention deficit hyperactivity disorder (ADHD). Patient 1 has a 517kb deletion within 16q23.2q23.3, including the entire CMIP gene and part of the PLCG2 gene. Patient 2 has a 1.59Mb deletion within 16q23.3 encompassing 12 genes, including part of the CMIP gene and three genes known to be associated with disease (GCSH, BCMO1, GAN). The minimal region of overlap includes only the CMIP gene. Parental studies confirmed that the deletions in both patients were de novo and were not associated with a familial chromosomal rearrangement. These two deletions were observed in a cohort of 11,000 pediatric samples tested for various clinical reasons, with at least 1,000 patients with ASD. In the literature, only one patient with a comparable de novo deletion has been reported at this time. This patient shared very similar phenotypes with our patients. In addition, one 280kb de novo deletion was found in Decipher (258184) and one 720Kb deletion without inheritance information was found in Clinvar (nsv532569). Although no detailed clinical information was available, both of these individuals were reported to have ASD. Association studies showed that the CMIP gene is a susceptibility locus for specific language impairment (SLI), which is a comorbid disorder with ASD. Our findings provide further support for the role of CMIP haploinsufficiency in ASD patients. Additionally, our study also provides evidence for the genetic overlap between SLI and ASD.

3186T

Cytogenetic studies of the drug Methotrexate (MTX) on the blood lymphocytes of colon cancer patients. *Z.MT Jaafar.* Biotechnology Center, Ministry of Science and Technology - Iraq, Baghdad, Baghdad, Iraq.

The aim of the study is to investigate the cytogenetic parameters in order to define the effect of methotrexate (MTX) on blood lymphocytes , manifested by blast genic index (BI) , mitotic index (MI) , replicative index (RI), and sister chromatid exchanges (SCEs). The collected blood samples were cultivated in RPMI 1640 supported with 10% fetal bovine serum , 0.3 ml of phytohaemagglutinin (PHA) , antibiotics (penicillin and streptomycin) and different concentrations of MTX (0,0.2,0.5, 0.5, 1, 2, 4, 8 μg/ml). The results showed significant reduction in BI and MI and RI indices with concentrations (1 , 2, 4, 8 μg/ml) when comparing with the control . While in 0.2, 0.5 μ/ml of MTX gave no significant decrease when compared with the controls . The results of BI shows significant reduction according to increasing of conc. Of drug , it gave 26% in (0)conc. and increase to 19.1% in 0.2 μg/ml and 11% at 2ug/ml and 4.5% in 8ug/ml . The replicative index also show reduction which is proportional with increasing conc. Of MTX , it gave 0.72% at zero conc. and 0.44% at conc . of 0.2 μg/ml of MTX and 0.22% at conc. of 0.5 μg/ml and 0.02% at conc. of 1 μg/ml of MTX . On the other hand the SCE which represent the breakage in the two double helices of DNA shows increases in the SCEs frequency in colon cancer samples which gave 8.69 in zero conc. and 8.81 in 0.2 μg/ml , 10.66 at conc. of 0.5ug/ml . The SCEs in the other conc. of drug can not be detected due to the toxicity of drug in high concentrations . In control samples , the SCEs frequency gave 5.45 at zero conc. , 5.66 at 0.2 μg/ml and 6.56 at conc. of 0.5 μg /ml .The mutation fraction increased in colon cancer patient which gave 8.93 in 0.2 μg/ml , and 15.72 in 0.5 μg/ml and 4.1 in 1ug/ml while in control gave 3.17 in 0.2 μg/ml and 2.17 in 0.5μg/ml and 0.74 in μg/ml . The conclusion showed decrease in the (MI) , (BI) and (RI) and increase in SCEs frequencies and mutation fraction in colon cancer patients when compared with control . The presence of mutant cells in lymphocytes of colon cancer that resistant to MTX, give an idea about amplification in DHFR gene that regulate the activity of DHFR enzyme and also indicate the resistance of cancer cells to drugs .

3187T

Molecular cytogenetic characterization of a patient diagnosed with dimorphic anemia carrying de novo rare ring chromosome 7 along with t(7;9). *S.K. Bhattacharya, V. Lal.* Cytogenetics, Dr. Lal Path Labs. Pvt. Ltd., Newdelhi, Delhi, India.

Cytogenetic abnormalities are described in a few patients with typical dimorphic anemia (DA). The possible clonal nature of this disease is still controversial. We present a case of a derivative chromosome 7 formed by a ring chromosome 7 and t(7;9). The patient is phenotypically normal. This is a unique case report from India, on occurrence of r(7) along with t(7;9). Patient is born to cytogenetically normal parents. We have performed conventional cytogenetic technique using GTG banding and molecular FISH technique using LSI D7S486 probe and WCP for chromosome 7 and 9. However, both the clinical features and the extent of cytogenetic imbalance of chromosome 7 and 9 are variable, and few reported cases of r(7) have been studied by molecular techniques. To our knowledge, this is the first report of r(7) and t(7;9) found in a child with dimorphic anemia, characterized by molecular cytogenetic analysis.

3188T

Reciprocal microdeletions and microduplications of *CNTN6* gene (3p26.3) in patients with intellectual disability. *I. Lebedev[1], A. Kashevarova[1], N. Skryabin[1], N. Chechetkina[2], O. Salyukova[2], L. Nazarenko[2].* 1) Laboratory of Cytogenetics, Institute of Medical Genetics, Tomsk, Tomsk region, Russian Federation; 2) Laboratory of Hereditary Pathology, Institute of Medical Genetics, Tomsk, Tomsk region, Russian Federation.

To date several reciprocal microdeletion / microduplication syndromes or «genomic sister disorders» have been described. Due to application of high resolution microarray technologies new submicroscopic chromosomal rearrangements are being published. The reciprocal rearrangements are particularly valuable, since they allow to determine new dosage-sensitive pathogenic genes in human genome. We performed array-CGH analysis for 80 patients with idiopathic intellectual disability using CGH Microarray Kits 4×44K and 8×60K (Agilent Technologies, USA). Pathogenically significant cases were confirmed by qPCR. We present two patients with microdeletion (369 kb) and patient with microduplication (766 kb) at 3p26.3 containing the only gene - *CNTN6*. The microduplication was inherited from apparently healthy father and grandmother. The brother and sister with microdeletion were orphans. The microdeletion was the same size and localization in both sibs. Recently, the microduplication in 3p26.3 (containing *CNTN6*) has been shown to be associated with autism spectrum disorders. Contactin 6 is also suggested to play a neuroprotective role in ischemic injury and contribute to granule cell maturation and/or synaptic formation in the developing cerebellum. Considering the experiments with mice we found myotonic syndrome, late development of sit and walk ability in the anamnesis, current fine motor skills impairment and dysarthria in patient with dup3p26.3. Dysarthria was also observed in the boy with del3p26.3. Obviously, *CNTN6* can be a novel pathogenic gene associated with autism spectrum disorders, intellectual disability, and motor functions impairment. This study was supported by Russian Scientific Foundation (grant N 14-15-00772).

Co-occurrence of non-mosaic trisomy 22 and inherited balanced t(4;6)(q33;q23.3) in a live-born female: Case report and review of the literature. *J. Liu[1], F. Kehinde[2], C. Anderson[3], J. McGowan[2], R. Jethva[3], M. Wahab[1], A. Glick[1], M. Sterner[1], J. Pascasio[1].* 1) Dept Path & Lab Med., St Chris Hosp for Children, Drexel University College of Medicine, Philadelphia, PA; 2) Department of Neonatology, St. Christopher's Hospital for Children, Drexel University College of Medicine, Philadelphia, PA 19134; 3) Department of Medical Genetics, St. Christopher's Hospital for Children,- Drexel University College of Medicine, Philadelphia, PA 19134.

Trisomy 22 is the third most common autosomal trisomy occurring in about 0.4% of all clinically recognized pregnancies. Complete non-mosaic trisomy 22 is extremely rare in live births, and most of the affected children died before one year of age. To date, only 29 cases have been reported in the literature, and none of them carried an additional genetic lesion. In this report, we describe clinical presentations, cytogenetics and cytogenomics findings in a live-born female with a complete non-mosaic trisomy 22 as well as a paternally inherited, balanced reciprocal chromosomal rearrangement t(4;6)(q33;q23.3). The proband manifested features commonly seen in individuals with non-mosaic trisomy 22 such as intrauterine growth retardation (IUGR), single umbilical artery, cranial abnormalities, short neck, cleft lip and palate, dysmorphic ears, congenital heart defects, dysplastic kidneys, genital anormalies, hypoplastic nipples, and digital malformations. In addition, she had lobar holoprosencephaly, aqueductal stenosis, limb and eye problems that have not been associated with complete trisomy 22. The proband died 35 days after birth due to complex heart disease and renal failure. We are hereby expanding cytogenetic and clinical spectrum of this rare chromosome disorder. Clinical features of live-born children with non-mosaic trisomy 22 are reviewed and compared to those in our proband. The impact of genomic content in relation with the survival of trisomies in humans is also discussed.

3190T

Identification And Characterization Of Marker Chromosome In a Patient with Turner's Syndrome. *s. sharma, p. srivastava.* indraprastha apollo hospital, New Delhi, new delhi, India.

Introduction: We are describing a 14 year old female who was referred to us with severe growth retardation, primary amenorrhea, poor development of secondary sexual characteristics, web neck, increased FSH and LH. A provisional diagnosis of Turners syndrome was made clinically. On routine cytogenetic analysis she was found to be mosaic for 45,X and 46,X,+marker chromosome. The presence of a marker chromosome in Turner syndrome generally implicates a sex chromosome origin but it may also originate from a non-sex chromosome. If the marker chromosome originates from Y, the patient is at risk of developing Gonadoblastoma. Therefore, FISH test was performed for marker chromosome to rule out the presence of Y chromosome so as to delineate the risk of gonadoblastoma in the patient. Methods: Peripheral blood sample was collected from the proband and cytogenetic examination was carried out using standard techniques of 72hr phytohemagglutinin stimulated peripheral blood lymphocyte culture. FISH was done using centromere enumerating probe for X and Y chromosome. Results: The marker chromosome identified in the chromosomal analysis was found to be centromeric part of X chromosome on FISH analysis, thus ruling out the Y chromosome and the risk of gonadoblastoma. Conclusion: We strongly recommend that FISH should be done in all cases of Turner syndrome where a marker chromosome is identified on chromosomal analysis so as to rule out the risk of gonadoblastoma and to provide appropriate genetic counseling. Keywords: Turner's Syndrome, Marker chromosome, Cytogenetics.

Cytogenetic Abnormalities in Products of Conception; Analysis and Review of NSUH series of cases. *J. Paul, I. Piechocki, C. Sreekantaiah.* Cytogenetics, North Shore LIJ Health System, Manhasset, NY.

Chromosomal abnormalities account for approximately 50 to 70% of sporadic first trimester miscarriages with the remainder usually classified as idiopathic. A majority of the abnormalities are numerical with structural chromosomal abnormalities or other genetic mechanisms accounting for less than 10% of cases. Cytogenetic analysis of products of conception (POC) is essential to determine the cause of pregnancy loss, aid the prenatal diagnosis of subsequent pregnancies, calculations of recurrence risks, and delineation of the different kinds of abnormalities causing spontaneous abortions. We report our case series of over 5000 POC samples referred to the North Shore University Hospital and compare our data with the published data.

3192T

Haploid-insufficiency and triploid-insensitivity of the same 6p25.1p24.3 region in a family. *Z. Qi[1], L. Jeng[2], A. Slavotinek[3], J. Yu[1].* 1) Dept. of Lab Medicine, University of California San Francisco, San Francisco, CA; 2) Dept. of Medicine, Pediatrics and Pathology, Program for Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, MD; 3) Dept. of Pediatrics, University of California San Francisco, San Francisco, CA.

Chromosome 6pter-p24 deletion syndrome is a clinically recognized chromosomal disorder (OMIM #612582). Of more than 40 reported cases of this disorder, only four showed interstitial deletions within the 6p25.3p23 region. To date, only two interstitial duplications involving the 6p25.3p23 region have been reported. We present a family carrying both deletion and duplication within the 6p25.1p24.3 region (4,745,144-10,384,769 bp, Build hg19). A 5.6 Mb interstitial deletion within the region was detected by array CGH in a 26-month-old female proband who presented learning disabilities affecting motor and speech skills, bilateral conductive hearing loss, dysmorphic features including hypertelorism, a left preuaricular pit, downturned corners of the mouth and small teeth, a hemangioma of the right neck and a small pectus excavatum. Instead of deletion, her typically developing 5-year-old brother carried an interstitial duplication of the same region. High-resolution G-banding and FISH studies demonstrated that the deletion and duplication were apparently inherited from their 35-year-old mother who carries both cell lines of the deletion (~70%) and duplication (~10%), as well as a normal cell line (~20%) in her peripheral blood. The proband showed phenotypes reportedly associated with the chromosome 6pter-p24 deletion syndrome. Their mother had an embolic stroke at age of 26 years, a patent foremen ovale, and an atrial septal aneurysm. Our findings are consistent with the reported haploid-insufficiency of the 6p25.1p24.3 region, and suggest possible triploid-insensitivity of the same region. In addition, the cells with the duplication may compensate the phenotypic effect of the cells with the deletion as implied by the maternal phenotype and karyotype that was most likely derived from a rare somatic inter-chromatid non-allelic recombination that occurred early in embryogenesis.

A (2;12)(p12;p13) translocation in a Down Syndrome patient with B-ALL. *Y. Kim[1], P. Traum[2], B. Lasky[2], L. Yang[2], D. Ngo[2], J. Pelkey[2], JN. Rao[2], C.A. Tirado[2].* 1) UCLA Department of Pathology & Lab Medicine 248 Backs Lane, apart B Placentia, CA92870; 2) UCLA Department of Pathology & Lab Medicine 1010 Veteran Ave, 2212F Los Angeles, CA 90024.

Children Children with Down syndrome have a greatly increased risk of developing acute leukemia, including B-Acute Lymphoblastic Leukemia (B-ALL). Herein we present a 9-year-old male Down syndrome patient who presented with pancytopenia, circulating lymphoblasts and increased megathrombocytes. His white blood cell count was 3,010 per μL, the hemoglobin was 8.9 g/dL and the platelet count was 43,000 per μL with a differential showing 7% neutrophils, 1% metamyelocytes, 1% myelocytes, 52% lymphocytes, 32% lymphoblasts and 4% monocytes. A bone marrow biopsy showed 90% marrow cellularity, with 95% of replacement by lymphoblasts. Flow cytometry of the bone marrow aspirate showed the blasts were positive for CD10, CD19(dim), CD22(dim), CD34(bright), CD38(dim, partial), HLA-DR, CD16(subset), and CD79a. Based on these clinical and pathologic findings, a diagnosis of B-ALL was made. Cytogenetic analysis revealed an abnormal karyotype described as 47,XY,+21c[25]/47,idem,t(2;12)(p12;p13),t(8;14)(q11.2;q32)[5] indicating two reciprocal translocations , one at 2p12; 12p13 and the second one at 8q11.2;14q32. The *IGH@* rearrangement seen in the second translocation was confirmed with FISH using the IGH@ break-apart probe. A FISH panel for *ETV6,RUX1* revealed an abnormal signal pattern in 51% of the cells examined with an extra signal for *ETV6* on 12p which confirmed the (2;12) translocation and all cells examined showed an extra signal for *RUNX1* which correlates with the constitutional +21. The t(8;14)(q11.2;q32) involving the *IGH@* gene has been observed as a rare abnormality in CD10+ B-ALL and more than 1/4 of these cases are Down syndrome patients . However to the best of our knowledge, the 2;12 translocation has been reported in cyclin-D1 negative/cyclin-D2 positive mantle cell lymphoma but not in ALL. Therefore the exact significance of this unique finding in this patient is unclear. Further case reports of similar cytogenetic abnormalities in patients with Down syndrome presenting with B-ALL is warranted.

3194T

An uncommon coincidation of multiple myeloma and myelodysplastic syndrome. *S. Berker Karauzum[1], C. Aydin[1], O. Salim[2], O. Kemal Yucel[2].* 1) Department of Medical Biology and Genetics, School of Medicine, Akdeniz University, Antalya, Turkey; 2) Department of Hematology, School of Medicine, Akdeniz University, Antalya, Turkey.

Multiple myeloma (MM) is a subgroup of disease called plasma cell dyscrasias and characterized by clonal proliferation of neoplastic plasma cells. The most common genetic abnormalities that cause multiple myeloma, are translocations which affect IgH chromosome locus on chromosome 14. This translocations are determined by using FISH methods in general. Advanced stage MM requires treatment of chemotherapy. Conventional chemotherapy is known to be an important factor to transformation of MM to MDS or AML. In this report, we present 48 years old case who was first diagnosed with MM in 2012 and our patient's karyotype was found to be normal (46, XY), but in FISH analysis t(11; 14)(q13; 32) translocation was observed in 70%. In addition to this abnormality 13q14, 14q32, 16q22 deletions were also identified. These results supported the MM diagnosis as a sole anomaly. The occurrence of the t(11; 14) and 20q together has marked the coincidence of MM and MDS in this patient. In december 2014 as t(11; 14) translocation was identified by FISH analysis in 19% , in conventional cytogenetic analysis revealed deletion of the 20q as a sole anomaly.

3195T

An easy cIg-FISH Protocol For Multiple Myeloma which can be incorporated as Routine Cytogenetic Laboratory Practice. *L. Gole[1], A. Lin[2], C. Chua[1], W.J. Chng[2].* 1) Department of Laboratory Medicine, National University Health Systems, Singapore, Singapore; 2) Department of Haematology Oncology, National Cancer Institute of Singapore.

The International Myeloma Working Group and the European Myeloma Network recommends that FISH findings in multiple myeloma should not be reported without either first concentrating the plasma cells (PC) or employing some means of PC identification so that only these cells are scored, making the patient report more meaningful. The more commonly practiced techniques seem to be staining plasma cells with lambda/kappa antibodies followed by FISH (cIg-FISH). We have made modifications to the current techniques making it simpler for cytogeneticists to incorporate this as a routine procedure. Bone marrow aspirates from 20 patients for conventional cytogenetics and FISH for myeloma panel were included in this study. Bone marrow cell pellets in Carnoy's fixative were washed with 100% methanol and dropped onto slides. An additional drop of 96% ethanol was applied before drying. Antigen retrieval was performed for 10 minutes in 10mM citrate buffer (0.1M citric acid / 0.1M sodium citrate) at 95°C. Slides were rinsed twice in 1x phosphate buffered saline (PBS) and incubated with 1:10 AMCA goat anti-human kappa and/or anti-human lambda antibodies at 37°C for 1 hour followed by two washes with 1xPBS. They were then incubated with 1:10 AMCA anti-goat antibody at 37°C for 1 hour. Standard FISH protocols were applied following antibody staining. The three FISH probes used were for t(4;14)(*FGFR3;IGH*), t(14;16)(*IGH;MAF*) and *TP53*. Slides were mounted with VECTASHIELD mounting medium without DAPI and viewed using a fluorescence microscope. AMCA-positive cells which stained blue were identified using a triple-bandpass filter and only these were scored. Our modified method showed clear antibody staining along with analyzable bright FISH signals. Plasma cells were well separated and resembled the larger nuclei obtained by routine FISH. All 20 samples had a reportable result and abnormalities were detected in 9 cases by cIg-FISH vs 7 by FISH and 5 by karyotyping. A total of 16/60 abnormalities were detected by cIg-FISH with the 3 probes. This modified method did not miss any abnormalities, produced clear results and increased confidence in setting tighter cutoff limits.

3196T

Homozygous Deletion of TEL (ETV6) in Childhood Acute Lymphoblastic Leukemia (ALL): Prognostic Implications. *G. Velagaleti, C. Mendiola, J. Rodriguez, M. Zhu, V. Ortega.* Dept Pathology, Univ Texas Hlth Sci Ctr, San Antonio, TX.

The fusion of TEL/AML1 (ETV6/RUNX1) gene regions resulting from the t(12;21), is the most common genetic abnormality observed in childhood ALL. The neoplasm in these patients persists not by the initial fusion event, but in most cases by a secondary or subsequent leukemogenic event involving deletion of the TEL gene region on the non-rearranged TEL allele. Although variant patterns are seen by fluorescence in situ hybridization (FISH) including extra copies of AML1, extra fusions of TEL/AML1 and rearrangements of TEL, deletion of the second TEL allele is the most common and can have significant prognostic implications. In these cases, persistence of the original pre-leukemic clone may indicate proliferative advantage and lead to prolonged remission followed by periods of relapse as the residual secondary clones emerge. We report a case on a 26 year old male with ALL harboring homozygous deletion of the TEL gene region. To our knowledge, this is the first reported case of a homozygous TEL deletion without a concomitant TEL/AML1 fusion. His initial presentation to our laboratory was in 2003 status post bone marrow transplant and showing normal result by chromosome analysis (CA). Nine years later (07/2012) the patient returned with relapse. CA showed a complex karyotype with multiple abnormalities. FISH analysis with ALL panel showed 3 copies of cMYC gene region, deletion of p16 gene region and homozygous deletion of TEL gene region with 6 copies of AML1. Follow-up chromosome and FISH studies up until 01/2014 were all normal. Homozygous deletion of the TEL gene region in our patient may suggest that absence of TEL gene region on both alleles behaves similarly to cases with the classic TEL deletion of only one allele. Furthermore, the manifestation of relapse following remission clearly supports TEL deletion being the principle causative factor for subsequent and late-onset relapses by its ability to evade complete elimination during therapy. Since our patient presented to us following BMT, we cannot ascertain if the homozygous TEL deletion, which was never before reported, is the second hit following the initial TEL/AML1 fusion, or is by itself the primary hit. We hypothesize that our patient had the initial TEL/AML1 fusion with deletion of one TEL allele at diagnosis and this in turn may have resulted in the loss of second TEL allele similar to loss of heterozygosity in other cancers.

3197T

A maternally inherited 697.4 kb *SOX3* duplication in a female fetus with neural tube defects. *N. Cohen[1], H. Mei[1], E. Chan[2], M. Babcock[1], J. Reiner[1], A. Li[2], A. Babu[1], S.A. Scott[1], L. Edelmann[1].* 1) Mount Sinai Genetic Testing Laboratory, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) New York-Presbyterian Lower Manhattan Hospital, New York, NY 10038.

The SRY-BOX 3 (*SOX3*) gene [MIM 313430] at Xq27.1 belongs to the highly conserved SOXB1 subfamily of transcription factors, which are expressed throughout the developing central nervous system and are involved in embryonic development and neuronal differentiation. Disruption of *SOX3* by polyalanine expansion has been reported among patients with X-linked mental retardation and growth hormone deficiency, and full gene duplication of *SOX3* is a cause of X-linked hypopituitarism with incomplete penetrance. In addition, structural rearrangements involving *SOX3* have been described in patients with XX male sex reversal, and increased expression of *SOX3* by gene duplication has very recently been proposed as a risk factor for neural tube defects (NTDs). Here we report on a female fetus with a maternally inherited submicroscopic duplication of the X chromosome containing the *SOX3* gene. Amniocentesis was performed at 17 weeks due to an abnormal maternal serum alpha fetoprotein (MS-AFP) consistent with an increased risk of NTD. Amniotic fluid AFP (AF-AFP) was also elevated at 60.46 ug/ml and acetylcholinesterase was detected, also consistent with open NTDs. Although chromosome analysis showed a normal 46,XX karyotype, array comparative genomic hybridization (aCGH) using the 180k CGH+SNP (Agilent Technologies) microarray revealed a 697.4 kb duplication on Xq27.1 between 139.1-139.8 (hg19) that includes *SOX3* and exons 1-3 of the long non-coding RNA, *LINC00632*. This duplication was inherited from an apparently phenotypically normal mother (G2P0), with a history of miscarriage and a family history of open NTDs. Ultrasound performed at 19 weeks of gestation showed bilateral ventriculomegaly and the pregnancy was terminated at 21 weeks. This case report provides additional support that overexpression of *SOX3* due to gene duplication may be a risk factor for NTDs and possibly additional brain malformations.

3198T

Phenotype/genotype effect of 14q32.3 terminal deletion and 9p duplication. *S.Ghareeb. Abd Allah, M.O. El Ruby, S.A. Hammad, A.K. Kamel, A.M. Mohamed.* Human Cytogenetics, National Research Centre, Cairo, Egypt.

Molecular cytogenetic studies with thorough clinical evaluation are needed for proper genotype phenotype correlation in specific chromosome deletion and duplication. We reported on a female patient aged 7 years , she had severe intellectual disability (ID), developmental delay, epilepsy. She had characteristic facies with high arched eye brows, epicanthic folds, hypertelorism, broad nasal bridge, broad nose, low set protruded ears, short hands, clinodactyly of little fingers, right semian cease , broad big toe, dysplastic nails, wide spaced hypo pigmented nipples, umbilical hernia, mild hypotonia, normal Echo, normal pelvi-abdominal ultrasound, EEG revealed right central epileptogenic activity. Cytogenetic study on periphersl blood lymphocytes revealed add(14)(q). Whole chromosome paint for chromosome 14 indicated that the add material to 14q was not originated from chromosome 14.Using total subtelomere probes we found deletion of chromosome 14q subtelomere and duplication of chromosome 9p , using locus specific probes 9p21 revealed duplication 9p. Both parents had normal karyotype. This de novo deletion/duplication occurred as a result of unbalanced translocation. All the clinical findings are typical of 14q32 deletion syndromes. Also there is an overlapping and similarity between 14q deletion syndrome and 9p trisomy syndrome like ID, developmental delay, the depressed nasal bridge, epicanthal folds, semian crease and wide spaced nipples. All manifestations of 14q32 deletion syndrome related to critical small region in 14q32 and also the same of the clinical manifestations of 9p trisomy dependent on the duplication of 9p22. The combined effect of these two chromosomal abnormalities may be the cause of the severe ID.

3199T

Two new cases of chromosome 7p22.1 microduplication detected by array CGH. *R.G. Hutchinson[1], J. Nicholl[1], L. Montgomery[1], C. Barnett[2], K. Boundy[3], S. Yu[1].* 1) Cytogenetics, SA Pathology, Adelaide, South Australia, Australia; 2) Clinical Genetics, SA Pathology at WCH, King William Rd, North Adelaide; 3) Neurology Department, TQEH, Woodville.

Array CGH has enhanced our ability to detect rare microduplications previously too small to be observed cytogenetically. Cytogenetically detectable aberrations are necessarily large and the clinical features associated with them have been variable. The use of microarray technology has enabled the phenotypic features more generally associated with duplication of a chromosomal region to be assigned to smaller chromosomal areas and even specific genes. Microarray also detects abnormalities where the pathogenicity of the change may be unclear. Interpretation of these rare abnormalities relies on the cooperation of institutions involved in genetic diagnosis in sharing and comparing cases where the anomaly is similar. Two cases of 7p22.1 microduplication (1.7Mb and 1Mb) detected by array have been reported in the literature. [1,2] We present two patients with 7p22.1 microduplications for comparison with the reported cases. Our cases include a 4Mb (case 1) and a 700kb (case 2) microduplication . The 700kb duplication is almost entirely contained within the 1mb duplication reported by Prelksaitene et.al. (2012) [2], while both published cases are encompassed within the larger duplication. Brief clinical descriptions of our cases are as follows. Case 1. A de novo 4Mb duplication was detected in a 2 1/2 year old girl with global developmental delay particularly language, autistic features, dysmorphic facies and renal pelvis dilatation. Case 2. A 700kb duplication was detected in a 22 year old male reported to have intellectual disability with language delay and dysmorphic features including macrocephaly. Parental studies are in progress to determine if this finding is de novo. . The clinical features common to both reported cases for this duplication include abnormal craniofacial development, developmental delay and skeletal abnormalities. The 7p22.1 region has been suggested as a candidate region for autism [3] with RNF216L highlighted as a candidate gene. This gene has been shown to be strongly expressed in adult and fetal brain. RNF216L was duplicated in both case 1 and 2. Our cases will be compared in more detail with those reported in the literature. 1.Chui J.V. et.al.(2011) Am J Med Genet 155A:2508-2511 2. Prelksaitene et.al (2012) Am J Med Genet 158A:1200-1203 3. Bayou et.al. (2010) J Biomed Biotechnol 2010:423893. doi: 10.1155/2010/423894.

3200T

Partial Microduplication of PTEN in a girl with multiple congenital abnormalities including agenesis corpus callosum. *C.P. Oliveira[1, 2], R.S.H.G Silva[2], R.O.A. Benicio[2], M.T.O. Cardoso[2], S.F Oliveira[3], A. Pic-Taylor[3], J.F. Mazzeu[4].* 1) Programa de Pós Graduação em Ciências Médicas, Faculdade de Medicina, Universidade de Brasilia (UnB), Distrito Federal, Brasil; 2) Núcleo de Genética (NUGEN), Hospital de Apoio (HAB), Secretaria de Saúde, Distrito Federal, Brasil; 3) Departamento de Genética e Morfologia, Instituto de Ciências Biológicas, Universidade de Brasilia (UnB), Distrito Federal, Brasil; 4) Programa de Pós graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasilia (UCB), Distrito Federal, Brasil.

The corpus callosum is the largest commissure connecting the cerebral hemispheres. Agenesis corpus callosum (ACC) is one of the most prevalent brain malformations with an incidence of 0.5-70 in 10,000, and can occur isolated or as part of many syndromes. Although ACC is predominantly genetic, few genes have as yet been identified and chromosome abnormalities have been described in a large number of patients. We report a patient with multiple congenital malformations including agenesis corpus callosum, asymmetrical face, microcephaly, hypertelorism, microphtalmia and short neck. She has two accessory nipples, asymmetric limbs, sacral dimple and a sacral hemangioma. ECG showed interatrial communication. To screen for chromosomal imbalances high-resolution array Genomic Hybridization Assay was performed using the Affymetrix® CytoScan™ HD platform. Analysis revealed a 49 Kb de novo microduplication 10q23.31 (89,629,908-89,679,426 - hg19) including exon 2 of PTEN gene. The phosphatase and tensin homolog (PTEN) gene on chromosome 10 was initially identified as a tumor suppressor gene that is frequently mutated in human cancers. Further studies showed that PTEN plays an important role in brain development involved in cell migration, cell number and cell size regulation. Clinical manifestations of inherited PTEN mutation occur with highly variable penetrance and also include benign hamartomas in multiple tissues, macrocephaly, seizures, ataxia, mental retardation and autism in addition to cancer predisposition. These disorders add to the already well-established role of PTEN mutations in causing the PTEN hamartoma tumor syndromes which include Cowden, Bannayan-Riley-Ruvalcaba, Lhermitte Duclos, and Proteus Syndromes. The patient here reported shows a complex phenotype that does not correspond to any of the syndromes listed above and includes ACC. Thickening of corpus callosum have been reported in patients with Bannayan-Riley-Ruvalcaba syndrome. Our report describes the first de novo PTEN microduplication in a patient with ACC. This finding suggests that PTEN may warrant further consideration as an ACC candidate gene. Financial support: UnB, CNPq, FAPDF.

3201T

Is it time to retire the standard 15colonies/20 cell chromosome analysis if chromosome microarray analysis (CMA) is concurrently ordered in prenatal testing? *A. Patel, J. Smith, A. Breman, P.A. Ward, S. Peacock, T. Vaughn, P. Hixson, W. Bi, C. Bacino, S.W. Cheung.* Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX.

The present standard of care for prenatal cytogenetic testing is AneuVysion FISH and a complete chromosome analysis. We present our experience with concurrently ordered CMA and a limited chromosome analysis of 5 cells. A total of 353 prenatal samples (amniotic fluid, CVS, cultured cells) submitted between 3/2012 and 3/2014 were analyzed on a custom-designed 180K or a 400K oligonucleotide array manufactured by Agilent Technologies and a 5 cell chromosome analysis performed. Of those 353 CMA/limited chromosome analyses, 90 (25%) showed a copy number variation (CNV) by CMA: 21 (6%) cases showed CNVs >10Mb that were consistent with chromosome analysis, 35 (10%) cases had a smaller familial CNV, 15 (4%) cases showed a CNV in an autosomal recessive locus, three cases (0.8%) showed regions of absence of heterozygosity suggesting consanguinity, and in 9 (2.5%) cases a copy number variant of unknown significance (VOUS) was identified. A VOUS is defined as a CNV < 5Mb in a non syndromic region with multiple genes, and either inherited or one or both parents were not available. Three cases showed a CNV in regions that are associated with variable expressivity (16p11.2, 16p13.11 and 15q11.2 - BP1-BP2). The losses in 16p11.2 and 16p13.11 were de novo, and the loss in BP1-BP-2 was paternally inherited. In addition 4 cases (1%) with normal cytogenetics showed CNVs <10Mb in clinically significant regions and were classified as abnormal: 16p11.2 deletion (2 cases), 14qter deletion and duplication of 22q11.2 (22q11.2 duplication syndrome). Two cases of balanced translocations were detected by chromosome analysis which could not be detected by CMA. Also, cytogenetics detected three cases with an abnormal colony or cell in the first 5 cells; when counts were extended, it was determined that the abnormality was pseudomosaic and of unlikely clinical significance. In this cohort, the CMA/limited chromosome analysis provided a comprehensive cytogenetic diagnosis with no apparent decrease in sensitivity compared to a full chromosome analysis. In the two cases with balanced rearrangements, the 5-cell analysis was sufficient for interpretation. Our data shows that CMA should be the first line test for prenatal cytogenetic testing with limited chromosome analysis (5 cells) as an adjunct to identify balanced rearrangements and distinguish between translocation and trisomy Down/Patau syndromes and to confirm mosaicism.

3202T

Pigmentary mosaicism with 45,X and an extra marker containing the Xp11.22-p11.23 region. *P. Pérez-Vera[1], V. Ulloa-Avilés[1], E. Lieberman-Hernández[1], C. Durán McKinster[2], S. Gómez Carmona[1], R. Cruz-Alcívar[1], M.P. Navarrete-Meneses[1], A. Reyes-León[1], V. Del Castillo-Ruíz[1], C. Salas-Labadía[1].* 1) Genética Humana, Instituto Nacional de Pediatría, Mexico, Distrito Federal, Mexico; 2) Dermatología, Instituto Nacional de Pediatría, Mexico, Distrito Federal, Mexico.

Pigmentary mosaicism is characterized by hypo and/or hyperpigmented macules following Blaschko lines. These lesions are strongly associated with the chromosomal mosaicism. We have studied a cohort of 52 patients under these clinical criteria. We present a patient with 2 abnormal cell lines, one with 45,X and the other with a small supernumerary marker chromosome. The proband is a 2 year and 7 months old female, first child of healthy non-consanguineous parents. She has psychomotor delay and suffers from epileptic seizures. Height is 88 cm (PC<25), weight 12.6 kg (PC>50), and head circumference 58.8 cm (PC 95). She has macrocrania, high hair implantation, prominent forehead, hypertelorism, telecanthus, left dacryostenosis, nasal bridge with broad root, bulbous nose and anteverted nares. She presents hyperpigmented lineal macules in arms and legs following Blaschko lines, and a dorsal inverted V macule. Cytogenetic analysis with GTG bands in lymphocytes revealed mos 47,XX,+mar[28]/45,X[6]/46,XX[16]. In fibroblasts from both types of skin, two cell lines were detected; light skin: mos 45,X[35]/47,XX,+mar[2]/46,XX[6], dark skin: mos 45,X[20]/47,XX,+mar[3]/46,XX[13]. The origin of the marker chromosome was determined by FISH using DXZ1, p11.23-p11.22 (49687273-49865097) and q11.1-q11.2 probes. The marker chromosome comprised Xp11.23-p11.22: ish der(X)(DXZ1+,49687273-49865097+). Based on this result, cytogenetic analysis in lymphocytes from the mother was performed revealing: mos 45,X[2]/47,XXX[1]/46,XX[181]. The partial trisomy observed in our patient resembles to that found in Xp11.22 duplication cases, who have neurological features such as intellectual discapacity and a typical EEG pattern. Our patient shares these characteristics, however, she has other dysmorphic features besides those compatible with her Turner syndrome karyotype. The mosaic condition and the unidentified regions including in the extra chromosome could influence the phenotype. SNPs array analysis must be performed to complete the genotype-phenotype correlation. Acknowledgements: CONACYT Salud-2012-01-182277.

The identification of ring 13 chromosome and breakpoint region at a Brazilian child requires karyotype, FISH and microarray analysis. *I.P. Pinto[1,2], L.B. Minasi[1,2], A.V. Melo[2,3], J.G. Almeida[1,2], D.M.C. Cunha[1,2], C.L. Ribeiro[2], G.P. Silva[2], M.G Brasil[4], D.M. e Silva[1,2,5], C.C. da Silva[1,2,3,6], A.D. da Cruz[1,2,3,6].* 1) Pontifical Catholic University of Goias, Genetics Master's Program; 2) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program; 4) Clinical Hospital of Federal University of Goias; 5) Federal University of Goias, Genetics and Molecular Biology Master's and PhD Programs; 6) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health.

Deletions of chromosome regions are generally the result of double strand chromosome breaks with loss of produced acentric fragments during the next cell division, and could lead to ring chromosome. Patients with r(13) presented different phenotypic abnormalities according to different breakpoints. Here, we report the first postnatal diagnosis in Central Brazil of a girl with cytogenetic abnormalities involving chromosome 13 using 3 different laboratory methodologies. At the age of 8 months, she presented low tubular renal function in both kidneys, craniofacial dysmorphisms, hypotelorism, bilateral microphthalmia, deep set eyes with reduction and change in shape of the eyeballs, atrophy of the optic nerves and chiasm, and epicanthal folds. Magnetic Nuclear Resonance (MNR) revealed decreased cervical and axial tonus, reduced fontanelle, lack of visualization of the septum pellucidum with persistent of the cavum septum pellucidum and cavum Vergae, atrophic hippocampus, absence of falx cerebri, partial fusion of the thalami with an appearance suggestive of holoprosencephaly. She also had hands with elongated fingers and disproportionate in size, and heart problems. At the age of 6 years, physical examination of the proband reveled severe delayed psychomotor development and intellectual disability. Cytogenetics analysis revealed a constitutive 46,XX,r(13)[77]/45,XX,-13[17]/46,XX,idic r(13)[6]. FISH analyses also showed the absence of 13qter and the presence of 13q14.3 in the cells with ring chromosome 13, and it was also observed the presence of an isodicentric chromosome. Chromosome Microarray Analysis (CMA) with Affymetrix CytoScan™ HD Array detected a *de novo* 15.39Mb deletions at 13q32.3-q34. This deletion involved 44 morbid genes from OMIM. Both monosomy and isodicentric were confirmed with FISH, which was also useful to determine the deletion of the terminal end of the long arm of chromosome 13 in the ring formation. However, banding karyotyping and FISH were not able to precisely define the breakpoint of the terminal deletion. It was evident that the ring chromosome led to a partial deletion of the long arm of chromosome 13. Haploinsufficiency of the genes within the deleted region is the most probable cause of the proband phenotype. Thus, based on probe density, high-resolution CMA made it possible to refine the breakpoint region for the affected chromosome 13 and also it was useful to determine the gene content within the deleted region.

3204T

Proximal 3p deletions: phenotypic characterization and molecular delineation. *I. Song[1], D.H. Lee[1], H.W. Yoo[2], J.O. Lee[3], E.J. Seo[1].* 1) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 2) Department of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 3) Asan Institute for Life Sciences, Seoul, Korea.

Proximal interstitial deletion of chromosome 3p is a rare intrachromosomal rearrangement known to cause neurodevelopmental delay and intellectual disability, and associated with various clinical manifestation such as autistic features, Waardenburg syndrome type 2, Larsen syndrome and Zimmermann-Laband syndrome. Recently, widespread implementation of chromosomal microarray in diagnostic testing has brought great advances in identifying genomic disorders and studies about microdeletion of relevant genes are being made to delineate genetic basis of spectrum of clinical manifestation. We report two cases of an interstitial deletion of proximal 3p that have been characterized by high-resolution array CGH. Both patients presented abnormal auditory brainstem response or ear canal obstruction, and heart anomalies like secundum atrial septal defect and patent ductus arteriosus. The first patient had a 16 Mb deletion at 3p14.1-p12.1. He had small mouth, epiblepharon, high arched palate and genital malformations: small scrotum and bilateral cryptorchidism. At 21 months of age he couldn't stand or walk alone and could only just babble. His brain magnetic resonance scan showed vermian hypoplasia and enlarged retrocerebellar CSF space. The second patient had a 4 Mb deletion at 3p14.1-p13. She was noted to have heterochromia iridis, strabismus, ulnar deviation of wrist and digit anomaly with overlapping fingers. There was no family history of congenital anomalies or intellectual disability. The genomic characterization and clinical findings in these patients were compared to those in public databases and the medical literature: OMIM, DECIPHER, ISCA, and recently published reports. Within the deleted region, FOXP1 and MITF genes are known to involve in nerve cell regulation and neurodevelopment, and PROK2 known for its mutation causing Kallmann syndrome, is associated with cryptorchidism. This study suggests that proximal 3p deletions show no common breakpoint or deletion size and haploinsufficiencies of those genes play a major role in these clinical phenotype.

A novel familial gain of 3q25.2-3q25.31 involving OMIM genes SLC33A1, GMPS, and MME. *K. Swisshelm[1], M. Haag[1], D. Hennerich[1], P. Brzeskiewicz[1], B. Lunt[1], K. Ha[1], J. LeRoux[1], G. Bellus[1,2], T. Schreiner[1,2].* 1) University of Colorado Denver, Denver, CO; 2) Children's Hospital of Colorado, Aurora, CO.

Four siblings, exhibiting various phenotypes, were studied for chromosomal deletions and duplications by chromosomal microarray (CMA), using a 180K oligo platform. The first sib, a 7-year-old male, showed phenotypes of developmental delays, dysmorphic facial features consistent with fetal alcohol syndrome (FAS), mild intellectual disability, and low muscle tone. The second sib, a 6-year-old female, showed dysmorphic facial features not consistent with FAS. The third sib, a 4-year-old male, exhibited a phenotype similar to sib 1, and the fourth, a 3-year-old male, exhibited autism, seizure disorder, and an abnormal EEG in addition to dysmorphic facial features consistent with FAS. The female sibling (sib 2) had a normal CMA result. However, the three male sibs' genomic DNA all showed a gain of 1.1 - 1.5 Mb in 3q25.2-3q25.31, which contained three OMIM disease genes: SLC33A1 (associated with autosomal recessive congenital cataracts, hearing loss, and neurodegeneration), GMPS (associated with a case of somatic acute myeloid leukemia), and a partial overlap with MME (associated with antenatal membranous glomerulonephritis). Sibling 4 also showed a partial duplication of KCNAB1 (potassium voltage-gated channel, shaker-related subfamily, beta). This latter gain may contribute to the patient's seizure disorder. This particular duplication has not been reported in the literature, although a smaller de novo duplication has been reported in DECIPHER, detected in a patient with intellectual disability and tics. To date there has been no parental follow-up testing and the clinical significance of this familial copy number gain is uncertain.

3206T

Position effects modify gene expression in a ring chromosome 14? *R.S. Guilherme[1], A.G. Dantas[1], M.M Oliveira[1], V.A. Meloni[1], D. Brunoni[1], A.T. Paes[2], L.D. Kulikowski[3], M.I. Melaragno[1].* 1) Morphology and Genetics, UNIFESP, Rua Botucatu 740, CEP: 04023-900, São Paulo, Brazil; 2) Setor de Estatística Aplicada, UNIFESP, Rua Diogo de Faria, 1087, CEP: 04023-900, São Paulo, Brazil; 3) Department of Pathology, Laboratório de Citogenômica, Universidade de São Paulo, Avenida Dr. Enéas Carvalho de Aguiar 647, CEP: 05403-000, São Paulo, Brazil.

Ring chromosomes (r) usually originate from breakage in their short and long arms followed by fusion of the broken ends resulting in genetic material loss. The most important factor affecting the phenotype of patients with rings is the chromosome involved in the rearrangement and the extension of the deleted region. We present a patient with an apparently complete r(14) characterized by G-banding, genomic array, FISH (Fluorescent in situ Hybridization) and MLPA (Multiplex ligation-dependent probe amplification). Although the r(14) did not have genomic loss, except by the telomere, the patient presents the main characteristics of the syndrome such as seizures, mild intellectual disability, microcephaly, dolichocephaly, downslanting palpebral fissures and bilateral cryptorchidism. Our aim is to verify if the ring configuration affect the expression of genes in two copies in the patient's genome, causing phenotypic alterations. Gene expression of eight genes was assessed using TaqMan assays, in peripheral blood from the patient and seven controls, matched by age and sex. qPCR experiments were run in triplicate and normalized by two endogenous genes (GAPDH and ACTB) using 2-$\Delta\Delta$Ct analysis method. PTGER2, RPS6KA5, RCOR1 and VRK1 genes presented normal level of expression. ARID4A, GPHN, RCOR1 and ACTN1 genes were significantly downregulated in the patient compared to controls. The website GeneMania (www.genemania.org) used to verify gene interaction network showed that, except for GPHN gene, all the other genes studied are co-expressed. We propose that these downregulated genes may affect the expression of other genes explaining the patient's phenotype. One mechanism proposed to explain ring syndrome phenotype is telomere effect position caused by the ring formation that changes the chromatin architecture and consequently the gene expression. The juxtaposition of the DNA from p-arm inactive, centromere and subtelomeric region close to the q-arm active euchromatin could have silenced the RCOR1 gene and others in 14q32 due to inactivation spreading. However, the other downregulated genes (ARID4A, GPHN and ACTN1) may have been silenced by other mechanisms as the repositioning of the ring chromosome in the nucleus that could change cis and/or trans interactions. Thus, the chromatin architecture needs to be taken into account in the evaluation of the genetic consequences of complete rings with clinical phenotype. (Financial support, FAPESP, Brazil).

Partial trisomy 17q and partial monosomy 20q in a boy with craniosynostosis. *F.A. Marques[1], R.S. Heredia[2], C.P. de Oliveira[2,3], M.T.O. Cardoso[2], J.F. Mazzeu[1,3], R. Pogue[1].* 1) Programa de Pós-Graduação em Ciências Genômicas e Biotecnologia, Universidade Católica de Brasília, SGAN 916, Asa Norte, Brasília, 70790-160-DF, Brazil; 2) Núcleo de Genética da Secretária de Saúde do Distrito Federal, Hospital de Apoio, SAIN Qd4, 70071-125-DF, Brazil; 3) Programa de Pós-Graduação em Ciências Médicas, Universidade de Brasília, Campus Darcy Ribeiro, Caixa Postal 4569, 70910-900, Brasília-DF, Brazil.

Craniosynostosis is defined as a premature fusion of at least one cranial suture, which can be accompanied by other phenotypes. Of syndromic cases, 14-22% have been associated with chromosomal rearrangements. This report describes a Brazilian boy with syndromic craniosynostosis who also presented with mental retardation, microcephaly, frontal bossing, bitemporal narrowing, short neck, syndactyly and cardiac defects. Chromosome banding showed an apparently normal male karyotype. Subsequent chromosomal microarray analysis (CMA) usingAffymetrix CytoScan 750K Array showed a duplication of 2.1 Mb on chromosome 17q and a deletion of 1.4 Mb on chromosome 20q. The data suggested an unbalanced translocation, which was confirmed by Fluorescence in situ hybridization analysis (FISH). While there are several reports in the literature of chromosome 17q duplication syndrome accompanied by partial monosomies of other chromosomes, this is the first case featuring partial monosomy of 20q. The patient's phenotype is generally consistent with 17q duplication syndrome, however the craniosynostosis has rarely been associated with this chromosomal anomaly. Thus, CMA provides a sensitive, rapid and powerful technology for a ''genotype-first'' approach in conditions such as craniosynostosis that are difficult to associated with a specific genetic defect based on clinical features alone.

3208T

Meiotic I error in a Thai girl with tetrasomy 9p syndrome identified by SNP microarray. *C. Charalsawadi[1], S. Jaruratanasirikul[2], J. Wirojanan[2], V. Praphanphoj[3], S. Puangpech[1], K. Jarauthamsophon[1], P. Limprasert[1].* 1) Department of Pathology, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand; 2) Department of Pediatrics, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand; 3) Rajanukul Institute, Bangkok, Thailand.

Tetrasomy 9p is a rare chromosomal disorder caused by the presence of an extra isochromosome consisting of the short arm of chromosome 9. The syndrome has a wide variation of phenotypic features, ranging from stillborn babies with multiple malformations to normal healthy adults. We report the case of a 4 year-old Thai girl with mild developmental delay and no major physical malformations. The girl also presented with pilomatricoma on the abdominal wall and skin pigmentary abnormalities. G-banding karyotyping of cultured lymphocytes revealed 47,XX,+mar in all analyzed cells. The Illumina HumanCytoSNP-12 v2.1 array was carried out on uncultured peripheral blood DNA and revealed an elevated logR ratio and an altered pattern of B allele frequency, consistent with tetrasomy of the short arm of chromosome 9. A FISH assay using probes specific to chromosome 9p and 9q subtelomeres confirmed the presence of 4 copies of chromosome 9p and 2 copies of chromosome 9q. Her karyotype was designated 47,XX, +idic(9)(q12).arr[hg19] 9p24.3p12 (46,587-42,374,011)x4 dn. G-banding karyotyping of tissues from hypopigmented skin, normal skin and the pilomatricoma revealed 28.5%, 5%, and none of the aberrant chromosome, respectively. Tissue-limited mosaicism may explain mild developmental delay in the patient and the pilomatricoma presented in this case was likely unrelated to the syndrome. Haplotype information obtained from a SNP microarray revealed meiosis I nondisjunction which determines the meiotic origin of tetrasomy 9p. The rearrangement thereafter which leading to duplication of the short arm and loss of the long arm of chromosome 9 was probably a mechanism of the isochromosome formation. Subsequent postzygotic tetrasomy rescue in certain tissues was a possible cause of tissue-limited mosaicism in our patient. To the best of our knowledge, we are the first to speculate a mechanism insight into a supernumerary isochromosome 9p formation using an extensive collection of SNP markers.

3209T

A case of probable constitutional trisomy 3 mosaicism. *M. Kekis[1], S. Hashimoto[1,4], A. McKinney[1], C. Deeg[1], C. Shuss[2], S. Hickey[2,4], C. Astbury[1,3].* 1) Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital, Columbus, OH; 2) Division of Molecular and Human Genetics, Nationwide Children's Hospital, Columbus, OH; 3) Department of Pathology, The Ohio State University College of Medicine, Columbus, OH; 4) Department of Pediatrics, The Ohio State University College of Medicine, Columbus, OH.

Constitutional mosaicism for trisomy 3 is extremely rare, with only a few postnatally diagnosed cases reported in the literature. We report a case of probable constitutional trisomy 3 mosaicism in a 16-year-old female, who presented with chronic joint pain, easy bruising, joint hypermobility and dysmorphic features (long, thin facies, over-folded dysplastic ears, micrognathia, and cleft palate). Microarray analysis with the Agilent GGXChip+SNP revealed a gain of an entire chromosome 3. FISH analysis with the centromere probe for chromosome 3 demonstrated the presence of an extra chromosome 3 in 5.4% (3/55) of the metaphase cells and 22.5% (9/40) of the interphase cells analyzed. Additional FISH analysis with the centromere probe was performed on buccal swab cells, which revealed the presence of the supernumerary chromosome 3 in 22% of the interphase cells counted. Clinical features previously reported in patients with trisomy 3 mosaicism include variable survival ranging from neonatal deaths to survival in adulthood, variable cognitive phenotype, intrauterine growth retardation, short stature, dysmorphic facies, cleft lip/palate, cardiac defects, hip dislocations, eye and/or ear abnormalities, macro/microcephaly, abnormal digits, spina bifida, scoliosis, gouty arthritis. Our patient was small at birth (5 lbs 6 oz at 38 weeks), had cleft palate repair, developed chronic joint pain at age 12, and has a history of mild leukopenia, mild thrombocytopenia, and Hashimoto's thyroiditis. She repeated the first grade and required speech therapy but currently attends a mainstream high school classroom. It is predicted that the clinical course of an individual with trisomy 3 depends on the proportion of cells with the supernumerary chromosome 3 and the tissue type where the aneuploidy exists. In our patient, both peripheral blood and buccal cells demonstrated mosaicism for trisomy 3. Although trisomy 3 has been seen as a somatic cytogenetic abnormality in lymphoma and renal cell carcinoma, these neoplasias have not been reported in previously reported patients with germline mosaicism for trisomy 3. Since it is not known whether germline mosaicism for trisomy 3 may increase the risk for neoplasia, a Hematology/Oncology consultation in addition to genetic counseling was provided for our patient. The oncologist's laboratory evaluation for malignancy was unremarkable. A bone marrow aspirate was not performed.

3210T

A de novo microduplication at 7q11.23 from Central Brazil detected by Chromosomal Microarray Analysis. *L.B. Minasi[1,2], I.P. Pinto[1,2], A.V. Melo[2,3], D.M.C. Cunha[1,2], C.L. Ribeiro[2], C.C. da Silva[1,2,3,5], D.M. e Silva[2,4], A.D. da Cruz[1,2,3,5].* 1) Pontifical Catholic University of Goias, Genetics Master's Program; 2) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program; 4) Federal University of Goias, Genetics and Molecular Biology Master's and PhD Programs; 5) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health.

The Chromosome 7q11.23 Duplication Syndrome (MIM 609757) is a genomic disorder caused by the duplication of a common 1.5 Mb segment spanning 26 genes. This region is also associated with the Williams-Beuren Syndrome (WBS [MIM 194050]), and duplications of the WBS region should occur at the same frequency as deletions based on an interchromosomal nonallelic homologous recombination mechanism. The duplication at 7q11.23 shows variable clinical manifestations most common being speech delay, mild craniofacial anomalies, and neurocognitive and behavioral impairment, specifically, intellectual disability. Herein, we report a first case of 16 years old boy who presented moderate intellectual disability, mild facial dysmorphisms with broad forehead, high- broad nose, short philtrum, straight eyebrows, and speech delay with a *de novo* 7q11.23 microduplication in Central Brazil. Chromosomal analysis by GTG banding using the software IKAROS® (Metasystems Corporation, Germany) showed 46,XY and Chromosomal Microarray Analysis (CMA) with Affymetrix's CytoScan™ HD SNP array revealed a *de novo* 1.43 Mb microduplication at 7q11.23, encompassing 1,540 markers, and spanning over described 28 genes (*NSUN5, TRIM50, FKBP6, FZD9, BAZ1B, BCL7B, TBL2, MLXIPL, VPS37D, DNAJC30, WBSCR22, STX1A, MIR4284, ABHD11-AS1, ABHD11, CLDN3, CLDN4, WBSCR27, WBSCR28, ELN, LIMK1, EIF4H, MIR590, LAT2, RFC2, CLIP2, GTF2IRD1, GTF2I*). The progenitor's CMA confirmed *de novo* genomic imbalances in their child. Some genes included in that genomic region have been shown to be implicated in Williams Beuren Syndrome. However, deletion or duplication in that region produces different degrees of impairment with variable phenotypes. In addition, strategically CMA has proving to be a powerful tool to carry out genetic diagnostic and it is especially useful to investigate children with developmental and neurobehavioral delays, reducing the time to reach a clinically relevant diagnoses in which genetic rearrangement display an important etiological role such as the genetic evidence found for our proband. Although, CMA will not replace classical karyotyping, it is an efficient method to delineate phenotypic variations and to guide medical diagnosis.

3211T

The 9p trisomy due to maternal t(9;22) in four patients suggesting a palindorm mediated mechanism involving chromosome 9q12. *A. Mohamed[1], A.K. Kamel[1], M.S. Zaki[2], M. Mekkawy[1], N.M. Meguid[3], S.G. Abdallah[1], S.A. Temtamy[2].* 1) Human cytogenetics, National Research Centre, Cairo, Egypt; 2) clinical genetics; 3) research on children with special needs.

We reported on four patients with trisomy 9p resulting from maternal balanced translocation t(9;22)(q12,q11.2).The 1st patient aged 4year, she had severe intellectual disability (ID), delayed milestones, dysmorphic features and congenital heart . Her karyotype was 46,XX,der(22). FISH using WCP9 and 22, subtelomere 22, CATCH, and 9p21 revealed that the patient has trisomy 9p due to the balanced translocation in her mother. Patient two aged 9 months had ID, developmental delay, hypotonia, brachycephaly, hypertelorism. The cytogenetic revealed balanced translocation in the mother, the proband had a derivative 22. FISH showed the presence of 9p duplication. Patients 3 and 4 were brothers , they had ID, MCA. Their mother had 46,XX,der(22),der(22). Both patients had 47,XY,der(22),+marker. FISH indicated that the mother had involvement of both chromosomes 22 in double translocation to 9p and 9q.The balanced translocation in the mother produce trisomy 9p in her sons. In the 4 patients the break points were at 22q11.2 and 9q12. Chromosome 22q11.2 is one of the best studied example of palindromic AT-rich repeat (PATRR) which induced recurrent constitutional translocation. This is the first time to record non random occurrence of translocation involved 22q11.2 and 9q12. We suggest the presence of palindromic sequence at 9q12. The repeated nonrandom balanced translocation between 22q11.2 and 9q12 depends on the same mechanism of Emanuel syndrome and resulted in trisomy 9p.Further investigations of those patients and other similar finding may lead to diagnose a new syndrome or new subtype of trisomy 9p due to the palindromic region at 9p12.

3212T

An Investigation of Pediatricians' Use of Microarray. *N.A. Watkins[1,2], J. Carroll[3,4], D. Chitayat[1,2,5], S. Khattak[6], J. Starvopoulos[7,8], C. Shuman[1,2].* 1) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Genetic Counselling Program, Department of Molecular Genetics, University of Toronto; 3) Dept. of Family & Community Medicine Mount Sinai Hospital, Toronto; 4) Department of Family and Community Medicine, University of Toronto; 5) Prenatal Diagnosis and Medical Genetics, The Hospital for Sick Children, Toronto; 6) Kids Clinic, Whitby ON; 7) Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto; 8) Cytogenetics, The Hospital for Sick Children, Toronto.

Objective: Chromosomal microarray (CMA) is used to detect microdeletions and microduplications throughout the genome. Both the Canadian and American Colleges of Medical Genetics recommend CMA as a first tier test for patients with developmental delay, multiple congenital anomalies, and autism. It is unclear how pediatricians are using CMAs and how comfortable they are incorporating this testing into their practices. Our objective was to determine pediatricians' use of and comfort with CMA. **Methods:** A self-complete questionnaire was mailed, with a reminder mailing, to all pediatricians listed on the website of The College of Physicians and Surgeons of Ontario in spring 2014. Descriptive results are reported. **Results:** Response rate was 23% (324/1419), 55% female, mean age 50. 68% of pediatricians reported they had ever ordered CMA with 25% ordering > 10 this past year. 52% reported increased use of CMA from the previous year. Commonest indications for ordering were: developmental delay (84%), intellectual disability (72%), dysmorphic features (92%), multiple congenital anomalies (89%). Of respondents currently using CMA, 10% reported above average knowledge and 62% reported average knowledge of CMA. Most pediatricians (82%) reported having an average or above average comfort level with ordering CMAs for their patients. When disclosing CMA results, respondents were least comfortable reporting a variant of unknown significance with 42% reporting below average comfort level. Barriers to ordering CMAs included: lack of sufficient genetic knowledge (23%), lack of clear clinical guidelines (20%), and questioning the benefit that the CMA will have for the patient (11%). 23% reported no barriers to ordering CMAs. Barriers to disclosing CMA results included lack of sufficient genetic knowledge (33%) and lack of clear clinical guidelines (14%). 27% listed no barriers to disclosing results. **Conclusions:** Our results suggest that many Ontario pediatricians have not ordered CMA testing. Those who are ordering CMAs are generally comfortable with ordering the tests and disclosing results, especially benign and pathogenic variants however pediatricians report barriers affect their utilization of CMAs. We recommend addressing these barriers with educational strategies to increase pediatricians' usage and comfort level with CMAs specifically focusing on lack of genetic knowledge, awareness of clinical guidelines and disclosure of variants of unknown significance.

3213T

Clinical and molecular cytogenetic characterisation of Williams syndrome. *B. Kar[1], S. Sivamani[1], G. Kalpana[2], K. Sivakumar[2].* 1) Center for Genetic Studies & Research; 2) Institute of Cardiovascular Diseases, The Madras Medical Mission, Chennai - 600037, Tamilnadu, India.

Williams syndrome (OMIM 194050) is a rare multisystem genetic disorder with an incidence of 1/75000 which usually occurs sporadically caused by the deletion of 26 contiguous genes, including elastin (*ELN*) (OMIM 130160) on chromosome 7q11.23. The Williams syndrome phenotype is characterized by facial dysmorphisms, cardiac abnormalities, behaviour characteristics, intellectual disability, elastin arteriopathy, short stature, connective tissue abnormalities, infantile hypercalcemia, and a unique personality and cognitive profile. We present here three cases of Williams syndrome who were referred to paediatric cardiologist because of a systolic murmur in upper sternal border. Case 1 aged 1 year had neonatal coarctation and arch hypoplasia with diffuse narrowing of ascending aorta. She underwent surgical correction of coarctation followed by balloon angioplasty for recoarctation. Her surgical findings were markedly thickened aortic wall. No aortic biopsies were done. Case 2 aged 9 months had mild supravalvar aortic stenosis (SVAS) and is on regular medical follow up. Case 3 aged 2 years was diagnosed to have large ventricular septal defect (VSD), bilateral peripheral pulmonary artery stenosis, mild SVAS had surgical fenestrated VSD patch closure, branch pulmonary artery pericardial patch repair with DOTY's repair of SVAS. With a triad of dysmorphic facies, cognitive disorder and characteristic congenital heart defect, a diagnosis of Williams syndrome was made clinically. Karyotyping and fluorescent in situ hybridization (FISH) techniques employing the elastin gene probe were performed. Karyotyping was normal in all the three patients whereas FISH result was positive for 7q11.23 microdeletion confirming Williams syndrome. Parents were screened for microdeletion by FISH and were found normal. In this paper we suggest a defined protocol with more attention while evaluating heart murmur in childhood period, especially when the patient has facial dysmorphisms or developmental delay.

3214T

Target-specific synthetic oligonucleotide libraries for use in Fluorescent In Situ Hybridization. *K.C. Semrau[1], Y.E. Murgha[1], E. Robinson[2], F.A. Ray[2], C. Proudhon[3], B. Hao[3], J. Skok[3,4], E. Gulari[1,5], J-M. Rouillard[1,5].* 1) MYcroarray, Ann Arbor, MI; 2) KromaTiD Inc., Fort Collins, CO; 3) Department of Pathology, New York University School of Medicine, New York, NY; 4) NYU Cancer Institute, New York University, New York, NY; 5) Department of Chemical Engineering, University of Michigan, Ann Arbor, MI.

Human cytogenetic applications rely on detecting the presence, position, and location of specific chromosomal regions within the nucleus as well as chromosomal abnormalities, mainly through the use of Fluorescent In Situ Hybridization (FISH). Conventionally, FISH probes have been generated from PCR amplification of genomic regions or BACs followed by nick translation to incorporate fluorophore(s). These probes are accompanied by limitations associated with the specificity of probes. We have developed a method to produce large quantities of customizable FISH probes from synthetic oligonucleotides that show improved specificity and coverage over traditional genome-derived probes. Here we present an algorithm to design complex probe libraries to target specific regions of the human genome (or any sequenced genome) optimized for reproducible hybridizations. The resulting probe sequences are synthesized on a microarray, cleaved, and linearly amplified by in vitro transcription before being converted to single-stranded labeled probes by reverse transcription. Through this IVT-RT procedure, we have shown improvement in the total yield of labeled probes over previously used methods. Here we present highly-specific detection of genomic regions ranging from a few kilobases to several megabases in size using probe densities ranging from 1 to several probes per kilobase. These libraries have been successfully used for FISH in mammalian, insect, and plant cells as well as for 3-D FISH.

3215T

Mapping breakpoints of a familial chromosome insertion (18:7) (q22.1; q36.2q21.11) to DPP6 and CACNA2D1 genes in an azoospermic male. *W. Fan[1], L. Li[2], H. Chen[3], C. Yin[1], C. Yang[3], B. Wang[1], S. Zheng[2], J. Zhang[2].* 1) Molecular genetics, Hebei University, Baoding, Hebei, China; 2) Institute of Medical Genetics, Linyi People's Hospital, Shandong 276003, China; 3) BGI, 11-2 Building, Northern Industry District, Shenzhen 518083, China.

It is widely accepted that the incidence of chromosomal aberration is 10-15.2% in the azoospermic male; however, the exact genetic damages are currently unknown for more than 40% of azoospermia. To elucidate the causative gene defects, we used the next generation sequencing (NGS) to map the breakpoints of a chromosome insertion from an azoospermic male who carries an balanced, maternally inherited karyotype 46, XY, inv ins (18;7) (q22.1; q36.2q21.11). The analysis revealed that the breakage in chromosome 7 disrupts two genes, dipeptidyl aminopeptidase-like protein 6 (DPP6) and contactin-associated protein-like 2 (CACNA2D1), the former participates in regulation of voltage-gated potassium channels, and the latter is one of the components in voltage-gated calcium channels. The deletion and duplication were not identified equal or beyond 100Kb, but 4 homologous DNA elements were verified proximal to the breakpoints. One of the proband's sisters inherited the same aberrant karyotype and experienced recurrent miscarriages and consecutive fetus death, while in contrast, another sister with a normal karyotype experienced normal labor and gave birth to healthy babies. The insertional translocation is confirmed with FISH and the Y-chromosome microdeletions were excluded by genetic testing. This is the first report describing chromosome insertion inv ins (18; 7) and attributes DPP6 and CACNA2D1 to azoospermia.

3216T

Refining 16p11.2 microdeletion region for Intellectual Disability/Developmental Delay (ID/DD). *P.S. Lai[1], Y. Rong[1], K.M. Eu[1], P.S. Low[1], E.C. Tan[2].* 1) Dept Pediatrics, National Univ Singapore, Singapore, Singapore; 2) KK Research Lab, KK Hospital, Singapore.

Copy number variations on chromosome 16p11.2 have been associated with extensive phenotypic variability and diverse phenotypes such as autism spectrum disorders (ASDs), intellectual and developmental disabilities (ID/DD), schizophrenia, etc. Within this region, a proximal 16q11.2 microdeletion region (≈ 593 kb spanning Chr16: 29.5 to 30.1 Mb) has been commonly associated with developmental delay, autism spectrum disorder, epilepsy and obesity. An atypical and less frequently reported microdeletion region (≈ 220 kb spanning Chr16:28.74 to 28.95 Mb) adjacent and distal to this has been reported in patients with developmental delays, behaviour problems and unusual dysmorphic features. We report a seven-year old child from non-consanguineous marriage, who presented with ID and DD. The child was diagnosed with severe learning impairment and psychomotor developmental delay. No dysmorphic features were observed with the exception of a bifid thumb. Array CGH analysis using the 180K oligo chip (Agilent) identified a de novo 1.8 Mb deletion at 16q11.2 (UCSC HG18, Chr16: 28,285094 - 30,098069). Further qPCR dosage analysis delineated the genomic deletion to a narrower region between 28.39 to 29.7 Mb with the breakpoints spanning EIF3CL gene to ZG16 genes. As this deletion spans the proximal 'typical' 16p11.2 microdeletion syndrome and distal 'atypical' 16p11.2 microdeletion syndrome, genotype-phenotype investigations can aid in delineating the critical regions underlying the clinical phenotypes. Our patient's phenotype most closely corresponds to that of proximal 16p11.2 microdeletion syndrome, with developmental delay as the predominant shared symptom, and without facial dysmorphism that is more closely associated with the distal 16p11.2 microdeletion syndrome. The deletion region in our patient overlaps with the microdeletion regions of both syndromes, harboring 19 annotated protein-coding genes, namely *ATXN2L*, *TUFM*, *SH2B1*, *ATP2A1*, *RABEP2*, *CD19*, *NFATC2IP*, *SPNS1*, *LAT*, *BOLA2*, *BOLA2B*, *SLX1B*, *SLX1A*, *SULT1A3*, *SULT1A4*, *SPN*, *QPRT*, *C16orf54* and *ZG16*. Recent gene dosage studies in animal models suggest that genes with deletion dosage sensor properties may contribute towards abnormal brain development and function leading to developmental and cognitive impairments. The clinical phenotype in our patient could most likely arise from the haploinsufficiency of one or more of the above genes, and contributes towards refining the critical 16p11.2 region underlying ID/DD.

3217T

A Five Year Retrospective Analysis of the Utility of Family Segregation Analysis in the Evaluation of the Clinical Significance of Variants of Uncertain Significance Detected by Chromosomal Microarray: The Greenwood Genetic Center Experience. *F. Bartel, A. Chaubey, B. DuPont.* Cytogenetics, Greenwood Gen Ctr, Greenwood, SC.

Chromosomal microarray (CMA) and massively parallel sequencing (MPS) technologies have been transformative to the practice of laboratory medical genetics over the past decade. These technologies allow the highest resolution interrogation of the entire genome in such a cost-effective manner that these techniques have become widely adopted by laboratories. In cytogenetics laboratories CMA has become a first tier test in the evaluation of nonsyndromal pediatric patients presenting with intellectual disability, autism or multiple congenital anomalies. CMA offers dramatic increases in the ability to detect genomic copy imbalances, but evaluation of the clinical significance of these imbalances presents a challenge for clinical diagnostic laboratories. Family segregation analysis (FSA) is among the best methods available to assist a clinical diagnostic laboratory in the evaluation of variants of uncertain significance (VUS) detected by whole-genome assays such as CMA and MPS. In order to evaluate the utility of FSA in attributing clinical significance to CMA detected VUS, we conducted a 5 year retrospective study of FSA performed for CMA detected VUS across all referral reasons at a single clinical cytogenetics laboratory. In total 2224 reported copy imbalances from 1682 consultands have been evaluated by quantitative PCR (qPCR) based FSA. Ten percent of VUS were found to be de novo in origin, with a 2.125:1 ratio of deletions to duplications. Deletions ranged from 50kb to 23Mb in size, with average and median of 2.4Mb, and 1.4Mb respectively. Duplications ranged in size from 95kb to 17.5Mb with average and median of 2.5Mb and 825kb, respectively. Among inherited cases, a 1.5:1 ratio of maternal to paternal transmission was detected. A clear inheritance pattern was only established for 64% of cases, largely due to the inability to obtain parental samples from one or both parents in 22.4% of cases. Analysis of de novo hot spots, and comparison of FSA results by referral reason will also be presented. Our studies underscore the value added by FSA in the evaluation of VUS, and highlight the inability to obtain relevant family members in a significant number of cases as a significant limitation of this approach.

3218T

Interstitial duplications of 19p13.3. *H. Risheg[1], R. Pasion[2], S. Schwartz[2], E. Prijoles[3], E.A. Keitges[1].* 1) Laboratory Corporation of America/ Dynacare, Department of Cytogenetics, Seattle, WA; 2) Laboratory Corporation of America, Center for Molecular Biology and Pathology, Department of Cytogenetics, Research Triangle Park, NC; 3) Greenwood Genetic Center, Columbia, SC.

Interstitial deletions involving 19p13.3 characterized by microarray analysis have recently been reported in the literature. However, there is little molecular cytogenetic information reported on interstitial copy number gains (i.e. duplications and triplications) of 19p13.3. We present 4 patients with overlapping copy number gains (3 duplications and 1 triplication) of 19p13.3 identified by high resolution SNP microarray analysis. Three of the 4 copy number gains with parental studies performed confirmed a *de novo* origin. Features described in these patients include intellectual disability, microcephaly, motor and speech delay, and short stature. Copy number gain sizes ranged from 0.613 Mb-2.45 Mb and included a common region arr[hg19]19p13.3(2,885,504-3,501,271). The patient phenotypes were compared with 7 additional patients with overlapping interstitial 19p13.3 duplications from DECIPHER and ISCA databases. All 7 patients from both ISCA and Decipher databases were reported as *de novo* 19p13.3 duplications. The common region of overlap of all 11 cases further narrowed the region of overlap to arr[hg19]19p13.3 (3,098,056-3,451,152) and includes 5 OMIM genes (*GNA11, GNA15, S1PR4, CELF5, NFIC*). The most common clinical features reported among all 11 were intellectual disability, microcephaly and short stature. Less common features were intrauterine growth retardation and fine motor and speech delays. Our results combined with those reported in the databases provide support for copy number gains within 19p13.3 as a cause of a constellation of findings, including intellectual disability/ developmental delay, microcephaly and poor growth. Identifying additional patients with imbalances within this region is important to further recognize associated clinical features.

Prenatal Chromosome Rearrangements and Markers: Normal SNP Microarray Analysis Associated with Favorable Pregnancy Outcome. *J.H. Tepperberg[1], R.M. Pasion[1], I. Gadi[1], R.D. Burnside[1], L. Kline[1], B. Williford[1], K. Phillips[2], E. Keitges[2], H. Risheg[1], A. Penton[1], J. Schleede[1], S. Schwartz[1], P. Papenhausen[1].* 1) Laboratory Corporation of America, Research Triangle Park, NC; 2) DynaCare/Laboratory Corporation of America, Seattle WA.

Prenatal microarray is effective in delineating copy number changes not detectable by cytogenetic analysis in and around chromosome rearrangements. The goals of this study were: 1. investigate how many prenatal cases with either G-banded chromosome rearrangement or marker chromosome analyzed by high resolution array were “balanced”, within the resolution of the 2.695,000 SNP/oligo microarray; 2. how many apparently balanced translocations were “balanced” by the array; 3. how many de novo balanced rearrangements had an unbalanced result on array. In order to understand the significance of chromosome rearrangements ascertained at the time of amniocentesis/CVS, we reviewed ~2675 prenatal cases from Oct 2011 to June 2012 by a SNP array. Of those referred for SNP microarray testing, 127 (4.75%) had a translocation, inversion, insertion or marker chromosome. Fifty of 127 G-banded chromosome rearrangments had a simple two-break translocation, 26 had an inversion, 3 had an insertion and 46 had a supernumerary marker. Of the 50 simple translocations, 19 cases (38%) were de novo. Of these, 17 (89.4%) had a normal SNP analysis and apparently normal ultrasound and/or pregnancy outcome. Two (10.5%) cases had copy number findings at the reported breaksite - one significant and one variant of unknown significance (VOUS). Two reported balanced translocations had pathogenic copy number changes identified by array that were presumed to be de novo. Of the 26 inversion cases, 22 (84.6%) had normal microarrays, two were VOUS findings within the inversion breakpoint and another two had secondary abnormal microarray findings unrelated to the inversion breakpoints. Of the 46 cases with supernumerary chromosomes, 16 (34%) were normal by array. In conclusion, the majority of apparently balanced chromosome rearrangements appeared to be balanced following microarray analysis. Including the two pathogenic cases that were presumed to be de novo, 19% (4/21) had a gain or loss at the reported rearrangement breaksite. Of the de novo rearrangements and normal microarray, only 1 of the cases was reported to have fetal anomalies. 34% of prenatal cases with supernumerary chromosome had a normal array result and only three of these had a reported abnormal ultrasound. One of these was UPD. While additional follow-up is pending, this preliminary data suggests that a normal microarray result after abnormal chromosome finding appears to reduce the risk for an abnormal pregnancy outcome.

Fusion transcripts resulting from translocation events in the oncogenic driver genes ALK, RET, ROS1, and NTRK play an important role in lung adenocarcinoma. There is a need to detect these fusion transcripts with up to date technologies as they may serve as viable therapeutic targets. We have utilized a targeted sequencing approach and developed an Ion AmpliSeq™ RNA Lung Fusion panel, a workflow, and an Ion Reporter analysis solution to detect these known fusion events. The panel detects transcripts from 37 ALK, 9 RET, 15 ROS1, and 11 NTRK fusion variants along with 5 housekeeping genes to serve as internal controls. The workflow is FFPE compatible requiring an input of only 10 ng of total RNA with the capacity to multiplex up to 16 libraries on a single Ion 318™ chip. The panel was initially validated using 10ng of total RNA from a cocktail of 3 cell lines containing known lung cancer fusions (H2228 - EML4-ALK variant 3a and 3b, HCC78 - SLC34A2-ROS1 and LC-2/ad - CCDC6-RET). The library was sequenced using the Ion PGM™ system and analyzed with the AmpliSeq™ RNA Lung Fusion workflow in the Ion Reporter. Analysis showed that the positive control sample contained all expected fusions and control genes and reported zero false positives fusions. This multiplexed fusion transcript targeted sequencing solution is currently being validated by all members of the OncoNetwork Consortium who will test lung cancer tissue samples that have been well characterized by FISH, real-time PCR, IHC, and/or massarray. Initial results from OncoNetwork Consortia members reveal 100% concordance between the AmpliSeq™ RNA Lung Fusion panel and FISH in 25 lung tissue samples.

Variation in the Zinc Finger Binding Domain of PRDM9 is Associated with the Absence of Recombination on 21q. *T. Oliver[1], C. Middlebrooks[2], A. Harden[1], B. Johnson[1], C. Wilkerson[1], S. Saffold[1], N. Scott[1], S. Sherman[3].* 1) Department of Biology, Spelman College, Atlanta, GA; 2) Laboratory of Translational Genomics, The National Institutes of Health, Bethesda, Maryland; 3) Department of Human Genetics, Emory University, Atlanta, GA.

Proline Rich Domain Containing 9 (PRDM9) is a major determinant of meiotic recombination. Variation in the zinc finger-binding domain (ZFBD) of PRDM9 is linked to altered placement of recombination in the human genome. As altered recombination (both the absence and altered placement of recombination) is also observed among chromosomes 21 that nondisjoin, we genotyped the PRDM9 ZFBD among mothers of children with trisomy 21 to examine the relationship between variation in the ZFBD of PRDM9 and chromosome 21 nondisjunction. In our approach, PCR was used to amplify the ZFBD of PRDM9 and these PCR products were then subjected to bi-directional Sanger sequencing. In order to identify samples with PRDM9 minor alleles, DNA sequencing reads were aligned and compared to the sequence of the PRDM9 major allele previously identified by Berg et al. 2010. Chi-Square analysis was then used to compare the distribution of major and minor alleles between our cases (N=228, mothers of children with Trisomy 21) and controls (N=94). Among individuals exhibiting no recombination on 21q, the PRDM9 major allele was observed at a significantly lower frequency among our cases (0.63) when compared to that of controls (0.86). This suggests that variation in the PRDM9 ZFBD plays a role in the absence of recombination on chromosome 21 which is a major risk factor for its nondisjunction and trisomy 21.

Importance of cytogenetic and molecular characterization of patients with pigmentary mosaicism. *C. SALAS-LABADÍA[1], R. CRUZ-ALCÍVAR[1], V. ULLOA-AVILÉS[1], A. REYES-LEÓN[1], M.P. NAVARRETE-MENESES[1], S. GÓMEZ-CARMONA[1], C. DURÁN-McKINSTER[1], E. LIEBERMAN-HERNÁNDEZ[1], V. DEL CASTILLO-RUIZ[1], P. PÉREZ-VERA[1], D.E. CERVANTES-BARRAGÁN[1,2].* 1) INSTITUTO NACIONAL DE PEDIATRÍA, MEXICO CITY; 2) Hospital Central Sur de Alta Especialidad, PEMEX MEXICO, CITY.

Pigmentary mosaicism (PM) describes a heterogeneous group of skin anomalies and in association with multisystem involvement (central nervous, musculoskeletal and ocular), could be related with chromosomal abnormalities in 30-60% of PM patients. Many patients often reveal chromosomal mosaicism (>80%) in different proportions and tissues. Microdeletions or point mutations may be present. Therefore, it is very likely that individuals with PM and systemic abnormalities have genetic mosaicism. The aim of this study was: a) To establish a complete cytogenetic and molecular characterization of patients with PM. b) To establish the relationship between chromosomal mosaicism and the presence of PM. It has been suggested that PM should be evaluated to exclude chromosomal mosaicism, especially when follows a Blaschko lines pattern. We have 52 patients with PM and other systemic anomalies that have been analyzed with GTG-bands; we performed karyotype in lymphocytes, light and dark skin samples reviewing 50 metaphases per tissue, in an attempt to exclude low level mosaicism. Molecular analysis with SNP array and FISH were performed in some patients to finely characterize chromosomal abnormalities, and establish if exists an undetected low level mosaicism. Until now, 50 cases have been completely analyzed by cytogenetics, the results could be classified as follows: 1) Mosaics with 2 or more different cell lines and structural alterations n=10; 2) Balanced translocations X;autosomes n=2; 3) Miscellaneous abnormalities n=4; 4) Normal karyotypes, n= 34. In 5/10 patients from group 1, the molecular analysis delineated the structural alteration; in one case, it was able to identify a cell line present in low-level mosaicism (<5%), not detected by cytogenetics. In 1/4 patients of group 4, the molecular analysis became evident a structural alteration not observed by GTG bands. It is well described that chromosome analysis on stimulated cultures may not detect somatic chromosomal mosaic in individuals with PM and the number of metaphases counted may not be sufficient to detect it. Here, we screened a large number of metaphases from three different tissues applying in some cases SNP array/FISH. This plan of analysis could contribute to a better characterization of anomalies in patients with PM. The molecular tools identified cases with chromosomal mosaicism, allowing the delineation of the abnormality, to perform better associations with the phenotype. CONACYT 2012-01-1882277.

Chromosome Therapy: Correction of Large Chromosomal Aberrations by Inducing Ring Chromosomes in Induced Pluripotent Stem Cells (iPSCs). *T. Kim[1], M. Bershteyn[2], A. Wynshaw-Boris[1,2].* 1) Department of Genetics and Genome Sciences, Case Western Reserve University School of Medicine, Cleveland, OH; 2) Institute for Human Genetics and Department of Pediatrics, University of California, San Francisco, CA, 94143.

Approximately 1 in 500 newborns are born with chromosomal abnormalities that include trisomies, translocations, large deletions and duplications. There is currently no therapeutic approach for correcting such chromosomal aberrations in vivo or in vitro. Recently, we attempted to produce induced pluripotent stem cell (iPSC) models from patients that contained ring chromosomes: one with a ring chromosome 17 (r17) and two patients with different ring chromosome 13s (r13). Surprisingly, while all three lines were reprogrammed to iPSCs efficiently, the ring chromosomes were eliminated and replaced by a duplicated normal copy of chromosome 17 in the r17 line and normal copies of chromosome 13 in the r13 lines (Bershteyn et al., 2014, Nature 507:99). This finding suggested a potential therapeutic strategy to correct large-scale chromosomal aberrations. We hypothesized that a chromosome with a large aberration could be corrected by producing a ring chromosome from the aberrant chromosome in iPSCs, which would then be eliminated and replaced by a normal chromosome. We are testing this hypothesis by inducing ring formation in patients with large deletions of chromosome 17 via a Cre/loxP approach. LoxP sites will be inserted by CRISPR/Cas9 mediated gene editing at sites near each end of chromosome 17. Once this is accomplished, we will infect these cells with Cre recombinase to induce the formation of a ring chromosome. To visualize cells that form a ring chromosome, we designed and cloned the partial tandem dimer Tomato (tdTomato) along with these loxP sites such that the cell will express tdTomato upon formation of a ring chromosome due to Cre-mediated recombination. If successful, we will have created a generalized system of “chromosome therapy” for the correction of large chromosomal aberrations by the induction of ring chromosomes through genome editing followed by duplication of the normal chromosome.

Targeted RNA sequencing of breast cancer genes using a genomic capture approach: cBROCA. *S. Casadei[1], S. Gulsuner[1], A.M. Thornton[1], J.B. Mandell[1], M.K. Lee[1], M.C. King[1,2], T. Walsh[1].* 1) Medical Genetics, University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA.

RNA sequencing provides a powerful method for measuring expression of transcripts of interest. We have adapted BROCA, our targeted hybridization and multiplex sequencing approach for genomic DNA, for RNA sequencing. We call this approach cBROCA. The goals of cBROCA analysis are to detect two classes of mutations: those that alter transcript length, as the result of altered splicing, and those that alter relative expression of the allelic forms of a transcript, as the result of possibly cryptic regulatory mutations. As a test of cBROCA, we evaluated RNA from 16 subjects with known mutations in BRCA1, BRCA2, ATM, and PALB2, and from 17 subjects with normal transcripts of these genes. The mutations were conventional and complex changes at splice sites, exonification of intronic sequence, and a small exonic insertion. RNA was obtained from patients' lymphoblast cell lines treated with puromycin to arrest protein synthesis. RNA samples were digested with DNAse-I for removal of genomic DNA. Libraries prepared from double stranded cDNA were captured with biotinylated RNA oligomers targeted to the transcribed regions of 21 genes. Computational analysis of the sequenced libraries was performed using TopHat2 and Cufflinks. Of the 16 samples with known transcript altering mutations, all were correctly identified, and cBROCA results matched those from previous RT-PCR. Splice site changes were identified by sequence reads mapping to novel exon-exon junctions. For each mutation, the number of reads mapped to the novel junction corresponded to the predicted strength of the splice site change. For all complex splice mutations, multiple transcripts were identified, consistent with previous RT-PCR results. Degradation of nonsense-associated transcripts was partially inhibited by puromycin treatment. From all samples with mutations leading to truncations, the nonsense-associated transcripts were detected, proving the efficacy of the puromycin treatment and sensitivity of the targeted sequencing approach. For all samples, sequence reads spanning exon-exon junctions were clear of genomic contamination. In summary, targeted RNA sequencing enabled us to align sequencing reads across splice junctions, to identify and characterize both constitutive and alternate transcripts, and to measure different proportions of alternate transcripts. We will next apply cBROCA to genomically characterized samples for which a causal mutation has not been identified.

3225M

The 12p13.33/RAD52 and 13q13.1/BRCA2 loci and genetic susceptibility to squamous cell cancers of upper aerodigestive tract. *M. Delahaye-Sourdeix[1], J. Oliver[1], M.N. Timofeeva[2,3], V. Gaborieau[2], M. Johansson[2], A. Chabrier[1], M.B. Wozniak[2], D. Brenner[2], M.P. Vallée[1], D. Anantharaman[2], G. Byrnes[4], P. Brennan[2], J.D. McKay[1], ARCAGE, CEE, IARC MC oral cancer, Latin America, Polish, ACTREC, Rome&Japan Head&Neck cancer studies.* 1) Genetic Cancer Susceptibility group (GCS), International Agency for Research on Cancer (IARC), Lyon, France; 2) Genetic Epidemiology group (GEP), International Agency for Research on Cancer (IARC), Lyon, France; 3) Colon Cancer Genetics Group, Institute of Genetics and Molecular Medicine, University of Edinburgh and Medical Research Council (MRC) Human Genetics Unit, Edinburgh, UK; 4) Biostatistics group (BST), International Agency for Research on Cancer (IARC), Lyon, France.

Recent meta-analysis of lung cancer GWAS have identified 13q13.1 and 12p13.33 regions, which encompass the BRCA2 and RAD52 genes respectively, as lung cancer susceptibility loci, and particularly lung squamous cell carcinomas (LUSC). Here, we report detailed investigation of two variants rs11571833 and rs10849605, located within the 13q13.1 and 12p13.33 regions respectively, for association with upper aerodigestive tract cancer squamous cell carcinoma (UADT). Using 5,942 UADT cases and 8,086 controls from 9 different studies, we demonstrate that rs11571833, a rare truncating variant in BRCA2 (K3326X), is also associated with risk of UADT (OR=2.53, 95% CI: 1.89-3.38, p=3×10-10). Similarly rs10849605, a common intronic variant in RAD52, is associated with UADT (OR=1.09, 95% CI: 1.04-1.15, p=6×10-4). There was little evidence for association between rs11571833 carrier status and the loss of wild type allele of the BRCA2 gene or a cis- expression quantitative trait locus (eQTL) effect in the Cancer Genome Atlas (TCGA) data. However, we identified rs10849605 as a RAD52 cis-eQTL in UADT (p=1×10-3) and LUSC (p=9×10-4), with the UADT/LUSC risk allele correlated with increased RAD52 tumor expression levels. The 12p13.33 locus, encompassing rs10849605/RAD52, was identified as a significant somatic focal copy number amplification in UADT (n=374, q-value=0.075) and LUSC (n=464, q-value=0.007) tumors and correlated with higher RAD52 tumor expression levels (p=6×10-48 and p=3×10-29 in UADT and LUSC, respectively). Within this 12p13.33 region, rs10849605 was a cis-eQTL for RAD52 only, making it the most plausible candidate gene at this locus. These results demonstrate that the 12p13.33/RAD52 and the 13q13.1/BRCA2 loci, linked by their roles in homologous recombination based DNA repair, are associated with genetic susceptibility of the UADT.

3226T

FOXA1 binding sites are predictive of breast cancer risk. *M. Ghoussaini[1], J. Allen[2], J. Simard[3], K. Michailidou[2], P. Soucy[3], J. Carroll[4], D.F. Easton[1,2], Breast Cancer Association Consortium (BCAC).* 1) Department of Oncology, University of Cambridge, Cambridge, UK; 2) Department of Public Health and Primary care, University of Cambridge, Cambridge, UK; 3) Genomics center, Centre Hospitalier Universitaire de Québec Research Center and Laval University, Quebec, Canada; 4) Cancer Research UK, Cambridge Institute. University of Cambridge, Robinson Way, Cambridge, UK.

FoxA1 acts as a transcription factor that is necessary for all estrogen receptor (ER) alpha-DNA interactions. When it attaches to its binding site, FOXA1 triggers the opening of condensed chromatin regions, the recruitment of ER and the activation of downstream genes crucial for cell division and proliferation. Recent fine-mapping of breast cancer susceptibility loci identified causal SNPs that affect FOXA1 binding. We hypothethised that FOXA1 binding sites could act as predictors for breast cancer susceptibility. To test this hypothesis, we analysed ~300,000 FOXA1 binding sites identified in three ER-positive breast cancer cell lines: MCF7, T47D and ZR751, and looked for enrichment of risk associated SNPs within them. We utilised association data for ~200,000 SNPs in more than 40,000 breast cancer cases and 40,000 control of European origin, from 41 studies participating in the Breast Cancer Association Consortium (BCAC). Associations (per-allele ORs and P-values) were generated for ~11.6M SNPs by imputation to the 1000 genomes project reference. SNPs associated with breast cancer at P<10-6 were ~4 fold enriched in FOXA1 sites in T47D and ZR751 cells and ~3.3 fold enriched in MCF7 cells. These data indicate that FOXA1 binding sites are a strong predictor of breast cancer susceptibility loci, consistent with the model that susceptibility to the disease is frequently mediated through differential FOXA1 binding.

3227S

Identification of Large Intergenic Non-coding genes as Candidate Targets for Prostate Cancer risk-SNPs Utilizing a Normal Prostate Tissue eQTL Dataset. *Y. Zhang[1], S. McDonnell[1], A.J. French[2], J. Cheville[2], S. Middha[1], S. Riska[1], S. Baheti[1], Z. Fogarty[1], L. Tillmans[2], M. Larson[1], N. Larson[1], A. Nair[1], D. O'Brien[1], J. Davila[1], L. Wang[3], J.M. Cunningham[2], D. Schaid[1], S.N. Thibodeau[2].* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Department of Pathology and MCW Cancer Center, Medical College of Wisconsin, Milwaukee, WI.

Prostate Cancer (PC) is the most frequently diagnosed solid tumor in men in the U.S. For PC, multiple genome-wide association studies (GWAS) have now been performed yielding a substantial number of well-validated SNPs that are associated with an increased risk. In general, only approximately 7% of disease-associated single nucleotide polymorphisms (SNPs) are located in protein-coding regions of the human genome, while the rest are located in gene regulatory regions or intergenic regions. Additionally, many GWAS have mapped disease-associated SNPs to the vicinity of noncoding regions, specifically long intergenic non-coding RNA (lincRNA) regions. Understanding how these genetic variations control the expression of lincRNAs in a tissue-specific manner is not well understood. In this study, we tested the association of SNP genotypes with expression levels of lincRNAs in 471 normal prostate tissue samples from men with PC using expression quantitative trait loci (eQTL) analysis. Genome-wide genotypes and genome-wide mRNA expression levels were obtained usingthe Illumina Human Omni 2.5M SNP array and RNA sequencing, respectively. We focused our analysis on 123 risk-SNPs previously identified by multiple GWAS studies for PC, as well as all SNPs (including imputed ones) that were in linkage disequilibrium (r2 larger than 0.5) with each risk-SNP. This resulted in 72 risk-intervals. Furthermore, we focused on cis-acting associations only where the lincRNA transcripts were located within a 2Mb region (+/-1Mb) of the risk-SNP interval. Of the 4,682 SNPs identified in the risk-intervals and 411 expressed known lincRNAs (median raw read counts larger than 10) within the cis regions, we identified 269 significant eQTL signals (p value with bonferroni correction less than 7.6e-7) in 11 risk-intervals associated with 16 genes. Of the 11 risk-intervals, 5 were associated with a lincRNA transcript only, whereas 6 were associated with both a lincRNA gene and a protein-coding gene. Our results suggest that lincRNA genes are important candidate targets for PC risk-SNPs, and, as such, may play an important role in PC susceptibility. Mapping of the causative risk-SNPs and their corresponding affected regulatory elements is currently in progress.

3228M

***BRCA1* and *BRCA2* mutational screening in 223 hereditary breast cancer patients in Chile: genotype-phenotype correlations.** *C. Alvarez[1], T. Tapia[1], E. Perez[1], D. Wiener[1], C. Ruiz[2], M. Ríos[3], I. Avendaño[4], C. Rodríguez[5], C. Cortés[5], L. Matamala[5], A. Cruz[4], C. Missarelli[3], M. Camus[2], P. Carvallo[1].* 1) Departamento de Biología Celular y Molecular, Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile; 2) Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile; 3) Hospital Base de Valdivia, Valdivia, Chile; 4) Hospital Barros Luco Trudeau, Santiago, Chile; 5) Hospital Regional de Antofagasta, Antofagasta, Chile.

BRCA1 and *BRCA2* are the only genes described so far which mutations confer a high risk for breast/ovarian cancer. Frequency of families carrying a mutation in these genes varies across populations and in Chile account for almost 20% of all hereditary cases. Usually, patients are selected for *BRCA1* and *BRCA2* genetic screening by defined criteria related to family history of breast and/or ovarian cancer. More recently, other patients with no family history are being screened for these mutations. These patients may present bilateral breast cancer, age of onset for breast cancer before 40 years old, and breast and ovarian cancer in the same woman. Taking all these criteria in consideration we selected 223 Chilean patients for screening of *BRCA1* and *BRCA2* mutations. Screening was performed through Sanger and Next Generation Sequencing. Considering familial cases 34/179 (19%) carried a mutation, 13 in *BRCA1* and 21 in *BRCA2*. Among patients without family history, 6/44 carried a mutation (13.6%) all in *BRCA1*, being those diagnosed before age of 40 or with bilateral breast cancer the most prone to carry a mutation. Those six patients correspond to the 31.6% of *BRCA1* mutation carriers. In contrast, all *BRCA2* mutation carriers had family history. Average age of onset of index patients was 35 years old for *BRCA1* mutation carriers vs 44.4 years old for *BRCA2* mutation carriers. Considering all patients, average age of onset of mutation carriers was 42 years old vs 44 years old in patients without mutation. It has been described that several types of cancer are recurrent in BRCA1 and BRCA2 families. In our group of families, ovarian cancer was more frequent in BRCA1 families (54%) than BRCA2 (29%). Other types of cancer found were prostate and gastric, either in BRCA1 or BRCA2 carrier families. Interestingly uterus/cervix cancer was present in 26% of BRCA1 mutation families, and absent in BRCA2 carrier families. These observations support different and specific cancer susceptibilities among *BRCA1* and *BRCA2* mutation carriers. Acknowledgments to FONDEF ca12i10152 and FONIS sa12i2299.

Identification of new familial breast cancer susceptibility genes: are we there yet? *I. Campbell[1], E. Thompson[1], M. Doyle[1], P. James[2], A. Trainer[2], R. Scott[3], G. Mitchell[2], Lifepool.* 1) Research Div, Peter MacCallum Cancer Ctr, East Melbourne, Australia; 2) Familial Cancer Centre, Peter MacCallum Cancer Ctr, East Melbourne, Australia; 3) Hunter Area Pathology Service, Newcastle, Australia.

The genetic cause of the majority of multiple-case breast cancer families remains unresolved. Next generation sequencing has emerged as an efficient strategy for identifying predisposing mutations in individuals with inherited cancer. We are conducting whole exome sequence analysis of germline DNA from multiple affected relatives from breast cancer families, with the aim of identifying rare protein truncating and non-synonymous variants that are likely to include novel cancer predisposing mutations. Data from more than 200 exomes show that on average each individual carries 30-50 protein truncating mutations and 300-400 rare non-synonymous variants. Heterogeneity among our exome data strongly suggest that numerous moderate penetrance genes remain to be discovered, with each gene individually accounting for only a small fraction of families (~0.5%). This scenario marks validation of candidate breast cancer predisposing genes in large case-control studies as the rate-limiting step in resolving the missing heritability of breast cancer. The aim of this study is to screen genes that are recurrently mutated among our exome data in a larger cohort of cases and controls to assess the prevalence of inactivating mutations that may be associated with breast cancer risk. We are using the Agilent HaloPlex Target Enrichment System to screen the coding regions of 168 genes in 1,000 BRCA1/2 mutation-negative familial breast cancer cases and 1,000 cancer-naive controls. To date, our interim analysis has identified 21 genes which carry an excess of truncating mutations in multiple breast cancer families versus controls. Established breast cancer susceptibility gene PALB2 is the most frequently mutated gene (13/998 cases versus 0/1009 controls), but other interesting candidates include NPSR1, GSN, POLD2 and TOX3. These and other genes are being validated in a second cohort of 1,000 cases and controls. Our experience demonstrates that beyond PALB2, the prevalence of mutations in the remaining breast cancer predisposition genes is likely to be very low making definitive validation exceptionally challenging.

3230S

Significant evidence for linkage of cutaneous malignant melanoma to 1q41. *L.A. Cannon-Albright[1], J.M. Farnham[1], K.K. Thai[1], J.J. Zone[2], C.C. Teerlink[1].* 1) Division of Genetic Epidemiology, Internal Medicine, University of Utah School of Medicine., Salt Lake City, UT; 2) Dermatology, University of Utah School of Medicine, Salt Lake City, Utah.

A genome-wide linkage analysis using various Illumina SNP platforms was performed in 46 high risk extended Utah melanoma pedigrees including 237 genotyped cutaneous malignant melanoma cases. For linkage analysis a set of 25,437 genomewide SNPs with no LD was selected from the intersection of the 3 illumina high density SNP platforms (550k, 610k, 720K) used. General dominant and recessive models with low disease allele frequency and partial penetrance were used in an affecteds-only analysis. By-pedigree LODs were considered for these singly informative pedigrees using the TLOD statistic. In one pedigree significant linkage evidence was noted at chromosome band 1q25 (max TLOD = 3.6 at 232.6 cM, 1-LOD drop spanning 232.1 - 233.6 cM). An additional linked pedigree in this region achieved a TLOD = 2.7 at 232.4 cM, 1-LOD drop spanning 232.2-233.7 cM. A 2 recombinant region from these 2 pedigrees runs approximately from 232.1-233.7 cM, or 222.1-223.8 Mbp region (hg19). This 1.7 Mb region contains 11 genes, including: MIA3 (homo sapiens melanoma inhibitory activity family, member 3); HHIPL2 (hedgehog interacting protein like 2); TAF1A (encodes a subunit of the RNA polymerase I complex); AIDA (axin interactor, dorsalization associated); DISP1 (dispatched homolog 1; protein product required for normal Hedgehog signaling); TLR5 (toll-like receptor 5); SUSD4 (sushi domain containing 4; novel complement inhibitor-complement is a protease inhibitor belonging to the serpin superfamily); CAPN8 (calpain 8 - involved in membrane trafficking in the gastric surface mucus cells); BROX, FAM177B, and C1ORF65. Sequence analysis of distantly related carrier cases in these 2 linked pedigrees is underway.

3231M

Expression and insertion of MMTV/HMTV env gene sequences in human breast cancer. *A. Cedro-Tanda, A. Cordova-Solis, E. Pina-Jimenez, D. Arenas-Aranda, F. Salamanca-Gomez, N. García-Hernández.* Genetica Humana, Hospital de Pediatría, CMN S XXI, IMSS, México, D. F., Mexico.

Breast cancer is the leading cause of cancer death for women in Mexico. Recently, it was demonstrated that MMTV/HMTV retrovirus contributes with breast cancer progression. The aim of this study was to identify env gene expression and insertion sites of MMTV/HMTV retrovirus in breast tumours in Mexican women. DNA and RNA were extracted from a total of 73 tumours and normal tissues. In order to assess DNA quality, a 700bp GAPDH fragment was amplified for all samples. MMTV detection was performed by nested PCR for two fragments of env gene (660bp and 250bp), as a positive control MMTV env gene (C3H) in pBR322 was used. Presence of the retrovirus was validated by qPCR with TaqMan probes and quantification of the number of copies using the env gene inserted into pBR322. Expression was evaluated by RNA treatment with DNase and then a RT-qPCR with TaqMan probes to detect env gene. MMTV / HMTV retrovirus insertion sites in the tumour genome were determined by splinkerette PCR. The presence of MMTV was 10% in 73 tumours. The data was confirmed by qPCR with TaqMan probes designed for a specific region of the env gene. Sequence analysis shows that env gene fragments present an identity of 95% with HMTV and 97% with MMTV. The number MMTV / HMTV viral copies is variable for each sample (228-7729 copies). env gene expression was determined in 50% of the positive samples. Preliminary analysis reveals retroviral insertions throughout the genome of infected breast tumours. We are working to establish the participation of MMTV or its homolog, HMTV in tumour progression and breast cancer development.

3232T

Association of P2RX7 gene polymorphisms and cervical squamous cell carcinoma risk. *T. Chang[1], Y. Yang[2,3], Y. Lee[1,4,5], T. Chen[2], W. Lin[1], S. Chang[1].* 1) Medical Research Department, Mackay Memorial Hospital, New Taipei, Taiwan; 2) Department of Gynecology and Obstetrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Gynecology and Obstetrics, Taipei Medical University, Taipei, Taiwan; 4) Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 5) Pediatrics, Taipei Medical University, Taipei, Taiwan.

Cervical cancer is a multifactorial disease and increasing evidence suggests that host immunogenetic background may contribute to its pathogenesis. P2X7 receptor has been implicated in the regulation of immune response and associated with certain cancer development. The aim of this study is to investigate associations between the P2RX7 gene single nucleotide polymorphisms (SNPs) and cervical cancer susceptibility. We genotyped 4 functional SNPs (rs17525809 C/T, rs208294 C/T, rs1718119 A/G, and rs3751143 A/C) in 507 cervical squamous cell carcinoma (CSCC) patients and 430 age/sex matched healthy controls by using the Pre-Developed TaqMan Allelic Discrimination Assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. We found no significant associations between the polymorphisms or haplotypes and CSCC. Stratified by the positivity of HPV-16 infection also did not find marked association. Our findings provide no support for the hypothesis that P2RX7 gene polymorphisms are associated with increased risk for CSCC in the Taiwanese population.

3233S

Functional Variants at The 21q22.3 Locus Involved in Breast Cancer Progression Identified by Screening of Genome-Wide Estrogen Response Elements. *H. Chu[1,2], C. Hsiung[1,2], Y. Huang[1], W. Chou[1], L. Hu[1], H. Hsu[3], P. Wu[1,2], M. Hou[4], J. Yu[3], C. Shen[1,2,5].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, 115, Taiwan; 2) Taiwan Biobank, Academia Sinica, Taipei, 115, Taiwan; 3) Department of Surgery, Tri-Service General Hospital, Taipei, 114, Taiwan; 4) Cancer Center and Department of Surgery, Kaohsiung Medical University Chung-Ho Memorial Hospital, Kaohsiung, 804, Taiwan; 5) College of Public Health, China Medical University, Taichung, 404, Taiwan.

Estrogen forms a complex with the estrogen receptor (ER) that binds to estrogen response elements (EREs) in the regulatory region of estrogen-responsive genes, and regulates their transcription. Since sequence variants in the regulatory regions have the potential to affect the transcription factor-regulatory sequence interaction, resulting in altered expression of target genes, this study explored the association between single-nucleotide-polymorphisms (SNPs) within the ERE-associated sequences and breast cancer progression. The ERE-associated sequences throughout the whole genome, demonstrated to bind ERα in vivo, were blasted against online information from SNP datasets, and 54 SNPs located adjacent to estrogen-responsive genes were selected for genotyping in two independent cohorts of breast cancer patients, 779 in the initial screening stage and another 888 in the validation stage. With death from breast cancer or recurrence of breast cancer being defined as the respective event of interest, the SNPs at 21q22.3 were significantly associated with overall survival and disease-free survival of patients. Furthermore, these SNPs (rs2839494 and rs1078272) could affect the binding of this ERE-associated sequence to ERα or Rad21 (an ERα coactivator), respectively, resulting in a difference in ERα-activated expression of the reporter gene. These findings support the idea that functional variants in the ERα-regulating sequence at 21q22.3 is important in determining breast cancer progression.

3234M

Post-GWAS functional characterization of the 12p11.23 renal cancer susceptibility locus. *L.M. Colli[1], P. Bigot[1,2], L. Jessop[1], M. Machiela[1], T. Myers[1], S. Chanock[1].* 1) Division of Cancer Epidemiology and Genetics, NCI - NIH, Gaithersburg, MD; 2) University Hospital of Angers, Department of Urology, Angers, France.

In previous GWAS, rs718314 and rs1049380 at 12p11.23 were associated with renal cell carcinoma (RCC). The aim of our study is to perform a functional analysis of the 12p11.23 region in relation to RCC risk. We performed an imputation analysis within 1 Mb of rs718314 in three different previously published RCC GWAS studies (4197 cases and 8527 controls). The genotyped and high-quality imputed SNPs were tested for association with RCC. After meta-analysis, 44 SNPs demonstrated nominally significant association with RCC risk ($p<5\times10\text{-}5$). The two initial GWAS SNPs, rs718314 and rs1049380, were strongly associated with RCC (Padj = $3.44\times10\text{-}6$ and Padj = $5.27\times10\text{-}6$). All nominally significant SNPs were in a non-coding region which contains the 3'-UTR of ITPR2. Six of the 44 variants were in regions enriched for H3K4me1 and H3K27ac, chromatin marks found in enhancers. Only rs7132434, which is highly correlated with the initial GWAS signal (rs718314, r2=1), showed allele specific regulatory activity in luciferase assays and allele specific differences in protein binding by EMSA. The RCC-associated variants were examined for an effect on nearby gene expression (ITPR2, SSPN, SHARP1), using the TCGA database. Five SNPs associated with RCC were present in the TCGA database and all of them were associated with SHARP1 expression in tumor tissues ($p<0.05$). The most significant association was found with rs12814794 ($p=1\times10\text{-}8$) which is in high linkage disequilibrium with rs718314 (r2=0.956) and rs7132434 (r2=0.956). There was no association between these SNPs and SSPN or ITPR2 expression. Recently, SHARP1 has been shown to be involved in the HIF pathway in breast cancer. Also, SHARP1 regulates adipogenic differentiation and could be a link between RCC and obesity, a known risk factor for RCC. Our results suggest rs7132434 is the functional SNP responsible for the GWAS signal and that this locus could act as an enhancer of SHARP1. Further investigations will be necessary to confirm the link between rs7132434 and SHARP1 and to understand the role of SHARP1 in renal carcinogenesis.

3235T

Targeted Gene Sequencing in Familial Colorectal Cancer Type X. *J. Cunningham[1], A. French[1], M. DeRycke[1], S. Riska[2], S. McDonnell[2], S. Gunawarden[1], Z. Fogarty[2], S. Middha[2], S. Much of the heritability of colorectal cancer (CRC) remains unexplained. Type X CRC cases are those that meet Amsterdam criteria for hereditary non-polyposis CRC but have microsatellite stable tumors and lack mutations in mismatch repair (MMR) genes. In our recent germline next generation sequencing custom capture project, 144 Type X CRC cases were sequenced. The capture covered 2.9Mb and included known hereditary colon cancer genes (HCC, n=18) and suspected HCC genes (sHCC, n=18). A minimum read depth of 20 and a genotype quality score of 30 were required for sample analyses. Regions containing pseudogenes and variants with < 90% total successful call rate were eliminated. Excluding synonymous SNVs, 64 variants in HCC genes and 64 variants in sHCC genes were detected in Type X CRC cases. Three were known pathogenic variants (*STK11* F354L, *MLH3* V741F and *APC* E1229Q). Three novel variants were splice variants (one each in *PALB2*, *NUDT1*, *RECQL5*), one was in an initiation codon (*NUDT1*), and 29 were predicted to be damaging in several in silico tools (*AXIN1*, *CTNNB1*, *FLCN, GALNT12, PALB2*, *RECQL5*, *APC*, *BMP4*, *CHEK2*, *MLH1*, *MSH2*, *MUTYH*, *PMS1*, *PTEN*, *SMAD4*). The occurrence of potentially deleterious MMR gene variants suggests possible misclassification of MMR status. Notably, among these 144 Type X CRC cases, 35 (24.3%) carried likely deleterious mutations in known CRC and suspected CRC genes, suggesting the value of a broad cancer gene panel. To uncover the remaining heritable factors in Type X CRC, however, more work remains. This work was supported by grant UM1 CA167551 from the National Cancer Institute.

***SF3B1* mutations in different cancer types cause recognition of sterically hindered cryptic splice-sites downstream of the branch point.** *C. DeBoever[1,2], E.M. Ghia[2], P.J. Shepard[3], L. Rassenti[4], K. Jepsen[5], C.H.M. Jamieson[2,4,5], D. Carson[2,5], T.J. Kipps[4], K.A. Frazer[2,3,6].* 1) Bioinformatics and Systems Biology, University of California San Deigo, La Jolla, CA; 2) Moores Cancer Center, University of California San Diego, La Jolla, CA; 3) Department of Pediatrics and Rady Children's Hospital, University of California San Diego, La Jolla, CA; 4) Department of Medicine, University of California San Diego, La Jolla, CA; 5) Institute for Genomic Medicine, University of California San Diego, La Jolla, CA; 6) California Institute for Regenerative Medicine, University of California San Diego, La Jolla, CA.

One of the biggest surprises to emerge from the growing catalog of somatic mutations in various cancer types is the recurrent mutation of genes encoding the RNA spliceosome. Recurrent mutations in the highly conserved HEAT 5-9 repeats of splicing factor 3B subunit 1 (*SF3B1*) have been reported in myelodysplastic syndrome (MDS), chronic lymphocytic leukemia (CLL), breast cancer, uveal melanoma (UM), and pancreatic cancer. Prior studies have shown that mutated *SF3B1* CLL samples use canonical 5' splice sites but cryptic 3' splice sites. However it is unknown whether *SF3B1* mutation causes the same 3' splicing defects in different cancers. The mechanism by which *SF3B1* mutations cause cryptic 3' splicing and the functional consequences thereof remain unresolved as well. Here we define the specific sequence requirements needed for cryptic 3' splicing in tumors with mutated *SF3B1*. We examined splice junction usage in transcriptome data from *SF3B1* mutant and unmutated CLL, UM and BRCA cases and found that *SF3B1* mutants use as cryptic acceptors AG dinucleotides ~13-17 bp downstream of the branch point that are likely sterically hindered when *SF3B1* is unmutated. The cryptic acceptors are also located >10 bp upstream of nearby canonical acceptors and thus avoid competing with them for splicing. In our genome-wide analysis only 617 AG dinucleotides met these specific sequence requirements and were used as cryptic acceptors. The same cryptic 3' splicing signature was observed in different cancers but only in samples with mutations in ~10 amino acid hotspots in the SF3B1 HEAT 5-9 repeats. We found that the cryptic acceptors used in the *SF3B1* mutants are typically spliced in at a low frequency (<10% relative to the canonical splice site) and are sometimes present in the SF3B1 unmutated tumors but at an even lower frequency (<0.5% relative to the canonical splice site). Nonetheless, we identified three genes previously implicated in cancer (TTI1, MAP3K7 and FXYD5) and four others (YIF1A, ORAI2, ZNF91, RP11-1280I22.1) with cryptic acceptors that were consistently preferred to the associated canonical acceptor in the CLL SF3B1 mutant samples. Our study suggests that cryptic 3' splicing in SF3B1 mutants results from altered sterics of SF3B1 and other proteins bound at the branch point allowing for the usage of acceptors that are normally hindered and provides a framework for understanding the effects of SF3B1 mutations on the pathophysiology of various cancers.

3237M

Targeted Germline Sequencing of Young Onset, Proficient Mismatch Repair Colorectal Cancer Genes. *M.S. DeRycke[1], S.M. Riska[1], S.K. McDonnell[1], A.J. French[1], Z.C. Fogarty[1], S. Middha[1], S. Baheti[1], S. Gunawardena[1], D.J. Schaid[1], Y. Zhang[1], D. Buchanan[2], M. Clendenning[2], G. Casey[3], M. Cotterchio[4], D.J. Duggan[5], S. Gallinger[6], R.W. Haile[7], J.L. Hopper[8], M.A. Jenkins[9], L. Le Marchand[10], J.D. Potter[11], P.A. Newcomb[11], M.O. Woods[12], N.M. Lindor[13], E.L. Goode[1], S.N. Thibodeau[1] on behalf of the Colon Cancer Family Registry.* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Oncogenomics Group, Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Melbourne, Australia; 3) Department of Preventive Medicine, Keck School of Medicine of USC, Los Angeles, CA; 4) Prevention and Cancer Control, Cancer Care Ontario, Ontario, Canada; 5) Translational Genomics Research Institute (TGen), Phoenix, AZ; 6) Lunenfeld Tanenbaum Research Institute, Toronto, Ontario, Canada; 7) Department of Medicine and Stanford Cancer Institute, Stanford, CA; 8) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, University of Melbourne, Melbourne, Victoria, Australia; 9) Centre for Epidemiology & Biostatistics, Melbourne School of Population & Global Health, University of Melbourne, Melbourne, Victoria, Australia; 10) Epidemiology Program, University of Hawaii Cancer Center, Honolulu, HI; 11) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 12) Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada; 13) Department of Health Sciences Research, Mayo Clinic, Scottsdale, AZ.

Although the overall incidence of colorectal cancer (CRC) is decreasing, incidence in individuals diagnosed before the age of 50 has increased. While familial syndromes account for approximately 20% of young onset cases, the genetic underpinnings remain unknown for the remaining cases. We studied 370 young-onset (YO, <50 years) proficient mismatch repair (pMMR based on IHC and/or MSI testing) cases using targeted capture and sequencing to search for genes contributing to the susceptibility of YO pMMR CRC. Agilent SureSelect custom capture targeted 2.9Mb of germline DNA for sequencing genes on an Illumina HiSeq2000, including known and suspected hereditary CRC genes (HCC, n=36), several miRNAs (n=118), and genes identified by linkage (n=185) or whole exome sequencing (n=363) studies. Samples from 1,483 individuals (various CRC case groups and controls) were sequenced. Variants in the 370 YO pMMR cases were investigated and compared to 95 unaffected spousal controls. Following filtering (based on quality and minor allele frequency, MAF), 17,826 variants (6,979 coding, 52 splice, 10,795 non-coding) were identified in 702 genes and miRNAs in the cases; 142 deleterious variants (nonsense, splicing, initial codon changes, and stoploss) were found in 116 genes (present in 247 cases). Twenty-two genes harbored >1 deleterious variant, including *DNAH7* with four and *APC* and *TMC2* with three. Nine of the deleterious variants occurred in HCC genes, all affecting a single case, suggesting some misclassification of MMR status. Three nonsense variants were identified in *APC*, while *CHEK2*, *MLH1*, *MSH2*, *MSH6*, and *MUTYH* all harbored one nonsense variant; one splicing variant was found in *MLH1*. Two variants were identified in the suspected HCC gene group, both affecting one individual: a *RECQL5* splicing variant and a *NUDT1* missense variant affecting the initial codon. The majority of variants were present in only a single case (n=11,305, 63%) and most were not present in the 95 unaffected controls (n=13,727, 77%), highlighting the need for large control datasets. Of 4,099 intersecting variants, the MAF in cases was five-fold higher than controls for 15 variants, including three missense (in *FMO5*, *MLH3*, and *PROZ*), one synonymous, and 11 non-coding variants. In depth analysis and comparison of the genes and variants present in the YO pMMR cases and other CRC subtypes will be presented. This work was supported by grant UM1 CA167551 from the National Cancer Institute.

3238T

Characterization of *OLFML3* mutations in non-small cell lung cancer. *C. Drennan, M. Orloff.* Department of Epidemiology, University of Arkansas for Medical Sciences, 4301 W. Markham Street, #820 Little Rock, Arkansas 72205.

In Arkansas and the U.S., lung cancer (LC) accounts for more deaths each year than breast, colon, and prostate cancers combined. To date, the phenotypic heterogeneity associated with LC, particularly non-small cell LC (NSCLC), has been the main obstacle in the development of effective prevention and treatment. Recently, an integrative 'omics' analysis of significant regions of tracts of homozygosity combined with genome-wide expression array data was used to map and shortlist NSCLC-related genes (p-values <0.0001). Of these 9 significant genes, *OLFML3* [MIM 610088], which has been implicated in apoptosis, tumor growth, and cell cycle regulation in cancer cells, was reported to be significantly under-expressed in LC cases who were ever and never smokers (p-values <0.0001 and <0.006, respectively). As a follow-up, we postulate that mutations located in *OLFML3* exons, splice sites, and promoter regions contribute to either a risk or protective effect in NSCLC patients.

To address our hypothesis, NSCLC tumor and matched adjacent normal tissues were retrospectively obtained from the University of Arkansas for Medical Sciences (UAMS) Tissue Procurement Facility. From these tissues, we simultaneously extracted DNA, RNA, and protein. We screened for mutations using the Sanger sequencing method and in patients who were positive for *OLFML3* mutations, the transcript levels of *OLFML3* are being assessed. We explored predicted transcription factor (TF) and microRNA (miRNA) binding sites located on *OLFML3*. Our search identified multiple TFs (MZF1, C/EBPb, SRY, Oct-1, SP1, AML-1a, delta E, HNF-3b, v-Myb, XFD1, Nkx-2, CdxA) that have been previously described as important regulators of carcinogenesis. Additionally, we explored the SNPs located on *OLFML3* to identify predicted TF binding patterns that could be affected and thus potentially change the expression levels. On *OLFML3* exon 3, rs2055542, resides 8 base pairs from where transcription factor SRY was predicted to bind at 100% threshold. SRY transcription factors have been shown to regulate lung as well as many other cancers. One miRNA, miR-155, was predicted to bind to *OLFML3* 3' UTR in humans and has been validated in animal models. Similar to *OLFML3*, miR-155 has also been linked to angiogenesis and tumor proliferation. Our continued investigation and characterization of *OLFML3* mutations combined with *OLFML3*-specific functional analyses may unravel a biologically plausible explanation to NSCLC.

3239S

Hox pattern expression and non coding transcripts in the HOX locus are associated with adult medulloblastoma subtype. *A.M. Fontes[1], K.J. Abraham[2], D.G. Pinheiro[3], D.T. Covas[4], J.B. Veiga[1], D.P.C. Tirapelli[5], F.S. Ramalho[6], A.A. Cardoso[7], S.L. Gerson[8], C.G. Carlotti[5].* 1) Department of Genetics, School of Medicine of Ribeirão Preto, University of Sao Paulo, Brazil; 2) Department of Pediatrics, School of Medicine of Ribeirão Preto, University of Sao Paulo, , Brazil; 3) Department of Technology, FCAV-UNESP; 4) Blood Center of Ribeirão Preto - FMRP/USP; 5) Department of Surgery and Anatomy, School of Medicine of Ribeirão Preto, University of Sao Paulo, Brazil; 6) Department of Pathology and Legal Medicine, School of Medicine of Ribeirão Preto, University of Sao Paulo, Brazil; 7) Hermann B Wells Center for Pediatric Research, Indiana University School of Medicine, Indianapolis, USA; 8) Case Comprehensive Cancer Center, School of Medicine, CWRU, USA.

Introduction: Medulloblastoma (MB) represents a heterogeneous group of neuroepithelial primary tumors arising from the cerebellum. MB can be classified at the molecular level into at least four major subtypes: WNT, SHH, Group C and Group D. Although the current managment of MB patients involves specific treatment approaches to their molecular subtype, a significant proportion of patients do not respond to treatment suggesting heterogeneity whithin these subtypes. We investigate for differences in HOX gene expression and their regulators among MB subtypes to provide additional biomarkers for MBs and molecular mechanisms of HOX regulation involved in tumor progression. Methodology: In this study we analyzed 5 frozen tumor samples from 5 adult MB patients, 3 control cerebellar tissues, 4 MB cell lines and 3 control cerebellar primary cells. Two color microarray-based gene expression profilling was performed according to the manufacturer's instructions. R and Bioconductor were used for analysis. Results: The hierarchical clustering of our samples suggests the existence of three groups among the tumor specimens analyzed (WNT, SHH and Group D). Hierarchical clustering based on the expression level of 39 Hox genes showed that Hox pattern expression might be related to MB subtype whereas in normal cerebellum Hox genes are downregulated or not expressed, with the exception of CN5. We found that: HoxD1, D3, D4, D8 and D9, HoxC4, HoxA9 and A10 are overexpressed in WNT MB; HoxA2, A3, A4, A5, A6, A7, A9, A10, A11, HoxB2, B6, HoxC8, C10 and C11 are overexpressed in SHH MB and Group D MB. Since HOTAIR is located a distance of 5,726 bp from HoxC11, we look for 5'-ends and 3'-ends of long ncRNAs located 1bp - 10 kbp apart from each 39 HOX genes. The analysis shows the presence of 5 Hox-related long ncRNAs: HOTSIR-56 mapped at HoxB9; HOTSIR-24 mapped at HoxD3; HOTSIR-49, HOTSIR-69 and HOTNSIR-27 mapped at HoxC domain. HOTAIR is not expressed in MB. These long ncRNAs are differentially expressed among MB subtypes. In our analysis, HOX regulators (MLL2 and LSD1) and Otx-2 are overexpressed in MB-WNT. Conclusion: This study suggests that differences in expression pattern of HOX genes, MLL and long ncRNAs are present depending on MB subtype. Validation analyses and genetic studies are ongoing to elucidate the molecular mechanisms of HOX regulation according to MB subtype, which can provide useful insights for biomarkers and therapeutic intervention.

3240M

Associations between UGT1A polymorphisms and haplotypes and lung cancer risk. *C.J. Gallagher[1,2], A.Y. Angstadt[1], K.M. Schieffer[1], J. Zhu[1], P. Lazarus[3].* 1) Public Health Sciences, PSU College of Medicine, Hershey, PA; 2) Pharmacology, PSU College of Medicine, Hershey, PA; 3) College of Pharmacy, Washington State University, Spokane, WA.

The UDP-glucuronsyltransferases (UGTs) are Phase II drug metabolizing enzymes that catalyze the detoxification of several cigarette smoke carcinogens. Polymorphisms in these genes may affect an individual's ability to detoxify carcinogens and therefore alter risk of lung cancer. There are hundreds of genetic variants that span the UGT1A gene cluster, but the effect of UGT1A polymorphisms on lung cancer risk has not been well-studied. The present study sought to better understand the effect of genetic variation within the UGT1A loci on lung cancer risk by conducting a comprehensive association study of SNPs (tag and coding SNPs) and haplotypes with lung cancer risk by genotyping 407 lung cancer cases and 582 healthy controls on 96 SNPs. Known lung cancer risk factors, including age, sex, smoking status and pack-years of smoking, were adjusted for in logistic regression analysis and stratification analysis by sex, age, smoking status, pack-years of smoking, and lung cancer histology was also conducted. Many UGT1A SNPs showed association with lung cancer risk overall, and in each of the stratifications. Interestingly, one SNP in intron 1 of UGT1A10 was consistently associated with lung cancer risk in the overall analysis and had an even larger effect in cases with adenocarcinoma and in former smokers. Four additional missense SNPs yielded associations with lung cancer risk in the stratified analysis. Even after correcting for multiple testing, a significant association between two haplotypes and small cell carcinoma risk was observed. This study indicates the importance of UGT1A genetic variation in lung cancer risk. As the genes within the UGT1A loci are important in the detoxification of several tobacco-related carcinogens, identification of the effect of genetic variants in the UGT1A family on lung cancer risk will aid in defining high-risk smokers and help to develop targeted interventions.

3241T

Ptprj-interacting susceptibility genes for colorectal cancer. *M. Gerber, M. Cianciolo, A. Toland.* Department of Molecular Virology, Immunology, & Medical Genetics, The Ohio State University, Columbus, OH.

Colorectal cancer (CRC) causes over 50,000 deaths in the United States each year and is the third leading cause of cancer deaths. The identification of genetic risk factors underlying CRC will have immense value as a tool to identify individuals with increased predisposition to this cancer and to highlight new potential therapeutic targets. In the mouse, the gene *Ptprj* maps to a region of the genome linked to colon cancer susceptibility in mice. The *Ptprj* locus interacts synergistically with two other CRC susceptibility loci mapped in the mouse (*Scc5* and *Scc13*) to further increase CRC risk. The *Scc5* locus also independently interacts in a reciprocal manner with *Scc4* to augment susceptibility. Importantly, the susceptibility genes at *Scc4*, *Scc5*, and *Scc13* have not yet been identified. Our goals are (1) to identify which of the multiple genes present at these *Scc* loci are responsible for modifying CRC risk, and (2) to understand how the combination of the susceptibility genes at these regions increases CRC risk. To achieve these goals, RNA-Seq was used to identify genes with genetic variants or expression levels that differ between the CRC-resistant and CRC-susceptible mouse strains used to map the *Scc* loci. Next, SNPs in the human orthologs of these candidate susceptibility genes were tested in 194 pairs of normal and colon tumor DNA (from human CRC patients) for evidence of allele-specific gains or losses. SNPs that showed statistical trends of gains or losses were genotyped in 296 additional DNA pairs. These studies revealed that 75 of 950 tested SNPs reproducibly show preferential gains or losses in colon tumor DNA samples compared to matched healthy colon DNA samples (p-values<0.05). From these studies, *Epas1* (*Scc4*), *Csnk1a1* (*Scc5*), and *Prdm5* (*Scc13*) emerged as leading candidates at the loci of interest. Preliminary studies to uncover interactions among these candidate genes using *in vitro* models have thus far shown that the transcription factor Epas1 may regulate expression of *Csnk1a1* and *Ptprj*. The epigenetic regulator Prdm5 may also exert regulatory effects at these loci. Furthermore, Epas1 may promote Wnt signaling in colon epithelial cells and therefore function in an oncogenic capacity. Future work will delve deeper into the exploration of this complex network of gene-gene interactions by manipulating levels and isoforms of the candidate genes in cell lines and assessing effects on cell growth, death, and other cancer-relevant phenotypes.

Hereditary Acute Myelogenous Leukemia (AML) in a Druze family. *Y. Hadid[1,2], Y. Ofran[1], M. Hayun[1], A. Ghanayim[1], K. Skorecki[1].* 1) Technion, Haifa, Israel; 2) Bnai-Zion Medical Center.

Population genetics studies of the Druze communities by the applicant and colleagues show a genomic architecture which should greatly facilitate gene discovery in health and disease states with both Mendelian and non-Mendelian inheritance. In particular, we have previously shown the Druze to represent a sanctuary or refugium of the population genetic structure of the Levant in antiquity. In contrast to previous formulations, it is apparent, that the contemporary Druze population is comprised of numerous globally diverse founding lineages. The past one thousand year history as a transnational population isolate, characterized by high levels of consanguinity and endogamy has therefore resulted in a disproportionate prevalence and accompanying challenge of genetic disease with both Mendelian and non-Mendelian inheritance patterns. We have recently identified three sisters in a Druze family, two with AML and one with Myelodysplastic Syndrome (MDS). A detailed genealogical family tree going back five generations and including 120 persons (with known medical history) revealed an additional three family members who had been diagnosed with AML at ages younger than 40. The incidence of AML in people younger than 50 years old is 1:100,000, therefore a cluster of 6 young AML/MDS patients in a family of 120 (5%) covering several generations is strongly suggestive for a heritable contribution Research Objectives 1. Map AML/MDS in this family to a specific chromosomal locus in linkage with the disease phenotype.2. Discover a disease-causing abnormality underlying AML/MDS in a gene located within the presumably identified linked interval.3. Verify the pathogenic effect of a discovered mutation by developing a suitable experimental model for gene expression and functional testing.4. Provide genetic counseling and pre-leukemic testing for people from the same family and the Druze community for timely identification of people at risk. Preliminary Results Mutations in RUNX1 and CEBPα are known to be associated with familial AML syndromes and full genetic sequencing of these two genes did not identify mutations. Accordingly, we have proceeded to whole exome capture coupled with heterozygosity mapping in order to progress to localization of a disease-causing gene and identify specific mutations underlying the disease in this family.

3243M

A Novel Risk Variant at the 8q24 Cancer Susceptibility Locus in Men of African Ancestry. *Y. Han[1], K.A. Rand[1], D. Notani[2], D.V. Conti[1], N. Rohland[3], S.S. Strom[4], R.A. Kittles[5], B.A. Rybicki[6], J.L. Stanford[7], P.J. Goodman[8], S.I. Berndt[9], A.JM. Hennis[10], E.A. Klein[11], V. Stevens[12], S. Wu[10], J.S. Witte[13], J. Xu[14], W.B. Isaacs[15], S.A. Ingles[1], A.W. Hsing[16], S.J. Chanock[9], M.B. Cook[17], D. Reich[3], B. Nemesure[10], W.J. Blot[18], D.O. Stram[1], M.G. Rosenfeld[2], S. Watya[19], B.E. Henderson[1], C.A. Haiman[1], The African Ancestry Prostate Cancer Consortium.* 1) University of Southern California, Los Angeles, CA; 2) University of California, San Diego, La Jolla, CA; 3) Harvard Medical School, Boston, MA; 4) The University of Texas MD Anderson Cancer Center, Houston, TX; 5) University of Illinois at Chicago, Chicago, IL; 6) Henry Ford Hospital, Detroit, MI; 7) Fred Hutchinson Cancer Research Center, Seattle, WA; 8) SWOG Statistical Center, Seattle, WA; 9) National Institutes of Health, Bethesda, MD; 10) Stony Brook University, Stony Brook, NY; 11) Cleveland Clinic, Cleveland, OH; 12) American Cancer Society, Atlanta, GA; 13) University of California, San Francisco, San Francisco, CA; 14) Wake Forest University School of Medicine, Winston-Salem, NC; 15) Johns Hopkins Hospital and Medical Institutions, Baltimore, MD; 16) Cancer Prevention Institute of California, Fremont, CA; 17) National Cancer Institute, Bethesda, MD; 18) Vanderbilt University School of Medicine, Nashville, TN; 19) Makerere University, Kampala, Uganda.

Background: The 8q24 locus harbors multiple risk variants for distinct cancers, including >10 that are specific for prostate cancer. In African American men with prostate cancer, African ancestry is over-represented in this region, which is a strong indication that some of the underlying disease-relevant variants are more common in men of African than European ancestry. Therefore, we searched for novel associations with common and rare variation across the 8q24 risk locus in men of African ancestry. **Methods:** We examined the 8q24 locus (127.8-128.8 Mb) in 4,853 prostate cancer cases and 4,678 controls from the African Ancestry Prostate Cancer GWAS Consortium. Genotyping was conducted using Illumina Infinium 1M Duo with imputation to a cosmopolitan reference panel from the 1000 Genomes Project (1KGP; March, 2012). To identify independent risk variants, we performed stepwise conditional logistic regression adjusted for age, study, global ancestry (the first 10 principal components) and local ancestry. **Results:** We identified 199 variants at 8q24 associated with prostate cancer risk at $p<5.0\times10^{-8}$. Of these, the most significant SNP was rs114798100 (odds ratio per allele (OR)=2.32, $p=1.6\times10^{-33}$), which is correlated with a previously reported African-specific variant (rs116041037, $r^2=0.63$ in AFR 1KGP). Conditioning on rs114798100 revealed a second nearby signal, captured by marker rs72725879 (OR=1.28, $p=2.2\times10^{-14}$), which is the most strongly associated signal across the 8q24 region in Japanese men. Further conditioning on rs114798100 and rs72725879 revealed a third and novel signal, defined by variant rs111906932 (OR=1.76, $p=7.9\times10^{-11}$), which is uncommon and only found in African ancestry populations (risk allele frequency, 3%). The associations with these markers were replicated in additional studies from Ghana and Uganda. These three risk variants for prostate cancer explained 7% of the heritability and 7% of the genetic variance on log relative risk scale. They are located within or in close proximity to a number of long non-coding RNAs, including *PRNCR1*, which is prostate-specific, as well as *PCAT2*. **Conclusions:** We identified a novel variant for prostate cancer that is only found in men of African ancestry. These findings highlight ancestry-specific variation, allelic and effect heterogeneity, and, further implicate non-coding RNAs as underlying associations of genetic variation at 8q24 with cancer risk.

3244T

Molecular characterization of oncogenic properties of *S100A4* in pancreatic and lung cancers and identification and characterization of candidate downstream genes. *A. Horii, N. Chen, H. Sekine, N. Tsukamoto, T. Tabata, Y. Saiki, S. Fukushige, M. Sunamura.* Dept Molec Pathol, Tohoku Univ Sch Med, Sendai, Miyagi, Japan.

S100A4 is one of the members of the S100 family that characterized as a small calcium-binding protein, and frequent overexpression as well as positive association between overexpression and metastasis were reported. However, detailed mechanisms for such characteristics are not well understood. We analyzed S100A4 in pancreatic and lung cancers and observed frequently overexpression in both tumor types, irrespective of histological subtype. Methylation status in the CpG sites in intron 1 associated with expression of *S100A4*. In some tumors, however, not methylation at the CpG sites but acetylation of histone regulates expression. Then we performed knockdown and forced expression of *S100A4* in pancreatic and lung cancers. Results of both tumor types shared high similarities; specific knockdown of *S100A4* effectively suppressed cell proliferation, mainly by induction of apoptosis, only in cancer cells with S100A4-overexpression, and forced expression of *S100A4* accelerated cell motility only in S100A4 low-expressing cancer cells. Furthermore, S100A4 expression was significantly correlated with perineural invasion (P = 0.029) and invasion pattern (P = 0.001) in primary pancreatic cancer tissues. Microarray analyses using pancreatic cancer were performed both after specific knockdown and forced expression of *S100A4*, and we identified several candidate genes such as *PRDM2* and *VASH1* after knockdown, and *IFI27* and *NOV* after forced expression. It is notable that positive association between *IFI27* expression and perineural invasion (P = 0.0023) was observed. Our results suggest that S100A4 plays an important role in pancreatic and lung carcinogenesis, and that these two tumor types may share the same or similar pathway in cell proliferation and motility.

Estrogen Receptor Gene Polymorphisms and Lung Adenocarcinoma Risk in Never-smoking Women. *CF. Hsiao[1], KY. Chen[2], GC. Chang[3], YH. Tsai[4], WC. Su[5], YM. Chen[6], MS. Huang[7], C. Hsiung[1], CJ. Chen[8], PC. Yang[1].* 1) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan; 2) Division of Pulmonary Medicine, Department of Internal Medicine, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan; 3) Division of Chest Medicine, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung; Department of Medicine, School of Medicine, National Yang-Ming University, Taipei, Taiwan; 4) Division of Pulmonary and Critical Care Medicine, Department of Internal Medicine, Chang Gung Memorial Hospital, Taipei, Taiwan; 5) Division of Hematology/Oncology, Department of Internal Medicine, National Cheng Kung University, Tainan, Taiwan; 6) Chest Department, Taipei Veterans General Hospital; School of Medicine, National Yang-Ming University, Taipei, Taiwan; 7) Department of Internal Medicine, Kaohsiung Medical University Hospital; School of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 8) Genomics Research Center, Academia Sinica; and Graduate Institute of Epidemiology, College of Public Health, National Taiwan University, Taipei, Taiwan.

Seldom is studied on the association between estrogen receptor gene polymorphism and lung cancer risk. This study is to explore the estrogen receptor gene polymorphisms associated with lung adenocarcinoma risk in never-smoking women. This case-control study included 532 never-smoking female patients with lung adenocarcinoma and 532 healthy controls. The ESR1 single nucleotide polymorphism (SNP) data were retrieved from a genome-wide association study. The associations of ESR1 SNPs with the lung adenocarcinoma risk were estimated by multivariate-adjusted logistic regression. For ESR1, a total of 98 SNPs were retrieved and analyzed. Among the retrieved SNPs, 7 tagged SNP associated with lung adenocarcinoma risk was identified. A stepwise forward selection logistic regression approach was performed, with adjustment for hormone replacement therapy (HRT), education level, passive smoking, cooking fume exposure, and other tagged SNPs. Two SNPs, rs7753153 and rs985192, were significantly associated with lung adenocarcinoma risk. (rs7753153: OR: 1.509, 95% CI: 1.168 - 1.950; rs985192: OR: 1.390, 95% CI: 1.001 - 1.712). Therefore, we may conclude that estrogen receptor gene SNPs may be associated with lung adenocarcinoma in never-smoking women.

3246M

***PALB2* mutations among unselected pancreatic cancer patients in the Czech Republic.** *M. Janatova[1], M. Borecka[1], J. Soukupova[1], P. Kleiblova[1], F. Lhota[1], J. Hojny[1], P. Soucek[2], Z. Kleibl[1], P. Pohlreich[1].* 1) Institute of Biochemistry and Experimetal Oncology, First Faculty of Medicine, Charles University in Prague, Prague 2, Czech Republic; 2) National Institute of Public Health, Prague 10, Czech Republic.

Pancreatic cancer is the fourth most common cancer-related cause of death in the Czech Republic and the incidence is still growing. It has one of the worst prognoses of any type of cancer. Early detection is needed for improving the survival. Because of a relatively low incidence of the disease, the screening should be limited for high-risk patients. Hereditary factors account for approximately 10% of patients with pancreatic cancer. The most prevalent gene responsible for familial pancreatic cancer is *BRCA2*. The *PALB2* gene was described as another gene predisposing to pancreatic cancer. The PALB2 protein has an important role in FA-BRCA pathway involved in DNA damage response and thus tumor suppression. Recently, we have described high frequency of the *PALB2* gene mutations in hereditary breast cancer patients in the Czech Republic (5.5%) that included large genomic rearrangements (LGRs). The aim of this study was to evaluate the frequency of *PALB2* mutations among Czech pancreatic cancer patients. We performed a mutation analysis of the *PALB2* gene in a set of 230 unselected patients with pancreatic ductal adenocarcinoma (PDAC). All exons and flanking intron-exon boundaries were analyzed by direct sequencing. Identified mutations were analyzed in a group of 1220 control samples by HRM analysis. We identified two pathogenic truncating mutations in the *PALB2* gene in 230 PDAC patients (2/230; 0.8%). One mutation is novel (c.1838delA, p.Q613Rfs*15) and one mutation is already described (c.509_510delGA; p.R170Ifs*14). This mutation was observed in one control sample (1/1220; 0.08%). Our findings show that the germline *PALB2* mutations are quite rare in unselected PDAC patients; however, frequency of LGRs needs to be determined. Our analysis will contribute to the improvement in estimation of the disease-associated risk in the *PALB2* mutation carriers. Moreover, unraveling the families with germline *PALB2* mutations can help to identify high-risk individuals who may benefit from early detection screening tests. Supported by grants: IGA MZCR NT 14006-3/2013, PRVOUK-P27/LF1/1, and SVV-UK 3362-2014.

Next-generation panel based characterisation of breast/ovarian cancer genetic predisposition. *R. Janavicius[1, 2], V. Rudaitis[3], L. Griskevicius[1].* 1) Hematology, oncology, transfusion medicine center, Vilnius University Hospital Santariskiu Clinics, Vilnius, VNO, Lithuania; 2) State Research Institute, Innovative Medicine Center, Vilnius, VNO, Lithuania; 3) Department of Gynecology, Centre of Women's Physiology and Pathology, Vilnius University Hospital Santariskiu Clinics, Vilnius, VNO, Lithuania.

BACKGROUND. Genetic predisposition to breast and/or ovarian cancer is largerly confined to mutations in BRCA1/2 genes, although rarer mutations in other known genes are also important. Massively parallel (or next-generation, NGS) resequencing technology is attractive for identifying cancer predisposing mutations in selected known genes (panels) and discover new associations. METHODS. We aimed to better characterise cancer predisposing landscape in clinically selected 127 breast (BC) and 88 epithelial ovarian (EOC) cancer cases from Lithuania (with family history or early age at diagnosis and negative for previously tested BRCA1/2 genes mutations) by performing NGS based targeted analysis (genomic DNA) of genes previously associated with both common (e.g., breast, ovarian) and rare cancers. Custom made TruSight Cancer Nextera Custom hybridization-based target enrichment method was used for the targeted hybridization and preparation of genomic libraries, which were sequenced on MiSeq (2x150-cycles; Illumina). VariantStudio software was used for annotation and filtering of genetic variants. Further analysis filter encompassed 32 genes previously associated with BC/OC predisposition and other mechanistically implicated cancer predisposition genes. RESULTS. Germline loss-of-function protein truncating mutations (PTM) were identified in 13,4% of BC (17/127) and 3,4% of OC (3/88) BRCA1/2 negative samples. Seven PTM were implicated in 6 genes previously not associated with BC/OC predisposition, which are under further investigation. Other PTM were in 6 known BC/OC genes (BRIP1, CHEK2, PALB2, RAD51C, MLH1, TP53). RESULTS. Potentially pathogenic missense mutations (MM) were identified in 10,2% of BC (13/127) and 3,4% of OC (3/88) BRCA1/2 negative samples. Twelve MM were implicated in 5 genes (ATM, CDH1, BRIP1, NBN, MUTYH) previously associated with BC predisposition. One compound HOXB13 p.V84E + NBN p.I171V and one MUTYH p.G396D + NBN p.I171V BC carrier was identified. Two MM were in 2 known OC susceptibility genes (PALB2, TP53) whereas CDH1 gene (1 MM) was not previously associated with predisposition to OC. Further functional characterisation of selected MM variants is currently ongoing. CONCLUSION. NGS panel based resequencing is effective way for better characterising of cancer predisposition landscape.

3248S

Identification of germline mutations in hereditary prostate cancer families satisfying clinical testing criteria for hereditary breast and ovarian cancer. *A.M. Johnson[1], K.A. Zuhlke[1], L.A. Okoth[1], K.A. Cooney[1,2].* 1) Department of Internal Medicine, University Michigan, Ann Arbor, MI; 2) Department of Urology, University Michigan, Ann Arbor, MI.

Co-clustering of breast cancer (BrCa) and prostate cancer (PCa) within families has been well described. Shared risk factors for hereditary BrCa and ovarian cancer (HBOC) and hereditary PCa (HPC) include increasing age, race, and family history. Epidemiological studies have suggested that mutations in *BRCA1*, *BRCA2*, and other BrCa susceptibility genes may account for some of the cancer risk within these families. Less than 1% of the general population is expected to have a *BRCA1/2* mutation; however, this number increases to 10-15% for those women diagnosed with BrCa. Overall, *BRCA1/2* pathogenic mutations are estimated to account for 20-25% of HBOC. The University of Michigan Prostate Cancer Genetics Project (PCGP) selectively enrolls families with 1) a living affected relative pair diagnosed with PCa at any age or 2) an individual diagnosed with PCa before age 56 regardless of family history. For this study, we restricted our sample to PCGP families with at least 1 male BrCa case or a female BrCa or ovarian cancer case in a first-degree relationship to a PCa case. With the exception of the families with male BrCa, we further enriched our sample set to increase our expectation of finding a mutation in *BRCA1/2* by requiring these families to meet at least two of the family history factors defined by the U.S. Preventive Services Task Force that would qualify an asymptomatic woman for clinical *BRCA1/2* testing (N=50). The PCa case with the earliest onset disease (Avg age dx = 54.9 years; range 41-77) , with some preference given for clinically significant PCa, was selected for sequencing of *BRCA1/2* and other candidate genes using a commercially available next-generation Comprehensive Cancer Panel (Qiagen, Valencia, CA). Investigation of the mutation status of 50 men from families enriched for HBOC and HPC resulted in the identification of four separate potentially deleterious (nonsense or frameshift) mutations in *BRCA1/2* amongst five (10%) of our highly selected cases. Two additional probands had truncating mutations in *ATM* and on proband had a truncating mutation in *TET2*. In conclusion, knowledge of positive family history of BrCa and/or ovarian cancer coupled with the application of clinical risk assessment guidelines has increased the likelihood of identifying mutations in *BRCA1/2* and other cancer genes in men with prostate cancer.

3249M

Fine-mapping of 67 prostate cancer GWAS regions identifies better and multiple association signals. *Z. Kote-Jarai[1], A. AminAl Olama[2], T. Dadaev[1], D. Leongamornlert[1], D.J. Hazelett[3], E. Saunders[1], D. Easton[2], G.A. Coetzee[2], D. Conti[3], R. Eeles[1], The PRACTICAL Consortium.* 1) Oncogenetics, Inst Cancer Research, Sutton, Surrey, United Kingdom; 2) Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, United Kingdom; 3) Keck School of Medicine, University of Southern CAlifornia, Los Angeles, CA, USA.

More than 70 common prostate cancer (PrCa) susceptibility loci have been reported in various genome wide association studies. However, the published associated SNPs are most often only tagging the genomic regions that include the possible causative variants and it remains challenging to identify these. We performed a comprehensive fine-mapping analysis to evaluate the association between genetic variation and risk across 67 PrCa regions. The genotyping data from a custom Illumina iSelect array, iCOGS, from PRACTICAL, a large multi-national collaboration and two UK GWAS studies were used for imputation using 1KG as a reference panel in 26,713 PrCa cases and 26,274 controls. We used the results of a meta-analysis from the above three studies and included all SNPs +/- 500 Kb around the previously reported top SNPs that reached $P< 10^{-4}$ significance. Stepwise logistic regression (SLR) was used to identify independent SNPs in each region and in 27 regions only one SNP remained in the model . In 9 of these the association did not reach genome wide significance, four regions were those identified in Asian population and five were identified as borderline significance previously in studies with a larger European sample sets than those used for this analysis. In 18 of 27 regions the top variant was either a novel SNP (16), or the original variant (2). Amongst these we could confirm 3 previously reported Asian ethnicity GWAS signals now in the European population. For the remaining 40 regions with more than one SNP remaining in the model in the first SLR, we analyzed all SNPs adjusted for the best signal and selected SNPs significant at $P<10^{-5}$ level for a second SLR. After this only one SNP remained in the model in 21 regions and 19 regions harbor multiple independent signals. Five of these are known complex regions at 5p15 (TERT), 8q24, 11q13, 17q12 and 19q13 (KLK), but within 14 regions we identified novel independent association signals. We used functional annotation using data from ENCODE filtered for PrCa cell lines and detailed account of possible protein disruption, microRNA target sequence disruption and regulatory response element disruption of all correlated SNPs at $r(2) \geq 0.80$ to support further selection of the most likely risk affecting variants within all studied regions. We also evaluated improvement in stratifying population risk using polygenic risk score after including the new signals identified in this fine-mapping study.

3250T

Localization and Expression Level of p16 Correlate with Patient's Survival and Human Papilloma Virus Status in Oropharyngeal Squamous Cell Carcinoma. *S. Lai[1,2], V. Sandulache[3,4], J. Zevallos[3,4].* 1) Department of Pathology, Michael E. DeBakey VA Medical Center, Houston, TX, USA; 2) Department of Pathology and Immunology, Baylor College of Medicine, Houston, TX, USA; 3) Department of Otolaryngology, Baylor College of Medicine, Houston, TX, USA; 4) Department of Otolaryngology, Michael E. DeBakey VA Medical Center, Houston, TX, USA.

p16 is a tumor suppressor gene. Its gene product has been reported to be overexpressed in many head and neck squamous cell carcinoma (SCC) during the last decade. The association between human papillomavirus (HPV) and head and neck SCC has also been recognized. HPV is thought to cause p16 overexpression by E7-induced inactivation of the retinoblastoma protein. p16 immunoreactivity is often considered as an excellent surrogate marker for HPV infection in head and neck SCC. However, the differential expression of p16 overexpression in nuclear and cytoplasm and correlation with HPV status of oropharyngeal SCC of veteran male patients has not been studied. Tumors in oropharyngeal area are difficult to be resected completely, often unresectable due to complexity of location. Study of the pattern of p16 overexpression, HPV infection, and patient's clinical outcomes plays an important role for therapeutic implication. We studied p16 expression by immunohistochemistry in 135 oropharyngeal SCC of veteran male patients. P16 expression pattern is divided into the five groups: low nuclei/low cytoplasm, high nuclei/low cytoplasm, low nuclei/high cytoplasm, high nuclei/high cytoplasm and no expression. Five year disease-free survival is 28.4%, 74.7%, 0%, 93.1% and 13.7% in each group, respectively. Five year overall survival is 23.5%, 74.2%, 0%, 88.7% and 24.2%, respectively. Nuclear and cytoplasmic expression of p16 correlates with HPV positivity detected by polymerase chain reaction. Our data suggests orophagyngeal SCC shows differential p16 overexpression. High nuclei/high cytoplasm p16 expression levels predict a better pathological response to chemoradiation therapy with longer disease free and overall survival. p16 immunoreactivity can be used as a prognostic marker for chemoradiation adjuvant therapy.

***HOXB13* G84E germline mutation and prostate cancer risk in the UK.** *D.A. Leongamornlert[1], C. Mikropoulos[1], T. Dadaev[1], M. Tymrakiewicz[1], E.J. Saunders[1], S. Jugurnauth-Little[1], K. Govindasami[1], M. Guy[1], R.A. Wilkinson[1], E.J. Sawyer[1], A. Morgan[1], D. Neal[2,3], F. Hamdy[4], J. Donovan[5], A.C. Antoniou[6], Z. Kote-Jarai[1], R.A. Eeles[1,7], The UK Genetic Prostate Cancer Study Collaborators.* 1) Cancer Genetics, The Institute of Cancer Research, Sutton, Surrey, United Kingdom; 2) Surgical Oncology, University of Cambridge, Addenbrooke's Hospital, Cambridge CB2 0QQ, UK; 3) Cancer Research UK Cambridge Research Institute, Li Ka Shing Centre, Cambridge CB2 0RE, UK; 4) Nuffield Department of Surgical Sciences, University of Oxford, John Radcliffe Hospital, Oxford OX3 9DU, UK; 5) School of Social and Community Medicine, University of Bristol, Bristol BS8 2PS, UK; 6) Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge CB1 8RN, UK; 7) The Royal Marsden NHS Foundation Trust, London SM2 5PT, UK.

A rare recurrent missense variant in *HOXB13* G84E (rs138213197) was recently reported to be associated with hereditary prostate cancer. Follow-up population based studies established that the frequency of this variant varies between geographic regions and consequently the associated risk for prostate cancer (PrCa) is also highly variable. We investigated the association of *HOXB13* G84E with PrCa risk and prognosis using data from the largest case-control study from the UK. We screened self-identified white men using a custom TaqMan® assay; 8653 PrCa cases from the UK Genetic Prostate Cancer Study (UKGPCS) and 5251 population based controls from the Prostate testing for cancer and Treatment (ProtecT) study. *HOXB13* G84E carrier status was associated with an increased PrCa risk odds ratio (OR) 3.03, (95%CI=2.01-4.58, P= 1.5×10^{-7}) when all cases were compared with controls (carrier frequencies: *1.55% vs. 0.51%*). The association was stronger when cases with a 1st or 2nd degree PrCa family history were compared with controls (carrier frequencies: *2.4% vs. 0.51%*; OR: 4.76, 95%CI=3.03-7.47, P= $9.847\ 10^{-12}$). There was no association of *HOXB13* G84E carrier status with Gleason Score, presenting PSA, TNM stage and NCCN recurrence risk group or survival. We also investigated the combined effects of the G84E allele and a polygenic risk score (PRS) based on the combined effects of 71 common PrCa susceptibility alleles identified through GWAS. We found no evidence of interaction between the HOXB13 G84E allele and the PRS, suggesting that the PRS and G84E allele act multiplicatively on the risk of developing PrCa. Men in our study carrying the G84E variant who were also in the highest quintile of the PRS were estimated to be at a ~5-fold increased risk of developing PrCa, compared with non-carriers in the middle quintile of the PRS. *HOXB13* G84E is rare in the UK population and confers intermediate risks of developing PrCa. However, in combination with other known PrCa susceptibility alleles, carriers of the *HOXB13* G84E allele may be at a substantially higher risk of developing the disease which in the UK male population is linked to familial prostate cancer. Conversely G84E carrier status does not significantly associate with any clinicopathological variables or survival. Based on our study this rare variant explains ~1% of the familial risk of PrCa in the UK population.

3252M

Identification of hereditary alterations predisposing to breast cancer using Next-Gen Sequencing. *F. Lhota[1], V. Stranecky[2], P. Boudova[1], J. Soukupova[1], H. Hartmannova[2], K. Hodanova[2], P. Kleiblova[1], M. Janatova[1], P. Pohlreich[1], S. Kmoch[2], Z. Kleibl[1].* 1) Inst. of Biochemistry and Exp. Oncology, 1st Faculty of Medicine, Charles University in Prague, Prague, Czech Republic; 2) Inst. of Inherited Metabolic Disorders, 1st Faculty of Medicine, Charles University in Prague, Prague, Czech Republic.

The most common cancer not only in the Czech Republic is represented by Breast cancer (BC). Previously, we have tested 1035 high-risk breast/ovarian cancer patients and identified 269 carriers of pathogenic variants in eight BC susceptibility genes (BRCA1, BRCA2, p53, PALB2, CHEK2, ATM, NBN, and PPM1D). The most frequent alterations in identified mutation carriers were pathogenic variants in BRCA1 (N=188). Identification of some pathogenic variant failed in 74% of analyzed patients from high-risk families. With the aim to identify underlying BC susceptibility variants within hereditary breast cancer (HBC) patient subgroup (N=853), we launched next-gen sequencing (NGS) project targeting 594 genes that code for proteins involved in DNA repair or influencing BC pathogenesis using custom sequence capture panel and SOLiD sequencing. The NGS analysis in 314 high-risk patients and 101 non-cancer controls has been performed so far. We identified 84 (66 unique) protein truncating variants in 58 genes; 35 of these mutations were found in DNA repair genes in 33 out of 314 patients (10%). Totally, 387 missense variants (in 186 genes) were predicted as deleterious (in 15% of patients). Moreover, we found also 19 splicing site alterations. All truncating mutations were confirmed by Sanger sequencing. These variants affect several interesting genes including genes coding for Fanconi anemia proteins and proteins involved in DNA-repair pathways (e.g. WRN, BRIP1, RAD18). We also identified two BRCA1 and one BRCA2 mutations affecting the conservative splicing sites that has not been detected by mutation analysis performed previously. Our preliminary data indicates that targeted NGS, using panels of BC-susceptibility genes tailored to the analyzed geographical population is a rational, powerful, and economic strategy surpassing the classical strategies of mutation analysis. However, the implementation of exome-wide or genome-wide NGS approaches will be indispensable for the detection of population-specific rare variants or private mutations in individuals with higher risk of BC. With identification of truncating variants in potentially "actionable" genes, we are reducing the percentage of uncertainty in characterization of BC-susceptibility genes in high-risk patients from 75% down to 50 %. Supported by grants: IGA MZCR NT14054, IGA MZCR NT14006-3, PRVOUK P27, and SVV-UK 3362-2014.

Germline copy number variant analysis as a mechanism to identify novel high-risk endometrial cancer gene mutations. *F. Lose[1], G.L. Moir-Meyer[1,2], J.F. Pearson[3], M. Bowman[1], R.J. Scott[4,5], M. McEvoy[6], J. Attia[6,7], E. Holliday[5,8], P.D. Pharoah[9,10], A.M. Dunning[10], D.J. Thompson[9], D.F. Easton[9,10], L.C. Walker[2], A.B. Spurdle[1], HCS, SEARCH, ANECS.* 1) Molecular Cancer Epidemiology, QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 2) Mackenzie Cancer Research Group, Department of Pathology, University of Otago, Christchurch, New Zealand; 3) Biostatistics Unit, University of Otago, Christchurch, New Zealand; 4) Centre for Information Based Medicine and the School of Biomedical Science and Pharmacy, University of Newcastle, Newcastle, New South Wales, Australia; 5) Hunter Medical Research Institute, Hunter Area Pathology Service, John Hunter Hospital, Newcastle, New South Wales, Australia; 6) Centre for Clinical Epidemiology and Biostatistics, School of Medicine and Public Health, University of Newcastle, Newcastle, New South Wales, Australia; 7) Department of General Medicine, Hunter Medical Research Institute, John Hunter Hospital, University of Newcastle, Newcastle, New South Wales, Australia; 8) Centre for Information Based Medicine and the School of Medicine and Public Health, University of Newcastle, Newcastle, New South Wales, Australia; 9) Department of Public Health and Primary Care, Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, UK; 10) Department of Oncology, Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, UK.

Current statistics indicate that 1 in 2 individuals will develop cancer in their lifetime. For 5-10% of patients - up to 25% for early onset/familial cases - cancer is shown to be due to "high risk" germline (inherited) mutation in a cancer predisposition gene. However, known cancer syndrome genes do not explain all familial cancer cases e.g. only 30% of breast cancer families are explained by mutations in the *BRCA1/2* "breast-ovarian" cancer genes, and our own data show that only 30% of endometrial cancer patients reporting multiple cancer-affected relatives have mutations in known endometrial-colorectal cancer mismatch repair (MMR) genes. It is increasingly recognised that, in addition to point mutations, rare copy number variations (CNVs) are a significant source of genetic susceptibility to cancer. In fact, pathogenic deletions are found in >40% of known familial cancer syndrome genes including "Lynch syndrome" colorectal-endometrial cancer MMR genes *MLH1, MSH2, MSH6, PMS2*, and also in *BRCA1, BRCA2, PTEN, PTCH1, STK11*. For some cancer syndromes/genes, deletions comprise such a high proportion of mutations that routine testing includes Multiplex Ligation-dependent Probe Amplification (MLPA) to detect structural aberrations. Although genome-wide association studies (GWAS) are principally aimed to assess the association between common single nucleotide polymorphisms and disease risk, the data generated from GWAS platforms can also be used to investigate the role of CNVs in cancer predisposition. While current findings from studies demonstrate CNVs have potential to drive discovery of novel cancer genes, there have been no CNV studies in endometrial cancer to date. We have utilised our published endometrial cancer GWAS of 1,190 cases to identify several rare patient-specific germline gene-disrupting CNVs that are recurrent (present in 4 or more cases and not in an ethnically-matched reference set of over 1,000 controls), which we have validated using quantitative Real-Time PCR. We propose that these CNVs identify novel genes involved in predisposition of endometrial cancer and potentially other cancers.

3254S

Fine-scale mapping of the 12q24 breast cancer susceptibility locus. *K. Michailidou[1], AM. Dunning[2], DF. Easton[1,2], Breast Cancer Association Consortium.* 1) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK; 2) Centre for Cancer Genetic Epidemiology, Department of Oncology, University of Cambridge, Cambridge, UK.

Genome-wide association studies (GWAS) and large scale replication studies have identified more than 80 common loci associated with breast cancer. However, for the majority of these loci the underlying causal genes and variants are unknown. We attempted to define the causal variants underlying one such locus, on 12q24, using dense genotyping of variants on a ~200K custom array (iCOGS), conducted by the Breast Cancer Association Consortium (BCAC). The region contains no RefSeq genes, and is flanked by TBX3, a gene known to be somatically mutated in breast tumours, and MD13L.

Across a 530kb region, 589 variants were genotyped on 48,155 cases and 43,612 controls of European ancestry from 41 studies and 6,269 cases and 6,624 controls of Asian ancestry from 9 studies. Genotypes for a further 4,799 variants were imputed using the 1000 genomes project data as a reference.

We identified 58 variants associated with breast cancer risk at $P<5\times10^{-8}$ in Europeans, the most strongly associated variant being rs1391721 (per-minor allele OR and 95% CI 0.92(0.9-0.94), $P=3.7\times10^{-17}$). rs1391721 is closely correlated with the original GWAS hit, rs1292011. Forward stepwise regression analysis in the region revealed two additional independent variants contributing to the breast cancer risk, at $P<5\times10^{-4}$: rs476780 which lies around 400kb centromeric to the original variant (adjusted OR and 95%CI 0.96(0.94-0.98), $P=8.2\times10^{-6}$), and a 4 base insertion rs200803242 (adjusted OR and 95%CI 1.06(1.03-1.08), $P=2.3\times10^{-4}$). rs1391721 was associated primarily with ER-positive disease (case-only P=0.00013), whereas rs476780 and rs200803242 were associated with both ER-positive and ER-negative disease. Analyses in the Asian samples revealed a significant association for rs1391721 (OR and 95%CI 0.89(0.84-0.94), $P=9.7\times10^{-5}$) but not the other two variants.

For the primary signal rs1391721, we defined a set of 8 variants, spanning a 1.1kb interval, that could not be excluded as causal (iCHAV1: based on a likelihood ratio of 100:1). Of these variants, only rs1391721 lies in in a predicted regulatory region, predicted to be binding site for multiple transcription factors including CTCF and FOXA1 in MCF7 cells based on ENCODE data. These results provide a basis for further analyses to define the causal gene(s) underlying this association.

BACKGROUND. Lynch Syndrome (LS) is characterized by germline mutations in the DNA mismatch repair (MMR) genes: MLH1, MSH2, MSH6 or PMS2. This syndrome is inherited in an autosomal dominant pattern and is characterized by early onset colorectal cancer (CRC) and extra-colonic tumors. The aim of this study was to identify mutations in MMR genes in four Mexican patients with LS. MATERIAL AND METHODS. The study comprised tumor and blood samples obtained from four patients diagnosed clinically with Lynch syndrome at the “Dr. Juan I Menchaca” Civil Hospital of Guadalajara, Jalisco, Mexico. All the patients signed an informed consent. The protein expression was evaluated by immunohistochemical analyses in tumoral tissues. Genomic DNA was extracted from peripheral blood samples for mutation analysis using dHPLC, sequencing and MLPA analysis. RESULTS. Immunohistochemical analyses; LS-23 and LS-41 samples showed the absence of nuclear staining for MLH1, and samples LS-3 and LS-52 showed loss of nuclear staining for MSH2. Germline mutation analysis; One was a substitution at splice donor site, located in first base of intron 18 of MLH1, c.2103+1G>C. Two different sequence variations in exon 16 MLH1 gene were found in the same patient. One allele had a deletion of a codon, c.1852_1854delAAG (p.K618del), and the other was a deletion/insertion of two bases, c.1852_1853delinsGC (K618A) which resulted in a Lysine to Alanine mutation at codon 618. The final sequence variation was a duplication c.638dupT resulting a frameshift in MSH2, exon 3, p.L213fs. No mutations were identified in patient LS-3. CONCLUSION. A compound heterozygous leading to mutation in MLH1 gene and a novel mutation for MSH2 gene are found in Mexican LS patients. REFERENCES 1.Boland CR, Lynch HT. The history of Lynch syndrome. Fam. Cancer. 2013, 12 (2):145-157. 2.Martín-López JV, Fisher R. The mechanism of mismatch repair and the functional analysis of mismatch repair defects in Lynch syndrome. Fam. Deep intronic sequencing of mutation-negative Lynch Syndrom patients. *A.M. Nissen[1,2], M. Morak[1], A. Benet-Pages[2], A. Laner[2], M. Locher[2], E. Holinski-Feder[1,2].* 1) Medizinische Klinik und Poliklinik IV, Klinikum der Universität München, Ludwig-Maximilians-Universität, Munich, Germany; 2) Medical Genetics Center Munich, Munich, Germany.

Lynch Syndrome (LS) is caused by germline mutations in genes involved in the DNA mismatch repair (MMR) pathway, and frequently indicated by a high microsatellite-instability and a protein loss in tumor tissue. The mutation detection rate of pathogenic mutations in our patients with MMR-defects is 65%, in 17% uncertain variants (VUS) were detected, and in 18% no variation was found in routine diagnostics. Hence, for a considerable number of patients with MMR-defects in the tumor and familial tumor clustering in many cases the causative genetic predisposition cannot be identified. We set up a cohort of 71 index patients with MMR-defect with no pathogenic variants/VUS or deletions/duplications in the corresponding gene (MSH2/EPCAM, MSH6, MLH1 or PMS2) detectable by DHPLC mutation screening or Sanger sequencing and MLPA analysis. In order to uncover further pathomechanisms in this cohort we performed deep intronic sequencing of eight genes associated with LS or involved in the MMR pathway (MLH1, MLH3, PMS1, PMS2, MSH2, MSH3, MSH6 and EPCAM). All exons, introns and chromosomal regions far upstream/downstream of the genes were included in the target region, allowing for detection of variants in regulatory regions and chromosomal rearrangements. Library preparation was done with the NEBNext Ultra DNA kit and capture enrichment with the Illumina TruSeq kit. We used paired-end sequencing on an Illumina MiSeq system. Data were analyzed using a bioinformatics pipeline consisting of BWA, Stampy, GATK, SAMtools, Pindel and snpEff. Deep intronic sequencing of the patients revealed no clear pathogenic variants within coding exons and flanking intronic regions of the pre-analyzed genes, except for a single nucleotide frame-shift deletion in MSH2 in one patient which was previously missed by DHPLC. No significant coding variants were found in the additional genes PMS1, MLH3, MSH3 and EPCAM. SNP analysis of the intronic and regulatory regions revealed 19 rare VUS, located in either TF binding sites, miRNAs or may introduce potential intronic splice sites, that are now under investigation for pathogenicity. Rearrangement analysis was first validated on control patients with known rearrangements. We confirmed these results and could reliably detect the exact breakpoints of an inversion in MLH1, a duplication in MSH2 and four deletions in MLH1, PMS2 and MSH6. Rearrangement analysis of the patient cohort with the validated pipeline is currently being performed.

Ephrin Receptor Genotypes Modify Chemotherapy-Induced Peripheral Neuropathy Symptoms: A Candidate Gene Study in Breast Cancer Patients. *K.N.H. Nudelman[1,4], N.R. Zanville[2,4], B.C. McDonald[3], D.J. Smith[3], J.D. West[3], B. Schneider[1,5], V.L. Champion[2,4,5], A.J. Saykin[1,3,5].* 1) Department of Medical and Molecular Genetics, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 2) School of Nursing, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 3) Department of Radiology and Imaging Science, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 4) Training In Research for Behavioral Oncology and Cancer Control Program, Indiana University-Purdue University Indianapolis, Indianapolis, IN; 5) Simon Cancer Center, Indiana University-Purdue University Indianapolis, Indianapolis, IN.

Chemotherapy-induced peripheral neuropathy (CIPN) affects up to 60% of breast cancer patients undergoing chemotherapy. However, work remains to elucidate the etiology of CIPN, including the role that genetic modifiers may play in CIPN symptom (CIPN-sx) onset and severity. Leandro-Garcia et al., 2013, found that SNPs in Ephrin A receptor genes *EPHA4*, *EPHA5*, and *EPHA6* were associated with CIPN in cancer patients treated with taxanes. In addition to replicating this finding, we investigated the association of significant SNPs with different types of CIPN-sx to further clarify the underlying biological mechanism and functional implications. This study utilized data from female breast cancer patients treated with (Ctx+, n=26) and without (Ctx-, n=26) taxanes, assessed at baseline (post-surgery, pre-treatment) and one month post chemotherapy completion. CIPN-sx type and severity was collected with a validated 11-item self-report subscale (FACT/GOG-Ntx). In additional to total score, items are divided into sensory (numbness and tingling), motor, hearing, and functional domains. Candidate SNPs were tested for association with CIPN-sx using PLINK and SPSS. Total CIPN-sx increased in Ctx+ compared to Ctx- (p=0.001); multivariate analysis showed that this signal was driven by significant increases in sensory (p=0.001) and motor (p=0.024) domains. Analysis of 18 Ctx+ white non-Hispanic individuals indicated that SNPs in *EPHA5* (rs1159057, p= 0.020, and rs7349683, p=0.035; in LD, r^2=0.79) were dominantly associated with pre/post change in total CIPN-sx, while *EPHA4* (rs17348202, p= 0.059) showed a trend level association, and *EPHA6* rs301927 (p=0.897) was not associated. Multivariate analysis indicated that six Ctx+ with the rs1159057 common genotype GG had increased scores for sensory (p= 0.022) and motor (p=0.040) CIPN-sx, as well as a trend towards functional CIPN-sx (p=0.079), compared to Ctx+ with GA and AA genotypes. This study replicated the previously demonstrated association of SNPs in *EPHA5* with CIPN, and additionally, rs1159057 was shown to be protective against sensory and motor symptoms. Given the function of Ephrin receptor genes in axonal guidance and repair following injury, and the potential impact of sensory and motor neuropathic symptoms on ability to work post-treatment, these genes may be important targets for future therapeutic development.

3258M

Identification of familial Wilms tumor predisposition genes using whole genome sequencing. *T.B. Palculict[1], E.C. Ruteshouser[1], Y. Fan[2], W. Wang[2], V. Huff[1].* 1) Genetics, MD Anderson Cancer Center, Houston, TX; 2) Bioinformatics and Computational Biology, MD Anderson Cancer Center, Houston, TX.

Wilms tumor (WT), a childhood tumor arising from undifferentiated renal mesenchyme, is diagnosed in North America at a frequency of 1 in 10,000 live births and accounts for 5% of all childhood cancers. The etiology of WT is heterogeneous with multiple genes known to contribute to the development of sporadic WT cases; however, these genes are rarely associated with familial Wilms tumor (FWT). Approximately 2% of WT patients have a family history of WT, which displays an autosomal dominant inheritance pattern and incomplete penetrance, estimated to be 30%. To identify genes that, when mutated predispose to FWT, we used whole genome sequencing of peripheral blood DNA from five individuals in two WT families. Intra-family shared variants were identified and prioritized based on minor allele frequency, expression in fetal kidney and the predicted functional significance of the alteration to protein structure. Our whole genome sequence analysis of three individuals in Family 1 resulted in the identification of a novel germline *DICER1* missense mutation that co-segregates with the affected status. Sanger sequencing data revealed loss of heterozygosity (LOH) in a tumor from one individual in this family. Mutational analysis of this exon in blood samples from members of 47 WT families revealed novel germline *DICER1* mutations that cosegregate in 2/47 families (G803R, R800fs). *DICER1* mutations have previously been reported in three families where WT, as well as other phenotypes of DICER1 Syndrome, are observed. Whole genome sequencing of two members from Family 2 revealed the presence of a 570kb duplication on chr2p, encompassing *NBAS*, *DDX1*, *MYCN* and *MYCNOS*. This duplication was found in 2/47 WT families, co-segregated with the affected status and was absent in all spousal controls. A similar constitutional microduplication was recently reported in a WT family and our data provides strong support for the hypothesis that this germline duplication predisposes to the development of WT. Our results underscore the utility of whole genome sequencing to identify familial predisposition genes, as well as the involvement of *DICER1* and a 570kb chr2p microduplication in the development of FWT.

3259T

The FANCM c.5791C>T nonsense mutation (rs144567652) induces exon skipping and is a risk factor for familial breast cancer. *P. Peterlongo[1,2], I. Catucci[1,2], M. Colombo[2], L. Caleca[2], E. Mucaki[3], F. Damiola[4], L. Bernard[5,6], V. Pensotti[1,6], S. Volorio[1,6], V. Dall'Olio[1,6], A. Kvist[7], H. Ehrencrona[8], S. Mazoyer[4], S. Pizzamiglio[9], P. Verderio[9], P.K. Rogan[3], P. Radice[1,2].* 1) IFOM, Fondazione Istituto FIRC di Oncologia Molecolare, Milan, Italy; 2) Unit of Molecular Bases of Genetic Risk and Genetic Testing, Department of Preventive and Predictive Medicine, Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy; 3) Department of Biochemistry, Schulich School of Medicine and Dentistry, University of Western Ontario, London Ontario, Canada; 4) Cancer Research Centre of Lyon, CNRS UMR5286, INSERM U1052, Université Claude Bernard Lyon 1, Centre Léon Bérard, Lyon, France; 5) Department of Experimental Oncology, Istituto Europeo di Oncologia, Milan, Italy; 6) Cogentech, Cancer Genetic Test Laboratory, Milan, Italy; 7) Department of Clinical Sciences, Division of Oncology, Lund University, Lund, Sweden; 8) Department of Clinical Genetics, University and Regional Laboratories, Lund University and Skane University Hospital, Lund, Sweden; 9) Unit of Medical Statistics, Biometry and Bioinformatics, Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy.

Several genetic factors conferring breast cancer risk are known. However, approximately two thirds of the overall familial risk remains unexplained. It is speculated that a fraction of this missing hereditability is due to rare variants with high to moderate risk. We tested the c.5791C>T nonsense mutation in exon 22 of FANCM, one of the genes involved in the Fanconi Anemia pathway, in 8,635 familial cases and 6,625 controls from different populations and found association with breast cancer risk (OR = 3.93, 95%CI = 1.28-12.11, P = 0.017). Following information theory-based prediction, we showed by transcript analysis that the mutation causes the deletion of exon 22, producing the incorporation of 11 frameshifted residues and the loss of 132 amino acids from the FANCM C-terminus (p.Gly1906Alafs12*). We also showed that this exon skipping is most likely due to the creation of a binding site for the pre-mRNA processing protein hnRNP A1. This is the first report providing robust evidence of a heterozygous loss-of-function mutation of the FANCM gene acting as a risk factor for familial breast cancer.

3260S

The *CDH1* gene as a susceptibility locus for lobular breast carcinoma. *C. Petridis[1,2], I. Shinomiya[1], S. Nowinski[1], I. Tomlinson[3], R. Roylance[4], M.A. Simpson[2], E.J. Sawyer[1].* 1) Research Oncology, Division of Cancer Studies, King's College London, Guy's Hospital, Great Maze Pond, London, SE1 9RT; 2) Medical and Molecular Genetics, King's College London, Guy's Hospital, Great Maze Pond, London, SE1 9RT; 3) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN; 4) Centre for Molecular Oncology, Barts Cancer Institute, Queen Mary, University of London, John Vane Science Centre, Charterhouse Square, London, EC1M 6BQ.

Introduction: Both Invasive lobular breast cancer (ILC) and lobular carcinoma *in situ* (LCIS) are characterised by loss of E-cadherin expression, an adhesion molecule encoded by the *CDH1* gene. While germline *CDH1* mutations have been described in cases of familial ILC associated with diffuse gastric carcinoma (DGC), they are rare in sporadic lobular breast cancer and have not been described in women with LCIS. Common variation at the *CDH1* locus has been associated with colorectal cancer but this association has not been observed in breast cancer to date. **Rare variants:** We sought to address the role of rare loss of function (LoF) *CDH1* variants in ILC/LCIS. We screened *CDH1* in 50 cases with bilateral lobular carcinoma (ILC and/or LCIS) using exome sequencing, Sanger sequencing and MLPA. We found four LoF germline mutations (c.48+1G>A, c.1465insC, c.1942G>T, c.2398delC). None of the four carriers had family history of gastric cancer. We were unable to detect any larger rearrangement in the gene and found no abnormality in any of the remaining cases using MLPA. **Common variants:** Further to the identification of the rare LoF mutations, we evaluated the role of common variants at this locus on ILC/LCIS using genotypic data from the iCOGS platform on 2500 cases and 5000 controls. No association was found in the *CDH1* locus using data from 55 genotyped SNPs on the iCOGs chip. These SNPs were selected to capture the majority of the known common genetic variation at *CDH1*. We have also generated genotypic data for 2500 cases and 1500 controls for rs35187787, which is relatively rare (MAF<1%), not genotyped on the iCOGs chip and predicted to be potentially pathogenic, but found no association (Fisher's exact, p= 0.49). **Conclusion:** We have described *CDH1* germline mutations in women with LCIS for the first time. We have shown that germline *CDH1* mutations are associated with early onset bilateral LCIS with or without ILC in women without a family history of gastric cancer. We have found no common variants in the *CDH1* locus associated with the disease based upon 55 genotyped SNPs. Imputing the 1000 genomes data in the *CDH1* locus, will allow capturing more common variation in *CDH1*. Our data suggest that *CDH1* screening should be considered in early onset (< 50 years) cases of bilateral ILC/LCIS and no family history of DGC in order to identify individuals who may benefit from breast MRI screening and endoscopic surveillance for DGC.

Melanoma Profiler Web Tool for Integrative Genomic Analysis of Melanoma. *K. Qaadri[1], C. Olsen[1], S. Stones-Havas[2], B. Ammundsen[2], A. Trevarton[3], C. Print[3].* 1) Biomatters, Inc., Newark, NJ; 2) Biomatters Ltd. Auckland, New Zealand; 3) University of Auckland, Auckland, New Zealand.

Despite ongoing research, metastatic melanoma five-year survival rates remain low and treatment options limited. Researchers can access a rapidly growing amount of molecular and clinical information about melanoma that may be critical to understanding this disease and making clinically relevant treatment decisions. However, this information is becoming difficult to collate and clinically interpret due to its dispersed nature. Presented here is Melanoma Profiler, a new cloud-based web application for clinically relevant metastatic melanoma genomic research. It performs a tumor/normal comparative variant analysis, comparing proband modified genes and pathways to those in a curated set of characterized melanoma tumor samples. To provide clinical decision support, modified genes and pathways are cross-referenced with clinical and molecular data. These data are incorporated from publicly available sources, including: associations between gene expression and patient survival, data concerning drug targets, biomarkers, and druggability as well as past clinical trials. The resultant MelanomaDB cross-reference database integrates data from cutting edge research on a continuous basis. The interface is presented in two tiers: a front-panel summary tier and an evidential detail tier. For the busy clinician, immediately presented in the summary view is a dynamic report clearly highlighting the relevant actionable information, potential drug targets, and a summary of affected genes and pathways. For researchers that wish to dig deeper, they may browse annotated pathway data, and view a comprehensive comparative summary of affected genes in waterfall and heatmap reports. Melanoma Profiler is a free research tool hosted by Biomatters, produced in collaboration with the University of Auckland, New Zealand. A recent Frontiers in Oncology methods article describing the research behind the application can be found at http://bit.ly/1bUilqS. The Melanoma Profiler web application may be found at https://apps.biomatters.com/melanoma-profiler/.

Development of a Next Generation Sequencing Panel for Clinical Diagnostic Analysis of Breast and Ovarian Cancer. *C. Rapp, A. Nissen, A. Benet-Pages, A. Laner, M. Locher, E. Holinski-Feder.* Medizinisch Genetisches Zentrum - MGZ, Muenchen, Germany.

Breast and Ovarian Cancer (BC, OC) are by far the most common cancers affecting women. Approximately 5-7% of BC and 11-15% of OC are estimated to be caused by germline DNA mutations mainly in the BRCA1 and BRCA2 genes, but mutations in additional genes have been also demonstrated to account for significant cancer risk. Knowing the underlying molecular defect can be very valuable for diagnosis, guiding treatment and estimating recurrence risks. Next generation sequencing (NGS) enables development of high-quality clinical tests for disease diagnosis with fast turnaround times. We developed a comprehensive NGS diagnostic panel including 38 genes relevant for breast and ovarian cancer. In order to increase the diagnostic yield we divided these genes into two subpanels according to both phenotypes. Our NGS diagnostic criteria require that sequencing reaches a medium quality of more than 30 per sequence cycle (detection precision of 99.9%) and that coverage of more than 20 sequences per base pair in at least 98% of the analyzed regions is assured. In addition, for BRCA1 and BRCA2 we achieve the highest level of exactitude for NGS that a lab can offer at the current stage (i.e. 100% sequencing of the coding region and flanking intronic sequences with more than 20 sequences per base pair, and deletion/duplication analysis with MLPA). The NGS platform at MGZ has been validated for diagnostic routing in terms of accuracy, analytical sensitivity, analytical specificity and precision. Up to 24 samples of patients with suspected hereditary breast and/or ovarian cancer are processed weekly on an automated workflow which combines capture enrichment sample preparation (TruSightTM Cancer Panel) with massive parallel sequencing (Illumina MiSeq). Data analysis is performed with a bioinformatics pipeline consisting of BWA, SAMtools, and snpEff. Our preliminary results show that 7.4% of the patients had BRCA1/2 pathogenic mutations and 92.6% were negative or inconclusive. Further analysis of these patients revealed in 13.9% of the cases pathogenic variants (CDH1, CHEK2 and RAD51D genes) and 25% presented inconclusive VOUS (ATM, BRIP1, FANCI, MSH2, PALB2, PMS2, PTEN, RECQL4 and RHBDF2 genes). Still 61.1% of the cases remained unsolved. Some of the genes were identified as causative only once, emphasizing the advantage of diagnostic panels for breast and ovarian cancer testing.

***ABRAXAS* (*FAM175A*) and breast cancer susceptibility: no evidence of association in the Breast Cancer Family Registry.** *A. Renault[1,2], F. Lesueur[1], P. Soucy[2], Y. Hamdi[2], Y. Coulombe[3], S. Gobeil[4], F. Le Calvez-Kelm[5], M. Vallée[5], J.L. Hopper[6], I.L. Andrulis[7], M.C. Southey[8], E.M. John[9,10], J.Y. Masson[3], S.V. Tavtigian[11], J. Simard[2], The Breast Cancer Family Registry.* 1) Curie Institute, Paris, France; 2) Cancer Genomics Laboratory, CHUQ Research Center, Quebec City, Canada; 3) Genome Stability Laboratory, Laval University Cancer Research Center, Quebec City, Canada; 4) CHUQ Research Center, Faculty of Medicine, Laval University, Quebec City, Canada; 5) Genetic Cancer Susceptibility, International Agency for Research on Cancer, Lyon, France; 6) Center for Molecular, Environmental, Genetic and Analytical Epidemiology, School of Population Health, EGA The University of Melbourne, Victoria, Australia; 7) Departement of Molecular Genetics, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada; 8) Genetic Epidemiology Laboratory, The University of Melbourne, Victoria, Australia; 9) Cancer Prevention Institute of California, Fremont, USA; 10) Stanford University School of Medicine and Stanford Cancer Institute, Stanford, USA; 11) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, USA.

Background: Currently, less than 20% of the familial breast cancer can be explained by highly penetrant mutations in the *BRCA1* and *BRCA2* genes. Other breast cancer susceptibility genes conferring a moderate increase in risk have been recently identified. However, approximately 50% of the heritability is still unexplained, suggesting than other susceptibility genes remain to be discovered. DNA double-strand breaks are one of the most damaging events occurring in a cell, as they can disrupt the integrity and stability of the genome. The majority of breast cancer susceptibility genes already identified, including *BRCA1, BRCA2, CHECK2, ATM, BRIP1* and *PALB2*, are involved in the DNA double-strand breaks repair pathway. *ABRAXAS* is involved in this pathway as a member of the “A complex” which leads BRCA1 to DNA damage sites during homologous recombination repair. Mutations in *ABRAXAS* impair BRCA1 recruitment to DNA damage foci and increase cell sensitivity to ionizing radiation. Moreover, a recurrent germline mutation has been reported in Finnish high-risk breast cancer families. To determine if *ABRAXAS* could be a breast cancer susceptibility gene in other populations, we conducted a population-based case-control mutation screening study in the Breast Cancer Family Registry. **Methodology/Principal finding:** The nine coding exons of *ABRAXAS* were screened by High Resolution Melting curve analysis in 1,332 early-onset breast cancer cases and 1,123 controls. Sixteen distinct rare variants were identified, 15 in cases and 11 in controls: of these one was an in-frame deletion, eight were non-synonymous, four were synonymous, two were intronic and one was located in the 5’UTR of the gene. The two variants p.Thr141Ile (found in cases and controls) and p.Gly39Val (found in one case), were predicted to affect protein function, and we confirmed experimentally that both of them diminish phosphorylation of gamma-H2AX, an important DNA damage signaling event. **Conclusion:** Overall, likely damaging or neutral variants were evenly represented among cases and controls suggesting that rare variants in *ABRAXAS* may explain at most a small proportion of hereditary breast cancer.

Association between rare and common variants in DNA repair genes and prostate cancer using the iCOGS genotyping array. *E. Saunders[1], T. Dadaev[1], D. Leongamornlert[1], M. Tymrakiewicz[1], S. Jugurnauth-Little[1], A. Amin Al Olama[2], S. Benlloch[2], R. Eeles[1], Z. Kote-Jarai[1], The PRACTICAL Consortium.* 1) Oncogenetics, Institute of Cancer Research, Sutton, Surrey, SM2 5NG, United Kingdom; 2) Centre for Cancer Genetic Epidemiology, University of Cambridge, Strangeways Research Laboratory, Cambridge, CB1 8RN, United Kingdom.

Prostate cancer (PrCa [MIM 176807]) is the most frequently diagnosed male cancer in developed countries and amongst the leading causes of cancer related death. It is known to have a strong heritable component and so far 77 common, low penetrance susceptibility variants have been identified by genome-wide association studies (GWAS). In addition, a small number of rare variants have been found to give rise to greater risk; the majority of which are in DNA repair genes. We previously genotyped 211,155 SNPs on a custom chip (iCOGS) in blood DNA from 21,780 PrCa cases and 21,727 controls of European ancestry from the international PRACTICAL consortium. These SNPs were selected predominantly to evaluate previous suggestive low penetrance associations, to finemap validated associations, or to evaluate candidate genes and pathways. In this study we have analysed the association between common and rarer variants in DNA repair genes and PrCa. The iCOGS chip contained 9,192 SNPs within 10kb of a widely recognised DNA repair gene and at 7 of the 77 known PrCa susceptibility loci these were also significantly associated with risk (Chr3 - *RUVBL1*; Chr5 - *FGF10*; Chr9 - *RAD23B*; Chr11 - *CCND1*; Chr14 - *RAD51B*; Chr20 - *RTEL1*; Chr22 - *BIK*). These may therefore represent potential candidate genes for the aetiology of prostate cancer risk. No statistically significant associations with risk were observed for any of the rare variants (predominantly BRCA1/2 missense SNPs) submitted on the iCOGS chip. We also investigated association between DNA repair gene variants on the iCOGS array and phenotypic characteristics of PrCa; to examine whether any of these variants could modulate risk towards developing aggressive, younger onset or familial disease, rather than increasing the risk of developing PrCa *per se*. We observed several potential associations between low frequency variants in multiple genes and the likelihood of nodal spread or metastases (*ATM*, *FANCL*, *RAD51B*, *RAD54L*, *XRCC3*) but found limited evidence for association with other variables such as age of diagnosis, family history of PrCa, PSA levels or tumour stage.

3265T

Frequency of novel and known deleterious germline variants in rhabdomyosarcoma and neuroblastoma by next-generation sequencing. *D.R. Stewart[1], R. Patidar[2], J. Shern[2], S. Zhang[2], T. Pugh[3], S.J. Diskin[4], S. Sindiri[2], Y.K. Song[2], H. Liao[2], J. Wang[2], S.X. Skapek[5], F.G. Barr[6], R.C. Seeger[7], J.M. Maris[4], D. Hawkins[8], J. Khan[2], J.S. Wei[2].* 1) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 2) Oncogenomics Section, Genetics Branch, Center for Cancer Research, National Cancer Institute, Bethesda, MD; 3) Clinical Genomics Research Program, Princess Margaret Cancer Centre, Toronto, Canada; 4) Children's Hospital of Philadelphia, Philadelphia, PA; 5) UT Southwestern Medical Center, Dallas, TX; 6) Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, Bethesda, MD; 7) Children's Hospital Los Angeles, Los Angeles, CA; 8) Seattle Children's Hospital, Seattle, WA.

INTRO Outside familial syndromes, the pathogenesis of rhabdomyosarcoma (RMS) and neuroblastoma (NB) remains obscure. We sought to identify rare deleterious germline variants that may play a role in the initiation of sporadic RMS and NB. **METHODS/RESULTS** We investigated two cohorts consisting of RMS (n=133) and NB (n=222) patients; the NB data is from the TARGET initiative. We first called high-quality protein-coding changing single nucleotide variants (SNVs) in both paired germline and tumor DNA from the Illumina, SOLiD and CGI platforms (exome and whole-genome sequencing). We excluded variants with minor allele frequency (MAF) > 0.01 in 1000G or NHLBI ESP to yield 56,336 germline variants. To find the most deleterious variants, we filtered for a C-score >= 20 (top 1%) using CADD, a method to integrate many diverse bioinformatics predictions (SIFT, PolyPhen, conservation) into a single score. We then binned variants in 3 categories: 1) variants in known cancer genes and select human syndromes (n = 177), 2) variants reported in >= 3 tumors from TCGA and our somatic NB and RMS data (n = 116), and 3) variants not known to be cancer-associated, have ESP MAF = 0 and a germline variant allele count of 2-8 in our data (n = 159). Of the resulting 446 SNVs (6 variants overlapped categories), we picked the 20 most-frequent and 198 random SNVs for Sanger verification sequencing. Out of the 305 verification sequencing reactions, no DNA was available for 121 sequencing reactions. Of the 184 sequencing reactions, 2 failed PCR, and the verification rate equaled 97%; none of the TARGET NB samples had a false positive. Of the 446 SNVs, there were 2/133 (1.5%) germline variants in 2 known RMS-associated genes (*TP53*, *CTCF*) and 10/222 (4.5%) germline variants in 4 known NB-associated genes (*ALK*, *NF1*, *PINK1*, *BARD*). We also observed 3/133 (2%) germline *ALK* variants in 3 patients with RMS and 1/222 (each) germline *TP53* and *BUB1B* variants in 2 NB patients. Known reported somatic mutations in NB with germline variants in NB patients included *NRAS* (1/222, 0.5%) and *VANGL1* (4/222, 2%). Known reported somatic mutations in RMS with germline variants in RMS patients included *FGFR4* (1/133, 1%) and *BCOR* (1/133, 1%). We also observed predicted deleterious germline variants in *SDHB* (NB), *DICER1* (NB), *ERCC2/3/4* (NB and RMS) and *TSC1/2* (NB and RMS). **CONCLUSION** In this high-quality dataset using stringent filtering, we found multiple novel germline variants associated with NB and RMS.

3266S

A recurrent germline mutation in the splicing factor *SRRM2* gene is implicated in papillary thyroid cancer predisposition. *J. Tomsic[1], H. He[1], K. Akagi[1], S. Liyanarachchi[1], Q. Pan[2], B. Bertani[1], R. Nagy[3], D. Symer[1,3,4], B. Blencowe[2,5], A. de la Chapelle[1].* 1) Department of Molecular Virology, Immunology and Medical Genetics, The Ohio State University, Columbus, OH, USA; 2) Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada; 3) Department of Internal Medicine, The Ohio State University, Columbus, OH, USA; 4) Department of Biomedical Informatics, The Ohio State University, Columbus, OH, USA; 5) Department of Molecular Genetics, University of Toronto, Toronto, Canada.

Purpose: Papillary thyroid carcinoma (PTC) is highly heritable, but the few predisposing genes identified until now account for relatively few cases. In this study we identified a candidate gene for PTC risk via next generation sequencing in PTC families. **Patients and Methods:** Next generation sequencing was used on two affected individuals from each of seven PTC families. Whole exome sequencing was carried out using HiSeq 2000 platform and the Illumina Genome Network (IGN; http://www.illumina.com) after exome enrichment. The Illumina short reads were aligned using Burrows-Wheeler Transform and genomic variants were called using Samtools/BCFtools. Several candidate DNA variants were tested in further PTC patients and controls. Linkage analysis was performed in the same families. Functionality of the most highly ranked candidate DNA variant was tested. **Results:** Whole exome sequencing, linkage analysis and population studies identified the serine/arginine repetitive matrix 2 gene (*SRRM2*) as a strong-appearing candidate gene in one family. The heterozygous missense mutation c.1037C→T (Ser346Phe) cosegregated with PTC in the family and was not found in 132 other families. The variant occurred in 7/1170 sporadic PTC cases and in 0/1404 controls (p=0.004). *SRRM2*, also known as *SRm300*, is part of the splicing machinery. The effect of the missense mutation on alternative splicing (AS) was tested using RNA-Seq on RNA extracted from blood cells. Significant differences in AS occurred in numerous genes between three unrelated mutation carriers and three controls. In a limited number of genes the RNA-Seq results were verified experimentally using RT-PCR demonstrating a higher ratio of inclusion of exons in RNA from carriers of the S346F mutation. **Conclusions:** Our data suggest that *SRRM2* is a candidate gene for PTC susceptibility. SRRM2 S346F is a rare, medium-penetrance mutation affecting alternative splicing.

BCL7B functions as a tumor suppressor in the Wnt signaling pathway. *T. Uehara[1], E. Kage-Nakadai[1], S. Yoshina[1], R. Imae[1], S. Mitani[1,2].* 1) Physiology, Tokyo Women's Medical University, Tokyo, Japan; 2) Tokyo Women's Medical University Institute for Integrated Medical Sciences, Tokyo, Japan.

Introduction; Cytogenetic abnormalities of chromosome 7 occur frequently in patients with cancer. Although some of the genes located on chromosome 7 are thought to act as tumor-related genes, little is known about the details of them. Williams-Beuren syndrome (WBS) is one of the most well-known diseases related to chromosome 7 microdeletions and thought to be at an increased risk of malignant transformation due to aberrations in candidate genes, such as *BCL7B*. However, there is a little knowledge regarding the specific functional roles of *BCL7B*. Here, we analyzed the functional significance of *BCL7B* in KATOIII human gastric cancer cells and its homolog in *Caenorhabditis elegans* (*C. elegans*). **Methods**; First, to analyze the function of *bcl-7*, which is the homolog of *BCL7B* in *C. elegans*, we generated a *bcl-7* deletion mutant, and observed and analyzed its phenotype. As a result, we found that *bcl-7* is required for the asymmetric differentiation of epithelial "stem-like" seam cells through the WNT pathway. This result suggested that BCL-7 functions as a negative regulator of the WNT pathway in *C. elegans*. In addition, *bcl-7*-deletion mutants exhibited nuclear enlargement, which was reminiscent of the anaplastic features of malignant cells. Second, to analyze the function of *BCL7B* in human cell line, we used KATOIII cells, which were derived from gastric signet-ring cell cancer and expressed only *BCL7B* of the *BCL*7 family members. As a result, *BCL7B*-knockdown induced nuclear enlargement, as observed in *C. elegans*, and promoted the multinuclei phenotype. Moreover, we showed that RNA levels were increased in the cells with enlarged nuclei. *BCL7B* knockdown also suppressed cell death by inhibiting the apoptotic pathway. In addition, our study showed that *BCL7B* negatively regulates the WNT-signaling pathway in KATOIII cells similar to that in *C. elegans*. **Results and Discussion**; In conclusion, we investigated the functional role of *bcl-7*/*BCL7B* genes in WNT signaling in *C. elegans* and in human gastric cancer cells. Additionally, human *BCL7B* may function as a negative regulator of Wnt signaling and a positive regulator of apoptosis in KATOIII cells. Furthermore, this study revealed that BCL-7/BCL7B is also involved in the mechanisms of nuclear enlargement, which is an important signature of malignancy. Collectively, our data suggests that the members of the BCL7 family and their homologous proteins may function as tumor suppressors by affecting multiple pathways.

Investigating the genetic basis of multiple primary tumors. Clinical and gene panel analyses. *J. Whitworth[1,2], J. Hoffman[1], AB. Skytte[3], ER. Maher[1,2,4].* 1) Clinical Genetics, Birmingham Women's Hosptial, Birmingham, United Kingdom; 2) Medical Molecular Genetics, University of Birmingham, Birmingham, United Kingdom; 3) Clinical Genetics, Aarhus University Hospital, Aarhus, Denmark; 4) Medical Genetics, University of Cambridge, Cambridge, United Kingdom.

Multiple primary malignant tumors (MPMT) are frequently taken as an indicator of potential inherited cancer susceptibility and occur at appreciable frequency both among unselected cancer patients and referrals to cancer genetics services. Analysis of a referral based series of 212 MPMT cases showed that only around 40% of those who underwent genetic testing and 20% of referrals overall were identified as having a pathogenic germline variant conferring predisposition to malignancy. Comparison of individuals who tested positive and negative revealed considerable overlap between the two groups with respect to clinical characteristics indicative of an inherited cancer syndrome, suggesting that many of the latter group also have a genetic basis. Analysis of PTEN and TP53 by Sanger sequencing, however, did not reveal any significant variants. Failure to detect a causative mutation may result from mosaicism for a mutation in a known inherited cancer gene, an unusual phenotype that leads to the relevant gene being overlooked or mutation in a novel inherited cancer gene. To address these possible explanations, next generation sequencing techniques are being applied to blood samples from an expanded series of mutation negative MPMT cases (≥2 cancers diagnosed before 60 years) ascertained through clinical genetics services. Initial analysis is being performed using a panel of 94 known inherited cancer genes. Results from the first 63 samples produced 309 variants, 10 of which could be assigned as pathogenic in the heterozygous state based on literature review and predicted effect. These 10 variants were identified among 8 cases (12.7%) and all but one was associated with a characteristic tumor. One case harboured three separate mutations in SDHC, FLCN and NF1, all of which were penetrant. In silico predictions revealed multiple further variants as potentially causative of the patient's phenotype. Individuals not identified with explanatory variants through panel analysis are being entered into a study conducting whole genome sequencing with the aim of identifying potential novel inherited cancer genes with subsequent functional validation. A sequencing dataset from large heterogeneous series such as this should provide opportunity for analysis of multiple phenotypic subsets and allow for potential pleiotropic effects of unidentified genes relevant to cancer predisposition.

3269S

Characterization of T gene sequence variants and germline duplications in familial and sporadic chordoma. *R.X. Yang[1], M.J. Kelley[2,3], J. Shi[1], B. Ballew[1], P.L. Hyland[1], W-Q. Li[1], M. Rotunno[1], D.A. Alcorta[2], N.J. Liebsch[4], J. Mitchell[5], S. Bass[5], D. Roberson[5], J. Boland[5], M. Cullen[5], J. He[5], L. Burdette[5], M. Yeager[5], S.J. Chanock[1], D.M. Parry[1], A.M. Goldstein[1].* 1) Division of Cancer Epidemiology & Genetics, NCI/NIH, Bethesda, MD; 2) Department of Medicine, Duke University Medical Center, Durham, NC; 3) Durham Veterans Affairs Medical Center, Durham, NC; 4) Department of Radiation Oncology, Massachusetts General Hospital, Boston, MA; 5) Cancer Genomics Research Laboratory, SAIC-Frederick, Inc., Bethesda, MD.

Background Chordoma is a rare bone cancer that is believed to originate from notochordal remnants. We previously identified germline T duplication as a major susceptibility mechanism in several chordoma families. Recently, a common genetic variant in T (rs2305089) was significantly associated with the risk of sporadic chordoma. Methods We sequenced all T exons in 24 familial cases and 54 unaffected family members from eight chordoma families (three with T duplications), 103 sporadic cases, and 160 unrelated controls. We also measured T copy number variation in all sporadic cases. Results We confirmed the association between the previously reported variant rs2305089 and risk of familial (odds ratio [OR]=2.6, 95% confidence interval [CI]=0.93, 7.25, P=0.067) and sporadic chordoma (OR=2.85, 95%CI=1.89, 4.29, P<0.0001). We also identified a second common variant, rs1056048, that was strongly associated with chordoma in families (OR=4.14, 95% CI=1.43, 11.92, P=0.0086). Among sporadic cases, another common variant (rs3816300) was significantly associated with risk when jointly analyzed with rs2305089. The association with rs3816300 was significantly stronger in cases with early age-onset. In addition, we identified three rare variants that were only observed among sporadic chordoma cases, all of which have potential functional relevance based on in silico predictions. Finally, we did not observe T duplication in any sporadic chordoma case. Conclusions Our findings further highlight the importance of the T gene in the pathogenesis of both familial and sporadic chordoma and suggest a complex susceptibility related to T.

3270M

Exome sequencing identified potential causative candidate genes for hyperplastic polyposis syndrome. *S. Aretz[1], C. Trueck[1], J. Altmueller[2,3], S. Horpaopan[1], P. Hoffmann[1,4,5], H. Thiele[2,3], I. Spier[1].* 1) Institute of Human Genetics, University Hospital Bonn, Bonn, Germany; 2) Cologne Center for Genomics, University of Cologne, Germany; 3) Institute of Human Genetics, University of Cologne, Germany; 4) Department of Genomics, Life & Brain Center, University of Bonn, Germany; 5) Division of Medical Genetics, University Hospital Basel; Department of Biomedicine, University of Basel, Basel, Switzerland.

Purpose: Hyperplastic polyposis syndrome (HPS), also known as serrated polyposis syndrome (SPS), is a yet poorly defined colorectal cancer (CRC) predisposition characterized by the occurrence of multiple and/or large serrated lesions throughout the colon. A serrated polyp-CRC sequence (serrated pathway) has been postulated, however, to date, only few molecular signatures of serrated neoplasia were described and neither the etiology of the syndrome nor the distinct genetic alterations during tumorigenesis have been identified. Methods: To uncover predisposing causative genes, the exomes of 11 unrelated and clinically well characterized HPS patients with sporadic appearance were sequenced (Illumina HiSeq platform). The variants were filtered for rare truncating germline mutations assuming a monogenic disease model. For data analysis and variant filtering the GATK software and in-house tools (VARBANK pipeline) were applied. Results: Altogether, 261 rare truncating germline variants were found. After stringent filtering steps including quality scores, the comparison with large datasets from population-based controls, detailed manual investigations of the variants and data mining according to functions and pathways, 139 unique variants in 136 genes remained. Of those, six genes were affected by biallelic variants (recessive model) in at least one patient and 19 genes by heterozygous variants (dominant model) in at least two patients. The majority of these genes is supposed to be associated with cancer or is involved in molecular and cellular functions related to tumorigenesis such as DNA repair, apoptosis, or cell proliferation. Another 53 genes, which are affected by heterozygous variants in only one of the patients, are regarded as interesting candidates according to functional scores and known somatic mutations in cancer. Conclusions: Using exome sequencing we identified several potentially causative genes for HPS. The further work-up includes the validation of all variants by Sanger sequencing and pathway analyses. The clinical relevance of the genes will be clarified in a cohort of another 20 HPS patients.

3271T

Identification of the frequent hereditary cancer mutations in high-risk non-BRCA breast cancer patients from Puerto Rico. *J. Dutil[1], J.K. Teer[2], S.J. Yoder[2], J.L. Matta[3], A. Monteiro[4].* 1) Biochemistry Dpt, Ponce School of Medicine & Health Sciences, Ponce, PR; 2) Dpt of Biomedical Informatics, Moffitt cancer Center, Tampa, FL; 3) Physiology and Pharmacology Dpt, Ponce School of Medicine & Health Sciences, Ponce, PR; 4) Dpt of Cancer Epidemiology, Moffitt Cancer Center, Tampa, FL.

Approximately 5-10% of all breast cancers are caused by mutations in highly penetrant susceptibility genes, such as BRCA1 and BRCA2. Deleterious mutations in genes such as PTEN, p53, CHEK2, ATM, NBS1, RAD50, BRIP1 and PALB2 also confer moderate to high risk of breast cancer, and together with BRCA1 and BRCA2, they may explain up to 50% of breast cancer risk. Hispanics make up 16.3% of the population, and accounted for 56% of the national growth between 2000 and 2010. Yet, these populations are often underrepresented in genetics studies. Our previous work has shown that the BRCA mutation spectrum underlying hereditary breast cancers in Puerto Rico is distinct from that of other Hispanic populations such as Mexican Americans. Our objective was to identify the common germline mutations underlying non-BRCA breast cancer in the Hispanic population from Puerto Rico. Thirty-two breast cancer patients that met the clinical criteria for BRCA testing but had received a negative BRCA1/2 result were recruited in this study. Exons and intron-exons junctions of 40 tumor suppressor genes that have been previously implicated in hereditary cancer predisposition were captured using the BROCA cancer risk panel. Massively parallel sequencing was performed on an Illumina MySeq platform. A total of 5,846 variants were identified within the targeted gene regions. Each patient carried on average 72 coding variants, which included 41 synonymous variants and 31 non-synonymous variants. Work is underway to prioritize variants according to their likelihood of being a causative deleterious mutation. Our findings may uncover genetic changes specific to this population that will allow for the development of custom-designed predisposition tests, taking into account natural differences in populations to maximize the identification of individuals at risk.

3272S

Deleterious mutations in multiple cancer-risk genes in individuals from a high-risk cancer genetics clinic. *C.M. Laukaitis[1,2], C. Mauss[2], M. Urquijo[2,3], A. Chaudhury[1], K. Maher[1,2], J. Jeter[1,2].* 1) Department of Medicine, University of Arizona College of Medicine, Tucson, AZ; 2) University of Arizona Cancer Center, Tucson, AZ; 3) Departamento de Medicina, Universidad de Sonora, Hermosillo, Sonora, Mexico.

The widespread use of massively-parallel next generation sequencing (NGS) technology has led to surprising findings. We are using NGS to identify inherited genetic changes predisposing to cancer in people cared for by the University of Arizona Cancer Center high-risk cancer genetics clinic. Under an IRB-approved research protocol, we sequenced a custom panel of 104 cancer-related genes in blood samples from 48 individuals. This was a heterogeneous population containing both patients who were diagnosed with cancer and people without a personal history of cancer but with a strong cancer family history. Surprisingly, 6 individuals (12.5 percent) carried clearly deleterious mutations in multiple genes linked to increased cancer risk. While 35 percent of the cohort has been diagnosed with cancer, five of six people with multiple deleterious mutations have had cancer ($p = 0.017$). Individual mutations are being validated by Sanger sequencing. Additional clinical characteristics (participant age, function of mutated genes, type of cancer, family history of cancer, type of cancer treatment) are being evaluated to identify associated characteristics in order to determine whether this evidence of genomic instability is the cause or an effect of the cancer diagnosis.

3273M

Whole exome sequencing to identify novel breast cancer susceptibility genes. *K.N. Maxwell[1], J. Vijai[2], K. Schrader[2], L. Guidugli[3], S. Hart[3], T. Thomas[2], X. Wang[3], B. Wubbenhorst[4], S.M. Domchek[1], M.E. Robson[5], S. Neuhausen[6], K. Offit[2], C. Szabo[7], J. Weitzel[6], K.L. Nathanson[4], F.J. Couch[3].* 1) Department of Medicine, Division of Hematology-Oncology, University of Pennsylvania, Philadelphia, PA; 2) Clinical Genetics Research Lab, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 4) Department of Medicine Division of Translational Medicine and Genetics, University of Pennsylvania, PA; 5) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 6) Beckman Research Institute of City of Hope, Duarte, CA; 7) National Institutes of Health.

Over 50% of the familial relative risk of breast cancer is unexplained by currently identified common low risk polymorphisms and rare moderate to high risk alleles in genes such as BRCA1/2. Early identification of the individuals with an inherited susceptibility to breast cancer may lead to enhanced screening and prevention strategies and the opportunity for targeted therapies of associated cancers. In order to identify novel genes which confer an inherited risk to breast cancer, whole exome sequencing was undertaken in 333 BRCA1/2 negative individuals with at least one primary breast and ovarian cancer or with high-risk familial breast cancer, defined as a proband and at least two first or second degree relatives with breast cancer. Samples included 256 individuals from 109 families and 77 unrelated individuals, for a total of 186 independent cases. Data were first analyzed for identification of rare mutations in 49 cancer susceptibility genes. Eight independent cases (4.3%) were found to carry deleterious mutations in high penetrance cancer susceptibility genes, namely TP53, CDH1, MSH6, and CDKN2A. In addition, sixteen of 186 independent cases (12.3%) were found to have deleterious mutations in other breast and/or ovarian cancer predisposition genes, namely ATM, CHEK2, PALB2, BARD1, RAD51D, RAD50, and MRE11A. For novel cancer susceptibility gene discovery, whole exome data was harmonized from three separate sites into a single vcf file for variant filtering and analysis. Two major methodologies were used to select genes for further study, a candidate gene approach and an agnostic gene ranking approach. In the candidate gene approach, genes matching either specific gene ontologies or those identified by published somatic tumor studies were queried for the presence of rare deleterious mutations in the dataset. In the agnostic gene ranking approach, genes were ranked based on the frequency of specific types of variants in the dataset versus population estimates and the level of segregation of these rare variants in families. These methodologies identified 636 candidate cancer susceptibility genes in the discovery exome set. These genes will be evaluated by a targeted sequencing approach in a validation set of over 2000 individuals with familial breast cancer. Overall, our data demonstrate a significant level of heterogeneity in the genetic basis of familial breast cancer in BRCA1/2 negative individuals.

3274T

Germline epigenetic inactivation of BAP1 in a subset of patients with uveal melanoma. *R. Pilarski[1], G. Boru[2], O.H. Saqr[2], K. Rai[1], J.B. Massengill[2], C.M. Cebulla[2], M.H. Abdel-Rahman[1,2,3].* 1) Dept of Internal Medicine and Comprehensive Cancer Center, Ohio State Univ, Columbus, OH; 2) Dept of Ophthalmology, Ohio State Univ, Columbus, OH; 3) Dept of Pathology, Menoufiya Univ, Egypt.

Objective: To identify the frequency of germline deletions and/or epigenetic inactivation in BAP1 in uveal melanoma (UM) patients with high risk for BAP1 tumor predisposition syndrome (TPDS) but no detectable mutation. Methods: Twenty three UM patients with high-risk for BAP1 TPDS, including 12 UM patients with family history of UM, one UM patient with bilateral disease and 10 UM patients with personal or family history of renal cell carcinoma (RCC), were studied. Constitutional decrease in BAP1 mRNA expression was assessed in an additional 17 UM patients with available non-tumor choroidal tissue. Germline copy number variation was studied by Multiplex Ligation-dependent Probe Amplification (MLPA). Methylation specific PCR and pyrosequencing was used to assess germline promoter hypermethylation. The expression of BAP1 mRNA was carried out utilizing quantitative RT-PCR. Results: No germline CNV or significant promoter methylation was detected in any of the 23 patients with high-risk for BAP1 TPDS. Two out of the 17 non-tumor choroidal tissues showed significant decreases in BAP1 expression compared to normal controls, but no germline CNV or aberrant promoter methylation were identified. Conclusion: Epigenetic inactivation of BAP1, through mechanisms other than promoter hypermethylation, could be responsible for germline constitutional inactivation of BAP1 in a subset of UM patients. Copy number variation is not a major mechanism for germline inactivation of BAP1. Our results have important implications for designing clinical assays for detection of BAP1 germline inactivation in patients at risk for the BAP1 TPDS.

Integrating Whole Genome and Exome Sequencing with Structural Variation Analysis to Identify Potential Causative Mutations in Patients with Cancer Phenotypes Suggestive of Li-Fraumeni Syndrome. *D.I. Ritter[1,2], B. Powell[2], J. Bojadzieva[3], D.A. Wheeler[1,2], R. Gibbs[1,2], L.C. Strong[3], S.E. Plon[2,4].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Cancer Genetics, University of Texas MD Anderson Cancer Center, Houston, TX; 4) Department of Pediatrics, Texas Children's Cancer Center, Baylor College of Medicine, Houston, TX.

While mutations in *TP53* explain ~70% of the inherited cancer condition Li-Fraumeni Syndrome (LFS), a sizeable fraction of families or individuals with cancer phenotypes suggestive of *TP53* mutations remains unexplained. To identify additional candidate genes underlying cancer phenotypes suggestive of LFS, we applied an integrative analysis of whole exome rare coding variants with whole genome structural variants (SV) and copy number variation (CNV) for 27 subjects who were negative for mutations in *TP53*, including family members when available (four kindreds). Probands demonstrated (1) childhood sarcoma and at least one additional primary malignancy by age 40 or (2) a rare childhood cancer with at least one first-degree relative with a rare cancer. Whole exome sequence data (VCRome2.1) were analyzed for rare heterozygous single nucleotide variants (SNVs) and insertions/deletions (INDELs), encoding missense, nonsense, frameshift and splice variants. We eliminated variants >1.5% in 1079 unaffected normal samples, and >1% dbSNP minor allele frequency. Variants were limited to those shared among affected family members, when available. We applied a proportions test to variants in genes and exons against 100 random controls. To identify structural variants, we applied complementary algorithms of insert-size (Breakdancer) and soft-clip stacking (CREST). We used an empirical annotative filtering strategy against normal, unaffected whole genomes. Structural variants were progressively clustered to identify recurrence and CNVs. We prioritized SV events in genes harboring rare variants, interrupting coding regions, introns or <=10kb of genes. We identified 110 unique genes harboring rare coding variants that affect >=4 independent families. The top genes of interest are *TEP1* (gene: p=3.6E-3, exon 30: p=0.02) and *ATR* (gene: p=0.02, exon38 p=4.9E-4). We found no rare coding SNVs or INDELS within *TP53*, nor in *CHEK2*, a gene known to be mutated in a subset of LFS phenotypes. We found no evidence for SV within 1MB of either of these genes. We have identified multiple additional regions of rare SVs and CNVs affecting alternative genes, and are combining these results with exome variant data. With this effort, we aim to identify additional genetic causes for pediatric inherited cancer syndromes with phenotypes suggestive of Li-Fraumeni. Supported by RP10189 from CPRIT and R01-CA138836 to SEP, and K12GM084897 from IRACDA to DIR.

Causative novel POLE mutations in hereditary colorectal cancer syndromes. *A.M. Rohlin[1], T. Zagoras[1], F. Eiengård[1], Y. Engwall[1], S. Nilsson[2], U. Lundstam[3], J. Björk[4], G. Karlsson[5], M. Nordling[1].* 1) ,Institute of Biomedicine, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden; 2) Mathematical Sciences, Chalmers University of Technology, Gothenburg, Sweden; 3) Department of Surgery, Sahlgrenska Academy at University of Gothenburg, Sahlgrenska University Hospital/Östra, Gothenburg, Sweden,; 4) The Swedish Polyposis Registry, Department of Medicine, Karolinska Institute, Stockholm, Sweden,; 5) The Swedish NMR-centre, University of Gothenburg, Gothenburg, Sweden.

Background: In Familial Adenomatous Polyposis (FAP) it is today possible to find almost all of the disease-causing mutations. However, in patients with a more attenuated phenotype (AFAP) with less than 100 polyps only a fraction of the disease-causing mutations can be identified. The low detection rate implicates the probable presence of additional disease-causing genes still to be identified. FAP is caused by autosomal dominantly inherited mutations in the APC (Adenomatous polyposis coli) gene. In AFAP families 20%-30% of the patients have a germline APC mutation. Recently a new CRC syndrome, polymerase proof reading associated polyposis (PPAP) was described. This syndrome is characterized by a dominantly inherited predisposition to the development of a variable number of colorectal adenomas and carcinomas [1] The aim of this study was to sequence the exonuclease domain of POLE in 88 index patients with a familial history of polyposis or non-polyposis and/or early onset CRC that had previously tested negative for mutations in APC, MUTYH and/or mismatch-repair genes MSH2, MLH1, MSH6 and PMS2. Method: In one large family exome sequencing was performed on four family members and for the remaining 87 index patients mutation screening by Sanger sequencing of POLE exonuclease domain (ex 3-14) was conducted. Results and Conclusion: We have identified two novel mutations in the exonuclease domain of POLE. The first mutation was identified from exome sequencing in a large Swedish family with CRC. The POLE: c.1089C>A, p.Asn363Lys mutation is directly involved in DNA binding. Family members carrying this mutation demonstrate a high penetrant predisposition not only to CRC but also to extra-intestinal tumours such as ovarian, endometrial and brain tumours [2]. The second mutation located in POLE: c.1274A>G, p.Lys425Arg was found in a patient with early onset CRC. Theoretical prediction of the amino acid substitution suggests a profound effect of the substrate binding capability and a severe impairment of the catalytic activity for both these mutations, which strongly suggest a pathogenic nature of these mutations. Screening the proofreading domains of POLE should be considered in routine genetic diagnostics in families with hereditary CRC. 1.Palles C, Nature genetics 2013, 45(2):136-144. 2.Rohlin A, International journal of oncology 2014, 45(1):77-81.

3277T

Parental Inheritance and *WT1* Abnormality Types May Affect the Penetrance Rate of Hereditary Wilms Tumor. *Y. Kaneko[1], H. Okita[2], M. Haruta[1], Y. Arai[3], T. Oue[4], T. Koshinaga[5], M. Fukuzawa[6], Japan Wilms Tumor Study Group.* 1) Research Institute for Clinical Oncology, Saitama Cancer Center, Ina, Saitama; 362-0806 Japan; 2) National Institute for Child Health and Development; Hematology/Oncology; 2-10-1, Ohkura, Setagaya-ku, Tokyo; 157-0074; 3) National Cancer Center Research Institute; 5-1-1 Tsukiji, Chuo-ku, Tokyo; 104-0045; 4) Osaka University Graduate School of Medicine; 2-15 Yamadaoka, Suita, Osaka; 565-0871; 5) Nihon University; 30-1 Ohyaguchi-Kamimachi, Itabashi-ku, Tokyo 173-8610; 6) Osaka Medical Center and Research Institute for Maternal and Child Health; 840 Murodo-machi, Izumi, Osaka 594-1101.

Background: Wilms tumor (WT) is a genetically heterogeneous disease which arises from developmental kidney. The percentages of hereditary WT are unknown, and only some hereditary WTs are thought to be caused by a germline mutation in *WT1*. *IGF2* is an imprinted gene expressed by the paternal allele. Both *WT1* and *IGF2* genes are located on the short arm of chromosome 11 (11p), and uniparental disomy (UPD) on 11p was found in 30-40% of WT, and regularly accompanied by maternal allele loss and paternal allele duplication. The inheritance of *WT1* mutations has been poorly studied in familial WTs, although carriers with *WT1* mutations are now increasing because multidisciplinary therapies have improved the survival rates of patients with bilateral WTs and those with a unilateral WT with a germline *WT1* mutation. We examined the statuses of *WT1* and *IGF2* in bilateral and familial WTs in Japan, and summarized the present and previous findings on the penetrance rate for children who inherited various types of *WT1* abnormalities from their fathers or mothers, or had *de novo WT1* abnormalities that occurred in the paternal or maternal germ cell. **Results:** We detected *WT1* abnormalities in 25 (81%) of 31 patients with bilateral WTs and 2 of 2 families with hereditary WT. Of 35 WTs from the 25 patients, 31 had duplications of a small *WT1* mutation and paternal *IGF2* caused by 11p UPD, while 4 had large deletions in one *WT1* allele and small mutations or deletions in the other with the retention of 11p heterozygosity. The high incidence of *WT1* abnormalities in bilateral WTs in Japan sharply contrasts with the lower incidence in America (27%). The penetrance rate was shown to be 100% if children inherited small *WT1* mutations from their fathers, and 67% if inherited the small mutations from their mothers, or inherited 11p13 deletions or had *de novo* 11p13 deletions irrespective of parental origin (P=0.057). The duplication was identified in most WTs with small *WT1* mutations of paternal origin, but not in WTs with large 11p13 deletions irrespective of parental origin. **Conclusion:** We hypothesize that individuals who inherited small *WT1* mutations from their fathers may be more likely to develop WT due to the expressing *IGF2* than those who inherited small mutations from their mothers or inherited large 11p13 deletions or had *de novo* large deletions irrespective of parental origin. These findings may be useful for the genetic counseling of individuals who may inherit *WT1* mutations.

3278S

Functional characterization of the 19p13 breast and ovarian cancer risk locus identifies *ABHD8* as a novel candidate breast-ovarian cancer susceptibility gene. *J. Beesley[1], K. Lawrenson[2], K. Kuchenbaecker[3], S. Kar[3], Q. Li[4], S. Edwards[1], J. French[1], H. Shen[2], S.J. Ramus[2], J.M. Lee[2], T.J. Spindler[2], D. Hazelett[2], S.K. Rhie[2], J. Simard[5], F. Couch[6], A. Dunning[3], G. Coetzee[2], M. Freedman[4], D. Easton[3], G. Chenevix-Trench[1], P.P. Pharoah[3], A.C. Antoniou[3], S.A. Gayther[2] on behalf of CIMBA, BCAC and OCAC.* 1) Department of Genetics and Computational Biology, QIMR Berghofer, Herston, QLD, Australia; 2) University of Southern California, Los Angeles, CA, USA; 3) University of Cambridge, Strangeways Research Laboratory, Cambridge, UK; 4) Dana-Farber Cancer Institute, Boston, MA, USA; 5) Centre Hospitalier Universitaire de Québec (CHUQ), Québec, Canada; 6) Mayo Clinic, Rochester, MN, USA.

Multiple independent genome-wide association studies (GWASs) have identified variation at the 19p13 locus that predisposes to estrogen receptor-negative breast cancer and high-grade serous ovarian cancer (HGSOC). Fine-mapping of the region using the iCOGS customized Illumina Infinium genotyping array, followed by imputation, limited the risk associated region to a 20 kb window encompassing two protein coding genes - *ANKLE1*, which may be involved in DNA repair, and *ABHD8* of unknown function - and just distal to the *BRCA1*-interacting gene *BABAM1*. The strongest association signal is represented by 13 highly correlated single nucleotide polymorphisms ($P \sim 10^{-22}$). By integrating genotyping data with epigenetic data generated from normal ovarian and breast epithelial cells we identified risk SNPs intersecting known or putative enhancers, and ELF1, ELK4, GABP and GATA3 transcription factor binding sites. Expression quantitative trait locus (eQTL) analyses identified significant genotype-gene expression associations for *ANKLE1* in normal ovarian epithelial cells (P = 0.02), and for *ABHD8* in both HGSOCs ($P = 3.0\times10^{-5}$) and normal breast tissues ($P = 2.8\times10^{-3}$), but not for *BABAM1*. Risk associated SNPs were also significantly associated with allele specific expression of *ABHD8* in breast cancer ($P = 2.5\times10^{-5}$). *ABHD8* (but not *ANKLE1* or *BABAM1*) was prioritized in a co-expression network analysis based on expression data in primary HGSOCs. Genes in the 19p13 region are frequently overexpressed in both breast cancers and HGSOCs; however, stable overexpression of neither *BABAM1* nor *ANKLE1* had a significant impact on the neoplastic phenotype of normal breast and ovarian epithelial cells. Using chromosome-conformation-capture (3C) assays in these same cell types, we identified interactions between a putative regulatory region and the promoter of *ABHD8*, as well as in breast and ovarian cancer cell lines. Taken together, these data suggest that the same functional mechanism at this locus underlies breast and ovarian cancer development, and that *ABHD8* may represent a novel breast/ovarian cancer susceptibility gene.

Identification of germline mutations in *TEP1* among familial and sporadic pediatric acute myelogenous leukemia cohorts. *N.R. Oak[1], D.I. Ritter[3], B.C. Powell[1], H.C. Cheung[1], M.M. Gramatges[2], D.A. Wheeler[1,3], S.E. Plon[1,2,3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Identification of cancer susceptibility gene mutations can impact surveillance for second primary malignancies and risk in family members. Germline mutations in genes related to telomere maintenance are associated with bone marrow failure and hematologic malignancies. To explore genetic predisposition to pediatric cancers, we performed whole exome sequencing of constitutive DNA from childhood cancer patients including seven kindreds with familial leukemia/lymphoma in at least two first degree relatives. We filtered for rare variants (<1% in dbSNP or in another non-cancer database, Atherosclerosis Risk in Communities (ARIC)) that are shared between affected individuals within a family and were predicted to exert deleterious effects on the protein. We limited our analysis to truncating (nonsense and frameshift) mutations. In one of the families, we found 7 frameshift and 4 nonsense mutations. The most interesting candidate among these was the novel variant p.R314X in *TEP1*. Loss-of-function mutations in *TEP1* are very rare in sequence databases including the NHLBI exome sequencing project. This rare mutation was shared by a parent-child pair affected by acute lymphocytic leukemia (ALL) and acute myeloid leukemia (AML) respectively. We further explored whether germline mutations in *TEP1* are found in larger cohort of apparently sporadic AML patients. AmpliSeq™ sequencing of 43 genes related to telomere maintenance and DNA repair pathways was performed on DNA samples from 82 pediatric AML patients. This analysis revealed 10 rare missense germline mutations in *TEP1*. Four of these 10 mutations predicted to have damaging effect on protein function according to Combined Annotation Dependent Depletion (CADD) tool (CADD scaled score of 15 or more). The *TEP1* familial p.R314X truncating mutation in addition to germline *TEP1* missense mutations in sporadic AML patients warrant further functional studies. These studies will include assessing the role of these *TEP1* mutations on the telomere length phenotype of cells from the patients carrying the mutation. The results of these studies are designed to determine whether *TEP1* represents another member of the telomere maintenance genes to be associated with AML predisposition. This work was supported by research grant RP10189 from the Cancer Prevention and Research Institute of Texas and R01-CA138836 to Plon, SE and training grant T32 GM007526 to Powell, BC.

***Hdac9* Intronic Enhancer Variants as Candidates for Skin Cancer Risk.** *A. Toland[1,3], T. Siekmann[2,3].* 1) Human Cancer Genetics; 2) Biomedical Sciences Program; 3) The Ohio State University, Columbus, OH.

The susceptibility to skin tumorigenesis 5 (*Skts5*) locus on mouse chromosome 12 was mapped through linkage analysis of skin tumor susceptible Mus musculus (NIH/Ola) and skin tumor resistant outbred Mus spretus (SPRET/Out) mice. Expression and sequence analysis of genes at *Skts5* led to the identification of *Hdac9* as a potential candidate for *Skts5*; *Hdac9* contains both amino acid variations and differential expression in skin between the strains. Furthermore, we found that variants in human *HDAC9* show allele-specific imbalance in human cutaneous squamous cell carcinomas (cSCC), suggesting a role for this gene in human cSCC. Interestingly, studies by others identified an exonic/intronic enhancer in *HDAC9* that impacted expression of *TWIST1*. From these data we hypothesized that mouse *Hdac9* might also contain an enhancer element and that variants in this region might contribute to differential expression of the oncogene, *Twist1*. To test this hypothesis we performed sequencing analysis and identified 45 sequence variants between NIH/Ola and SPRET/out mice from the orthologous region of the human *HDAC9* enhancer. We subcloned this region into nine segments; two of these segments differentially impacted luciferase expression in vitro. NIH/Ola clones showed 2-fold increased luciferase expression relative to vector alone or the similar region in SPRET/Out. Furthermore, cells transfected with this segment of the NIH/Ola intron 17 led to a 2.2 fold increase in *Twist1* expression, but the same region in SPRET/Out resulted in no up-regulation of *Twist1*. *In silico* transcription factor analyses identified a number of transcription factors that were predicted to differentially bind NIH/Ola and SPRET/Out variants. Chromatin immunoprecipitation studies of two transcription factors, Gata3 and Oct1, demonstrated differential binding between NIH/Ola and SPRET/Out DNA that fit the in silico predictions. Together these studies show evidence that the mouse orthologous region to a human *HDAC9* enhancer, also acts as an enhancer for *Twist1*. As *Hdac9* intron 17 sequence variants between NIH/Ola and SPRET/Out differentially impacted luciferase expression, *Twist1* expression and Gata3 and Oct1 binding, they are candidates for differences in skin tumor susceptibility locus *Skts5*.

3281S

Allelic imbalance in gene expression as a mechanism in breast cancer development. *I. Pulyakhina[1], M.P.G. Vreeswijk[1], J.F.J. Laros[1,2], C.M. Meijers[1], J.T. den Dunnen[1,2], P. Devilee[1], P.A.C. 't Hoen[1].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, the Netherlands; 2) Leiden Genome Technology Center, Leiden University Medical Center, Leiden, the Netherlands.

Differential allelic expression (DAE) refers to differences in expression levels between the two alleles of a gene. DAE can be caused by genetic variation and is known to affect a considerable fraction of genes in the human genome. DAE has been suggested to play an important role in human phenotypic variability, including complex traits and diseases. We hypothesize that DAE contributes to the pathogenesis of breast cancer. Loss of the highest expressed allele of a tumor suppressor gene would lead to substantially lower expression levels of the gene than loss of the lowest expressed allele. This may promote tumorigenesis. We performed whole transcriptome sequencing of paired normal-tumor samples from breast cancer patients and analyzed the allelic ratios for heterozygous, coding SNPs. We focused specifically on SNPs that showed DAE in the normal samples and a switch or loss of DAE in the tumor. We separated genomic variants from RNA editing events and investigated the behavior of allelic imbalance and the underlying molecular mechanism in a subset of these SNPs. 102 SNPs in 60 genes demonstrated significant changes in allelic ratios between normal and tumor tissue. A decrease in allelic imbalance in tumor was most frequently observed. 20% of SNPs showed a complete switch in ratios, where the allele with higher expression in normal cells was lower expressed in tumors and *vice versa*. Multiple coding SNPs in the same gene and the same sample showed consistent changes in allelic imbalance. Genes showed recurrent and consistent changes in allelic imbalance across multiple samples, although sometimes measured by different SNPs. Some of the affected genes have been shown to play a role in cancer development, but contribution of their allelic imbalance has not been described so far. The validation of the findings in a larger cohort and investigation of a possible role for DAE in other cancer types is ongoing.

Germline Mutations in Men with Multiple Primary Malignancies from a Hereditary Prostate Cancer Cohort. *P.G. Pilie, K. Zuhlke, A. Johnson, K. Cooney.* Internal Medicine, University of Michigan, Ann Arbor, MI.

There exists a variety of well-known familial cancer syndromes originating from germline mutations that lead to multiple primary malignancies in a single individual. Cases of men with early-onset and/or familial prostate cancer in addition to other primary cancers, even including other urogenital cancers, are relatively rare. Furthermore, the molecular underpinnings are not well understood. High-throughput DNA sequencing encompassing large comprehensive cancer whole-gene exome panels allows for the rapid identification of novel, rare germline mutations in cancer patients. To search for these mutations, germline DNA from eight men with prostate cancer who also had a history of pathologically-confirmed multiple primary cancers involving other sites were selected for the study. Each individual provided a cancer family history which was pathologically-confirmed where possible. Blood DNA from the proband was screened using a PCR-based Comprehensive Cancer Panel (Qiagen) DNA sequencing platform. Two of eight probands (25%) from the prostate cancer cohort with multiple primary cancers harbored deleterious germline mutations, one a frameshift mutation in *FGFR3* gene and the other a truncating variant in *ATM* gene. The *FGFR3* mutation was discovered in a man with a personal history of thyroid cancer diagnosed at age 44, prostate cancer diagnosed at age 55, renal cell cancer diagnosed at age 57 as well as significant family history of prostate cancer. Interestingly, multiple first and second degree relatives with only prostate cancer tested negative for *FGFR3* mutation. In summary, our strategy of selecting men with prostate cancer and multiple other primary cancers led to the identification of novel deleterious mutations in *ATM* and *FGFR3* which likely contribute to cancer risk in these individuals and their families. Whereas somatic *FGFR3* mutations have been described in a number of cancers, this is the first report of a *FGFR3* germline mutation that may increase cancer risk and studies are ongoing to understand the biologic implications.

3283T

Genetic analysis of the chromosome 15q25.1 region identifies IREB2 variants associated with lung cancer. *C. Amos[1], I. Gorlov[1], Y. Han[1], L. LeMarchand[2], X. Ji[1], D. Christiani[3], M. Frazier[4], C. Wei[4], J. McKay[5], P. Brennan[5], J. Field[6], Y. Li[1], R. Hung[7].* 1) Dartmouth, Lebanon, NH; 2) University of Hawaii Cancer Center, Honolulu, HI; 3) Harvard University, Boston, MA; 4) U.T. M.D. Anderson Cancer Center, Houston, TX; 5) International Agency for Research on Cancer, Lyon, France; 6) University of LIverpool, Liverpool, UK; 7) University of Toronto, Toronto, CA.

Genome-wide association studies of lung cancer identified the region of chromosome 15q25.1 that includes a nicotinic acetylcholine receptor cluster as being the most strongly associated with lung cancer risk. To characterize the impact that specific functional variants in this region have upon risk for lung cancer development, we performed fine mapping selecting all currently known SNPs influencing lung cancer risk along with all coding SNPs in the 200 megabase region surrounding CHRNA5, a gene known to influence smoking behavior in this region. SNPs were initially identified by Sanger sequencing of 96 individuals for CHRNA5, CHRNA3, CHRNB4, and PSMA4. Additional markers were selected from dbSNP. Markers that were selected for genotyping were chosen based upon the following criteria: known functional effect on activity of genes in the region, validation in African or European populations, position across the region, predicted effect on function, r-square value for LD with respect to other markers being less than 80%. We carried out fine mapping of the 15q25.1 region by genotyping 1395 SNPs extending from the gene CRABP1 to ADAMTS7 from position 79103132 to position 79103132 using a custom Affymetrix Axiom array in 3063 cases and 2940 controls of European ancestry from 5 studies: MSH-PMH, EPIC, MEC, LLPC, HPFS & NHS. Odds ratios (OR) adjusted for age, sex, the first two principal components and site of analysis were estimated using logistic regression. Across this region, 268 markers had p-values less than 0.05 and 101 SNPs met the multiple testing corrected threshold ($p<3.5\times10\text{-}5$). The most significant SNPs lie in a region including of IREB2, with the most significantly associated variant being rs17483686 (OR=1.26, p=8.93 x 10-12). The previously well characterized SNP in CHRNA5, rs16969968, which causes reduced signaling, yielded a less significant association (OR=1.24, p=8 x 10-10) than many variants in IREB2, and iron sensing protein. These findings support an independent effect of IREB2 on lung cancer risk beyond the role of nicotinic receptor variants in this region. Findings will be further evaluated as results from studying additional samples become available in the next month.

Body mass index (BMI) is a complex phenotype that is consistently associated with risk of colorectal cancer, although associations are often stronger for men than for women. There is limited information, however, on whether genetic variants interact with BMI to modify colorectal cancer risk. We tested interactions between approximately 2.7M single nucleotide polymorphisms (SNPs) and BMI with colorectal cancer risk among 17,122 colorectal cancer cases and 17,609 controls. We used comprehensive statistical methods with individual-level data to evaluate sex-specific multiplicative interactions between each SNP and BMI with colorectal cancer risk. BMI per 5 kg/m^2 was associated with higher risk of colorectal cancer (men, odds ratio (OR): 1.26; p-value: 4.2×10^{-25}; women, OR: 1.14; p-value: 2.1×10^{-16}). Among men, from traditional case-control logistic regression models, we identified a suggestive interaction between BMI and a locus in *adiponectin receptor 2* (*ADIPOR2*, rs9805042, OR: 0.77; p-value: 9.2×10^{-7}; p-threshold: 5×10^{-8}). Among women, we identified a statistically significant interaction between BMI and a locus in *SMAD7*. Specifically, when using the Cocktail method or the EDGxE method, which each involves two-step screening and testing methods and corrects for multiple testing using weighted hypothesis testing, an interaction was detected between BMI and rs4939827/*SMAD7* (p-observed: 0.0009; p-threshold: 0.005). A statistically significant interaction was also detected between BMI and rs4939827/*SMAD7* using a 2-d.f. joint test (p-value: 2.4×10^{-10}). ORs for the association between BMI per 5 kg/m^2 and colorectal cancer risk differed according to strata of rs4939827 genotype (T/T, OR: 1.08; p-value: 0.02; G/T, OR: 1.13; p-value: 5.4×10^{-6}; G/G, OR: 1.25; p-value: 7.6×10^{-9}). rs4939827/*SMAD7* was previously identified in GWA studies as a colorectal cancer susceptibility locus. Herein, we showed that a common susceptibility locus in *SMAD7* modifies the association between BMI and colorectal cancer risk for women. Further functional analyses are needed to understand this interaction. Future work with larger study samples is warranted to explore the borderline interaction between *ADIPOR2* and BMI in men, especially given the strong biological plausibility for a connection between obesity, circulating adiponectin and colorectal cancer. Our results identify a novel gene-BMI interaction for colorectal cancer risk, which may have implications for disease prevention.

3285M

Estimation of Whole Genome Variations of Hepatocellular Carcinoma among Chronic Hepatitis C Patients. *Y. Chang[1], M. Lee[2], C. Liu[1], H. Yang[3], H. Chen[1], C. Chen[3].* 1) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 2) Institute of Clinical Medicine, National Yang Ming University, Taipei, Taiwan; 3) Genomics Research Center, Academia Sinica, Taipei, Taiwan.

Background & Aims: Host genetic susceptibility may be associated with the occurrence of hepatocellular carcinoma (HCC) among patients with chronic infection of hepatitis C virus (HCV). This study aimed to discover genomic variations associated with hepatocellular carcinoma risk through the genome-wide association study (GWAS) and imputation analysis. Methods: There were 472 HCC cases and 806 unaffected controls. All study subjects were adults seropositive for antibodies against HCV and seronegative for HBsAg. The demographic characteristics and serum markers for liver functions were also evaluated. High quality human genomic DNA was extracted from each blood sample to perform genotyping by AxiomTM Genome-Wide CHB Array. Then, imputation algorithm was applied to get whole genome variations in patients based on genotyping data from SNP microarrays. The reference genomes of imputation were Han Chinese population in 1000 genome project. The logistic regression was used to evaluate association between disease and genotype based on four different genetic models (allelic, dominant, additive and recessive). P values $<10^{-5}$ were considered significant. Results: A total of 36,175,343 SNPs were obtained in the samples after imputation. There were 765, 134, 612, and 855 SNPs significantly associated with HCC based on additive, recessive, dominant, and allelic genetic models, respectively. Among the SNPs discovered in our analysis, less than 4% could be detected by microarray chips. In addition, 18 nonsynonymous SNPs were found to be significantly associated with HCC under different genetic models. Only 3 out of 18 nonsynonymous SNPs could be detected in microarray chips. Interestingly, 7 nonsynonymous SNPs clustered on the human leukocyte antigen (HLA) complex region. It indicated that HLA region play a important role in host susceptibility to hepatocellular carcinoma within chronic hepatitis C patients. Conclusion: The SNPs associated with HCV-related HCC were identified in this study. It provide insight for identification of high risk population in HCV after clinical validation.

Functional characterization of *PARP1* melanoma-associated locus. *J. Choi[1], M. Makowski[1], M. Xu[1], T. Zhang[1], M. Law[2], W. Kim[1], M. Kovacs[1], H. Parikh[1], L. Aoude[2], M. Gartside[2], H. Yin[3], J. Trent[3], S. Macgregor[2], N. Hayward[2], K. Brown[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Queensland Institute of Medical Research, Brisbane, QLD, Australia; 3) Translational Genomics Research Institute, Phoenix, AZ.

Recent genome wide association studies (GWAS) identified several new loci for melanoma susceptibility. While these results highlight potential pathways predisposing to melanoma, functional risk variants in these regions as well as the mechanism by which they influence risk have yet to be elucidated. To nominate functional variants we performed expression quantitative trait loci (eQTL) analysis in 62 melanoma cell lines. Transcript levels were measured using Affymetrix U133Plus2 expression microarray. SNPs (>700K) were then typed on Illumina OmniExpress arrays and the ones in GWAS loci were further imputed using 1000 genomes (1KG) data. Among 16 GWAS loci tested two chromosome 1 loci exhibited significant *cis*-eQTL. Subsequent validation using Taqman quantitative PCR (qPCR) demonstrated that Poly [ADP-ribose] polymerase 1 (*PARP1*) expression is significantly associated with the lead SNP (p=0.03, genomic copy number adjusted). Namely, the risk allele is correlated with an increased *PARP1* transcript levels after adjusting for genomic copy number (p=0.03). We then further interrogated the genotype-expression correlation by Taqman allele discrimination qPCR in 21 melanoma cell lines heterozygous for the GWAS lead SNP. The results demonstrated significantly higher proportion for the risk allele in *PARP1* transcripts (p=0.0001). To identify functional risk variants mediating these effects we annotated the *PARP1* locus using ENCODE database. Among 56 SNPs of strong linkage disequilibrium (LD) with the lead SNP (r^2>0.5 using 1KG genotypes), six exhibited strong evidence as potential transcriptional enhancers in melanoma relevant cell types. One of them is a six-base pair indel in GC-rich region poorly covered by 1KG. Genotype reassessment of this indel using gel-based fragment analysis in 745 healthy Europeans from DCEG imputation reference set resulted in remarkably enhanced LD with the lead SNP (r^2=0.94 from 0.67) supporting direct link to melanoma susceptibility. Subsequent Electro Mobility Shift Assays and luciferase assays for this indel demonstrated allele-specific protein binding and differential transcriptional activities in melanoma cell lines. Chromatin immunoprecipitation indicated that enhancer-binding proteins are enriched in melanoma-associated deletion allele in melanoma cell lines. Identification of proteins directly mediating this function will further elucidate PARP1 contribution to melanoma susceptibility.

Heritable missense variant rs3731249 underlies the *CDKN2A* association with childhood ALL and is preferentially retained by tumors harboring somatic *CDKN2A* loss. *A.J. de Smith[1], K.M. Walsh[2], H.M. Hansen[2], L.F. Barcellos[3], A.P. Chokkalingam[3], R.B. Jenkins[4], M.R. Wrensch[2], J.K. Wiencke[2], C. Metayer[3], J.L. Wiemels[1].* 1) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 2) Department of Neurological Surgery, University of California, San Francisco, San Francisco, CA; 3) Division of Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 4) Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Rochester, MN.

Little is known about the interaction between constitutive and somatic genetic variation in carcinogenesis. Genome-wide association studies (GWAS) of childhood acute lymphoblastic leukemia (ALL [MIM 613065]) have identified 6 genetic associations, including rs3731217, located between the *CDKN2A* [MIM 600160] and *CDKN2B* [MIM 600431] genes. Somatic deletions of this 9p21.3 region are common in cancer, and occur in ~30% of childhood ALL. We replicated the rs3731217 association with childhood ALL in Hispanics (p=0.021) via a GWAS of 323 childhood ALL cases and 454 controls, using the Illumina OmniExpress SNP array. SNP imputation analysis across 9p21.3 revealed a stronger association at rs3731249 ($p=6.4\times10^{-4}$; OR = 2.77), a low-frequency missense variant in exon 2 (p.Ala148Thr) of *CDKN2A* ($MAF_{controls}$=2.1%). These associations were replicated in an additional 378 ALL cases and 536 controls using Taqman assays, where the missense variant again had a greater magnitude of effect ($P_{rs3731249}=6.5\times10^{-3}$; $OR_{rs3731249}$ = 2.00 versus $P_{rs3731217}$=0.029; $OR_{rs3731217}$ = 1.38). We assessed the effect of rs3731249 on risk of other cancers with known chr9p21.3 GWAS associations, but observed no association between this variant and either adult glioblastoma or melanoma risk, suggesting an ALL-specific role for rs3731249. We hypothesized that cases heterozygous for rs3731249 may show allelic imbalance, with preferential loss of the wildtype (WT) allele when hemizygous chr9p21.3 deletions occur in leukemic cells. To test this, we developed a novel method termed "SMART-ddPCR" (Somatic Mutation Allelic Ratio Test using Droplet Digital PCR). Concentration of risk and WT alleles was measured by ddPCR using the rs3731249 Taqman assay in diagnostic bone marrow (*i.e.* tumor) DNA from 35 known heterozygotes. Allelic imbalance due to somatic *CDKN2A* alterations was identified in 17 cases, of which 14 had higher risk:WT allele ratio (p=0.006, 1-sided binomial significance test), thus demonstrating preferential loss of WT rs3731249 and retention of the missense allele. Subclonal heterogeneity in *CDKN2A* copy number was also evident, suggesting that this is a late event in leukemogenesis. Preferential allelic imbalance towards the rs3731249 risk allele in ALL tumor DNA provides strong evidence of an important role for this missense variant in leukemogenesis and shows, for the first time, a direct relationship between the constitutive and somatic genetic variants underlying ALL development.

Leveraging Sequence and Phenotype-Specific Information to Design Custom Genotyping Arrays: Example from Prostate Cancer. *N. Emami[1], T. Hoffman[1], J. Mefford[1], K. Lindquist[1], C. Cario[1], E. Wan[1], S. Wong[1], J. Gollub[2], A. Finn[2], P. Kwok[1], N. Risch[1,3], S. Van Den Eeden[3], J. Witte[1].* 1) University of California, San Francisco, San Francisco, CA; 2) Affymetrix, Inc., Santa Clara, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA.

Association studies are increasingly focused on the contribution of rare genetic variants to phenotypic variation. Detecting rare variants via sequencing large numbers of samples remains expensive. Moreover, there is a limit to the statistical power for detecting associations with extremely rare variants. These issues have resulted in the continued used of DNA microarrays. While various array designs are commercially available off-the-shelf, these may not adequately reflect rare variation in the target population and may misallocate space to uninformative, monomorphic markers. Instead, recent large-scale studies of human genetic variation, as well as sequencing studies for disease, have provided a repository of information upon which custom array solutions can be tailored to particular phenotypes. We illustrate the potential of such custom arrays for studying rare- and putative trait-specific variation in prostate cancer. First, we sequenced tumor and normal DNA from a limited number of African-American men with prostate cancer, and obtained prostate cancer germline exomes from the Cancer Genome Atlas and dbGaP; these data were then filtered to select rare variants for inclusion on the array. Second, we included the following additional custom content in our target set: pleiotropic loci previously associated with multiple cancers, loci with measured DNA hypersensitivity in prostate cancer cell lines, and regions of dense genotyping centered at loci previously associated with prostate cancer, with the purpose of discovering potentially causal variation. Third, we selected sets of target markers recently distinguished as assaying informative rare and putatively functional variation. Finally, the custom array was designed to complement existing GWAS data on our study samples by using a greedy SNP-selection algorithm to minimize redundancy of typed markers while optimizing coverage of our target set. The final array includes 415,664 assayed markers, and we have typed it on a population of 8,000 prostate cancer cases and 8,000 controls nested within the Kaiser Permanente Research Program on Genes, Environment, and Health (RPGEH). In preliminary results, we replicated the strong association between the rare HOXB13 G84E mutation and prostate cancer (p=0.002, OR=2.74, 95% CI 1.45-5.22). Our approach and results provide a framework for designing highly informative custom arrays to study rare and trait-specific genetic variation and complement existing GWAS data.

Genome-wide scan identifies variants in 2q12.3 and 9q22.33 associated with risk of multiple myeloma. *S.W. Erickson[1], V.R. Raj[1], O.W. Stephens[1], I. Dhakal[1], S.S. Chavan[1], N. Sanathkumar[1], E.A. Coleman[1], J.Y. Lee[1], J.A. Goodwin[1], S. Apewokin[1], D. Zhou[1], C.J. Heuck[1], A.J. Vangsted[2].* 1) UAMS, Little Rock, AR; 2) Roskilde Hospital, Copenhagen, DK.

Despite recent studies which have identified multiple susceptibility loci for multiple myeloma (MM), the genetic contributions to risk of the disease are only partially understood. In the current study, we performed a genome-wide association study (GWAS) of MM risk on 972 patients who underwent melphalan-based high-dose treatment supported by autologous stem cell transplant (HD-ASCT), using genotype data from 1064 cancer-free adults as controls. We identified two novel susceptibility loci, one in 2q12.3 upstream of the gene ST6GAL2, and one in 9q22.33 between the genes FOXE1 and XPA. Risk genotypes in 9q22.33 were also associated with lower expression of FOXE1. All three of these genes have been previously associated with risk of cancer or apoptosis. Our study also replicated six out of seven previously published germline associations to MM risk.

Genetic determinants of Breslow tumor thickness and their impact on melanoma progression. *S. Fang[1], Y. Wang[1], D. Deng[1], Q. Liu[2], R. Feng[1], K. Xu[1], H. Liu[1], M. Ross[1], J. Gershenwald[1], J. Cormier[1], R. Royal[1], A. Lucci[1], J. Wargo[1], C. Schacherer[1], J. Reveille[3], D. Sui[1], R. Bassett Jr[1], F. Demenais[4], L. Wang[1], M. Lu[1], Q. Wei[5], C. Amos[6], J. Lee[1], GenoMEL group.* 1) University of Texas MD Anderson Cancer Center, Houston, TX; 2) The fifth affiliated Hospital of ZhengZhou University, Zhengzhou, Henan; 3) The University of Texas Health Science Center at Houston, Houston, TX; 4) Université Paris Diderot Paris; 5) Duke University School of Medicine, Durham, NC; 6) Dartmouth College, Lebanon, NH.

Breslow thickness of the primary melanoma tumor is one of the most important clinicopathologic factors predicting risk of melanoma progression. Genetic mechanisms determining Breslow thickness are not yet known. We performed a genome-association study of Breslow thickness using 1547 patients in MD Anderson (MDA) in discovery analysis and further evaluated their association using GenoMEL (UK and European) and French melanoma datasets. None of the SNPs identified in 4 candidate gene regions (MUC2/MUC5AC/CALR/RAD23A) in the MDA dataset was replicated in the GenoMEL or French datasets. However, gene-based VEGAS testing confirmed that two MDA candidate genes, MUC2 and MUC5AC, were significantly related to tumor thickness in the MDA dataset (both P-values<2.8×10-6). Additionally, both CALR and RAD23A genes were associated with melanoma disease-free and overall survival (P-value<0.05) in the MDA dataset. Finally, immunohistochemistry of primary melanoma tumors demonstrated that both MUC2 and CALR expression levels increased with tumor thickness; expression of MUC2 was also elevated in regional nodal metastases from melanoma patients. These data suggest that MUC2 and CALR genes may determine melanoma tumor thickness and influence melanoma disease severity.

Association of *2R3R* polymorphism of the Thymidylate synthase gene with toxicity in breast cancer patients treated with FEC chemotherapy. *M.P. Gallegos-Arreola[1 y 2], R. Ramírez[1 y 3], IA. Gutíerrez[1 y 3], OM. Soto[1 y 2], DI. Carrillo[1 y 3], AM. Puebla[6], GM. Zúñiga[4], LE. Figuera[5].* 1) Lab. de Genética Molécular. Div Med Mol, CIBO, IMSS, Guadalajara, Jal,. Mex; 2) Doctorado en Farmacología, CUCS, U de G; 3) Doctorado en Genética Humana, CUCS, U de G,; 4) Lab. Mutagénesis, CIBO, IMSS; 5) División de Genética, CIBO, IMSS; 6) Laboratorio de Inmunofarmacología. Departamento de farmacología, CUCEI, U de G.

Background: The influence of polymorphisms in the TYMS gene involved in metabolism of chemotherapeutic agents has been studied in different cancers. Thymidylate synthase (TS) plays a major role in folate metabolism and consequently could be an important factor for the efficacy of a treatment with FEC (fluorouracil-epirubicin-cyclophosphamide) in breast cancer patients. Our aim was to evaluate the association of 2R3R polymorphism with toxicity effects in breast cancer patient's neoadjuvantly treated with FEC chemotherapy. Methods: DNA genomic samples from 525 patients (UMAE gynecology and obstetrician Hospital, CMNO, IMSS), that received FEC neoadjuvant chemotherapy; were included in the study. Protocol was support by FIS/IMSS/PROT/G13/1231. The 2R2R polymorphism was determinate by polyacrylamide gels electrophoresis, previously PCR amplification analysis. The association was determinate by odds ratio. Results: The genotype heterozygous (2R3R) was associated with hepatotoxicity (high levels of GGT enzyme) in breast cancer patient with response at FEC chemotherapy [2.7(IC95% 1.07-3.4), p=0.026], as well as with hematological toxicity (neutropenia) [2.7(IC95% 1.3-5.5), p=0.024] and mucositis toxicity [2.9(IC95% 1.03-8.2), p=0.027] in breast cancer patients non responder at FEC chemotherapy. Conclusion: The polymorphism 2R3R could be a good marker of toxicity in breast cancer patients treated with FEC chemotherapy in the analyzed sample.

3292T

Regulatory polymorphisms in lymphoma and chronic lymphocytic leukemia risk. *J. Hayes[1,2], G. Trynka[3,4], V. Joseph[1], K. Offit[1], S. Raychaudhuri[3,4,5,6], R. Klein[7].* 1) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA; 2) Biochemistry, Cellular, and Molecular Biology Program, Weill Cornell Graduate School of Medical Sciences, New York, NY, USA; 3) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 4) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 6) NIHR Manchester Musculoskeletal Biomedical, Research Unit, Central Manchester NHS Foundation Trust, Manchester Academic Health Sciences Centre, Manchester, UK; 7) Icahn Institute for Genomics and Multiscale Biology and Department of Genetics and Genomic Sciences, Icahan School of Medicine at Mt. Sinai, New York NY USA.

The first genome-wide association study (GWAS) was published in 2005. Since then, there have been over 1,300 published GWAS papers spanning over 200 diseases and more than 3,000 disease susceptibility loci identified. However, one of the major challenges of the field is that over 90% of these identified risk variants do not result in an amino acid change, thus failing to explain the mechanism for increased risk. We hypothesize that the GWAS-identified risk-SNPs, or those variants highly correlated with them, increase risk by altering transcriptional regulatory elements.

To test this hypothesis, we generated a flexible and customizable computational pipeline to ask if a set of SNPs associated with a phenotype are enriched in a particular functional annotation of the genome. To demonstrate the power of this approach, we tested risk-SNPs for both lymphoma and chronic lymphocytic leukemia (CLL) for enrichment in regions of the genome reported to be biochemically functional by the ENCODE project. Using this pipeline we were able to identify numerous SNPs that fell into putative regulatory regions by several measures, including DNase-hypersensitivity regions, ChIP-Seq peaks, and integrative analysis of histone methylation data.

The computational pipeline utilizes a Monte Carlo approach to test for enrichment, taking linkage disequilibrium patterns into account when compared to feature-matched random SNP sets. We observed a statistically significant enrichment of the lymphoma and CLL risk SNPs in a lymphoid-lineage specific manner for numerous regulatory marks, including DNase peaks and segmentation defined “strong enhancers” at $p<0.001$. However, even though the LCLs tested are of the same tissue of origin, we were able to detect inter-individual variability among the cell lines. These results suggest that regulatory variants can explain many of the known high-frequency genetic risk factors for lymphoma and chronic lymphocytic leukemia.

3293S

Role of polymorphic fibroblast growth factor receptor (FGFR) Gene and Breast Cancer Risk. *M. Hosseini[1], M. Houshmand[2].* 1) Biological Science, Islamic Azad Univ, Islamshahr Branch, Islamshahr, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran.

Background: Genetic factors related to cancer have been extensively studied and several polymorphisms have been associated to breast cancer. Breast cancer (BC) is one of the most common causes of death among women, and second in Iran. The objectives of this study were to determine the frequency of the fibroblast growth factor receptor (FGFR) Gene polymorphism in patients with breast cancer. Methods: For the first time, we evaluated these polymorphisms and effects on the breast cancer risk association in an Iranian sporadic population-based case-control study of 126 breast cancer cases and 160 controls using a PCR-RFLP-based assay. Results: Analyses of affected and controls show that homozygote genotype FGFR4 Gly/Gly has the highest frequency in patients and control groups (30.4 and 18.9%). Genotype FGFR4 Gly/Gly most risk factor were in our population: ArgGly /GlyGly, OR= 2.359, 95% CI= 0.208 - 4.621, p=0.001; ArgArg / ArgGly, OR=0.412, 95% CL=0.082 - 0.547, p=0.078 , ArgArg /GlyGly, OR= 0.076, 95% CI=0.030 - 0.189, p=0.26. Conclusions: There was a significant association of breast cancer risk with FGFR4 GlyGly and ArgGly polymorphism. Keywords: FGFR4 gene, polymorphism, breast cancer, BstNI , PCR-RFLP.

3294M

GWAS meta-analysis identifies three novel risk loci for melanoma at 6p22, 7q21 and 9q31. *M.H. Law[1], D.T. Bishop[2], C.I. Amos[3], M. Brossard[4], S.V. Ward[5], N.K. Hayward[6], N.G. Martin[7], R. Melanoma is the deadliest form of skin cancer, representing a significant burden in terms of mortality and healthcare costs. Prior to the advent of genome-wide association studies (GWASs), our understanding of the melanoma genetics was limited to rare familial mutations in cell cycle check point genes and single nucleotide polymorphisms (SNPs) that impacted pigmentation. Our first wave of melanoma GWASs in 2009 confirmed the importance of pigmentation genes in melanoma, and our second wave in 2011 identified additional pathways including DNA repair genes, greatly increasing our understanding of melanoma aetiology.

We build on these findings through meta-analysis with genomic imputation of 11 melanoma GWASs totalling 12,814 cases and 23,204 controls, representing the largest genetic study of melanoma to date. In addition to 14 established melanoma risk loci reaching genome-wide significance, we have confirmed that genetic variants at 15q13.1 near the eye colour gene *oculocutaneous albinism 2* (*OCA2*) are associated with melanoma (rs4778138 $p = 3.95 \times 10^{-9}$, $I^2=8.33$).

Further, we have identified three novel genome-wide significant loci ($p<5 \times 10^{-8}$) with homogenous effects across studies ($I^2=0$). First, rs6914598 ($p=3.86 \times 10^{-8}$) at 6p22.3 lies in the *CDK5 regulatory subunit associated protein 1-like 1* gene (*CDKAL1*). CDKAL1 methylthiolates tRNAs, modulating expression of a range of genes including proinsulin. Additional SNPs in *CDKAL1* have been associated with numerous diseases including type-2 diabetes and bladder cancer; these SNPs are not obviously associated with melanoma (rs9348440 $p=0.024$ with melanoma, all others $p>0.2$), indicating that the rs6914598 signal is independent. Second, rs1636744 ($p=2.79 \times 10^{-9}$) in 7p21.1 is near the *anterior gradient 3 homolog* gene (*AGR3*). This SNP is reported as an eQTL for *AGR3* in lung and thyroid tissue, and *AGR3* expression has been associated with breast cancer risk and poor survival in ovarian cancer. rs1636744 is not in a conserved region, nor is there reported evidence of functional regulation at rs1636744 or SNPs in strong LD. Third, rs10739221 ($p=1.38 \times 10^{-8}$) in 9q31.2 is intergenic, with nearby genes including *transmembrane protein 38B* (*TMEM38B*) and the nuclear excision repair gene, *RAD23 homolog B* (*RAD23B*). The success of this meta-analysis indicates the power of combining GWASs to further uncover the biological architecture of melanoma susceptibility.

3295T

Detection of *trans* and *cis* splicing QTLs through large scale cancer genome analysis. *K. Lehmann[1], A. Káhles[1], C. Kandoth[1], W. Lee[1], N. Schultz[1], O. Stegle[2], G. Rätsch[1].* 1) Memorial Sloan-Kettering Cancer Center, Computational Biology, New York, NY; 2) European Bioinformatics Institute; Hinxton; Cambridge; CB10 1SD; United Kingdom.

The comprehensive survey of molecular characteristics provided by The Cancer Genome Atlas (TCGA) enables large scale analyses across multiple cancers. However sophisticated tools for the joint analysis of the thousands of samples and cancer specific challenges are needed. In an effort to enable joint analysis, we have re-aligned and re-analyzed RNA and whole exome sequencing data of ~4.000 individuals across 12 cancer types in a uniform manner. We used a newly developed open source SplAdder pipeline to count gene expression as well as annotate and quantify a comprehensive set of alternative splicing events. We identified threefold more high confidence alternative splicing events than annotated in the GENCODE annotation which reflect cancer-specific and tissue-specific splicing variation. Comparisons to matching tissue normal samples confirm a ~20% increase of splicing complexity in tumor samples. We have identified 22 genes with splicing changes that recurrently occur in tumor samples (>10%) but are virtually never observed in normal samples or ENCODE cell lines (<0.5%) and could be possible targets for new drugs. While population structure is one of the most severe confounding factors in QTL analysis, tumor samples open up many new additional challenges. Tumor specific somatic mutations and recurrence patterns as well as sample heterogeneity can lead to spurious associations. Thus, we have developed a new strategy to perform a common variant association study using mixed models on tumor samples enabling us to account for tumor specific genotypic and phenotypic heterogeneity in addition to population structure. Due to sample size constraints, many previous QTL studies have been limited to the analysis of *cis*-associated variants. The large sample size available from TCGA enables us to overcome this limitation and discover *trans*-associated variants as well. Preliminary data demonstrates that we find *cis*-associations for ~10% of the analyzed genes, of which a large fraction replicates across tissue and cancer types. We also confirm a recently reported *trans*-association in the splice factor U2AF1 and detect several additional *trans*-associations with effect sizes >20%. Current work includes the follow-up analysis on these discoveries. To address the commonly found rare somatic variants in cancer, we have also designed a rare variant test for splicing QTLs in order to identify recurrently affected genes and networks leading to aberrant splicing.

3296S

Genome-wide association study of breast cancer in Japanese population. *S. Low[1], A. Takahashi[1], M. Kubo[2], T. Katagiri[3].* 1) Lab. for Statistical Analysis, Ctr. for I.M.S., RIKEN., Yokohama, Kanagawa., Japan; 2) Lab. for Genotyping Development, Ctr. for I.M.S., RIKEN, Yokohama, Kanagawa, Japan; 3) Division of Genome Medicine, Inst. for Genome Res., The Univ. of Tokushima, Tokushima, Japan.

Breast cancer is the most common malignancy among women in worldwide including Japan. Many genome-wide association studies have been performed to identify genetic variants that are associated with the risk of breast cancer. Owing to the complex linkage disequilibrium structure and various environmental exposures among different populations, it is of important to investigate associated genetic variants with breast cancer in a specific population. In this study, we conducted a genome-wide association study as well as whole-genome imputation with 2,642 cases and 2,099 unaffected female controls collected from the Biobank Japan. We further examined 13 suggestive loci ($P<1.0\times10^{-5}$) using an independent sample set of 2,885 cases and 3,395 controls and successfully validated two previously-reported loci, rs2981578 (combined *P*-value of 1.31×10^{-12}, OR=1.23; 95% CI=1.16-1.30) on chromosome 10q26 (*FGFR2*), rs3803662 (combined *P*-value of 2.79×10^{-11}, OR=1.21; 95% CI=1.15-1.28) and rs12922061 (combined *P*-value of 3.97×10^{-10}, OR=1.23; 95% CI=1.15-1.31) on chromosome 16q12 (*TOX3-LOC643714*). Weighted genetic risk score by using three significantly associated variants and two previously reported breast cancer associated loci in East Asian population revealed that individuals who carry the most risk alleles have 2.2 times higher risk of developing breast cancer in the Japanese population compare to those who carry the least risk alleles. In addition, pathway analysis suggested that variants within aryl hydrocarbon receptor signaling pathway from Ingenuity database are associated with the risk of breast cancer. Although we could not identify additional loci associated with breast cancer, our study utilized one of the largest sample sizes reported to date, and provided genetic status that represent the Japanese population. Further local and international collaborative study is essential to identify additional genetic variants that could lead to a better, accurate prediction for breast cancer.

New insights into ovarian cancer from the investigation of overall genetic sharing. *Y. Lu[1], A.B. Spurdle[2], G.W. Montgomery[3], K.T. Zondervan[4], P.D. Pharoah[5,6], G. Chenevix-Trench[7], S. Macgregor[1], Ovarian Cancer Association Consortium.* 1) Statistical Genetics, QIMR Berghofer Medical Research Institute, Herston, Queensland, Australia; 2) Molecular Cancer Epidemiology, QIMR Berghofer Medical Research Institute, Herston, Queensland, Australia; 3) Molecular Epidemiology, QIMR Berghofer Medical Research Institute, Herston, Queensland, Australia; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 5) Department of Public Health and Primary Care, University of Cambridge, Strangeways Research Laboratory, Cambridge, UK; 6) Department of Oncology, University of Cambridge, Strangeways Research Laboratory, Cambridge, UK; 7) Cancer Genetics, QIMR Berghofer Medical Research Institute, Herston, Queensland, Australia.

Epithelial ovarian cancer (EOC) is not a single disease but is comprised of many tumour types, with substantial heterogeneity between the subtypes. To date, most genetic studies have focused on the common subtype, serous carcinoma. Studying rare histological subtypes of EOC (clear-cell, endometrioid, or mucinous) has been challenging because a large sample size is often required but not readily available. Epidemiological studies observed that certain subtypes of EOC are associated with other women's diseases, e.g. clear cell and endometrioid carcinoma occur more frequently in women with endometriosis. But it remains to be elucidated whether there is a genetic overlap underlying the association observed from epidemiological studies. We investigated this question in the largest ovarian cancer data set to-date from Ovarian Cancer Association Consortium, explicitly modelling the "polygenic" effect shared between EOC subtypes and other women's diseases using polygenic risk prediction approach and bivariate linear mixed models implemented in GCTA. We found a highly significant genetic overlap between ovarian and endometrial cancer, endometrial cancer and endometriosis, and a borderline significant overlap between breast and endometrial cancer. These findings are consistent with previous work on the familial aggregation of women's cancers, serving as a proof of principle of our method. We also found significant overlaps between clear cell, endometriod EOC with endometriosis, which strongly support the hypothesis that endometriosis is a probable precursor of clear cell and endometriod EOC. In addition, there were also suggestive genetic overlaps between multiple EOC subtypes and endometrial cancer. Altogether, these intriguing genetic overlaps suggest that treatment for other women's diseases may be used as preventive intervention for certain EOC subtypes.

Exploring the Role of Regulatory Variation in Linkage Disequilibrium with Cancer Risk SNPs. *D.S. Park, N. Zaitlen, J. Witte.* Bioengineering & Therapeutic Sciences, UC San Francisco, San Francisco, CA.

Genome Wide Association Studies (GWAS) have identified large numbers of single nucleotide polymorphisms (SNPs) that reproducibly influence disease risk (Manolio et al. 2009). Such SNPs are more likely to be expression quantitative trait loci (eQTL) than random SNPs (Nicolae et al. 2010), suggesting that they may exert their phenotypic effect by altering gene regulation rather than modifying the product of the implicated gene.

To investigate this phenomenon, we examined whether there is an over-representation of regulatory variants in linkage disequilibrium (LD) with cancer risk SNPs from all GWAS reported in the NHGRI catalogue, and whether these regulatory SNPs display 'variant pleiotropy' (i.e. when multiple variants affect the same gene/pathway). To test for enrichment at the SNP-level we first created random sets of SNPs by conditioning on minor allele frequency (MAF), genotyping array, function, and distance to transcription start site of cancer-associated SNPs. All proxy SNPs in LD at a threshold of $r^2 \geq 0.8$ and max-distance of 500kb were generated for the random sets, and RegulomeDB (Boyle et al. 2012) scoring categories were assigned to the proxy SNPs. The number of proxy SNPs in each scoring category was used to create an empirical distribution of functional SNPs in LD with the random sets to calculate the enrichment of the cancer SNPs for each scoring category. The cancer SNPs were pruned ($r^2 > 0.2$) while the random sets were not in order to obtain a conservative estimate of enrichment. To determine if functional variants affect similar genes/pathways we used DAVID (Huang et al. 2007) and GREAT (McLean et al. 2010).

We tested for functional variant enrichment and 'variant pleiotropy' in the HapMap populations CEU and CHB/JPT. At the SNP-level, in CEU we saw an enrichment of functional regulatory variants across all cancers as well as in bladder and prostate cancer. On the other hand, CHB/JPT was not enriched across all cancers but was in hepatocellular carcinoma, lung, and prostate cancer. Genes that were regulated by SNPs in the cancers identified were enriched for cancer related gene families and pathways such as the MAPK pathway, TGF-Beta pathway, Basic-Helix-Loop-Helix genes, and Zinc Finger genes. Our findings support the hypothesis that regulatory variants play a role in disrupting the normal function of cancer associated genes and pathways.

3299S

Association of *2R3R* polymorphism of the Thymidylate synthase gene with in breast cancer advanced stage patients. *A.M. Puebla-Pérez[1], A. Ramos[2 y 3], R. Ramírez[2 y 4], IA. Gutíerrez[2 y 4], OM. Soto[2 y 3], DI. Carrillo[2 y 4], LE. Figuera[5], MP. Gallegos[2].* 1) Laboartorio de Farmacología. Departamento de Farmacología, Universidad de Guadalajara, Guadalajara, Jalisco. México; 2) Lab. de Genética Molecular. Div de Med Mol, CIBO, IMSS; 3) Doctorado en farmacología, CUCS, U de G; 4) Doctorado en Genética Humana, CUCS, U de G; 5) División de Genética, CIBO, IMSS.

Background: The 2R3R polymorphisms in the TYMS gene have been studied in different cancers however exist contradicted results to respect at their association with breast cancer. Our aim was to evaluate the association of 2R3R polymorphism with advanced stage in breast cancer patients. Methods: DNA genomic samples from 525 patients (UMAE gynecology and obstetrician Hospital, CMNO, IMSS), were included in the study. Protocol was support by FIS/IMSS/PROT/G13/1231. The 2R2R polymorphism was determinate by polyacrylamide gels electrophoresis, previously PCR amplification analysis. The association was determinate by odds ratio. Results: The genotype 3R3R was associated with presence of metastatic nodules [1.9(IC95% 1.03-3.7), p=0.040], as well as the union of genotypes 3R3R-2R3R were associated advanced stages (III-IV) in breast cancer patients [2.2(IC95% 1.1-4.1), p=0.015]. Conclusion: The polymorphism 2R3R could be a good marker in advanced clinical stage in breast cancer patients, in the analyzed sample.

Differences of nitric oxide level in Mexican breast cancer patients. *R. Ramírez-Patiño[1,2], Jl. Delgado[3], A. Ramos[1,4], AM. Puebla[3], LE. Figuera[5], MP. Gallegos[1].* 1) Lab de Genética Molécular. Div Med Mol, CIBO, IMSS, Guadalajara, Jal,. Mex, Mexico; 2) Doctorado en Genética Humana, CUCS, u de G; 3) Laboratorio de Inmunofarmacología, Departamento de Farmacología, CUCEI, U de G; 4) Doctorado en Farmacología, CUCS, U de G; 5) División de Genética, CIBO, IMSS.

Nitric Oxide (NO) level plays an important role in several biological functions. Recent evidence suggests that NO may also increase metastatic ability in human cancers. We examined the Nitrite/nitrate levels in 234 breast cancer and 84 healthy Mexican women. The NO levels in plasma observed were 648.67±167.19 nM, with significant differences. The NO level is associated with breast cancer in the analyzed samples from the Mexican population.

3301T

Admixture scan of breast cancer in U.S. black women: the AMBER consortium. *E.A. Ruiz-Narvaez[1], L.E. Sucheston-Campbell[2], J.T. Bensen[3], S. Yao[2], S.A. Haddad[1], A.F. Olshan[3], C.B. Ambrosone[2], J.R. Palmer[1], K.L. Lunetta[4].* 1) Slone Epidemiology Center, Boston University, Boston, MA; 2) Department of Cancer Prevention and Control, Roswell Park Cancer Institute, Buffalo, NY; 3) Department of Epidemiology, Gillings School of Global Pubic Health, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

Breast cancer incidence varies by racial groups in the United States. Estrogen receptor (ER) positive breast cancer is more frequent in European and Asian ancestry populations, and ER negative breast cancer is more common in women of African ancestry relative to other populations. We conducted a genome-wide admixture scan in order to identify loci that may contribute to the racial differences in incidence of breast cancer and the specific ER subtypes. We analyzed 2,624 autosomal ancestral informative markers (AIMs) in 3,130 breast cancer cases (including 1,622 ER-positive, and 952 ER-negative) and 3,698 controls from the African American Breast Cancer Epidemiology and Risk (AMBER) consortium, a collaborative study from four of the largest studies of breast cancer in African American women (Carolina Breast Cancer Study, Black Women's Health Study, Women's Circle of Health Study, and Multi-Ethnic Cohort). We used ADMIXMAP software to conduct the analyses. Mean European ancestry percentage was 17.6% for controls, 17.7% for all breast cancer cases, 17.5% for ER-positive cases, and 16.7% for ER-negative cases. In case-only analyses, lower European ancestry was observed over a region on chromosome 12q24 for all cases (Z-score = -3.97, $p = 7.2\times10^{-5}$), and for ER-positive cases (Z-score = -4.04, $p = 5.3\times10^{-5}$). In case-only analyses of ER-negative women, the largest excess of European ancestry was observed over the 8q21 region (Z-score = 3.59, $p = 3.4\times10^{-4}$). In summary, we found that African American women with ER-negative tumors tended to have lower overall European ancestry relative to women with ER-positive breast cancer. These results add to the findings from the GWAS in Caucasian populations and suggest novel regions containing multiple variants with weak to modest effects that may jointly contribute to the racial differences in breast cancer risk.

3302S

Estimation of de novo mutation rates in the offspring of Lynch syndrome families. *S. Shankaracharya, C.D. Huff, F.A. San Lucas, C. Wei, J. Rother, P.A. Scheet, P.M. Lynch, M.L. Frazier.* Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX.

Lynch syndrome [LS] is a hereditary disorder characterized by an increased risk of developing colorectal cancer and other specific cancers. LS follows an autosomal dominant pattern of inheritance and is caused by genetic variants that decrease DNA mismatch repair capacity. Individuals with LS have a 50-80% lifetime risk of developing colorectal cancer, with an average age-of-onset of 45 years. In LS families, offspring develop cancer approximately 10 years earlier than their parents, but the cause of anticipation in LS is not yet understood. Here, our goal is to determine whether anticipation in LS results from an excess of single nucleotide and small indel de novo mutations due to decreased DNA mismatch repair capacity. To test this hypothesis, we sequenced 39 individuals from 3 control and 7 LS families to greater than 30X coverage on two separate whole genome sequencing (WGS) platforms, Illumina and Complete Genomics. To identify single nucleotide and small indel de novo mutation candidates, we analyzed the Illumina WGS data with four pedigree-aware variant callers (GATK PhaseByTransmission, Denovogear, Famseq and Polymutt) as well as two general-purpose variant callers (GATK HaplotypeCaller and GATK UnifiedGenotyper). We report the estimated single nucleotide and small indel de novo mutation rates in each family for candidates identified from the Illumina data and validated by the Complete Genomics data. With this approach, the expected number of false positive mutations is less than 1 per family. We also report the accuracy of the six variant callers as measured by the specificity, sensitivity and receiver operating curves (ROC) of each method.

3303M

Excess Prevalence of Gastric Cancer Family History Among Hispanic Breast Cancer Patients. *I. Solomon, A. Sunga, K. Yang, J. Weitzel.* City of Hope National Medical Center, Duarte, CA.

Purpose: As the 2nd most common cause of cancer death and 4th most common incident cancer, gastric cancer (GC) accounts for approximately 10% of all cancer deaths. Environmental and genetic risk factors have been established to play a role in the etiology of GC. However, outside of the few known inherited syndromes that cause GC, there is a lack of data exploring other contributing genetic factors, specifically family-based studies. In addition, there is a dearth of information regarding familial GC in the background of breast cancer aside from Hereditary Diffuse Gastric Cancer and Peutz-Jeghers syndromes. This report aims to characterize a population with a family history of GC from the City of Hope Clinical Cancer Genetics Community Research Network (CCGCRN) and explore the presence of familial GC in individuals with a personal history of breast cancer. We aim to contribute to the knowledge-base of familial GC and illuminate potential associations. **Methods:** The CCGCRN's Institutional Review Board-approved registry was queried (Progeny® v9.1) for the keywords “family history of GC” obtained from patients’ individual data spreadsheets. Family information was entered into a database for analysis. Individual pedigree evaluations were completed for families with more than one family member afflicted with GC. Descriptive analysis using SPSS® v19 was conducted to create frequency tables. **Results:** There were 1116 (9.4%) families with a history of GC. Notably, 33% (365) reported Hispanic ancestry as compared to 26% Hispanic representation in the registry overall. Most families had one member with GC (919), 143 had 2 family members with GC and 54 had ≥ 3. A majority (657) of these families were based on a breast cancer index case. Only 153 (14%) of these families carried a known mutation, with the majority (99) carrying an HBOC gene mutation. The most common mutation was the Ashkenazi Jewish Founder mutation BRCA1 185delAG (11), then 3492insT (7) and 6174delTT (5) in *BRCA2* . Two of these mutations have been previously shown to be common Hispanic mutations in the U.S. Gastric cancer has been previously reported in association with HBOC. Our findings raise the question of an under appreciated association of GC in HBOC. However, a larger sample is needed to further define the phenotypic variation of GC in HBOC families. In addition, this data prompts the idea of population-dependent genetic modifiers that may play a role in Hispanic HBOC families.

3304T

Association of polymorphism in GSTM1 null with obesity in breast cancer patients triple negative. *O. Soto-Quintana[1,2], B. Sánchez[6], R. Rámirez[1,3], A. Ramos[1,2], DI. Carrillo[1,3], IA. Gutíerrez[1,3], AR. Rincón[4], AM. Puebla[5], MP. Gallegos[1].* 1) División de Genética Molecular, CIBO, IMSS, Guadalajara, Jal,. Mex, Mexico; 2) Doctorado en Farmacología, CUCS, U de G; 3) Doctorado en Genética Humana, CUCS, U de G; 4) Coordinación del Doctorado en Farmacologia, Departamento de Fisiología, CUCS, u de G; 5) Laboratorio de Inmunofarmacología, Depertamento de framacología, CUCEI, U de G; 6) Consulta Externa de Oncología, UMAE Hospital de Gineco'Obstetricia, CMNO, IMSS.

Glutathione S-transferases M1 (GSTM1) is an important phase II metabolizing enzyme. The null genotype of GSTM1 causes total loss of GSTM1 enzyme activity and numerous studies have investigated the association between GSTM1 null genotype and breast cancer risk. In this study was analyzed 67 breast cancer patients triple negative. The GSTM1 null genotype was determined by PCR. Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated to estimate the association. The null genotype was associated with obesity in breast cancer patient's stage IV triple negative [OR 4.8(95%CI 1.5-14.8), p=0.00642]. The GSTM1 null genotype is associated with an increased risk of breast cancer patient's stage IV triple negative.

3305S

Genetic Variants related to presence of Bladder Cancer in a high risk, arsenic-exposed population in Northern Chile (Antofagasta). *C. Vial[1], K. Espinoza[1], E. Chaparro[2], G. Repetto[1], M.I. Fernández[1,3].* 1) Centro de Genética y Genómica, Facultad de Medicina, Universidad del Desarrollo Clinica Alemana, Santiago, Chile; 2) Servicio de Urología, Hospital Regional de Antofagasta, Chile; 3) Departamento de Urología, Clinica Alemana.

Introduction: Bladder Cancer (BC) is a heterogeneous disease with a variable natural history. It is currently the fourth most common malignancy among men in the western world, following prostate, lung, and colon cancers. Incidence in an arsenic-exposed city in Northern Chile (Antofagasta 24.8/100,000) is 4 to 5 times higher than in the rest of the country. Concentrations in drinking-water in Antofagasta increased significantly from 90 to 800-900 μg/L when new drinking-water sources were introduced in 1958. Following this, nearly all of the population in Antofagasta was exposed to arsenic levels up to seventeen times over the WHO recommendation between 1958 and 1971. In the present study we aim to perform a Genome Wide Association Study (GWAS) on people exposed to Arsenic comparing cases with controls. Methodology: Individuals were invited to participate after signing an informed consent. A blood sample was obtained and a questionnaire with epidemiological and clinical information was applied. DNA samples were analyzed using Affymetrix Genome-Wide SNP Array 6.0. After filtering by missingness per individual, missingness per marker allele frequency and Hardy Weinberg Equilibrium we obtained 788,705 SNPs to be analyzed. Results: 42 BC patients and 36 control subjects have been enrolled so far in the study. All of them were exposed to arsenic at some point between 1955 and 1971. The epidemiological data showed that males are predominant among cases and controls (64.3% and 83.3%; respectively) and there is no significant difference concerning mean age, familial history of BC, occupational exposure or smoking status between groups. It is interesting to note that smoking prevalence is high and similar among cases and controls (59.5% and 58.3%; respectively; p=0.55). The sample for population stratification was analyzed using principal component analysis (PCA), clustering the different patients with the identity by state and found them to be a homogeneous population. An association test comparing cases and controls was performed and found two regions with a significant association: (a) rs4838646 in chromosome 10 (p=3.8E-06) and (b) rs12371702 in chromosome 12 (p=5.8E-06). Previous studies have linked polymorphisms in the former region to BC susceptibility. Conclusion: Initial results of a BC genomic case-control study in an arsenic exposed population are presented. Further analysis is warranted after completion of recruitment. Fondecyt1120987.

Heterogeneous DNA methylation contributes to tumorigenesis by inducing the loss of co-expression connectivity in colorectal cancer. *Q. Wang[1], P. Jia[1], F. Cheng[1], Z. Zhao[1,2,3,4].* 1) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN; 2) Center for Quantitative Sciences, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN.

Increasing evidence indicates the high heterogeneity of cancer cells. Recent studies have revealed distinct subtypes of DNA methylation in colorectal cancer (CRC); however, the mechanism of heterogeneous methylation underlying tumor process remains poorly understood. Gene expression is a natural, intermediate quantitative trait that bridges genotypic and phenotypic features. In this work, we studied the role of heterogeneous DNA methylation in tumorigenesis via gene expression analyses. Specifically, we integrated methylation and expression data in normal and tumor tissues, respectively, and examined the perturbations in co-expression patterns. We found that the heterogeneity of methylation leads to significant loss of co-expression connectivity in CRC. Moreover, validation in an independent cohort confirmed the reliability of our findings. Functional analyses showed that the lost co-expression partners participate in important cancer-related pathways/networks, such as ErbB and MAPK signaling pathways. To our knowledge, this is the first study interpreting methylation heterogeneity in cancer from the perspective of co-expression perturbation. Our analyses suggest that the loss of co-expression connectivity induced by methylation heterogeneity plays an important role in CRC. These findings provide new perspectives in tumor biology and may facilitate the identification of potential biomedical therapies for cancer treatment.

3307T

Pathways associated with susceptibility of nasopharyngeal carcinoma (NPC) identified by whole-exome sequencing in Taiwanese NPC families. *G. Yu[1], W. Hsu[1], M. Yeager[1], CGR. Cancer Genomics Research Lab[1], C. Wang[2], P. Lou[2], S. Diehl[3], C. Chen[4], A. Hildesheim[1], A.M. Goldstein[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) National Taiwan University, Taiwan; 3) Rutgers School of Dental Medicine, Newark, NJ; 4) Academia Sinica, Taiwan.

NPC is a cancer that is known to be caused by infection with Epstein-Barr virus (EBV), a ubiquitous DNA virus that establishes lifelong latency in infected individuals. While >90% of the world population is infected with EBV during childhood or early adult life, only a very small fraction of infected individuals develop NPC. It is believed that, In addition to EBV infection and other environmental factors, genetic predisposition plays an important role in the pathogenesis of NPC. However, except for the genes that encode human leukocyte antigen (HLA), no other specific genes or chromosome regions have been shown to be consistently associated with NPC. In this study, we sequenced 83 exomes from 32 NPC families with 2-4 cases by Nimblegen v2.0 and v3.0 exome capture array and the Illumina HiSeq2000 sequencer. Reads were aligned using Novoalign v.2.07.14 and variants were called using GATK software. We prioritized 637 rare deleterious variants (frequency <1% in dbSNP, 1000 genomes or NHLBI exome database; no segmentally duplicated genes/variants; not in the repeated region; predicted as deleterious mutation by PolyPhen-2) with at least 10 reads and fitting a dominant segregation model in families with multiple NPC patients sequenced. Forty genes with functions related to EBV or NPC or infection and immunity were prioritized for technical validation in other members of the sampled families. Pathway enrichment analysis for the 637 prioritized deleterious variants in Kobas 2.0 (http://kobas.cbi.pku.edu.cn/home.do) suggested that three pathways including Notch signaling, ECM (extracellular matrix)-receptor interaction and Focal adhesion were significantly enriched in NPC cases (P<0.00087). All these pathways are critical for cell survival, growth and metastasis. Another set of NPC families (218 exomes, 110 families with 2-3 cases) will be exome sequenced to confirm our results and expand the search for NPC susceptibility genes.

3308S

Female Reproductive Traits and Lifespan in *BRCA* Families. *W. Zhuang[1], C. Snyder[1], M. Casey[2,3], M. Stacey[1], H. Lynch[1].* 1) Department of Preventive Medicine and Public Health, Creighton University, Omaha, NE; 2) Department of Obstetrics and Gynecology, Creighton University, Omaha, NE; 3) Department of Pathology, Creighton University, Omaha, NE.

Objective: A longer female reproductive lifespan increases exposure to endogenous estrogen and number of ovulations, which can be risk factors for breast and ovarian cancers. We investigated the effects of *BRCA1* and *BRCA2* on female reproductive traits and lifespan to understand the differences in risks for breast and ovarian cancers in *BRCA1* compared with *BRCA2* mutation carriers. Further, we explored the potential of other genes that influence reproductive traits/lifespan and are functionally independent of *BRCA1* and *BRCA2* mutations. **Methods:** We studied a total of 1058 women from the Creighton University Hereditary Cancer Registry. The women who tested positive or negative for their family's deleterious mutation in *BRCA1* and *BRCA2*, and provided age at menarche, age at natural menopause (ANM), or both were included in the study. The linear mixed-effects model was used to explore the effects of *BRCA1* and *BRCA2* on female reproductive traits and lifespan. Heritability estimates were calculated using variance-components methods in Sequential Oligogenic Linkage Analysis Routines (SOLAR) to explore the potential of other genes with respect to female reproductive traits and lifespan. **Results:** The reproductive lifespan of the women with a *BRCA1* mutation was 3.12 years shorter (p-value = 0.048, n=38) than the non-carrier relatives. The significant difference was not observed in the *BRCA2* families. Age at menarche was significantly heritable after adjusting for the presence of a *BRCA1* or *BRCA2* mutation (heritability [h^2] = 0.57 and 0.34, and n= 810 and 416, respectively; p-values <0.01). **Conclusions:** Women with a *BRCA1* mutation may have a shorter reproductive lifespan as compared to non-carrier relatives, causing a shorter period of exposure to estrogen and lower number of ovulations. The high heritability after adjusting for the presence of a *BRCA1* or *BRCA2* mutation underscores the importance of further work to identify other specific genes that contribute significantly to the variation in age at menarche in *BRCA* families.

Assessing the Cumulative Contribution of New and Established Common Genetic Risk Factors to Early-Onset Prostate Cancer. *K.A. Zuhlke[1], J.V. Ribado[2], A.M. Johnson[1], G.R. Keele[2], J. Li[2], Y. Wang[2,3], Q. Duan[2], G. Li[4], Z. Gao[4], Y. Li[2,3], J. Xu[4], S. Zheng[4], K.A. Cooney[1,5], E.M. Lange[2,3].* 1) Department of Internal Medicine, University of Michigan, Ann Arbor, MI; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC; 3) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 4) Center for Genomics and Personalized Medicine Research, Wake Forest University, Winston-Salem, NC; 5) Department of Urology, University of Michigan, Ann Arbor, MI.

Genome-wide association studies (GWAS) have identified more than 60 loci associated with prostate cancer (PCa) in men of European ancestry, including 23 loci recently identified in a large study from the PRACTICAL consortium. We assessed the evidence for these 23 new PCa loci and the aggregate predictive value of these 23 SNPs plus 40 established SNPs with respect to early-onset (EO) PCa using 931 unrelated men diagnosed with PCa prior to age 56 years from the University of Michigan Prostate Cancer Genetics Project and 1126 male controls. Ten of the 23 new SNPs demonstrated evidence ($p < 0.05$) for association with EO disease. On average, EO PCa cases carried one more total risk alleles compared to controls across these 23 SNPs (21.61 vs. 20.69, $p=2.0\times10^{-12}$) and 3.5 more risk alleles across all 63 SNPs (58.02 vs. 54.49, $p=8.9\times10^{-59}$). We constructed receiver operating characteristic curves and calculated the corresponding area under the curves (AUC) for weighted aggregate risk allele counts for the 23 new PCa SNPs (AUC=0.59), 40 established PCa SNPs (AUC=0.69) and the set of 63 total PCa SNPs (AUC=0.71). The defined risk alleles and their associated weights were based on previous reports. We found that the aggregate burden of common risk alleles across previously associated PCa SNPs is highly predictive of EO PCa for men with values of total risk burden in either tail of the total risk allele distribution. The odds of a man having EO PCa given a burden of risk alleles in the upper, or lower, 5% of the combined case-control distribution of risk alleles across all 63 SNPs was estimated to be 11.11 [95% CI (5.91,20.90)] or 0.24 [95% CI (0.14,0.40)], respectively. While attenuated, odds remained strong for men in the upper or lower 25% of the total risk allele distribution (OR=3.81 [3.08,4.72] or OR= 0.27 [0.21,0.33], respectively). Inclusion of results from the 23 new variants only modestly improved disease prediction over the 40 established stronger effect SNPs. Our results provide the first formal replication for many of the 23 new variants recently reported to be associated with PCa and firmly establishes the importance of common variants, identified to be associated with PCa in GWAS, in men with early-onset disease.

3310T

Determination of cancer susceptibility in early-onset colorectal cancer (CRC) patients. *K.A. Schrader[1,6], J. Vijai[1,6], M. Artomov[2,6], T. Thomas[1], A. Kiezun[2], X. Wei[3], M. Corines[1], L. Jacobs[1], A. Lincoln[1], D. Villano[1], R. Rau-Murthy[1], L. Margolin[2], N. Gupta[2], M. Robson[1], R.J. Klein[4], L. Ellisen[5], M. Daly[2], S. Lipkin[3], G. Getz[2], S. Gabriel[2], D. Altshuler[2], K. Offit[1], Z. Stadler[1].* 1) Memorial Sloan Kettering Cancer Center, New York, NY; 2) Broad Institute of Harvard and MIT, Cambridge, MA; 3) Department of Medicine, Weill Cornell College of Medicine, New York, NY; 4) Department of Genetics and Genomic Sciences, Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai New York, NY; 5) Massachusetts General Hospital, Boston, MA; 6) equal contributions.

Germline mutations in high-penetrant cancer susceptibility genes have been implicated in CRC risk. As part of a larger project elucidating the genetic basis of CRC, we surveyed whole-exome sequencing (WES) data from early-onset CRC patients, for germline variants in known cancer predisposition genes. CRC patients, diagnosed at ≤45 years of age, with unrevealing clinical genetics evaluations, were ascertained under IRB-approved research protocols allowing for WES at MSKCC's Clinical Genetics Service. Cases were enriched for DNA mismatch repair (MMR) proficient CRC or MMR-deficient CRC due to somatic *MLH1* hypermethylation. Germline DNA was subjected to exome capture, paired-end sequencing, and variant calling by GATK Unified Genotyper. Variant curation was by Ingenuity Variant Analysis(c) with 150 cancer susceptibility genes analyzed. Variants were excluded, with minor allele frequencies (MAF) >5% in public databases, at base positions with >10% missing calls and if novel and at >20% MAF within the cohort. Preliminary analysis involved visualization of BAM files and inclusion of only unique protein truncating variants. Analysis of 63 early-onset CRCs revealed 15 patients with presumed deleterious heterozygous protein truncating variants in 11 genes; *MSH2*, *STK11*, *MUTYH*, *BAP1*, *BUB1B*, *BLM*, *FANCL*, *COL7A*, *ATR*, with 2 variants in *PMS2* and 4 in *ATM*. Family history in the *MSH2* variant carrier was consistent with Lynch Syndrome. In one *PMS2* variant carrier, the tumor showed isolated PMS2 protein loss. No polyps were detected in carriers of *MUTYH* or *BUB1B* variants, but were present in both family histories. The *STK11* variant carrier also had bronchioloalveolar carcinoma (BAC) at age 39, and no classic Peutz-Jeghers stigmata. In 2 *ATM* variant carriers, family histories included pancreatic, ovarian and breast cancer. The *BAP1* variant carrier had no relevant history. Half of the cancer susceptibility genes harboring unique protein truncating variants found by WES of early-onset CRC are not implicated in CRC susceptibility and in most cases, clinical history was not suggestive of the identified genetic variant. However, among these findings, an identified *STK11* variant carrier without classical features of Peutz-Jeghers had BAC, that has been reported in association with *STK11* germline and somatic mutations. Multiplex panels will potentially broaden the phenotypic spectrum of well-defined syndromes; clinical correlation and proof of causation will remain a challenge.

Hispanic MMR Mutations: A Multi-Institutional Report from Southwestern United States and Puerto Rico. *A. Sunga[1], C. Ricker[2], C. Espenschied[3], J. Herzog[1], S. Bannon[4], M. Cruz Correa[5], P. Lynch[4], S. Gruber[2], J. Weitzel[1].* 1) Clinical Cancer Genetics, City of Hope, Duarte, CA; 2) Clinical Cancer Genetics, USC Norris Comprejhensive Cancer Center, USC Los Angeles, CA; 3) Ambry Genetics, Aliso Viejo, CA; 4) Clinical Cancer Genetics, MD Anderson Cancer Center, Houston, TX; 5) Clinical Cancer Genetics, University of Puerto Rico Comprehensive Cancer Center, Rio Piedras, Puerto Rico.

Background Knowledge of founder mutations enable efficient and cost-effective strategies for genetic testing, a potential benefit for populations with limited access to services. We have shown several BRCA mutations, most of Spanish origin, to be founder mutations in Hispanic populations. We hypothesized that the same population factors may be operative in Lynch syndrome. There is limited literature on the spectrum of mutations in mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) in Hispanic populations. Our goal was to identify recurrent MMR mutations in Hispanic patients and explore potential ancestral origins of identified mutations. **Methods** Subjects: Hispanics patients seen for genetic risk assessment at City of Hope Clinical Cancer Genetics Community Research Network collaborating institutions, MD Anderson Cancer Center, USC Norris Cancer Center and the University Of Puerto Rico Cancer Center. A total of 397 patients underwent evaluation for Lynch syndrome by genotyping of one or more of the MMR and/or tumor analysis by IHC. A comprehensive literature review and of MMR variant databases was conducted for all mutations. **Results** Seventy one (18%) unrelated Hispanic families were found to have at least one MMR disease predisposing gene mutation. Most (90%) of the mutations were noted in the *MLH1* and *MSH2* genes and more than half (55%) were frameshift and nonsense type. Nine mutations were observed two or more times: *MLH1* 350C>T, 1790del2ins9, 2041G>A, 1852del3, 1024del16, and IVS7+5G>A; and *MSH2* 1216C>T, 425C>G, and 1705delGA. Most (6/9) recurrent mutations were detected in multiple institutions. *MSH2* 1216C>T and *MLH1* 1852del3 were seen 5 and 4 times respectively and have been reported multiple times in European populations. *MLH1* 350C>T, 2041G>A, 332C>T, and 676C>T and *MSH2* 1216C>T, exon 4-8 del, and exon 8 del have all been reported previously in Spain. The *MSH2* exon 4-8 del was seen in one Mexican family and has been reported as a Spanish founder mutation. **Conclusion** Our finding that 3/9 recurrent mutations and the *MSH2* exon 8 del identified in our cohort were previously reported in Spain supports the hypothesis of the likely influence of Spanish ancestral heritage on MMR gene mutations in Hispanic populations. While this is the largest reported cohort of Hispanic patients with MMR mutations in N America, a larger sample and haplotype analyses are needed to better define the spectrum and origin of MMR mutations in Hispanic populations.

Hodgkin lymphoma (HL) is a highly heritable B-cell lymphoma that primarily affects young adults. Its epidemiology and pathology are unique and more closely aligned with immunological diseases than with other solid tumors. To test this hypothesis, we conducted studies examining the genetic overlap between HL and multiple sclerosis (MS) and asthma. We performed a meta-analyses of HL and MS consisting of 1,816 HL patients, 9,772 MS patients, and 25,255 controls using 464,424 single nucleotide polymorphisms. Genetic overlap was observed in the HLA region and genome-wide, including modest genome-wide significant associations at two loci that did not reach genome-wide significance in either disease alone: IL12B (rs2546890, $OR_{MS\text{-}HL\text{-}meta}$=1.1, p=3.37 x 10^{-8}), a gene encoding a subunit of a cytokine involved in T-helper cell Type 1 (Th1) immunity, and NCOA5 (rs2425752, $OR_{HL\text{-}MS\ meta}$=1.11, p=2.96 x 10^{-8}), a gene included in an estrogen-dependent oncogenic pathway. We conducted a separate analysis of HL and asthma combining GWAS meta-analysis of 1,816 HL cases and 7,877 HL controls with a GWAS meta-analysis of 2,088 asthma cases and 2,743 asthma controls examining 904,634 SNPs in common. We found associations with two linked SNPs in the T-helper cell Type 2 (Th2) transcription factor gene GATA3 (rs422628, $OR_{HL\text{-}asthma\ meta}$ =1.247, p=3.36 x 10^{-9} and rs444929, $OR_{HL\text{-}asthma\ meta}$ = 1.264, p=2.09 x 10^{-8}), both of which were significant at the p <0.05 level in the disease-specific GWAS, but reached genome-wide significance in the HL-asthma meta-analysis. The effect was stronger in the subset of nodular sclerosis HL (rs422628, $OR_{HL\text{-}asthma\ meta}$ = 1.32, p=2.33 x 10^{-9} and rs444929, $OR_{HL\text{-}asthma\ meta}$ = 1.32, p=4.28 x 10^{-8}). Another genome-wide significant SNP near KIAA1279 reached genome-wide significance only in the nodular sclerosis subtype subset (rs6864, $OR_{HL\text{-}asthma\ meta}$ = 0.81, p=4.65 x 10^{-8}). In a genetic diseasome analysis, HL was more closely aligned to both MS and asthma and other immunological diseases than to solid cancers. Recognition of overlap in genetic predisposition to HL and immune diseases sheds light on the complex etiology of HL and may enable novel diagnostic and therapeutic approaches.

3313T

Prospectively Identified Incident Testicular Cancer Risk in a Familial Testicular Cancer Cohort. *A. Pathak[1], C. Adams[1], J. Loud[1], K. Nichols[2], M. Greene[1], D. Stewart[1].* 1) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA; 2) Westat, Inc., Rockville, MD, USA.

Testicular germ cell tumors (TGCT) are the most common form of cancer in men aged 15-35 years. Approximately 8,820 new cases and 380 TGCT deaths are projected for 2014. Human testicular germ cell tumors (TGCT) have a strong genetic component and a high familial relative risk. TGCT has an estimated heritability that ranks as the 3rd highest for all cancers. Compared with most cancers - which have familial relative risks between 1.5-to-2.5 fold - sons and brothers of affected men with TGCT have a 4- to 6-fold and 8- to 10-fold increased risk of TGCT versus the general population, respectively. These risks increase to 37-fold and 76.5-fold in dizygotic and monozygotic twins. However, linkage analysis has failed to identify any rare, highly-penetrant familial TGCT (FTGCT) susceptibility loci. Currently, multiple low-penetrance genes are hypothesized to underlie the familial multiple-case phenotype. Despite the apparent heritability of TGCT, families with more than two affected members are unusual, unlike other hereditary cancer syndromes in which a single multigenerational pedigree can harbor many affected individuals. Importantly, the prospective TGCT risk in this context is unknown. Thus, we performed a prospective quantitative analysis of TGCT incidence in a cohort of multiple affected person and sporadic bilateral case families; 1,260 men from 140 families (10,207 person-years of follow-up) met our inclusion criteria. Age-, gender-, and calendar time-specific standardized incidence ratios (SIR) for TGCT relative to the general population were calculated using SEER*Stat. Eight incident TGCTs occurred during prospective FTGCT cohort follow-up (versus 0.67 expected; SIR= 11.9; 95% confidence interval [CI]=5.1-23.4). We demonstrate that the incidence rate of TGCT is much greater among bloodline male relatives in multiple-case testicular cancer families than that expected in the general population, a pattern characteristic of adult-onset Mendelian cancer susceptibility disorders. Remarkably, two incident TGCTs occurred in healthy relatives of sporadic bilateral cases (0.15 expected; SIR=13.4; 95% CI=1.6-48.6). Our data are the first to indicate that, despite relatively low numbers of affected individuals per family, members of both multiple affected person FTGCT families and sporadic bilateral TGCT families comprise high-risk groups for incident testicular cancer, which might benefit from tailored risk stratification and surveillance strategies.

3314S

The significance of N-acetyltransferase 2 (NAT2) genotypes in combination with phenotypes to risk of bladder cancer in a Chinese population. *K. Chattopadhyay[1], Y-B. Xiang[2], H.H. Nelson[3], R. Wang[1], Y-T. Gao[2], J-M. Yuan[1].* 1) University of Pittsburgh Cancer Institute, and Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 2) Department of Epidemiology, Shanghai Cancer Institute, Shanghai Jiatong University, Shanghai, China; 3) Masonic Cancer Center, and Division of Epidemiology and Community Health, School of Public Health, University of Minnesota, Minneapolis, Minnesota, USA.

1) Current Affiliation: F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute, Department of Gastroenterology, Cedars-Sinai Medical Center, Los Angeles, California, USA. Background: The incidence rates of bladder cancer in Chinese men and women are only one-third those in U.S. whites although smoking rate, a major risk factor for bladder cancer, is higher in Chinese males than U.S. white males. N-acetyltransferase 2 (NAT2) plays a major role in catalyzing the detoxification of aromatic amines in cigarette smoke and other environmental sources. Some of aromatic amines are carcinogenic to the urinary bladder. The difference in genetically determined acetylation status may contribute to the differential risk of bladder cancer between Chinese and whites. Methods: A population based case-control study of bladder cancer (499 cases, 513 controls) in Shanghai, China was conducted. Six common single nucleotide polymorphisms (SNPs) of NAT2 gene (803A>G, 282C>T, 481C>T, 590G>A, 857G>A, 341T>C) were determined using TaqMan assay. The NAT2 acetylation phenotype was determined by the ratio of urinary caffeine metabolites. Unconditional logistic regression methods were used to calculate odds ratio (OR) and 95% confidence interval (CI) of bladder cancer associated with NAT2 phenotypes, genotypes and haplotypes with adjustment for age, sex, alcohol intake and cigarette smoking. Results: Mutant alleles of any six NAT2 SNPs were associated with reduced acetylation status in a dose-dependent manner among healthy individuals. The NAT2 genotypes referring to intermediate acetylation status was associated with significantly reduced risk (OR = 0.70, 95% CI = 0.53-0.92, p = 0.012) of bladder cancer compared to the genotypes referring to rapid acetylation status. The genotypes referring to slow acetylation status did not show any significant association with the disease. Conclusion: Our results show a novel association of NAT2 genotypes with bladder cancer in a Chinese population. The results must be interpreted cautiously and further work with a larger population is warranted.

DEPTH: A Novel Algorithm for Feature Ranking with Application to Genome-Wide Association Studies Identifies that Variation in the ESR1 Gene Region is Associated with Risk of Estrogen Receptor Negative Breast Cancer from a Small Study. *E. Makalic, D.F. Schmidt, M. Kapuscinski, J.L. Hopper.* School of Population and Global Health, The University of Melbourne, Victoria, Australia.

A conventional Genome-Wide Association Study (GWAS) involves selecting single nucleotide polymorphisms (SNPs), from among a very large set of correlated SNPs, that discriminate between two groups. The ultimate aim is to identify susceptibility genes, or gene regions; the dominant paradigm to date has been to identify SNPs associated with risk of disease. We propose a new algorithm, called DEPendency of association on the number of Top Hits (DEPTH), that achieves the aim more efficiently by using bootstrap statistics and stability selection and considering contiguous SNPs as a group. DEPTH is applicable to ordinary, logistic, and Cox regression and can be run on a commodity computer but is implemented to run much faster on the IBM BlueGene/Q supercomputer. In the context of a GWAS, the algorithm passes a sliding window across the whole genome, and can be applied to subsets of SNPs (e.g. in a region or pathway, or of a particular 'type'). We have found, using simulated data, that the algorithm shows good statistical performance when compared to several established procedures.

We applied DEPTH to data from the hypothesis-generating Phase I of a GWAS that included Australian women with breast cancer diagnosed before age 40 years (72 estrogen receptor (ER) -ve; 88 ER +ve) and 287 women 40 years and older without breast cancer, genotyped using the Illumina 610KQUAD platform with standard QC. DEPTH identified that germline variation in the region of the *ESR1* gene was implicated in risk of ER-ve disease, and more so than ER+ve disease, a finding not evident from applying the conventional 'genome-wide significant' threshold to these data. Subsequent analysis of iCOGS data for ~9,500 ER-ve and ~32,000 ER+ve cases and ~51,000 controls found evidence consistent with these hypotheses. Our insights from a small GWAS validates the utility of our approach in terms of the novel design - using cases (controls) enriched (depleted) for putative genetic risk - and analysis using DEPTH.

DEPTH: A Novel Algorithm for Feature Ranking with Application to Genome-Wide Association Studies Identifies that Variation in the CHEK2 Gene Region is Associated with Risk of Breast and Colorectal Cancer. *D.F. Schmidt[1], E. Makalic[1], M. Kapuscinski[1], W. Chen[2], P.M. Lynch[3], C.I. Amos[4], J.L. Hopper[1], M. Pande[3].* 1) School of Population and Global Health, The University of Melbourne, Victoria, Australia; 2) Department of Clinical Applications and Support, MD Anderson Cancer Center, TX, USA; 3) Department of Gastroenterology - Research, MD Anderson Cancer Center, TX, USA; 4) Department of Community and Family Medicine, Geisel School of Medicine, Dartmouth College, Lebanon, NH, USA.

A conventional Genome-Wide Association Study (GWAS) involves selecting single nucleotide polymorphisms (SNPs), from among a very large set of correlated SNPs, that discriminate between two groups. The ultimate aim of a GWAS is to identify susceptibility genes, or gene regions; the dominant paradigm to date has been to do this by identifying individual SNPs associated with risk of disease. We propose a new algorithm, called DEPendency of association on the number of Top Hits (DEPTH), that achieves the above aim more efficiently by using bootstrap statistics and stability selection and considering contiguous SNPs as a group. DEPTH: (i) exploits information from the correlation structure of the predictors without specifying an underlying model; (ii) applies to ordinary, logistic, and Cox regression, so can be used to study continuous, binary and survival data, and (iii) can be run on a commodity computer but has also been implemented to run much faster in a parallel computing environment on the IBM BlueGene/Q supercomputer. In the context of a GWAS, the algorithm can consider SNPs across the whole genome, or subsets of SNPs (e.g. in a region or pathway, or of a particular 'type'). We have found, using simulated data, that the algorithm shows good statistical performance when compared to several established procedures. We applied DEPTH to a subset of GWAS data from the Breast and Colon Cancer Family Registries to try to elucidate genes/regions associated with susceptibility to breast and/or colorectal cancer. Cases (985) were women with breast cancer and a family history of colorectal cancer, or persons with colorectal cancer with a family history of breast cancer. Controls (1769) were frequency matched to cases for age and sex and had neither breast nor colorectal cancer. DEPTH identified that germline variation in the region of the checkpoint kinase 2 (CHEK2) gene is associated with risk of breast and/or colorectal cancer, a finding not evident from applying the conventional 'genome-wide significant' threshold. Lending support to our finding, several germline mutations in CHEK2 (e.g., 1100delC, IVS2+1G>A and I157T) are known to be associated with the risk of breast, colorectal, ovarian, lung and other cancers. Our finding from studying a modestly sized GWAS validates the utility of our approach both in terms of the novel design (using family history across diseases) and analysis (DEPTH).

3317S

Integrated pathway and gene-gene interaction analysis reveals novel candidate genes for melanoma. *M. Brossard[1,2], S. Fang[3], A. Vaysse[1,2], Q. Wei[4], H. Mohamdi[1,2], W.V. Chen[1,2], N. Lavielle[1,2], E. Maubec[1,2], M.-F. Avril[5], M. Lathrop[6], J.E. Lee[3], C.I. Amos[7], F. Demenais[1,2], MELARISK and MDACC Melanoma Study Groups.* 1) INSERM UMR-946, Paris, France; 2) Université Paris Diderot, Paris, France; 3) MD Anderson Cancer Center, Houston, Texas, USA; 4) Department of Medicine, Duke University School of Medicine, Durham, USA; 5) Hôpital Cochin, Université Paris Descartes, Paris, France; 6) Genome Quebec Innovation Centre, McGill University, Montreal, Canada; 7) Geisel College of Medicine, Dartmouth College, New Hampshire, USA.

Genome-wide association studies (GWAS) have identified 17 loci associated with melanoma risk. However, these loci account for a small part of melanoma susceptibility. These GWAS, which have focused on the analysis of individual SNPs, are underpowered to detect SNPs with small marginal effect. To increase the yield from GWAS, alternative approaches that use biological knowledge and allow testing for association on the basis of functional units (pathways) have been proposed. To identify new candidate genes for melanoma, we proposed an analysis strategy that combines pathway analysis and tests of gene-gene interactions (GxG) within melanoma-associated pathways. Pathway analysis was conducted using the gene-set enrichment analysis (GSEA) approach, which searches for gene sets, defined by gene ontology (GO) classes, enriched in genes associated with melanoma. GSEA was applied to single-SNP statistics obtained from GWAS of the French MELARISK study (3,976 subjects) and the North-American MDACC study (2,827 subjects). To identify enriched GO categories, we computed the false discovery rate (FDR), using 100,000 permutations of SNP statistics. We tested all cross-gene SNP-SNP interactions within each identified GO using INTERSNP. One million Hapmap3-imputed SNPs were assigned to 22,000 genes, that were assigned to 316 Level4-GO classes. Five GO categories were found to be significantly enriched in genes associated with melanoma (FDR≤5% in both studies): response to light stimulus, regulation of mitotic cell cycle, induction of programmed cell death, cytokine activity and oxidative phosphorylation. A total of 101 genes were driving the enrichment signals in these pathways. Five of these genes (*TP63*, *IL6*, *IL15*, *MAPK1*, *NDUFA2*) were found to occur frequently with melanoma-related terms through text mining of PubMed abstracts and represent novel candidates for melanoma risk. Analysis of SNP-SNP interactions within each of the five identified GO showed evidence for interaction for 4 SNP pairs ($P \leq 10^{-4}$ in MELARISK and replication at 5% in MDACC). One of these gene pairs, *TERF1-AFAP1L2* (combined P-value over the two samples=2×10^{-6}), is particularly biologically relevant. TERF1 and AFAP1L2 proteins have been recently reported to interact for telomere signaling, a process which is emerging as playing a key role in melanoma. Thus, an integrated pathway and gene-gene interaction analysis is a powerful approach to uncover new disease genes.

3318M

Combined pathway and gene-gene interaction analysis pinpoints biologically relevant genes for a major melanoma prognosis factor. *A. Vaysse[1,2], S. Fang[3], M. Brossard[1,2], H. Mohamdi[1,2], W.V. Chen[3], N. Lavielle[1,2], E. Maubec[1,2], Q. Wei[4], M. Lathrop[5], M.-F. Avril[6], C.I. Amos[7], J.E. Lee[3], F. Demenais[1,2], MELARISK and MDACC Melanoma Study Groups.* 1) INSERM U946, Paris, France; 2) Université Paris Diderot, Paris, France; 3) MD Anderson Cancer Center (MDACC), Houston, Texas, USA; 4) Department of Medicine, Duke University School of Medicine, Durham, USA; 5) Genome Quebec Innovation Centre, McGill University, Montreal, Canada; 6) Hôpital Cochin, Université Paris Descartes, Paris, France; 7) Geisel College of Medicine, Dartmouth College, New Hampshire, USA.

Cutaneous melanoma is one of the deadliest cancers if diagnosed at a late stage. Breslow thickness (BT), a measure of invasion of melanoma in the skin, is a major predictor of melanoma survival. To date, the genetic factors underlying BT are largely unknown and have not yet been investigated at the genome-wide level. We first conducted a GWAS of BT in the French MELARISK study (966 cases) and the North-American MDACC study (1546 cases) using Hapmap3-imputed SNPs. Single SNP analysis in MELARISK showed evidence for five loci that reached $P<10^{-5}$ but none of these associations was replicated in MDACC, suggesting the existence of many genetic variants with small effect. Since the analysis of individual SNPs may be underpowered to detect SNPs with modest effect, we used a multi-marker analysis strategy that integrates pathway analysis and tests of cross-gene SNPxSNP interactions within BT-associated pathways. Pathway-analysis was based on the gene-set enrichment analysis (GSEA) approach, which searches for gene sets, defined by Gene Ontology (GO) classes, enriched in genes associated with BT. For each GO, we computed the false discovery rate (FDR), using 100,000 permutations of SNP statistics. Cross-gene SNPxSNP interactions within each identified GO were investigated through linear regression. One million Hapmap3-imputed SNPs were assigned to 21,917 genes using NCBI Build 37.1. These genes were assigned to 317 level 4-GO categories. Three GO categories were found to be significantly enriched in genes associated with BT (FDR≤5% in both studies): Hormone activity, Cytokine activity and Myeloid cell differentiation. A total of 61 genes were driving these pathways in both studies. Interestingly, expression of four of these genes (*CXCL12, TNFSF10, VEGFA, CDC42*) was reported to be associated with melanoma progression in tumors. Analysis of cross-gene SNPxSNP interactions within each identified pathway showed evidence for interaction for three SNP pairs ($P \leq 10^{-4}$ in MELARISK and replication at $P \leq 0.05$ in MDACC). One of these gene pairs (*SCINxCDC42*, combined P over the 2 samples=2×10^{-6}) has biological relevance. SCIN and CDC42 proteins are both involved in actin cytoskeleton dynamics, that plays a major role in cell migration, and have opposite roles: CDC42 stimulates actin assembly while SCIN severs the actin filaments, thus preventing their growth. This study outlines the importance of integrating various approaches for gene identification. Funding: INCa_5982.

3319T

A Population-based survey of excess cancers observed in NF1 cases and in their first- and second-degree relatives. *D. Abbott[1], D. Viskochil[2], D.A. Stevenson[2], L.A. Cannon-Albright[1,3].* 1) Division of Genetic Epidemiology, Department of Internal Medicine, University of Utah School of Medicine, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT; 3) George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, UT.

Background: Neurofibromatosis type I (NF1) is an autosomal dominant disorder that affects approximately 1 in 3000 individuals and is caused by a mutation in NF1, a tumor suppressor gene that encodes the protein neurofibromin. While NF1 individuals often have benign peripheral nerve sheath tumors (neurofibromas) and intracranial low-grade astrocytomas (gliomas), they are also at increased risk for malignant peripheral nerve sheath tumors (MPNST) and high-grade astrocytomas. Current research purports that NF1 individuals have increased risk for other cancers. We analyzed a unique population-based resource to characterize the increased risk of various cancers in NF1 individuals and their relatives in an unbiased fashion. Methods: The Utah Population Database (UPDB), a population-based Utah genealogy linked to both the Utah Cancer Registry and to hospital data from the University of Utah Health Sciences Center, was used to calculate relative risks (RR) of cancer in NF1 cases and in their first- and second-degree relatives. RR was calculated using age-, birth-state-, and birth-year-specific cancer rates. Results: We identified 237 individuals with NF1 who had ancestors in the UPDB. These cases had 1055 first-degree and 2770 second-degree relatives in the UPDB. The RRs for 6 cancers were significantly higher in NF1 cases: Malignant Peripheral Nerve Sheath Tumor-MPNST (RR=646.9; 95%CI: 260.07, 1332.83), brain (43.80: 20.03, 83.15), central nervous system (511.08: 165.94, 1192.66), lymphoma (6.04: 1.65, 15.47), skin melanoma (4.97: 1.02, 14.52), and breast cancer (3.6;1.01, 9.23). The RR of seven cancers were significantly higher in first-degree relatives: MPNST (RR=118.03:47.45, 243.18), brain (5.48: 2.20, 11.29); mature T-cell lymphoma (13.75: 1.67, 49.68), acute lymphocytic leukemia (6.26: 1.29, 18.29), lentigo maligna melanoma (6.24: 1.29, 18.24), breast cancer (1.74: 1.01, 2.82), and small intestine (7.07: 1.01, 25.54). Lastly, in second-degree relatives there was a significantly increased risk of two cancers: MPNST (16.29; 3.36, 47.60), and prostate (1.44; 1.11, 1.84). Conclusion: These results support an increased risk of distinct cancers in individuals with NF1 and also in their first- and second-degree relatives. Relative risks for various cancers are much higher for NF1 cases themselves, but first- and second-degree relatives still display a significant excess of some cancers.

3320S

Identification of somatic structural events associated with L1 element activity in 208 colorectal cancers using whole genome sequence analysis. *T. Cajuso[1,2], E. Pitkänen[1,2], R. Katainen[1,2], E. Kaasinen[1,2], J. Taipale[1,3], LA. Aaltonen[1,2], O. Kilpivaara[1,2].* 1) University of Helsinki, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Science for Life Center, Department of Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden.

L1 insertions have been shown to be frequent events in colorectal cancer (CRC). The role of L1 insertions to CRC tumorigenesis remains, however, unclear. L1 elements are retrotransposons that spread by copying themselves into an RNA intermediate and integrating at distant locations in the genome. Whole genome sequencing (WGS) has emerged as a novel tool to systematically search for structural variation. Utilizing WGS analysis, we recently detected insertions stemming from an active L1 element, located in the first intron of *Tetratricopeptide repeat domain 28* (*TTC28*). We have extended our WGS data to 208 CRC and respective germline DNA samples. We identified somatic structural variation including deletions, tandem duplications, inversions and translocations in the WGS data with DELLY. To reduce false positive calls, data was filtered against structural variation in the germline genomes and repeat regions in the genome. Structural events with breakpoints close to L1 elements as described in retrotransposon databases were investigated in detail. We first identified a total of 661818 structural somatic events. Subsequently, we focused on the 2619 structural somatic events located in close proximity to L1 elements (< 1000bp distance). From those, we have selected the 178 events that were present in more than one CRC, for visual inspection of mapped sequencing data and validation by Sanger sequencing. Careful analysis of WGS data is a prerequisite for accurate identification of structural variation and it should include consideration of retrotransposition events in cancer.

3321M

Duplication of 7p21.3-p14.3: metastasis risk, cancer susceptibilities and ethical implications. *M.R.S. Carvalho[1], M.P. Almeida[1], M. Miranda[1], L.T. Grillo[1], T.B. Teixeira[3], A.C.A. Prado[3], A.E. Paiva[1], P.A. Fonseca[1], L.L. Leão[3], M.J.B. Aguiar[3], V.G. Haase[2].* 1) Departamento de Biologia Geral, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 2) Departamento de Psicologia, Faculdade de Filosofia e Ciências Humanas, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 3) Serviço Especial de Genética Médica, Hospital de Clínicas, Faculdade de Medicina, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil.

The advent of powerful tools to identify copy number variations (CNVs) has opened new practical and ethical questions related to the functional implication of some chromosomal variants. Specifically, these questions include incidental findings. Recently, we evaluated a 17-year-old female with a history of psychomotor developmental delay, borderline intelligence, dysmorphic features, triphalangeal thumbs, hypotonia and severe hyperextensibility. A large 7p chromosome insertion was detected in the karyotype. Using CytoSNP-850K BeadChip (Illumina Technologies), we were able to identify a previously undescribed 16.4 Mb duplication (arr[hg19]7p21.3-p14.3 (13.265.700- 29.668.638)x3). Genes related to cancer and epithelial-mesenchymal transition (and therefore, metastasis) map to this chromosomal region, including the *HOXA* cluster, *TWIST1* (MIM 601622) and *HOTAIRM1.* The *HOXA4* (MIM 142953), *HOXA5* (MIM 142952), *HOXA7* (MIM 142950), *HOXA9* (MIM 142956) and *HOXA13* (MIM 142959) have been related to leukemia. Overexpression of these five *HOXA* genes, due to duplication of chromosome 7 in a gastric cell line, has been associated with tumorigenicity. Most notably, *HOXA9* overexpression has been described in the accelerated phase of chronic myeloid leukemia (CML[MIM 608232]). Overexpression of *TWIST1* has been related to metastatic cancer in general, advanced oral squamous cell carcinoma (OSCC), and with poor survival rates. Since large duplications have been only rarely described, it is impossible properly to establish the risks and management protocols for cancer surveillance for this patient. Moreover, the high metastasis risk unrelated to one specific type of cancer represents a complex situation in genetic counseling. In conclusion, the incidental findings associated with this specific chromosomal duplication, particularly the high metastasis risk, puts forward ethical dilemmas concerning the right not to know, as well as a strategy to care the patient.

A copy number variation genome-wide association study identifies two new cervical cancer susceptibility loci at NEDD4L and CTDSPL. *D. Chen[1], Z. Li[2], T. Cui[1], D. Zhang[2], U. Gyllensten[1].* 1) Department of Immunology, Genetics and Pathology, Uppsala University, Sweden, Uppsala, Sweden; 2) Department of Pathology, School of Medicine, Zhejiang University, Hangzhou, People's Republic of China.

Cervical cancer is the third most common cancer in women worldwide. Genome-wide association studies (GWASs) focusing on evaluating common single nucleotide polymorphisms (SNPs) have identified several genetic susceptibility loci for cervical cancer. However, the vast majority of risk variants identified to date have small effect sizes and only explain a small fraction of the heritability. Very few studies have evaluated copy number variation (CNV), another important source of human genetic variation, in relation to cervical cancer risk. We have conducted the first CNV GWAS in 1034 cervical cancer patients and 3948 control subjects in a Swedish population using data from Illumina HumanOmniExpress BeadChip. We used two CNV detection software suites-PennCNV and QuantiSNP for detecting both rare and common CNVs. Only the samples and CNVs that passed the quality control steps of both programs were included in the final analysis. Burden analysis showed that the average number of common CNVs (frequency ≥1%) per person and that of rare CNVs (frequency <1%) per person were significantly higher in cervical cancer patients than in controls (6.56 compared to 5.55 for common deletion, $P<10^{-6}$; 1.12 compared to 0.87 for common duplication, $P<10^{-6}$; 2.35 compared to 2.0 for rare deletion, $P<10^{-6}$; and 0.94 compared to 0.74 for rare duplication, $P<10^{-6}$; respectively). We also found that one deletion in *NEDD4L* (odds ratio [OR]= 4.09, 95% confidence interval [CI]=2.08-8.04, $P=7.0\times10^{-5}$) and one deletion in *CTDSPL* (OR=2.98, 95% CI=2.14-4.15, $P=1.0\times10^{-6}$) were significantly associated with increased risk of developing cervical cancer, respectively. These findings were further validated using real-time quantitative polymerase chain reaction (qPCR) in the same subjects. *NEDD4L* encodes a member of the Nedd4 family of HECT domain E3 ubiquitin ligases. The encoded protein mediates the ubiquitination of multiple target substrates and plays a critical role in epithelial sodium transport by regulating the cell surface expression of the epithelial sodium channel. *CTDSPL*, also known as *RBSP3*, is a tumor suppressor gene implicated in major epithelial malignancies and is frequently altered in premalignant cervical lesions. Our study provides evidence for two novel cervical cancer loci and new insights into the genetic etiology of cervical cancer. These two CNVs are the strongest genetic risk variants identified so far for cervical cancer.

Cell-free circulating nucleic acids (cfDNA/cfRNA), so-called "liquid biopsies", hold great promise for future molecular diagnostics development. Analysis of circulating tumor DNA (ctDNA) for non-invasive detection and monitoring of cancers has been an active area of clinical research. We have used multiple approaches to access genetic information from circulating nucleic acids. We first applied a whole-genome random shotgun sequencing methodology to detect cancer dysploidy patterns in cfDNA. Second, we developed a targeted cfDNA-based drug response assay for melanoma. This assay is a somatic mutation panel developed to assay specific genomic regions with a variety of molecular aberrations such as SNVs, CNVs, and translocations from 1-10 ng cfDNA inputs. Next we focused on DNA methylation profiling which offers additional advantages over somatic mutation analysis for the detection of cancer: (1) higher clinical sensitivity and dynamic range; (2) a multitude of affected methylation targets in disease; (3) multiple affected CpG sites within each targeted genomic region, enabling robust sequencing calls. We developed a targeted methylation panel corresponding to >1,000 differentially methylated genomic regions to measure minimal residual disease (MRD) and recurrence in colorectal cancer. Lastly, we have developed highly sensitive total RNA (including non-coding RNA) sequencing protocols that can be used to analyze RNA/miRNA expression and cDNA/mutation in exosomal RNA or cfRNA isolated from serum/plasma.

Chromosomal Mosaicism in Patients with Familial Chronic Lymphocytic Leukemia. *L.R. Goldin[1], W. Zhou[2], M. Yeager[2], M. Dean[3], M.J. Machiela[4], M.L. McMaster[1], J. Boland[2], M. Cullen[2], N.E. Caporaso[1], S.J. Chanock[2].* 1) Genetic Epidemiology Branch, DCEG, NCI, Bethesda, MD; 2) Cancer Genomics Research Lab, DCEG, NCI, Bethesda, MD; 3) Laboratory of Experimental Immunology, Center for Cancer Research, NCI; 4) Laboratory of Translational Genomics, DCEG, NCI, Bethesda, MD.

Chronic lymphocytic leukemia (CLL) is a malignancy characterized by the accumulation of small, mature-appearing lymphocytes in the bone marrow, blood, and lymphoid tissues accounting for about one third of the leukemias in US adults. About one third of patients have an indolent disease course. Studies have shown significant familial aggregation of CLL and its precursor trait, monoclonal B-cell lymphocytosis (MBL). CLL tumors are characterized by several cytogenetic abnormalities, the most common being deletions of 13q14, 11q, 17p, 6q, and trisomy 12. We have used Illumina Omni Express arrays to detect these and other abnormalities in DNA derived from blood. Our analytic method can identify abnormalities present in 7% of cells or higher, allowing us to detect abnormalities in DNA from mixtures of tumor and normal cells. We genotyped 130 CLL patients from high-risk families (including some patients with longitudinal samples), as well as 24 first degree relatives with MBL. We use B-allele frequency and log2 intensity ratio to score copy number gains and losses, as well as copy neutral loss of heterozygosity. Mosaic abnormalities were found in 55% of CLL patients, but in none of the relatives with MBL. These abnormalities included those commonly seen in CLL patients as well as more recently reported trisomies of chromosomes 18 and 19. We also found evidence of chromothripsis in some patients. The rate of mosaic abnormalities in familial CLL patients is consistent with that seen in sporadic CLL patients. Among 15 patients studied on two or more time points, changes in the pattern of abnormalities could be seen over time. We are correlating the pattern of abnormalities with disease progression and treatment in this study with more patients, relatives, and time points. Future analyses will be conducted on purified tumor cells compared to normal cells and whole genome sequencing will be performed in selected patients to better define abnormalities. Together, these studies will allow us to identify the earliest genetic changes present in CLL, highlight those associated with progression, and aid in identifying genomic alterations in relatives at increased risk for developing CLL .

Cancer genomes are complex and harbor somatic variation that ranges from single nucleotide changes to numerical chromosomal abnormalities. Recent cancer genome sequencing studies have greatly improved our understanding of cancer genome variation. However, this progress is limited to the ends of the spectrum of variation: Single nucleotide changes on the short length scale and gross copy number changes/aneuploidy on the long length scale. Accordingly, current platforms and analyses do not comprehensively discover mid-sized somatic variation (structural variation; 1kb- megabases), which includes balanced and unbalanced events like insertions, deletions, translocations, inversions and other complex genomic rearrangements. In this work, we use an integrative approach that employs Optical Mapping - a single molecule whole genome analysis system, and DNA sequencing to identify widespread structural variation in a Multiple Myeloma (MM) genome. Furthermore, by studying the longitudinal evolution of this MM genome, we found evidence for increased mutational burden, clonal tides and clonal evolution at the level of structural variation. Our work demonstrates high prevalence of structural variation in a cancer genome, and highlights the importance of routinely studying structural variation in cancer genomes.

3326S

A meta-analysis of somatic copy number alterations in Hepatocellular Carcinoma. *K. Hao[1,2], Z. Zhang[1,2], Y. Hoshida[3], D. Sia[3,4,5], M. Mahajan[1,2], V. Mazzaferro[4], R. Pinyol[5], X. Sun[3], E.E. Schadt[1,2], J.M. Llovet[3,5,6].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Mount Sinai Liver Cancer Program, Division of Liver Diseases, Department of Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Gastrointestinal Surgery and Liver Transplantation Unit, National Cancer Institute, Milan, Italy; 5) HCC Translational Research Laboratory, Barcelona-Clinic Liver Cancer Group, Institut d'Investigacions Biomediques August Pi I Sunyer (IDIBAPS), CIBERehd, Liver Unit, Hospital Clinic, University of Barcelona, Catalonia, Spain; 6) Institucio Catalana de Recerca i Estudis Avancats (ICREA), Catalonia, Spain.

Introduction: Hepatocellular carcinoma (HCC) is the second leading cause of cancer mortality worldwide. With the development of high-throughput technology, several studies have surveyed genome-wide somatic copy number alterations (SCNAs) and unveiled a few altered genes as potential drivers. However, more potential driver alterations are yet to be identified. Here we conducted a meta-analysis of SCNAs in 594 resected HCCs with different etiologies. **Methods**: We collected whole-genome SNP array data of 594 HCCs and adjacent normal tissues in three published studies (Lamb et al (2011), n=162; Wang et al (2013), n=286; European Commission Framework Program 7 (HEPTROMIC), n=146). The individual SCNA profiles were quantified using a segmentation-based approach. To compare the results from different studies, the SCNA signals were properly rescaled with the germline copy number variants (CNVs) information detected in adjacent normal tissues. We applied GISTIC2 to the combined dataset as well as to etiology specific datasets. Genes within these regions were compared with existing HCC driver genes and established oncogenes and tumor suppressor genes (TSGs) in other tumors. **Results**: The three cohorts analyzed consisted mostly of East Asian and European patients with HBV (n=388, 65%) or HCV infection (n=89, 15%). Broad gains and losses of chromosome arms detected in our analysis were consistent with previous studies. Among the focal CNVs, we identified focal amplifications at 11q13.3 (FGF19, CCND1), 6p21.1 (VEGFA), 8q24 (MYC), 5p15.33 (TERT), and 7q31.2 (MET), and focal deletions at 9p21.3 (CDKN2A/B), 1p36 (ARID1A), 13q14.2 (RB1), and 10q23.31 (PTEN), which were equally distributed among HBV and HCV-infected patients. Interestingly, focal deletion at 16p13.3 (AXIN1) occurred more frequently in HBV than HCV-infected individuals (111/388, 29% vs 9/89, 10%; p< 0.01). Similarly, focal deletion of the potential TSG PTPRS (19p13.3) were found more frequent in HBV-related patients (79/388, 20% vs 8/89, 9%; p=0.03). Previously unknown focal CNVs were also unveiled, such as focal amplifications at 19p13.11 (JAK3, 5%), 19p13.12 (NOTCH3, 4%) and 9p24.1 (JAK2, 2%), and focal deletion at 8p23.2 (CSMD1, 36%). **Conclusions**: By performing a large meta-analysis, we can estimate more reliably the prevalence of recurrent SCNAs in HCC with different etiologies as a basis to develop therapeutic strategies and identify novel candidate drivers with increased statistical power.

A t(1;19) translocation involving *TCF3/PBX1* fusion within a context of a hyperdiploid karyotype in adult B-ALL. *B.J. Lasky[1], L. Yeh[2], M. Kallen[2], S. Pullarkat[2], L. Yang[2], A. Hasan[2], Y. Kim[2], D. Shabsovich[2], N. Rao[2], C.A. Tirado[2].* 1) Pathology & Laboratory Medicine, UCLA, San Pedro, CA. 90731; 2) Pathololgy & Laboratory Medicine, Cytogenetics UCLA 1010 Veteran Ave, 2212F, Los Angeles, CA 90024.

Hyperdiploidy is found in 5% of adults with B-Lymphoblastic Leukemia (B-ALL) and portends a favorable prognosis. The t(1;19)(q23;p13) is a common translocation in adult and pediatric B-ALL, often present as a lone abnormality, and is associated with an intermediate prognosis. Herein we present a 44-year-old female with a history of relapsed precursor B-ALL. First diagnosed in March 2013 with leukemic cells showing a normal karyotype, she underwent four cycles of UK ALL 14 protocol consolidation therapy, and although initially found to be in remission, she relapsed in December 2013. A bone marrow biopsy showed 85% blasts with a pre-B immunophenotype and a hyperdiploid, complex, poor-risk karyotype. In January 2014, she underwent FLAG-IDA therapy and the subsequent bone marrow biopsy showed a hypocellular marrow without a significant residual blast population. The patient presented with relapse to our institution in April 2014 for enrollment in a clinical trial with blinatumomab. A bone marrow biopsy showed extensive tumor necrosis with B-lymphoblasts constituting 5% of the total surface area. Touch preparations showed clusters of B-lymphoblasts representing 90% of viable cells. Immunophenotyping was positive for CD10, CD19, PAX-5, CD79a and TdT (weak, rare) and negative for CD34 and CD20. Chromosome analysis demonstrated a female karyotype with numerous numerical and structural abnormalities including extra copies of chromosomes 1, 8, 11, 20, 22, a (1;19) translocation, an unbalanced rearrangement of the long arm of chromosome 13 leading to 13q- and a marker chromosome of unknown origin. The (1;19) translocation is among the most common translocations in B-ALL, resulting in a fusion of *TCF3* at 19p13 with *PBX1* at 1q23, which can occur in a balanced or unbalanced form. The pattern seen here, with a complex karyotype (>3 abnormalities), extra copies of chromosomes 8, 11 and 22 (confirmed by FISH), a (1;19) translocation and the presence of marker chromosomes of unknown origin portends an unfavorable prognosis in B-ALL. This case is one of few that shows both hyperdiploidy and a TCF3/ PBX1 fusion, which underscores the importance of FISH for proper classification of these cases and to distinguish them from those with hyperdiploidy and *TCF3/PBX1* negativity.

3328T

PROMOTER-SPECIFIC ALTERATIONS OF APC ARE A RARE CAUSE FOR MUTATION-NEGATIVE FAMILIAL ADENOMATOUS POLYPOSIS. *T.T. Nieminen[1], W. Pavicic[1], A. Gylling[1], J-P. Pursiheimo[2], A. Laiho[2], A. Gyenesei[2], H.J. Jarvinen[3], P. Peltomaki[1].* 1) Medical Genetics, Haartman Institute, Helsinki, University of Helsinki, Finland; 2) University of Turku, Finland; 3) Helsinki University Central Hospital, Finland.

Familial adenomatous polyposis (FAP) syndrome predisposes to colorectal cancer (CRC). FAP individuals suffer from even hundreds or thousands of colon adenomas and if untreated, CRC develops. The average age at onset of CRC is 39 years. FAP is caused by a germline mutation in the APC gene and it is inherited by an autosomal-dominant manner. In FAP, 20% of classical and 70% of attenuated/atypical (AFAP) cases remain mutation-negative after routine testing; yet, allelic expression imbalance may suggest an APC alteration. Our aim was to determine the share of families attributable to genetic or epigenetic changes in the APC promoter region. We studied 51 unrelated families/cases (26 with classical FAP and 25 with AFAP) with no point mutations in the exons and exon/intron borders and no rearrangements by multiplex ligation-dependent probe amplification (MLPA, P043-B1). Promoter-specific events of APC were addressed by targeted re-sequencing, MLPA (P043-C1), methylation-specific MLPA, and Sanger sequencing of promoter regions. A novel 132-kb deletion encompassing the APC promoter 1B and upstream sequence occurred in a classical FAP family with allele-specific APC expression. No promoter-specific point mutations or hypermethylation were present in any family. In conclusion, promoter-specific alterations are a rare cause for mutation-negative FAP (1/51, 2%). The frequency and clinical correlations of promoter 1B deletions are poorly defined. This investigation provides frequencies of 1/26 (4%) for classical FAP, 0/25 (0%) for AFAP, and 1/7 (14%) for families with allele-specific expression of APC. We will continue investigations with the remaining 6 families with allele-spesific expression of APC by RNA-sequencing. Clinically, promoter 1B deletions may associate with classical FAP without extracolonic manifestations.

3329S

Comparison of CNV detection from whole-exome sequencing and microarray platforms using matched tumor-normal samples from TCGA. *A. O'Hara, L. Culot, Z. Che, R. Keshavan, S. Shams.* BioDiscovery Inc., Hawthorne, CA.

Copy number variants (CNVs) have been implicated as drivers in many different tumor types. The platform of choice to detect genome-wide CNVs has traditionally been microarray (including SNP arrays that can also detect copy neutral loss of heterozygosity regions); however, since samples have often undergone sequencing to discover pathogenic sequence variants, it is desirable to exploit these data to also detect CNVs. Various methods have been proposed to detect CNVs from NGS data, but little information is available which compare the success of these approaches to orthogonal methods. Using a data set of matched tumor-normal samples from the TCGA that have been subjected to both whole-exome sequencing (WES) and to a genome-wide SNP microarray, we compare the ability to detect CNVs between these platforms. CNV detection results from the WES data using ngCGH are compared with an established HMM-based method for detection of CNVs from the microarray platform. We will further discuss benefits, and potential shortfalls of each method.

3330M

A New Method for High Fidelity Copy Number Analysis in Solid Tumor Samples and its implementation in the OncoScan™ FFPE Assay Kit. *J. Schmidt[1], B. Liu[1], M. Ghent[1], B. Bolstad[1], F. Siddiqui[1], D. Abdueva[2], M. Marjanovic[1], R. Saplosky[1], A. Shukla[1], S. Venkatapathy[1], C. Chen[1], C. Bruckner[1], V. Huynh[1], L. Liu[1], K. Suyenaga[1], P. Weaver[1], L. Greenfield[2], E. Fung[1].* 1) R&D, Affymetrix, Santa Clara, CA; 2) Formerly R&D Affymetrix, Santa Clara, CA.

Copy number analysis in tumors is rapidly gaining importance in cancer therapy as a tool for differential diagnosis with impact on potential treatment, [1]. Although formalin fixed paraffin embedded (FFPE) blocks are common sources of material for both research and clinical diagnostics, DNA degradation in FFPE presents a major challenge for accurate measurement of copy number. We address this challenge using molecular inversion probes, which capture the alleles of over 220,000 SNPs at carefully selected genomic locations, evenly distributed across the genome and with increased density within ~900 cancer-related genes. Additionally, we created a reference that establishes the baseline response for a normal copy number state at each locus. This reference was generated by assessing the probe-by-probe response in 400 normal FFPE samples from over 20 sources covering a broad range of geographic locations, block ages, gender and tissue of origin. Another challenge of FFPE samples is the presence of normal cells in most biopsy samples, which affects copy number estimates. To address this problem of variable tumor burden, we developed TuScan™, an algorithm inspired by ASCAT [2], to estimate the integer copy number in the tumor at each locus. When a major clone is responsible for the majority of copy number changes, the algorithm estimates the tumor burden in the sample and reports the integer copy number in the cancer portion only, effectively subtracting the normal component, thereby enabling a comparison between samples with different tumor burden. For highly heterogeneous samples or very low tumor burden, the algorithm reports the fractional (average) copy number of all cells within the sample. To validate the method, 28 FFPE tumors which included copy number events previously determined by FISH were titrated at various percentages (80%, 70%, 60%, 40%) with their matched normal and were analyzed for copy number changes using the TuScan™ algorithm. Given that the algorithm computes copy number states in the tumor portion, the same copy number state should be reported at each locus for each of the titration levels. Over 90% of aberrant markers had concordant copy number states across titration points for 26/28 samples. For two tumor samples the algorithms were not able to determine a tumor burden for the lower titration levels.

[1] G. Ciriello et al, Nat. Gen. 45, 1127-1133, 2013. [2] Peter Van Loo et al, PNAS 107 (39) 16910-16915, 2010.

3331T

The dilution dilemma; a method to accurately estimate tumor fractions in complex tumor/normal DNA dilutions. *Z.M. Weber[1], S. Vattathil[2], Y. Hu[1], P. Scheet[2], G.E. Davies[1], E.A. Ehli[1].* 1) Avera Institute for Human Genetics, Sioux Falls, SD., USA; 2) The University of Texas M.D. Anderson Cancer Center, Houston, TX., USA.

The objective of this project was to create a series of highly accurate dilutions of matched tumor/normal DNA to test computational methods for detecting low-frequency chromosomal aberrations, such as allelic imbalance and copy number changes, in a sample of DNA obtained from heterogeneous cells. Such methods (e.g. hapLOH, GAP, BAFsegmentation, ASCAT) offer the potential to determine tumor cell fractions from surgically removed tumor sections that contain normal tissue margins and to identify tumor sub-populations in samples that possess heterogeneous genetic profiles. Qubit is a fluorescence-based method used to quantify double stranded DNA. Using this method of quantitation, we created 32 tumor/normal mixes (16 dilutions in 2 cancer cell lines) with tumor fractions ranging from 0.98 to 0.005. Dilutions containing ultra-low fractions of tumor DNA required a method of highly accurate quantitation. Breast cancer (CRL-2363) and lung cancer (HTB-172) tumor cells were grown up in culture with their respective matched normal cell line lymphocytes, CRL-2343 and CRL-5958, respectively. DNA was extracted from the four cell lines using the QIAamp DNA Blood Midi protocol. The DNA from each cell line pair was normalized and quantitated in five replicates using Qubit High Sensitivity assays. The standard deviation (SD) and coefficient of variation (CV) between the five replicates was calculated for each DNA sample. Next, a series of tumor DNA fractions was prepared for both the breast and lung cancer DNA sets. Two sets of 16 dilutions were run on Infinium HumanOmni2.5-8 Beadchips. The SNP genotype data was used to generate Log R ratios and B-allele frequency plots used for downstream analyses with hapLOH (for example). Low SD values were successfully achieved between replicate sets (0.69 - 1.45 ng/ul) along with low CV values (0.013 - 0.028). Using a mathematical algorithm which incorporated the volume of DNA used in the dilution and the mean concentrations, we were able to estimate the amount of tumor DNA in the complex mixture. The mean GenCall score across all samples was p10 GC = 0.41 and p50 GC = 0.78 following the genotyping experiment. Call rates were all > 99% and error rates between the three tumor fractions at 0.03 were all < 0.00001. The primary scientific contribution of this experiment was creating a data set on which to test methods to accurately identify mutations in extreme stromal contamination and estimate tumor/normal DNA fractions.

3332S

Age-related mosaic loss of chromosome Y is associated with cancer in cohort studies. *W. Zhou[1], M. Machiela[2], M. Dean[2], J. Sampson[2], N. Rothman[2], N. Freedman[2], S. Wacholder[2], K. Jacobs[1,5], M. Tucker[2], F. Real[3,6], L. Perez-Jurado[3,4], M. Yeager[1], S. Chanock[2].* 1) Cancer Genomics Research Laboratory, National Cancer Institute, Division of Cancer Epidemiology and Genetics, Leidos Biomedical Research Inc., Frederick, MD; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), National Institutes of Health (NIH), Bethesda, MD; 3) Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Barcelona, Spain; 4) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain; 5) Bioinformed, LLC, Gaithersburg, MD; 6) Epithelial Carcinogenesis Group, Spanish National Cancer Research Centre (CNIO), Madrid 28029, Spain.

Prior studies indicate that loss of the Y chromosome occurs during the aging process and is associated positively with hematologic cancer, including acute myelogenous leukemia (AML), myelodysplastic syndrome (MDS), and pre-leukemia. To investigate the relationship between mosaic loss of chromosome Y and non-hematologic cancer, we utilized existing genome-wide association study intensity data from 14,099 males (8,545 non-hematologic cancer cases and 5,554 cancer-free controls) drawn from three prospective cohort studies: Alpha-Tocopherol and Beta-Carotene Cancer Prevention Study (ATBC), Prostate, Lung, Colorectal, Ovarian Cancer Screening Trial (PLCO), and Cancer Prevention Study-II (CPSII). Subjects were examined for deviations from expected log2 intensity ratio for evidence of loss of the male specific region of chromosome Y (MSY) between 6,671,498-22,919,969 (hg18/build36). DNA derived from blood or buccal samples was genotyped on one of four Illumina SNP BeadChips with sufficient coverage of MSY (Human610, Human1M, HumanOmni1M, and HumanOmni2.5M). A total of 1,000 (7.09%) individuals have detectable mosaicism of the MSY with the proportion of affected cells ranging from 9.9% to 61.7%; this is substantially higher than what has been observed for autosomal events of size >=2MB, approximately 1% overall. Mosaic chromosomal Y loss is associated with older age at DNA collection, with frequencies of 1.09% in individuals less than 60 and 18.63% in those 80 years or older (OR per year of age = 1.11, 95% CI = 1.10-1.13; P = 5.34E-69) and ever-smoking (OR = 1.43, 95% CI = 1.21-1.71; P = 8.16E-05). In addition, mosaic chromosomal Y loss is more common in individuals developing cancer (8.05%) than in cancer-free controls (5.37%) (OR = 1.57, 95% CI = 1.36-1.81; P = 1.02E-10). Mosaic Y loss was associated with bladder cancer (OR = 1.47, 95% CI = 1.19-1.84; P = 7.15E-04) and prostate cancer (OR = 1.29, 95% CI = 1.08-1.56; P = 7.52E-03) but not lung cancer. Further studies are required to determine the role of mosaic Y loss in cancer.

The actual impact of Fluorescence in Situ Hybridization (FISH) in the diagnosis and follow up of Acute Lymphoblastic Leukemia (ALL). *H. Akin, E. Karaca, B. Durmaz, A. Durmaz, A. Aykut, O. Cogulu.* Ege University Medical Faculty, The Department of Medical Genetics, IZMIR, Turkey.

Acute lymphoblastic leukemia (ALL) is a disease characterized by abnormal clonal proliferation of lymphoid precursors which lose their ability to differentiate. It is the most common malignancy in childhood, accounting for 80% of all leukemia. Although it can occur at any age, its incidence is highest among children from 2 to 5 years at rate of about 70%, decreasing among adolescents and young adults. Cytogenetics and FISH have been the gold standard for defining genetic abnormalities and facilitating therapeutic stratification of pediatric ALL cases. In this study, it is aimed to determine the cytogenetic and molecular cytogenetic profile of submitting patients with ALL during the period from January 1st, 2013 to December 31st, 2013 to Ege University Medical Faculty, Medical Genetics Department. In ALL, the most important molecular markers are BCR/ABL, all MLL translocations with their respective partner genes, and c-MYC aberrations that have to be detected at diagnosis and for minimal residual disease (MRD) studies . Furthermore, for more than 90% of ALL patients specific markers can be detected by IGH mutations and serve as the most important MRD marker. We used a standardized a FISH panel for ALL including, BCR/ABL, cMYC, TCF/PBX, IGH, MLL, p16 and TEL/AML. We performed 150 FISH analyses for 77 patients .The most frequent aberration rate was 10.67% for IGH. The second most frequent aberration was detected for delp16 as 5.33%. They were all commented as diagnosis and follow up markers for ALL. The vast majority of this study group are of pediatric age group (85.33%). The repetitive analyses by the aim of follow up and cytogenetic results were also evaluated. It was noted a substantially lack of an algorithm at diagnosis and follow up request for ALL patients. A more reliable approach would be to standardize wider FISH panels in order to detect more anomalies and using an algorithm to reach effective diagnose and follow up in ALL patients.

System for high throughput Identification of breast and ovarian cancer associated chromosomal abnormality. *Y.W. Chang[1], J. Chen[5], N. Limthong[4], Y.Y. Chang[1], D. Chen[3, 4], Y. Elshimali[2].* 1) La Sierra University, Riverside, CA; 2) Charles R. Drew University/UCLA, Los Angeles, CA; 3) Dept. of Path & Lab Med, David Geffen School of Med at UCLA, Los Angeles, CA; 4) Dept. of Path & Lab Med, UCI Med Center, Orange, CA; 5) Rosemead Clinic, Rosemead, CA.

Investigation of biochemical pathways of breast and ovarian cancer has greatly increased our understanding of the pathogenesis of breast and ovarian cancer. 48 breast cancer susceptible genes have been identified in the literature. These genes are potential candidates to expand the genetic testing panel for both the familial and somatic forms of breast and ovarian cancers. One challenge for current genetic testing technology is the relative inefficiency in identifying complex chromosomal structure abnormalities. Non-allelic homologous recombination (NAHR) and non-homologous end joining (NHEJ) are major mechanisms involved in such chromosomal changes. Since the locations for potential chromosomal changes are non-random and limited by the genomic location of homologous sequence pairs, a targeted DNA sequencing approach for chromosomal abnormalities in these candidate genes can significantly facilitate the depth of reads and thereby increase sensitivity at detecting chromosomal changes. Specifically, we conducted a computational analysis of the genomic sequences around all 48 potential breast and ovarian cancer susceptible genes and globally identified the potential target pairs for NAHR and NHEJ events. Over 700 potential genomic sequence pairs were identified with greater than 200bps length and 85% sequence homology. We designed a solution phase genomic DNA capture system for capturing genomic DNA of tumor specimens. We then use NGS technology to sequence the genomic fragments. Using normal genomic DNA for optimization, we have conducted deep sequencing with the goal of 50x depth. Overall, 94% of genomic areas are tagged as “readable sequence”. In addition, 86% of which achieve sequencing depth of greater than 50X. In conclusion, the system has the potential to serve as screening system for breast and ovarian specific chromosomal changes.

Unique Recurrent Cytogenetic Aberrations Distinguish Between Molecular Subtypes of DLBCL and Burkitt Lymphoma: An Analysis of Unsupervised Clusters and Logistic Regression Based Models. *R. Garcia, N. Guruju, P. Koduru.* Pathology, UT Southwestern, Dallas, TX.

Morphologic classification of non-Hodgkin lymphoma is reliable in majority of cases. Nonetheless, overlapping features between diffuse large B-cell lymphoma (DLBCL) and Burkitt lymphoma (BL) with MYC rearrangements are persistent and problematic to distinguish them. The aim of this study was to build and test predictor models based on recurrent cytogenetic aberrations (RCAs) that may help distinguish between DLBCL and BL. This study involved the analysis of available information from the Mitelman Database, other publications and institutional cases. Two separate cytogenetic datasets were used to build and test hierarchical clusters (HCs) and logistic regression (LR) predictor models. The first dataset comprised of 254 DLBCL and 84 BL tumors that were used to identify RCAs. The test dataset comprised of 117 cases of DLBCL and 60 BL obtained from the published literature and institutional sources; this was used to test predictability of the RCAs identified in the first dataset. An independent group t-test, performed with the Statistical Analysis Software (SAS), was used to assess the differences in the frequency of aberrations between comparative groups. A Fisher exact test was then used to determine correlations between the different types of RCAs and comparative groups. A p-value less than .05 was considered significant. Specificity of RCAs was also determined. The R package was used to build HC models and SAS was used for LR analysis. We identified 21 RCAs significantly associated with DLBCL than with BL. These included +12, +3, and +18 previously reported as associated with DLBCL than BL. HC and LR analysis of the second dataset was performed to determine the predictability of the remaining RCAs. This analysis identified RCAs +16, +2, -8, -2, 14qL, +X, 16qL, 1p36L, 15qL, 17pL, -4, 19pL and 22qL as predictors of DLBCL by their closeness in Euclidian distance to BCL2, +12, +3 and +18 and by their distance away from MYC . Further evaluation of the data revealed two major clusters one associated with GCB and the other with the ABC DLBCL molecular subtypes. Predictive value of the models was 95% for the HC heat map, 96% for the PAM algorithm, 85% for the LR and 98% for the HC with p-values. Our findings indicate HC with p-values based on Euclidean distance is a better predictive model. Future studies correlating these RCAs with molecular signatures such as gene expression profiles are warranted. Key words: DLBCL, BL, RCAs.

A rare transformation case report: from Chronic Lymphocytic Leukemia to Multiple Myeloma. *C. Hangul[1], C. Aydin[1], O.K. Yucel[2], O. Salim[2], S. Berker Karauzum[1].* 1) Department of Medical Biology and Genetics, School of Medicine, Akdeniz University, Antalya, Turkey; 2) Department of Hematology, School of Medicine, Akdeniz University, Antalya, Turkey.

Chronic Lymphocytic Leukemia (CLL) and Multiple Myeloma(MM) are closely related B-cell malignancies. The genetic characterization of CLL has made significant progress in the recent years. Genetic aberrations are detected in over 80% CLL cases with FISH methods. In the other hand, 30-50% cases of multiple myeloma shows random genetic rearrangements. Transformation from CLL to MM is seen in very rare cases. In this report, we present 62 years old patient who was first diagnosed with Chronic Lymphoid Leukemia in 2009. Marked lymphoid population (CD5+, CD19+, CD23+) was detected by flow cytometric immunophenotyping in peripheral blood and bone marrow. In the first diagnosis in 2009, his karyotype revealed from bone marrow sample was designed as 45, X, -Y[4]/46,XY[10] and in FISH analysis, an 11q22.3 deletion was found of 55% in this case as a sole anomaly. At the second biopsy, cytoplasmic kappa light chain positivity was seen. Lambda and CD20 staining were found negative in 2012. Bone marrow immunophenotyping revealed 30% of clonal plasma cells (CD38+, CD56+) and 0.9% of abnormal B Lymphocytes (CD5+,CD23+,CD19+) with these findings the patient was diagnosed as Multiple Myeloma. In the second bone marrow sample, his karyotype was found to be: 46,XY,der (6)t(1;6)(q11;q23),t(11;14)(q13;q32), dup(17)(q23q25)[17]/46,XY[2]. Additionally two hundred nuclei were analysed for each probe from MM FISH panel and t(11;14) (q13.1;q32) translocation and deletion of 6q23 was found of 48% in interphase nuclei. All these results supported the diagnosis of MM and by the same time to transformation from CLL to MM. Clinical and labaratory findings will be discussed in detail with the company of literature.

3337T

Specific Gene Expression Profiles of Diffuse Large B-cell lymphoma and Burkitt Lymphoma Identified a Set of Enriched Genes that Positively Correlates with Cytogenetics Data. *P. Koduru, R. Garcia, N. Guruju.* Dept Pathology, Univ Texas Southwestern Med Ctr, Dallas, TX.

In 2008, the World Health Organization created a provisional category for Unclassifiable B-cell lymphoma with features intermediate of diffuse large B-cell lymphoma (DLBCL) and Burkitt lymphoma (BL) mainly due to overlapping morphological features. The purpose of this study was to identify differences between DLBCL and BL at the molecular level and to correlate these differences with the recurrent cytogenetic abnormalities (RCAs) between them identified by us previously. The data for this analysis consisted of 44 lymphoma tumors characterized by HGU 133A Affimatrix gene chip, and extracted from the National Center of Biotechnology Information (NCBI) Gene Expression Omnibus database (GSE4475 dataset). These 44 tumors included 21 DLBCL and 23 BL. The statistical package 'R-package' was used to analyze the expression data. Samples were normalized and differentially expressed genes were determined by a p-value <.01 with a false discovery rate adjustment applied to the p-value in order to decrease false positives. To further characterize the gene expression in both tumor types, a gene set enrichment analysis was performed using the GSEA software package. The identified differentially expressed genes were uploaded onto Ingenuity program to gain insight into the molecular interactions and biological processes in these lymphomas. In addition, a list of RCAs and copy number alterations previously identified by us was correlated with gene expression data. This study revealed differentially expressed genes in DLBCL and BL previously reported in the literature, mainly MYC, ID3, SOX11 and CSE1L. Moreover, our analysis revealed 180 and 3 upregulated genes in DLBCL and BL respectively, and 137 and 29 down regulated genes for DLBCL and BL respectively. This data closely correlated with recurring cytogenetic abnormalities (+X, +2, -2, +12, 14qL, +16, 16qL, +3, +18, 1p36L, 15qL, 17pL, 19pL, -4 and 22qL) we identified as markers to distinguish these tumors. In addition we identified a number of genes not previously reported in the literature in association with DLBCL. These included: CDK5R1, SAMSN1, FNBP1 and ELK3. Expression profiling data from additional tumors are needed to validate these findings. In brief, our analysis identified molecular expression markers that may be used to distinguish DLBCL and BL, and these molecular markers correlated with RCAs identified by us in a previous study. Key words: Gene Expression, DLBCL, BL, RCAs.

3338S

The Clinical Utility of CpG-Oligodeoxynucleotide Stimulation in Chromosomal Analysis for patients with Chronic Lymphocytic Leukemia (CLL) and a possible secondary Myeloid Neoplasm. *C.A. Marcou, P.T. Greipp, T.A. Goble, D.L. Van Dyke.* Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN., USA.

CLL is the most common leukemia affecting adults in the western world. Detection of cytogenetic abnormalities in CLL is useful in the diagnosis, prognosis, and therapeutic guidance for this disease. However, the detection of these abnormalities proves difficult due to the low mitotic rate of mature B cells. Interphase FISH analysis has been the standard test to detect 11q, 13q, and 17p deletions, trisomy 12, and *IGH* rearrangements, but has the limitation that cytogenetic complexity and other recurrent CLL-associated changes are not detected. To overcome these limitations, CpG-oligodeoxynucleotide (CpG) stimulation has been widely adopted for chromosome studies of CLL. Our cytogenetics laboratory receives blood & bone marrow samples referred from Mayo Clinic-affiliated sites and other clients via Mayo Medical Laboratories. In 2013, we began using CpG-stimulation in addition to unstimulated cell cultures to identify either a myeloid or lymphoid neoplasm in samples referred for chromosome analysis with a "reason for referral" that included lymphocytosis, CLL, small lymphocytic lymphoma, chronic lymphoproliferative disease, or a history of a CLL FISH study. Many and perhaps most of these samples were from patients with CLL or other lymphoproliferative disease who presented with a new cytopenia. Presumably, the principle concern was to identify a cytogenetically abnormal myeloid neoplasm if present; however, in most cases we did not obtain a final pathologic diagnosis. We performed a retrospective analysis identifying 568 cases that fit the criteria above. Of these, 253 (44.5%) had a normal karyotype in the CpG-stimulated and unstimulated cultures. The remaining 315 cases had an abnormal karyotype; of these, 40 (13%) had no analyzable metaphase cells in the unstimulated cell cultures. An abnormal karyotype interpreted as representing a myeloid neoplasm was present in 14/568 cases (2.5%). Among the 301/568 cases (53%) representing a lymphoid neoplasm, 97 exhibited trisomy 12, 87 had a 13q-, 78 had an 11q-, 63 had a 17p-involving TP53 loss, and 42 had a 14q deletion or rearrangement. In addition, 23 cases exhibited translocations between *IGH* and *MYC*, *BCL2*, *BCL3*, or *CCND1*. It is clear that CpG-stimulation is useful to identify the cytogenetically abnormal lymphoproliferative clone, and along with unstimulated cell cultures provides dual surveillance of both lymphoid and emerging secondary myeloid neoplasms in patients with lymphoproliferative disease.

Chromosomal Aberrations associated with methylation in ependymomas in Mexican pediatric patients. *M. Pérez Ramírez[1,5], A. Hernández[1,5], A.J. Hernández[3], A. Guerrero[3], A. García[3], F. Chico[4], E. Benadón[4], I. Del Angel[3], G. Ballesteros[3], M. Pérezpeña[4], A.G. Siordia[2], A. Sánchez[4], D.J. Arenas[1], F.A. Salamanca[1], N. García Hernández[1].* 1) Unidad de Investigación Médica en Genética HuUnidad de Investigación Médica en Genética Humanamana, Centro Médico Nacional "Siglo XXI", IMSS, Mexico DF, Mexico; 2) Servicio de Patología, Hospital de Pediatría "Dr. Silvestre Frenk Freud", Centro Médico Nacional "Siglo XXI", IMSS; 3) Servicio de Neurocirugía Pediátrica, Hospital General "Dr. Gaudencio González Garza", Centro Médico Nacional "La Raza", IMSS; 4) Hospital Infantil de México "Federico Gómez; 5) Universidad Nacional Autónoma de México.

Ependymoma (EP) is a slow-growing tumor, originates from the ependymal cell lines of the ventricular system, plexus choroid and central canal, located in regions within the Central Nervous System, principally developed at the fourth ventricle and less frequently in the brain parenchyma as a result of migration of ependymal cells during embryogenesis. It is known that the EP can proceed of cells derived from the transformation of neural stem cells and their progenitors to contribute to the initiation and the development of brain tumors. In recent studies in brain tumors, it has been found that the methylation affects genes responsible for DNA repair, regulation, migration and cellular apoptosis. Methylation is associated with the development of cellular malignancy by oncogene activation, promotion of genomic instability and loss of genomic imprinting. Additionally, the chromosomal aberrations are important for the development of EP, as amplifications in 7p, 9q, 15q and losses in 14q, 6q; it is known that changes in gene expression in oncogenic processes are responsible for large cell changes; so it is interesting to analyze the methylation pattern to relate with the chromosomal aberration in ependymomas. Ependymal tumors were collected surgically in pediatric patients, genomic DNA was extracted by organic method of phenol-chloroform-isoamyl, subsequently were performed microarrays methylation and aCGH with the platform of Agilent microarrays following the manufacturer's recommended protocol. In this work was found amplification in 14q32.3 (100%), 2p11.2 (83%), 8p22 (83%), and losses in 11q11 (83%), 15q11.2 (66%), 16q12.2 (66%), with respect to the methylation pattern, found hypomethylated regions in 2p11.2, 8p22, whereas the region 14q32.33 showed hypo and hypermethylated of genes related to growth and neuronal development, apoptosis, transcription factors and system immune. It is suggested to the region 14q32.33 as alteration of great importance for the Mexican population, because of the genes located in this chromosomal region.

Toward rapid identification of coding fusions and structural rearrangements in cancer genomes: Multiple Myeloma First. *M. Rossi[1,2], H. Dai[4], H. Cao[4], M. Saghibini[4], X. Yang[4], A. Pang[4], A. Hastie[4], T. Dickinson[4], J. Hauenstein[2], C. Curnow[2], A. Nooka[3], J. Kaufman[3], S. Matulis[3], L. Zhang[2], D. Saxe[2], K. Mann[2], D. Jaye[2], L. Boise[3], S. Lonial[3].* 1) Radiation Oncology, Winship Cancer Institute of Emory University, Atlanta, GA; 2) Pathology and Laboratory Medicine, Emory University, Atlanta, GA; 3) Hematology and Medical Oncology, Emory University, Atlanta, GA; 4) Bionano Genomics, San Diego, CA.

The use of G-banded karyotype and FISH have been standard diagnostic tools in monitoring response to treatment and disease progression in hematological disorders, including multiple myeloma, for over 40 years. However, with the availability of array and NGS technologies in most clinical diagnostic laboratory settings, it is time to consider evaluated the use of more modern methods in diagnosing plasma cell dyscrasias. Although we routinely run RNA-Seq, SNP-CN arrays and a deep sequencing cancer panel as a cost effective workflow for clinical trials, we find the validation of translocations and structural rearrangement by PCR and/or FISH cumbersome. Moreover, because of the limited applicability of using whole genome sequencing as a clinical diagnostic tool for multiple myeloma, we remain confined to the use of conventional cytogenetics for primary risk stratification of all patients. More recently, we have identified the BioNano Genomics Irys System which utilizes nanochannel technology and high resolution imaging for whole genome mapping of translocations and copy number abnormalities. As proof of concept, we have used the Irys system to analyze the multiple myeloma cell line, KMS11, and will demonstrate the ultility, speed and accuracy in detecting structural rearrangements in this line compared to whole genome, RNA-seq and SNP-CN datasets. We will also demonstrate the use of the system with CD138+ enriched bone marrow samples from consented patients currently on clinical trials compared to FISH, G-band karyotype and SNP-CN arrays. We are confident that these data demonstrate that the Irys ststem is a disruptive innovation with broad applicability to genome research and refinement of normal variation and disease.

3341S

Conventional Cytogenetic and Molecular Genetic Analysis of Pancreatic Cancer. *D. Shabsovich, N. Rao, J. Ji, K. Park, L. Yang, C.A. Tirado.* Pathology and Laboratory Medicine, UCLA, Los Angeles, CA.

Pancreatic cancer is the fourth leading cause of cancer-related death in the United States, with an average 5-year survival rate of less than 5 percent. Cytogenetic analysis has allowed for the elucidation of clinically significant chromosomal abnormalities in both solid tumor and hematological malignancies, but pancreatic cancer still does not have any FDA-approved cytogenetic assays despite its known intratumor cytogenetic heterogeneity. In the present study, conventional cytogenetic and molecular genetic analysis was performed on the following 9 pancreatic cancer cell lines: AsPC-1, MIA PaCa-2, BxPC-3, Capan-2, CFPAC-1, HPAF-II, Panc-3.27, Panc-10.05, and Panc-2.13. Giemsa-banding (G-banding), targeted fluorescence in situ hybridization (FISH), and chromosomal microarray (CMA) analysis was completed for each cell line, and results were pooled to elucidate commonly aberrant regions identified by all three methods. Recurrent numerical and structural abnormalities were observed on chromosomes 7, 8, 9, 18, and 20, and these findings were further corroborated by interphase and multicolor FISH studies. Abnormalities included deletion of *SMAD4* (18q21.2), which has been associated with increased metastasis and consequent poor prognosis in pancreatic cancer, deletion of *DCC* (18q21.1), and deletion of *p16* (9p21). Ultimately, phenotypic correlation of cytogenetic abnormalities using a larger population of patients can provide a framework for the development of diagnostic and prognostic cytogenetic assays as well as targeted therapies to combat pancreatic malignancies.

3342M

The *ZNF384* gene in pediatric acute lymphoblastic leukemia - multiple partner genes, immature (CD10 negative) immunophenotype, and potential good outcome. *M. Shago[1,3], O. Abla[2,4], J. Hitzler[2,4], S. Weitzman[2,4], M. Abdelhaleem[1,3].* 1) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Paediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada; 4) Department of Pediatrics, University of Toronto, Toronto, Ontario, Canada.

The *ZNF384* (*CIZ*) gene, located distal to the *ETV6* (*TEL*) gene at 12p13.31, is a putative zinc finger transcription factor which has been reported to be rearranged in acute leukemia. Rearrangement of the *ZNF384* gene results in attachment of various 5' partner gene sequences to form *ZNF384* fusion genes. The *ZNF384* gene has three known partners: *TAF15* at 17q12 (19 cases), *EWSR1* at 22q12 (4 cases), and *TCF3* (E2A) at 19p13 (3 cases). The proteins encoded by the fusion genes consist of the transactivation domains of the 5' partner genes fused to the entire coding region of ZNF384. We present detailed karyotypic, genomic copy number, and gene expression analyses of seven new pediatric pre-B ALL patients with *ZNF384* gene rearrangement. Our patients had lymphoblasts with a CD10-negative immunophenotype, similar to the immunophenotypic profile seen in *MLL* gene-rearranged ALLs. Follow up on the patients ranges from 5 to 7 years, and none of the patients have relapsed. Identification of the rearrangements was facilitated using dual-colour breakapart probes for the *ZNF384*, *TCF3*, and *EWSR1* loci. Four of the patients had *TCF3-ZNF384* gene rearrangement and one had *EWSR1- ZNF384* gene rearrangement. Two patients had novel *ZNF384* gene translocations involving regions on chromosomes 6 and 22, identified as the *ARID1B* and *EP300* genes respectively by RNA sequencing analysis. Similar to the previously identified *ZNF384* partners, these novel partner genes, which function in chromatin remodeling, contribute 5' gene sequences to the *ZNF384* gene fusion. Based on the total number of ALL patients seen at our centre during the study period, our data suggests that, collectively, *ZNF384* gene rearrangement may have an incidence of ~3% in pediatric pre-B ALL, with an incidence of at least 18% in CD10-negative pre-B ALL. *ZNF384* gene rearrangement may be associated with a more favorable prognosis than *MLL* gene rearrangement. Both good and poor outcomes have been proposed in the literature, however, the majority of the data are based on *TAF15-ZNF384* rearrangement in adult patients. The *ZNF384* gene rearrangements described above are cryptic and not easily identified by G-banding. Inclusion of *ZNF384* FISH analysis in patients with CD10-negative ALL, after *MLL* gene rearrangement has been excluded, will assist with the determination of the prognostic significance of *ZNF384* gene rearrangement in pediatric ALL.

3343T

A complex karyotype with a cryptic t(11;14)(q13;q32) in a Blastoid Crisis of Mantle Cell Lymphoma. *C.A. Tirado, Y. Kim, L. Yang, G. Abusaba, B.J. Lasky, N. Rao.* Pathology & Laboratory Medicine, UCLA, 669 Levering Ave, apart 15 Los Angeles, CA 90024.

Mantle cell lymphoma (MCL) comprises 3-10% of all NHL. The t(11;14)(q13;q32) is present in virtually all cases of MCL, independent of their morphologic or clinical presentation. Herein we describe an 80-year-old female patient with splenomegaly, thrombocytopenia, elevated absolute lymphocyte count, and anemia. A bone marrow biopsy demonstrated a hypercellular marrow for age showing 50% cellularity with 30-40% of the total cellularity involved by a mature B-cell neoplasm with immunohistochemistry showing co-expression of CD20 and BCL-1 in the aggregates of small B-cells. Flow cytometry of the bone marrow aspirate revealed a monotypic, kappa-restricted B-cell population representing 37% of total cells, positive for CD5, CD19, CD20, CD22, FMC-7, and CD38; and negative for CD23 and CD10. These results were consistent with a diagnosis of mantle cell lymphoma. Conventional cytogenetics performed on the bone marrow showed a complex abnormal female karyotype with numerical and structural abnormalities but no evidence of a (11;14) translocation in 6/20 metaphase cells examined. These results were described as: 44-45,XX,del(6)(q25),add(8)(p21),add(10)(p15),add(11)(q13);add(11)(q13), -14, tas(12;21)(pter;pter),+mar[cp6]/46,XX[14]. However, FISH on interphase nuclei using the CCND1-IGH (CCND1-IGH@) dual-color, dual-fusion from Abbott showed evidence of *CCND1-IGH@* fusion signals in 23% of the interphase cells studied. These findings were described as: nuc ish (CCND1,IGH@)x3(CCND1 con IGH@x2)[46/200]. FISH on previously G-banded metaphases showed a *CCND1-IGH@* fusion signal on the derivative chromosome 10 which was cryptic and not identifiable by conventional cytogenetics and another fusion signal on one of the abnormal copies of chromosome 11. Therefore the karyotype was reinterpreted as: 44-45,XX,del(6)(q25),add(8)(p21),der(10)(11q25->11q13::14q32->14pter::10p15->10qter),der(11)t(11;14) (q13;q32),add(11)(q13),14,tas(12;21)(pter;pter), +mar[cp6].ish der(10)(p15)(CCDN1+,IGH+),der(11)t(11;14)(IGH+,CCND1+)/46,XX[14]. This particular pattern with a complex karyotype with three or more numerical and structural changes along with 6q-, t(11;14) and a marker chromosome are common findings in mantle cell lymphoma of the blastoid subtype and are usually associated with an unfavorable prognosis. This case also highlights the importance of FISH on previously G-banded metaphases to elucidate cryptic rearrangements.

3344S

Identification of Semi-Cryptic and Variant Translocation Partners of RUNX1 gene in Acute Myeloid Leukemia (AML). *A. Yenamandra[1], F.C. Wheeler[1], A. Hollis[1], D. Zalepa[1], M. Kapp[1], N.C. Richardson[2], S.C. Borinstein[2].* 1) Department of Pathology, Immunology and Microbiology, Vanderbilt Univ. Medical Center, Nashville, TN; 2) Dept. Pediatrics, Division of Pediatric Hematology/Oncology, Vanderbilt University School of Medicine, Nashville, TN.

Rearrangements of RUNX1 locus at 21q22 include translocation of t(8;21), t(12;21), t(1;21), t(3;21), t(5;21), t(17;21) and t(16;21) in myeloid and lymphoid malignancy. We report here three cases of AML with variant translocation partners of RUNX1; a pediatric AML with t(7;21), and two adult secondary AML cases with t(10;21) and t(16;21) respectively. Sequential metaphase FISH and Cytogenetics were performed in all cases to identify the partner chromosome in the RUNX1 rearrangements. Case #1. A 9 year old male was referred for fever, fatigue, and pancytopenia. Bone marrow analysis revealed hypercellularity with a mixture of myoblasts and immature monocytic elements in 90% of cells as determined by both morphology and flow cytometry. Molecular analysis for mutations in FLT3, NMP1 and C-KIT were negative, although FISH revealed rearrangement of RUNX1 locus in the chromosome 7p22 region. Karyotype analysis confirmed this finding, revealing a unique translocation: 46,XY,t(7;21)(p22;q22)[20]. Three adults and one child have been reported in the literature with AML or high grade MDS with t(7;21) involving RUNX1-ubiquitin-specific protease gene (USP42-)fusion, however, to date no consistent prognostic information has emerged from these cases. Our patient had reinduction chemotherapy and is currently in remission, awaiting stem cell transplant. Case #2. A 58 year old male was diagnosed with treatment related AML following urothelial cell carcinoma. In this case, cytogenetics was normal (46,XY) at diagnosis, but follow up bone marrow analysis four and eleven months later revealed progressive abnormalities (46,XY,del(9)(q13q22)[2]/46,XY[18] and t(10;21)(p13;q22)[12]/46,XY[9], respectively). The latter BMA was FLT3+ also demonstrated RUNX1 rearrangement. The gene at the 10p13 region is unknown. Case #3. A 73 year old female was diagnosed with a myeloproliferative disorder. Karyotype revealed 46,XX,t(16;21)(q24;q22)[16]/46,XX[4] with FLT3 positivity. FISH analysis revealed rearrangement of RUNX1 with MTG16 gene locus at 16q24. The majority of the cases with t(16;21) (MTG16; RUNX1) translocation have been reported in treatment occur in the context of MDS/ANLL and the prognosis is poor. We present here three cases with semi-cryptic RUNX1 translocation in pediatric primary and adult secondary AML with unique RUNX1 rearrangement indicating the importance of the regulatory role of RUNX1 gene in hematopoiesis.

Somatic gene fusions in human cancer revealed by whole exome sequencing. *L. Yang, P. Park.* CBMI, Harvard Medical School, Boston, MA.

A small fraction of somatic genomic rearrangement breakpoints in human cancer locate in exons or near exon-intron boundaries, and thus can be identified by paired end reads from the whole exome sequencing (WES) data. The main advantage of using WES data to detect somatic rearrangements is the larger sample size (at least 10 times more for The Cancer Genome Atlas [TCGA] samples) compared to whole genome sequencing (WGS) data. We first used 120 TCGA patients that have both WES and WGS to test sensitivity and specificity and to design additional filters in order to remove WES specific artifacts. Using Meerkat, an algorithm we previously developed to detect genomic rearrangements, we found about 1% of the somatic rearrangements detected by WGS can be recovered in WES data and about 50% of the somatic rearrangements detected by WES present in WGS. Some WES specific somatic rearrangements, which were of low allele fraction and thus probably sub-clonal events, weren't detected by WGS due to higher sequencing coverage of WES data. Over 9,000 high confidence somatic rearrangements were identified from TCGA WES data in a total of 4,600 human cancer patients across 15 tumor types. The somatic rearrangement breakpoints occur preferentially in highly express genes. Hundreds of novel gene fusions were identified in addition to known cancer driver fusions such as RET fusions in thyroid cancer, FGFR3-TACC3 fusion in GBM and TMPRSS2-ERG fusion in prostate cancer, etc. RNA-seq data were used to identify activating fusions with following criteria: the 3' fusion partners are up-regulated and the expression changes in at least one of the fusion breakpoints in exon specific expression profile. We identified a total of 150 activating gene fusions. The Gene Ontology (GO) term enrichment analysis for activating fusions revealed that the 5' fusion partners are often house-keeping genes while the 3' fusions partners are enriched in tyrosine kinase and chromatin regulators. We also identified 200 patients (4%) with massive rearranged chromosomes (chromosomes significantly over-represented with somatic rearrangement breakpoints) using the binomial model with Bonferroni correction. The massive rearrangements are often associated with up-regulation of oncogenes. For example, chr17 is often massively rearranged in breast cancer which is associated with up-regulation of ERBB2. Such association can only be revealed by analyzing thousands of patients.

3346T

A Personalized Genomic Signature of Lung to Brain Metastasis. *J.M. Furgason[1], E.M Bahassi[1,2].* 1) Hematology & Oncology, University of Cincinnati, Cincinnati, OH; 2) UC Brain Tumor Center, Cincinnati, OH.

Brain metastases(BMs) are commonly diagnosed intracranial neoplasms that occur during the progression of many systemic malignancies. Approximately 40-50% of these lesions come from lung cancer. Previous efforts to characterize patients that will develop BMs have yielded relatively little results. The purpose of this study is to leverage the power of next-generation sequencing in order to circumvent prior issues in characterizing the metastatic potential of lung tumors. Whole genome sequencing data was obtained from 3 primary non-small cell lung tumors and matched BMs as well as and normal lung tissue. Data was then processed using the GATK quality control pipeline and somatic variants were called using Breakdancer and Somatic Sniper. Copy number variation was determined using Control-FREEC. Calls were validated using Integrative Genomics Viewer. Data was visualized using Circos Diagrams. In all three cases, we were able to identify specific mutations leading to the activation of pathways that have been implicated in metastasis, including those involved in cellular adhesion, motility, and proliferation. Several genes that have been identified are now candidates for future studies. This evidence not only highlights the merits of this analysis in classifying primary tumors based on metastatic potential and stratifying patients based on the risk of developing BMs, but also provides potential signaling pathways that can be therapeutically targeted to prevent brain metastases.

3347S

RAS driver mutations are present in 36% of acute lymphoblastic leukaemia cases in children with Down syndrome and are mutually exclusive with JAK2 mutations. *D. Nizetic[1,2,3], S. Nikolaev[4], M. Garieri[4], F. Santoni[4], E. Falconnet[4], P. Ribaux[4], M. Guipponi[5], A. Murray[6], J. Groet[1], E. Giarin[6], G. Basso[6], S.E. Antonarakis[4,7].* 1) The Blizard Institute, Barts and The London School of Medicine, Queen Mary Unive, London, Switzerland; 2) LonDownS Consortium, The Wellcome Trust, United Kingdom; 3) Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Unit 04-11, Proteos Building, 61 Biopolis Drive, 138673 Singapore; 4) Department of Genetic Medicine and Development. University of Geneva Medical School. 1 rue Michel Servet, 1211 Geneva 4, Switzerland; 5) Geneva University Hospitals - HUG. Service of Genetic Medicine. 4 Rue Gabrielle-Perret-Gentil, 1211 Geneva 4, Switzerland; 6) Dipartimento di Salute della Donna e del Bambino, University of Padua, IRP - Istituto di Ricerca Pediatrica - Fondazione Città della Speranza, Padua, Italy; 7) IGE3 institute of Genetics and Genomics of Geneva. 1 rue Michel Servet, 1211 Geneva 4, Switzerland.

Children with Down syndrome (DS) and acute lymphoblastic leukaemia (ALL) have poorer survival and more relapses, than non-DS children with ALL, highlighting an urgent need for deeper mechanistic understanding of DS-ALL. Using full exome or cancer genes-targeted sequencing of 42 ALL samples from 39 DS patients, we uncover driver mutations in RAS (KRAS and NRAS) recurring to a similar extent (15/42) as JAK2 (12/42) mutations or P2RY8-CRLF2 fusions (14/42). RAS mutations were almost completely mutually exclusive with JAK2 mutations (p=0.016), driving a combined total of two thirds of analysed cases. Clonal architecture analysis revealed that both RAS and JAK2 drove sub-clonal expansions primarily initiated by CRLF2 rearrangements, and/or mutations in chromatin remodellers and lymphocyte differentiation factors. Remarkably, in 2/3 relapsed cases there was a switch from a primary JAK2 or PTPN11 mutated sub-clone to a RAS-mutated sub-clone in relapse. These results provide important new insights informing the patient stratification strategies for targeted therapeutic approaches for DS-ALL.

3348M

Integrated analysis of transcriptome and exome in cancer samples improves interpretation and reveals additional therapeutic insights. *S.M. Boyle[1], M.J. Clark[1], E. Helman[1], D.M. Church[1], S. Lou[1], S. Kirk[1], P. Sripakdeevong[1], M. Karbelashvili[1], M. Pratt[1], M. Snyder[2], R. Altman[2], R. Chen[1], J. West[1].* 1) Personalis, Menlo Park, CA; 2) Department of Genetics, Stanford University, Stanford, Ca.

Next-generation sequencing is increasingly applied as a method for cancer analysis in both research and clinical settings. Many research studies used DNA or transcriptome sequencing to assess the genetic basis of tumor progression and, on some occasions, guide therapeutic decision-making. While gene panel, exome and whole genome sequencing of tumors are widely used for clinical guidance and translational research, transcriptome sequencing has yet to be widely adopted in the clinical environment. However, analyzing the transcriptome allows for improved detection of expression changes, gene fusions, and alternative splicing events. To assess these unique features of RNA, we performed whole transcriptome sequencing along with ACE exome sequencing of cancer samples. Our sample set included commonly used cell lines, cell lines modified to contain specific mutational ratios, and real-world patient samples. We assessed important genetic alterations and limits of detection through analysis of gene expression levels, gene fusion events, and RNA-derived variant calls. These calls were then filtered and annotated with our cancer gene database. There are a growing number of therapeutically relevant gene fusions, which are critically important for accurate tumor mutational analysis. We identified important gene fusion events at the expression level and cross-referenced these with exome findings, where present. Many fusion events would have been missed by exome or gene panel analysis alone. Additionally, transcriptome analysis improves upon assessment of the impact of CNVs on expression. We performed gene expression analyses to accurately quantify differential regulation, something that can only be assumed when analyzing CNVs from DNA alone. By combining expression and DNA-based CNV analyses, we were able to generate more accurate CNV interpretations. A third area transcriptome gives us additional information on is the expression of mutant alleles. To that end, we called variants directly from the RNA, and identified variants that are truly expressed in the tumor. We observed variants in important cancer driver genes which were selectively identified in either genomic or transcriptomic samples through allele specific expression, poorly covered regions, or lack of expression. Taken together, these joint approaches demonstrate how dual interpretation substantially bolsters accuracy and leads to changes in both research results and clinical decisions.

3349T

Deep targeted sequencing for accurate identification of low frequency somatic variation in cancer. *D. Burgess, D. Green, K. Jefferson, M. Brockman, R. Bannen, M. D'Ascenzo, K. Heilman, L. Feng, J. Patel, J. Voichick, T. Richmond.* Research & Development, Roche NimbleGen, Inc., 500 South Rosa Road, Madison, WI.

Somatic genome variation is a key feature underlying the pronounced cellular and clinical heterogeneity observed across a wide range of cancers. The ability to detect and accurately quantify this variation in tumors, particularly as it evolves over time, may be useful for predicting the effectiveness of therapy and monitoring subsequent tumor burden, the emergence of pharmacoresistance, the occurrence of metastasis and, ultimately, projecting a patient's prognosis and survival. If functionally relevant variants can be detected at a low molecular frequency during monitoring, the time and options available for clinical intervention would be greater. For a tumor genome analysis method to be effective for this application, but also practical for widespread implementation, it must be sensitive, accurate, reproducible, fast, low-cost, uncomplicated, amenable to automation and have robust data analysis and reporting outputs. For primary tumor analysis, and for utility in noninvasive screening or monitoring applications, efficacy with low sample input is also an essential element. Targeted next-generation sequencing (tNGS) approaches are a good fit for many of these requirements. We developed a tNGS method based on optimized, multiplexed, molecular inversion probes (MIPs) for the identification of low frequency somatic variation in cancer. A panel of ~700 MIPs was synthesized to interrogate mutational hot spots within a set of 55 cancer genes. The probes targeted both DNA strands and were designed to facilitate bioinformatic error correction. They also incorporated unique molecule identifiers (UIDs) to facilitate tagging of PCR duplicates and the accurate assessment of molecular complexity free of amplification bias. A performance evaluation was executed using a series of normal and cancer mutation reference samples. Analysis of experimental results using ≤100ng of input sample DNA and <40Mb of raw sequencing (paired-end Illumina MiSeq) indicated that >98% of the target region was covered to at least 50x coverage depth, with a duplicate read rate less than 20%, and with >96% of the probes exhibiting ≥20% of the mean panel coverage. Initial evaluation of sensitivity for the panel demonstrated that known single nucleotide variants in the samples could be reliably detected when present at frequencies down to below 1%, with low false-positive rates. We conclude that optimized MIP panels are a promising solution for important applications in cancer genomics.

3350S

Exome sequencing identifies novel cancer-predisposing genes in familial thyroid cancer. *A. Chaudhuri[1], R. Gupta[1], T. Boben[2], P. Kumar[1], V. Ram Prasad[1], S. Santhosh[1].* 1) MedGenome Inc., San Francisco, CA; 2) Kerala Institute of Medical Sciences, Kerala, India.

Thyroid cancer is the most common endocrine malignancy accounting for ~1.7% of all cancer incidences in the world. In India, incidence of thyroid cancer ranges from 2-3% of all cancer incidences. However, certain regions in India - in particular, the state of Kerala, have a significantly higher incidence (3-4-fold higher) of thyroid cancer than the rest of the country. There is no clear mechanistic explanation for this observation. We have applied next generation sequencing (NGS) to identify novel cancer predisposing genes in this population. To this end, we have sequenced exomes of four affected members (3 females + 1 male) of a family diagnosed with thyroid cancer, along with a normal female member from the same family. Three of the four affected were diagnosed with papillary thyroid carcinoma (PTC) and one with follicular thyroid carcinoma (FTC) leading to the identification of variants specific to each cancer type. Our analysis revealed 209,135 variants in genes, which included 36,084 coding region variants. By selecting variants with minor allele frequency of ≤ 5% from 1000genome, and those that resulted in non-synonymous alterations in the coding sequence, we identified multiple variants in genes involved in tissue inflammation, cell survival and extracellular matrix organization in all samples of thyroid cancer. However, further analysis of variants present only in the FTC sample identified truncating mutations in two negative regulators of NFκB pathway, along with mutations in the catalytic subunit of phosphoinositol-3 kinase catalytic subunit 2 alpha (PIK3C2A) suggesting activation of pro-survival pathways in this cancer type. By contrast, the PTC subtype was characterized by mutations in genes associated with growth, cell polarity and cell adhesion functions. In conclusion, our analysis revealed the underlying mechanism of familial thyroid cancer to be inflammatory in origin with distinct pathways participating in the origin of FTC and PTC.

Dysregulation of TGFB pathway in the formation of chordoma. *W. Chen[1], Q. Hu[1], L. Wang[2], J. Zhang[2], C. Zeng[1].* 1) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China; 2) Beijing Tian Tan Hospital, Capital Medical University, Beijing, China.

As a rare malignant tumor chordomas arises from notochordal remnants and frequently occurs in skull base of patients. miRNA dysregulation has been observed in chordomas when comparing miRNA array data in chordoma tissues with skeletal muscle, notochord, or nucleus pulposus. To give a more comprehensive profiling of miRNA in chordomas, we sequenced both miRNA and mRNA in two chordoma tissues and two fetal notochords on HiSeq 2000. In both notochords and chordomas, there are over 600 miRNA expressed. The top five most abundantly expressed miRNAs accounted for more than 50% of total miRNAs in the whole expression library of chordomas or notochords, and among these top miRNAs, two tissues had 3 in common. A total of 45 significantly differentially expressed miRNAs were identified in chordomas, including 16 up-regulated and 29 down-regulated with changed transcriptional activities of their targeted mRNAs accordingly. The functions of these genes were enriched in retinoic acid receptor activation, DNA methylation, transforming growth factor beta (TGFB) pathway, etc. The chordoma up-regulated miR-29b-3p and its down-regulated target gene TGFB3 were further validated in additional 8 chordoma tissues and 8 notochords. Compared to notochords, miR29b-3p was over expressed in all chordoma tissues together with TGFB3 down expressed as revealed by qPCR. As shown by analysis of TGFB pathway in KEGG, we further found the genes involved in apoptosis were dysregulated in chordorma in comparison with notochords, suggesting the missing regulation of TGFB induced cell death had important contribution to chordoma. To identify some variations in DNA level that cause the dysregulation of miR-29b-3p and TGFB3, we further compared the copy number of their corresponding genes between chordoma tissues and their paired blood samples. Among the 8 chordoma patients, 5 had somatic copy number gain at miR-29b1 and miR-29b2 loci, while 4 had copy number loss in TGFB3 locus, suggesting suggests the dysregulation of TGFB pathway may play a critical role in the formation of chordoma.

Whole Exome Sequencing study of HPV-Positive and HPV-Negative Oropharyngeal Squamous Cell Carcinoma: Mutational Profile and Predisposition Gene Identification. *JS. CHOI[1], YS. JUNG[3], JI. KIM[1,2].* 1) Dept. of Biomedical Science, Seoul National Univ, College of Medicine, Seoul, South Korea; 2) Genomic Medicine Institute, Seoul National Univ, College of Medicine, Seoul, South Korea; 3) Head and Neck Oncology Clinic, National Cancer Center, Goyang-si, Gyeonggi-do, South Korea.

Head and neck squamous cell carcinoma (HNSCC) is the sixth leading cancer around the globe, arising in the oral cavity, oropharynx, larynx, and hypopharynx. There are 0.5 million new cases a year worldwide and the five-year survival rate of patients with HNSCC is about 40-50%. Head and neck cancer is strongly associated with certain environmental and lifestyle risk factors, including tobacco smoking, alcohol consumption, UV light, particular chemicals, and certain types of viruses, such as human papillomavirus (HPV). Oropharyngeal squamous cell carcinomas (OSCC), a subtype of head and neck squamous cell carcinoma, is a disease where malignant cells form in the tissue of the oropharynx and which is strongly associated with HPV infection. Oropharyngeal cancers can be divided into two groups, HPV positive, which are associated to HPV infection, and HPV negative cancers, which are usually related to heavy alcohol or tobacco consumption. Particularly, a rapidly rising HPV related oropharyngeal cancers in the developed countries has been well shown in some epidemiological studies. But there are not enough therapeutic molecular targets for HNSCC. We performed whole exome sequencing (WES) on three sets (blood, normal mucosa issue and oropharyngeal tumor tissue) of each 6 HPV positive and 3 HPV negative patients to reveal what genetic factors affect tendency to predispose to OSCC and to compare genetic profile on the basis of HPV infection. We found two of three HPV negative cases have sporadic mutation on TP53 and some others previously known genes to be involved in HNSCC (for example, CDKN2A, CSMD1), while HPV negative cases don't have alterations of TP53. We also found some OSCC predisposition genes by sequential comparisons with normal mucosa tissues. Furthermore, we found that HPV negative samples show more aberrant genetic alteration compared to HPV positive cases and these aberrations do not appear at the level of normal mucosa. This work reveals distinctive mutational genetic profiles of HPV positive and negative OSCC and shows genome wide mutational states of OSCC predisposition giving a clue how normal mucosa changes into malignant tumor cells. These findings open new approach for characterization of biological mechanisms and finding therapeutic targets of OSCC.

3353S

Evaluation of a multiplex PCR targeted enrichment approach for the detection of actionable mutations in FFPE samples via Next-Generation Sequencing. *F. de Abreu[1], J. Peterson[1], R. Samara[2], J. Collins[2], G. Tsongalis[1].* 1) Department of Pathology , Dartmouth Hitchcock Medical Center , Lebanon, NH; 2) QIAGEN Sciences, LLC, Germantown, MD.

Targeted Next Generation Sequencing (NGS) is rapidly becoming an essential tool in personalized cancer treatment. Patient tumor samples can be comprehensively genotyped to identify mutations with a wide variety of both therapeutic and prognostic implications. The often poor quantity and quality of patient samples, however, remains a significant challenge in routine clinical sequencing. The GeneRead DNAseq Panel for Tumor Actionable Mutations is capable of identifying actionable mutations in 8 cancer-associated genes from relatively low-concentration formalin-fixed paraffin embedded (FFPE) samples. This study will show the validation of this panel for the detection of tumor actionable mutations in FFPE samples. The GeneRead DNAseq Panel workflow can be completed in 3-4 days, and can be divided into 2 steps: library preparation, and sequencing/data analysis. 20ng of FFPE gDNA is required for library preparation. Ten samples and two controls were amplified using the GeneRead DNAseq Panel Primer Mix Pool. Sequence adapters were incorporated and purified using the GeneRead Size Selection Kit, and size selection was done using AMPure XP beads. Purified libraries were PCR amplified, and quantified using the GeneRead DNAseq Library Quant Array. Finally, libraries were normalized, pooled, and sequenced on Illumina's MiSeq® system. FASTq files were uploaded to the GeneRead DNAseq Variant Calling portal, where sequence alignment, annotation, and variant classification were performed. The GeneRead panel was able to detect and annotate previously-described mutations with very similar allelic frequencies. Additionally, the panel was able to detect previously-described insertions and deletions; however their annotation was incomplete. Using a commercially-available and thoroughly-annotated control, all five point mutations were correctly identified with similar allelic frequencies to manufacturer specifications. The Qiagen GeneReader Panel for Tumor Actionable Mutations is capable of obtaining both high read-depth and uniformity of coverage using samples with low concentration, producing high-confidence clinically significant variant calls.

3354M

Whole Genome Sequencing of Aggressive, Treatment-Naïve Prostate Tumors. *B. Decker[1,2], D.M. Karyadi[1], E. Karlins[1], B.W. Davis[1], L.S. Tillmans[3], J.S. Stanford[4], S.N. Thibodeau[3], E.A. Ostrander[1].* 1) Cancer Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD; 2) Centre for Cancer Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, UK; 3) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 4) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, 98109.

Prostate cancer (PCa) is the most common and second most lethal malignancy in American men, with approximately 239,000 diagnosed cases and 30,000 deaths in 2013. Early identification of men with aggressive versus indolent disease is a critical challenge in the clinical management of PCa. Recent sequencing-based studies have illuminated important aspects of PCa tumor development and molecular biology. In spite of recent progress, the coordinated role of SNVs, indels, and structural variants has not been well described, especially in the most aggressive tumors. To access the genomic landscape of aggressive prostate tumors, we performed deep whole genome sequencing of nine fresh frozen Gleason 8-10 prostatectomy samples and one nodal metastasis from a tenth patient. Subjects had a mean age at diagnosis of 63.6 years and all were of Caucasian ancestry. Tumor DNA was sequenced to an average depth of 95.3X, with an average germline coverage of 48.3X. Somatic SNVs, indels, and SVs were identified, and coordinated evaluation of somatic mutations is underway. Tumors harbor 2,387 - 15,500 somatic single nucleotide variants, and 96 - 491 such variants fall in coding regions. We also found 274 - 2,578 high-confidence somatic indels, and 112 - 927 somatic structural variants per tumor. All variants that are predicted to damage the encoded protein are being evaluated with gene set enrichment analysis, in order to uncover pathways and functional gene groups that are enriched for somatic mutations in aggressive PCa. We are also investigating the order of somatic genetic events in the evolution of aggressive PCa tumors using allelic imbalance, which informs variant clonality and enables analysis of earlier versus later mutations. Future work will focus on recurrently mutated pathways and comparison of our highly aggressive tumors with PCa tumors from other PCa Tumors. Ultimately, we aim to 1) Define the spectrum of somatic variation in ten high-grade, treatment-naïve PCa tumors; 2) Characterize genes and pathways that are recurrently disrupted by somatic mutations; and 3) Describe somatic variant chronology and clonal evolution in aggressive PCa tumors. As more tumors across the aggressiveness spectrum are sequenced, this approach may uncover valuable markers for PCa diagnosis, prognosis and treatment selection.

3355T

iCAGES: integrated CAncer GEnome Score for understanding personal cancer genomes. *C. Dong[1,2], H. Yang[1], X. Liu[4,5], K. Wang[1,2,3].* 1) Zilkha Neurogenetic Institute, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Biostatistics Division, Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Department of Psychiatry, Keck School of Medicine, University of Southern California, Los Angeles, CA 90033, USA; 4) Human Genetics Center, The University of Texas Health Science Center at Houston, Houston, Texas, 77030, USA; 5) Division of Epidemiology, The University of Texas Health Science Center at Houston, Houston, Texas, 77030, USA.

Cancer is a disease caused by accumulation of somatic mutations. Integration of personal genomic information with prior biological knowledge allows better understanding of cancer on a personal and systematic level. Here, we propose iCAGES (integrated CAncer GEnome Score), a statistical model that integrates multiple sources of information, from personal genomic information, to prior knowledge of its genes and networks and finally to drug-gene interactions. For each patient, iCAGES takes as input the genomic somatic mutations and calculates a prioritized list of cancer driver genes and candidate drugs, using a three-layer estimation procedure: The first layer summarizes personal genomic information using radial SVM (Support Vector Machine) algorithm based on the observation of a novel non-linear relationship between evolutionary conservation and function alterations of potential cancer driver mutations retrieved from COSMIC database, modeled with nine different deleteriousness prediction scores (PolyPhen-2, SIFT, MutationTaster, Mutation Assessor, FATHMM, LRT, GERP++, SiPhy and PhyloP, retrieved from ANNOVAR website and dbNSFP database) as its features. The second layer is based on previous knowledge on the association of each gene with cancer, modeled using Phenolyzer. Natural language processing schema was used for summarizing related biological research publications compiled from various databases, such as OMIM, ClinVar and GWAS catalog. Overall conditional probability for each gene on cancer was calculated and then integrated with protein-protein interaction and other network information from sources, such as HPRD protein interaction, NCBI's Biosystem and HGNC gene family, to adjust for known protein-protein interactions. The third layer is based on gene-drug interaction, currently modeled using publicly available algorithm from DGIdb (Drug-Gene Interaction database), but novel algorithms are also under development. We evaluated the performance of iCAGES using somatic nsSNV data retrieved from a recently published case on sorafenib-sensitive lung adenocarcinoma. Within 10 minutes, iCAGES prioritized ARAF gene and sorafenib as the candidate gene and drug, using a list of nsSNP as input, consistent with the original publication. In summary, we developed a statistical model that leverages personal genomic information with prior biological knowledge, shedding light into cancer driver genes identification, personalized drug discovery and cancer treatment.

3356S

The Activation of LINE-1 Retrotransposition in Barrett's Esophagus and Esophageal Carcinoma. *T.T. Doucet[1,2], N. Rodić[3], T. Jungbin Choi[1], J. Young Ahn[1], Y. Cheng[4], K.H. Burns[1,3], S.J. Meltzer[4], H.H. Kazazian[1].* 1) Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Pre-doctoral training program in Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA; 3) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland, United States of America; 4) Division of Gastroenterology and Hepatology, Department of Medicine and Department of Oncology, Johns Hopkins University, Baltimore, Maryland.

One cause of genomic instability is the insertion of human retrotransposons that copy and paste themselves into new sites. We investigated how retrotransposition is involved in genomic instability in esophageal carcinogenesis. Using the L1-seq technique, we enriched for young, active LINE-1 (L1) sequences and utilized next generation sequencing coupled with our analysis pipeline to isolate L1 insertions unique to the tumors of twenty-one esophageal adenocarcinoma (EAC) cases and squamous cell carcinoma (SCC) patients, divided into three cohorts. Our first cohort contained 1 EAC case and 4 SCC cases; the second cohort had eleven EAC cases. The third cohort contained five cases of EAC with matched DNA from the precursor lesion, Barrett's esophagus (BE). Between the three cohorts, we confirmed 86 somatic insertions many of which occurred in introns of genes known to be involved in carcinogenesis. To investigate whether these confirmed insertions were clonal, we validated a subset of them in BE as well as tumor DNA. After validation, eight insertions were present only in BE, while two occurred in both BE and tumor from the same individual. In esophageal carcinoma cases for which we had tissue, at least 20 of the 42 high-stringency insertions were present in multiple regions of each tumor, suggesting that these insertions were clonal and occurred early in tumorigenesis. By immunohistochemistry, we also observed high levels of ORF1p, one of two L1 proteins, in 6 of 9 patient samples evaluated. In the individuals in whom we observed ORF1p expression, protein concentration increased linearly with progression from dysplasia to frank cancer. We are also investigating germline insertions within introns of genes involved in carcinogenesis to determine whether or not certain insertions predispose individuals to develop esophageal carcinoma. 174 germline insertions, including the genes PADI6, AKT3, and THADA (not polymorphic in the general population), were recurrent in multiple cohorts of patients. Furthermore, there was one germline insertion predicted to reside in an internal exon of a CDH17 gene in two cohorts. We are currently elucidating effects of these insertions on gene expression. In light of these data, we conclude that the process of retrotransposition is a potential cancer driver in at least a subset of EAC patients. Using multiple approaches, we now seek to understand how retrotransposition contributes to genomic instability in tumorigenesis.

3357M

A big family of adenomatous polyposis with different extraintestinal manifestations. *M. Duz[1], A. Gezdirici[1], H. Ulucan[1], G. Guven[1], M. Seven[1], A. Yuksel[1,2], M. Ozen[1,3].* 1) Department of Medical Genetics, Cerrahpasa, Istanbul, Turkey; 2) Biruni University, Istanbul, Turkey; 3) Department of Pathology & Immunology Baylor College of Medicine, Houston, TX, 77030, USA.

Familial adenomatous polyposis (MIM #175100) (FAP) is an autosomal dominant disorder characterized by predisposition to colorectal cancer. Affected individuals usually develop hundreds to thousands of adenomatous polyps of the colon and rectum. These findings can progress to colorectal carcinoma in a small proportion of these patients. Moreover, extraintestinal manifestations can appear as osteomas, dental anomalies, congenital hypertrophy of the retinal pigment epithelium, soft tissue tumors, and desmoid tumors. Molecular genetic testing of APC, which is frequently used in the early diagnosis of at-risk family members, in addition to verification of the diagnosis of FAP and attenuated FAP in individuals with suspected findings, detects disease-causing mutations in about 90% of individuals with typical FAP. Here, we report a big family of five generations with thirty five individuals whose referral reasons were ranging from gastrointestinal problems to total colectomy. The proband, a 23-year-old female, had altered bowel habits with 20 adenomatous polyps in her colonoscopy. Her father has also history of colorectal cancer, accompanied with hundreds to thousands of adenomatous polyps of the colon and rectum at age 28 years, followed by total colectomy. Molecular testing revealed deleterious nonsense germline mutation c.C1370G, p.S457X in 11th exon of APC in thirteen of twenty three members of the family studied. This clinical picture and mutation within the family are compatible with FAP. The mutation carriers in the family show different symptoms and extraintestinal manifestations. Our results suggest that a single APC germline mutation might come up with clinical variability even in closely related individuals due to modifier genes of APC and epigenetic factors.

3358T

Exomic and transcriptomic patterns of colitis-associated carcinoma. *D. Esser, M. Falk-Paulsen, K. Aden, P. Rosenstiel.* Institute of Clinical Molecular Biology, Kiel, Schleswig-Holstein, Germany.

Inflammatory bowel diseases (IBDs) are chronic inflammatory disorders in the gastrointestinal tract, which arise as a result of the interaction of environmental and genetic factors. The risk of developing colorectal cancer (CRC) is increased for a person with IBD and correlates with the degree of colonic inflammation and disease duration. Patients with colitis-associated cancer (CAC) are younger than patients with sporadic colorectal cancer and show a poorer survival in the advanced stage. Both cancer types are multi-step processes, but differ in certain mutation types. Compared to the more frequent sporadic CRC, the genomic signatures of CAC are far less understood.

In order to investigate the genetic background of colitis-associated carcinoma we chose a well established inflammation-associated colorectal carcinogenesis model in mice (AOM/DSS) and compared the results from early and late stage cancer with inflamed tissue from DSS-treated and with healthy samples from untreated mice. Three experimental settings with different DSS concentrations and treatment durations were investigated. After tissue collection, the whole exome as well as the whole transcriptome of tumor and all proximal colonic non-tumor samples were sequenced on the Illumina HiSeq 2000, followed by bioinformatic analyses. Beside known CAC-associated single nucleotide variants (SNVs) in e.g. *Ctnnb1*, we were able to identify a multitude of novel potentially damaging mutations. Furthermore, we observed regional clustering of somatic SNVs in several tumor samples and could show that the cancer stage is associated with the mutation rate and the mutation pattern. Additionally, we found a tumor specific gene expression profile. This also included the investigation of novel transcriptionally active regions, fusion transcripts and splice variants. Based on exome and transcriptome data, relevant genes and pathways were filtered out using different methods.

We performed one of the first studies analyzing the genetic background of CAC with next-generation sequencing technologies and demonstrated that a combined application of whole exome and strand-specific whole transcriptome sequencing can reveal new insights into the development of CAC.

Analysis of metastatic diffuse gastric cancer genomes in a Mendelian family with an inherited *CDH1* mutation. *S. Greer[1], J. Bell[2], E. Hopmans[2], L. Miotke[1], S. Grimes[2], H. Ji[1].* 1) Stanford University School of Medicine, Stanford, CA; 2) Stanford Genome Technology Center, Stanford, CA.

Gastric cancer (GC [MIM 137215]) is the fourth most common malignancy and the second leading cause of cancer deaths worldwide. Based on distinctive histopathological features, GC can be classified into two subtypes: intestinal GC and diffuse GC, with evidence suggesting that different carcinogenic pathways are involved in the development of each subtype. Compared with intestinal GC, the incidence of diffuse GC is increasing more rapidly and has an overall worse prognosis as a result of its diagnosis after metastasis has occurred. For this study, we investigated the underlying genetics of diffuse gastric cancer metastasis, leveraging the highly informative Mendelian genetics of a family with Hereditary Diffuse Gastric Cancer (HDGC), an inherited cancer syndrome in which germline mutations in the *CDH1* gene confer a 70% lifetime risk of developing diffuse GC. *CDH1* [MIM 192090], which encodes the E-cadherin protein, is well known to be associated with diffuse GC. However, very few additional cancer driver genes that work in coordination with *CDH1* loss-of-function in the diffuse subtype have been identified to date. In the case of Mendelian cancer genomes, the initial cancer driver event is known, which offers a unique scientific opportunity to delineate additional cooperative cancer drivers involved in metastasis. With whole genome sequencing, we analyzed a primary gastric tumor and ovarian metastasis (Krukenberg tumor) from an individual with a germline, hereditary *CDH1* mutation, as well as a Krukenberg tumor from her sister. Both sisters were found to have a germline splice site mutation in intron 10 of *CDH1*, leading to loss of function of the critical *CDH1* tumor suppressor, representing the first hit in the development of their primary tumors. Several cooperative cancer drivers were identified in this study, including SNVs in *TP53* [MIM 191170], and amplification of the *FGFR2* [MIM 176943] gene was observed in the tumors of both sisters. This study has significant implications in the consideration of precision medicine approaches for treating metastatic cancer by shedding light on the genetics of diffuse gastric cancer, molecular mechanisms of metastasis, and oncogenic events that are therapeutic targets.

3360M

The mutational landscape of peritoneal malignant mesothelioma. *O. Harismendy[1,3,5], H. Alakus[2,3,6], S.E. Yost[3,7], C.-P Cheng[3,8], D.V. Jaquish[2], E.S. Mose[2], R.P. French[2], B. Woo[1,3], K. Jepsen[4], K.A. Frazer[1,2,4,5], A.M. Lowy[1,2].* 1) UC San Diego Moores Cancer Ctr, La Jolla, CA; 2) UCSD Department of Surgery, La Jolla CA; 3) UCSD Department of Pediatrics, La Jolla CA; 4) UCSD Institute for Genomic Medicine, La Jolla CA; 5) UCSD Clinical and Translational Science Institute, La Jolla CA; 6) Department of General, Visceral and Cancer Surgery, University of Cologne, Cologne, Germany; 7) UCSD Bioinformatics Graduate Program, la Jolla CA; 8) National Cheng Kung University, Tainan, Taiwan.

Malignant mesothelioma (MM) arises from mesothelial cells that line the pleural, peritoneal and pericardial surfaces. The majority of MM are pleural and have been associated with asbestos exposure. Previously, pleural MM have been genetically characterized by the loss of BAP1, either somatic or inherited, as well as loss of NF2 and CDKN2A. The rare peritoneal form of MM (PeMM) occurs in ~10% cases. With only ~300 cases diagnosed in the US per year, its link to asbestos exposure is not clear and its mutational landscape unknown. We analyzed the somatic mutational landscape of epithelioid PeMM using whole exome sequencing (N=7) and copy number analysis (N=9). In total, we identified 87 non-silent mutations in 83 genes with a median of 8 mutated genes per tumor, therefore resulting in a relatively low mutation rate (~1.6 10-6). BAP1 is the most recurrently mutated gene in PeMM, affecting 6/9 samples. BAP1 deletions occurred as focal events in 4/9 cases, in the context of a loss of chromosome 3p21 and are frequently accompanied by somatic mutations of the remaining allele. In one additional case, the loss of the entire chromosome 3 (encoding for BAP1) leaves a non-functional copy of BAP1 carrying a rare nonsense inherited variant, thus suggesting a potential genetic predisposition in this patient. The PeMM mutational landscape, dominated by the loss of chromosome 3p21, is reminiscent of the one observed in clear-cell renal carcinoma. In contrast to pleural MM, we do not observe deletions of NF2 and CDKN2A in PeMM, suggesting genetic differences between the two diseases. These findings support the use of molecularly guided clinical trials and therapies in PeMM.

3361T

The Landscape of Inherited and Somatic Mutations in Fallopian Tube Carcinoma. *M.I. Harrell[1], T. Walsh[2], S. Gulsuner[2], K.J. Agnew[1], B. Norquist[1], M.K. Lee[2], S. Bernards[1], K.P. Pennington[1], M.C. King[2], E.M. Swisher[1].* 1) Obstetrics and Gynecology, Division of Gynecologic Oncology, University of Washington, Seattle, WA; 2) Medical Genetics, University of Washington, Seattle, WA.

Fallopian tube (FT) carcinoma is a rare gynecological malignancy, whose incidence is most likely underestimated due to misdiagnoses as ovarian cancer. Recent advances in pathology with more thorough serial sectioning techniques have led to better identification. We undertook to define germline and somatic mutations in 98 FT carcinoma cases enrolled at diagnosis in IRB-approved studies at the University of Washington, excluding cases with carcinoma identified at the time of risk-reducing surgery. We sequenced DNA from blood and neoplastic tissue using BROCA, a targeted capture and massively parallel genomic sequencing approach that detects all classes of mutation in 64 genes. The fraction of all primary ovarian, peritoneal and FT carcinoma defined as a FT primary has increased over time: FT diagnoses accounted for 23% of cases in the past five years compared to 5% in the previous 10 years (p=0.002). Of 98 subjects with FT carcinoma, 32 (33%) had loss of function germline mutations in 9 genes. Germline mutations were identified in *BRCA1* in 18 (19%), and in *BRCA2* in 4 (4%) patients. Germline mutations were also identified in other known or candidate breast and/or ovarian cancer susceptibility genes including 2 in *BRIP1* (2%), 2 in *CHEK2* (2%), and 1 each in *BARD1*, *BLM*, *MRE11A*, and *ATM* (1%). One mutation was found in *FANCL*. Mosaic mutations were found in *TP53* (1%) and in *PPM1D* (2%). Together, germline and mosaic mutations were identified in 34 (35%) cases. Neoplastic DNA from 30 FT advanced stage carcinomas sequenced with BROCA revealed 27 somatic mutations in *TP53* (90%), 1 in *PTEN* (3%), and 1 in *CHEK2* (3%). The germline mutation rate was higher in FT carcinoma compared to our previous studies in ovarian carcinoma (35% versus 22%), and the profile of mutant genes was similar. Recently identified ovarian cancer susceptibility genes such as *BRIP1*, *BARD1*, and *PPM1D* are also associated with hereditary fallopian tube cancer. Known breast cancer genes (i.e. *CHEK2, ATM*) and other cancer-associated genes (*BLM*, *FANCL*) require further study to test their association with FT or ovarian cancer. Increased recognition by pathologists of the FT as a primary site of disease is changing the relative distribution of FT, ovarian, and peritoneal carcinoma as primary diagnoses, making the profiling of FT cancers increasingly important.

3362S

A rare somatic mutation in the TEL patch of telomere protein TPP1 acts as a driver of childhood acute lymphoblastic leukemia. *J. Healy[1], J.F. Spinella[1], P. Cassart[1], N. Garnier[1], C. Drullion[1], R. Vidal[1], V. Saillour[1], C. Richer[1], M. Ouimet[1], S. Busche[2], B. Ge[3], T. Pastinen[2,3], D. Sinnett[1,4].* 1) Division of Hematology-Oncology, Sainte-Justine UHC Research Center, Université de Montréal, Montreal, QC, Canada; 2) Department of Human Genetics, McGill University, Montreal QC, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 4) Department of Pediatrics, Faculty of Medicine, Université de Montréal, Montreal, QC, Canada.

Childhood acute lymphoblastic leukemia is a heterogeneous disease both biologically and clinically, and is the leading cause of cancer-related deaths among children. Thorough investigation of pediatric ALL genomes, and identification of not only recurrent but also rare/private somatic driver mutations, is crucial in order to understand the underlying genomic complexity of this disease and thus better diagnose and treat it. Here we performed deep re-sequencing of a hyperdiploid pre-B childhood ALL patient and used a strict filtering strategy to identify somatic events with high driver potential. Among the candidate mutations, we identified a rare non-synonymous mutation (p.G223V) in the oligonucleotide-/oligosaccharide-binding(OB)-folds of the TEL patch of telomere protein TPP1/ACD, member of the shelterin complex that protects chromosome ends and regulates telomerase activity. Using in vitro cytotoxicity assays in ALL cells, we demonstrated a strong protective effect of this mutation against apoptosis associated with telomere maintenance. Thus, for the first time we identified a somatic mutation in TPP1 with functional implications in cellular transformation, suggesting a role for TPP1 as a novel driver of childhood ALL and highlighting the importance of rare/private somatic mutations in understanding disease etiology.

3363M

Mutational spectrum of RET Proto-oncogene in Iranian Patients with Medullary Thyroid Carcinoma. *M. Hedayati[1], M. Zarif Yeganeh[1], S. Sheikholeslami[1], F. Azizi[2].* 1) Cellular and Molecular Research Center, Research Institute for Endocrine Science, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 2) Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Introduction: Thyroid cancer is the most common endocrine malignancy. It divides into four groups, including papillary (80%), follicular (10-15%), medullary (5-10%), and anaplastic thyroid cancer. Medullary Thyroid Carcinoma (MTC) is one of the most aggressive thyroid tumors which occur in both hereditary (25%) and sporadic (75%) forms. Mutations of the RET proto-oncogene in MTC development have been well demonstrated. The aim of the study was to investigate the mutational spectrum of exons 3, 5, 8, and 10-18 of RET proto-oncogene in MTC patients. Material and Methods: This retrospective study has been started since 2001 in Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, and Tehran, Iran. 370 participants, including 224 patients (168sMTC, 39FMTC, 8MEN2A, 3MEN2B, 5pheochromocitoma), and 146 relatives were evaluated. Genomic DNA was extracted by the standard Salting Out/ProteinaseK method and mutation detection was performed through direct DNA sequencing. Sequence analysis was performed by Chromas Software version 2.3. Results: Totally, in 224 patients (124 Female, 100 Male) and 146 relatives (80 Female, 66 Male), 79 mutations were identified in RET main exons, including exons 10, 11, 13-16. Furthermore, 282 Single Nucleotide Polymorphism (SNP) were found in exons 3, 13, and 14. Interestingly, SNPs G691S and S904S were 100% in linkage disequilibrium in 125 patients and 70 relatives. The most common mutation in our population was C634Y (4%) whereas C618R, C618S, C620G, L887L mutations had rare allele frequency (0.3%). Moreover, R886Q mutation was detected in exon 15 in two members of a family affected with MTC, for the first time. Discussion: Exon 11 and after that exon 10 were the most frequently mutated exons of RET proto-oncogene in MTC patients in Iranian population. As about half of patients with the hot spot mutations had the G691S/S904S haplotype simultaneously, further analysis needs for clarifying the collective effects of multiple risk alleles in MTC development. Key words: Medullary Thyroid Cancer, RET proto-oncogene, Germline mutation.

3364T

Analysis of RNA-Sequencing Data Reveals Association of JAK-STAT Pathway with NK/T-Cell Lymphoma. *JH. Hwang[1], HY. Park[1], SB. Lee[2], JS. Choi[1], YH. Ko[3,5], WS. Kim[4,5], SJ. Kim[4,5], HY. Yoo[5], JI. Kim[1,2].* 1) Seoul National Univ, College of Medicine, Seoul, South Korea; 2) Genomic Medicine Institute, Medical Research Center, Seoul National University, Seoul, Republic of Korea; 3) Department of Pathology, Samsung Medical Center; 4) Department of Medicine, Samsung Medical Center; 5) SungKyunkwan University School of Medicine, Seoul, Republic of Korea.

NK/T-cell lymphoma is a rare and aggressive subtype of non-Hodgkin lymphoma. Although it has been identified that lymphoma is associated with JAK-STAT pathway, there are few studies of NK/T-cell lymphoma using RNA-sequencing. We sequenced the transcriptomes of three tissues, seven cell lines of NK/T-cell lymphoma, and three normal NK/T cell lines to identify a diverse transcriptional spectrum such as gene fusions, differentially expressed genes, and transcription factors that affect differentially expressed genes. In this study, we discovered 24 in-frame fusion genes in two tissues and five cell lines. Among these, we found SND1-LEP fusion in a single cell line, and theLEPgene in this sample was expressed 20 times more than normal samples. It has been reported that leptin is involved in the tumorogenesis by activation of cellular signal transduction of JAK-STAT pathway. The genes showing abnormal expression patterns were also shown to be enriched in the JAK-STAT pathway(p-value = 1.92×10-4). Based on the expression data, we tested enrichment of predicted transcription factor binding sites for genes specifically activated in each sample. The binding sites of KLF4, MZF1, and SP1, which were known to be associated with JAK-STATpathway and lymphoma, were enriched in both tissues and cell lines.Taken together, these results show the association between NK/T-cell lymphoma and JAK-STAT pathway again at the transcriptional level.

3365S

Exome sequencing reveals novel mutation hotspots in microsatellite unstable colorectal cancer. *U.A. Hänninen[1,2], S. Tuupanen[1,2], J. Kondelin[1,2], P. von Nandelstadh[2], T. Cajuso[1,2], A.E. Gylfe[1,2], R. Katainen[1,2], T. Tanskanen[1,2], H. Ristolainen[1,2], J. Böhm[3], J-P. Mecklin[4], H. Järvinen[5], L. Renkonen-Sinisalo[5], C. Lindbjerg Andersen[6], M. Taipale[2,7], J. Taipale[2,7], P. Vahteristo[1,2], K. Lehti[2], E. Pitkänen[1,2], LA. Aaltonen[1,2].* 1) Haartman Institute, Department of Medical Genetics, University of Helsinki, Finland; 2) Research Programs Unit, Genome-Scale Biology Research Program, University of Helsinki, Finland; 3) Department of Pathology, Jyväskylä Central Hospital, University of Eastern Finland, Finland; 4) Department of Surgery, Jyväskylä Central Hospital, University of Eastern Finland, Finland; 5) Department of Surgery, Helsinki University Central Hospital, Finland; 6) Department for Molecular Medicine (MOMA), Aarhus University Hospital, Denmark; 7) Science for Life Center, Department of Biosciences and Nutrition, Karolinska Institutet, Sweden.

Colorectal cancer (CRC) with microsatellite instability (MSI) defines a subgroup (15%) of CRCs with distinct clinical characteristics. The mutation pattern in MSI CRC consists of small insertions and deletions in microsatellite regions throughout the genome. This pattern results from defects in the mismatch repair system, having either a hereditary (Lynch syndrome) or sporadic origin. Improved cancer diagnostics, novel therapeutic interventions, and personalized care require more comprehensive knowledge on mutations affecting tumor formation. The most frequently mutated cancer genes are already well known; mutations occurring at intermediate or low frequencies remain largely unidentified, however. Because mutations in oncogenes emerge recurrently at the same amino acid positions, a newly suggested criterion for defining new driver genes, rather than frequency, is mutation pattern. Genes with recurrent codon-specific somatic mutations are likely drivers of tumorigenesis, and potential therapeutic targets. The exomes of 25 sporadic MSI colorectal tumors and their corresponding normal tissue samples served as the discovery set for identifying base-specific somatic mutation hotspots. These were found in 43 genes, of which three were the following known oncogenes: BRAF (V600E), CTNNB1 (T41A) and PIK3CA (H1047R). The findings were validated by Sanger sequencing. The known genes and 33 novel potential hotspot genes were confirmed and thus further screened in an additional set of 254 MSI tumors. Fourteen potential hotspot genes displayed mutations also in the validation set with a mutation frequency of 0.4-2.8%. A database search revealed many of the identified hotspot mutations in other cancer types.

3366M

Detection of mutation hotspots through mutation set enrichment analysis. *P. Jia[1,2], Q. Wang[1], Q. Chen[1,3], K.E. Hutchinson[4], W. Pao[4,5], Z. Zhao[1,2,4,6].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Center for Quantitative Sciences, Vanderbilt University, Nashville, TN; 3) Department of Biostatistics, Vanderbilt University, Nashville, TN; 4) Department of Cancer Biology, Vanderbilt University, Nashville, TN; 5) Department of Medicine/Division of Hematology-Oncology, Vanderbilt University, Nashville, TN; 6) Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN.

Although cancer genomes are extremely heterogeneous both within and among tumors, mutation hotspots are a prevalent disruptive mechanism in many cancer genes. Many of these mutation hotspots disrupt functional domains or active sites, leading to gain- or loss-of-function of the protein product. We leveraged these observations to identify and prioritize candidate cancer genes and formulated a mutation set enrichment analysis (MSEA). MSEA assesses whether somatic mutations within a gene have a tendency to cluster within certain regions of the gene's coding sequence. We proposed two complementary approaches, MSEA-clust and MSEA-domain. MSEA-clust simulates a walk through the sequences and renders a quantitative measurement of the location and extent to which mutations cluster. MSEA-clust is hypothesis-free because the convergent regions to be discovered are independent of a priori annotations of domains or functional sites. In contrast, MSEA-domain explicitly detects whether the mutations occur in a pre-defined functional domain more frequently than remaining regions. MSEA-domain implements a regression-based test and can only assess a priori domains; thus, it is hypothesis-driven. We assessed the two MSEA approaches using somatic mutation data from a comprehensive public resource (the Catalog of Somatic Mutations in Cancer database, COSMIC) and found that many known cancer genes have mutation hotspots. We then applied these approaches to available somatic mutation data in eight cancer types from The Cancer Genomic Atlas (TCGA) project. With false discovery rate (FDR) being less than 0.2, both MSEA-clust and MSEA-domain were effective in detecting well-studied cancer genes and new candidates that have not been intensively studied in cancer. Collectively, these analyses demonstrate that MSEA methods are well suited to detect cancer genes based on mutation hotspots and provide valuable tools for future cancer gene studies.

3367T

Advanced qualification and quantification of amplifiable genomic DNA (gDNA) for PCR-based targeted enrichment prior to next-generation sequencing. *Q. Jiang, Q. Peng, J. DiCarlo, Y. Wang, R. Samara, V. Devgan, E. Lader.* Biological Research Content, QIAGEN Sciences, LLC, Frederick, MD, USA.

Formalin-fixed paraffin-embedded (FFPE) tissue archives are an invaluable source for the molecular characterization of disease using next-generation sequencing (NGS). Unfortunately, heavy damage and fragmentation from the preservation process often results in FFPE DNA samples that cannot be amplified by PCR. Commonly used methods, such as fluorometry and spectrometry, are inadequate in assessing the amount of PCR-amplifiable DNA present in a sample. To overcome these challenges, we describe the development of a novel qPCR-based method for quantifying and qualifying FFPE samples for NGS. This method utilizes two qPCR assays to target multi-copy loci mapping to regions distributed across the genome. 329 assays in 85 distinct genomic regions were screened for qPCR performance. Assays with outstanding performance and consistency across all major human populations were selected. Plotting assay CT values against amplicon sizes generated a QC score, which provided size distribution information of sample gDNA. Additionally, the inclusion of a high-quality reference gDNA allowed quantification of amplifiable gDNA molecules, without the need for serial dilutions. To address suitability of this method for NGS, DNA from more than 100 FFPE samples with varying quality characteristics was extracted and subjected to qPCR analysis. For comparison, 50 FFPE samples were also quantified by spectrometry. All samples underwent PCR-based targeted enrichment, and were sequenced on either the PGM®, MiSeq®, or HiSeq®. All (high- or low-quality) FFPE samples quantified (and guided for input amount) by this strategy achieved good library yields, high specificity (>90%), and fairly even coverage on all sequencing platforms. Qualitatively, NGS results from these samples indicated that the calculated QC score predicted false positive rates. However, spectrometry was of limited usefulness in qualifying or quantifying these samples, which frequently failed to yield satisfactory NGS results. These samples produced varied library yields, mostly of low quantity, and low-specificity NGS reads. This advanced system for sample QC prior to NGS can assess both the quality and quantity of gDNA samples. This is critical for identifying whether a particular gDNA sample is suitable for NGS analysis and determining the appropriate DNA input for successful targeted enrichment via multiplex PCR. The applications presented here are for research use only. Not for use in diagnostic procedures.

Genetic Alterations and Evolutionary Behavior in Liver Metastatic Colorectal Cancer. *B. Lim[1], J. Kim[2], S. Kim[1].* 1) Medical Genomics Research Center, Korea Research Institute of Bioscience and Biotechnology (KRIBB), Daejeon, Republic of Korea; 2) Institute of Innovative Cancer Research and Asan Institute for Life Sciences, Asan Medical Center, Seoul, Republic of Korea.

Colorectal cancer (CRC) develops through well-established pathogenesis steps accompanying with specific mutations. However, mutations associated with CRC liver metastases (LMs) and their evolutionary behaviors are not fully understood. To investigate somatic mutations found in CRC LMs, we performed exome- and RNA-sequencing using 101 tissues from 41 CRC patients, comprising 22 non-metastatic and 19 liver-metastasized patients. Global genomic patterns, including variant allele frequency (VAF), base substitution spectrum and chromosomal aberration, of liver-metastatic primary tumors (LMPTs) were distinct from those of non-metastatic primary tumors (NMPTs) as well as LMs. Particularly, *PIK3CA* mutations were more frequently detected in LMPTs than NMPTs and significantly associated with clinical characteristics of advanced cancer. We observed 4 categories of evolutionary behavior of mutations (from Class 1 to 4) based on dynamic patterns of VAFs from LMPTs to LMs. The Class 1, which probably has high fitness to metastasis, was significantly associated with clinical characteristics of advanced cancer and frequently co-occurred with chromosomal aberrations in LMs compared with the Class 2, which probably has low fitness to metastasis. We also observed discrepant VAFs between exome and transcriptome. Importantly, VAFs of mutant alleles from *TP53* and *APC* at the transcriptomic level were significantly correlated with expression level of transcriptional target genes, revealing the functional implications of selective expression of mutant alleles. Especially, *TP53* mutant alleles tended to be positively selected through chromosomal aberration and allele specific expression in LMs. The examination of mutations and evolutionary behaviors at the genomic and transcriptomic level is required to apply precision medicine for liver-metastatic CRC patients.

3369M

Whole exome sequencing reveals that DNA repair and apoptosis pathways are affected in hereditary breast cancer cases. *J.L.D. Mentoor[1], F. Joubert[1,2], E. J. van Rensburg[1].* 1) Department of Genetics, University of Pretoria, Pretoria, South Africa; 2) Bioinformatics and Computational Biology Unit, Department of Biochemistry.

Family history serves as the most significant risk factor for breast cancer (BC). Variants in the *BRCA1&2* breast cancer susceptibility genes account for ~30-60% of hereditary BC. Moderate risk genes (e.g. *RAD51C, PALB2 & ATM* etc.) account for ~3-5% of familial cases. A considerable number of familial BC cases are not due to mutations in high/moderate susceptibility genes identified thus far i.e. *BRCAx* families. Mutant alleles in novel risk genes may account for the missing heritability. The aim of our research is to discover variants in novel high-penetrant genes that may increase susceptibility for BC.

Nine cases (*BRCA1&2* negative) were selected from 6 families with a history of breast and/or ovarian cancer (≥3 cases). Paired-end exome sequencing was completed by the Beijing Genomics Institute (Illumina). The Genome Analysis Toolkit 2.4.9 was used for variant calling and annotation. Mutations were filtered and interrogated from multiple biological perspectives by the Ingenuity variant analysis tool. High-quality, rare variants (truncating & splice-site) were selected based on minor allele frequency thresholds i.e. 1000genomes (<0.01) and ESP6500 (<0.01). High-priority mutated genes were cross-referenced to known BC and/or ovarian cancer genes with the ToppGene gene enrichment analysis suite and compared to somatic variant data derived from breast cancer resources. To further refine this list Sanger sequencing was used to confirm true-positive variants in high-priority genes within selected family members of index cases. Genes were ranked according to the presence of mutant alleles in index cases and affected family members. We then acquired gene expression data of highly ranked genes from databases containing comprehensive information of tissue specific gene regulation.

Thirteen biologically significant genes were identified that play a role in the inhibition of cell growth as well as DNA homologous recombination repair. Three of the most promising genes include; a novel putative tumour suppressor (*TCHP*) that is pro-apoptotic; the XPF-endonuclease homolog, *EME2*; and a POLQ-like helicase enzyme (*HELQ*). The latter two genes code for proteins that promote cross-linked DNA repair. Currently these genes are being screened in high-risk families and cohorts of women with breast cancer in order to explore their possible roles in breast cancer susceptibility.

3370T

Selective depletion of abundant RNAs to enable transcriptome analysis of low input and highly degraded RNA from FFPE breast cancer samples. *D. Munafo[1], B. Langhorst[1], S. Russello[1], F. Stewart[1], D. Sinicropi[2], J. Morlan[2], K. Qu[2], M. Liu[2], J. Jeong[2], M. Pho[2], R. Ambannavar[2], E. Dimalanta[1], T. Davis[1].* 1) New England Biolabs, Inc. 240 County Road, Ipswich, MA 01938, USA; 2) Genomic Health, Inc. 301 Penobscot Drive, Redwood City, CA 94063, USA.

Next generation sequencing of cDNA prepared from total RNA (RNA-seq) has become the method of choice for transcript profiling, and discovery. The standard whole-transcriptome approach faces a significant challenge as the vast majority of reads map to ribosomal RNA (rRNA). One solution is to enrich the RNA sample for polyadenylated transcripts using oligo (dT)-based affinity matrices; however, this also eliminates other biologically relevant RNA species, such as noncoding RNAs, and relies on having a high quality and quantity RNA sample. Here, we present a method to eliminate abundant RNAs from total RNA based on hybridization of probes to the targeted abundant RNA, followed by subsequent enzymatic degradation. We applied this method to remove cytoplasmic and mitochondrial rRNA from different eukaryotic total RNA samples (human, mouse and rat). We optimized this method for RNA with different degradation levels, from intact RNA to highly degraded formalin-fixed paraffin-embedded (FFPE) samples. We applied this method to remove ribosomal RNA from FFPE RNA extracted from breast cancer biopsy with an archive age of 1 and 10 year-old. We evaluated the depletion efficiency and off target effect of this method using strand specific RNA high-throughput sequencing. Ribosomal RNA depletion resulted in a minimal percentage of total reads mapping to rRNA sequences (<1% total reads), regardless of the species, input amount (1μg or 100 nanograms), or degradation level (intact or FFPE RNA). Additionally, there was very good transcript expression (FPKM) correlation (R>0.93) between rRNA depleted and non-depleted libraries. This indicates that rRNA depletion by this method is not altering the transcript expression levels. This method offers a robust and simple solution for transcriptome analysis of a variety of samples, including low quality and low quantity clinical samples such as FFPE RNA. Moreover, it is amenable to high-throughput sample preparation and robotic automation. This method is sensitive, specific, and produces increased coverage of less abundant, non-targeted transcripts in RNA-Seq studies.

3371S

Development of a novel Hotspot Frequency Ladder for Next Generation Sequencing (NGS) assay workflows. *N. Nataraj, M. Shahbazian, A. Lau, K. Norman.* AcroMetrix, ThermoFisher Scientific, Benicia, CA.

Increasing adoption of next-generation sequencing (NGS) technology has shed light on the need for more standardized controls to evaluate and optimize system performance. However, samples containing mutations of interest are difficult to source and cell line pooling experiments to determine limit of detection require significant investments of time and money. To simultaneously evaluate variant calling performance in >200 unique amplicons across 50 genes targeted by NGS tests, AcroMetrix® has developed a proprietary genomic/synthetic DNA blended material. This material contains over 400 commonly sequenced COSMIC mutations. All variants were confirmed by Sanger sequencing and the genomic DNA was characterized by the Genome in a Bottle Consortium. A material was developed to contain ~400 variants at six finely tuned frequencies, with one frequency level per tube. Variants were quantified by digital PCR, enabling the materials to be manufactured consistently at a range of frequencies including near the limit of detection for NGS or PCR platforms. The frequencies constructed were 48%, 29%, 18%, 11%, 5%, and 3%, and samples were tested using the Ion AmpliSeq™ Cancer Hotspot Panel v2 (CHPv2) with the Ion Torrent Personal Genome Machine® and Illumina® TruSeq® Amplicon Cancer Panel and TruSight® Tumor Panel on the MiSeq® instrument. At each frequency, the variants observed on each platform was compared to the expected engineered mutations. The limit of detection was then determined for ~400 variants. At the 48% level, the Ion AmpliSeq™ and TruSeq® tests detected greater than 99% of all SNPs (383/385 for CHP2 and 351/351 for TruSeq®). Detection dropped to 78% (302/385 for CHP2 and 279/351 for TruSeq®) at the 3% level. Indel detection at the 48% level was 79% (23/29) for CHPv2 and 74% (25/34) for the TruSeq® test. At the 3% level, indel detection ranged from 28% (8/29) for CHPv2 and 44% (15/34) for TruSeq® test, respectively. To determine whether the material performs similarly to tumor tissue samples, tumor samples were diluted with matched normal samples to mimic a range of frequencies. Linearity and limit of detection between the material and diluted tumor tissue samples were compared. Overall, highly multiplex controls with tunable frequencies allow for much more extensive, yet streamlined, assay evaluation and facilitate implementation and impart confidence to NGS testing. The Hotspot Frequency Ladder is under development.

Shared driver genes of familial and sporadic pancreatic cancer may explain the similar age of onset. *A.L. Norris[1], N.J. Roberts[1,2], R.H. Hruban[1,3], A.P. Klein[1,3], J.R. Eshleman[1,3].* 1) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, MD; 2) Ludwig Center for Cancer Genetics, Johns Hopkins School of Medicine, Baltimore, MD; 3) Department of Oncology, Johns Hopkins School of Medicine, Baltimore, MD.

Familial pancreatic cancer (FPC) accounts for approximately 10% of pancreatic ductal adenocarcinoma cancer (PDAC) cases. While an earlier age of onset is a hallmark of most familial cancer syndromes, FPC does not present at an obviously earlier age. In this study, we collated the age of onset in FPC and sporadic PDAC reported in the literature. FPC cohorts had a reported mean or median age of 52 to 69 years old at diagnosis, while the range for sporadic PDAC cohorts was 60-74 years old. In our own small cohort, the median age of onset was 66 years old for both the FPC and PDAC patients. From our analysis of the literature, we show that any difference in the age of onset in FPC and sporadic PDAC cohorts is likely a result of ascertainment bias. The molecular progression of sporadic PDAC is well documented and the high prevalence driver genes are *KRAS* (>90%), *CDKN2A/p16* (95%), *TP53* (50-75%), and *SMAD/DPC4* (55%). We determined the prevalence of alterations in these PDAC driver genes in our cohort of FPC cell lines using an integrated genomics approach of whole exome sequencing (WES), whole genome sequencing (WGS), RNA-Seq, and high density SNP microarrays. We found that our FPC cohort had high frequencies of alterations in the 4 PDAC driver genes. Activating KRAS mutations were identified in all (12/12) FPC cases, predominately at the codon 12 hotspot (11/12, 92%). Inactivation of CDKN2A/p16 was identified in all (12/12) FPC cases, predominately by homozygous deletion (9/12, 75%). TP53 mutations were identified in 92% (11/12), predominately by single base substitutions with loss of heterozygosity (LOH) (9/11, 82%). Inactivation of SMAD4/DPC4 was identified in 75% (9/12) of FPC cases, predominately by homozygous deletion (5/9, 56%). Our collation of the literature confirms that FPC has a similar age of onset as its sporadic counterpart, when ascertainment bias is accounted for. Our annotation of alterations in the dominant 4 PDAC driver genes using an integrated genomic approach, confirms that these 4 genes are also altered in the majority of FPC cases. We conclude that FPC molecular progression parallels that of sporadic PDAC, possibly accounting for the similar age of onset.

3373T

Features of variants called from whole exome sequencing versus transcriptome sequencing in lung cancer. *T. O'Brien[1], P. Jia[2], J. Xia[2], H. Vuong[2], Q. Wang[2], H. Jin[3], U. Sukhija[4], M. Aryee[5], A.J. Iafrate[5], J. Engelman[6], R.S. Heist[6], M. Mino-Kenudson[7], L.P. Le[7], W. Pao[3,8], Z. Zhao[2,9,10].* 1) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Cancer Biology, Massachusetts General Hospital, Boston, MA; 5) Department of Pathology Services, Massachusetts General Hospital, Boston, MA; 6) Department of Medicine Service, Division of Hematology and Oncology, Massachusetts General Hospital, Boston, MA; 7) Department of Pathology, Massachusetts General Hospital, Boston, MA; 8) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN; 9) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN; 10) Department of Cancer Research, Vanderbilt University School of Medicine, Nashville, TN.

Whole exome sequencing (WES) and RNA sequencing (RNA-Seq) are two widely applied next-generation sequencing (NGS) technologies used for detecting somatic mutations in cancer. In this study, we used 27 matched tumor-normal samples that have both WES and RNA-Seq data to systematically compare single nucleotide variants (SNVs) called from WES and RNA-Seq of the same patients. WES reads were mapped to the human reference genome (hg19) using bwa. Post-processing of the initial mapping included steps to mark duplicate reads using Picard and perform local realignment using GATK. RNA-Seq reads were mapped using TopHat 2. We used MuTect to call SNVs for both WES and RNA-Seq, VarScan 2 to determine supporting reads of SNVs, and Cufflinks to compute gene-based expression levels (FPKM) of RNA-Seq data. Interestingly, we found a low overlap rate (on average 14%) of SNVs called from WES and RNA-Seq. Among WES-unique SNVs, 38 - 73% were missed in RNA-Seq due to no coverage (<1 read) and 10 - 23% due to low coverage (<8 reads). Interestingly, 9 - 53% of WES-unique SNVs were highly covered with ≥8 reads in RNA-Seq but were still not called. We next explored WES-unique SNVs' gene expression levels in RNA-Seq. As expected, 55% of WES-unique SNVs were located in unexpressed genes (FPKM<1). However, 3 - 12% of SNVs were in highly expressed regions (FPKM >20) yet remained undetected. We further examined WES-unique SNVs with available cDNA information, and found on average 51% were located on the non-transcribed strand causing them to be undetected in RNA-Seq. We also explored exon skipping as a factor for WES-unique SNVs being missed in RNA-Seq, and preliminary work discovered at least 4 mutations which reside in potentially skipped exons. Among RNA-Seq-unique SNVs, 22 - 89% were in positions not covered by the WES kit. For SNVs covered by the WES kit, 81 - 97% had a callable coverage (≥ 8 reads) in WES. These SNVs were not missed due to technical issues. We therefore analyzed their allele frequency and determined only 3% (0 - 12%) of the alternate alleles occurred with a frequency ≥ 20% in WES. We also analyzed the mutation patterns of all RNA-Seq-unique SNVs. 54% of them displayed a T:A → C:G pattern, which is a signature of potential adenosine deaminase acting on RNA (ADAR) induced RNA-editing occurring in these samples. In summary, this work provides a systematic view of SNV calling using two main NGS platforms.

Patterns of somatic mutations in hepatitis B virus-associated hepatocellular carcinomas. *Q. Pan[1], W. Yin[1], S. Tong[1], D. Li[2], X. Li[3], D. Zhao[4], M. Li[5], H. Hu[1], H. Ren[1], K. Ding[1].* 1) Key Laboratory of Molecular Biology for Infectious Diseases, Ministry of Educati, Chongqing, China; 2) Department of Hepatobiliary Surgery, The First Affiliated Hospital of Chongqing Medical University, Chongqing, P. R. China; 3) Department of Medical Oncology, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, P. R. Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide. Most hepatocellular carcinomas develop in the background of the advanced liver fibrosis and cirrhosis through a stepwise accumulation of various genetic alterations from cirrhotic nodule to HCC. The patterns of somatic mutations in the liver cancer and its matched cirrhotic tissues were not fully characterized. We performed whole exome sequencing on liver cancer tissues, its matched cirrhotic liver tissues and peripheral blood leukocyte (PBL) in 13 patients of hepatitis B virus-associated HCC. Diagnoses of HCC cases and the matched liver cirrhosis were histologically confirmed by two pathologists. Only HCCs with the percentage of tumor cells more than 70% were used for the analysis. Whole exome sequencing resulted in approximate 106 million raw reads with an average coverage of 110× in each sample. A bioinformatics pipeline was used to analyze sequencing reads and identify somatic mutations. The prevalence of somatic mutations differed significantly among HCCs. Among 6,972 non-silent mutations (i.e., missense, nonsense mutations, splice sites and translation start sites) identified in 13 HCC patients, we found that T:A>A:T transversion showed the highest percentage of non-silent mutations, followed by C:G>T:A transversion and C:G>A:T transversion. By comparison of somatic mutations identified in liver cancer tissues and cirrhotic tissues, we found that somatic mutations were not accumulated in genes in HBV-associated cirrhotic liver tissues. Notably, two genes (TP53 and KRTAP4-3) were shown to be significantly mutated by MutSigCV analysis, suggesting that there were evidence for 'driver' mutations of these genes contributing to the development of liver cancer. Our study may provide an overview of patterns of somatic mutation in hepatitis B-virus associated HCC and its precancerous lesions (i.e., cirrhosis).

3375M

Highly sensitive, non-invasive detection of colorectal cancer mutations using single molecule, third generation sequencing. *G. Russo[1], A. Patrignani[1], L. Poveda[1], F. Hoehn[2], B. Scholtka[3], R. Schlapbach[1], A. Garvin[2].* 1) Functional Genomics Center Zurich - ETH/UZH, Zurich, Switzerland; 2) Droplet Diagnostics SAS, Mulhouse, France; 3) Department of Nutritional Toxicology, Institute of Nutritional Science, University of Potsdam, Nuthetal, Germany.

Colorectal cancer (CRC) represents one of the most prevalent and lethal malignant neoplasms and every individual of age 50 and above should undergo regular CRC screening. Currently, the most effective procedure to detect adenomas, the precursors to CRC, is colonoscopy, which reduces CRC incidence by 80%. However, it is an invasive approach that is unpleasant for the patient, expensive, and poses some risk of complications such as colon perforation. A non-invasive screening approach with detection rates comparable to those of colonoscopy has not yet been established. The current study applies Pacific Biosciences third generation, single molecule sequencing to the inspection of CRC-driving mutations. Our approach combines the screening power and the extremely high accuracy of circular consensus (CCS) third generation sequencing with the non-invasiveness of using stool DNA to detect CRC-associated mutations present at extremely low frequencies and establishes a foundation for a non-invasive, highly sensitive assay to screen the population for CRC and early stage adenomas. We performed a series of experiments using a pool of fifteen amplicons covering the genes most frequently mutated in CRC (APC, Beta Catenin, KRAS, BRAF, and TP53), ensuring a theoretical screening coverage of over 97% for both CRC and adenomas. The assay was able to detect mutations in DNA isolated from stool samples from patients diagnosed with CRC at frequencies below 0.5 % with no false positives. The mutations were then confirmed by sequencing DNA isolated from the excised tumor samples. Our assay should be sensitive enough to allow the early identification of adenomatous polyps using stool DNA as analyte. In conclusion, we have developed an assay to detect mutations in the genes associated with CRC and adenomas using Pacific Biosciences RS Single Molecule, Real Time Circular Consensus Sequencing (SMRT-CCS). With no systematic bias and a much higher raw base-calling quality (CCS) compared to other sequencing methods, the assay was able to detect mutations in stool DNA at frequencies below 0.5 % with no false positives. This level of sensitivity should be sufficient to allow the detection of most adenomatous polyps using stool DNA as analyte, a feature that would make our approach the first non-invasive assay with a sensitivity comparable to that of colonoscopy and a strong candidate for the non-invasive preventive CRC screening of the general population.

3376T

Integrating eQTLs from a range of normal human tissues with cancer genomics to help identify germline risk alleles in cancer driver genes. *A.V. Segre[1], D.S. DeLuca[1], T. Sullivan[1], E. Gelfand[1], L. Lappalainen[2,3], M. Lawrence[1], A. Kiezun[1], D.G. MacArthur[1,4], K. Ardlie[1], G. Getz[1,4], the GTEx consortium.* 1) Broad Institute of Harvard and MIT, Cambridge, MA; 2) New York Genome Center, NY; 3) Department of Systems Biology, Columbia University, NY; 4) Massachusetts General Hospital, Boston, MA.

A comprehensive analysis of somatic point mutations in whole exome sequences from >4,700 human cancer and their matched normal tissue samples has increased the number of cancer driver genes to 260 for 21 different tumor types. The extent to which germline variants in these somatic cancer genes may predispose people to certain cancers is not yet known. Furthermore, the contribution of gene expression-altering variants to tumor development compared to changes in protein structure or function is not well understood. To address these questions and gain mechanistic insight into the potential role of germline variants in tumorigenesis, we are testing the hypothesis that increase in expression of oncogenes and/or decrease in expression of tumor suppressor genes in normal human tissues may increase risk of cancer development. To this end, we will annotate the cancer genes as potential oncogenes and/or tumor suppressor genes, based on large-scale experimental gene perturbation studies that measure the effect on cell proliferation, growth arrest or cell death. We will then examine which cancer genes are affected by cis-eQTLs (expression quantitative trait loci) or allele specific expression (ASE), using the Genotype-Tissue Expression (GTEx) project with data in 40 normal human tissues and up to 450 unrelated individuals. Based on the pilot phase of GTEx with 178 individuals, 36% of the 260 somatic cancer genes, e.g. AKT1, CASP8 and CDKN2A have significant cis-eQTLs at FDR<5% in at least one of 9 tissues tested, including skin, lung and nerve. Following characterization of cancer genes with eQTLs, we will test whether the germline genotypes of tumor samples in the pan-cancer cohort, such as melanoma, lung cancer, and blood cancers, are enriched for eQTL or ASE alleles that increase oncogene expression or decrease tumor suppressor expression compared to a control panel. If so, this would suggest that the regulatory variants are cancer risk factors. Furthermore, we will integrate the results with somatic mutations from whole exome and whole genome sequences in the pan-cancer project and loss of heterozygosity (LOH) analyses, to evaluate how eQTLs acting on cancer genes may be contributing to tumor progression. This study may help propose new cancer germline risk variants and shed light on potential causal regulatory mechanisms in cancer. In future work, such integrative studies can be extended to testing the regulatory role of somatic mutations during tumorigenesis.

Identification of mutations in oral cavity squamous cell carcinoma induced by betel quid chewing in Taiwan. *Y. Shih[1], L. Wang[4], J. Chen[5], N. Limthong[7], H. Chen[6], D. Chen[3, 7], Y. Elshimali[2].* 1) La Sierra university, Riverside, CA; 2) Charles Drew Univ Med. Los Angeles. CA; 3) Dept of Path and Lab Med David Geffen School of Medicine at UCLA. Los Angeles. CA; 4) Rite Aid Pharmacy, Fontana, CA; 5) Rosemead Clinic, Rosemead, CA; 6) Maternal & Child Center, Taipei, Taiwan; 7) Dept of Path and Lab UCI Medical Center, Orange, CA.

Squamous cell carcinoma of the head and neck (HNSCC) is the sixth most common cancer worldwide, the most common site being the oral cavity. In Taiwan, squamous cell carcinoma of the oral cavity is the fourth most common type of cancer. Environmental carcinogens, including betel quid chewing and alcohol, are the major identifiable risk factors. The development of squamous cell carcinoma of the oral cavity arising from premalignant lesions, such as leukoplakia, follows a multi-step process involving sequential activation and inactivation of oncogenes and tumor suppressor genes, resulting in a clonal population of cells. Chromosomal deletions at 3p and 9p21 are characterized as the first step of the tumorgenesis process. However, additional genomic abnormalities are well characterized. Such abnormalities can contribute to histological variations often observed in a tumor sample, such as invasiveness and, more specifically, the ability to penetrate the basement membrane. To better characterize any chromosomal structural abnormality, we employed next-generation DNA sequencing technology on a patient sample with squamous cell carcinoma of the tongue. The patient has a known history of betel quid chewing. Specifically, we isolated DNA samples from normal, premalignant (leukoplakic), in situ and invasive components of the tumor. A mate-pair library was constructed from each of the four DNA samples. Individual DNA samples were sequenced using a next-generation Illumina H2000 sequencer. By analyzing the sequences, we have identified a novel chromosomal structural abnormality, as well as known chromosomal variations, including deletions of 3p and 9p21, and a deletion at the genomic area containing the p53 gene. In addition, several mutations specific to the invasive component of the tumor were identified. Our findings confirm the previously known fact that tumorgenesis can result in the evolution of subclonal populations of tumors.

3378M

Subclonal evolution and genomic drivers of relapse in childhood acute lymphoblastic leukemia. *JF. Spinella[1], V. Saillour[1], N. Garnier[1], R. Vidal[1], J. Healy[1], D. Sinnett[1,2].* 1) Hematology Oncology, CHU Sainte-Justine (Montreal University), Montreal, Quebec, Canada; 2) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Qc, Canada.

Refractory childhood acute lymphoblastic leukemia (cALL) has a dismal outcome with overall long-term survival rates around 45%, making it the leading cause of death by disease among children. We now know that intratumoral genetic heterogeneity and clonal evolution contribute to treatment resistance. In order to build a catalogue of somatic-specific variations and identify genomic drivers of relapse in cALL, wWe hypothesized that relapse-specific single nucleotide variants (SNVs) or showing a significant gain of allele frequency in the relapse material compared with the matched-primary tumor, are putative drivers of ALL relapse performed whole-genome-sequencing on 10 matched primary tumor (diagnosis), relapse and normal (remission) cALL patient trios. We hypothesized that putative relapse drivers would either be relapse-specific (detected in relapse samples only) or show a significant shift in variant allele frequency in the relapse versus matched-primary tumour samples, due to clonal evolution. Combining deep re-sequencing with genome-wide genotyping (to determine local ploidy), allowed us to accurately call single nucleotide variants (SNVs) with a wide range of frequencies, including SNVs from minor subclonal populations. Changes in the fitness of somatic SNVs (rise or fall of allele frequencies) were assessed and clustering analysis was used to illustrate subclonal complexity and clonal evolution within the individual ALL tumours. Strikingly, our data suggest the presence of a fitter ancestral subclonal population, harbouring specific relapse-drivers, that is present at diagnosis and that rises during relapse. In a minority of tumours the major diagnostic clone was resistant to therapy and was maintained at relapse. We queried putative relapse drivers against public pharmacogenomics databases (DGIdb, PharmGKB) and identified known drug-gene/pathway interactions which could lead to new avenues for improved targeted treatment of refractory cALL. By dissecting the clonal evolution of individual tumors and identifying the underlying genetic events driving cALL relapse, we hope to improve prognosis for refractory cALL and ultimately provide targeted personalized care for children diagnosed with ALL.

3379T

Integrative analysis of regulatory aberrations in lung adenocarcinoma cell lines. *A. Suzuki[1], T. Kohno[2,3], K. Tsuchihara[2], Y. Suzuki[1].* 1) Department of Medical Genome Sciences, The University of Tokyo, Japan; 2) Division of TR, The Exploratory Oncology Research and Clinical Trial Center, National Cancer Center, Japan; 3) Division of Genome Biology, National Cancer Center Research Institute, Japan.

Integrative multi-omics analysis is a powerful approach to understand the biological relevance of the genomic, epigenomic and transcriptomic aberrations in cancer. In this study, we performed whole-genome sequencing, RNA-Seq, target-captured bisulfite sequencing and ChIP-Seq for eight chromatin marks using 26 lung adenocarcinoma cell lines. By this approach, we conducted a multi-omics analysis of cancer cells, which still remain technically difficult in clinical samples.

Using whole-genome sequencing data, we identified a mean of 536 non-synonymous SNVs and indels in the protein-coding regions and 13,573 mutations in the promoters and enhancers. In representative tumor-suppressor genes, we detected splice-site mutations which cause aberrations of splicing patterns in RNA sequences. For transcriptome analysis, we examined gene expression abundances using RNA-Seq data and detected an average of 352 higher and 1,967 lower differentially expressed genes such as EGFR and SMARCA4. We also detected 135 fusion transcript candidates including known ALK and RET fusion transcripts. We analyzed DNA methylation statuses using bisulfite sequencing and identified an average of 118 higher and 278 lower differential DNA methylated genes such as the IGF1R, NRAS and CDKN2A (p16) genes. We also analyzed ChIP-Seq data for seven histone modification (H3K4me1, H3K4me3, H3K9me3, H3K9/14ac, H3K27ac, H3K27me3 and H3K36me3) and RNA Polymerase II, which were further subjected to ChromHMM analysis to identify eight chromatin states. To publicly open and visualize the multi-omics data, we have also developed a database (http://dbtss.hgc.jp/).

In this study, we particularly focused on the genomic and epigenomic aberrations affecting eventual gene expression levels. We detected different patterns of aberrations depending on genes. For example, genomic alterations were characteristic to the STK11. On the other hand, expression levels in the CDKN1A were repressed by DNA methylation or repressive marks of histone modification (H3K27me3 and H3K9me3). By complementing whole-genome and exome sequencing data of clinical samples, the multi-omics analysis using cell lines should be important to understand how variable regulatory aberrations result in transcriptional alterations in cancer cells.

3380S

Molecular profiling in diagnosis and determining prognosis of "early" myelodysplastic syndrome. *M. Thangavelu[1], S. Brodie[2], C. Mixon[3], S. Agersborg[1], E. Wei[2], M. Albitar[1].* 1) Neogenomics Laboratories, Irvine, California; 2) Neogenomics Laboratories, Ft. Myers, Florida; 3) Neogenomics Laboratories, Nashville, Tennessee.

Confirming diagnosis of myelodysplastic syndrome (MDS) can be very difficult, especially in the early stages of the disease. Cytogenetic abnormalities are detected by conventional cytogenetics (and FISH) in approximately 50% of cases of MDS and are used to confirm diagnosis. Identification of mutations in RNA splicing, DNA methylation, chromatin modification, transcription regulation, DNA repair, signal transduction, and cohesin complex genes has heightened the interest of utilizing these characteristics in the diagnosis of MDS. Most published data on molecular characterization are retrospective studies. We report the use of a panel of 14 genes in a prospective fashion as an objective means for confirming the presence of MDS rather than a reactive process. 133 patients with cytopenia involving at least one lineage, no evidence of cytogenetic abnormalities and blast count less than 5% were included in the study. DNA from bone marrow or peripheral blood specimens were analyzed for mutations in the following genes: ASXL1, ETV6, EZH2, IDH1, IDH2, NRAS, CBL, RUNX1, SF3B1, SRSF2, TET2, TP53, U2AF1 and ZRSR2. Direct bidirectional Sanger sequencing was used in all patients and next generation sequencing was used in some patients. Fifty five of the 133 patients (41.4%) had mutation in 1 to 4 genes. Mutations were seen in TET2 (23 cases), ASXL1 (15 cases), SF3B1 (15 cases), SRSF2 (10 cases), U2AF1 (6 cases), ZRSR2 (5 cases), ETV6 (3 cases), and IDH2, RUNX1, NRAS and EZH2 (2 cases each), and CBL, IDH1 and TP53 (1 case each). TET2 mutations were the most common occurring in was mutated in 17.3% of cases studied. Although only 41.4% of the tested patients had a mutation confirming the diagnosis of MDS, most patients without mutations had no diagnostic morphologic evidence of MDS. All patients were suspected of having MDS based on cytopenia(s) at the time of testing only, without documented previous history of cytopenia. Longer follow up is needed to rule out MDS and confirm a reactive process in patients without a mutation. These results suggest that utilizing an appropriately designed, relatively small, molecular panel can provide valuable objective diagnostic means for the diagnosis of MDS in patients without cytogenetic abnormalities. Furthermore, such a panel provides very important prognostic information that can be used for stratifying patients and determining therapeutic approach.

3381M

The Mutation Profiles of JAK2, MPL, CALR, LNK, CBL, ASXL1 and DNMT3A genes in BCR/ABL1 and JAK2V617F Negative Myeloproliferative Neoplasms. *B. Türkgenç[1, 2], E. Pinarbasi[3], S. Ratip[4], A. Uzay[4], A. Ozer[2], C. Akyerli Boylu[5], M.C. Yakicier[1, 5].* 1) Acibadem Genetic Diagnostic Center, ISTANBUL, Turkey; 2) Department of Medical Biology and Genetics, Marmara University, Istanbul, TURKEY; 3) Department of Medical Biology, Cumhuriyet University, Sivas, TURKEY; 4) Department of Hematology, Acibadem Kadikoy Hospital, Istanbul, TURKEY; 5) Biochemistry and Molecular Biology, Department of Acibadem University, Istanbul, TURKEY.

Background: Myeloproliferative neoplasms (MPNs) are clonal myeloid cancers characterized by overproduction of mature blood cells. BCR/ABL1 and JAK2V617F are the most frequent mutations in MPNs. Other JAK2-exon12 and MPL-exon10 mutations were less common in suspected MPNs (2% and 3-7%, respectively). Several other genes such as LNK, CBL, ASXL1, DNMT3A and TET2 have been found to be responsible for small minority of MPNs. Recently, in the majority of MPN patients, CALR mutations have been identified. Purpose: The aim of our study is to establish the mutation profiles of BCR/ABL1 and JAK2V617F negative MPNs. Methods: 152 non-mutated BCR/ABL1 and JAK2 V617F patients were selected among a thousand patients who were referred from different centers to Acibadem Diagnostic Center, from May 2007 to February 2014. Genomic DNA and RNA samples were isolated from bone marrow and peripheral blood samples. RNA samples were used for detection of JAK2-exons 11-17 mutations and MPL-exon 10 mutations by RT-PCR and nested PCR followed by Sanger sequencing. DNA samples were used to detect the frequent mutations in other reported genes; CALR-exon9, CBL-exon8-9, DNMT3A-exon23, ASXL1-exon13 and LNK-whole exons by PCR and DNA sequencing. Results: We identified 11/152 JAK2-exon11-17 (7,2%) and 6/152 MPL-exon10 mutations (3,9%). Although, all MPL mutations were reported previously, 6/11 JAK2 mutations were novel. We found 17/152 CALR mutations (11,2%); while L367fs*46 (8/17) and K385fs*47 (5/17) were the most common variants, the remaining 3 out of 4 variants were novel. Also, we identified 3 novel mutations all in the coding sequence of LNK (2%). In CBL, 2 patients had the same splice site variant in intron 8 (1,3%). We identified 10/152 ASXL1 mutations (6,6%) 2 of which were novel. None of the patients had DNMT3A mutation. Conclusion: To the best of our knowledge, this is the first mutation profile study associated with BCR/ABL1 and JAK2V617F negative MPNs in Turkish population. Our study enabled to improve the screening strategy of MPNs and provided genetic diagnosis of 49 of the selected 152 BCR/ABL1 and JAK2V617F negative MPNs. We observed several novel mutations as well as previously reported ones. Mutation profiles will contribute to the development of therapeutic drugs (such as tyrosine kinase inhibitors-TKIs) and diagnostic strategies. Functional studies should be carried out in order to reveal the mechanism underlying these unique variants.

3382T

Whole genome sequencing of high-risk families to identify new mutational mechanisms of breast cancer predisposition. *T. Walsh, S. Gulsuner, S. Casadei, M.K. Lee, J. Mandell, M-C. King.* Division of Medical Genetics, University of Washington, Seattle, WA.

Multiple genes in addition to *BRCA1* and *BRCA2* are known to harbor mutations that significantly increase risk of breast cancer. The increasing use of comprehensive cancer gene panels allows women to be tested for all known breast cancer susceptibility genes in a single assay. For families severely affected with breast cancer, but without mutations in any known breast cancer gene, exome sequencing has been applied to identify new candidate genes, with a somewhat disappointing yield. In our experience, approximately 50% of families with four or more relatives with breast cancer remain unresolved after comprehensive panel and exome sequencing. We hypothesize that in many of these families, breast cancer is due to individually rare alleles of moderate-to-severe effect located in the non-coding regions of the genome. A subset of these are likely influencing their mutational effect via alterations on expression or regulation of known breast cancer genes. We selected pairs of cousins with young-onset breast cancer from each of 20 very severely affected kindreds. Whole genome sequencing was carried out on genomic DNA of the 40 individuals. We are filtering variants shared by the members of a pair with the following criteria: (i) rarity, (ii) within 5 MB of a known breast cancer gene, (iii) conservation of the site harboring the variant, and (iv) annotation of potential regulatory function. In parallel, we are performing targeted RNAseq of all known breast cancer genes from lymphoblast derived RNA of the same individuals (see abstract by Casadei S et al.). RNAseq data may reveal genes with asymmetrically expressed alleles in a family, thereby focusing regions of interest in the whole genome data from that family. Candidate variants will be tested for co-segregation with breast cancer in the host kindred. Our long-term goal is to integrate newly identified mutational mechanisms into clinical practice.

3383S

DICER1 mutations occurring in childhood anaplastic sarcoma of kidney. *M. Wu[1], H. Druker[2], P. Thorner[3], J. Traubici[4], R. Grant[3], S. Albrecht[5], E. Weber[6], A. Charles[7,8], J.R. Priest[9], M.R. Fabian[10], N. Watanabe[11], G. Vujanic[12], W.D. Anaplastic sarcoma of the kidney (ASK) is an extremely rare renal neoplasm with fewer than 30 cases reported. We report two cases of children with ASK. The first patient (Case 1) carried a germline *DICER1* mutation (c.2062C>T) which is predicted to cause a nonsense mutation (p.R688X) and her ASK bore a somatic in trans missense *DICER1* mutation (c.5425G>A) which is predicted to cause an amino acid substitution at a critical residue in the catalytic domain of RNase IIIb (p.G1809R). In addition, Case 1 had presented prior to the ASK with a pleuropulmonary blastoma (PPB) which bore a different somatic mutation in *DICER1* (c.5125G>A; predicted p.D1709N). The ASK in Case 2 also possessed a somatic *DICER1* RNase IIIb mutation (c.5125G>A; predicted protein change p.D1709N). The germline *DICER1* mutation status of Case 2 is pending. Thus, the somatic mutations in both ASKs are in a DICER1 catalytic domain (RNase IIIb) and are predicted to affect the production of the "5p" class of microRNA by DICER1 protein. A previous report identified several cases of "DICER1 renal sarcoma", two of which had germ-line and/or somatic *DICER1* mutations. Taken together, we hypothesize that these tumors and ASKs currently described are the same entity. Our findings, therefore, build upon previous observations and suggest that *DICER1* mutations may be an important cause of these rare tumors.

Single-cell mutation detection with multiplex PCR-based targeted enrichment sequencing. *Z. Wu, R. Vijaya Satya, R. Samara, Y. Wang, E. Lader.* Biological Research Content, QIAGEN Sciences, LLC, Frederick, MD, USA.

Mutations are the driving molecular causes of various biological processes such as development and cancer. Recent findings of genomic heterogeneity among ostensibly homogeneous cell populations such as cancer cells demand genomic characterization of mutations at the individual cell level to better understand the underlying biology. Additionally, single-cell technologies make genomic analysis feasible for the characterization of rare cells, such as circulating tumor cells and in-vitro fertilized embryos. Due to its high sensitivity, next-generation sequencing (NGS) represents the ideal technology to analyze a collection of mutations in single cells. The challenge, however, is the limited amounts of DNA, which need to be amplified prior to NGS. To overcome this challenge, whole genome amplification (WGA), coupled with multiplex PCR-based targeted enrichment, was tested for mutation detection in single cells isolated from two colon cancer cell lines, Lovo and HT29. A NGS panel targeting genes relevant to colon cancer was used to enrich DNA from WGA single-cell DNA (WSC), DNA from bulk cells (BC), or bulk-cell DNA which underwent WGA (WBC), followed by mutation detection with NGS. Forty (40) ng DNA was used across 4 PCR pools in a multiplex PCR set up to enrich for 38 genes known to harbor colon cancer-relevant mutations. The amplicons went through a standard library construction protocol, followed by sequencing on a MiSeq®. Previously reported mutations such as KRAS (G13D) in LoVo and BRAF (V600E) in HT29 cells were successfully detected with this enrichment method on WSC as well as on BC. These mutations were further confirmed by Pyrosequencing. A strikingly similar mutation frequency was observed between targeted NGS and Pyrosequencing in each sample. Interestingly, mutation frequencies observed between BC and WBC were similar, but varied greatly with respect to individual cells. Similar variations were observed on additional heterozygous mutations in WSC as compared to BC. Whether the variation is due to tumor cell heterogeneity, selective WGA amplification, or both needs to be further defined. These results demonstrate that multiplex PCR targeted enrichment can be successfully applied for mutation detection on WSC. However multiple single cells need to be analyzed for accurate interpretation of genomic alterations among heterogeneous cell populations. The applications presented here are for research use only. Not for use in diagnostic procedures.

3385T

Patient-oriented functional genomics analysis of p53 mutations in cancer. *O. Zill[1], T. Shamu[1], S. Fields[2,3], B.S. Taylor[1].* 1) Epidemiology & Biostatistics, University of California, San Francisco, San Francisco, CA; 2) Departments of Genome Sciences and Medicine, University of Washington, Seattle, WA; 3) Howard Hughes Medical Institute, Seattle, WA.

Over the last few years, thousands of cancer genomes have been sequenced and hundreds of recurrent cancer-associated mutations have been identified. A defining challenge for cancer genetics is to determine which mutations in a patient's tumor genome are biologically or clinically relevant and how two or more driver mutations co-occurring in that tumor might interact. We are using multi-dimensional computational analysis of cancer genomics data combined with human somatic-cell genetics experiments to address these questions. We have focused initially on the most frequently mutated cancer gene, TP53, because of the wealth of experimental data available for many mutations and to provide sufficient sample numbers to power association tests across many tumor types. Using a compendium of somatic mutations from the sequenced exomes and genomes of over 10,000 human tumors, we assessed the co-occurrence of codon-specific TP53 mutations with those in 188 significantly mutated genes in cancer. Co-mutation patterns fell into several distinct categories that were partly explained by tumor-type-specific TP53 mutational patterns. Interestingly, certain missense TP53 mutations preferentially co-occurred with mutations in specific oncogenes or tumor suppressors. To determine the relative functionality of these specific-SMG-enriched TP53 mutations, we are introducing them into human cell lines and competing them against each other in FACS-based transcriptional reporter assays. For these mutant competition assays, we constructed transcriptional reporters using the promoters of p53 target genes whose pattern of expression from RNA sequencing data across 12 tumors types was associated with TP53 mutation status. An example of a mutation co-occurrence we detected was the hotspot alleles IDH1-R132H and TP53-R273C, which co-occurred predominantly in Lower Grade Glioma samples. In parallel to the mutant competition assays, We are testing whether IDH1-TP53 co-mutation contributes to specific, cancer-relevant phenotypes by introducing the mutations into human cell lines. The mutation combinations we identified are being evaluated for associations with alterations in copy number, gene expression, and methylation in tumors. This work should help delineate the functional contributions of specific combinations of driver mutations to inform personalized cancer treatments.

Expression of genomic somatic mutations at the levels of transcriptome and proteome in a patient of hepatocellular carcinoma with MSH2 haploinsufficiency. *K. Ding[1], S. Wu[2], W. Ying[2], W. Yin[1], S. Tong[1], Q. Pan[1], X. Li[3], D. Zhao[4], H. Hu[1], X. Qian[2], H. Ren[1].* 1) Key Laboratory of Molecular Biology for Infectious Diseases, Ministry of Educati, Chongqing, China; 2) State Key Laboratory of Proteomics, Beijing Proteome Research Center, Beijing Institute of Radiation Medicine, Beijing, P.R. China; 3) Department of Medical Oncology, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, P. R. China; 4) Department of Pathology, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, P. R. China.

The expression of genomic somatic mutations, i.e., at the levels of transcriptome and proteome, were not fully characterized in cancer genome sequencing studies. It is unknown how genomic mutations were transmitted from DNA to messenger RNA, and finally affected its function of protein. A patient of hepatitis-B associated hepatocellular carcinoma that showed an extremely elevated prevalence of somatic mutations with a heterozygous nonsense mutation in the mutS homolog 2 (MSH2) gene (leading to MSH2 haploinsufficiency) was present in Peking Union Medical College Hospital. Using this patient as a model, we performed whole exome sequencing, transcriptome sequencing, and proteome profiling on liver cancer tissues and its matched liver cirrhotic tissues (i.e., adjacent 'normal' tissues). By whole-exome sequencing, we identified 20,382 genomic somatic mutations (single nucleotide variants, SNVs), and 4,998 were classified as non-silent mutations. For non-silent somatic mutations, we found that, 1,823 somatic mutations (36%) in genes were not expressed or covered, 1,892 (37.8%) where only the wild-type allele were expressed, 1199 (24.0%) where both alleles were expressed, and 84 (1.7%) where only the mutant allele were expressed by transcriptome sequencing. At the levels of proteome, we identified 118 mutations whose mutated peptides are identified in the liver cancer tissues, and their un-mutated peptides were identified in the liver cirrhotic tissues. These results suggested that only a small fraction of genomic somatic mutations were expressed, and leveraging 'trans-omics' strategies may provide important implications for conducting cancer-genome sequencing studies.

***APC* promoter 1B deletion in seven American families with familial adenomatous polyposis.** *A.K. Snow[1], T.M.F. Tuohy[1], N.R. Sargent[1], L.J. Smith[1], R.W. Burt[1,2,3], D.W. Neklason[1,2,4].* 1) High Risk Clinical Research, Huntsman Cancer Institute, Salt Lake City, UT 84112; 2) Department of Medicine, University of Utah, Salt Lake City, UT 84112; 3) Division of Gastroenterology, University of Utah, Salt Lake City, UT 84112; 4) Division of Genetic Epidemiology, University of Utah, Salt Lake City, UT 84112.

Familial adenomatous polyposis (FAP [MIM 175100]) is a colorectal cancer predisposition syndrome caused by mutations in the adenomatous polyposis coli (*APC* [MIM 611731]) gene. University of Utah has a large Hereditary Gastrointestinal Cancer Registry with over 600 FAP patients from 244 kindreds. A clear deleterious mutation is known in 122 of these kindreds, but in the remaining kindreds, *APC* genetic testing has either failed to detect a mutation (16%) or has not been pursued (40%). We have applied a simple and cost-effective approach to screen for families who may harbor identical pathogenic mutations due to a common founder. Members of our registry with FAP have been genotyped using a set of 4 short tandem repeat markers (STR) with high heterozygosity across the chr.5 *APC* locus. Following the inclusion of probes specific for *APC* promoter 1B, multiplex ligation-dependent probe amplification (MLPA) identified a proband from our registry with a deletion of promoter 1B. Six additional families shared the *APC* haplotype and the deletion, which is distinct from previously reported promoter 1B deletions. The clinical phenotype of 17 mutation carriers is classic colonic polyposis with colectomy at an average age of 24. The majority report having a large number of duodenal and gastric polyps, and there were single reports of a desmoid and a hepatoblastoma. Measurements of allele-specific expression of *APC* mRNA using TaqMan assay specific to a common polymorphism, rs459552, on cDNA from 3 tissue sources confirmed that the relative expression was reduced in the allele containing the promoter 1B deletion. The relative reduction in expression of the mutant allele was more pronounced in mRNA extracted from duodenal tissue (88%) and blood (98%) than in mRNA extracted from EBV transformed lymphoblast cell lines (42%). Previous work has shown down regulation of the alternative *APC* promoter 1A through methylation. This methylation, along with deletion of promoter 1B, is thought to be the underlying mechanism for the allelic imbalance in primary tissues. This study confirms the importance of *APC* promoter deletions as a cause of FAP. Alternations in promoters and other regulatory elements should be considered critical targets of future genetic research as a cause of syndromes. This study also highlights the utility of using STR analysis to identify patients lacking a genetic diagnosis by linking them to a genetic haplotype of a known deleterious mutation.

Therapy-related Acute Myeloid Leukemia Transformed from Juvenile Myelomonocytic Leukemia with Loss of a PTPN11 Somatic Mutation. *Y. Kim[1], J. Kim[2], K-A. Lee[3].* 1) Department of Laboratory Medicine, Samkwang medical laboratories, Seoul, Seoul, South Korea; 2) Department of Laboratory Medicine, Yonsei University Wonju College of Medicine, Wonju, Korea; 3) Department of Laboratory Medicine, Gangnam Severance Hospital, Yonsei University College of Medicine, Seoul, Korea.

Therapy-related myelodysplastic syndrome and acute myeloid leukemia (t-MDS/t-AML) is a well-recognized clinical syndrome. However, therapy-related juvenile myelomonocytic leukemia (t-JMML) induced by prior chemotherapy for treatment of primary neoplasm has not previously been reported. Here, we report the first known case of a t-JMML with PTPN 11 somatic mutation and monosomy 7 developing during chemotherapy for retinoblastoma with RB gene mutation, which, during treatment for JMML, progressed into t-AML harboring monosomy 7 but not the PTPN11 mutation initially seen at the time of diagnosis of JMML. The patient was born at 39 weeks and was a healthy female at birth. At 5 months, she was diagnosed with sporadic bilateral retinoblastoma. After diagnosis, she received a total of 26 courses of chemotherapy from June 2010 to August 2012. During the follow-up, complete blood count (CBC) showed a hemoglobin (Hb) level of 6.1 g/dL, a platelet count of 28,000/L, and a WBC count of 8,150/L with immature granulocytes, January 2013. The peripheral blood monocyte count had significantly increased, to 1.98 x 106/L (45%), and the findings of touch imprint of bone marrow biopsy were most consistent with JMML, with less than 20% blasts in the bone marrow aspirate. PTPN11 mutation (c.215C>A, p.Ala72Asp) was detected, but no mutation was found in codons 12, 13, and 61 of KRAS and NRAS. Monosomy 7 was observed in all 20 of 20 metaphases. The patient was diagnosed with JMML in February 2013, and treated with 6-mercaptopurine (50 mg/m2) and cis-retinoic acid (100 mg/m2). After 4 months, bone marrow examination revealed development of t-AML with 25.0% myeloblasts among all nucleated cells. At the time of t-AML diagnosis, the pathogenic mutation (p.Ala72Asp) of PTPN11 initially observed at the time of t-JMML diagnosis was not detected. Monosomy 7 was still observed in all 20 of 20 metaphases. We evaluated the known secondary mutations (SETBP1 and JAK3) which are detected with relatively high frequency in JMML. Based on the hypothesis that new mutations might develop with leukemic transformation and loss of PTPN11 mutation, mutations in other genes have been sought, but no mutations in the SETBP1 or JAK3 genes were detected in our case. We propose that PTPN11 mutation may be associated with t-JMML, but in the present case, other factors including monosomy 7, and cytotoxic chemotherapy might contribute to the leukemic transformation.

High-resolution characterization of a leiomyoma on Mayer-Rokitansky-Kuster-Hauser syndrome. *Y. Wu[1], M. Kan[2], Y. Wu[3], Z. Zhang[4], D. Zhou[4], Y. Liu[5], H. Huang[1].* 1) The International Peace Maternity & Child Health Hospital of China welfare Institute, Shanghai Jiao Tong University, Shanghai, 200030, China; 2) Institute for Nutritional Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Graduate School of the Chinese Academy of Sciences, Shanghai, 200031, P. R. China; 3) School of Medicine, Zhejiang University, Hangzhou, Zhejiang, China; 4) Bio-X Institutes, Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders (Ministry of Education), Shanghai Jiao Tong University, Shanghai, 200030, P.R. China; 5) Institutes of Biomedical Sciences, Fudan University, Shanghai, 200032 P. R. China.

Mayer-Rokitansky-Kuster-Hauser (MRKH [MIM 27700]) syndrome is characterized by Mullerian duct aplasia (uterus plus upper two-thirds of the vagina) with female phenotype and a 46, XX karyotype. MRKH is infrequent thus uterine leiomyoma of the rudimentary uterus in MRKH is an extremely rare case. We performed whole-genome sequencing (WGS) for uterine leiomyoma, rudimentary uterus and peripheral blood from a patient with MRKH syndrome, and conducted analyses for chromosomal structure variations (SVs), copy number variations (CNVs) as well as point mutations. We further performed array comparative genomic hybridization (CGH) for rudimentary uterus and peripheral blood to validate CNVs from the WGS findings. Our results confirmed 8q23.1 germline deletion in MRKH patient and we also observed several somatic CNVs in leiomyoma including deletions in 1q24.2, 4q34.3 and 19q13.33. Interestingly, the number of CNVs in rudimentary uterus showed more abundant than that in leiomyoma, suggesting that leiomyoma might be initiated from undifferentiated mesenchymal cells or immature smooth muscle cells instead of mature smooth muscle cells in rudimentary uterus. We also detected two translocation events t(16:21) and t(11:x) in rudimentary uterus and three translocation events t(1:7), t(2:10) and t(10:16) in uterine leiomyomas. Additionally, many somatic point mutations were newly identified in leiomyoma with probably damaging function involved in other type of cancers or tumors. Our study initially characterized rudimentary uterus and uterine leiomyoma from whole genome level, which may provide insight into development of rudimentary uterus in MRKH syndrome and pathogenesis of leiomyoma in further studies.

Comparison of NGS solutions for rapid and cost-effective analysis of degraded FFPE and cancer biobanked specimens with limited quantity. *A. Brooks[1], M. Moreau[1], I. Liang[1], A. Sahota[1], K. Hirschfield[2], L. Rodriguez[2], H. Zhong[2], J. Tischfield[1], R. DiPaola[2], S. Ganesan[2].* 1) RUCDR Infinite Biologics, Rutgers University, Piscataway, NJ; 2) Rutgers Cancer Institute of New Jersey, Rutgers University, Piscataway, NJ.

In order to unlock genetic sequence information hidden in millions of tissue biopsies and cancer biobanks around the world, scientists require a robust Next-Generation Sequencing (NGS) platform that offers consistent, cost-effective, high quality and high coverage results. We examined the utility of two of the leading NGS content enrichment methods with key evaluation criteria including input material needs, sequencing coverage specificity and sensitivity, workflow ease and robustness, scalability, and all-in total sample cost. We evaluated the combination of the RainDance ThunderBolts™ Cancer Panel and Illumina MiSeq System with the Ion Torrent AmpliSeq™ Cancer Hotspots v2 panel and Proton™. We used the RainDance ThunderBolts™ Cancer Panel to enrich 10ng of both FFPE and fresh frozen (FF) samples of colorectal cancer tumor and adjacent normal tissue. The amplicon-based ThunderBolts Cancer Panel uses single molecule PCR technology to target 50 important cancer genes including tumor suppressors, hotspots and drug resistance markers and features a DirectSeq™ workflow method that integrates sequencing adapters and attaches sample indexers directly, without additional library preparation steps. The enriched samples were sequenced on an Illumina MiSeq System. The results were compared to those using 20ng of the samples with the Ion Torrent AmpliSeq Cancer Hotspots v2 panel and Proton. Sequence validation was performed using RainDrop digital PCR (dPCR) for positive targets derived from both sequencing panels. Both targeted sequencing panels demonstrated comparable sequencing metrics and minor allele calls and frequencies. We found that the sensitivity and specificity of droplet-based PCR (ThunderBolts) enrichment outperformed traditional PCR methodology. The correlation of variant frequency by dPCR validation was more closely aligned to droplet-based enrichment and Illumina sequencing. Furthermore, the reproducibility and ease of use for droplet-based enrichment allowed for a more efficient and directed workflow for clinical laboratories We concluded that the combination of theRainDance ThunderBolts Cancer Panel and Illumina MiSeq System was the best available NGS solution for analyzing common somatic mutations on FFPE tissue, and Fluid Biopsy™ samples (circulating tumor DNA).

3391T

Molecular characterization of over growth syndromes using NGS reveals potential phenotype-genotype correlation. *F. Chang[1], L. Liu[1], E. Fang[1], G. Zhang[1], L. Emrick[1], M. Li[1,2].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dan Duncan Cancer Center, Baylor College of Medicine, Houston, TX.

Recent studies have shown that a group of overgrowth syndromes, such as congenital lipomatous overgrowth with vascular, epidermal, and skeletal anomalies (CLOVES), Proteus syndromes, and two overlapping disorders, megalencephaly-polymicrogyria-polydactyly-hydrocephalus (MPPH) and megalencephaly-capillary malformation (MCAP), are caused by somatic activating mutations in genes involved in the PI3K-AKT signaling pathway. Due to the low-abundance nature of these mutations, routine Sanger sequencing often yields negative results. We have developed a next generation sequencing (NGS) panel that targets all known mutations in multiple genes involved in the PI3K-AKT pathway for this group of overgrowth syndromes. Eight patients including two prenatal cases and six postnatal cases suspected of overgrowth syndromes were tested using the NGS sequencing panel. A somatic mutation in the PIK3CA gene was identified in all 8 cases including one G542K mutation, two H1047L mutations, two H1047R mutations, two G914R mutations and one E110del mutation with the mutant allele frequencies ranging from 4.65% to 38.36%. These PIK3CA mutations were only present in the affected tissues in the majority of the cases demonstrating causal role of the mutations in the development of the diseases and the importance of obtaining affected tissue for testing. Phenotype-genotype correlation analysis showed that mutations at amino acid residue 1047 are often associated with CLOVES syndrome or isolated overgrowth of extremities or fatty mass; while the G914R mutation is preferentially related to syndromes with over growth of brain, such as MPPH/MCAP. In addition, in vitro cell culture showed significant enrichment of the cells harboring mutant alleles, indicating that the activating mutation may render growth advantages to the mutant cells. In a prenatal case, the PIK3CA G542K mutation was positive in the DNA extracted from cultured amniocytes but negative in uncultured cells of the same amniotic fluid specimen, suggesting that cultured amniocytes can be used for prenatal diagnosis of these syndromes. Our experience demonstrates that NGS technology is highly sensitive for the detection of low-level mosaic mutations and can be used for the diagnosis of these overgrowth syndromes in both prenatal and postnatal settings.

3392S

Small clone of JAK2V617F positive chronic eosinophilic leukemia detected by realtime PCR. *N. Yu[1], Y.J. Kim[2], S.J. Park[1], Y.R. Kim[3], K.A. Lee[1], J.W. Kim*[4].* 1) Department of Laboratory Medicine, Yonsei University College of Medicine; 2) Samkwang medical laboratories; 3) Department of Internal Medicine, Yonsei University College of Medicine; 4) Department of Laboratory Medicine, Yonsei University Wonju College of Medicine*.

Chronic eosinophilic leukemia (CEL) is defined as clonal proliferation of eosinophil precursors resulting in persistently increased numbers of eosinophils. Evidence of clonality is crucial in making a diagnosis of CEL. Herein we report a case of CEL with JAK2V617F positive by allele specific PCR and realtime PCR but negative by pyrosequencing and direct sequencing. A 33-year-old Korean female patient was admitted to our hospital in March 2012 for evaluation of persistent abdominal pain, diarrhea, vomiting. The patient had no previous history of hematologic malignancies or cytotoxic therapy. Peripheral blood smear showed eosinophilia. Bone marrow aspiration and biopsy revealed normocellular marrow with increased number of eosinophils and its precursors (19.7% of all nucleated cells). Endoscopic gastric biopsy revealed eosinophilic infiltration. Conventional karyotyping showed 46,XX in all metaphases. In fluorescence in situ hybridization and gene rearrangement studies, no BCR-ABL, FGFR1 and PDGFR rearrangements were detected. Allele specific PCR for JAK2V617F mutation (Seeplex JAK2 Genotyping kit, Seegene, Seoul, Korea) revealed faint positive band. Direct sequencing for exon 14 of JAK2 gene (ABI3500 genetic analyzer, Applied Biosystems, CA, USA) did not reveal any point mutation that prompted further investigation. The pyrosequencing (JAK2 pyro kit, Qiagen, CA, USA) showed negative results while realtime PCR using Real-Q JAK2V617F detection kit (BioSewoom, Seoul, Korea) was confirmed positive for the mutation. To date, only 6 cases of JAK2V617F has been reported in the literature. However, JAK2V617F positive CEL cases always demonstrated negative results for other gene rearrangement; therefore, indicating that JAK2V617F could be an early event in the leukemogenesis. Although prognosis are not well defined due to paucity of CEL cases with JAK2V617F mutation, in our case, steroid alone led to a good response and outcome. In this case, the small mutated clone was detected using most sensitive methods such as allele specific PCR and realtime PCR which could detect a burden as low as 0.01%, while direct sequencing and pyrosequencing with low sensitivity failed to detect mutated clone, causing a false negative. Therefore, selection of a more sensitive molecular method would be helpful for accurate diagnosis. Investigation into more cases with JAK2V617F positive CEL are needed to gain a deeper understanding of the mechanism involved in leukemogenesis.

3393M

Approaches to Integrating Germline and Tumor Genomic Data in Cancer Research. *L.E. Mechanic[1], H. Spencer Feigelson[2], K.A.B. Goddard[3], C. Hollombe[3], S.R. Tingle[1], S.A. Nelson[1], E.M. Gillanders[1].* 1) Epidemiology and Genomics Research Program, Division of Cancer Control and Population Sciences, National Cancer Institute, Rockville, MD; 2) Institute for Health Research, Kaiser Permanente Colorado, Denver, CO; 3) Center for Health Research, Kaiser Permanente Northwest, Portland, OR.

Cancer is characterized by a diversity of genetic and epigenetic alterations occurring in both the germline and somatic (tumor) genomes. Hundreds of germline variants associated with cancer risk have been identified, and similarly large amounts of data have been generated identifying mutations in the tumor genome that play important roles in tumorigenesis. Increasingly, these two genomes are being explored jointly to better understand how cancer risk alleles contribute to carcinogenesis and whether they influence development of specific tumor types or mutation profiles. To understand how data from germline risk studies and tumor genome profiling is being integrated, we reviewed 160 articles describing research that incorporated data from both genomes, published between 2009 and 2012, and summarized the current state of the field. We identified three types of research questions being addressed using these data: (1) use of tumor data to determine the putative function of germline risk variants; (2) identification and analysis of relationships between host genetic background and particular tumor mutations or types; and (3) use of tumor molecular profiling data to reduce genetic heterogeneity or refine phenotypes for germline association studies. We also found several descriptive studies comparing germline and tumor variation in a gene, related genes, or gene families. We identified a large and expanding set of resources that can be used to analyze and integrate data from both genomes and discuss opportunities and challenges for this approach.

Multiplex detection of KRAS mutations in colorectal cancer FFPE samples using droplet digital PCR. *S. Cooper, W. Yang, D. Shelton, J. Berman, B. Zhang, S. Tzonev, E. Hefner, J. Regan.* Digital Biology Center, Bio-Rad Laboratories, Inc., Pleasanton, CA.

Targeted therapies in many cancers have allowed unprecedented progress in the treatment of disease. However, routine implementation of genomic testing is limited due to: 1) limited amounts of sample (pg-ng range) per biological specimen, 2) diagnostic turnaround time and workflow, 3) cost, and 4) difficulties in detection of mutational loads below 5%. KRAS is mutated in approximately 40% of colorectal cancers. The majority of these KRAS mutations are activating mutations in codons 12, 13, and 61, and are predictive of a negative response to αEGFR therapy. To optimize therapy strategies for personalized care, it is critical to rapidly screen patient samples for the presence of multiple KRAS mutations. We have developed a multiplexing strategy to screen clinically-actionable KRAS mutations in cancer samples using digital PCR. This multiplex assay targets seven KRAS point mutations prevalent at greater than 1% , resulting in an effective profiling tool for 98% of KRAS mutant colorectal cancers (Faulkner et al. 2010). No pre-amplification step is required. This KRAS screening assay was used to quantify KRAS mutational load in a panel of FFPE specimens from advanced metastatic colorectal cancer patients. KRAS mutations present at <1% fractional abundance were detected in multiple samples. This sensitive and inexpensive method reduces the risk of contamination and can be easily implemented in molecular diagnostic laboratories for rapid, routine screening of cancer patients.

3395S

Evidence of multiple independent *NF2* somatic inactivation and tumor initiation events in neurofibromatosis type 2-associated vestibular schwannomas. *A. Pemov[1], R. Dewan[2], J. Kim[3], K. Morgan[2], R. Vasquez[2], P. Chittiboina[2], X. Wang[2], A. Ray-Chaudhury[2], S. Chandrasekharappa[4], J. Butman[5], A. Asthagiri[6], D.R. Stewart[1].* 1) NIH/NCI, Bethesda, MD; 2) NIH/NINDS, Bethesda, MD; 3) NIH/NIODCT, Bethesda, MD; 4) NIH/NHGRI, Bethesda, MD; 5) NIH/CC, Bethesda, MD; 6) University of Virginia, Charlottesville, VA.

Background and hypothesis. Neurofibromatosis type 2 (NF2) is a tumor predisposition syndrome that results from mutation of the *NF2* tumor suppressor gene (chromosome 22q12). The hallmark of NF2 is the presence of bilateral vestibular schwannomas (VS). It is generally accepted that somatic inactivation of the second copy of *NF2* is the initiating event for neoplastic transformation in NF2-associated tumors including VS. Though NF2-associated and sporadic VS share identical histopathologic findings and underlying cytogenetic alterations, NF2-associated VS are less responsive to radiosurgery, are associated with worse surgical outcomes and often appear as a cluster of grapes. We hypothesized that the distinct multi-lobulated morphology of NF2-associated VS is determined by the genetics of the tumors and that the “grapes” in the cluster are in fact individual tumors that arose independently with distinct somatic mutations in the *NF2* gene and overall genomic architecture. **Study design and methods.** To test this hypothesis, we analyzed the mutation status of *NF2* by Sanger sequencing and genomic architecture by Illumina HumanOmniExpress SNP-arrays in 24 tumor samples procured from five VS, or 4.8 specimen per tumor on average, in four NF2 patients. **Results.** First, we identified *NF2* germline mutations in each of four NF2 patients. Two patients carried deleterious point mutations in *NF2* and the other two presented with large chromosomal deletions affecting the gene. Second, we identified 18 distinct *NF2* somatic mutations (13 point mutations and five chromosome 22 LOH events) in five tumors, or 3.6 average independent somatic *NF2* hits per tumor and ranging from 1 to 7 per tumor. Finally, SNP-array analysis revealed that a deletion or mitotic recombination affecting the entire chromosome 22 or its q-arm was the most frequent large-scale chromosomal aberration in the tumors (5/24, or 21 per cent). The rest of the genome in all but one tumor sample resembled that of normal diploid cells. **Conclusions.** These findings support our hypothesis that NF2-associated multi-lobulated VS are not single tumors, but rather are clusters of multiple smaller tumors, each arising from their own unique second hit event. These data suggest, for the first time, that the majority of NF2-associated VS arise from multiple independent tumor initiation events. These findings have important clinical implications and will be critical when establishing clinical trials endpoints.

MicroDNA (Extra Chromosomal Circular DNA) in Mammalian Tissues and Cancer Cell Lines. *P. Kumar, L.W Dillon, Y. Shibata, A. Dutta.* DEPT. OF BIOCHEMISTRY & MOLECULAR GENETICS, SCHOOL OF MEDICINE, UNIVERSITY OF VIRGINIA, CHARLOTTESVILLE, VA.

DNA in normal mammalian somatic cells primarily exists as long chromosomes or in mitochondria. However, we previously reported the presence of thousands of short (mostly 200-400 bps) extra chromosomal circular DNAs (microDNAs), single- or double-stranded, arising mainly from the GC rich regions in the genome, and enriched in genic regions in embryonic mouse brain, heart and liver tissues (Shibata, Y. et al. Science 336, 82-86, (2012)). More than 95% of microDNAs could be mapped uniquely to a genome. Chromosomal loci that are enriched sources of microDNA in the adult brain are somatically mosaic for microdeletions that appear to arise from the excision of microDNAs. MicroDNAs often have micro homology of 2-15 bases at the start and after the end of the corresponding chromosomal sequence suggesting that a micro homology mediated mechanism could be the mechanism of microDNA biogenesis. In the current research we studied the characteristics of microDNAs in chicken cell lines deleted in various DNA repair genes, including DNA ligase IV and Ku70 involved in non-homologous end joining (NHEJ); BRCA1, BRCA2, NBS1, and Rad54 involved in homologous recombination (HR); CtIP required for microhomology-mediated alternative end joining (MMEJ); and MSH3 involved in DNA mismatch repair (MMR). The MSH3-deleted cells had a striking change in their microDNA population, suggesting that the mismatch-repair pathway, and by extension replicative polymerase slippage is involved in the generation of a fraction of the microDNAs. To determine tissue specificity of microDNA generation, we examined a panel of mouse tissues (brain, heart, lung, liver, kidney, muscle, sperm, spleen, testis and thymus) and human prostrate (C4-2, LnCap and PC-3) and ovarian (ES2 and OVCAR-8) cancer cell lines. MicroDNAs were observed in all tissue types, confirming that microDNAs are universally present even in germ cells. We discovered that there are hot spots of microDNA generation distributed throughout the genome that are common between tissues and correlate with areas of high gene density and high GC content. However, hierarchical clustering on the basis of microDNA co-ordinates classified the prostate and ovarian cancer cell lines into two separate groups suggesting that at least some microDNAs are tissue-specific and therefore their sites of origin are affected by tissue-specific gene expression patterns or epigenetic marks.

Heterozygous mutations in *PALB2* predispose to breast cancer by causing DNA replication and damage response defects. *R. Winqvist[1,2], M. Bose[1,2], J. Nikkilä[1,2,8], A.C. Parplys[3], K. Borgmann[3], Y. Huo[4], K. Rapakko[2], N. Laurila[1,2], P. Nieminen[5], B. Xia[4], H. Pylkäs[1,2], H. Pospiech[6,7].* 1) Laboratory of Cancer Genetics and Tumor Biology, Department of Clinical Chemistry and Biocenter Oulu, University of Oulu, Oulu, Finland; 2) Northern Finland Laboratory Centre NordLab, Oulu, Finland; 3) Laboratory of Radiobiology and Experimental Radiation Oncology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; 4) Department of Radiation Oncology, Rutgers Cancer Institute of New Jersey and Robert Wood Johnson Medical School, Rutgers, The State University of New Jersey, New Brunswick, NJ, USA; 5) Medical Informatics and Statistics Research Group, University of Oulu, Oulu, Finland; 6) Faculty of Biochemistry and Molecular Medicine, University of Oulu, Oulu, Finland; 7) Research group Biochemistry, Leibniz Institute for Age Research—Fritz Lipmann Institute, Jena, Germany; 8) Present address: Gene Function Team, Breakthrough Breast Cancer Research Centre, ICR, London, UK.

Breast cancer is the most common cancer among females. Although the majority of the breast cancer cases appear to be sporadic, it has been estimated that as much as 5-10% is significantly contributed by powerful hereditary genomic risk factors. Besides mutations in *BRCA1* and *BRCA2*, also defects in the *PALB2* gene occur worldwide and are important in hereditary predisposition to breast cancer. PALB2 interacts with BRCA1 and BRCA2 to regulate homologous recombination and to mediate cellular DNA damage response. We have previously shown that in the Finnish population a relatively common heterozygous mutation in *PALB2* increases the risk of malignancy in carrier individuals about sixfold. About 1% of the breast cancer patients in Finland carry this mutation. Unfortunately, however, the mechanistic details for how heterozygous mutations in cancer predisposing genes such as *PALB2* trigger disease development are currently largely obscure. By analysing lymphoblastoid cell lines from heterozygous female *PALB2* mutation carriers, we have recently been able to demonstrate that haploinsufficiency for PALB2 causes aberrant DNA replication/damage response. Mutation carrier cells show increased origin firing and shorter distance between consecutive replication forks. Carrier cell lines also show compromized S and G2/M cell cycle checkpoint functions and aberrant DNA repair capabilities, which result in gradual accumulation of various genomic lesions. Elevated chromosome instability was also observed in primary blood lymphocytes of heterozygous *PALB2* mutation carriers, indicating that the described mechanisms of genome destabilization operate also at the organism level. Thus the functional loss of one copy of the *PALB2* gene causes instability in the genome, even though the other allele is still intact and functioning. These exciting findings provide a new mechanism for early stages of breast cancer development that may also apply to other heterozygous homologous recombination signaling pathway gene mutations involved in hereditary cancer predisposition.

Investigation of *de novo* mutation rates in families with DNA Polymerase ε and Δ exonuclease domain mutations. *S.E.W. Briggs, O. Venn, C. Palles, G. McVean, I.P. Tomlinson.* The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

DNA polymerases ε and Δ have an essential role in eukaryotic DNA replication, proofreading newly synthesised DNA and identifying and excising mispaired nucleotides. Mutations in the exonuclease domains (EDMs) of DNA polymerases *POLE* (MIM #174762) and *POLD1* (MIM #174761) have been identified as causal mutations in a novel cancer predisposition syndrome, polymerase proofreading associated polyposis (PPAP [MIM #615083; #612591]). PPAP displays high penetrance and a variable phenotype including colorectal, endometrial and ovarian tumours. Sporadic colon and endometrial tumours with somatic *POLE* EDM mutations are defined by a hypermutated phenotype with a distinct mutational spectrum of increased transversion mutations.

To investigate the effect of germline mutations on *de novo* mutation rates we performed whole genome sequencing of two parent-offspring quintets. One quintet carries *POLE* L424V (c.1270C>G, NM_006231), and one *POLD1* S478N (c.1433G>A, NM_002691); in each family the mother and two of three offspring carry the mutation.

The whole genomes of each family member were sequenced to a read depth of 7.9x. We applied alignment based calling to each family without incorporating relatedness, detected 4.9 million variants with a transition:-transversion ratio of 2.16. To these calls we applied a modified Lander-Green algorithm to construct a transmission scaffold across chromosomes for each family. Probabilistic models were used to classify sites inconsistent with transmission, followed by filtering for false-positive errors. Candidate mutations were then validated using independent targeted sequencing to estimate the false positive rate, and direct paired-end phasing was conducted.

We sought to test whether there is an elevated incidence of *de novo* mutations in the carriers. Preliminary results suggest that in both pedigrees the transition:transversion ratio is decreased (1.2 in *POLE*; 1.5 in *POLD1*), with an abundance of indels (23% in *POLE*; 34% in *POLD1*) suggesting an impact of germline mutation in line with the biological expectation. Paternal bias in *de novo* mutation origin has been reported in humans and chimpanzees. If DNA polymerase mutations do impact germline mutation, we may observe an increase in the female contribution given that the mothers are the carriers in both families.

3399M

NBN gene expression and cytogenetic changes in irradiated cells with NBN gene mutations. *D. Januszkiewicz-Lewandowska[1, 2, 3], B. Swiatek-Koscielna[1], J. Rembowska[1], A. Dzikiewicz-Krawczyk[1], M. Zawada[1], J. Nowak[1].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 2) University of Medical Sciences, Poznan, Poland; 3) Department of Medical Diagnostics, Poznan, Poland.

NBN gene product is part of the MRE11/RAD50/NBN complex, which plays essential role in genomic stability. Homozygous mutation of NBN gene c.657-661del causes Nijmegen breakage syndrome in the course of which there is a high susceptibility to cancer. Heterozygous NBN gene mutations are considered to be a minor cancer risk factor. The study tries to answer the following questions: Does mutations of NBN gene influence the DNA synthesis and expression of NBN gene in irradiated immortalized cells? What is the effect of NBN gene mutation and irradiation on the chromosome stability in lymphoblastic cell line with germinal NBN gene mutations? Radioresistant DNA synthesis measured by 3H thymidine incorporation assay, NBN gene expression and chromosomal aberrations were assessed in cultured cells before and after irradiation with doses 1-8 Gy. Our results indicated that only cells with homo- and heterozygous c.657-661del mutation showed higher 3H thymidine incorporation after irradiation, particularly in the 48-hour culture and after higher doses of irradiation. These results suggest that those cells showed significantly lower rates of DNA synthesis inhibition. Radiosensitivity measured as a numer of chromosomal aberrations per one metaphase was significantly higher in cells with all NBN gene mutations studied as compared to the control cell line and was clearly marked for homozygous and heterozygous c.657-661del cell lines. Cells with homozygous and heterozygous c.657-661del and p.R215W mutations possessed significantly higher relative NBN gene expression when compare to the control. After irradiation the relative expression of NBN was significantly higher only in homozygous c.657-661del and heterozygous p.R215W. Our observation may indicate on a compensatory increase in the expression of p70-NBN subunit in cells with homozygous c.657-661del and heterozygous c.657-661del and p.R215W mutations. Similarly, irradiation may in an alternative way in these cell lines stimulate significantly higher increase of NBN gene expression. Financial support - National Science Centre 2011/01/B/NZ5/04322.

Mechanism of formation of complex chromosomal aberrations in patients with myelodysplastic syndromes (MDS): clonal evolution or chromothripsis? *Z. Zemanova[1], H. Lhotska[1], J. Brezinova[2], I. Sarova[1, 2], L. Lizcova[1], S. Izakova[1], S. Ransdorfova[2], K. Svobodova[1], Z. Krejcik[2], M. Belickova[2], M. Siskova[3], A. Jonasova[3], R. Neuwirtova[3], J. Cermak[2], K. Michalova[1].* 1) Center of Oncocytogenetics, IMBLD, General University Hospital and First Faculty of Medicine, Charles University in Prague, Czech Republic; 2) Institute of Hematology and Blood Transfusion, Prague, Czech republic; 3) 1st Medical Department, General University Hospital and First Faculty of Medicine, Charles University.

Complex chromosomal aberrations (CCAs) are seen in approximately 20% of patients with newly diagnosed MDS and are associated with a poor prognosis. The mechanisms leading to its formation remain poorly understood. It is not clear whether CCAs arise by a gradual acquisition of genetic changes during the clonal evolution or by extensive chromosome fragmentation through a unique cellular crisis (chromothripsis). The aim of the study was to perform detailed genome wide analyses of bone marrow cells of patients with MDS and CCAs and to assess the frequency and clinical significance of chromothripsis. A comprehensive molecular cytogenetic analysis was performed of bone-marrow cells from 177 adults with CCAs (≥3 aberrations) identified with conventional G-banding at the diagnosis of MDS. The CCAs were studied by FISH with Vysis DNA probes (Abbott, Des Plaines, IL) and mFISH/mBAND methods (MetaSystems, Altlussheim, Germany). Genomic imbalances were identified with CytoChip Cancer SNP 180K (BlueGnome, Cambridge, UK) or with Illumina Human CytoSNP-12 arrays (Illumina, San Diego, CA). The findings in 86/177 patients corresponded to the gradual accumulation of random aberrations over clonal evolution. In remaining 91 patients, mFISH/mBAND and microarray assays showed breaks with a large number of chromosomal losses and gains, probably resulting of chromothripsis. The fragmentation or shattering of chromosomes into many pieces was also observed. Parts of the fragmented chromosomes were translocated or inserted elsewhere in the genome, leading to chaotically reassembled chromosomes. The most frequently shattered were Nos. 5, 7, 17, and 12. The OS of patients with shattered chromosomes did not differ from that of patients with no evidence of fragmentation (median OS in both groups, four months; $p = 0.224$). We observed signs of chromothripsis in 51.4% of MDS patients with CCA. Although initial studies have suggested that patients displaying a chromothripsis have more aggressive tumors and poor outcomes, in this cohort, we found no significant difference in the OS of patients with and without chromothripsis. We assume that in MDS, CCA can occur by either mechanism, i.e., as the result of chromothripsis or with gradual clonal evolution. The prognosis in both cases is very poor and deteriorates with increasing number of aberrations, regardless of mechanism of complex karyotype formation. Supported by RVO-VFN64165, GACR P302/12/G157/1, PRVOUK-P27/LF1/1, MHCR 00023736.

A new control mechanism for repair of DNA in human cells: MDC1 and ATR regulate DNA Double-Strand Break (DSB) resection independently of ATM. *P.S Bradshaw[1,2], M. Komosa[1], M.S Meyn[1,2,3,4].* 1) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Division of Clinical and Metabolic Genetics, Department of Paediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) The Department of Paediatrics, University of Toronto, Toronto, Ontario, Canada.

To maintain genome stability, human cells have developed strategies to detect, repair or induce cell death/apoptosis in response to DNA damage. DNA DSBs frequently arise from exposure to exogenous and endogenous sources and are one of the most lethal forms of DNA damage. Detection of DNA DSBs result in the activation of the PIK-related kinase ATM and its phosphorylation mediated signaling pathway. ATM is mutated in the autosomal recessive disorder Ataxia-Telangiectasia (A-T) in which defective DSB repair leads to genome instability, radiation sensitivity, cerebellar ataxia, immunological defects, radiation sensitivity and high cancer risk. Here we report that ATM is rapidly recruited to DNA breaks in the nuclei of human cells, where it forms distinctive spatially well-defined, non-diffusible, foci. Using interative deconvolution microscopy, we find that ATM belongs to a novel class of DSB repair proteins that rarely co-localize with Rad51 and RPA (proteins directly involved Homologous Recombination Repair - HRR), resected DSBs, or proteins that make up the mega-base region of γ-H2AX containing chromatin that surround DSBs. Human cells lacking ATM display reduced numbers of RPA and Rad51 foci following the generation of radiation-induced DSBs. RPA foci formation is dependent on CtIP a protein target for ATM phosphorylation and implicated in DNA resection and the generation of single stranded DNA (ssDNA). Our data indicate that ATM promotes the initiation of resection and subsequent HRR, through the CtIP dependent generation of ssDNA. In contrast, MDC1, a downstream member of the ATM-dependent signaling pathway, acts independently of ATM to restrain the initiation of DSB resection and prevent the formation of ssDNA. Interestingly, we find that MDC1 restrains DNA resection by inhibiting the ATR dependent activation of CtIP. Like ATM, ATR is a PIK-related kinase involved in DNA damage signaling. Mutations in ATR can cause Seckel Syndrome (SCLK1), an autosomal recessive disorder characterized by growth retardation, dwarfism, microcephaly, mental retardation and facial dysmorphology. Significantly, CtIP mutations can also cause Seckel Syndrome (SCLK2). Our work identifies a new MDC1 / ATR dependent pathway of DSB resection that functions independently of the classical ATM-mediated DNA damage signaling pathway. Further, our demonstration of MDC1/ATR control of CtIP mediated resection establishes a molecular link between SCLK1 and SCLK2 syndromes.

Breast cancer eQTLs from the Nurses' Health Study. *A. Hazra[1,5], A. Quiroz-Zarate[2], B. Harshfield[1], R. Hu[1], N. Knoblauch[3], A.H. Beck[3], S.E. Hankinson[4], V. Carey[1], R.M. Tamimi[1,5], D.J. Hunter[5], J. Quackenbush[2].* 1) Medicine, Brigham and Women's Hospital, Boston, MA; 2) Center for Computational Biology, Dana Farber Cancer Institute, Boston, MA; 3) Pathology, Beth Israel Deaconess Medical Center, Boston, MA; 4) Division of Biostatistics and Epidemiology, School of Public Health and Health Sciences, University of Massachusetts, Amherst, MA; 5) Program in Genetic Epidemiology and Statistical Genetics, Harvard School of Public Health, Boston, MA.

Genome-wide association studies (GWAS) of breast cancer have identified 71 single nucleotide polymorphisms (SNPs), majority of which are located in intergenic or intronic regions. To identify regulatory variants we conducted expression quantitative loci (eQTLs) analysis among invasive postmenopausal breast cancer cases in the Nurses' Health Study (NHS) diagnosed from 1990-2004 with GWAS data. RNA extracted from formalin fixed paraffin embedded (FFPE) breast tumor (tumor) and normal adjacent (normal) breast tissue was profiled using the Affymetrix Human Transcriptome Array (HTA 3.0v1). Multivariate linear regression was conducted separately for 376 tumor and 264 normal samples using 71 loci and 26,004 expression probes. We also developed the functional QTLs (fQTLs) method to gain pathway-level insight and evaluate the hypothesis that SNPs are associated with regulation of processes. We identified 12 trans-acting SNPs in normal tissue, 9 trans-acting SNPs in estrogen-receptor positive (ER+) tumors and 13 trans-acting SNPs associated ER- tumors, including 3 2 overlapping loci across normal adjacent, ER+ tumors and ER- negative tumors (false discovery rate (FDR)<10%). Although not statistically significant after FDR correction, we identified suggestive cis-acting loci. For the fQTL analyses, we tested the association of SNPs with genes as repeated measurements of a specific pathway. We used the Molecular Functions (MFs) of the Gene Ontology and identified 2 SNPs associated with 2 MFs in normal tissue, 1 SNP associated with 5 MFs in ER- tumors but no significant associations in ER+ tumors (FDR<10%). Using bioinformatic tools we identified trans-acting loci that alter transcription-binding motifs and were associated with transcripts in chromatin enhancer regions or non-coding RNA. The overlapping loci are associated with multiple unique transcripts in breast tissue and may be key regulatory SNPs in breast tissue. Further functional work is needed to elucidate the mechanism of these associations. Our results provide functional insights on the underlying biology of breast cancer loci in the specimen type that is most impactful in translation to clinical practice.

Utilization of Bioluminescence Resonance Energy Transfer (BRET) for functional evaluation of missense variants at the BRCA1-BARD1 heterodimeric RING-RING interface. *T. Kayoko[1], E.L. Young[1], B. Luo[2], S.V. Tavtigian[1].* 1) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 2) Drug Discovery Core, University of Utah, Salt Lake City, UT.

[Background] The clinical significance of BRCA1 RING domain missense substitutions has been underlined by multiple studies of familial breast/ovarian cancer cases. The structural interaction between BRCA1 and its binding partner, BARD1 (BRCA1-associated ring domain 1), is essential for their tumor suppressor function. To evaluate the impact of missense substitutions on BRCA1/BARD1 complex formation, we applied a Bioluminescence Resonance Energy Transfer (BRET) system to quantify protein-protein interactions. [Method] The BRET assay measures the efficiency of energy transfer from a donor to an acceptor moiety. NanoLuciferase-fused BRCA1 RING domain (donor construct) and HaloTag-fused BARD1 (acceptor construct) were generated as BRET biosensers to monitor the interactions. 24 hours after these were transfected into human embryonic kidney 293 cells, the reactive ligands were covalently attached to the HaloTag proteins; donor luminescence (460nm/40nm) and acceptor fluorescence (620nm/40nm) emission intensity were then measured with a microplate reader. Sample values were normalized by donor activity in each well, and BRET ratios (acceptor/donor emission) were calculated. [Results] We made an initial test of BRET assay suitability using wild-type and mutant constructs of the BRCA1 RING domain. Two cancer-predisposing mutations (BRCA1 p.C61G and p.C64G), known to disrupt the BRCA1/BARD1 dimerization, showed significantly decreased BRET ratios (p.C61G = 0.137±0.0004, p.C64G = 0.135±0.0052) compared to wild-type (WT = 0.374±0.0372), whereas BRCA1 p.I42V, which has been reported to retain the ability to bind BARD1, showed a BRET ratio that is comparable to wild-type (I42V = 0.330±0.0220). [Conclusions] Clinically significant missense mutations are often found in protein binding regions. The BRET-based protein interaction assay has several advantages over conventional methods: 1) protein interactions can be measured in living mammalian cells in a real-time manner, which enables monitoring of modification-dependent protein interactions, 2) no artifact prone washing steps are required before measurement, 3) high-throughput screening compatible. Additional BRCA1 and BARD1 RING domain missense substitutions will be evaluated to further assess the suitability of BRET for interpretation of unclassified variants in these two genes.

Somatic mutations in the epidermal growth factor receptor (EGFR) gene are oncogenic drivers for non-small cell lung cancer (NSCLC). It has been suggested that EGFR mutation-positive (EGFRmut+) NSCLC might be a unique orphan disease with genetic susceptibility. EGFR mutations are associated with lung adenocarcinoma histology, female gender and non-smoking history. NSCLC with these features has been consistently associated with an intronic polymorphism rs2736100 in the telomerase reverse transcriptase (TERT) gene. We therefore hypothesized that rs2736100 may be a risk factor for EGFRmut+ NSCLC. To test this, we conducted a genetic association study in Chinese NSCLC patients (n=714) and healthy controls (n=2,520). Among the cases, 42% (n=303) were EGFRmut+. We further tested the association between the EGFR mutation status and mean leukocyte telomere length (LTL). The potential function of rs2736100 in lung epithelial cells was also explored. We found that while the rs2736100-C allele was significantly associated with NSCLC as an overall phenotype (OR=1.24, 95%CI=1.1-1.39, $p=4\times10^{-4}$), it was more strongly associated with EGFRmut+ NSCLC (OR=1.52, 95%CI=1.28-1.80, $p=1.6\times10^{-6}$) compared to the EGFRmut- NSCLC (OR=1.07, 95%CI=0.92-1.24, p=0.4). There was also a significant difference in the allele frequency between EGFRmut+ and EGFRmut- populations (OR=1.42, 95%CI=1.15-1.76, $p=1.1\times10^{-3}$). The results remained significant after controlling for age, gender, smoking status and histology (corrected $p\leq0.035$). Further analyses demonstrated that while NSCLC patients as a whole have significantly longer LTL compared to healthy controls ($p\leq10^{-13}$), the EGFRmut+ patients have even longer LTL compared to EGFRmut- patients (p=0.008, corrected p=0.043). Meanwhile, rs2736100 was significantly associated with TERT mRNA expression in both normal and tumor lung tissues after controlling all covariates (corrected $p\leq0.047$). We also found that the rs2736100 DNA sequence has an allele-specific affinity to nuclear proteins extracted from lung epithelial cells. The polymorphism was also associated with an altered enhancer activity in vitro. Our study for the first time linked a TERT polymorphism to EGFRmut+ NSCLC. The data further revealed insight into the role of TERT and its polymorphisms in the carcinogenesis of EGFR mutation-driving lung cancer.

Dean[4].* 1) Leidos Biomedical Research, Inc., Frederick, MD USA; 2) Instituto de Cancerologia, Guatemala City, Guatemala; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Gaithersburg, MD USA; 4) National Cancer Institute, Frederick, MD USA; 5) Hospital Central Universitario "Dr. Antonio M Pineda", Barquisimeto, Lara State, Venezuela; 6) Unidad de Medicina Genómica, Facultad de Medicina, Universidad Nacional Autónoma de México, México, D.F. México; 7) Hospital General de México. México, D.F. México.

Cervical cancer is the most common cause of cancer mortality for women living in poverty, causing over 28,000 deaths annually in Latin America and 266,000 worldwide. We identified somatically mutated PIK3CA genes using exome and ultra-deep targeted sequencing of invasive cervical tumors from Guatemala, Venezuela, and Mexico. Analysis of 636 HPV positive cervical cancer revealed activation of PIK3CA genes in up to 34% of tumors. The novel PIK3CA mutations including delN107 (ABD domain); P134T (link between ABD and RBD domains); T229I and M232L (RBD); V952G and E1034Q (Kinase domain) and mutations, D350N, D454Y (C2) and E726K (Kinase domain) lacked function study, were identified in the study. To future study the effect of these mutations on PIK3CA catalytic activity, we expressed wild type and mutant constructs in vitro and measured levels of AKT (Thr308) and AKT (Ser473) phosphorylation, respectively. The result showed that these novel PIK3CA mutations led to significantly and slightly increased levels of phospho-AKT (Thr308) and phospho-AKT (Ser473), respectively. Furthermore PIK3CA and HPV E6 and E7 gene expression is significantly higher in PIK3CA mutation-positive tumors. Our study demonstrates that PIK3CA/AKT pathway activation contributes to the development of HPV positive cervical cancer in Latin America.

CARP Is a Potential Tumor Suppressor in Gastric Carcinoma. *F. Lu[1,2], J. Xue[2], Y. Hu[2], L. Gan[2], H. Yang[2], Y. Wei[2].* 1) Center for Molecular Genetics, Sichuan Provincial People's Hospital, chengdu, Sichuan, China; 2) State Key Laboratory of Biotherapy, West China Hospital, Sichuan University, Chengdu, P.R. China.

Background The caspase-associated recruitment domain-containing protein (CARP) is expressed in almost all tissues. Recently, the tumor-suppressive function of CARP was discovered and attracted increasing attention. This study aimed to investigate the role of CARP in the carcinogenesis of human gastric carcinoma. Methods/Result Compared with normal gastric tissue, the downregulation of CARP expression was observed in gastric carcinoma tissue by cDNA array and tissue microarray assay. In vitro, the gastric carcinoma cell line (BGC-823) was stably transfected with pcDNA3.1B-CARP or plus CARP siRNA, and we used MTT, flow cytometry, cell migration on type I collagen, cell-matrix adhesion assay and western blot analysis to investigate the potential anti-tumor effects of CARP. Our data showed that overexpressing CARP suppressed the malignancy of gastric carcinoma BGC-823 cell line, including significant increases in apoptosis, as well as obvious decreases in cell proliferation, migration, adhesion ability, and tumor growth. The tumor-suppressive effects of CARP were almost restored by siRNA-directed CARP silence. In addition, overexpression of CARP induced G1 arrest, decreased the expressions of cyclin E and CDK2, and increased the expressions of p27, p53 and p21. In vivo, the tumor-suppressive effect of CARP was also verified. A single-nucleotide polymorphism (SNP) genotype of CARP (rs2297882) was located in the Kozak sequence of the CARP gene. The reporter gene assay showed that rs2297882 TT caused an obvious downregulation of activity of CARP gene promoter in BGC-823 cells. Furthermore, the association between rs2297882 and human gastric carcinoma susceptibility was analyzed in 352 cases and 889 controls. It displayed that the TT genotype of rs2297882 in the CARP gene was associated with an increased risk of gastric carcinoma. Conclusions CARP is a potential tumor suppressor of gastric carcinoma and the rs2297882 C>T phenotype of CARP may serve as a predictor of gastric carcinoma.

3407S

Association of Platelet Derived Growth Factor-B (PDGF-B) and Human Epidermal Growth Factor Receptor -2 (HER-2/neu) Single Nucleotide Polymorphisms (SNP's) with Gallbladder Cancer (GBC). *K. Mishra[1], V.K. Kapoor[1], A. Behari[1], S. Khan[2], S. Agrawal[1].* 1) Surgical Gastroenterology, Sanjay Gandhi Post-Graduate Institute of Medical Sciences (SGPGIMS), Lucknow, Uttar Pradesh, India; 2) Integral University, Kursi Road, Lucknow, Uttar Pradesh, India.

Purpose: Gall bladder cancer (GBC), a highly malignant gastrointestinal tumour, is very common in north India. Platelet derived growth factor-B (PDGF-B) at chromosome 22q12.3-q13.1 and Her-2/neu at 17q12-q21 play an important role in tumour angiogenesis. PDGF-B and Her-2/neu overexpression has been found in many cancers. We studied PDGF-B and Her-2/neu single nucleotide polymorphisms (SNPs) in GBC and gall stone associated benign diseases viz. chronic cholecystitis (CC) and xanthogranulomatous cholecystitis (XGC). Methods: DNA was extracted from blood in patients with GBC (n=195), CC (n=140), XGC (n=47) and normal controls (n=300). PDGF-B polymorphisms were investigated using ARMS PCR for +286A/G and +1135A/C, and for Her-2/Neu Ile655Val by PCR-RFLP method. Results: +286A/G polymorphism homozygous GG genotype, and +286G allele was found to be risk associated for GBC (OR=5.25 P= 0.0001 and OR=2.02 P= 0.0001). Recessive model (GG vs. AA+GA) of +286A/G polymorphism was risk associated (OR=4.78, P=0.0001) whereas dominant model (AA vs. GG+GA) was risk protective (OR=0.56, P=0.003) with GBC. +1135A/C polymorphism CC genotype and +1135C allele was risk associated (OR=3.19, P=0.0001 and OR=1.81, P=0.0001) with GBC. Recessive model (CC vs. AA+AC) was risk associated (OR=2.75, P=0.0003) whereas dominant model (AA vs. CC+AC) showed protective association (OR=0.56, P=0.0024) with GBC. In HER-2 Ile655Val polymorphism, dominant model and Val allele of this polymorphism was risk protective for XGC. Allele frequencies of GBC were compared with CC and XGC. Homozygous GG genotype, recessive model and +286G allele of +286A/G genotype were risk associated but dominant model of this genotype was risk protective for GBC as compared with CC. In case of GBC vs XGC, GG genotype, recessive model and +286G allele were risk associated for GBC. In +1135A/C polymorphism, homozygous CC genotype, recessive model and 1135C allele were risk associated whereas dominant model was risk protective when GBC was compared with CC. In HER-2 Ile655Val polymorphism, Val allele was risk associated when GBC was compared with XGC. In haplotype analysis, haplotypes ACIle (OR= 1.48), GAVal (OR=1.70) and GAIle (OR=2.00) were risk associated with GBC. Conclusion: PDGF-B +286A/G and 1135A/C are risk susceptibility markers for GBC and need further evaluation.

3408M

Highly Sensitive Fusion Transcript Detection and Quantification in Cancer. *L.C. Watson, S.M. Gross, I. Khrebtukova, F. Schlesinger, S. Pathak, T. Hill, T. Singer, G. Schroth.* Functional Genomics, Illumina, Inc., San Diego, CA.

Gene fusion detection in cancer samples can provide tumor-specific information for cancer research, clinical diagnosis and targeted treatment. Common fusion detection methods such as qPCR and FISH are restricted to known fusion junctions and limited in the number of genes that can be detected in parallel. In contrast, RNA sequencing is a powerful approach for simultaneous discovery of all possible fusion junctions in a single reaction. But, the sequencing depth required for sensitive detection of fusions from whole-transcriptome libraries can be cost-prohibitive. Here we describe a cancer-specific capture-based approach for fusion detection by RNA sequencing that requires only a fraction of the sequencing depth of whole-transcriptome methods. We designed biotinylated oligo probes that densely target coding regions of ~1500 cancer-associated genes including more than 300 genes associated with clinically relevant fusions, 80 alternatively spliced transcripts derived from TCGA RNA-Seq data, and more than 400 genes that show expression differences in tumor/normal pairs across TCGA subtypes. This panel was used to capture cancer-specific fusions from total RNA-Seq libraries. We used commonly studied cancer cell lines—including MCF-7, K562, PC-3, T47D, U20S—and Universal Human Reference RNA (UHRR) to compare the sensitivity of fusion detection across three RNA-Seq library prep methods: (1) cancer gene library capture (2) whole-transcriptome library capture and (3) PolyA selection. We show that probes targeting individual exons can robustly capture well-characterized cancer gene fusions such as *BCR-ABL* and *BCAS3-BCAS4.* Furthermore, these comparisons demonstrate the sequencing efficiency of using highly targeted and specific panels. By including *in vitro*-transcribed RNA gene fusions as spike-in controls, we also establish that fusion detection is quantitative. We show that selective enrichment of RNA-Seq libraries with cancer-specific capture probes enables high-resolution mapping of genomic rearrangements in patient cancer samples, even those derived from FFPE, facilitating sequencing studies that were not previously possible.

Charting gene regulatory networks for interpreting prostate cancer GWAS results. *G. Wei, P. Gao, Q. Huang, Y. Yang, R. Lin.* Biocenter Oulu and Faculty of Biochemistry and Molecular Medicine, University of Oulu, P.O. Box 5000, Oulu FIN-90014, Finland.

Prostate cancer represents one of the most common cancers in males and the second most common cause of cancer-related death among men in developed world. Driver transcription factors (TFs) including androgen receptor, TMPRSS2-ERG, FOXA1 and HOXB13 are known to be important in prostate cancer progression, and frequently overexpressed in human prostate tumors. Particularly, genetic evidence shows that HOXB13 also affects prostate cancer susceptibility but with unknown genetic and functional mechanisms. To understand underlying function for these TFs, we chart gene regulatory networks driven by them using chromatin immunoprecipitation coupled to high-throughput sequencing (ChIP-seq) and define up to 50,000 binding sites in average for each TF. Through systematic localization analyses, we find that the prostate cancer risk-associated single nucleotide polymorphisms (SNPs) identified by genome-wide association studies (GWASs) are significantly enriched in these TF binding sites, revealing potential causal roles for these non-coding genetic variants. Intriguingly, this suggests that GWAS-identified non-coding SNPs are more likely to affect chromatin binding affinity for disease cell-type-specific TFs. We further provide compelling evidence to substantiate the causality for several prostate cancer risk-associated SNPs including rs339331. We find that rs339331 lies within a HOXB13 functional binding site and causes upregulation of RFX6 gene, promoting prostate cancer cell growth and metastasis. Together, our study suggests a gene regulatory network approach in interpreting GWAS results of prostate cancer and other diseases.

Functional analysis of mutations in polymerase epsilon gene that predispose to polymerase proofreading associated polyposis (PPAP). *E. Heitzer[1], C. Palles[2], P. Ulz[1], M.R. Speicher[1], S. Kearsey[3], I. Tomlinson[2].* 1) Institute of Human Genetics, Medical University Graz, Graz, Austria; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) Department of Zoology, University of Oxford, UK.

Germline mutations in the exonuclease domain of genes encoding the catalytic subunits Polymerase δ and ε, i.e. POLD1 and POLE, predispose to "polymerase proofreading associated polyposis" (PPAP) resulting in multiple colorectal adenomas and carcinoma with high penetrance and dominant inheritance. Moreover, somatic mutations in the ED of POLE have been frequently found in sporadic CRCs and endometrial carcinoma. Tumors, with both inherited and somatic EDMs, were microsatellite stable and showed a mutator phenotype with a dramatic increase of base substitutions indicating impaired proofreading. To assess the functional consequences of POLE germline and somatic mutations, we characterized exonuclease domain mutant alleles in S.pombe. We therefore generated constructs encoding the equivalent changes in the fission yeast protein and determined the effect of this change on reversion of the ade6-485 allele, 5-fluoroorotic acid and canavanine resistance. The somatic mutations including P286R, S297F, and S459F showed a dramatically increased mutation rate (up to more than 100-fold) compared to the wild type strain. V411L was only slightly increased (4-7 fold). Also the germline variant L424V showed increased mutation rates (2-11-fold) compared the wild type strain. As expected whole genome sequencing of POLE mutated strains and strains with a deficient MMR background revealed an elevated rate of base substitutions. This data indicate that EDMs in POLE indeed lead to proofreading deficiency and can induce replication errors during synthesis of oncogenes and tumor suppressors resulting in tumor formation.

From GWAS to therapy: Fatty acid synthase in uterine leiomyomata. *Z. Ordulu[1], M. Hayden[1], S. Eggert[2], M. Shinohara[3], C. Serhan[3], B.J. Quade[2], C.C. Morton[1,2].* 1) Obstetrics, Gynecology and Reproductive Biology, Brigham and Women's Hospital, Boston, MA; 2) Pathology, Brigham and Women's Hospital, Boston, MA; 3) Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital, Boston, MA.

Uterine leiomyomata (UL) pose a major public health problem given their high prevalence (>70%) in women of reproductive age and their indication for >200,000 hysterectomies in the U.S. annually. Genome-wide association studies for fibroid predisposition performed in white women identified a candidate SNP (rs4247357) under a linkage peak in 17q25.3 that spans the gene fatty acid synthase (*FASN*). By immunohistochemistry we found FAS protein levels elevated (3-fold) in UL in comparison to matched myometrial tissue. It has been reported that FAS is upregulated in various neoplasms and implicated in tumor cell survival. We assessed effects of FAS inhibitors Orlistat and C75 in primary cell cultures of 17 matched myometrium and UL by cell proliferation assays. Cell counts are reduced in a dose-dependent manner with a half maximal inhibitory concentration ranging between 50-75 uM (Orlistat) and 30-45 uM (C75). Further, we showed that Orlistat treatment reduced C16:0, C18:0 free fatty acids and increased CoA-ester of C14:0, C16:0 and C18:0 by gas chromatography-mass spectrometry analysis, supporting its role through inhibition of the thioesterase domain of FAS. *In vivo* experiments are underway in an immunocompromised mouse model with subcutaneous fibroids derived from primary human fibroid cells. *FASN* represents the first potential UL predisposition gene identified in white women with responsiveness of UL to inhibition of FAS a potential model for targeted therapy to mitigate risks and complications of surgical management.

3412T

Evaluation of miR-338-3p role in the progression of Esophageal Squamous Cell Carcinoma. *H. Mollaei[1,2], M. Shafiee[1,3], S.A. Aleyasin[3], S.J. Mowla[4], M. Moghaddam-Matin[5,6], †The two first authors (M. Shafiee and H. Mollaei) contributed equally to this work.* 1) Golestan Research Center of Gastroenterology and Hepatology (GRCGH), Golestan University of Medical Sciences, Gorgan, Iran; 2) Department of Biology, Faculty of Natural Sciences, University of Tabriz, Tabriz, Iran; 3) Department of Medical Genetics, National Institute of Genetic Engineering and Biotechnology, Tehran, Iran; 4) Department of Molecular Genetics, Faculty of Biological Sciences, Tarbiat Modares University, Tehran, Iran; 5) Cell and Molecular Biotechnology Research Group, Institute of Biotechnology, Ferdowsi University of Mashhad, Mashhad, Iran; 6) Department of Biology, Faculty of Sciences, Ferdowsi University of Mashhad, Mashhad, Iran.

Objective: Esophageal cancer is one the most lethal form of human malignancies, mostly due to its late diagnosis. Golestan province in Northeastern Iran, as a part of Caspian littorals, has been identified as one of the highest risk areas in the world. This high incidence, highlighting the necessity of identifying novel and potent diagnostic and prognostic biomarkers for early detection of the disease. Alterations in the expression of miRNAs have been widely reported in numerous diseases including almost all types of cancers. Act as oncogenes (oncomiRs) or tumor suppressors, miRNAs are playing prominent roles in cancer-related processes such as proliferation, apoptosis, metastasis and angiogenesis. Motivated by our recent data on downregulation of miR-338-3p expression in esophageal squamous cell carcinoma, we aimed to investigate its potential causative role in tumorigenesis of an Esophageal Carcinoma cell line, KYSE-30. Materials and Methods: The human KYSE-30 cell line was obtained from Pasteur Institute in Tehran, Iran. After seeding the cells, they were transfected with either pEGFP-C1 vector containing the miR-338-3p precursor sequence or the mock pEGFP-C1 vector with Lipofectamin 2000 transfection reagent. 48 h after transfection, the cells were harvested for RNA isolations and flow cytometry analysis. Experiments were repeated at least twice and cell cycle alterations were analyzed using FlowJo software. Results: In contrast to the cells transfected with a mock vector, as a negative control, the KYSE-30 cells overexpressing miR-338-3p showed a remarkable increase (15.5 times) in miR-338-3p expression 48 hours after transfection. Over-expression of miR-338-3p caused a dramatic alteration in cell cycle distribution of transfected cells, including around two folds increase in the number of cells distributed in the sub-G1 phase of the cell cycle. Conclusion: The data suggests that miR-338-3p may act as an anti-apoptotic role in epithelial cells of esophagus. A similar observation has been reported in other cancer cells such as pancreatic interepithelial neoplasia, gastric cancer and colorectal carcinoma. A functional causative role of miR-338-3p in ESCC is also supported by bioinformatic analyses using miRwalk and DIANALAB. These softwares predicted MMP2, MMP9, SMO, n-Ras, c-Myc and Cyclin D as potential targets of this miRNA. These findings and further studies may suggest miR-338-3p as a good biomarker for ESCC diagnosis and treatment target.

3413S

Assessment of the clinical relevance of variants of uncertain significance in BRCA2 by functional and computational approaches. *L. Guidugli[1], N.M. Lindor[2], V.S. Pankratz[1], D.L. Masica[3], R. Karchin[3], F.J. Couch[1].* 1) Lab Med and Path, Mayo Clinic, Rochester, MN; 2) Health Sciences Research, Mayo Clinic Arizona, Scottsdale, AZ; 3) Institute for Computational Medicine, Department of Biomedical Engineering, Johns Hopkins University, Baltimore, MD.

Genetic testing of individuals with a family history of breast and/or ovarian cancer has led to the identification of many unique BRCA2 missense variants of uncertain significance (VUS). Current methods for classification of BRCA2 mutations depend heavily on the availability of information on segregation of VUS with breast and ovarian cancer within families, and on predicted probabilities of pathogenicity based on evolutionary sequence conservation. The failure to assess the clinical relevance of VUS, owing to insufficient genetic information, may deprive patients of the benefits of risk assessment and enhanced risk management available to those found to carry pathogenic mutations in BRCA2. In order to classify greater numbers of VUS that may or may not have available family data for segregation analysis, we have developed a homology directed DNA repair (HDR) assay for evaluation of the pathogenicity of BRCA2 VUS. This assay measures the influence of VUS in the DNA binding domain of BRCA2 on the HDR activity of the protein and has high sensitivity and specificity for established pathogenic missense mutations. Here we report on the assessment of 106 VUS located inside the BRCA2 DNA Binding Domain (DBD) (amino acid 2459 to 3190) using this assay. Whereas 47 variants had a 99% probability of being non-pathogenic, and were classified as non-pathogenic, 41 variants had a 99% probability of being pathogenic, and were classified as pathogenic by the HDR assay. The results from the assay were subsequently compared to predictions from the Align-GVGD sequence based prediction model (r=0.49). The categories of Align-GVGD associated with high probabilities of pathogenicity (p=0.66 to 0.81) were significantly different from the results of the HDR assay (p<0.05). In contrast, the Phenotype Optimized Sequence Ensemble (POSE) sequence model, trained on functional properties, displayed a moderate to strong correlation with the HDR assay (r=0.69). Overall, the results suggest that the prior probability of pathogenicity assigned to a number of VUS by the Align-GVGD model is too high and that the POSE model may be a useful method for selecting BRCA2 VUS for further evaluation by functional or family-based methods.

The role of the cilia protein Arl13b in activated-Smoothened medulloblastoma oncogenesis. *S.N. Bay[1,2], R.C. Castellino[3], T. Caspary[2].* 1) Genetics and Molecular Biology Program; 2) Dept of Human Genetics; 3) Dept of Pediatrics, Emory University, Atlanta, GA.

The proper balance of Shh signaling is critical to both development and adult homeostasis. Too little Shh signaling causes birth defects such as holoprosencephaly, while too much Shh signaling results in tumors, as occurs repeatedly in Gorlin syndrome patients. Indeed, overactive Shh signaling in a variety of tissues contributes to the formation of cancers including basal cell carcinoma and medulloblastoma - a tumor of the cerebellum that is the most common pediatric malignancy in the central nervous system. Many available treatments are inadequate; surgery, chemotherapy, and radiation are invasive and can cause long-term cognitive defects in patients, and current molecular therapies are prone to fail due to tumor resistance. The drawbacks of current treatments mean that new approaches are needed. Recent research has shown that Shh-derived medulloblastomas are “addicted” to cilia since cilia are required for proper Shh signaling. We study a ciliary GTPase called Arl13b that uniquely regulates Shh signaling, both upstream of Smoothened (Smo) and between Smo and Gli activation. Loss of Arl13b results in ligand-independent constitutive low-level pathway activation but prevents maximal signaling. Due to this unique relationship to Shh signaling, we predict that the loss of Arl13b will reduce the high levels of pathway output caused by constitutive activation of Smo. To determine whether loss of Arl13b can prevent or delay tumor formation, we deleted *Arl13b* in a mouse model of medulloblastoma. We also use mouse embryonic fibroblasts to define how the loss of Arl13b affects Smo localization and Shh pathway output in an activated-Smo signaling context. Together, these experiments will define whether Arl13b is a viable target for molecular therapies for the treatment of medulloblastoma and will reveal mechanistic details of Arl13b’s role in the regulation of normal Shh signaling and a disease-relevant activated Shh signaling context.

Modeling cancer in zebrafish embryos. *L. Francescatto, N. Katsanis.* Center for Human Disease Modeling, Duke University, Durham, NC.

Zebrafish has emerged as an invaluable model organism to study cancer proliferation, metastasis and invasiveness. Many characteristics make this model organism attractive to research experimentation, such as external embryonic development, transparency, high fecundity rate, and short generation time. In particular, the lack of an adaptive immune system during the first four weeks of development facilitates cancer xenotransplantation acceptance and survival. Chemical screenings have also enabled studies of cancer maintenance and proliferation. To date, several types of cancer cells have been successfully transplanted into different stages of the zebrafish embryo. The feasibility of this model prompted us to ask whether we could take primary cancer cells from patients and test them for tumorigenicity. We have successfully observed proliferation and migration of colon cancer cells from two patients, further confirming the potential of zebrafish in studying cancer. Using this model of cancer, we have undertaken a two-pronged approach that harnesses the power of this system. First, we have compared the exomes of distally attached human cells to non-migrating cell populations as a surrogate to identify candidate metastatic drivers. In parallel, we have initiated a small molecule screen to identify potential drugs that can inhibit either proliferation or migration of cancer cells. Zebrafish cancer xenotransplants provide an in vivo model that is cost and time efficient, and can be a first line of evidence for anticancer therapies.

Lifestyle Issues of BRCA Mutation Carriers that May Affect and Health Outcomes. *A. Caceres, R. McLamara, O. Ivanov, K. Wiercinski, C. Buffington.* Florida Hospital Celebration Health, Celebration, FL.

Rationale and Objectives. The BRCA protein helps to prevent cancer by repair of damaged or mutated cells and by enhancing apoptosis. Obesity, sedentary activity, a poor diet, life stressors and sleep loss cause metabolic and hormonal changes that increase the risk for mutagenesis, tumor growth and progression. Therefore, a healthy lifestyle is likely to be particularly important for reduction of cancer occurrence among BRCA mutation carriers. The purpose of this study was to study the lifestyles of BRCA mutation carriers and identify conditions that could increase their risk for primary or secondary cancer. Methods. The study population included 38 BRCA mutation cancer survivors, 45 BRCA mutation previvors, and 26 controls. Diet was analyzed by 3-day food records; physical activity, anxiety, quality of life were assessed by standardized questionnaires; and body size and composition were determined by 4-lead bioelectric impedance. Results. No significant differences between BRCA previvors, survivors or the non-BRCA mutation controls were found as regards diet (calories, macronutrient, micronutrient content), blood pressure, heart rate, body mass index, education, use of coffee, cigarettes or alcohol. Body weight and BMI also did not differ between groups although the BRCA survivors, as compared to previvors and controls, had a greater % of body fat and lower lean tissue mass in association with reduced physical activity and function. BRCA carriers (previvors and survivors, in comparison to controls) exhibited significantly (p<0.05) greater psychological distress (high anxiety, reduced emotional quality of life) than non-BRCA controls and in association to poor sleep quality and reduced sexual activity and libido. Conclusion. BRCA mutation carriers display several lifestyle conditions that could adversely affect health and quality of life including psychological distress, reduced sexual activity and libido, poor sleep quality, and adverse body composition relative to low physical activity and function.

3417M

Small molecule of natural origin has potential to activate TLR3 and aid in immunotherapy for cancer. *A. Das, J. Kaur, S. Sharma.* Biotechnology, Delhi Technological University, Delhi, Delhi, India.

Cytotoxic T lymphocytes (CTLs) and Natural killer (NK) cells mediate cellular immunity against tumor cells and virus infected cells.. CTLs recognize the peptides presented by MHC class I molecules present on the surface of target cells and kill them. But certain tumor and virus infected cells downregulate their MHC class I expression to escape this T cell response. Hence, NK cell mediated cytotoxicity, which is not MHC restricted becomes important for response against such MHC class I deficient target cells. Viral dsRNA triggers NK cell response by binding to their surface TLR3 receptors. In the presence of dsRNA the ectodomains of two TLR3 molecules dimerize which brings their cytoplasmic domains in close proximity to start the relay of intracellular signaling. So far only synthetic oligonucleotides have been used for studying the activation of NK cells. Here, we have proposed small molecules of natural origin which could dimerize the TLR3 ectodomains in a manner similar to dsRNA. These small molecules showed high affinity for TLR3 receptor. Hence, with the potential to activate NK cells and capability to selectively eliminate transformed cells; these compounds can be used as a combinatorial immunotherapy for cancer.

Accurate and inexpensive sequencing of *BRCA1* and *BRCA2*: Application to a US-wide study of breast cancer in Latinas. *M. Dean[1], J.F. Boland[2], M. Yeager[2], K.M. Im[1], J. Mitchell[2], D. Roberson[2], K. Jones[2], J. Sawitzke[3], S. Bass[2], X. Zhang[2], H. Lee[2], R. Eggebeen[2], V. Robles[4], C. Hollis[5], C. Barajas[5], E. Rath[6], C. Arentz[7], J.A. Figeroa[7], D.D. Nguyen[7], Z. Nahleh[6].* 1) Lab Experimental Immunology, NCI-FCRDC, Frederick, MD; 2) Cancer Genetics Research Laboratory, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Gaithersburg, MD; 3) Basic Science Program, Leidos Biomedical Research, Inc., Frederick, MD; 4) Nueva Vida, Richmond, Richmond, Virginia; 5) Latino Community Development Agency, Oklahoma City, OK; 6) Texas Tech University Health Sciences Center, El Paso, TX; 7) Texas Tech University Health Sciences Center, Lubbock, TX.

Germline mutations in the *BRCA1* and *BRCA2* genes are the most common cause of inherited breast cancer and are found in 5-10% of all cases. Detection of BRCA mutation carriers can lead to therapeutic interventions such as mastectomy, oophorectomy, hormonal prevention therapy and improved screening; as well as targeted therapies such as PARP-inhibition. African Americans and Hispanics are 3-4 times less likely to receive BRCA screening, despite having approximately the same mutation frequency as non-Jewish European Americans. Furthermore, both of these minorities have a higher mortality for breast cancer. To begin addressing this health disparity, we initiated a nationwide trial of BRCA testing of Latinas with breast cancer. Patients were recruited through community organizations, clinics, public events, and through the mail and internet. Subjects completed the consent process and questionnaire over the phone, and/or email contact, and provided a saliva sample by mail. DNA from 117 subjects was extracted from saliva and used to sequence the entire *BRCA1* and *BRCA2* coding regions and splice sites using a community designed panel at a total supply cost of $80/subject. A newly developed, more accurate polymerase (HiQ) allowed for the detection of mutations and elimination of many false positive results. Subjects ranged in age from 23-81 years (mean of 51 years), 6% had bilateral disease, 57% were ER/PR+, 23% HER2+; and 17%; had triple-negative disease. A total of 6 different predicted deleterious mutations, one newly described and the rest rare, were identified along with 4 variants of unknown effect. An alignment of all available primate *BRCA1* and *BRCA2* sequences was useful in analysis of unknown variants. Application of this strategy on a larger scale could lead to improved cancer care of minority and under-served populations.

3419S

How choriocarcinoma DNA identification can interfere in treatment decision? A report of two unexpected cases. *G.JF. Gattas[1], P. Exman[2], VD. Cantagalli[1], FT. Gonçalves[1], FN. Aguiar[2], REO. Ramos[2], MDPE. Diz[2].* 1) Dept of Legal Medicine, Bioethics and Occupational Health, Faculty of Medicine, University of Sao Paulo, Sao Paulo, Brazil; 2) Cancer Institute of Sao Paulo, Faculty of Medicine, University of Sao Paulo, Sao Paulo, Brazil.

Choriocarcinoma is a rare, highly malignant tumor, mainly with gestational origin, and rarely germ cell origin. The clinical presentation and histological characteristics of both tumors are identical but the origin differentiation is critical for treatment decision. DNA polymorphisms (STRs) used for forensic pourposes can be useful to identify paternal cells in paraffin wax embedded choriocarcinoma tumor cells, compared to patient's healthy cells, to characterize gestational origin. We here describe two patients that were evaluated after histologic diagnosis of choriocarcinoma. The first patient was a 21 years old woman with previous abortion history and clinical presentation extremely suggestive of gestational disease. After no favorable treatment results the tumor DNA analysis, using MiniFiler Kit (Applied Biosystems), was realized and revealed identical profile when compared to the patient's blood sample. Thus, the treatment was changed for BEP (Bleomicin, Ethoposide and Cisplatin) that is considered the first line treatment for an ovarian germ cell tumor. The patient achieved pathologic complete response, with no disease evidence in 2 year follow-up. The second case was a 54 years old woman with initial presentation of metastasis within the pulmonary artery and absence of other disease site with biopsy confirmation as choriocarcinoma. The main hypothesis was gestational origin and she was firstly treated with BEP with partial results and no serum marker response. DNA STRs analysis showed the presence of additional genetic material, beyond the maternal one for all 8 STRs evaluated, including Y chromosome. The results indicated paternal contribution (confirmed with the husband DNA) and the treatment was then changed to dactinomycin, and patient achieved complete radiologic and of serum marker response. These two cases suggest that DNA STRs could be used as a necessary tool to confirm the gestational origin of choriocharcinomas even when the clinical case is not indicative of it. Financial Support: LIM-40 (HC-FMUSP); FAPESP (09/54868-6).

3420M

A simple mainstreamed, oncogenetic pathway delivers fast, affordable routine BRCA testing for ovarian cancer (OC) patients. *H. Hanson[1,2], D. Riddell[1], F. Smith[1], V. Cloke[1], M. Gore[3], S. Banerjee[3], N. Rahman[1,2], MCG consortium.* 1) Division of Genetics & Epidemiology, The Institute of Cancer Reserach, London, United Kingdom; 2) Cancer Genetics Unit, Royal Marsden NHS Foundation Trust, London, United Kingdom; 3) Gynaecology Unit, Royal Marsden NHS Foundation Trust, London, United Kingdom.

Background ~15% of ovarian cancer (OC) patients carry a BRCA mutation, yet historically are under-referred to Cancer Genetics (CG) services. NICE (2013) recommended that BRCA testing be offered to individuals with ≥10% chance of mutation detection. This and development of targeted agents e.g PARP inhibitors make it essential that OC patients can access genetic testing within an appropriate time frame. We developed an "oncogenetic model" to facilitate testing in routine oncology care. Methods Patients with non-mucinous OC <65 years at Royal Marsden Hospital were offered BRCA gene testing at their oncology appointment by cancer team members who had completed 30min online training. The test results were interpreted by genetics and returned to the patient by the cancer team. All mutation carriers attended a Genetics appointment for detailed discussions and to organise testing for relatives. Any patient could contact genetics at any time, if required. Patients and clinicians were sent a questionnaire to assess their experience. Results 119 OC patients were tested in 6 months. Patients were tested during initial treatment (n=32), relapse (n=45) or follow-up (n=42). 20 (17%) carried a mutation: 8 *BRCA1*, 12 *BRCA2*. 12 had no family history, 8 met current genetic referral criteria. BRCA results changed management in 9/20 (45%) carriers. No patient requested additional Genetics input before testing. Questionnaires were sent to 71 patients; 46/57 non-carriers and 11/14 carriers responded. All were pleased to have had testing, and to have accessed testing within Oncology. All understood the results potentially had implications for themselves and their family. 25 clinicians undertook training. All welcomed the opportunity to offer testing and felt confident in consenting and giving results. Conclusions The Oncogenetic testing pathway provides flexible, patient-centred, equitable, high-throughput gene testing with considerable time and cost savings compared to traditional pathways. It is now the standard BRCA testing pathway for non-mucinous OC patients at Royal Marsden and roll-out to other NHS centres is planned.

3421T

Inhibition of STAT3 and RelA expression levels Bortezomib treated K-562 leukemic cells and indiction of apoptosis. *N. Selvi Günel[1], B. Tazcanli Kaymaz[1], S. Kipçak[1], A. Dalmizrak[1], B. Kosova[1], G. Saydam[2].* 1) Department of Medical Biology, Ege University, Izmir, Turkey; 2) Department of Hematology. Ege University, Izmir, Turkey.

Signal transducer and activator of transcription (STAT) proteins; especially STAT3, are crucial for signalling pathways leading to discover the underlying cancer development mechanism. Activated STAT3 increases leukemic cell proliferation and survival; also suppresses anti-tumour immunity and apoptosis by promoting pro-oncogenic pathways, including nuclear factor-κB (NF-κB). RelA is one of the gene products of NF-κB that gives rise to increase in STAT3 activation. Bortezomib (BOR) is a first class of proteasome inhibitor, and used in of multiple myeloma and mantle cell lymphoma treatment. In this study, we aimed to identify the cytotoxic and apoptotic effects of BOR upon chronic myelogenous leukemia (CML) cell model K562, with determining STAT3 and RelA expressions both at mRNA and protein levels. Cell proliferation was assessed by XTT assay in order to determine cytotoxicity of BOR upon leukemic cells. While mRNA expression levels of STAT3 and RelA were analyzed by qRT-PCR; protein expressions were detected via western-blot method. IC50 was calculated as 17.7 nM for 72th hour. Number of apoptotic cells were increased by 37% and 38% for 72th-96th hours (p=0.0041, p=0.0038). While STAT3 mRNA expression was significantly decreased by 66% [(2.86 fold; p= 0.0043)] at 72th hour, Rel A was downregulated by 45.8% and 83.63% [(1.83 fold; p= 0.003), (6.1 fold; p=0.0002)] for 72th and 96th hours. As for protein results, both Rel A and STAT3 protein expressions were highly inhibited in a time dependent manner.

Real-time and sequential profiling of cancer through concurrent somatic mutation and gene amplification analysis of cancer by digital sequencing of cell-free DNA from patients with metastatic solid tumors.

A. Talasaz[1], S. Mortimer[1], B. Schiller[1], G. Mei[1], D. Sebisanovic[1], L. Siew[1], A. Zapanta[1], S. Huang[2], D. Hoon[2], H. Eltoukhy[1]. 1) R&D, Guardant Health, Redwood city, CA; 2) Dept Molecular Oncology, John Wayne Cancer Institute, Santa Monica, CA 90404.

Introduction: Genomic profiling of cell-free DNA (cfDNA) through a simple blood test is non-invasive, sequential and can potentially be more predictive than tumor profiling. Due to high concordance of tumor and cfDNA, this blood test can be considered when biopsies are not an option due to the risk, cost, or time. **Methods:** We used single-molecule digital sequencing technology, Guardant360 for high-fidelity and comprehensive profiling of 54 actionable genes in cfDNA of more than 500 metastatic cancer patients. This technology allows concurrent profiling of somatic mutations, gene amplifications and fusions. The longitudinal blood samples from patients have been processed to assess residual disease post surgical resection or targeted treatments. **Results:** The overall detection rate of somatic alterations in cfDNA approached 90% for all indications (breast, lung, colorectal, melanoma and prostate). When blood samples were concurrent with biopsies, the concordance of alterations was 93%. Residual disease in 30 colorectal and melanoma patients post multi-surgical resection has been studied (2-7 draws). The alterations were positively correlated with clinical status of the patients. In 70 colorectal patients, plasma samples post targeted treatment were processed. A combination of previously reported and novel resistance-related alterations were found in cfDNA from the post targeted treatment samples. **Conclusions:** Comprehensive sequencing of patient's cancer in real-time through simple blood test can empower oncologists in making more informed treatment decisions, especially when tissue biopsy is not an option.

Introduction. Constitutive mismatch repair deficiency syndrome (CMMR-D) is a recently described childhood cancer predisposition syndrome involving biallelic mutation of MMR genes (MLH1, MSH2, MSH6 and PMS2). More than 140 cases have been previously reported but only as case reports. Methods. We performed a retrospective review of all 31 cases of CMMR-D from 23 families diagnosed in French genetics laboratories in order to describe clinical characteristics, treatment and outcome of malignancies, and biological diagnosis data of an unselected series of patients. Results. Overall, 67 tumors were diagnosed in these 31 patients, 17 (25%) hematologic malignancies, 22 (33%) brain tumors, 25 (37%) Lynch syndrome-associated malignancies, and 3 (5%) other tumors. Median age of onset of first tumor was 6.98 years [1.23-33.53]. 23 (74%) patients had NF1-unrelated CALMs or hypopigmented macules and 4 (13%) had brain malformative features. Colorectal adenomas were found in all 16 patients who have had colonoscopy with synchronous colorectal cancer or advanced adenoma in all of them. Overall, 18 patients died, 7 (39%) due to the primary tumor. Median survival after diagnosis of the primary tumor was 23 months [0.26-213.2]. Among the patients who survived after their first malignancy, 20 developed a second malignancy. No obvious excess of toxicity to treatment was reported. A familial history of LS-associated cancer was found in only 6 families, and consanguinity in 43% of cases. PMS2 mutations (18 patients) were more frequent than mutations of MLH1 (4 pts), MSH2 (3 pts) and MSH6 (6 pts). Conclusion. CMMR-D is a severe condition associated with multiple malignancies in childhood. Its rarity warrants international collaboration to define diagnosis criteria and guidelines for surveillance and prevention in order to decrease tumor-related mortality.

3424T

Germline *TP53* mutation analysis in HER2-positive breast cancer patients from Southern Brazil. *M. Fitarelli-Kiehl[1,2], J. Giacomazzi[1,2], P. Santos-Silva[1,3], V.B. Sempé[1], D. de Mendonça Uchôa[4], L.F. Rivero[4], M.S. Graudenz[4], P. Ashton-Prolla[1,2,3,5].* 1) Experimental Research Center, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 2) Post-Graduate Program in Genetics and Molecular Biology, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 3) Post-Graduate Program in Medicine: Medical Sciences, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 4) Department of Pathology, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 5) Department of Genetics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil.

Germline *TP53* mutations are associated with Li-Fraumeni Syndrome (LFS), an autosomal dominant disorder characterized by predisposition to multiple early-onset cancers including breast cancer (BC), the most prevalent tumors among LFS women. Recent reports show that *TP53* mutation carriers have a significantly higher likelihood of developing a BC overexpressing HER2 (63-83%) when compared to mutation-negative BC cases (16-25%). Germline *TP53* mutations are estimated to occur in 1 to 8.6% of patients with early onset BC unselected for family history of cancer, and HER2-positive status supposedly increases the odds of having a germline *TP53* mutation by nearly 7-fold. In this work, we determined the prevalence of germline *TP53* mutations in a cohort of women with HER2 overexpressing BC, diagnosed before age 60, unselected for family history of cancer. We retrospectively reviewed the immunohistochemistry data of BC from patients diagnosed at Hospital de Clínicas de Porto Alegre between years 2007 and 2012, and 106 women who fullfilled inclusion criteria were recruted and periferic blood was colected. Germline *TP53* sequence variants were identified by High Resolution Melting (HRM) analysis followed by Sanger DNA sequencing of the entire coding sequence and flanking intronic regions. Among 106 patients analyzed, 2 (1.9%, 95% CI 0.5-6.6%) were found to carry a *TP53* mutation with known pathogenic effect, and other 5 patients (4.7%, 95% CI 2.0-10.5%) shown sequence variants with unknown effect on p53 function (all variants with MAF<0.01). One patient with pathogenic mutation met classic LFS criteria. Although we found a low prevalence of germline *TP53* pathogenic mutations in HER2 overexpressing BC patients, *TP53* testing should be considered in these cases even in the absence of family history of cancer.

3425S

The *DICER1* Leiden Open Variation Database (LOVD). *N. Hamel[1], W.D. Foulkes[1,2,3].* 1) Dept Med Gen, McGill Univ Hlth Ctr, Montreal, PQ, Canada; 2) Lady Davis Res Inst Jewish Gen Hospital, Montreal, PQ, Canada; 3) Depts Oncology & Hum Genet, McGill University, Montreal, PQ, Canada.

Over the past several years, we and others have worked to describe the phenotypes associated with the *DICER1* pleiotropic tumor syndrome (OMIM 601200). While some tumors are strongly indicative of an inherited *DICER1* mutation even in the absence of other phenotypes (e.g. pituitary blastoma), many tumor types must be seen in combination with other *DICER1*-associated tumors or tell-tale phenotypes such as multinodular goiter in the patient or his or her relatives in order for the presence of a *DICER1* mutation to be expected. The Leiden Open Variation Database (LOVD) is an open source database framework that provides a flexible, freely available tool for Gene-centered collection and display of DNA variations. The *DICER1* LOVD database, https://grenada.lumc.nl/LOVD2/mendelian_genes/home.php?select_db=DICER1, is curated by our research group and contains an inventory of index patients with reported germ-line mutations in *DICER1* along with the associated phenotypes observed in the carrier family. Data compiled from the database to date shows that the majority of inherited mutations are frameshift and nonsense mutations predicted to result in protein truncation, though some pathogenic missense mutations are also observed. Some mutations are observed more than once in apparently unrelated families, suggesting either a common ancestry dating back several generations or a hot spot area in the gene where these specific mutations are more likely to arise. No case of homozygous or compound heterozygous mutation carrier has been reported to date, suggesting that carrying two mutated copies of *DICER1* in the germ-line may be incompatible with life. Associated tumor types reported in the database include pleuropulmonary blastoma, Wilms tumor, cystic nephroma, Sertoli-Leydig cell tumor and embryonal rhabdomyosarcomas, among others. It is our goal to make the *DICER1* LOVD database a central repository for all germ-line *DICER1* mutations. We believe that compiling all genotype and phenotype data relating to this syndrome in one publicly available location will provide an increasingly clearer picture of this syndrome and will be a useful resource for anyone attempting to assess whether phenotypes observed in particular patients are consistent with a *DICER1* inherited mutation. We therefore invite all research and clinical teams who have mutation and phenotype data from affected families to contribute to this group effort and submit their information to the database.

3426M

Breast Cancer in *PTEN* Hamartoma Tumor Syndrome: Can a Predictive Fingerprint Be Identified? *A. Machaj[1], J. Mester[2], C. Eng[2].* 1) Case Western Reserve University, Cleveland , OH; 2) Genomic Medicine Institute, Cleveland Clinic, 9500 Euclid Ave. NE50 Cleveland, OH 44195.

Breast cancer is predicted to occur in up to 85% of women with PTEN Hamartoma Tumor syndrome (PHTS) in a lifetime. PHTS includes patients with Cowden Syndrome (CS) and other conditions with germline mutation of the *PTEN* tumor suppressor gene. Little is known about the histopathologic features and molecular profile of PHTS-related breast cancers. Previous work found that CS-related breast cancer is associated with a molecular apocrine subtype (Banneau et al. 2010). Our study sought to validate these pilot observations in a large independent series and investigate other predictors of germline *PTEN* mutation status in a breast cancer series. A total of 1844 adult women with CS/CS-like features and invasive breast cancers were enrolled. Patients had germline *PTEN* PCR-based mutation analysis and MLPA/qPCR. Outside pathology reports and materials were requested for re-review and immunohistochemical analysis (IHC) of PTEN, pAKT, and androgen receptor (AR). Blood-PTEN/pAKT protein levels and *a priori* mutation risk via the Cleveland Clinic PTEN risk calculator (CC score) were available for 1258 patients. Nominal descriptive statistics, chi-square bivariate analyses, and multivariate logistic regression were used to find associations between potential predictors and germline *PTEN* mutation status. 43 female adults had germline *PTEN* mutation; pathology materials were available for 25. Most breast cancers had ductal histology (80%), and were ER/PR+ (64%), AR+ (75%) and HER2+ (14%). Apocrine features, atypical apocrine adenosis, and atypical ductal hyperplasia were found more often in background breast tissue of PHTS patients compared to published frequencies. Of 12 cases with complete biomarker data, 1 (8%) fit the molecular apocrine profile criteria. All tumors expressed PTEN and pAKT on IHC. Low blood-PTEN protein (p=0.01), high blood-pAKT (p=0.04), and higher CC score (p=0.01) were predictive of germline *PTEN* mutation. Breast cancer histology and molecular profile in these PHTS patients were comparable to general population patterns and not consistent with a molecular apocrine profile. Distinctive PTEN-associated features were noted in surrounding non-malignant breast tissue. Blood PTEN/pAKT protein levels and CC score were significant predictors of germline *PTEN* mutation, and if replicated, could be applied in a clinical setting to rapidly identify breast cancer patients who may benefit from genetics referral.

3427T

Further Defining the Polyposis Phenotype Associated with *PTEN* Mutations. *L. Panos[1], E. Weltmer[1], H. LaDuca[1], R. McFarland[1], E. Chao[1, 2].* 1) Ambry Genetics, Aliso Viejo, CA; 2) University of California, Irvine, School of Medicine, Irvine, CA.

PTEN hamartoma tumor syndrome (PHTS) is associated with an increased risk for colonic polyposis, particularly hamartomatous polyps. With the advent of multi-gene panel testing, *PTEN* mutations have been identified in patients with other polyp histologies, potentially widening the spectrum of gastrointestinal disease burden in these patients. We sought to define the polyp spectrum amongst *PTEN* mutation carriers identified by multi-gene panels. In a review of over 14,000 results of five multi-gene panels (*BRCA*plus, BreastNext, ColoNext, OvaNext, and CancerNext) that include full gene sequencing and gross deletion/duplication analyses of *PTEN* resulted between March 2012 and March 2014, 23 (0.15%) *PTEN* positive cases were identified. Clinical histories provided by ordering clinicians were reviewed, and clinicians were contacted to confirm history. Family history of polyposis was not assessed. Of the *PTEN* positive cases, 11/23 (47.8%) had a reported personal history of colonic polyps of varying type and quantity. Four patients met criteria for attenuated or classic familial adenomatous polyposis, with one having 20-99 adenomas, one having 20-99 adenomas and 20-99 hamartomas, and two having greater than 100 adenomas. Two patients presented with less than 10 adenomas, but had other polyp types including mucosal, inflammatory, hyperplastic, and a rectal lipoma. One patient presented with 10-19 hamartomas. In 4 individuals polyps were reported without further information. These results reveal that the polyp burden in *PTEN* positive patients expands beyond hamartomatous polyps. However, our study was limited to information reported by ordering providers, which may be influenced by patient recall, inability to access prior medical records, or lack of prior screening colonoscopy. Furthermore, subjective pathological review of polyps may complicate the characterization of CS-associated gastrointestinal manifestations. Additional studies focused on polyp histologies of *PTEN* mutation carriers would help further delineate the gastrointestinal disease burden in these individuals. Our findings suggest that *PTEN* mutations should be part of the differential diagnosis for individuals with adenomatous and mixed polyposis and support the use of multi-gene panel testing in patients with colonic polyposis.

3428S

Mutation and uncertain variant findings in ethnic minority patients undergoing multi-gene panel testing for cancer risk assessment at a safety-net public hospital. *CN. Ricker, JD. Sturgeon, SB. Gruber.* USC Norris Comprehensive Cancer Center 1441 Eastlake Ave. Los Angeles California 90033.

Rapid integration of multi-gene testing into clinical cancer genetics has lead to an emerging body of literature that has not yet focused on individuals from diverse racial/ethnic minority groups. We report on a retrospective IRB approved chart review of 170 underserved minority patients who underwent a 25 cancer gene test (Myriad Genetics) from September 2013 to May 2014 at Los Angeles County + USC Medical Center. The majority were female (n=155, 91.2%) and race/ethnicity was; 81.2% Latino (n=138); 11.8% Asian (n=20), and 7.1% Black (n=12). Eighty-one percent had a cancer diagnosis (n=137) with an average age at diagnosis of 44 years (SD=9), 60.6% (n=83) with breast cancer and 19.7% (n=27) with colorectal cancer. Overall, 15.9% (n=27) had a deleterious mutation identified and rates were comparable across race/ethnic groups. Eighteen percent of cancer patients had a mutation detected (n=25); 17 in high-risk genes (*APC* n=1; *BRCA1* n=6; *BRCA2* n=3; *CDH1* n=2; *MLH1* n=3; *MSH2* n=1; *TP53* n=1), 5 in moderate-risk genes (*ATM* n=2; *CHEK2* n=1; *RAD51C* n=1; *RAD51D* n=1) and 3 *MUTYH* heterozygotes. Two mutations were detected (*BRIP1* and *MUTYH*) in 33 unaffected women tested. A total of 133 variants of uncertain significance (VUS) were identified in 90/170 patients (52.9%), 41.1% with two or more VUSs and 12.1% with three or more. While not statistically significant, there was a marginally higher proportion of VUSs in individuals with cancer (0.54) compared to those without cancer (0.48). When stratified by race/ethnicity, the VUS rate was 83.3% for Blacks, 65.0% for Asians, and 48.6% for Latinos. Several variants were seen at least four times; *ATM* (c.2289T>A), *CDKN2A* (c. -2G>A), and *PTEN* (c.802-51_802_del14). The proportion of VUSs was compared to four published cohorts and was statistically significantly higher (p=0.001). Deleterious mutations were identified in 18% of cancer patients tested, 40.0% (10/25) in genes that would not have been interrogated prior to multi-gene panel testing, given the limited resource setting of this safety net hospital. Over 50% of individuals had at least one VUS, emphasizing the need for greater attention to the classification of VUSs in racial/ethnic minority patients. Further studies are necessary to expand understanding of implementation and utilization of genetic advances across broad clinical settings. Supported by Norris Cancer Center Core Grant NCI P30CA014089; ACS RSGT 1020301; Avon Foundation 052011057; Lynne Cohen Foundation.

3429M

Majority of *PTEN* mutations identified on multi-gene panel tests are in non-classic patients: Expanding clinical phenotype or incomplete clinical history? *E.C. Weltmer[1], L. Panos[1], H. LaDuca[1], R. McFarland[1], E.C. Chao[1,2].* 1) Ambry Genetics, Aliso Viejo, CA, USA; 2) University of California, Irvine, School of Medicine, Irvine, CA, USA.

PTEN hamartoma tumor syndrome (PHTS), including Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome (BRRS), and *PTEN*-related Proteus syndrome (PS), is a phenotypically diverse but well-described clinical condition. Pathogenic *PTEN* mutations are detected in most patients meeting clinical criteria for CS and BRRS (up to 85% and 65%, respectively). However, individuals harboring *PTEN* mutations without meeting criteria for PHTS have been reported. In this study, we sought to characterize the clinical phenotypes of individuals who were found to harbor a pathogenic *PTEN* mutation through hereditary cancer multi-gene panel testing. A retrospective analysis of 14,897 hereditary cancer multi-gene panels including comprehensive analysis of *PTEN* reported at our laboratory from March 2012 to March 2014 identified 23 cases with pathogenic *PTEN* mutations (0.15%). Multi-gene tests included: high risk breast cancer panel (6 genes), moderate/high risk breast cancer panel (18 genes), colon cancer panel (14 genes), ovarian cancer panel (23 genes), and general cancer panel (28 genes). Clinical histories were reviewed for these cases, with emphasis on whether a clinical diagnosis of CS, BRRS, or other PHTS condition was suspected. Six of the 23 *PTEN*-positive cases (26.1%) met National Comprehensive Cancer Network (NCCN) CS/PHTS testing criteria. Most of the *PTEN*-positive cases in our study population (n=17, 73.9%) did not meet diagnostic or testing criteria for CS. Of these 17 cases who did not meet criteria, histories were confirmed in 15 by additional consultation with the ordering clinician. Seven individuals reportedly met one major and one minor criterion, five met one major criterion only, one met two minor criteria only, and two individuals met no CS criteria. Ordering clinician bias toward cancer history may result in incomplete clinical data and explain why most positive patients did not appear to meet CS criteria. It is also possible that a broader PHTS phenotype is being revealed through multi-gene panel testing, which is often ordered for individuals whose clinical features are atypical or of lower penetrance. Follow-up analyses of PHTS features in *PTEN*-positive individuals identified through panel testing, who have a broader spectrum of referral indications, will provide additional insight regarding the lack of CS in a panel-based PHTS-positive cohorts.

3430T

DNA methylation profiling to assess pathogenicity of *BRCA1* unclassified variants in breast cancer. *K. Flower[1], N.S. Shenker[1], M. El-Bahrawy[2], D.E. Goldgar[3], M.T. Parsons[4], A.B. Spurdle[4], J.R. Morris[5], R. Brown[1,6], J.M. Flanagan[1], KConFab Investigators, AFFECT study group.* 1) Epigenetics Unit, Department of Surgery and Cancer, Imperial College London, London, UK; 2) Department of Histopathology, Hammersmith Hospital, Imperial College London, UK; 3) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, USA; 4) QIMR Berghofer Medical Research Institute, Brisbane, QLD, Australia; 5) Genome Stability Unit, School of Cancer Sciences, University of Birmingham, UK; 6) Section of Molecular Pathology, Institute for Cancer Research, Sutton, UK.

Germline pathogenic mutations in *BRCA1* increase the risk of developing breast cancer, and can inform clinical decisions on treatment of breast cancer cases as well as risk reduction for mutation carriers. However, screening for mutations in the *BRCA1* gene frequently identifies sequence variants of unknown pathogenicity (unclassified variants) and recent work has aimed to develop methods for determining variant pathogenicity. We have previously shown that tumour DNA methylation profiles can differentiate *BRCA1* mutated tumours from *BRCA1* wild type tumours from high-risk families with no known mutations (BRCAx). We hypothesised that we could predict pathogenicity of variants based on DNA methylation profiles of tumours that had arisen in carriers of unclassified variants. We selected 150 FFPE breast tumour DNA samples (47 *BRCA1*, 65 BRCAx, 38 *BRCA1* test variants) and analysed a subset of these (n=60) using the Illumina 450K methylation platform. We identified 23 probes associated with mutation status (fdr p<0.05), and apparently independent of ER status and grade. Bisulphite pyrosequencing of the remaining 90 samples validated four independent novel loci (*BACH2*, *C8orf31*, *C17orf108* and *LOC654342*) to be associated with mutation status, but three of these were shown to be at least partially correlated with ER status and grade. These methylation markers were combined into a logistic regression model to predict pathogenicity of 27 unique variants from the independent test set, and LRs determined from methylation status used to calculate a posterior probability of pathogenicity. There were no major inconsistencies in predictions based on tumour methylation compared to those determined using standard multifactorial likelihood analysis that included information from segregation, co-occurrence, family history and ER-grade histopathological predictions. In particular, prediction of pathogenicity was consistent for *BRCA1* IVS 19-12 G>A with high probability of pathogenicity (P>0.99), whereas 15 variants were considered not pathogenic or likely not pathogenic using both approaches. A further two variants that are currently of uncertain classification using current methods show low probability of pathogenicity using our methylation prediction model. We conclude that tumour DNA methylation data has potential to be used in prediction of *BRCA1* variant pathogenicity.

3431S

Overexpression of MicroRNA-200c predicts poor outcome in patients with PR-negative breast cancer. *K. Luostari[1], M. Tuomarila[1], Y. Soini[1], V. Kataja[2], V.-M. Kosma[1], A. Mannermaa[1].* 1) Institute of Clinical Medicine, Clinical Pathology and Forensic Medicine, University of Eastern Finland, Kuopio, Finland; 2) Institute of Clinical Medicine, Oncology, University of Eastern Finland, Kuopio, Finland.

Micro-RNAs are small, noncoding RNAs that can act as tumor suppressors or oncogenes. MiR-200c is a member of the miR-200 family; it is known to be dysregulated in invasive breast carcinoma. MiR-200c maintains the epithelial-mesenchymal transition and inhibits cell migration and invasion. Recent studies have shown miR-200c to regulate steroid hormone receptors, estrogen receptors (ER), and progesterone receptors (PR). The present study detected miR-200c in 172 invasive breast carcinoma cases selected from a prospective cohort enrolled in Kuopio, Eastern Finland, between 1990 and 1995. MiR-200c expression was determined with relative qPCR, and results were compared to clinicopathological variables and patient outcome. We found that PR status combined with miR-200c expression was a significant marker of outcome. High miR-200c expression was associated with reduced survival in PR-negative cases (n = 68); low miR-200c expression indicated reduced survival in PR-positive cases (n = 86) (Cox regression: P = 0.002, OR = 3.433; and P = 0.004, OR = 4.176, respectively). In addition, in PR-negative cases, high miR-200c expression was associated with shortened relapse-free survival (Cox regression: P = 0.001, OR = 3.613); increased local/distant recurrence (Logistic regression: P = 0.006, OR = 3.965); and more frequent distant metastasis (Logistic regression: P = 0.015, OR = 3.390). We also found that high grade and low stage tumors were positively correlated with high miR-200c expression (Logistic regression: P = 0.002, OR = 2.791 and P = 0.013, OR = 3.911, respectively). Our results indicate that miR-200c may play a role in invasive breast carcinoma. Furthermore, miR-200c combined with PR status provides a refined predictor of outcome. This data may provide a basis for new research target - progesterone receptor - regulated microRNAs in breast cancer.

3432M

PDGFB hypomethylation is a favorable prognostic biomarker in primary myelofibrosis. *M. Miozzo[1, 2], C. Augello[1], F. Rossella[1], S. Tabano[1], E. Bonaparte[1, 2], M. Ciboddo[1], L. Paganini[1], D. Cattaneo[3], A. Iurlo[3], A. Cortellezzi[1, 3], S. Bosari[1, 2], S.M. Sirchia[4].* 1) Department of Pathophysiology and Transplantation, Università di Milano, Milano Milano, Italy; 2) Unit of Pathology, Fondazione IRCCS Ca' Granda Ospedale Maggiore, Milano; 3) Hematology and Transplantation UnitFondazione IRCCS Ca' Granda Ospedale Maggiore, Milano; 4) Department of Health Sciences, Università di Milano.

Primary myelofibrosis (PMF) is a myeloproliferative condition characterized by the clonal proliferation of the hematopoietic precursors and progressive development of bone marrow fibrosis. This stromal alteration is an important clinical issue and specific prognostic markers are not today available. JAK2, MPL and CALR genes are frequently mutated in PMF and are mutually exclusive. Mutations of TET2, ASXL1, DNMT3A and IDH1/2 are present in about 20% of PMF cases. It is intriguing that these loci are involved in the epigenetic regulation of cells and are associated with epigenetic alterations in cancer, suggesting that epigenetic defects could be also present in PMF. In 65 bone marrow biopsies from 58 PMF patients, stratified by clinical classification and JAK2/CALR and IDH mutations, we explored the methylation pattern of genes encoding for cytokines involved in the stromal reaction: PDGF, TGFB and FGF2. We also evaluated the methylation profile of the LINE-1. The methylation was analyzed using the pyrosequencing approach. In agreement with the European consensus of bone marrow fibrosis grading, the cases were categorized at diagnosis as cellular phase (MF-0 n=12) and fibrotic phases (MF-1 n=30; MF-2 n=18 and MF-3 n=5). The follow-up ranged from 6 to 287 months (average 76 months). As controls, we included 20 cases of iliac bone fragments from patients who underwent surgery for iliac bone prosthesis. We found that PDGFB, FGF2 and LINE-1, but not TGFB, methylation levels were heterogeneous and dynamic in the different phases of PMF compared to controls. The distribution of PDGFB and FGF2 methylation percentages in the subgroups of PMF cases showed that for both genes the methylation values in MF0 are significantly higher compared to controls (PDGFB, FGF2: $p < 0.0005$) and MF1 and MF2 cases showed a subgroup of cases with hypomethylation. PDGFB hypomethylation (<15%) was correlated with a favorable PMF prognosis ($p=0.03$, $p=0.01$ and $p=0.02$ for fibrosis, the International Prognostic Scoring System and the Dynamic International Prognostic Scoring System, respectively). In addition, low PDGFB methylation levels were mainly present in cases from young patients with normal karyotype and LINE-1 hypermethylation, genetic features associated with global genome stability.

MiR-145 regulates stem cell characteristics of human laryngeal squamous cell carcinoma Hep-2 cells. *M. Ozen[1,2], O.F. Karatas[2,3], I. Suer[2], B. Yuceturk[2], M. Yilmaz[4], H. Cansiz[4], M. Ittmann[1], M. Solak[5].* 1) Department of Pathology & Immunology Baylor College of Medicine, Houston, TX, 77030, USA; 2) Department of Medical Genetics, Istanbul University Cerrahpasa Medical School, Istanbul, Turkey; 3) Molecular Biology and Genetics Department, Erzurum Technical University, Erzurum, Turkey; 4) Department of Otorhinolaryngology, Cerrahpasa Medical School, Istanbul University, Istanbul, Turkey; 5) Afyon Kocatepe University Medical School Department of Medical Genetics.

The Cancer Stem Cells (CSCs) are tumorigenic cells promoting initiation, progression and spread of the tumor. Accumulating evidences has proven the existence of CSCs in a variety of tumors including lung, brain, breast, prostate, colon, head and neck and ovarian cancers. They are identified by their tissue specific stem cell-like properties including self-renewal and having potential to differentiate. miRNAs have been proposed as significant regulators of carcinogenesis and CSCs. A recent study that utilized Dicer or Dgcr8 knockout mice, which lacks global miRNA processing, showed that cells failed in self-renewal due to lack of downregulation of stem cell specific markers, pointing the importance of miRNAs in establishing stem cell identity. Furthermore, a number of miRNAs have been proposed to have direct roles in survival of CSCs. Understanding the contribution of miRNAs as regulators in these processes will help providing the opportunity to develop miRNA-based therapeutic approaches. In this study, we aimed to explore the role of miR-145, which is downregulated in laryngeal squamous cell carcinoma (LSCC), on cancer stem cell potency of laryngeal cancer cells. First of all, we demonstrated the downregulation of miR-145 expression in CD133+ cells directly isolated from freshly resected LSCC tumor tissues (n=20). qRT-PCR analysis of miR-145 transfected Hep-2 cells demonstrated the inhibition of stem cell markers such as SOX2, OCT4, KLF4 and ABCG2 upon miR-145 upregulation. We further investigated the stem cell features of miR-145 overexpressing Hep-2 cells by sphere formation assay, single cell cloning assay, colony formation assay, and Aldehyde Dehydrogenase assay, which all demonstrated the inhibition of stem cell potency upon miR-145 overexpression. In conclusion, we have demonstrated the regulatory role of miR-145 in stem cell characteristics of Hep-2 cells. Based on these results, we propose that mir-145 might carry crucial roles in LSCC tumorigenesis, prognosis, metastasis, chemoresistance and recurrence through regulating stem cell properties of tumor cells.

Methylation of *MLH3* Promoter: new recurrent finding in low grade gliomas. *H. Lhotska[1], Z. Zemanova[1], H. Cechova[2], L. Lizcova[1], S. Ransdorfova[2], F. Kramar[3], Z. Krejcik[2], K. Svobodova[1], D. Bystricka[1], K. Michalova[1,2].* 1) Center of Oncocytogenetics, General University Hospital and 1st Faculty of Medicine, Charles University, Prague, Czech Republic; 2) Institute of Hematology and Blood Transfusion, Prague, Czech Republic; 3) Department of Neurosurgery, Central Military Hospital and 1st Faculty of Medicine, Charles University, Prague, Czech Republic.

Astrocytomas and oligodendrogliomas (WHO grade II) are the most common histological subtypes of low-grade gliomas (LGGs). Several markers such as 1p/19q codeletion, mutations of *TP53*, *IDH1* and/or *IDH2* genes and epigenetic biomarkers, i.e. methylation of *MGMT* promoter have been used to predict patient's prognosis or response to treatment. The aim of this study was to investigate genetic and epigenetic background of LGGs in order to search for new markers that might play a role in tumor progression or patient's response to the treatment.

Biopsies from 41 patients with LGGs (25 astrocytomas, 16 oligodendrogliomas) were analysed using iFISH with the panel of VYSIS locus specific and centromeric probes (Abbott Molecular), SNP array (HumanCyto SNP-12 Bead Chip, Illumina), and MLPA (P370-A1 kit, MRC-Holland) to assess copy number variations and *IDH1*/*IDH2* mutations status in glial cells. Methylation of promoters was investigated using methylation-specific MLPA (ME011 kit, MRC-Holland).

In oligodendrogliomas, 1p/19q codeletion was frequent finding observed in 81% of patients. In astrocytomas, recurrent aberration was uniparental disomy of 17p (60%). Somatic mutation R132H of *IDH1* gene was detected in 81% of oligodendrogliomas and in 72% of astrocytomas. Methylation of *MGMT* promoter was present in 100% of oligodendrogliomas and in 84% of astrocytomas. *MLH3* (DNA mismatch repair gene) promoter methylation was observed in 69% of oligodendrogliomas and 28% of astrocytomas.

Methylation of *MGMT* promoter, 1p/19q codeletion and mutated *IDH1* were the most recurrent aberrations found in oligodendrogliomas. On the contrary, the findings in astrocytomas were more diversified. To our knowledge, this is the first time that methylation of *MLH3* gene promoter was described in LGGs. The loss of *MLH3* function leads to microsatellite instability which may contribute to tumor progression. Moreover, *MLH3* mutations have been associated with susceptibility to endometrial and colorectal cancers. The larger study of patients have to be investigated in order to reveal the role of methylated *MLH3* promoter as well as other detected aberrations in tumorigenesis of LGGs.

3435M

A Custom 5m-Seq™ Cancer NGS Panel to Detect Epigenetic Signatures of Various Cancer Types. *J. Alexander, A. Meyer, J. Zhou, R. Drennan, M. Reddy, M. Poulin, L. Yan.* EpigenDx, Hopkinton, MA.

The number of genes that show some type of dys-regulation of DNA methylation in cancer cells continues to increase. In order to develop a panel for the determination of a DNA methylation pattern in cancer cells, we started with a candidate gene approach, in contrast to genome-wide methylation screening. Genes from different functional groups were selected. The cancer panel includes tumor suppressor genes (BRCA1, RASSF1, RUNX3), DNA methyltransferases (DNMTs and MGMT), DNA repeats (Line1 and Sat2), oncogenes (MYC,ERBB2), receptor genes (EGRF, ESRRA, NR2E1), Homeobox genes (HOXA10, HOXA11, EN1) and detoxification genes (GSTM1, GSTM2) and others. A total of 80 genes covering over 1500 CpG sites were selected and assays for these regions were developed and validated using PCR/Pyrosequencing, individually. The development of 5m-Seq™ Cancer NGS Panel using an Ion Torrent PGM™ system requires that the PCR amplicons be grouped into different pools based on the amplicon size, amplicon GC contents, and PCR conditions. DNA methylation controls (0%, 5%, 10%, 25%, 50%, 75%, and 100%) were sequenced on an Ion 314 Chip to validate each target region. The correlation between the calculated methylation levels and the detected methylation levels were examined. Additionally, 10 pairs of DNA samples (tumor vs adjacent normal) for each cancer type (ovarian cancer, breast cancer, cervical cancer, and colorectal cancer) were further tested using both an Ion Torrent PGM™ system and Pyroseqencing. The comparison of the results obtained by Pyrosequencing and Next-Gen Sequencing using PGM shows that PCR pools with common amplicons gave linear correlation. PCR pools with extreme conditions, i.e. AT-rich (less than 20% GC contents) or GC-rich (greater than 70% GC contents) required further optimization. In summary, high-throughput 5m-Seq™ NGS has the capability to generate equivalent or better results compared to Pyrosequencing with the potential of using less DNA for the analysis at lower cost. In addition, the panel gave different methylation signatures for each cancer type.

3436T

Differential DNA Methylation Patterns in Hereditary Non-polyposis Colorectal Cancer with or without Germline MLH1/MSH2 Mutation. *C.H. Chen[1,2], S.S. Jiang[1], L.L. Hsieh[3], R. Tang[4], I.S. Chang[1,2,5], C.A. Hsiung[5], H.J. Tsai[5].* 1) National Institute of Cancer Research, National Health Research Institutes, Zhunan, Taiwan; 2) Taiwan Bioinformatics Core, National Health Research Institutes, Zhunan, Taiwan; 3) Department of Public Health, Chang Gung University, Guieshan, Taoyuan County, Taiwan; 4) Colorectal Section, Chang Gung Memorial Hospital, Guieshan, Taoyuan County, Taiwan; 5) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Taiwan.

Introduction: In spite of several DNA methylation studies reported in sporadic colorectal cancer, the aberrant global methylation patterns in hereditary non-polyposis colorectal cancer (HNPCC) remain unclear. It has been suggested that the global methylation patterns may vary among subtypes of HNPCC patients. Methods: A total of 40 HNPCC patients with tissue samples were incuded in this study. Global DNA methylation patterns were measured using Illumina Infinium HumanMethylation27 BeadChip in 40 HNPCC patients for both tumor and adjacent normal tissues. Paired t-test was used to identify CpG sites differentially methylated between tumor and adjacent normal tissues among HNPCC patients, among those with mismatch repair deficiency (MMP) and among those without such deficiency (MMN). Student's t test was applied to identity the differential methylated CpG sites between HNPCC patients with MMN and with MMP. Pathway analysis was applied to explore the global DNA methylation patterns between HNPCC patients with MMN and with MMP. Results: At false discovery rate 0.01 (q-values<0.01), 65.6% and 46.6% of CpG sites are hypomethylated in tumor tissues, compared with adjacent normal tissues, among MMN and MMP respectively. Our agnostic approach also confirmed the previous candidate gene approach reporting that hypomethylation in RUNX3, MLH1, NEUROG1, SOCS1 and CACNA1G in HNPCC MMN patients, compared with MMP patients. Conclusions: The findings provided suggestive evidence that global hypomethylation in tumor tissues are more prominent in HNPCC patients with MMN (Familial Colorectal Cancer Type X) than those with MMP (Lynch syndrome). The underlying pathogenesis between HNPCC patients with MMN and with MMP may be differentially regulated through methylation. Further investigation will be needed to gain more understanding in regulatory mechanisms of DNA methylation on HNPCC development and progression.

3437S

A Custom 5m-Seq™ Immunology NGS Panel to Detect Epigenetic Signatures in Various Cancer Types. *A. Meyer, J. Alexander, J. Zhou, R. Drennan, M. Reddy, M. Poulin.* EpigenDx, Hokinton, MA.

The study of the immune system in different cancers is of interest for the role it may be playing in the onset and development of the disease and in the role immunotherapy might play in the treatment of different cancer types. The epigenetic regulation of immunologically relevant genes in different cancer types may provide important information for the role they may play in cancer etiology. In order to develop an immunology panel for the determination of a DNA methylation pattern in cancer, we started with a candidate gene approach, in contrast to genome-wide methylation screening. Genes from different functional groups were selected as candidates for methylation analysis. The immunology panel includes interleukins and their receptors (i.e. IL1B, IL6, IL8, IL27RA), TNFs and their receptors (i.e. TNFA, TNFS11, TNFRSF25), Interferon-gamma, chemokines and their receptors (i.e. CXCL10, CXCR1), and CD families (i.e. CD5, CD21), cell adhesion molecules (i.e. BCAM, ICAM1) and others such as the insulin gene and its receptor (INS, INSR) and PDCD1. A total of 50 genes with over 100 amplicons covering over 500 CpG sites were selected and assays for these regions were developed and validated using PCR/Pyrosequencing, individually. The development of a 5m-Seq™ Immunology NGS Panel using an Ion Torrent PGM™ system requires that the PCR amplicons be grouped into different pools based on the amplicon size, amplicon GC contents, and PCR conditions. DNA methylation controls (0%, 5%, 10%, 25%, 50%, 75%, and 100%) were sequenced on an Ion 314 Chip to validate each target region. The correlation between the calculated methylation levels and the detected methylation levels were examined. Additionally, 10 pairs of ovarian cancer DNA samples (tumor vs adjacent normal) were further tested using both an Ion Torrent PGM™ system and Pyroseqencing. The comparison of the results obtained by Pyrosequencing and Next-Gen Sequencing using PGM shows that PCR pools with common amplicons gave linear correlation. PCR pools with extreme conditions, i.e. AT-rich (less than 20% GC contents) or GC-rich (greater than 70% GC contents) required further optimization. In summary, high-throughput 5m-Seq™ NGS analysis has the capability to generate equivalent or better results compared to Pyrosequencing with the potential of using less DNA at lower cost. These results support future use of a custom 5m-Seq™ panel for efficient and sensitive epigenetic detection and analysis of cancer samples.

HES1 gene expression in patients with Medullary Thyroid Cancer is independent of its promoter methylation. *M.G. Cardoso[1], M.M.L. Kizys[2], S.C. Lindsey[2], J.H. Lee[3], D.F. Ierardi[4], C.P. Camacho[2], R. Delcelo[3], J.M. Cerutti[5], R.M.B. Maciel[2], M.G. Jasiulionis[4], M.R. Dias-da-Silva[2].* 1) Biochemistry, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Medicine, Universidade Federal de São Paulo, São Paulo, Brazil; 3) Pathology, Universidade Federal de São Paulo, São Paulo, Brazil; 4) Pharmacology, Universidade Federal de São Paulo, São Paulo, Brazil; 5) Genetics, Universidade Federal de São Paulo, São Paulo, Brazil.

Abnormal methylation seems to play an important role in differentiated thyroid carcinomas, in which several of the tumor suppressor genes are epigenetically silenced. Little is known about the methylation profiles of genes that are associated with medullary thyroid carcinoma (MTC [MIM 155240]). Studies have reported that aberrant Notch signaling in MTC results in the downregulation of the HES1 [MIM 139605] gene, increase in expression of the tumor markers chromogranin A and calcitonin. Therefore, we aimed to determine if the downregulation of HES1 is caused by hypermethylation at its regulatory region. From 128 patients followed for MTC, we obtained formalin-fixed, paraffin-embedded (FFPE) tumor tissues from 29 patients, and peripheral blood samples from 18 patients with persistent disease. We also studied a human MTC cell line (TT). For HES1 analysis in tumor DNA we used bisulfite sequencing and methylation-specific PCR. HES1 protein expression was evaluated by immunohistochemistry , and mRNA levels were evaluated by RT-qPCR of peripheral blood. We observed increased expression of HES1 in peripheral blood samples of patients with persistent MTC compared with healthy individuals (p=0.007). Likewise, immunohistochemical analysis revealed moderate staining for HES1 in MTC tissues. Hypermethylation of a CpG island previously implicated in HES1 silencing was assessed, but no evidence of methylation at this promoter was found in sporadic or familial MTC tissue, the TT cell line or nontumorigenic tissues. The finding of increased expression of HES1 observed in persistent MTC is not mediated by methylation of DNA in its promoter region. This expression of HES1 suggests that the Notch signaling pathway may be involved in the cellular response to the constitutively active MAPK signaling in MTC tumorigenesis. Funding: FAPESP.

Genetic characterization of near-haploid and low hypodiploid acute lymphoblastic leukemia. *S. Safavi, B. Johansson, K. Paulsson.* Division of Clinical Genetics, Department of Laboratory Medicine, Lund University, Sweden.

Near-haploid (23-29 chromosomes) and low hypodiploid (HoL; 30-39 chromosomes) acute lymphoblastic leukemia (ALL) are two rare subtypes associated with a dismal prognosis. The aim of the present study was to investigate the underlying genetic mechanisms in these cases, in order to detect genetic aberrations and imbalances specific for near-haploidy/HoL. We performed methylation array analysis, whole transcriptome sequencing and whole exome sequencing on 9 near-haploid and HoL cases. Results from methylation array and gene expression analyses show that near-haploidy forms a group with an expression profile separate from HoL, emphasizing the divergent genetic nature of these two subtypes. Methylation array analysis detected 100 genes that showed significantly different methylation in near-haploid/HoL group compared with the control group ($P < 0.05$, false discovery rate (FDR) < 0.1). Forty-five genes showing a significantly different expression between the near-haploid/HoL group and the control group ($P < 0.05$, FDR < 0.2) were detected by gene expression analysis. *PARD3B*, involved in cell polarization, was one of four genes found to be upregulated in both subtypes and downregulated in the control group. By genetically characterizing near-haploidy and HoL ALL we can potentially identify therapeutic targets that may be used in a clinical setting for an improved prognosis.

3440S

Functional HPSE gene SNP rs4693608 modifies heparanase expression and thereby affects the responsiveness to broad number of treatments. *O. Ostrovsky[1], P. Baryakh[1], A. Shimoni[1], Y. Margulis[1], M. Mayorov[1], I. Vlodavsky[2], A. Nagler[1].* 1) Bone Marrow Transplantation, Sheba Medical Center, Ramat Gan, Israel; 2) Cancer and Vascular Biology Research Center, Rappaport Faculty of Medicine, Technion, Haifa, Israel.

Heparanase is an endo-glucuronidase, which responsible for heparan sulfate degradation, plays important roles in processes of angiogenesis, tumor metastasis, inflammation and autoimmunity and regulates histone methylation by binding to target gene control regions. Our previous studies indicated that HPSE gene SNPs (rs4693608, rs11099592 and rs4364254) significantly correlated with expression level of heparanase among healthy persons. SNP rs4693608 was the most prominent. Analysis 414 patients with hematological malignancies and their donors revealed a highly significant correlation of rs4693608 with the risk of developing graft vs. host disease (GVHD). The discrepancy in this SNP between recipients and donors was found to be a more significant factor for the risk of aGVHD than patient genotype. Expression of the HPSE gene was increased following pre-transplantation treatment and correlated with the rs4693608 both before and after conditioning. In the present study we analyzed HPSE gene expression in response to LPS treatment in 128 umbilical cord blood (CB) and 104 peripheral blood (PB) samples. LPS was found to up-regulate HPSE gene expression ($P<10^{-7}$) through TLR4. Post-treatment heparanase expression correlated with rs4693608 in both PB and CB MNCs. RQ (relative quantification) in PB MNCs of AA carriers was 16.3 (7.5-34.5), while RQ in GG possessors was 6.4 (3.3-19.9), P=0.014. Analysis of HPSE gene expression in CB MNCs showed similar results (24.9 (15.2-40.5) *versus* 5.4 (3.1-13.0), P=0.0006). In addition, we examined association between HPSE gene SNPs and $CD34^+$ cell mobilization in 279 healthy individuals receiving granulocytes colony-stimulating factor (G-CSF). We found significant correlation between rs4693608 and total $CD34^+$ cells$\times 10^6$ (754 *versus* 502; P=0.02). Opposed effect of rs11099592 to mobilization of $CD34^+$ cells was identified. Allele A of rs11099592 was found in linkage disequilibrium with allele G of rs4693608. However, the mobilization of $CD34^+$ cells was higher in GG-AA carriers in comparison to GG-GG possessors (1022 *versus* 506; P=0.005). The present study indicated that the level of heparanase strongly correlates with the rs4693608 and depend on cell type and it activity. Functional HPSE gene SNPs may be used as a marker for prediction of acute inflammation, useful key for analysis of heparanase involvement in various biological processes and may lead, in the future, for correct heparanase level modification by potential inhibitors.

3441M

Distinct molecular signature of Giant Cell Tumor occurring in pagetic or non-pagetic patients suggests distinct pathologic entities. *F. Gianfrancesco[1], G. Divisato[1], D. Formicola[1], D. Rendina[2], M. De Lucia[1], L. Pazzaglia[3], L. Michou[4], D. Merlotti[5], M.S. Benassi[3], T. Esposito[1], L. Gennari[5].* 1) Institute of Genetics & Biophysics, National Research Council of Italy, Naples, Italy; 2) Department of Clinical and Experimental Medicine, Federico II University, Naples, Italy; 3) Laboratory of Experimental Oncology, Rizzoli Orthopaedic Institute, Bologna, Italy; 4) Department of Medicine, Faculté de Médecine de l'Université Laval, Quebec City, Canada; 5) Department of Clinical, Surgical and Neurological Sciences, University of Siena, Siena, Italy.

Giant cell tumor of bone (GCT) is an aggressive bone tumor caused by the uncontrolled proliferation of the spindle-like stromal cells which promote osteoclast-like giant cells formation responsible for the osteolitic lesions. PDB patients who develop GCT, show the polyostotic form of disease (93%), an increased prevalence of familial PDB (59%) and an earlier age at diagnosis of PDB (52±12 yrs). In contrast, in non-pagetic patient GCT mainly occurs in Asiatic subjects while pagetic GCT affect white Caucasian patients in up to 83% of cases and is rarely multifocal (<1% vs 25% in pagetic GCT). The skeletal localization of GCT is also different between pagetic and non pagetic patients, with involvement of the axial skeleton in 75% vs 15% of cases, respectively. A recent study showed that GCT is due to recurrent somatic mutations in H3F3A gene in the stromal cells. We analysed a cohort of giant cell tumor of bone for the presence of H3F3A mutations identifying somatic mutations in 38 out of 44 cases (86%). In contrast, the analysis of patients with Paget's disease of bone (PDB) associated with giant cell tumor did not show any mutation in H3F3A gene, at both somatic and germline level, suggesting a different genetic background. Recently we reported an extended Italian family in which 4 out of 14 PDB affected members developed multiple GCTs at pagetic skeletal sites. Clinically, all affected members had polyostotic PDB, but subjects developing giant cell tumors showed an increased disease severity with a reduced clinical response to bisphosphonate treatment and an increased prevalence of bone pain, deformities, and fractures. Whole exome sequencing, in this family identifies a missense mutation in a novel uncharacterized gene. Additional genetic analysis in 7 independent affected patients with the same clinical phenotype, discloses the same mutation in all patients, strongly suggesting that this clinical phenotype is due to a founder effect. Therefore, GCT associated or not with PDB is due to mutations in different genes, suggesting different molecular signatures.

3442T

miR-22 supresses cell proliferation in zoledronic acid treated glioblastoma cells by inducing autophagy and targeting mTOR. *C. Caliskan[1], B. Goker[1], Z. Mutlu[1], C. Kayabasi[1], S. Yilmaz Susluer[1], T. Balci[1], B. Ozmen Yelken[1], N. Oktar[2], C. Gunduz[1], C. Biray Avci[1].* 1) Ege University Medical School Department of Medical Biology, Izmir, Turkey; 2) Ege University Medical School Department of Neurosurgery, Izmir, Turkey.

Glioblastoma multiforme (GBM) is the most common and malign type tumors of central nervous system in elderly people. It is non-responsive to chemotherapy in many cases and carries the lowest chances of survival. Despite various treatment, the median survival time of patients with GBM is 12-16 months. FDA approved for treatment of metastatic bone disease is one of nitrogen-containing bisphosphonate is zoledronic acid (ZA). It demonstrates anticancer activity in various cancers. MicroRNAs are small (19-24 nucleotides) and non-coding RNA that regulate post-transcriptional gene expression via disrupting the stabilization of target transcripts or inhibiting protein translation. miRNAs serve as oncogenes and tumor suppressors through unlighted mechanisms in human. Autophagy is a physiological process that triggered degradation of cellular components by lysosomal mechanism and controlled by genetically. The aim of the study was to evaluate the expressions of miRNAs that are associated with GBM genetics after treatment with zoledronic acid; to investigate target genes of miRNAs which show significant expression alterations and molecular mechanisms of zoledronic acid treatment. U87-MG cell line (human glioblastoma-astrocytoma) is used as an in vitro model to investigate the cytotoxic and apoptotic effect of ZA in glioma cells. U87-MG cells were treated with 25 μM (IC50) ZA during 72 hours and cytotoxicity was evaluated by using WST-1 assay. Apoptosis assays were performed by using ApoDIRECT In Situ DNA Fragmentation Assay. The RT-qPCR is used for miRNA expression analysis. Results showed that IC50 dose of ZA induced apoptosis 4,25 fold when compared to control cells that untreated with ZA. Also IC50 dose of ZA of miRNA expression results showed that; miR-22 expression level was upregulated 3,08 fold according to control group. Also RT-qPCR results showed that; Bcl-2 gene expression decreased 2,14 fold according to control cells. Inhibition of Bcl-2 expression showed that ZA induces autophagy. In additional, Akt1 and mTOR genes' expressions decreased 3,7 and 3,36 fold, respectively according to control cells. Inhibition of AKT/mTOR cascade can allow the phosphorylation/inactivation of Bcl-2. These novel findings showed that ZA is very important in glioma progression and it is necessary to question whether it can be used as a drug candidate in glioma treatment with further research on miR-22 and its target gene expression.

MicroRNA in biofluids - Robust biomarkers for disease. *D. Andreasen[1], A.R. Thomsen[1], T. Blondal[1], J. Krummheuer[1], M.W. Teilum[1], N. Tolstrup[1], M. Borre[2], C. Haldrup[3], T.F. Ørntoft[3], K.D. Sørensen[3], P. Mouritzen[1].* 1) Exiqon A/S, Vedbaek, Denmark; 2) Dept of Urology, Aarhus University Hospital, Denmark; 3) Dept of Molecular Medicine, Aarhus University Hospital, Denmark.

microRNAs constitute a class of small cellular RNAs (typically 19-23 nt) that function as post-transcriptional regulators of gene expression. Current estimates indicate that more than one third of the human cellular transcriptome is regulated by this small class of RNA (~2000 miRNA). The study of extracellular microRNAs and their potential as pathophysiological markers has greatly expanded in the last couple of years. microRNAs have been shown to be actively exported from tissues into the circulation through a variety of mechanisms including exosome and microvesicle transport, and complexing with RNA binding proteins or HDL. The high relative stability of microRNAs in common clinical source materials (FFPE blocks, plasma, serum, urine, saliva, etc.) and the ability of microRNA expression profiles to accurately classify discrete tissue types and specific disease states have positioned microRNAs as promising new biomarkers for diagnostic application in cancer. We have applied Exiqons highly sensitive LNA™-based qPCR platform for detection of microRNAs, which has enabled microRNA profiling in biofluids where levels are extremely low. The platform uses a single RT reaction to conduct full miRNome profiling and allows high-throughput profiling of microRNAs without the need for pre-amplification. Thousands of biofluid samples including serum/plasma and urine have been profiled to determine normal reference ranges for circulating microRNAs as well as to identify biomarkers of disease. Extensive data qualification and analysis methods have been developed and are central parameters to secure high quality data from biofluids. The methods can quickly and robustly be applied in biomarker discovery and validation projects. We will present examples from our collaborative cancer diagnostic projects. Also we recently developed a new exosome enrichment method and will present a characterization of the exosome fraction obtained with this method. We will also present a comparison of microRNA profiles obtained with this method to profiles obtained with different commercially available exosome isolation methods. For plasma and serum we will furthermore compare to standard profiles of non-fractionated samples.

3444M

Resveratrol up-regulates tumor suppressor mir-31 expression via inhibiting histon deacetylase 1 gene expression in chronic myeloid leukemia. *C. Biray Avci[1], Z. Mutlu[1], C. Caliskan[1], B. Goker[1], S. Yilmaz Susluer[1], F. Sahin[2], G. Saydam[2], C. Gunduz[1].* 1) Ege University Medical School Department of Medical Biology, Izmir, Turkey; 2) Ege University Medical School Department of Hematology Izmir, Turkey.

Chronic myeloid leukemia (CML) is characterized by a reciprocal translocation between chromosomes 9 and 22. The Philadelphia chromosome is available as a result of this translocation and causes BCR-ABL1 fusion gene which produces actively tyrosine kinase. Resveratrol (RES) is a natural phytoalexin found in grapes and induces apoptosis, erythroid differentiation and autophagy in leukemic cells. MicroRNAs are small (~22 nucleotides), single strand, non-coding RNA molecules that regulate post-transcriptional gene expression. miRNAs cause modulation of oncogenic or tumor suppressive pathways in different cancer types. In this study we aimed to determine cytotoxic effect of RES in K562 human CML cell line and to evaluate the expressions of miRNAs that are related with leukemogenesis after the treatment with RES. Also we analyzed target genes of miRNAs which show notable expression levels. K562 cells were treated with 100 μM (IC50 dose) RES during 72 hours and cytotoxicity was evaluated by using WST-1 assay. The RT-qPCR is used for miRNA and gene expression analysis. miRNAs and gene expression levels were evaluated by using miScript miRNA PCR Array and RT2 Profiler PCR Array, respectively. Results showed that; RES up-regulated tumor suppressor miR-31 level 3.60 fold and significantly down-regulated HDAC1 gene expression (p=0.003), according to the control cells. Our findings showed that Resveratrol acts as a HDAC inhibitor targeting HDAC1 gene expression level. HDACs play a key role in the regulation of gene expressions in cell progressions such as tumorigenesis and cell proliferation. Downregulation of HDAC1 provides post-translational modification for expression of tumor supressor genes and leads to cell cycle arrest and increases apoptosis. These results provide that Resveratrol could be a therapeutic candidate as a HDAC inhibitor for chronic myeloid leukemia treatment.

3445T

Association of Ile655Val polymorphism of the HER2 gene with Neutropenia toxicity in breast cancer patients treated with trastuzumab chemotherapy. *D.I. Carrillo-Moreno[1, 2], L.E. Figuera[3], L. Gómez Flores[1], A. Ramos[1, 4], R. Ramírez[1, 2], O. Soto[1, 4], I. Gutíerrez[1, 2], G.M. Zúñiga[5], M.P. Gallegos[1].* 1) Laboratorio de Genética Molecular, División de Médicina Molecular, CIBO, IMSS, Guadalajara, Jal,. Mex, Mexico; 2) Doctorado en Genética Humana, Centro universitario de Ciencias de la Salud, Universidad de Guadalajara,; 3) División de Genética, CIBO, IMSS; 4) Doctorado en Farmacología, Centro universitario de Ciencias de la Salud, Universidad de Guadalajara; 5) Loboratorio de Mutagenesis, División de Médicina Molecular, CIBO, IMSS, Guadalajara,.

Background: The influence of *Ile655Val* polymorphisms in the *HER2* gene involved in trastuzumab metabolism has been studied in breast cancer. *HER2* (*erbB-2, neu*) is a proto-oncogene which encodes a transmembrane protein with tyrosine kinase activity but with no identified physiological ligand. The *HER2* gene is amplified in 30% of invasive breast cancers and correlated with reduced patient survival. Our aim was to evaluate the association of Ile655Val polymorphisms in the *HER2* gene with toxicity effects in breast cancer patient's treated with trastuzamab chemotherapy. Methods: DNA genomic samples from 175 patients (UMAE gynecology and obstetrician Hospital, CMNO, IMSS), that received trastuzumab chemotherapy; were included in the study. The *Ile655Val* polymorphism was determinate by polyacrylamide gels electrophoresis, previously PCR and BsmAI restriction enzyme analysis. The association was determinate by odds ratio. Results: The genotype 677*ValVal-IleVal* was associated with gastrointestinal [3.1(IC95% 1.11-9.138), p=0.030] and hematological [3.2(IC95% 1.12-9.08), p=0.029] toxicity (diarrhea and neutropenia grade II- III) respectively in breast cancer patient. Conclusion: The *Ile655Val* polymorphisms in the *HER2* gene could be a good marker of toxicity in breast cancer patients treated with trastuzamab in the analyzed sample.

3446S

The BIM Deletion Polymorphism Cannot Account for Intrinsic TKI Resistance of Chinese CML Patients. *X. Chen[1], H. Liu[2], Y. Zhang[2], F. Wang[2], W. Teng[2], P. Zhu[1], C. Tong[2], D. Lu[2].* 1) Department of Hematology, Peking University First Hospital, Beijing, beijing, China; 2) Medical Laboratory Division, Ludaopei Hematology & Oncology Center, Beijing.

Background: BIM is a pro-apoptotic protein of the Bcl-2 family. Recently it has been reported that a common deletion polymorphism in the BIM gene mediates intrinsic resistance to imatinib mesylate (IM), a tyrosine kinase inhibitor (TKI). Chronic myeloid leukemia (CML) patients with the deletion experienced inferior responses to IM. **Method and Cases:** To identify the influence of this deletion on TKI responses in Chinese individuals, we collected 141 newly diagnosed patients with chronic phase CML whose first-line therapy was a standard dose of IM and 200 healthy individuals. Patients were classified as resistant or sensitive to IM according to the European Leukemia Net (ELN) criteria. The 2,903bp deletion of BIM was detected by PCR. **Results:** 1) 20 patients were heterozygous for the deletion and the other 121 did not harbor the deletion. 2) Of the patients with the deletion, 15 (75%) were sensitive to IM and only 5 (25%) were resistant. For patients without the deletion, 86 (71%) were sensitive to IM and 35 (29%) were resistant. 3) 41 of 200 healthy individuals carried the deletion. One was homozygous and the other 40 were heterozygous. The carrier frequency was 20.5%, which was much higher than previously reported (12.3%) and indicated a different genetic background. 4) Logistic regression analysis shows the overall odds ratio for resistance among patients with the deletion compared to those without it was 1.221 (P=0.719, 95% CI 0.412-3.616). **Conclusion:** The BIM deletion polymorphism cannot account for intrinsic TKI resistance of Chinese patients with CML.

3447M

Association of CD44 expression before, during and after treatment in patients with head and neck cancer in comparison with healthy controls. *K. Chukka[1], Z. Vishnuvardhan[2], S. Dasari[3], U. Radhakrishna[4].* 1) Department of Biotechnology, Acharya Nagarjuna University, Nagarjuna Nagar, Guntur, India; 2) Department of Botany & Microbiology, Acharya Nagarjuna University, Nagarjuna Nagar, Guntur, India; 3) Department of Biotechnology, Dravidian University, Kuppam, India; 4) Green cross Pathology and Molecular Biology laboratory, Paldi, Ahmedabad, India.

Cancer Stem Cells (CSCs) are presumed to be responsible for recurrence of cancer even after treatment. CSCs have been identified in various types of cancers, including head and neck (HNC) cancer, breast cancer, prostate cancer and pancreatic tumors. The lack of reliable markers to identify CSCs is the major problem in the development of new strategies to tackle cancer. CD44 molecule is one of the promising surface markers of CSCs in HNC patients to identify and assess the stage of cancer diagnosis before and later treatment. We have measured the levels of CD44 expression in 40 HNC cases undergoing treatment and compared with post treatment levels of marker protein. The expression levels of CD44 in normal controls (healthy individuals), cases before, during and after treatment was significantly correlated. Low levels correlated with healthy condition and positive response to cancer treatment. A lower CD44 expression was observed in those from the healthy controls (269.3±46.3) compared to cases. Also observed lower levels of CD44 expression after treatment (475.24±7.27) compared to during (549.38±9.77) and before treatment (583.64±8.82) respectively. There is a significant difference between HNC cases and controls as well as cases before, during and after treatment at 5% level. CD44 appears to be a suitable marker of head and neck squamous cell carcinoma having potential diagnostic value, since its detection is easy.

3448T

PCA3 prostate cancer biomarker long non-coding transcription unit: Transcriptional interference of overlapping genes. *R. Clarke[1,2], M. Lavin[2], R. Gardiner[2,3], C. Chow[2], R. Stirling Richards[2], Z. Fang[1].* 1) Ingham Institute University of Western Sydney School of Medicine, Liverpool, NSW, Australia; 2) University of Queensland Centre for Clinical Research, Brisbane, Qld, Australia; 3) Department of Urology, Royal Brisbane & Women's Hospital.

PCA3 is arguably the most specific diagnostic biomarker for prostate cancer with great potential to improve clinical screening of men at risk. Given the over-riding need for prognostic and therapeutic biomarkers for prostate cancer the question remains as to whether PCA3 has a functional role in the disease and whether it could serve as a target or facilitator of therapy. The PCA3 gene appears to be a long non-coding transcription unit which is transcribed at high levels in prostate cancer. The PCA3 gene recently emerged in primates to give rise to a processed transcript with weak conservation and no detectable PCA3 protein product suggesting that PCA3 may have no direct functional role in prostate cancer. However, PCA3 is nested within another gene, BMCC1, and the transcription of PCA3 is discordantly regulated with BMCC1 in prostate cancer cells and after androgen treatment. BMCC1 is involved in Rho signalling and vesicular trafficking and may play roles in cellular transformation and metastasis. We apply novel technology to the BMCC1/PCA3 overlapping gene complex that suggests that the nested status of PCA3 within BMCC1 modulates transcription in a discordant fashion. These results suggest that PCA3 transcription may be a surrogate biomarker for BMCC1 and useful not only for the early detection of prostate cancer but to better understand prostate cancer initiation and development. If functional, interference of PCA3 transcription may represent a possible therapeutic application for early prostate cancer. Alternatively, novel PCA3 transcription products specific for prostate cancer could be used to selectively trigger a lethal exogenous target vector.

3449S

Creation of an open data sharing exchange to optimize BRCA clinical variant assessment. *N. Conti[1], C. Strom[2].* 1) Quest Diagnostics, Madison, NJ; 2) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Following the Supreme Court of the United States (SCOTUS) decision invalidating certain BRCA gene patents, several clinical laboratories in the US began to offer BRCA sequence testing. As with any sequence based test, some patients will have sequence variants that require clinical assessment Clinical assessment encompasses literature review, population frequency determination, database searches, segregation and coinheritance analyses, computer modeling, and functional studies. Databases aid in this process by summarizing non-published data (such as segregation analyses) and previous interpretive conclusions, and serving as a gateway to published literature. Careful review of databases and confirmation, in general, are required. The Universal Mutation Database (UMD) collects data from 16 contributing laboratories throughout France. The UMD is actively curated. As of May 2014, UMD contained 6902 BRCA1 (MIM 113705) variants and 8082 BRCA2 (MIM 600185) variants. UMD is comparatively richer in BRCA content than US databases, because European labs have been doing BRCA testing for more than a decade. Until the recent SCOTUS decision, BRCA testing in the US had been limited to a single laboratory that no longer contributes variants to public databases. Our objective was to optimize patient care through facilitated access to UMD and to create a mechanism to assure contributions of new variant information to the database. Quest Diagnostics obtained a commercial use license for UMD with the stipulation that any research laboratory would continue to have free access to the database. Any commercial laboratory willing to share their data and provide user group fees through a user group will also have access to UMD. The fees will allow UMD to expand access with both hardware and software upgrades, develop processes for incorporation of new variant data, and increase the number of curators for the expected increase in uploading of new variants. The user group agreement also allows participating laboratories to request functional studies for families with potentially clinically relevant variants. The planned transparency of the processes will permit independent assessment of the level of evidence for any variant in the UMD database and provide the scientific and medical communities with a valuable resource to optimize research and patient care.

3450M

Towards the minimal breast cancer genome and its relevance to chemotherapy. *S.N. Dorman[1], J.H.M. Knoll[2], K. Baranova[1], C. Viner[3], P.K. Rogan[1,3].* 1) Biochemistry, University of Western Ontario, London, Ontario, Canada; 2) Pathology, University of Western Ontario, London, Ontario, Canada; 3) Computer Science, University of Western Ontario, London, Ontario, Canada.

We are investigating whether the variable response to chemotherapy in breast cancer (BC) can be explained by the diversity of somatic mutations among patients. Our laboratory proposed that there is a minimal genome required for BC cell survival. A stable set of 5,804 genes was derived by comparing regions of BC genomes unaltered in copy number (CN) with genes normal in expression levels in tumours (*Mol. Oncol.* 6: 347-359). A subset of these genes are targets of well-established therapies (ie. paclitaxel, gemcitabine). We hypothesize that that the effectiveness of these or other chemotherapy treatments may rely on the integrity of stable genes. We analyzed integrated genomic data for BC tumours from The Cancer Genome Atlas to re-define and/or narrow the minimal BC genome. Consistent with the design of our previous study, we identified genes stable in CN and gene expression, but now also exclude genes with deleterious somatic point/indel mutations (in ≥ 90% tumours). An analysis of 318 tumours revealed 6,994 stable genes, of which 2,364 genes were identified in the previous stable gene set. There are 3,856 unstable genes with deleterious somatic point/indel mutations, of which 32 genes exhibit ≥ 10 mutations in different tumours. Removing somatic point/indel mutations reduced the stable gene set by 122 genes. This is because unstable genes were often mutated by different mechanisms: 3,353 genes with somatic mutations also showed either abnormal CN or gene expression. Dysregulated pathways present in both stable gene sets (n = 265) are enriched for transcription (n = 37), mRNA processing and transport (n = 41), translation (n = 16), signaling (n = 19), and the formation of protein complexes (n = 19). Growth inhibition studies (GI50 values) of 27 BC cell lines show that chemotherapy sensitivity is not consistent across all cell lines (*Genome Biol.* 2013, 14:R110). Paclitaxel and gemcitabine metabolic pathways include 33 (9 stable) and 14 (7 stable) genes, respectively. We related GI50 of BC cell lines, to CN, gene expression, and somatic mutation data for these genes. Paclitaxel sensitivity was correlated with *MAPT*, *BCL2*, and *CSAG2* expression levels, and somatic mutations in *CYP2C8*, *FGF2*, and *TWIST1*. *BCL2* and *MAPT* are direct targets, and the remaining genes have previously been associated with paclitaxel resistance. Growth inhibition by gemcitabine was inversely correlated with *RRM2* and *RRM2B* expression, which interact with known drug targets.

3451T

Whole exome sequencing approach in sib pairs identifies oligogenic germline mutations predisposing to early lung adenocarcinoma in non-smokers. *E. Frullanti[1], M.A. Mencarelli[1], F. Cetta[2], M. Baldassarri[1,3], F. Mari[1,3], S. Furini[4], P. Piu[5], T.A. Dragani[6], F. Ariani[1,3], A. Renieri[1,3].* 1) Azienda Ospedaliera Universitaria Senese, Siena, Siena, Italy; 2) IRCCS MultiMedica, Milan, Italy; 3) Medical Genetics, University of Siena, Siena, Italy; 4) Department of Medical Biotechnology, University of Siena, Siena, Italy; 5) Department of Medicine, Surgery & Neuroscience, University of Siena, Siena, Italy; 6) Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy.

A polygenic model is commonly assumed for the predisposition to common cancers. Despite the great bulk of research to identify genetic susceptibility genes in lung cancer by genome-wide association studies, only three loci have been identified at 15q25, 5p15.33, and 6p21, respectively. It is noteworthy that findings have not been replicated consistently in subsequent studies. In addition to confer a very low risk, they have been associated with lung cancer in smokers, but not in non-smokers. The polygenic nature of common cancers has frequently been suggested, but its biological basis still remains elusive. We tested the hypothesis that genetic susceptibility may rely on a restricted number of genes, disrupted by germ-line mutations. A combination between an advanced technical tool, i.e. the exome sequencing, and a new patient selection strategy was used. The strategy relies on the selection among 964 lung adenocarcinoma patients those with early onset disease (mean age 43) in absence of cigarette smoking, and having a first degree healthy sibling available for genome comparison with an age difference of at least 7 years. Germ-line truncating mutations were detected in 8 and 5 different cancer predisposing genes in each affected subject, respectively, but not in the healthy sib of two pairs (p=0.0026). Some of them are well known cancer players in lung tumors and others are genes previously identified in other cancer tissues. This study demonstrated for the first time that never-smoker patients with lung adenocarcinoma carry a specific and private oligogenic combination of germ-line mutations in cancer predisposing genes. These findings, if replicated with further studies, support the hypothesis of an oligogenic nature of common cancers. At the moment, we are performing exome sequencing in other pairs of siblings.

3452S

Epigallocatechin-3-gallate induces apoptosis and autophagy via up-regulation of TNF and GABARAPL2 gene expression in chronic myeloid leukemia cells. *B. Goker[1], C. Caliskan[1], Z. Mutlu[1], B. Erbaykent Tepedelen[2], M. Korkmaz[3], G. Saydam[4], C. Gunduz[1], C. Biray Avci[1].* 1) Department of Medical Biology, School of Medicine, Ege University, Izmir, Turkey; 2) Department of Molecular Biology and Genetics, Faculty Of Science And Letters, Avrasya University, Trabzon, Turkey; 3) Department of Medical Biology, School of Medicine, Celal Bayar University, Manisa; 4) Department of Hematology, School of Medicine, Ege University, Izmir, Turkey.

Chronic myeloid leukemia (CML) is a clonal hematopoietic stem cell disease. Philadelphia chromosome (Ph) is the result of a reciprocal (9;22) translocation is responsible for developing leukemic phenotype of CML. Epigallocathecin-3-gallate (EGCG) which has significant therapeutic effects on different human tumor types is a major flavonoid of green tea. Autophagy known as programmed cell death is one of the main response of cell to stimulus. Raise of autophagic activity in cancers is novel therapeutic target with using different active substance. In this study we aimed to determine cytotoxic and autophagic changes in K562 CML cell line treated with EGCG compared to untreated control group, and detect the expression changes ofautophagy related genes with the treatment of EGCG. The cytotoxic effect of EGCG on K562 cells was determined in time and dose dependent manner by using WST-1 analysis. Total RNA was isolated from K562 cells treated with EGCG and untreated cells as control group. Reverse transcription procedure was performed for cDNA synthesis. Apoptotic effect of EGCG was evaluated with ApoDIRECT and gene expressions were shown by RT-qPCR. IC50 (24th hours) dose of EGCG was determined as 50μM. EGCG induced apoptosis 10.9 fold compared to control cells. EGCG up-regulated TNF and GABARAPL2 genes 13.1775 and 9.5137 fold according to the control cells, respectively. Increase of TNF, most significiant cytokine is placed in apoptotic and autophagic pathways, and GABARAPL2, responsible for autophagic vacuol formation, expressions are associated with apoptotic and autophagic cell death in several human cancer cells. Our current findings manifested that EGCG treatment increases cancer cell death via up-regulation of genes are part of both apoptotic and autophagic signalling pathways. Therefore EGCG suggests a nontoxic herbal agent for chronic myeloid leukemia treatment.

3453M

Hypomorphic *CYP2C9* *2 and *3 alleles associate with improved non-small-cell lung cancer (NSCLC) prognosis. *L.N. Gordon[1], A. Pozzi[2,3], J.H. Capdevila[2,3], S.M. Williams[1,4].* 1) Dartmouth College, Department of Genetics Hanover, NH 03755; 2) Vanderbilt University, Department of Medicine Nashville, TN 37232, USA; 3) Vanderbilt University, Department of Nephrology Nashville, TN 37232, USA; 4) Dartmouth College, Institute for Quantitative Biomedical Sciences Hanover, NH 03755.

Lung cancer is the leading cause of cancer death in the United States, despite the higher incidences of other cancers. Given this disproportionate mortality, more effective treatments are needed. In mice knockout of the Cyp2c44 epoxygenase is associated with reduced angiogenesis and tumor growth. Interestingly, expression of the Cyp2c44 gene can be downregulated by treatment with PPARα ligands with a corresponding decrease in angiogenesis tumor growth, and distant metastasis. The human homologue of Cyp2c44, CYP2C9 epoxygenase, and its variants *CYP2C9*2* and *CYP2C9*3* have been linked to breast and colon cancer. However, whether *CYP2C9*, influences survival in non-small-cell lung cancer (NSCLC) patients and if it is linked to PPARα is not known, but could constitute an excellent drug target. We genotyped *CYP2C9* alleles *2* and *3* along with tag SNPs in *CYP2C9* in a sample of 398 Caucasian NSCLC patients. Possession of either *CYP2C*2* or *3* in female patients associated with increased survival (HR = 0.383, p-value = 0.035) adjusted for cancer staging, chemotherapy, and tumor resection. However, not only is this genetic association limited to females, but these alleles may interact with gender because the interaction between the hypomorphic alleles and gender borders the significance threshold (p-value = 0.100). Together, these results suggest not only that genetic variation in *CYP2C9* influences NSCLC survival, but modulation of this gene with PPARα ligands, such as clinically used fibrates, may be a viable clinical treatment.

3454T

Evaluation of miR-27a, miR-181a, and miR-570 Genetic Variants with Gallbladder Cancer Susceptibility and Prognosis in North Indian Population. *A. Gupta, B. Mittal, A. Yadav, A. Sharma, K.L. Sharma, N. Rastogi, S. Agrawal, A. Kumar.* Sanjai Gandhi Post Graduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India.

Purpose of study: microRNAs are small endogenously expressed short non-coding RNAs. They appear to be critical regulators of tumour biology as their aberrant expression is well characterized in cancer progression. Many miRNAs genetic variants have been found to play important role in many cancers but their contribution in gallbladder carcinoma has not been fully explored. So, in present study, we investigated the role of cancer-specific miR-27a, miR-181a, and miR-570 genetic variants with gallbladder cancer (GBC) susceptibility, therapeutic response and toxicities to chemo-radiotherapies. Methods: The present study was carried out in 515 GBC patients and 200 healthy controls in North Indian population. Among them, 126 patients receiving adjuvant or neoadjuvant therapies as per requirement were followed up for treatment outcome. Treatment response was recorded according to Response Evaluation Criteria in Solid Tumors (RECIST) criteria. Hematological and gastrointestinal toxicities profile were recorded as per CTCAE version 3.0 2006. Genotypes were determined by TaqMan probes. Statistical analysis was done by SPSS ver. 16. Results: Logistic regression analysis showed no significant association of miR-27a, miR-181a, and miR-570 polymorphism with GBC susceptibility ($p > 0.05$). On stratifying data on the basis of gall stone status, the [AG+GG] genotypes of miR-27a rs895819 (A>G) were significantly associated with increased risk of GBC in patients without stone (*p-value*=0.003; p_{corr} =0.006; OR=1.83; CI=1.23-2.72). The genetic risk by miR-27a, rs895819 (A>G) was modulated by tobacco consumption as the heterozygote's (AG) were at higher risk p-value=0.005, p_{corr} =0.01, OR=1.94; CI=1.22-3.08]. Univariate analysis revealed that AG+GG genotype of miR-27a and CT+TT genotype of miR-181a were significantly associated with non-responsiveness to chemo-radiotherapies (*p-value*=0.03 and 0.04 respectively) whereas miR-570 variants did not show any association. None of the studied polymorphism had any influence on haematological and gastrointestinal toxicities. Conclusion: We found significant association of miR-27a rs895819A>G with gallbladder cancer risk through gallstone independent pathway and tobacco usage. Our results are also suggest that variant allele of miR-27a (rs895819 A>G) and miR-181a (rs12537 C>T) may be associated with poor therapeutic response in GBC patients. However study needs to be validated in independent cohorts.

3455S

A case-control study of SNPs affecting microRNA binding sites in chronic myeloid leukemia. *H. Gutiérrez-Malacatt[1,2], M. Ayala-Sánchez[3], X. Aquino-Ortega[3], A. Martínez-Tovar[4], I. Olarte-Carrillo[4], J.A. Rebollar-Sánchez[2], U. Hernández-Guzmán[2], E.J. Córdova-Alarcón[2], L. Orozco[2].* 1) Posgrado en Ciencias Biológicas, Universidad Nacional Autónoma de México, Ciudad Universitaria 3000, C.P. 04510, Coyoacán, Distrito Federal, México; 2) Laboratorio de Inmunogenómica y Enfermedades Metabólicas, Instituto Nacional de Medicina Genómica, Tlalpan 14610 México, D.F; 3) Servicio de Hematología, Hospital de Especialidades, CMN La Raza, IMSS; 4) Laboratorio de Biología Molecular, Servicio de Hematología. Hospital General de México, Cuauhtémoc, 06726 México, D.F.

Chronic myeloid leukemia (CML [MIM 608232]) is one of the most frequent hematopoietic malignancies in the elderly population. However, genetic factors associated with an increase risk to CML development are unknown. Recent studies have shown that SNPs affecting miRNA biogenesis or mRNA:miRNA interaction are important risk factors in the development of different types of cancer. Thus, we carried out a case-control study to test the association of SNPs located in the microRNA machinery genes AGO1 (rs636832), and GEMIN4 (rs2740348), as well as SNPs in the microRNA binding sites of the genes BRCA1 (rs799917) and KRAS (rs61764370) with CML susceptibility. We genotyped 828 Mexican-mestizo individuals (497 healthy subjects and 331 CML cases) using TaqMan probes. We found a significant association between the minor homocygote of the KRAS rs61764370 SNP (G/G) genotype and an increased risk for CML susceptibility (OR = 13.39, p = 0.015). After gender stratification, this association remains only in female individuals (OR = 13.41, p =0.016). None of the other studied SNPs showed a significant association with CML, even after gender stratification. In addition, the minor allele (C) of GEMIN4 rs2740348 SNP was significantly associated with an early age at CML diagnosis (OR= 2.14, p = 0.034) and with a high-risk Sokal score, (OR= 3.15, p = 0.01254). To the best of our knowledge this is the first study to show a significant association of the KRAS rs61764370 SNP and the GEMIN4 rs2740348 SNP with CML susceptibility and early age of CML diagnosis, respectively. To further determined the participation of these SNPs in CML susceptibility it is necessary to replicate our findings in different populations.

3456M

The role of Stem Cell Markers in Prostate Cancer Recurrence. *E. Guzel[1,2], OF. Karatas[1,3], MB. Duz[1], M. Ittmann[4,5], M. Solak[6], M. Ozen[1,4].* 1) Istanbul University, Cerrahpasa Medical School, Istanbul, Turkey; 2) Department of Electroneurophysiology Biruni University, Istanbul, Turkey; 3) Molecular Biology and Genetics Department, Erzurum Technical University, Erzurum, Turkey; 4) Department of Pathology & Immunology, Baylor College of Medicine, Houston, TX, 77030, USA; 5) Baylor College of Medicine, Michael E. DeBakey VAMC, Houston, TX, 77030, USA; 6) Afyon Kocatepe University Medical School Department of Medical Genetics.

Prostate cancer (PCa) is one of the most common tumor types related to mortality in males in the developed countries. Studies have demonstrated that therapeutic tools mostly ineffective to give positive outcome especially for PCa. Cancer stem cells are composed of a small cell population, which are supposed to have roles in tumorigenesis, metastasis, and tumor recurrence after chemo-radiotherapy. The aim of this study is to explore the differential expressions of stem cell markers in recurrent PCa and non-recurrent PCa tumors as well as in adjacent normal prostate tissues. Here we compared the expression of important stemness regulators like SOX2, OCT4, KLF4, and ABCG2 genes in recurrent, non-recurrent PCa and adjacent normal tissue samples using quantitative real-time polymerase chain reaction. Our results demonstrated that SOX2 and OCT4 are strongly over-expressed in PCa samples. Recurrent PCa samples are markedly positive for stem cell markers SOX2, OCT4 and KLF4. Furthermore, non-recurrent PCa samples presented low levels of ABCG2, a multidrug resistance protein, compared to both normal and recurrent samples, which might be associated with chemo-sensitivity. Enhanced expression of ABCG2 and stem cell markers in the recurrent PCa tissues postulates the suggestion that enrichment for cells with stem cell characteristics in these tissues might be critical for enhancement of chemoresistance and recurrence of cancer.

Box 5000, FI-90014 University of Oulu, Finland; 7) Imaging Center, Clinical Pathology, Kuopio University Hospital, P. O. Box 1777, FI-70211 Kuopio, Finland.

Defects in response to oxidative stress may increase cancer susceptibility. In tumors the function of the rescue mechanisms may cause chemo- and radioresistance and affect the outcome of patients. We previously showed that genetic variation in nuclear factor erythroid 2-related factor 2 (NRF2) gene *NFE2L2* associates with breast cancer risk and prognosis. Here we studied further this pathway by investigating the Kelch-like ECH-associated protein 1 (KEAP1). Five tagging single nucleotide polymorphisms in *KEAP1* gene were genotyped in 996 breast cancer cases and 880 healthy controls from two Finnish case-control sets. KEAP1 protein expression was studied in 373 invasive breast cancer tumors by immunohistochemistry. Statistical significance of the associations between genotypes, protein expression, clinicopathological variables and survival were assessed. The genotype *TT* of rs34197572 associated with increased risk of breast cancer (P_{Trend}= 0.015). The minor allele *A* of rs11085735 associated with lower KEAP1 protein expression (*P*=0.040) and high extent nuclear NRF2 protein expression (*P*=0.009). It also associated with worse survival in all invasive cases (*P*=0.023). When treatment data were included rs11085735 associated with recurrence-free survival (RFS) (*P*=0.020) and breast cancer-specific survival (BCSS) (*P*=0.016), and rs34197572 with overall survival (OS) (*P*=0.045). rs34197572 and rs8113472 associated with OS also among radiation therapy-treated cases (*P*=0.018 and 0.025, respectively). rs9676881 and rs1048290 associated with RFS among all invasive cases (*P*=0.024 and 0.020, respectively), and among ER positive tamoxifen treated cases (*P*= 0.018 and 0.015, respectively). These associations possibly indicate the effect of the SNPs in response to oxidative stress by cancer treatment, thus providing further support to the involvement of the NRF2-KEAP1 pathway in breast cancer susceptibility and patient outcome.

Rare and Common Variants Contribute to Lung Cancer Survival in African Americans. *C.C. Iverson[1], W.S. Bush[1], D.C. Crawford[1], H.H. Dilks[2], J. Long[3], W.J. Blot[3,4], E.L. Grogan[5,6], M.C. Aldrich[1,3,5].* 1) Center for Human Genetics Research, Vanderbilt University Medical School, Nashville, TN; 2) VANTAGE, Vanderbilt University, Nashville, TN; 3) Division of Epidemiology, Vanderbilt University Medical School, Nashville, TN; 4) International Epidemiology Institute, Rockville, MD; 5) Department of Thoracic Surgery, Vanderbilt University Medical School, Nashville, TN; 6) Tennessee Valley Health System Veterans Affairs, Nashville, TN.

Lung cancer is the leading cause of cancer-related mortality in the U.S. Survival rates differ by race, with blacks experiencing poorer survival than whites, yet few studies have focused on blacks. Germline genetic variation may influence overall lung cancer survival. A total of 305 incident non-small cell lung cancer African American cases were identified from the prospective Southern Community Cohort Study through linkage with 12 state cancer registries. Vital status was determined by linking with the National Death Index or Social Security Administration. After 8.6 years of follow-up, 87% of lung cancer cases were deceased. We performed genotyping using the Illumina HumanExome BeadChip. After standard quality control, 301 individuals (60% male) and 274,438 variants remained for analysis. We identified variants previously associated with lung cancer survival from the NHGRI GWAS catalog on the ExomeChip array. For each of these SNPs, we ran a Cox proportional hazards model adjusted for age, sex, percent African ancestry (estimated from ancestry informative markers), stage at diagnosis, and treatment. We found the C allele at rs1878022, in the chemokine receptor-like 1 (*CMKLR1*) gene, was associated with reduced mortality [hazard ratio (HR): 0.72, 95% confidence interval (CI): 0.54-0.97, p=0.03]. The improved survival is in contrast to a prior lung cancer survival GWAS of similar sample size conducted in whites, suggesting ethnic-specific associations. We then sought to identify rare variants in protein coding regions associated with lung cancer survival. We identified variants with a MAF < 5% (n=114,646) and mapped them to 9,725 genes. We used the sequence kernel association test (SKAT) and burden test, adjusting for age, sex, and African ancestry, to examine associations between rare variants and lung cancer survival. The strongest association was with the *MICAL-L2* gene (HR =1.84, 95% CI: 1.42-2.37, $p=1.04\times10^{-6}$) that interacts with actinin-4, which in turn harbors variants associated with poor lung cancer survival. A significant association was also found for the vascular epidermal growth factor B (*VEGFB*) gene ($p=4.0\times10^{-6}$), which may play a role in tumor survival. We identified 3 genes associated with overall survival, which if validated could suggest potential new targets for lung cancer treatments. Fine-mapping in larger populations and functional studies are required to understand the role of these variants in lung cancer survival.

3459M

Cytogenetic abnormalities of 50 AML patients by FISH detection and conventional karyotype analysis. *E. Karaca, A. Aykut, B. Durmaz, A. Durmaz, I.M. Tekin, O. Cogulu, H. Akin.* Ege University Faculty of Medicine, Department of Medical Genetics, Izmir, Turkey.

Cytogenetic analyses in acute myeloid leukemia (AML) have come to light a great number of chromosome abnormalities. The cytogenetic analysis is an important laboratory tool for diagnosis, prognosis, in clinical decision-making and in follow-up for pediatric and adult patients with AML. Fluorescence in situ hybridization (FISH) is increasingly being used in the cytogenetic diagnosis of AML. In this study the detectable rate of cytogenetic abnormalities including t(8;21)(q22;q22), t(15;17)(q24;q21), t(9;22)(q34;q11), inv(16)(p13q22) and MLL rearrangements by FISH was evaluated. The aim was to investigate the ratio of cytogenetic abnormalities and compare it with the literature. FISH analysis for mentioned cytogenetic abnormalities were performed in 50 bone marrow samples obtained from adult patients with AML diagnosed according to the WHO criteria. The results showed that the cytogenetic abnormalities were identified in 12 (24 %) of the patients. The most frequent aberration rate was 10 % for inv(16)(p13q22). The second most frequent aberration was 6 % for t(9;22)(q34;q11). t(8;21)(q22;q22), t(15;17)(q24;q21), and MLL rearrangements detection rates were 4 %, 2 %, 4 % respectively. The repetitive analyses by the aim of follow up and cytogenetic results were also evaluated. It was noted a substantially lack of an algorithm at diagnosis and follow up request for AML patients. A more reliable approach like wider FISH panels are necessary in order to detect more anomalies and using an algorithm to reach effective diagnose and follow up in AML patients.

DNA methylation profiling reveals novel diagnostic biomarkers in renal cell carcinoma. *B.N. Lasseigne[1, 2], T.C. Burwell[1], M.A. Patil[3], D.M. Absher[1], J.D. Brooks[3], R.M. Myers[1].* 1) HudsonAlpha Institute for Biotechnology, Huntsville, Al; 2) Department of Biological Sciences, University of Alabama in Huntsville, Huntsville, AL; 3) Department of Urology, Stanford University, Stanford, CA.

Renal cell carcinoma (RCC) is the 10th most commonly diagnosed cancer in the United States. While it is usually lethal when metastatic, RCC is successfully treated with surgery when tumors are confined to the kidney and have low tumor volume. Because most early stage renal tumors do not result in symptoms, there is a strong need for biomarkers that can be used to detect the presence of the cancer as well as to monitor patients during and after therapy. We examined genome-wide DNA methylation alterations in renal cell carcinomas of diverse histologies and benign adjacent kidney tissues from 96 patients. We observed widespread methylation differences between tumors and benign adjacent tissues, particularly in immune, G-protein coupled receptor, and metabolism-related genes. Additionally, we identified a single panel of DNA methylation biomarkers that reliably distinguishes tumor from benign adjacent tissue in all of the most common kidney cancer histologic subtypes (area under receiver operating characteristic curve, 0.991), and a second panel does the same specifically for clear cell renal cell carcinoma tumors (area under receiver operating characteristic curve, 0.990). This set of biomarkers were validated independently with excellent performance characteristics in more than 1,000 tissues in The Cancer Genome Atlas clear cell, papillary, and chromophobe renal cell carcinoma datasets (area under receiver operating characteristic curves, >0.97). These DNA methylation profiles provide insights into the etiology of renal cell carcinoma and, most importantly, demonstrate clinically applicable biomarkers for use in early detection of kidney cancer.

3461S

Association of LEP rs7799039 (G-2548A) polymorphism with obesity in breast cancer patients. *A. Méndez'Hernández[1, 2], JA. Espinosa[1], R. Pérez[3], MP. Gallegos[2].* 1) Laboratorio de Investigación, Facultad de Medicina, Universidad Juárez del Esta, Durango, Mexico; 2) Laboratorio de Genética Molecular, División de Medicina Molecular, CIBO, IMSS, Guadalajara. Jalisco; 3) Facultad de Ciencias Químicas, , Universidad Juárez del Estado de Durango, Gómez Palacio, Dgo.

Background: *LEP* rs7799039 polymorphism (*G-2548A*) has been correlated with changes in leptin levels, the degree of obesity and is involved in the evolution of breast cancer. The *LEP -2548AA* genotype was associated with increased leptin concentrations, increased expression of leptin mRNA in adipose tissue, and more high body mass index, thereby increasing the risk for overweight and obesity and evolution breast cancer. Our goal is to evaluate the association of polymorphism rs7799039 *LEP* (*G-2548A*) in obese patients with breast cancer. Methods: DNA genimic of 245 samples (UMAE Hospital Gyneco-Obstetrician, CMNO, IMSS) were included in the study. The *LEP* rs7799039 (*G-2548A*) genotyping was determinate by Taq-Man® probe and allelic discriminated was determinate by StepOne Software v.2., of Applied Biosystems. The association was determinate by odds ratio (OR). Results: The genotype *LEP- 2548AA* was associated with overweight and obesity [OR = 2.1 (95% CI 0.96 - 4.71) , p = 0.05] in patients with breast cancer, while the *LEP- 2548GG* genotype was found as a protective factor to overweight and obesity [OR = 0.47 (95% CI 0.20 . 0.82) , p = 0.011]. Conclusion: *LEP* rs7799039 polymorphism (*G-2548A*) may be an indicator of risk for overweight and obesity and explain the possible mechanism of obesity in the progression of breast cancer.

3462M

Changes in Colorectal Carcinoma Genomes under Anti- EGFR Therapy Identified by Whole-Genome Plasma DNA Sequencing. *S. Mohan[1], E. Heitzer[1], P. Ulz[1], I. Lafer[1], S. Lax[2], M. Auer[1], M. Pichler[3], A. Gerger[3], F. Eisner[3], G. Hoefler[4], T. Bauernhofer[3], J.B Geigl[1], M.R Speicher[1].* 1) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 2) Department of Pathology, General Hospital Graz West, Graz, Austria; 3) Division of Oncology, Medical University of Graz, Graz, Austria; 4) Institute of Pathology, Medical University of Graz, Graz, Austria.

Monoclonal antibodies targeting the Epidermal Growth Factor Receptor (EGFR), such as cetuximab and panitumumab, have evolved to important therapeutic options in metastatic colorectal cancer (CRC). However, almost all patients with clinical response to anti-EGFR therapies show disease progression within a few months and little is known about mechanism and timing of resistance evolution. Here we analyzed plasma DNA from 10 patients treated with anti-EGFR therapy by whole genome sequencing (plasma-Seq) and ultra-sensitive deep sequencing of genes associated with resistance to anti-EGFR treatment such as *KRAS*, *BRAF*, *PIK3CA*, and *EGFR*. Surprisingly we observed that the development of resistance to anti-EGFR therapies was associated with acquired gains of *KRAS* in 4 patients (40%), which occurred either as novel focal amplifications (n=3) or as high level polysomy of 12p (n=1). In addition, we observed focal amplifications of other genes recently shown to be involved in acquired resistance to anti-EGFR therapies, such as *MET* (n=2) and *ERBB2* (n=1). Overrepresentation of the *EGFR* gene was associated with a good initial anti-EGFR efficacy. Overall, we identified predictive biomarkers associated with anti-EGFR efficacy in 7 patients (70%), which correlated well with treatment response. In contrast, ultra-sensitive deep sequencing of *KRAS*, *BRAF*, *PIK3CA*, and *EGFR* did not reveal the occurrence of novel, acquired mutations. Thus, plasma-Seq enables the identification of novel mutant clones and may therefore facilitate early adjustments of therapies that may delay or prevent disease progression.

3463T

Zoledronic acid treatment up-regulates miR-15a via targeting antiapoptotic BCL2 gene expression in chronic myeloid leukemia. *Z. Mutlu[1], C. Caliskan[1], B. Goker[1], C. Kayabasi[1], B. Tezcanli Kaymaz[1], G. Saydam[2], C. Gunduz[1], C. Biray Avci[1].* 1) Ege University Medical School Department of Medical Biology, Izmir, Turkey; 2) Ege University Medical School Department of Hematology, Izmir, Turkey.

Chronic myeloid leukemia (CML) is associated with a characteristic chromosomal translocation called the Philadelphia chromosome (Ph). This genetic alteration for the diagnosis of CML causes the formation of the BCR-ABL1 fusion gene which produces actively tyrosine kinase. Apoptosis is a form of programmed cell death and autophagy is a lysosomal degradation pathway essential for homeostasis that contributes to cell death. Zoledronic acid (ZA), a nitrogen-containing bisphosphonate, is a potential inhibitor of osteoclast-mediated bone resorption and also remarkable for anticancer activities. Autophagic effect of ZA in leukemia is still unknown. miRNAs cause regulation of autophagic and apoptotic pathways in different cancers. In this study, we aimed to evaluate the cytotoxic, autophagic and apoptotic effects of ZA and to examine expression levels of miRNAs treatment with ZA in K562 CML cells. Also we investigate the roles of miRNA target genes during leukemogenesis. K562 cells were treated with dose range of 2 μM to 80 μM ZA during 24, 48, 72 hours and cytotoxicity was performed by WST-1 analysis. Apoptosis assays were evaluated by AnnexinV and by ApoDIRECT In Situ DNA Fragmentation Assay Kits. The RT-qPCR is used for miRNAs and genes expressions analyses. miRNAs and genes expression levels were evaluated by using miScript miRNA PCR Array and RT2 Profiler PCR Array, respectively. According to results, ZA upregulated expression level of miR-15a 9.88 fold and downregulated expression level of BCL2 gene 3,16 fold which is a miR-15a target gene, according to control cells. The results provide that ZA can be played a role as a kinase inhibitory in CML. Because, apoptomirs, such a miR-15a were down-regulated and this downregulation of miR-15a was dependent on BCR-ABL kinase activity in ZA-untreated CML cells. Consequently, ZA upregulated miR-15a expression and miR-15a directly targeted BCL2 gene and induced apoptosis or autophagy progressions in CML. These data indicated that downregulation of miR-15a could be a pioneering target in CML treatment. With these results further experiments are required for the usage of ZA in CML.

Towards a national implementation of DNA-based personalized cancer treatment in the Netherlands. *I.J. Nijman on behalf of the Netherlands Center for Personalized Cancer Treatment.* Center for Personalized Cancer Treatment.

In the past 30 years, cancer treatment has improved enormously, partly due to the development and implementation of targeted therapies. These therapies are designed to tackle specific characteristics of a cancer cell, such as growth factor receptors. Unfortunately, the presence or absence of such characteristics only paints a partial picture of the tumor's responsiveness. Instead, treatment outcome can be better predicted by a combination of genetic mutations. As each tumor has its own genetic characteristics, the appropriate treatment-decision differs per patient and is therefore called "personalized treatment". This approach can improve treatment outcome for patients with metastatic cancer, decrease the number of patients unnecessarily exposed to toxic agents, and reduce costs. Being able to classify patient populations into groups with different likelihoods to benefit from a particular treatment is key in this process. The Center for Personalized Cancer Treatment brings this concept to the patient today by forging collaborations between all academic cancer centers in the Netherlands. The CPCT focusses on two DNA analysis tracks. First, rapid screening for actionable mutations and amplifications to select the appropriate standard targeted treatment or to allocate patient into investigator and pharma-driven Phase1 trials. At the moment over 1200 patients have been analyzed through this route. Secondly, cohorts of patients with evaluable response to targeted treatments are sequenced and analyzed in a system biology perspective to identify predictive biomarkers. Detailed follow up data for over 700 patients is now being collected in an electronic clinical response form (eCRF) and integration with genetic, pathology and pharmacological is ongoing. Combined with public datasets, this integrated dataset provides a huge and growing national resource that can be used for biomarker- or target evaluation, systems biology analyses, as well as for improving care for individual patients.

Integration of microarray meta-analysis with RNASeq and genome-wide genetic data to identify variants associated with endometrial cancer histological subtype. *T.A. O'Mara, A.B. Spurdle.* Genetics and Computational Biology Dept, QIMR Berghofer Medical Research Institute, Brisbane, QLD, Australia.

Non-endometrioid endometrial cancer comprises approximately 20% of new endometrial cancer diagnoses, but is responsible for an estimated 50% of deaths from this disease. Microarrays have been successfully used to measure mRNA expression in biological samples to identify differentially expressed genes. However, it is recognized that results from individual microarray studies are often not reproducible. Public availability of gene expression microarray data has facilitated research assessing the increased reliability of combined datasets. Furthermore, the availability of genome-wide scale "-omics" data on the same sample sets, such as that provided by The Cancer Genome Atlas (TCGA), allows for a powerful, integrative approach to identify genes and genetic variants important in cancer initiation and/or progression. We have used patient derived microarray data from multiple datasets to identify differences between endometrioid (EEC) and non-endometrioid (NEEC) histological subtypes of endometrial cancer, and then validated these differences using an independent endometrial cancer set with RNASeq data from the TCGA. A literature review and repository search conducted in April 2014 identified 15 endometrial cancer microarray studies. Raw microarray data was accessed from publication supplementary data, the NCBI Gene Expression Omnibus (GEO) and the TCGA data portal, or otherwise requested by directly contacting authors. Overall raw microarray data was accessed for 9 of 15 studies, with a maximum of 79 EEC and 12 NEEC cases in one study. Following QC and meta-analysis using the MetaOmics package in R, 1,910 genes from 6 studies were identified by Fisher's test as displaying significant differential expression between the two subtypes (FDR < 5%). The expression of these genes was then analyzed using normalized RNASeq data for 328 EEC and 97 NEEC non-overlapping samples from the TCGA. For the 1,186 genes captured by the RNASeq analysis, moderated t-test identified differences in expression for 912 genes at $P < 0.05$ (77% of genes analysed), of which 261 were at $P < 1\times10^{-19}$. These findings demonstrate a strong relationship between microarray meta-analysis and RNASeq results, and identify candidate genes differentially expressed in aggressive endometrial cancer histological subtypes. Future analysis will investigate genetic variation associated with differential gene expression in the TCGA dataset, to prioritize genetic variants for downstream prognostic studies.

The type II transmembrane serine proteases hepsin and TMPRSS3 are associated with breast cancer survival. *M. Pelkonen[1, 2, 3], K. Luostari[1, 2, 3], H. Ahonen[1, 2, 3], B. Berdel[1, 2, 3], V. Kataja[4, 5], Y. Soini[1, 2, 3], V-M. Kosma[1, 2, 3], A. Mannermaa[1, 2, 3].* 1) Institute of Clinical Medicine, Pathology and Forensic Medicine, University of Eastern Finland, P.O. Box 1627, FI-70211 Kuopio, Finland; 2) Biocenter Kuopio and Cancer Center of Eastern Finland, University of Eastern Finland, P.O. Box 1627, FI-70211 Kuopio, Finland; 3) Imaging Center, Clinical Pathology, Kuopio University Hospital, P.O. Box 1777, FI-70211 Kuopio, Finland; 4) Institute of Clinical Medicine, Oncology, University of Eastern Finland, P.O. Box 1627, FI-70211 Kuopio, Finland; 5) Cancer Center, Kuopio University Hospital, P.O. Box 1777, FI-70211 Kuopio, Finland.

Background: Hepsin, (also called TMPRSS1) and TMPRSS3 are type II transmembrane serine proteases (TTSPs) that are involved in cancer progression. TTSPs can remodel extracellular matrix (ECM) and, when dysregulated, promote tumor progression and metastasis by inducing defects in basement membrane and ECM molecules. This study investigated whether the gene and protein expression levels of these TTSPs were associated with breast cancer characteristics or survival. Methods: Immunohistochemical staining was used to evaluate hepsin levels in 372 breast cancer samples and TMPRSS3 levels in 373 samples. *TMPRSS1* mRNA expression was determined in 125 invasive and 16 benign breast tumor samples, and *TMPRSS3* mRNA expression was determined in 167 invasive and 23 benign breast tumor samples. The gene and protein expression levels were analyzed for associations with breast cancer-specific survival and clinicopathological parameters. Results: Low *TMPRSS1* and *TMPRSS3* mRNA expression levels were independent prognostic factors for poor breast cancer survival during the 20-year follow-up (*TMPRSS1*, P = 0.023; HR, 2.065; 95% CI, 1.106-3.856; *TMPRSS3*, P = 0.013; HR, 2.106; 95% CI, 1.167-3.800). Low expression of the two genes at the mRNA and protein levels associated with poorer survival compared to high levels (log rank P-values 0.015-0.042). Grade III tumors, large tumor size, and metastasis were associated with low mRNA and protein expression levels. Conclusions: The results suggest that the TTSPs hepsin and TMPRSS3 may have similar biological functions in the molecular pathology of breast cancer and that they represent potential novel therapeutic targets. Low mRNA and protein expression levels of the studied TTSPs were prognostic markers of poor survival in breast cancer.

Genetic variants in the gene *ARID5B* associated with susceptibility to childhood acute lymphoblastic leukemia. *A. Reyes-León[1], C. Salas-Labadía[1], J. García-Cruz[1], M. Zapata-Tarrés[1], M. Ramírez-Martínez[1], R. Paredes-Aguilera[1], R. Rivera-Luna[1], S. Jiménez-Morales[2], L. Orozco-Orozco[2], M. Dean[3], P. Pérez-Vera[1].* 1) Instituto Nacional de Pediatría, Mexico city, Mexico; 2) Instituto Nacional de Medicina Genómica, Mexico city, Mexico; 3) National Cancer Institute, Frederick, Maryland, USA.

In Mexico the acute lymphoblastic leukemia (ALL) is the most common cancer in pediatric population. According to the National Popular Medical Insurance Program, in our country the incidence is 60 cases per million per year. Some individual genetic variations might contribute to the increased incidence, and simultaneously influence susceptibility to the disease development. Recently, some authors have reported single nucleotides polymorphisms (SNPs) of *ARID5B* gene that could be associated with susceptibility to childhood ALL in Latin American population; however these observations are not representative of the real situation in Mexico. The purpose of this study was to determine the presence of 2 SNPs of *ARID5B* in ALL children for establishing their possible association with susceptibility to develop the disease. The study population included 112 children with ALL and 114 controls. Informed consent was obtained before taking saliva samples. The DNA was extracted, and genotyping analysis was performed using TaqMan probes for the SNPs rs10821936 and rs10994982 of *ARID5B*. The allele and genotype frequencies of ALL cases and controls were calculated. Odds Ratio (OR) with 95% confidence intervals [95% CI] were performed using FINETTI software. *P* values less than 0.05 was considered statistically significant. For the SNP rs10821936, 112 ALL cases and 114 controls were analyzed and for SNP rs10994982 only 52 ALL cases and 99 controls were studied. The frequency of the risk allele C of the SNP rs10821936 was significantly higher ($p<0.0001$) in cases (89.3%) than in controls (70.2%); the behavior of the frequencies for the allele A of the SNP rs10994982 was similar, the frequency in cases was 92.3% and in controls 78.8% ($p=0.0001$). The risk for developing ALL was increased in the presence of the homozygous CC ($p=2.8e-6$, OR 6.5, CI) and AA ($p=0.0009$ OR 6.6, CI) genotypes compared with the heterozygous CT ($p=0.02$, OR 2.3 CI) and AG ($p=0.3219$, OR 1.8 CI). The frequency of the risk alleles C and A in our patients was higher than reported in other populations. The frequency of these alleles in the control group is similar to that observed in healthy indigenous population from Mexico and Guatemala. These results suggest that the genetic component of our patients could be influencing the susceptibility to develop ALL and could also explain its high incidence in Mexico. This work was supported by Fondos del Presupuesto Federal para la Investigación 2012 (085/2012).

3468M

Cell cycle progression gene expression score and prostate cancer outcomes in a population-based cohort. *R. Rubicz[1], S. Zhao[1], C. April[2], J.L. Wright[1,3], S. Kolb[1], I. Coleman[4], D.W. Lin[1,3], P.S. Nelson[4,5,6], E.A. Ostrander[7], Z. Feng[8], J.-B. Fan[2], J.L. Stanford[1].* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Illumina, Inc., San Diego, CA; 3) Department of Urology, University of Washington School of Medicine, Seattle, WA; 4) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Division of Clinical Research, Fred Hutchinson Cancer Research Center, Seattle, WA; 6) Department of Medicine, University of Washington, Seattle, WA; 7) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 8) Department of Biostatistics, University of Texas MD Anderson Cancer Center, Houston, TX.

Prostate cancer (PCa) is clinically heterogeneous, making it difficult to accurately predict which patients will have an indolent vs. aggressive disease course. Therefore markers that can help distinguish aggressive tumors in high-risk patients are urgently needed. In 2012 Cuzick et al. reported a cell cycle progression (CCP) score (based on expression of 31 genes in tumor tissue) as a predictor of PCa death in a conservatively managed patient cohort. To further evaluate the CCP score we tested its performance in a population-based cohort of 383 men diagnosed with clinically localized PC in 1993-1996 or 2002-2005 who underwent radical prostatectomy (RP). Recurrence information was obtained from participant surveys, medical records, and the SEER cancer registry. Over a follow-up period of 12 years, 278 men (73%) had no evidence of recurrence and 105 (27%) had recurrence events, including 27 (7%) patients who developed metastasis or died of PCa (lethal PCa). Tumor RNA was isolated from FFPE blocks of RP samples and gene expression data were obtained using the Illumina Whole-Genome DASL HT Assay. CCP score was based on average expression levels of 30 of the 31 progression genes (c18orf24 was excluded due to low quality). Based on Cox proportional hazards models, the hazard ratio (HR) associated with a change from the 25th to 75th percentile of the CCP score (range 7.97-9.96) was 1.25 (95% CI 0.96-1.62; P = 0.10) for overall recurrence, and for the subset of patients with lethal PCa it was 2.01 (95% CI 1.26-3.21; P = 0.004), adjusted for clinical variables (ie, age at diagnosis, Gleason score, PSA level, and pathologic stage). Adding the proliferation marker *Ki67* to the model did not change the results. CCP score was only weakly correlated (by Pearson correlation) with Gleason score (0.13) and PSA (0.16). Secondary analyses showed similar associations when patients were stratified by Gleason score, *TMPRSS2-ERG* fusion status, or family history of PCa. The ROC curve for CCP score (AUC = 0.740) did not perform as well as clinical variables (AUC = 0.803) for predicting lethal PCa, and the ROC curve combining CCP score with clinical variables was only slightly improved (AUC = 0.831). These results confirm a significant association between CCP score and risk of lethal PCa. However, the CCP score did not substantially improve the AUC and had less discriminatory accuracy than clinical variables alone.

3469T

Gene expression profile of human telomere and telomerase complex in intestinal-type gastric cancer. *L.C. SANTOS[1], F. Wisnieski[1], M.F. Leal[1], D.Q. Calcagno[2], C.O. Gigek[1], E.S. Chen[1], S. Demachki[2], P.P. Assumpção[2], R. Artigiani[3], L.G. Lourenço[4], R.R. Burbano[5], M.A.C. Smith[1].* 1) Genetics Division, Department of Morphology and Genetic, Federal University of São Paulo, São Paulo, Brazil; 2) Nucleu of Research in Oncology, João de Barros Barreto University Hospital, Federal University of Pará, Belém, Brazil; 3) Department of Pathology, Federal University of São Paulo, São Paulo, Brazil;; 4) Department of Surgical Gastroenterology, Federal University of São Paulo, São Paulo, Brazil; 5) Human Cytogenetics Laboratory, Institute of Biological Sciences, Federal University of Pará, Belém, Brazil.

Gastric cancer is the fourth most prevalent and the second cause of cancer death worldwide. Changes in gene expression of telomere and telomerase complex have been observed in carcinogenic processes. The investigation of these genetic mechanisms may help to determine more accurate diagnosis, prognosis and the establishment of a therapeutic approach. In the present study, we aimed to identify differentially expressed genes of telomere and telomerase complex in gastric tumors compared to matched noncancerous gastric samples. The expression of 84 key genes involved in telomere replication and maintenance was evaluated using the Human Telomeres & Telomerase RT² Profiler™ PCR Array (SABiosciences, PAHS-010). We analyzed 22 paired intestinal-type gastric cancer and adjacent noncancerous gastric tissues from individuals of Northern Brazil. We observed that ACD, BCL2, MUS81, RAD17, RAPGEF1, SIRT2 and SIRT6 expression were downregulated in neoplasic samples compared to matched noncancerous (-1.9, -2.3, -1.8, -1.6, -1.8, -1.5 and -1.6 - fold regulation; and p = 0.004, p = 0.01, p = 0.04, p = 0.008, p = 0.01, p = 0.04, p = 0.04; respectively). And HSP90AA1 and NBN were upregulated (1.8 and 1.8 - fold regulation; and p = 0.008 and p = 0.02; respectively). ACD gene encodes a protein that is involved in telomere maintenance. This protein is one of six core proteins of shelterin telomeric complex. RAPGEF1 mediate binding events that control the activity of shelterin complex. MUS81 and RAD17 are required for efficient DNA repair of telomere-associated complexes. The BCL2 gene encodes a protein that has a role in the control of apoptosis and inhibition of the telomerase action. SIRT2 and SIRT6 have been implicated in influencing a wide range of cellular processes like aging, DNA repair, telomere maintenence and energetic metabolism. HSP90AA1 has anti-apoptotic function and NBN promotes repair of damaged DNA. These differentially expressed genes highlight the importance of telomere and telomerase complex in intestinal-type gastric carcinogenesis. These results contribute to the understanding of gastric cancer biology with possible future clinical implications to be tested in a subsequent study in a larger number of gastric cancer patients, and to be associated to sex, age, tumor location, H. pylori, tumor extension, limph node metastasis and distant metastasis.

3470S

Study of expression of AKAP4, RGS22, SPAG9 and NY-ESO-1 genes as probable diagnosis and prognosis biomarkers in colorectal cancer. *A. Tavakoli Koudehi[1], F. Mahjoubi[1], B. Mahjoubi[2], R. Mirzaee[2].* 1) National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran; 2) Hazrat Rasoul Hospital, Iran University of Medical Sciences and Health Care Services, Tehran, Iran.

Background: Colo-rectal cancer (CRC) is the most common gastrointestinal cancer and the second leading cause of death in women after breast cancer and the third leading cause of death in men after lung and prostate carcinomas in the world. Because of the slow progression of CRC and the ability of treatment in primary levels (before lymph-vascular invasion), there is an urgent need to identify non-invasive tumor bio-markers (biological markers) that can prognostic the CRC in primary levels and subsequently decrease the prevalence and mortality of it. Cancer-Testis Antigens (CTAs) are a group of tumor-associated proteins which typically are expressed in normal reproductive cells of men, but their expression in normal somatic cells is off. Several reports have been identified the CTAs expression in various human tumors, such as, ovarian, endo-metrial, cervical, esophageal, and breast cancers. CTAs due to their limited expression pattern, are as promising targets for cancer diagnosis and immuno-therapy. Method: We study the expression of AKAP4, RGS22, SPAG9 and CTAG1B genes from the CTAs family in both tumor and normal tissues of 80 Iranian CRC patients by RT-PCR with the aim of comparing the genes expression and finding a biomarker for early detection and anticipated progress to CRC. According to studies, AKAP4, RGS22, and NY-ESO-1 gene expressions in colorectal cancer tissues has not been investigated so far. The SPAG9 gene expression by RT-PCR was first investigated in Iranian patients. Result: Results are pending.

Gene polymorphisms as risk factors for Cervical Cancer in a South Indian Population. *P. Upendram[1], S. Poornima[1], G. Apoorva[1], K. Jayanthi[1], V. Kiran Kumar[1], A. Shah[2], Q. Hasan[1].* 1) Department of Genetics & Molecular Medicine, Kamineni Hospitals, L.B.Nagar, Hyderabad, Andhra Pradesh, India; 2) Department of Oncology, Kamineni Hospitals, L.B.Nagar, Hyderabad, Andhra Pradesh, India.

Carcinoma of the uterine cervix is the most frequent gynecological malignancy affecting women in developing countries despite being a potentially preventable disease. Globally, it is the second most frequent cancer affecting women with a steady rise in incidence among younger women. It is evident from current literature that specific gene polymorphisms in hormone receptor genes and the cell cycle regulating genes along with ineffective host immune response may enhance the risk for gynecological malignancies. The aim of this case control study from South India was to evaluate four gene polymorphisms (i) T/C SNP of estrogen receptor (ER) alpha gene recognized by PvuII enzyme (rs2234693), (ii) 306bp Alu insertion in the progesterone receptor (PGR) gene (rs1042838), (iii) G870A SNP of CCND1 gene (rs9344) and (iv) C850T SNP of TNF alpha gene (rs909253) in cervical cancer patients. DNA was isolated from a total of 200 women comprising 100 cases with cervical cancer and 100 age-matched healthy controls using the salting out technique. Polymorphisms were evaluated by Polymerase Chain Reaction followed by restriction enzyme digestion / gel electrophoresis. Our results showed a statistically significant association of the C allele of ER gene (OR= 5.8072; 95% CI=3.7671 to 8.9521; p<0.0001) with cervical cancer. While, the T2 allele of PR gene did not show any significant association with cervical cancer (OR=1.3700; 95% CI=0.7193 to 2.6093; p= 0.33). The A allele CCND1 gene was associated with cervical cancer (OR= 1.917; 95% CI=1.286 to 2.857; p<0.0014) and the T allele of TNF alpha gene was not significantly associated with this cancer (OR= 1.413; 95% CI=0.95 to 2.102; p<0.087), however the heterozygous CT genotype was protective. In Multifactor Dimensionality Reduction (MDR) analysis, the ER and CCND1 gene polymorphisms showed an interaction with cervical cancer (p<0.0001). Our results suggest that the ER PvuII polymorphism and CCND1 G870A polymorphism can be used as biomarkers in identifying women with an increased risk of getting cervical cancer. A larger study in different ethnic groups is warranted for establishing them as biomarkers for cervical cancer.

3472T

Association of common Cancer stem cells (CSCs) genes variants with gallbladder cancer susceptibility and prognosis in North Indian population. *A. Yadav[1], B. Mittal[2], A. Gupta[3], K.L. Sharma[4], V. Kumar[5], A. Kumar[6].* 1) Medical genetics, Sanjay Gandhi Post Graduate Institute of medical Sciences, Lucknow, Uttar pradesh, India; 2) Dr. Balraj Mittal, Medical genetics, Sanjay Gandhi Post Graduate Institute of medical Sciences, Lucknow, Uttar pradesh, India; 3) Annapurna Gupta, Department of Medical Genetics, Medical genetics, Sanjay Gandhi Post Graduate Institute of medical Sciences, Lucknow, Uttar pradesh, India; 4) Kiran lata Sharma, Medical genetics, Sanjay Gandhi Post Graduate Institute of medical Sciences, Lucknow, Uttar pradesh, India; 5) Dr. Vijay Kumar, King George's Medical University, Lucknow, Uttar pradesh; 6) Dr. Ashok Kumar, Medical genetics, Sanjay Gandhi Post Graduate Institute of medical Sciences, Lucknow, Uttar pradesh, India.

Introduction: Genes important to stem cell development have been significantly implicated in the etiology and clinical outcome of various cancers. However, the associations of genetic variations in these genes with gallbladder cancer (GBC) have not yet been established. We investigated germline variants in Cancer stem cell genes (CSCs) to predict patient's susceptibility and efficacy with chemoradiotherapy treatment response. Methods: The study included 830 subjects, 580 GBC patients and 250 healthy controls. Among 580 patients, 164 patients were analyzed for chemoradiotheruaptic response. This study examined association of CD44 rs13347C/T, CD44 rs353639A/C, CD44 rs187116G/A, CD44 rs187115T/C, ALCAM rs1157G/A, ALCAM rs10511244 T/C, EpCAM rs1126497T/C, EpCAM rs1421T/C, CD133 rs3130C/T, CD133 rs2240688T/C, ALDH1A1 rs13959A/G, OCT-4 3130932T/G, LIN-28B rs4274112T/C, NANOG rs11055786C/T, SOX-2 rs11915160A/C polymorphisms. Genotyping was done by PCR-RFLP, ARMS-PCR and Taqman allelic discrimination assays. The association of clinicopathological, treatment response and toxicity with CSCs genetic variants was performed by SPSSver16. In-silco analysis was performed using Bioinformatics tools (F-SNP, FAST-SNP). Results: Statistical analysis by logistic regression showed significant association of CD44 rs353639A/C [CC, p=0.02], ALCAM rs1157G/A [AA, p=0.007], ALCAM rs10511244T/C [CC, p=0.009], OCT-4 rs3130932T/G [GG, p=0.01], LIN-28B rs4274112T/C [TC, p=0.03 CC, p=0.03], NANOG rs11055786 C/T [CT, p=0.03] polymorphisms with increased risk of GBC. Haplotype of CD44 [TAAC] showed significant association with reduced risk in GBC males and ALCAM [AC] haplotype associated with increased risk in GBC females. EpCAM rs1421T/C [TC, p=0.01] showed a statistically significant association with hematological toxicity and negative Lymph node status while SOX-2 rs11915160 A/C [CA, p=0.02] and NANOG rs11055786T/C [CT, 0.01] were associated with positive lymph node status. CD44 rs13347C/T [TT, p=0.02] and EpCAM rs1126497T/C [CC, p=0.04] were associated with good treatment outcome response. In-silico analysis of SNPs revealed variable change in transcriptional and splicing regulation. Conclusion: This is the first report of association of cancer stem cell genetic variants with GBC susceptibility and prognosis. Our results suggest that cancer stem cell genetic variants may also have a role with GBC susceptibility and clinical outcomes in North Indian population.

3473S

Association of GST polymorphism with susceptibility to Leuekmia and differential chemotherapy response. *S. Caplash[1], S. Kaur[1], R. Arora[2].* 1) Department of Human Genetics, Punjabi University, Patiala, India; 2) Oswal Cancer Hospital, Ludhiana.

Glutathione S-transferases (GST) isoenzymes play a significant role in phase II biotransformation and detoxification of many xenobiotics including environmental carcinogens, pollutants and drugs. Both the genetic polymorphisms and expression pattern of GST genes may have a major impact on cancer susceptibility, inter-individual variability in the prognosis, drug effects and toxicity. Of these, GSTT1 and GSTM1 isoenzymes are highly polymorphic with homozygous deletion of either or both genes resulting in absence of enzyme activity. We carried out a case-control study involving 150 Leukemia patients and 134 normal healthy controls from Punjab (North India). Multiplex PCR was carried out to determine GSTM1 and GSTT1 polymorphism. The frequency of individuals carrying GSTM1 and GSTT1 null genotypes was higher among Leukemia patients (42 % and 23 %) as compared to the control group (41 % and 19 %), although the difference found was not statistically significant (p>0.05). Heterogeneity in patients's response to chemotherapy is consistently observed across populations so follow up of patients is in process to analyze the association of GST genotypes with differential chemotherapy drug response.

3474M

BCR-JAK2 Translocation with Compleks Chromosomal Karyotype. *A. Ozturk Kaymak[1], C. Sonmez[2], S. Oztomurcuk[1], G. Guntas[2], S. Civriz Bozdag[3], F. Altuntas[3].* 1) Medical Genetics, Dr. A.Y. demeteveler Oncology Research and education Hospital, ANKARA, Turkey; 2) Biochemistry, Dr. A.Y. demeteveler Oncology Research and education Hospital, ANKARA, Turkey; 3) Heamatology,Dr. A.Y. demeteveler Oncology Research and education Hospital, ANKARA, Turkey.

sequencing is routinly used for diagnosis in chronic myeloproliferative neoplasms(2). Polycythemia vera, primary myelofibrosis and essential thrombocythemia have been occured because of V617F, the common gain of function mutation. Although the high ratio of JAK2 point mutations, JAK2 rearrangments are rare and have been associated with ALL and CML. Today only about 22 cases are reported with JAK2 rearrangment. Previous cases with JAK2 rearrangments are diagnosed with acute myeloid leukemia and lymphoblastic leukemia, atypical chronic leukemia, myelofibrosis, myelodysplastic syndrome (4, 5). The partners of chromosome 9 are various such as chromosome 2, 3, 4, 5, 6, 8, 12 and 22 at JAK2 reaarangments. The fusion genes are ETV6, PCM1, RPN1, NFE2, PAX5,SSBP2 and BCR. BCR-JAK2 fusion has leukemogenic role in myeloproliferative disorders. Our patient had also chromosme 5q deletion that is one of the most common structural rearrangements in MDS. The last anomaly of our patient was 8p11 deletion that is also associated with myeloproliferative neoplasms. Here we present BCR- JAK2 translocation with kompleks chromosomal karyotype. With our case, the total number of cases with BCR-JAK2 fusion in leukemia become five. But our case is the first one with kompleks chromosomal karyotype.

3475T

Evaluation of rapid whole-body magnetic resonance as screening strategy for early cancer detection in Li-Fraumeni syndrome patients. *M. Achatz[1, 2], D. Paixao[1], M.D. Guimaraes[3], A. Nogueira[1], R. Chojniak[3].* 1) Department of Oncogenetics, A.C.Camargo Cancer Center, Sao Paulo, Brazil; 2) International Research Center, A.C. Camargo Cancer Center; 3) Department of Imaging, A.C. Camargo Cancer Center.

Li-Fraumeni Syndrome (LFS) is a rare autosomal dominant syndrome that predisposes to a high-risk for developing multiple early onset cancers that includes breast, sarcomas, brain and adrenocortical carcinoma. It is related to germline mutations in TP53 gene. Screening strategies for early diagnosis in carriers constitutes a major challenge due to the wide tumor spectrum. Rapid whole body MRI (RWB-MRI) has been proposed as a screening strategy according to the Toronto protocol and its effectiveness needs to be accessed in different populations. In Brazil, there is a high prevalence of TP53 mutation carriers due to the occurrence of a founder mutation, p.R337H TP53, detected in 0.3% of South and Southeastern Brazilian population. This mutation occurs in the oligomerization domain and has a lower penetrance than regular DNA biding domain mutations in the TP53 gene. Moreover, due to genetic modifiers, tumors occur at a later age than in the regular LFS carriers. This was probably one of the reasons why the mutation spread to such proportions in Brazil. This constitutes a public health issue since its occurrence may be present in a large number of people in the most populated area in the country. The aim of this study is to evaluate the efficacy of RWB-MRI for early cancer detection in p.R337H TP53 mutation carriers and compare it to classical LFS mutation carriers.RWB-MRI was performed in 33 TP53 germline mutation carriers, including 29 cases with p.R337H. One malignant lesion was detected in an eighteen years-old p.R337H female carrier. RWB-MRI evidenced bilateral renal cortical alterations. Images were further confirmed with abdominal MRI which showed a solid lesion with enhancement in right kidney and a lesion with benign aspects in the left kidney. Lesion in the right kidney was surgically removed and anatomic-pathological findings indicated a papillary renal cell carcinoma. Incidental findings were detected in two out of the 33 patients. Further imaging techniques were done to detail diagnosis and no unnecessary biopsies were performed. No lesions were detected among the classical LFS carriers. The same cohort will further undergo WB-MRI in a 12- and 14 month interval. Preliminary results from this study demonstrated the effectiveness of RWB-MRI in detecting one case of a malignant lesion among 29 p.R337H LFS patients. It indicates that this might be an important imaging tool for early detection in LFS p.R337H TP53 mutation carriers.

Spectrum of mutations in BRCA1 and BRCA2 genes in Hereditary Breast/Ovarian Cancer families from Algeria: current knowledge and implications in genetic counseling and testing. *F. Cherbal[1], R. Bakour[1], C. Mehemmai[1], H. Gaceb[1], I. Derouiche[1], K. Akli[1], K. Boualga[2].* 1) Unit of Genetics, LMCB, Faculty of Biological Sciences, USTHB, Algiers, Algeria; 2) Anti Cancer Center, Blida, Algeria.

Background: Breast cancer is currently the leading cause of cancer morbidity and mortality among Algerian women. To date, the mean age of breast cancer cases in Algeria is younger than in North America or Europe. Between 2008 and 2014, 136 Algerian breast/ovarian cancer families were screened for BRCA1 and BRCA2 germline mutations (70 families) and for common mutations detected previously in BRCA1 gene of Algerian, Moroccan and Tunisian patients (66 families), respectively. Methods: 152 Algerian probands and relatives were screened for complete BRCA1 and BRCA2 germline mutations by using HRM- direct sequencing (86 individuals) and for 5 recurrent germline mutations detected previously in BRCA1 gene of patients from Algeria, Morocco and Tunisia by using PCR-direct sequencing (66 individuals). Screening for large genomic rearrangements (LGR) in BRCA1 and BRCA2 genes was performed in 76 patients tested negative for small point mutations by using MLPA technique. To confirm the genomic rearrangement and its genomic breakpoints, we performed long-range PCR of genomic DNA. In silico prediction for novel missense variants effects was carried out by using 5 bioinformatics programs: Align-GVGD, Polymorphism Phenotyping2, SIFT program, Mutation Taster and Mutation Assessor. Results: The analysis of DNA samples of 152 individuals revealed that 12 patients and one male relative carried pathogenic germline mutations: 11 within BRCA1 and 2 within BRCA2. In addition, 10 new missense variants have been detected in our study (3 BRCA1 and 7 BRCA2). Four distinct pathogenic mutations, c.19_47del, c.83_84delTG, c.181T>G, c.798_799delTT and two LGR were identified in BRCA1 gene. A novel deletion of BRCA1 exon 2 (c.-19-?_80?del/p.?) and a novel genomic breakpoint in deletion of BRCA1 exon 8 (c.442-?_547?del/p?) were identified in two unrelated breast cancer patients. No LGRs were detected in BRCA2 gene. We found by using long range PCR technique that our patient with the BRCA1 exon 8 deletion is heterozygous for a 2.6 kb deletion. Interestingly, the three common BRCA1 mutations, c.83_84delTG, c.181T>G and c.798-799delTT have been detected in 6 unrelated families (each mutation/2 families). We noted that three new missense variants BRCA1 R1753G, BRCA2 H2116D and BRCA2 G3086R were predicted to be likely pathogenic in silico. Conclusions: The identification of common mutations in BRCA genes in Algerian population may facilitate genetic counseling and testing.

Single-cell genetic analysis reveals insights into clonal development of prostate cancers and indicates loss of *PTEN* as a marker of poor prognosis. *K.M. Heselmeyer-Haddad[1], L.Y. Berroa Garcia[1], A. Bradley[1], L. Hernandez[1], Y. Hu[1], J. Habermann[3], C. Dumke[3], C. Thorns[4], S. Perner[5], E. Pestova[6], C. Burke[10], S.A. Chowdhury[7,8], R. Schwartz[8,9], A.A. Schäffer[2], P.L. Paris[10], T. Ried[1].* 1) Genetics Branch, CCR, NCI, NIH, Bethesda, MD; 2) Computational Biology Branch, NCBI, NIH, Bethesda, MD; 3) Section for Translational Surgical Oncology and Biobanking, Department of Surgery, University of Lübeck, Germany; 4) Institute of Pathology, University of Lübeck, Germany; 5) Department of Prostate Cancer Research, Institute of Pathology, University Hospital of Bonn, Germany; 6) Abbott Molecular, Des Plaines, IL; 7) Joint Carnegie Mellon/University of Pittsburgh Ph.D. Program in Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 8) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 9) Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA; 10) Department of Urology, Helen Diller Family Comprehensive Cancer Center, UCSF, San Francisco, CA.

One of the major challenges in the clinical management of patients with prostate cancer is to gauge the risk of developing progressive disease. We therefore used genetic markers to understand the dynamics of genomic alterations during disease progression. Using a novel, advanced multicolor fluorescence in situ hybridization (FISH) approach, we enumerated copy number of six genes previously identified by array CGH to be involved in aggressive prostate cancer - *TBL1XR1*, *CTTNBP2*, *MYC*, *PTEN*, *MEN1*, and *PDGFB* - in six non-recurrent and seven recurrent radical prostatectomy cases. An *ERG* break-apart probe to detect *TMPRSS2-ERG* fusions was included. Subsequent hybridization of multicolor probe panels and relocation of cells resulted in signal counts for all probes in each individual cell analyzed. We neither observed differences in the degree of chromosomal and genomic instability, i.e., intratumor heterogeneity, nor in the percentage of cells with *TMPRSS2-ERG* fusion between samples with or without progression. However, tumors from patients that progressed had more chromosomal gains and losses, and showed a higher degree of selection for a predominant clonal pattern. The loss of *PTEN* was the most frequent aberration in progressors (57%), followed by the gain of *TBL1XR1* (29%). The gain of *MYC* was observed in one progressor, which was the only lesion with an *ERG* gain, but no *TMPRSS2-ERG* fusion. According to our results, a probe set consisting of *PTEN*, *MYC* and *TBL1XR1* would detect progressors with 86% sensitivity and 100% specificity. This will be evaluated further in larger studies.

3478T

Sequence variations in known cancer susceptibility genes identified in high-risk breast cancer cases from the French GENESIS study. *F. Lesueur[1], E. Girard[1], F. Damiola[2], M.G. Dondon[1], L. Barjhoux[2], S. Eon-Marchais[1], M. Gauthier-Villars[3], B. Buecher[3], C. Lasset[4], P. Berthet[5], C. Delnatte[6], J.P. Fricker[7], M. Longy[8], O. Caron[9], P. Pujol[10], A. Chevrier[11], P. In France, a pathogenic BRCA1 or BRCA2 mutation is found in at most 16% of tested index cases of families predisposed to breast and ovarian cancers. Other breast cancer (BC) predisposing genes have been recently identified (PALB2, BRIP1, RAD51C, RAD51D, XRCC2, etc.), and with the introduction of massive-parallel sequencing (MPS) in clinical laboratories some of these genes are already being screened in patients referred to the clinics as part of multigene panel testing. However their use remains limited in clinical practice because their associated cancer risks have not been precisely estimated yet due to the too small number of families segregating the mutations identified so far. Our goal was to assess the frequencies of protein-truncating variants and rare likely deleterious missense substitutions in the newly identified BC susceptibility genes in a sample of high-risk women participating to the GENESIS study, in order to estimate the number of families that would need to be tested to get a precise estimate of cancer risks in mutation carriers. GENESIS is a unique French national existing resource for familial BC research where >1700 index cases affected with BC and negative for BRCA1/2, >800 affected sisters and >1,500 unrelated matched healthy women have been enrolled. Blood samples, clinical and epidemiological data have been collected for each study participant through the national network of cancer genetics clinics. High-throughput genotyping and MPS projects have been initiated in order to decipher the genetic landscape of BC. Here we examined rare variants (with reported frequency <0.5% in the public sequencing databases) in known BC susceptibility genes, mismatch repair genes and Fanconi Anemia genes identified through exome sequencing in a subset of 100 GENESIS high-risk cases. We found 2 protein-truncating mutations (TM) and 3 likely deleterious missense substitutions (MS) in ATM, 1 TM and 4 MS in CHEK2, and 1 TM and 5 MS in genes of the MRN complex (MRE11A, RAD50 and NBN) occurring in unrelated families. We will next conduct full mutation screening of the gene panel in GENESIS cases and controls to estimate the frequency and the distribution of the different classes of variants in the two groups. National family studies will be set up to assess penetrance and to study cancer spectrum associated with the pathogenic variants. This should help clarifying relevance of mutation screening of these genes to familial cancer clinics and counselors.

3479S

Genome-wide association study (GWAS) for transaminase elevations in pazopanib-treated patients. *X. Wang[1], Z. Xue[1], C. Carpenter[2], P. Harter[3], K. King[1], S. Stinnett[1], T. Johnson[4], J. Shen[1], C. Spraggs[4], M.R. Nelson[1], M. Chen[2], K. Deen[2], I. Mitrica[2], L. Pandite[1], N. Kaplowitz[5], C-F. Xu[4].* 1) GlaxoSmithKline, Research Triangle Park, NC, USA; 2) GlaxoSmithKline, Collegeville, PA, USA; 3) Kliniken Essen-Mitte, Essen Germany; 4) GlaxoSmithKline, Stevenage, UK; 5) Keck School of Medicine, University of Southern California, Los Angeles, CA, USA.

Background: Pazopanib (Votrient™, GlaxoSmithKline), an oral angiogenesis inhibitor, has been approved for the treatment of advanced renal cell carcinoma and soft tissue sarcoma. Transaminase elevations have been commonly observed in pazopanib-treated patients in clinical studies. We conducted a GWAS using data from 8 phase II and III pazopanib clinical studies to evaluate association between genetic variants and treatment-emergent alanine transaminase (ALT) elevation. **Methods:** 1271 pazopanib-treated (monotherapy) patients with cancer were included in the analysis. Thirty million genotyped or imputed variants were tested for association with on-treatment peak ALT and time to first ALT ≥3x upper limit of normal (ULN) or ≥5xULN. Further analysis with sequence-based 4-digit HLA alleles from 5 genes was also performed. **Results:** One genetic variant, near NNT, rs80228453 (minor allele frequency 7.5%) was associated with peak ALT ($P=2\times10^{-8}$) at a genome-wide significance level for common variants ($P\leq5\times10^{-8}$), with the variant genotype associated with increased ALT. Among patients with ALT≥3xULN, 18% carried the NNT variant genotype (vs 6% in patients with ALT≤ULN). NNT encodes nicotinamide nucleotide transhydrogenase, which is essential for mitochondrial defense against oxidative stress and redox detoxification. Additional variants associated with ALT elevation at $P\leq5\times10^{-7}$ were observed, some of which are in genes/regions of known implications for drug-induced liver injury, including the MHC region. Subsequent HLA analysis identified an association between HLA-B*57:01 and maximum ALT ($P=1\times10^{-4}$) as well as time to 5xULN ($P=9\times10^{-5}$), statistically significant after adjustment for the number of HLA alleles tested ($P\leq5\times10^{-4}$). HLA-B*57:01 carriers were seen in 5% of all patients, 10% of patients with ALT≥3xULN and 12% with ALT≥5xULN. The incidence rates of ALT≥3xULN and ALT≥5xULN were 36% and 27%, respectively, in B*57:01 carriers, and 19% and 11%, respectively, in B*57:01 non-carriers, with an odds ratio (95% confidence interval, P value) of 3.2 (1.6-6.6, 9×10^{-4}) and 4.6 (2.1-9.9, 1×10^{-4}), respectively. **Conclusions:** We identified statistically significant associations at NNT and HLA-B for ALT elevation in pazopanib-treated patients. If replicated, these findings would provide novel insight into independent mechanisms of pazopanib liver toxicity and may influence clinical management.

Correlation among MDR1, MRP and hTERT expression level and clinical response in colon cancer patients. *s. sha'bani[1], f. mahjoubi[1], s. samanian[1], b. mahjoubi[2], r. mirzaei[2], a. tavakoli[1].* 1) national institue of genetic engineering and biotechnology, tehran, Select a Country; 2) iran university of medical science.

Introduction: Colon cancer is one of the common cancers in the world. Despite current advances in the treatments of cancer, the clinical result is far away from expectation yet. Drug resistance is still a major obstacle in treatment of cancer .In this study, we attempted to investigate the possible correlation among MRP1, MRP and hTERT expression level and multidrug resistance in colon cancer patients. Materials and Methods: Tumor and adjacent normal tissues from 35 colorectal cancer patients were assessed for the mRNA expression level of MDR1, MRP and hTERT by Real Time RT-PCR. Results: A statistically significant increase in MDR1 and hTERT expression level was observed in tumoral tissues in comparison with normal tissues. However MRP expression level was not significantly increased in tumoral tissues. Furthermore, no correlation was seen among MDR1, MRP and hTERT expression level. Conclusion: MDR1 and hTERT have no direct correlation, but mRNA expression of these two genes in addition to other factors indirectly helps to tumorgenesis and cancer progression.

3481T

Association of IL-1β gene Polymorphism with HCC related to viral causes. *H.A. Abdalla[1], A.A. Badawy[1], R. Monir[1], K. Farag[2].* 1) Medical Biochemistry, Faculty of Medicine, Mansoura University, Mansoura, Egypt; 2) Oncology Center, Mansoura University, Egypt.

Hepatocellular carcinoma (HCC) is the 5th most common malignancy in the world. In Egypt, the incidence of HCC is doubled over the last decade. Recently, numerous functional gene polymorphisms among pro-inflammatory and pro-fibrogenetic factors and their inhibitors have been thought to influence carcinogenesis including Interleukine-1β (IL-1β), which is considered one of the potent cytokines that has effects on cell survival and proliferation. The aim of the current study was to investigate the association of IL-1β gene polymorphism with HCC patients on top of viral versus non viral cases. The study included 134 subjects; 89 patients suffering from HCC; 61 patients with HCC on top of viral hepatitis (37 HCV and 24 HBV) and 28 patients with HCC without viral hepatitis, and 45 healthy individuals with no liver affection. IL-1β -31 gene polymorphism was studied by PCR amplification followed by RFLP analysis. Quantitative determination of serum IL-1β level was performed by ELISA. In patients with HCC on top of chronic HCV infection, IL-1β TT genotype was found to be more frequent than other genotypes ; whereas in patients with HCC on top of chronic HBV infection, IL-1β CT genotype was more frequent than other genotypes. IL-1β is significantly elevated in HCC patient on top of both types of virus hepatitis when compared with HCC due to non-viral causes ($p<0.05$). It is shown that IL-1β was highly significant elevated in patients with TT genotype of IL-1β gene rather than other IL-1β genotypes ($p=0.004$). In conclusion, People with T homozygous of IL-1β -31 gene polymorphism in combination with serum level of IL-1β could be considered as candidate molecular biomarkers for development of HCC on top chronic HCV or HBV infection. Further studies are recommended to explain and confirm these conclusions.

3482S

Opposite expression regulation of ATP-binding cassette transporters (ABC) genes in leukemic cells during granulocyti maturation processes on imatinib therapy. *L.SRA Pedroza[1], C.A.F. Nunes[1,2], J.A.R. Lemos[1,2].* 1) Federal University of Pará State (UFPA) Belem, Brazil; 2) HEMOPA and Fundação Centro de Hemoterapia e Hematologia do Pará (HEMOPA), Brazil.

Despite the results of imatinib (TKI) therapy to control patients Chronic Myeloide Leukemia (CML) progress, prolong overall survival of 88% of new diagnosed patients, 20% will fail. Indeed, TKI are not curative options, cause it can not eliminated all cancer stem cells that differentiated to mature hematopoietic blood cells, and disease can relapse. The search for mRNA related to prognostic predicts, and membrane transports responsible for imatinib efflux from the stem cells became a way to overcome resistance. Multiresistant protein - MRP and Multidrug resistant - MDR, associated to drug resistance in a tumor/drug specific way and ABCG2/B1 responsible for the imatinib extrusion are members of ABC superfamily. To gain more insight about the ABCs expression on leukemic cells on imatinib therapy we assess the transcriptome of CD34+ cells and CD66b+ cells into a pool of 4 CML patients in sustained major molecular response - MMR in imatinib treatment, and a control (1). A total of 19 (A3, A4, A7, C5, C11, C6P1, A13, A9, A8, B5, B4, B7, B6, C9,C12,C2,D2,D3) and 16 (A4,A5, A8, B5, B6,B8,C1,C5,C13,D4,E1,A13,A9,C6,C4) genes have differential expression in CD34+ cells and CD66b+ leukemic cells when compared to normal counterpart respectively. Leukemic CD34+ cells are less different from their control counterpart than leukemic CD66b+. These cells have a lake of expression to three subfamilies as in stem cells, all subfamilies presenting in patient group have at least one representative expresses gene in normal sample and the ranking of representatives genes to each subfamilies is the same for CD34+ cells from the two groups. We observe threaten upregulated ABC genes in CML CD34+ cells and twelve downregulated ABC genes in leukemic CD66b+ cells compared to the health counterparts, highlight a possible opposite regulation of ABC genes in leukemic cells during granulocyti maturation processes. We are choice possible candidate genes to modulation through imatinib therapy and understanding the ABCs possible functions in hematopoietic stem cells and mature blood cells. We aim to validate these finds on peripheral blood and in cito. Understand the pathways involved in ABCs function and know patients ABC expression profile considering pharmacogenetic interaction are crucial to test new therapy protocol in vitro or to clinical trial and management.

Inherited NK Cell Defective Mutations in Chinese Lymphoma Patients with HHV infection. *Y. Zhang[1], H. Liu[1], F. Wang[1], W. Teng[1], X. Chen[2], P. Zhu[2], C. Tong[1], Y. Lin[1], J. Yang[1], D. Lu[1].* 1) Clinical Laboratory Division, Ludaopei Hematology & Oncology Center, Beijing, China; 2) Department of Hematology, Peking University First Hospital, Beijing.

Background: It has been reported that some patients with lymphoma may harbor mutations of PRF1, UNC13D and STXBP2, which lead to NK cell deficiency and are causative genes of familial hemophagocytic lymphohistiocytosis (FHL). Data of the association between genetic defects and lymphoma is limited for Chinese patients. **Methods and Cases:** This study included 45 unrelated Chinese patients with either Hodgkin or non-Hodgkin lymphomas (26 males, 19 females; age range 3 to 60 years) and with active HHV1-8 infection. PCR and Sanger sequencing of all coding exons and flanking sequences of UNC13D, PRF1, STXBP2 and STX11 were performed. Active HHV1-8 infections were tested by PCR method. **Results:** Mutations were observed in 12/45 patients (26.7%). 9/12 (75%) patients carried a total of 8 different UNC13D mutations, including 6 with monoallelic mutations, 1 with homozygous mutation, and 2 with compound heterozygous mutations. 2 patients had PRF1mutations, one with monoallelic mutation and the other with biallelic mutations. 1 patient was detected to carry STX11 monoallelic missense mutation. No patient carried STXBP2 mutation. All mutations in these patients were confirmed to be germline derived by pedigree analysis or sequencing of non-lymphoma tissue of the same patient. **Conclusions:** Germline UNC13D mutations are frequent in Chinese lymphoma patients with HHV infection. Involvement is less frequent for PRF1 and STX11. Inherited NK cell defective mutations might be the innate predisposing factor of active HHV infection and together lead to the lymphomagenesis.

3484T

Whole genome exome sequencing to identify novel candidates for hereditary predisposition to UM uveal melanoma. *M.H. Abdel-Rahman[1, 2, 3], D. Hedges[2], R. Pilarski[2], G. Boru[1], J.B. Massengill[1], K. Rai[2], F.H. Davidorf[1], C.M. Cebulla[1].* 1) Dept Ophthalmology, The Ohio State University, Columbus, OH; 2) Division of Human Genetics, Department of Internal Medicine, The Ohio State University, Columbus, OH; 3) Pathology Department, Menoufiya University, Shebin Elkom, Egypt.

Background: About 12% of uveal melanoma (UM) patients have features suggestive of hereditary cancer predisposition. Germline mutation in BAP1 explains only a small subset of these patients suggesting the existence of other candidate genes. Methods: Whole exome sequencing (WES) was carried out on six BAP1 mutation-negative UM patients from 5 different families. Three patients had family history of UM and two patients had personal history of UM and personal or family history of cancers associated with the BAP1 tumor predisposition syndrome (TPDS). In one family, the index case and a paternal 1st cousin once removed with UM were sequenced. Results: We focused our primary analysis on identifying unreported, deleterious or potentially deleterious (stop loss, stop gain, nonsynonymous, splice variant, frame shift) germline variants in any of the 522 COSMIC "cancer census genes". We identified deleterious or possibly deleterious mutations in MAML2, TPR, ARID1A, PBRM1, PRDM1 and MUTYH. These variants were subsequently confirmed by direct sequencing. Segregation analysis ruled out contribution of MAML2, ARID1A, PBRM1, PRDM1 and MUTYH. Also, sequencing of the tumor tissue from the patient with germline TPR (translocated promoter region) mutation showed significant loss of the mutant allele in tumor suggesting that it is likely not contributing to the pathogenesis of the disease. No pathogenic variant was detected in any of the cancer predisposition gene in more than one patient. However, we identified several potential candidate genes that have not been previously implicated in hereditary cancer predisposition. Conclusions: This pilot whole exome sequencing (WES) study suggests that hereditary cancer predisposition in these patients is not caused by coding mutation in any of the 522 COSMIC cancer census genes. It also suggests locus heterogeneity across families, causative genetic alterations in non-coding regions and/or both as mechanisms for hereditary predisposition to UM. We have identified several additional potential candidate genes that we are further exploring. Our study provides important preliminary data to further identify potential candidate genes for hereditary predisposition to UM.

3485S

Two novel germline *BAP1* mutations in two unrelated families with features of the *BAP1* Tumor Predisposition Syndrome. *C.M. Cebulla[1], R. Pilarski[2], K. Rai[2], JB. Massengill[1], G. Boru[1], FH. Davidorf[1], MH. Abdel-Rahman[1,2,3].* 1) Ophthalmology and Visual Science, The Ohio State University, Columbus, OH; 2) Division of Human Genetics, Department of Internal Medicine and Comprehensive Cancer Center, The Ohio State University, Columbus, OH; 3) Department of Pathology, Menoufiya University, Egypt.

Objective: The *BAP1* Tumor Predisposition Syndrome (TPDS) is a recently recognized hereditary cancer predisposition syndrome. Four main cancers, uveal melanoma (UM), cutaneous melanoma, mesothelioma, and renal carcinoma, are associated with this syndrome, in addition to other cancers. Here we report the clinical phenotype of two new independent families with novel germline *BAP1* mutations and features suggestive of the *BAP1* TPDS.

Methods: Germline *BAP1* mutations were evaluated by direct sequencing of all *BAP1* exons and adjacent intronic regions. Two new families were evaluated, one presenting with cutaneous melanoma and mesothelioma in the proband and a family history of UM and several other cancers. In the second family, the proband presented with peritoneal mesothelioma and a strong family history of pleural mesothelioma as well as UM.

Results: In the first family we identified a nonsynonymous mutation in the ubiquitin carboxyl-terminal hydrolase domain of *BAP1* (c. 539T>C, p. Leu180Pro). The mutation was present in a first degree relative with UM (obligate carrier) and in an unaffected second degree relative of the proband. However, the mutation was not identified in other first and second degree relatives in the family, including those with cutaneous melanoma and liposarcoma. In the second family a 3 bp intronic deletion was identified (g.2270_2272delACA, c. 256-4_256-2del). This mutation was predicted to be a splice site pathogenic variant by NetGene2 and Mutation Taster software. Validation studies and testing of additional family members are ongoing.

Conclusion: We report 2 novel germline mutations in *BAP1* in two unrelated families associated with the typical *BAP1* TPDS phenotype.

3486M

Predisposition to Burkitt Lymphoma in Williams-Beuren syndrome. *D. Guenat[1,2], J. Soulier[3], C. Rizzari[4], H. Fryssira[5], C. Lundin[6], C. Borg[2,7], PS. Rohrlich[2,8].* 1) Laboratory of Cellular and Molecular Biology, University Hospital of Besançon, Besançon, France; 2) UMR1098 Inserm/EFS-BFC/UFC, LabEx LipSTIC, Besançon, France; 3) Saint-Louis Hospital APHP and Hematology University Institute (IUH), University Paris-Diderot, Paris, France; 4) Department of Pediatrics, San Gerardo Hospital, University of Milano-Bicocca, Monza, Italy; 5) Department of Medical Genetics, Medical School, University of Athens, Greece; 6) Department of Clinical Genetics, University and Regional Laboratories, Skåne University Hospital, Lund University, Lund, Sweden; 7) Department of Medical Oncology, University Hospital of Besançon, Besançon, France; 8) Department of Hematology, University Hospital of Nice, Nice, France.

Chromosomal disorders are frequently associated with predisposition to cancer as shown by the increased incidence of leukemia in Down syndrome. Williams-Beuren Syndrome (WBS [MIM 194050]) is a multisystem disorder caused by a hemizygous microdeletion on chromosome 7q11.23 spanning 1.5 Mb and encompassing 28 genes and 2 miRNA loci. WBS is not currently considered as a risk factor for cancer. However, a thorough review of the literature shows that 9 cases of pediatric cancers have been reported in WBS patients and, strikingly, 6 (66%) of them were Burkitt Lymphomas (BL). We report here 2 novel cases of BL in children with WBS. DNA isolated from lymphoma cells and normal tissue of the 2 novel cases (one from France and one from Italy) was analyzed. In addition, tumor and normal DNA of 2 other children were investigated: a Greek child with WBS who presented a BL whose case was reported in 2004 and a Swedish child without WBS but with a sporadic lymphoma that has shown a 7q11.23 deletion in a previous study. CGH-array and Next Generation Sequencing were used to characterize the size of the WBS deletion and to seek for the presence of a loss of heterozygosity (LOH) in the 7q11.23 locus. The constitutional microdeletion observed in the normal DNA of the 3 WBS patients corresponded to the typical WBS critical region with a length of 1.5 Mb and there was no evidence of LOH in the tumor DNA. Interestingly, the somatic deletion observed in the sporadic BL was mono-allelic and similar to the one observed in WBS patients. No other rearrangement was observed in this tumor. Thus, BL may arise in the presence of either constitutional or somatic microdeletion of 7q11.23 and in the absence of LOH in the WBS critical region. A number of genes mapping to this region are involved in DNA repair pathways (*BAZ1B*, *RFC2*, *GTF2I* family genes) or B-cell proliferation and differentiation (*LAT2*, *FZD9*). The haploinsufficiency of one or of a combination of these genes might be responsible for genetic instability and lymphoma initiation. Given these observations and the difficult management of epidemiological data concerning association of rare diseases such as WBS and BL, we suggest that the deletion of the WBS critical region is involved in the initiation of BL and that WBS patients have an enhanced risk of Burkitt lymphoma occurring at an early age. Functional studies are needed to identify the precise molecular pathways that drive the B-cell lymphomagenesis in WBS patients.

3487T

Familial Inflammatory Fibroid Polyps Syndrome (FIFPS): Phenotype much broader than having polyps. *J. Walia[1,2], S. Abu-Abed[2], A. Hawrysh[1], N. Perrier[1], L. Hookey[3], R. Giddell[4], J. Chien-Hung[2], R. Kirsch[4], H. Feilotter[2], P. Manley[2].* 1) Division of Medical Genetics, Department of Pediatrics, Queen's University, Kingston, ON, Canada; 2) Department of Pathology and Molecular Medicine, Queens University, Kingston, ON Canada; 3) Division of Gastroenterology, Department of Internal Medicine, Queen's University, Kingston, ON, Canada; 4) Pathology & Lab Medicine Mount Sinai Hospital, Toronto, ON, Canada.

Inflammatory fibroid polyps (IFPs) are mesenchymal benign tumors of the gastrointestinal tract that have been reported to harbor somatic mutations in Platelet Derived Growth Factor Receptor Alpha (PDGFRA) especially in exon 12, 14 and 18. Three case reports have been documented with germline mutations as well. We report a family with germline mutation is exon 18 of PGFRA gene with a further description of physical features segregating with this mutation. The proband, a 59 year old female, presented with severe abdominal pain. Surgical exploration showed multiple intussusceptions of the small intestine. Direct and indirect imaging techniques revealed hundreds of small bowel sub-mucosal nodules and a few gastric and colonic ones. These were described as 'mutiple submucosal, intramural and serosal firm circumscribed lesions'. Pathological examination confirmed them to be IFPs. Molecular testing showed two different mutations- D846V (c.2537A>T) mutation in exon 18 was found in two polyps as well as normal small bowel tissue and an additional D576Y (c.1726G>T) mutation in exon 12 in one of the two polyps. D846V mutation was also indentified in DNA derived from blood, thus confirming it to be a germline mutation. Investigations are ongoing to see any susceptibility/presence of Gastrointestinal Stromal Tumors (GISTs). Multiple other members were also tested positive for the same mutation. Physical examination of mutation positive individuals showed coarser skin, and broader hands and feet as compared to mutation negative family members. In addition, the mutation positive members lost most of their teeth in late 30s or early 40s. PDGFRA gene has been reported to have an important role in skeletal development in addition to other developmental pathways and we hypothesize that this gain of function mutation is the cause of abovementioned phenotypic features. To our knowledge, this is a first report of a family with a comprehensive genetic, morphological, pathological and clinical characterization of Familial IFPs Syndrome. Such information will not only help in the clinical recognition of affected individuals, but also in follow-up investigations for IFPs and possibly related GISTs.

3488S

High Depth HPV16 Whole Genome Sequencing of 830 PaP Cohort Specimens using Crude Exfoliated Cervical Extracts. *J. Boland[1], M. Cullen[1], L. Mirabello[2], J. Mitchell[1], S. Bass[1], X. Zhang[1], M. Yeager[1], M. Andersen[7], M. Osentoski[7], M. Laptewicz[7], J. Smith[7], N. Wentzensen[2], K. Yu[2], Z. Chen[3], T.R. Raine-Bennett[5], P.E. Castle[6], M. Schiffman[2], R. Burk[3,4].* 1) Cancer Genomics Research Lab, NCI_Leidos, Gaithersburg, MD; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Rockville, MD; 3) Division of Gynecologic Oncology, Department of Obstetrics & Gynecology and Women's Health, at Albert Einstein College of Medicine, Bronx, NY; 4) Department of Epidemiology and Population Health, at Albert Einstein College of Medicine, Bronx, NY; 5) Women's Health Research Institute, Division of Research, Kaiser Permanente Northern California, Oakland CA; 6) Global Cancer Initiative, Chestertown, MD; 7) Thermo Fisher Scientific, 5781 Van Allen Way, Carlsbad, CA.

In this report, complete 7.9 kb genomes of 830 PaP (Persistence and Progression) cohort specimens were sequenced on the Thermo Fisher Scientific Ion Torrent Personal Genome Machine using a custom HPV16 Ion AmpliSeq panel. Pre-pooled multiplexed primers targeted the 7.9kb circular viral genome amplifying 47 overlapping amplicons at a coverage of 99%. As little as four microliters of low quality exfoliated cervical tissue extract was amplified, regardless of viral load, in a robust multiplex reaction. Total time from sample to sequence data was three days. Sequence read alignment to the HPV16 reference genome and variant calls were done utilizing the on board Ion Torrent Suite of sequence analysis tools. Total aligned reads across all 47 overlapping amplicons translated into a depth of coverage per sample ranging from 400x to over 5000X. This depth of coverage has enabled the discovery of rare variants present at frequencies down to 2%. Over 750 variants were identified of which 480 were novel and not seen in the eight HPV16 reference genomes used to define HPV sub lineages. Concordance of variant calls across 32 sample duplicates within our study was 97.76 percent. As a fine measure of this novel method of sequencing HPV16 genomes we looked at concordance of variant calls between Sanger methods and our AmpliSeq/Ion Torrent data in a subset of 96 PAP samples. Lastly, with barcodes, your sequencing throughput can range from one sample to an entire 96 sample plate per sequencing run. Sequence output of the three different Ion Torrent sequencing chips (314, 316 and 318) enable scaling of sequencing needs. With a cost of ~$50/sample the AmpliSeq HPV16 panel is a low cost, high quality, throughput and depth (>400X) of read alternative to the Sanger method.

3489M

Genome-wide DNA methylation patterns and genetic ancestry in sporadic breast cancer patients from a Latino population. *M. Cappetta[1], L. Brignoni[1], N. Artagaveytia[2], O. Stefansson[3], M. Esteller[3,4,5], B. Bertoni[1], M. Berdasco[3].* 1) Departamento de Genética, Facultad de Medicina, Universidad de la República, Montevideo, Uruguay; 2) Departamento Básico de Medicina, Facultad de Medicina, Universidad de la República, Montevideo, Uruguay; 3) Cancer Epigenetics and Biology Program (PEBC), Bellvitge Biomedical Research Institute, L'Hospitalet de Llobregar, Barcelona, Catalonia, Spain; 4) Department of Physiological Sciences II, School of Medicine, University of Barcelona, Barcelona, Catalonia, Spain; 5) Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Catalonia, Spain.

Genetic variants alone are not enough to explain a complex disease like cancer. Alterations in DNA methylation patterns have been associated with different types of tumors. Although methylation profiles are often tissue-specific, recent data indicate that epigenetic changes in peripheral blood leukocytes are promising risk markers for solid tumors.

In order to detect risk markers for sporadic breast cancer in the Uruguayan population, we integrated genetic and epigenetic information of individuals. We determined the level of global leukocyte DNA methylation (glDNAmet) in cancer patients by relative quantification of 5mC by HPLC-MS; and then, we focused on site-specific studies using HumanMethylation450 BeadChip.

A global DNA hypomethylation in breast cancer patients was detected when it was compared with healthy controls. This result suggests its potential use as a risk marker. Since the Uruguayan population is admixed, we studied the correlation between glDNAmet and individual genetic ancestry (determined by analyzing ancestry informative markers). We found a negative correlation between African ancestry and glDNAmet in cancer patients. These results suggest that the ancestral admixture genome structure could be modeling DNA methylation patterns and its effect and underscore the importance of considering genetic ancestry as a modifying variable in epigenetic association studies in admixed populations like Latino ones.

We detected 77 differentially methylated CpG sites in blood of breast cancer patients including known cancer genes involved in disease-specific pathways and also novel candidates with possible implication in breast tumorigenesis. This set was characterized and validated in an independent sample of breast tissue belonging to European breast cancer patients. These CpG sites are able to differentiate leukocytes of sporadic breast cancer patients from controls. It also distinguishes healthy tissue from breast tumor, even in cases of hereditary breast cancer.

We identified differential DNA methylation at global and site-specific level in leukocytes of patients with sporadic breast cancer, which suggests the existence of a systematic variation in DNA methylation associated with susceptibility to tumor development.

3490T

Routine use of massively parallel sequencing for BRCA1 and BRCA2 diagnosis: a comprehensive workflow combining PCR Multiplex and sequencing chemistry on Miseq. *F. Coulet, F. Pires, E. Guillerm, M. Eyries, C. Colas, F. Soubrier.* Oncogenetics, APHP- Pitie Salpetriere Hospital, Paris, France.

The aim of this study was to develop a massively parallel sequencing workflow for routine diagnosis for hereditary breast and ovarian cancer syndrome. The aim was to reduce the delay of results with a highly specific and sensitive method. A workflow was designed using a multiplex amplification approach (BRCA MASTR Dx) with 5 multiplex PCR reactions covering the complete coding regions of BRCA1 and BRCA2, followed by synthesis sequencing on Miseq. Bioinformatic analysis of the results was made through the use of adaptated settings in SeqNext software. A training set of 56 DNA samples containing polymorphisms, unclassified variants and pathogenic mutations previously identified by others technologies, was used. This group consisted of 448 variants controls polymorphisms, 23 deleterious mutations (2 missense, 2 nonsense, one splice mutation and 18 frameshift mutations) including 4 located in homopolymers. The worflow developped on the Miseq permitted the identification of all variants (n = 491), including those located in or close to homopolymers. The routine diagnosis was established for series of 48 patients per run to achieve a high depth reading (averaged per amplicon 4000X). Eighteen series of 48 patients (n=864) were analyzed by this approach. A series of 48 patients from DNA extraction to results is performed by a technician in 10 days, included medical validation. The workflow meets the sensitivity and specificity requirements for genetic diagnosis of breast and ovarian cancer and improves on the cost-effectiveness of current approaches. It could be respond to situations in which the expectation of the mutational status is an emergency such as the practice of contralateral prophylactic surgery or the development of targeted therapies (Anti PARP).

3491S

New genome-wide technologies and low volume, archival, formalin-fixed paraffin embedded material: are the two compatible? *L.M. FitzGerald[1], E.M. Wong[2], J.E. Joo[2], J. Pedersen[3], J. Mills[3], CH. Jung[4], J. Chung[4], G. Severi[5], M.C. Southey[2], G.G. Giles[1].* 1) Cancer Epidemiology Centre, Cancer Council Victoria, Melbourne, Victoria, 3004, Australia; 2) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Victoria 3010, Australia; 3) TissuPath Specialist Pathology, Victoria 3149, Australia; 4) Victorian Life Sciences Computation Initiative, Carlton, Melbourne, Victoria 3010, Australia; 5) Human Genetics Foundation, Torino, 10126, Italy.

Purpose: Archival formalin-fixed, paraffin-embedded (FFPE) tumour material is a widely available, valuable resource for genomic research but one that has been under-utilised due to low yields of highly degraded nucleic acids. This limitation has prevented assaying such samples on early generation, whole-genome arrays, which required high quality and quantities of starting material. However, with improved whole transcriptome amplification systems and the evolution of next-generation array technologies, it is becoming more feasible to use low quantities of FFPE material. In a pilot study, we investigated whether low volume, FFPE diagnostic samples of prostate cancers (PCa) could be successfully applied to the Infinium HumanMethylation450 Beadchip (HM450K) array and the Agilent SurePrint G3 Human Gene Expression v2 Microarray. Here we present the results of both the individual and combined analyses of these assays. Methods: Fourteen FFPE diagnostic PCa samples, consisting of six transrectal ultrasonography biopsies and six transurethral resection samples were selected from the Cancer Council Victoria Prostate Cancer Program. DNA and RNA were extracted from macro-dissected prostate tumour tissue. DNA samples were whole genome amplified and assayed on the Infinium HM450K array. RNA samples were amplified in duplicate using two different whole-transcriptome amplification kits and assayed on the Agilent SurePrint array. Quality control measures and analyses were performed using publicly available and in-house analysis tools. Results: DNA and RNA were successfully amplified for 11 samples. These samples were applied to the Infinium HM450K and the Agilent SurePrint arrays, and quality control assessment and analyses are currently underway. Conclusion: One of the greatest challenges in PCa management is distinguishing at diagnosis those men who are at risk of progressing to life-threatening disease from those whose disease will remain indolent. Diagnostic tumour samples are a vital resource for biomarker discovery but have been under-utilised due to the nature of the material. This pilot study suggests that low volume, FFPE tumour material can be successfully interrogated using next-generation, genome-wide arrays, thereby opening up a previously under-utilised resource for epidemiological studies.

3492M

Genomic sequencing reveals significantly higher mutation load in genomes of fathers of children with *de novo* germline mutation in RB1 gene. *A. Ganguly[1], E. Toorens[2], J. Richards-Yutz[1], T. Ganguly[2], KG. Ewens[1].* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Penn Genomic Analysis Core, University of pennsylvania, Philadelphia, PA.

Background: Retinoblastoma (RB) is a neoplasm of the retina that occurs in infants and young children. Sporadic bilateral retinoblastoma (RB), results from a *de novo* germline mutation in the RB1 gene. This *de novo* mutation occurs in the father's gamete before the child's conception in about 94% of cases. However, paternal age is not significantly associated with risk of having a child with *de novo* germline mutation in RB. We have previously shown that paternal diet, occupation, and medical exposures to mutagens before the child's conception affect this risk. **Methods:** We investigated the mutation load of the paternal genome and compared it to that of the mother and unrelated control adults using whole genome or exome sequencing from 12 parent-child trios with sporadic bilateral RB and four controls . Whole genome sequencing library was prepared using Illumina TruSeq DNA library protocol. Exome capture was performed using NimbleGen V3.0 oligonucleotide libraries. Following sequencing on Illumina HiSeq, variant calling was done with the GATK Unified Genotyper and filtered using the GATK VariantFiltration and SelectVariants tools. Exome sequencing reads were filtered against the target regions to remove off target reads. Remaining variants were annotated with Annovar before further filtering via Python script and in Excel. **Results and Discussion:** The results indicate that the distribution of mutations including non-synonymous, synonymous, frameshift and non-frameshift mutations was significantly different between the paternal and maternal genomes ($p < 0.001$). The paternal genomes included increased number of non-synonymous damaging changes. Analysis of the mutated genes indicated novel mutations in genes in nucleotide excision repair and mismatch repair pathways, as well as in notch signaling, purine and caffeine metabolism pathways. These results provide a strong association with our epidemiologic data on risk enhancing paternal exposures that includes medical radiation, diet and occupation. In conclusion, this data validates our hypothesis that paternal exposure and mutation load increase the risk of having a child with sporadic RB. We acknowledge that the data set is very small; however considering that RB is a rare disease, it is important to emphasize that we have the largest number of RB parent-child trios currently available in any institution, and we are in the process of enlarging the data set.

3493T

Differential Gene Expression In Key Oncolytic Pathways Observed Between Caucasian-American and African-American Women with Triple-Negative Breast Cancer. *J.E. Getz[1], L.L Baumbach-Reardon[1], C. Gomez[2], M.E. Ahearn[1], M. Jorda[2], C.R. Legendre[1], W. Tembe[1], S. Nasser[1], V. Yellapantula[1], M.D. Pegram[3], J.D. Carpten[1].* 1) Integrated Cancer Genomics Division, Translational Genomics Research Institute., Phoenix, AZ; 2) Miller School of Medicine, University of Miami Medical School, Miami, FL; 3) Stanford Cancer Institute, Stanford University School of Medicine, Stanford, CA.

In the U.S., breast cancer (BC) incidences among African American women (AA) and Caucasian women (CA) are similar, however, AA have a significantly higher mortality rate (20%). AA often presents with tumors of higher grade, later stage, and are more likely to be triple-negative breast cancer (TNBC). Although multiple factors contribute to these cancer disparities, it is essential that we identify the molecular characteristics and underlying biological differences between CA and AA TNBC. In this study, we performed gene expression array analysis on archived formalin fixed paraffin embedded (FFPE) blocks from a multi-ethnic U.S. cohort of node-negative (N0) TNBC samples. Total RNA was isolated from 10 μm scrolls from each FFPE block. Following cDNA synthesis, each sample was hybridized to a breast-enriched gene expression array (Affymetrix, BC DSA Research Tool). Expression analysis was conducted using GeneSpring 12.1 analytical software and after contemporary data analyses, the final study cohort consisted of 10-AA, 13-CA. PCA analysis revealed that the samples clustered well with respect to ethnicity and unsupervised cluster analysis, based on ethnicity and genes, was performed. The resulting dendogram segregated into distinct subgroups based on ethnicity, revealing a pattern of differential gene expression between the cohorts. A list of differentially expressed genes from each cohort (DEG) were selected using ANOVA analysis (fold change > 3.0, p value <.05) followed by the Benjamin/Hochberg method for multiple-testing correction. Finally, the lists of DEG were uploaded into GeneGo MetaCore to identify functionally enriched pathways. These analyses revealed differentially expressed genes pathways enriched for cytoskeletal remodeling, cell adhesion and EMT pathways. In particular, significantly deregulated genes associated with the Wnt/β-catenin pathway were observed in the AA cohort as compared to the CA, suggesting that this pathway may contribute to the more aggressive phenotype in AA women diagnosed with TNBC. In summary, our results indicate gene expression differences within several key oncolytic pathways across these ethnic groups and these results are currently being validated through several parallel approaches. These studies have important implications for further understanding BC and TNBC health disparities, as well as future tailored approaches to prediction, prevention and therapeutic advances.

3494S

Shared genetic background between chronic gastroesophageal reflux and Barrett's esophagus and esophageal adenocarcinoma, consistent with a causal relationship. *P. Gharahkhani[1], J. Tung[2], T.L. Vaughan[3], D.C. Whiteman[1], S. MacGregor[1], Barrett's and Esophageal Adenocarcinoma Consortium.* 1) QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 2) 23andMe, Mountain View, CA, USA; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

Esophageal adenocarcinoma (EA) is a cancer with rising incidence and high mortality rate. Every year 0.12-0.5% of patients with Barrett's esophagus (BE), a precancerous metaplastic change, develop EA. Chronic gastroesophageal reflux (GERD) is a risk factor for both BE and EA. However, it is not clear whether GERD actually causes those diseases. In a previous study we found genetic overlap between BE and EA but did not detect significant evidence of common genetic background between GERD and BE/EA. The previous study was limited by small sample size, which may have resulted in false negative findings. Here we aimed to further investigate the polygenic overlap between GERD and BE/EA using larger datasets, and to use the Mendelian randomization approach to investigate the causality of GERD for those diseases. The top genome-wide GERD-associated SNPs from a study of 23andMe in 8,743 GERD cases and 43,932 controls were used to calculate polygenic risk scores for GERD in our study population (2,051 BE cases, 1,239 EA cases, and 2,088 controls of European descent from the Barrett's and Esophageal Adenocarcinoma Consortium (BEACON)). We showed the 23andMe risk scores significantly ($P<5e-4$) predicted BEACON reflux status, providing the strongest evidence to date for a role of genetic variation in reflux predisposition. Further, the scores were used as an instrumental variable in a Mendelian randomization approach using logistic structural mean model estimator to investigate the causality of GERD for BE and EA. Unlike our earlier smaller study of GERD, we found a significant polygenic overlap between GERD and BE/EA. Our preliminary Mendelian randomization analysis provides estimates for the role of GERD on BE and EA risk which are consistent with causality. Our findings on causality are potentially clinically important as they support the use of GERD interventions to control cancer risk.

The Kaiser Permanente Biobank: A multi-region, multi-ethnic resource linking specimens and electronic medical records for broad research in an integrated health care delivery system. *KAB. Goddard[1], N. Cardoza[2], LA. Croen[3], HS. Feigelson[4], K. Harris[5], S. Honda[6], M. Horberg[7], C. Jonas[7], C. Koebnick[8], MK. Nguyen[8], AA. Owen-Smith[5], S. Rowell[3], C. Schaefer[3], KS. Smith[1], C. Somkin[3], J. Vu[2], MG. Wrenn[4], C. Yonehara[6], K. Emmons[2].* 1) Center for Health Research, Kaiser Permanente Northwest, Portland, OR; 2) Kaiser Permanente Program Office and Kaiser Foundation Research Institute, Oakland, CA; 3) Kaiser Permanente Division of Research, Oakland, CA; 4) Institute for Health Research, Kaiser Permanente, Denver, CO; 5) Center for Health Research Southeast, Kaiser Permanente Georgia, Atlanta, GA; 6) Center for Health Research, Hawai'i, Kaiser Permanente Hawaii, Honolulu, HI; 7) Mid-Atlantic Permanente Research Institute, Mid-Atlantic Permanente Medical Group, Rockville, MD; 8) Kaiser Permanente Southern California, Department of Research and Evaluation, Pasadena, CA.

Kaiser Permanente (KP) is an integrated healthcare delivery system spanning seven geographic regions in the US and including 9.3 million members. The diverse membership reflects the US population, where about half of the members are non-Hispanic white. Membership includes between 4% and 29% of the total population in the coverage areas, and broadly represents regional populations in overall demographic and socioeconomic status measures. In the last decade, KP established several regional biobanks that now include specimens and phenotypic data for a total of 210,000 members. We describe the design and features of a new initiative to consolidate these efforts into a single entity, called the KP Biobank, and to expand the cohort to a total of 500,000 participants. The KP Biobank will include a general cohort (410,000 participants), designed to represent the diversity of KP members, and two specialized cohorts: a cancer cohort with 30,000 participants, and a pregnancy cohort with 60,000 participants. Specimens will be stored centrally and linked to phenotypic information from the medical record. Our data systems capture comprehensive and longitudinal records on every medical encounter, including diagnoses, procedures, pharmacy data, tumor registry, pathology records, imaging, and laboratory results. Participants have about 23 years of membership on average (range 0 - 71 years), with comprehensive electronic records for about the last 15 years. We also collect patient reported information on demographics and behavioral and environmental exposures via survey. The KP Biobank is designed for both discovery and translational research. Our setting of research units embedded within a healthcare delivery system supports clinical integration of new discoveries and research across the translational continuum. The KP Biobank Translational Research Center will specifically support this function. The consolidated governance of the KP Biobank will streamline and facilitate collaboration and partnerships through a single Access Review Committee and application procedure. Any researcher, including external scientists, may apply for use of specimens. Participants consent to broad future uses of specimens and data, and allow for broad data sharing, including through dbGaP. This novel resource will facilitate future genomic research, particularly on research questions addressing diverse populations, longitudinal measures to assess changes over time, and long-term outcomes.

3496T

Diverse types of lymphoid cancers cluster in families. *S.J. Jones[1,2], J. Voong[3], R. Thomas[2], G.W. Slack[4], J. Connors[4], J. Graham[3], A.R. Brooks-Wilson[2,3].* 1) University of British Columbia, Vancouver, British Columbia, Canada; 2) Canada's Michael Smith Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, British Columbia, Canada; 3) Simon Fraser University, Vancouver, British Columbia, Canada; 4) Centre for Lymphoid Cancers, British Columbia Cancer Agency, Vancouver, British Columbia, Canada.

Lymphoid cancers are collectively the sixth most common cancer in the USA and impose a large health and financial burden on individuals and health care systems. Lymphoid cancers are a biologically diverse group of neoplasms, yet familial aggregation of various lymphoproliferative disorders has been observed, suggesting shared genetic risk factors. Specifically, non-Hodgkin lymphoma, Hodgkin lymphoma, multiple myeloma and chronic lymphocytic leukemia aggregation may be specific to gender, age, ethnicity, infectious agents and familial relationship. Our collection of over 120 families with more than one lymphoid cancer diagnosis will aid in understanding the inter-relationship of lymphoid cancers between and within lymphoid cancer families. The relationships between different lymphoid cancers observed in these families was investigated by categorizing affected individuals by type of lymphoid cancer, age of onset, affected generation and rarity of each type of lymphoid cancer. We have observed that within these families, some types of lymphoid cancers co-occur more frequently than expected based on their incidence in the general population. This co-aggregation of specific types of lymphoid cancers may be due to genetic and/or other risk factors that are shared within families. In addition, we observe anticipation in the set of families; the mean age of diagnosis among generations was significantly different for non-Hodgkin lymphoma, Hodgkin lymphoma, chronic lymphocytic leukemia and all lymphoid cancers collectively.

3497S

Cancer Predisposition Genes in Whole Exome Sequencing: How Do Findings Correlate with Cancer Histories? *N.M Lindor[1], S. Middha[2], S.K. McDonnell[2], J.E. Olson[2], J.R. Cerhan[2], E.D. Wieben[3], K.J. Johnson[4], G. Farrugia[5], S.N. Thibodeau[6] For the Mayo Clinic Community Biobank, Center for Individualized Medicine.* 1) Dept Health Science Research , Mayo Clinic, Scottsdale, AZ; 2) Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN; 4) Ariosa Diagnostics, Inc, San Jose CA; 5) Internal Medicine, Div of Gastroenterology, Ctr for Individualized Medicine, Mayo Clinic, Rochester, MN; 6) Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Background: Prospective demonstration of clinical utility of Whole Exome Sequencing (WES) will require many years of data collection, so retrospective analyses are needed to inform future uses. In this study we examined how DNA variants in known cancer predisposition genes correlated with cancer histories of individuals who had completed their lifespan. **Methods**: WES was performed on 89 deceased individuals from the Mayo Clinic Biobank. Mean age at death was 74 yrs (range 28-93). The Mayo medical record was abstracted for each individual. WES findings including SNVs and indels were filtered and sorted to identify high quality Tier 1 (likely damaging) changes and Tier 2 (missense variants) for which either SIFT or Polyphen predicted pathogenicity in 58 cancer predisposition genes. No copy number variants were evaluated. Variants were scored for likely pathogenicity using IARC scale (1=neutral; 5=pathogenic). **Results:** Of the 89 individuals studied, 39 (26 M, 13 F) had invasive cancers and 50 had no cancers (25M, 25F). A total of 115 Tier 1 or Tier 2 variants were found. Among those with cancers, a mean of 1.5 variants (range 0-3) involved 24 different genes; in those without cancer, a mean of 1.1 (range 0-4) were found involving 20 different genes. Manual curation of pathogenicity scores, blinded to cancer status, resulted in most variants remaining Class 3(VUS:variant of unknown significance): 46/58 variants in those with cancer and 48/57 in those without cancer were VUS. However, there were 3 Class 4 or 5 variants in the subjects with cancers (likely pathogenic) compared to zero in the subjects without cancer. **Conclusions:** Among 89 individuals, 39 who had developed a cancer were apparently more likely to have likely pathogenic mutations (3/39) within cancer predisposition genes than those individuals without cancer (0/50). However the majority of DNA variants found on WES of these genes currently will not be able to be interpreted beyond calling them a VUS. Copy number variants, inadequately covered regions in some genes, and untested genes could still account for some of the cancers. Nevertheless, because VUS with *in silico* assignments of pathogenic/damaging in cancer predisposition genes occurred at about the same frequency in those who had cancer as in those without cancer, great caution is warranted in assigning significance to VUS in these genes in an unselected population.

3498M

The prostate cancer risk mutation G84E in *HOXB13* is associated with the subtype of ETS fusion negative adenocarcinoma with early age of diagnosis. *M. Luedeke[1], A. Rinckleb[1], J. Stanford[2,3], L. FitzGerald[2], J. Schleutker[4,5], T. Wahlfors[4], R. Eeles[6,7], Z. Kote-Jarai[6], S. Weikert[8], H. Krause[8], K. Herkommer[9], J. Hoegel[10], C. Maier[1], and. the ICPCG[11].* 1) Department of Urology, University Hospital of Ulm, Ulm, Germany; 2) Fred Hutchinson Cancer Research Center, Division of Public Health Science, Seattle, Washington, USA; 3) Department of Epidemiology, School of Public Health, University of Washington, Seattle, Washington, USA; 4) Institute of Biomedical Technology, University of Tampere and FimLab Laboratories, Tampere, Finland; 5) Department of Medical Biochemistry and Genetics, University of Turku, Turku, Finland; 6) The Institute of Cancer Research, Sutton, UK; 7) Royal Marsden National Health Service Foundation Trust, London and Sutton, UK; 8) Department of Urology, University Hospital Charité, Berlin, Germany; 9) Department of Urology, Klinikum rechts der Isar der Technischen Universität München, Munich, Germany; 10) Institute of Human Genetics, University Hospital of Ulm, Ulm, Germany; 11) International Consortium for Prostate Cancer Genetics.

HOXB13 was discovered as the first prostate cancer (PrCa) specific high-risk susceptibility gene. The most prevalent *HOXB13* germline mutation in PrCa patients of European descent is *HOXB13* G84E, which likely originated in Northern Europe. Previous molecular examination of a set of G84E driven tumors suggested a distinct somatic phenotype, where oncogenic ETS gene fusions appear at unusually low frequencies as compared to the general prevalence of ETS fusions in PrCa (22 % vs approx. 50 %). Hypothesizing that *HOXB13* could predispose to ETS fusion negative PrCa we have analyzed 942 cases from three European ancestry populations for the coincidence of *HOXB13* G84E and the most common ETS fusion, *TMPRSS2-ERG* (T2E), in corresponding tumor samples.

While the prevalence of T2E fusions was similar among study sites (range: 57.2% - 60.1%), the frequency of G84E genotypes differed markedly between US (1.5%), German (3.6%) and Finnish samples (8.3%). Despite the expected frequency gradient among study populations, all subsamples showed a strong enrichment of G84E mutation carriers among T2E fusion negative cases as compared to fusion positive cases (center adjusted OR = 4.96; 95% CI = 2.30 - 11.9; p = 0.0001). Consistent with the previous study, the crude frequency of the T2E fusion in *HOXB13* G84E carriers was 23.5 % (range 16.7 % - 28.5 %). Examination of disease characteristics highlighted age at diagnosis, with fusion positive cases being diagnosed 1.85 (0.95 - 2.74) years earlier than negative cases ($p < 0.0001$). Age at diagnosis in G84E carriers did not differ significantly from non-carriers (p = 0.13). However, within the subtype of fusion negative carcinoma, which is usually associated with later ages at diagnosis, carriers of G84E were diagnosed on average 3.45 (0.61 - 6.3) years earlier (p = 0.018). No associations were seen for tumor stage, tumor grade or diagnostic PSA levels.

In conclusion, this study has demonstrated a tumor type specific association for *HOXB13* G84E mutation carriers having a higher frequency of T2E fusion negative PrCa. Although the T2E fusion negative subtype is known to be associated with later ages of diagnosis, *HOXB13* driven tumors within this subtype may represent an early onset subgroup.

3499T

Complexities in genetic testing for allogeneic bone marrow transplant recipients and patients with hematologic malignancies. *D. Mancini-DiNardo, M. Landon, B. Abbott, M. Elias, J. Rinsky, B. Roa.* Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

Allogeneic bone marrow transplant (allo-BMT) recipients and patients with a hematologic malignancy present unique challenges when their blood/buccal samples are submitted for genetic testing. White blood cells from allo-BMT recipients are usually entirely derived from the transplant donor. Buccal samples from such patients can be chimeric, containing cells derived from both the recipient and the bone marrow donor. Therefore, molecular genetic testing performed on DNA derived from blood/buccal samples of allo-BMT patients may reflect the genetic status of the transplant donor and not the recipient. Blood/buccal samples from individuals with a hematologic malignancy (HM) are also not recommended for genetic testing. This is because genetic analysis may detect somatic, non-heritable mutations caused by the hematologic malignancy, which are present only in the patient's blood. Genetic testing on blood/buccal samples submitted by patients with hematologic malignancies may therefore reflect the genetic status of the tumor rather than the germline genetic status of the patient. Here we present data from three representative cases that illustrate the complexity of genetic testing for allo-BMT recipients and patients with a hematologic malignancy. In one case, we tested a buccal sample from an allo-BMT patient that was sufficiently chimeric such that the donor DNA was detected on the genetic test results. In the second case, we illustrate the potential to report out a false negative result on a blood sample from an allo-BMT patient. In the final case, we demonstrate the detection of a mosaic large rearrangement in a patient with a hematologic malignancy. This large rearrangement was subsequently determined to be a somatic mutation present only in the patient's blood cells. We have therefore determined that cultured cells derived from skin fibroblasts are the most suitable sample type for allo-BMT patients, which is in accordance with the published 2012 NCCN guidelines. Fibroblasts are also recommended for HM patients where there is a high likelihood of leukemic cells circulating at a quantity that is detectable by our genetic analyses. We have collaborated with ARUP to assist in the procurement of fibroblast cells. It is imperative that germline genetic testing results reflect the heritable mutation status of the patient being tested, as they may impact the interpretation of test results and subsequent clinical management of the patient and their family members.

Familial lung cancer: A genetic epidemiology study. *D. Mandal[1], A. Bencaz[1], J. Chambliss[1], J.E. Bailey-Wilson[2].* 1) Department of Genetics, LSU Health Sciences Center, New Orleans, LA; 2) National Human Genome Research Institute, National Institutes of Health, Baltimore, MD.

The association between lung cancer (LC) and smoking is well known. However, only 15% of smokers are diagnosed with LC. Inherited genetic factors have a major role in lung cancer etiology. About 10% of LC cases (22,000 cases per year in the U.S.) have at least one first-degree relative affected with LC, and 25% of cases at least one first- or second-degree affected relative, indicating that family history is a significant risk factor. In the last few years histology specific genetic alterations in lung cancer have been reported in epidemiologic studies. In our previous studies, we have reported adenocarcinoma (38%) being the most common histologic subtype, followed by squamous cell (25%) and small cell (15%) in familial cancer cases. The objective of the present study is to describe the rapid ascertainment of familial lung cancer cases and to determine the co-segregation of histologic subtypes transmitted in familial lung cancer families. Eligible subjects (N=203) with two or more relatives affected with primary lung cancer were recruited from 24 parishes across southern Louisiana. Diagnosis of primary LC was confirmed by medical records, and histologic subtype (N= 173) was abstracted from pathology reports. About 20 of these families were developed as multigenerational families and biological specimens were collected on affected lung cancer cases and unaffected family members. Annual follow up on these families confirm a change of health status and new diagnosis in the families. Histological data on these families will be analyzed and co-segregation of specific histologic subtypes and lung cancer affection status will be determined in this unique collection of families. Methods for rapid ascertainment of lung cancer cases maintaining HIPAA compliance and communication about dbGaP policies with general public in the development of bio-repository will be discussed in detail.

3501M

Identification of a novel founder *MSH2c.705delA mutation causing colon cancer in a Druze population.** *M. Melas[1], C.C. Studenmund[1], K. McDonnell[1], L. Raskin[2], P.S. Boonstra[3], M. Zawistowski[3], B. Mukherjee[3], F. Lejbkowicz[4], H.S. Rennert[4], G. Rennert[4], S.B. Gruber[1].* 1) USC Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA; 2) USC Division of Epidemiology, Department of Medicine, Vanderbilt University, Nashville, Tennessee; 3) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 4) CHS National Israeli Cancer Control Center, Haifa, Israel.

Lynch Syndrome is an autosomal dominant cancer genetic syndrome resulting from mutations in the DNA mismatch repair genes *MSH1, MSH2, MSH6, PMS2* and *EPCAM*. Individuals carrying mutations in these genes characteristically develop cancer of the colon, rectum, endometrium and other cancers at an early age. A number of founder mutations in Lynch-causing genes have previously been described as important in identifying individuals at risk within specific populations. The Druze are a unique religious and ethnic population that originated approximately 11,000 years ago in the Arabian Peninsula. The population subsequently migrated throughout the Middle East, primarily to modern Syria, Lebanon, Israel and Jordan, between 1,000 and 500 years ago. The Druze are culturally discouraged from marrying outside their communities and endogamy rates are relatively high. In the present study we report a novel *MSH2* mutation, c.705delA, in a group of Druze individuals who developed Lynch Syndrome. To establish whether this variant is a founder mutation we performed haplotype analysis using SNP genotyping data from 12 Druze carrying *MSH2**c.705delA mutation (Infinium HumanCore Beadchip) and 47 Druze individuals from the Human Genome Diversity Project (HGDP) with chromosome 2 phasing. Concomitantly, recombination length was determined by carrying out a short tandem repeat genetic analysis of the same Druze carriers together with 9 Druze non-carriers and 8 Christian Arab non-carriers employing six highly polymorphic microsatellite markers near the *MSH2* gene: D2S367, D2S370, D2S378, D2S391, D2S1248 and D2S2238. Haplotype phasing using ShapeIt2 software showed a 13 Mb haplotype common to all *MSH2**c.705delA mutation carriers. This haplotype was not found in non-carriers and also not in the 47 Druze individuals from the HGDP. Attempts to determine the age of the mutation were confounded by significant consanguinity and complicated population structure of the Druze, which highlights the difficulty of estimating the age of a mutation that depends on the assumption of independent ascertainment. In summary, the present study describes a novel *MSH2**c.705delA mutation among the Druze population, establishes this deletion as a founder mutation and illustrates the challenges of statistical genetic analyses in highly inbred populations. Additionally, the results of this study may contribute to improved cancer genetic screening and cancer care in the Druze.

3502T

Investigating the Genetic Basis of Breast Cancer Disparities Using Whole Genome Sequencing and Parallel Computing. *J.J. Pitt[1,2], TY. Yoshimatsu[3], Y. Zheng[3], AJ. Grundstad[2], J. Tuteja[2], A. Odetunde[4], G. Khramtsova[3], TO. Ogundiran[5], CP. Babalola[4], OA. Ojengbede[6], CO. Olopade[7], D. Huo[8], KP. White[1,9], OI. Olopade[3,9].* 1) Committee on Genetics, Genomics, and Systems Biology, The University of Chicago, Chicago, IL, USA; 2) Institute for Genomics and Systems Biology, The University of Chicago, Chicago, IL, USA; 3) Center for Clinical Cancer Genetics and Global Health, Department of Medicine, The University of Chicago, Chicago, IL, USA; 4) Institute for Advanced Medical Research and Training, College of Medicine & Faculty of Pharmacy, University of Ibadan, Ibadan, Oyo, Nigeria; 5) Department of Surgery, University of Ibadan, Ibadan, Oyo, Nigeria; 6) Centre for Population & Reproductive Health, College of Medicine, University of Ibadan, Ibadan, Oyo, Nigeria; 7) Section of Pulmonary and Critical Care, Department of Medicine, The University of Chicago, Chicago, IL, USA; 8) Department of Health Studies, The University of Chicago, Chicago, IL, USA; 9) Department of Human Genetics, The University of Chicago, Chicago, IL, USA.

Breast cancer incidence and mortality rates vary widely based on geography and ethnicity. Compared to Caucasians, individuals with African ancestry are more likely to die from breast cancer, which is in part attributable to higher prevalence of the triple negative subtype. It is hypothesized that these disparities manifest through population-specific inherited and somatic genetic variation. Breast cancer specimens and germline DNA have been collected from the University College Hospital Ibadan in southwest Nigeria. To date, 17 tumor-normal pairs and 50 germline breast cancer samples have undergone whole genome sequencing on the Illumina platform, with neoplastic and non-neoplastic sequenced to average depths of 90x and 30x, respectively. In addition, 25 asthmatics and 75 healthy Nigerians from the surrounding community have been sequenced as controls. To handle the computational burden inherent to large-scale sequencing analyses, we have developed SwiftSeq, a modular, highly-parallel workflow for fast, efficient, and robust processing of DNA sequencing data. Using Genome Analysis Toolkit's best practices, SwiftSeq is able to completely align, process, genotype, and annotate a 30x genome in ~36-40 hours. By scaling with compute resources, our framework can analyze hundreds of genomes in days, rather than weeks. Currently, 19 germline case and 21 control genomes (mean depth ~27x) have been pushed through SwiftSeq. Each harbor, on average, 3,921,264 SNPs; 621,141 indels; and 306,882 variants not reported in dbSNP 137. To investigate the effects of below average sequencing depth, we down-sampled to 30x, 25x, and 20x in triplicate using two well-covered samples (~35x and ~37x). Genotypes from all replicates showed only marginal differences relative to the original data, indicating our germline calls are robust to dispersions from the targeted sequencing depth. While early onset and/or familial cases lacking deleterious BRCA1/2 mutations were explicitly selected for sequencing, damaging mutations were found in other known cancer susceptibility genes such as BRIP1, FANCC, and SMARCE1. This underlies a potentially expanded role for these genes in African breast cancer pathogenicity. With continued sequencing, analysis, and comparison to Caucasian tumor-normal genomes from The Cancer Genome Atlas, we will elucidate the unique characteristics of African breast cancer genomes.

3503S

The Genetic Testing in Epithelial Ovarian Cancer (GTEOC) Study: Direct access to BRCA1/2 genetic testing in oncology. *M. Tischkowitz[1,2], J. Drummond[2], E. Thompson[2], G. Sagoo[3], B. Newcombe[4], E. Barter[5], P. Ridley[6], S. Miller[7], F. Thompson[8], H. Webb[9], C. Hodgkin[4], L.T. Tan[7], M. Daly[9], S. Ayers[5], B. Rufford[6], C. Parkinson[10], H. Earl[10], T. Duncan[8], P. Pharoah[11], S. Abbs[2], N. Hulbert-Williams[12], R. Crawford[10], J. Brenton[10,13], H. Shipman[1,2].* 1) University of Cambridge, Cambridge, United Kingdom; 2) East Anglian Medical Genetics Service, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK; 3) PHG Foundation, Cambridge, UK; 4) Cambridge Cancer Trials Centre, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK; 5) Clinical Oncology, Peterborough and Stamford Hospitals NHS Foundation Trust, Peterborough, UK; 6) Cancer Services, The Ipswich Hospital NHS Trust, Ipswich, UK; 7) Clinical Cancer Services, Hinchingbrooke Health Care NHS Trust, Huntingdon, UK; 8) Department of Obstetrics and Gynaecology, Norfolk and Norwich University Hospitals NHS Foundation Trust, Norwich, UK; 9) Department of Oncology, The Queen Elizabeth Hospital King's Lynn NHS Foundation Trust, King's Lynn, UK; 10) Cancer Services, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK; 11) Department of Primary Care and Public Health, University of Cambridge, Cambridge, UK; 12) Department of Psychology, University of Chester, Chester, UK; 13) Cancer Research UK Cambridge Institute, Cambridge, UK.

Background: Genetic testing for germline mutations in BRCA1/2 has been available for many years, but until recently technical complexity and cost has limited testing access to high-risk cases. Further, many epithelial ovarian cancer (EOC) patients who would be eligible for testing are not referred for a genetic assessment. The advent of targeted therapies for BRCA1/2 mutation carriers will necessitate new service delivery models for genetic testing. The Genetic Testing in Epithelial Ovarian Cancer (GTEOC) Study started in July 2013 and explores the feasibility and acceptability of offering direct genetic testing to all women recently diagnosed with EOC. Methods: Recruitment is on-going through six centres in East Anglia, UK, which has an outbred population of 2.5 million with no BRCA1/2 founder mutations. All women with serous or endometriod ovarian cancer diagnosed with in the last 12 months are eligible, irrespective of age and family history of cancer. Consent for genetic testing is obtained by the research team after participants have reviewed the study information sheet. Descriptive statistics are used to present data collected to date. Economic analysis is being undertaken using a cost effectiveness evaluation. The psychosocial arm of the study is utilising quantitative questionnaires and qualitative interviews subjected to Interpretive Phenomenological Analysis. Results: To date we have recruited 76 participants out of a total of 139 eligible women. The mean age at diagnosis was 65.5 years (range 29-85), mean time since diagnosis to recruitment = 142 days (range 15-355 days). BRCA1/2 gene testing has been completed on 65 samples, resulting in detection of pathogenic mutations in 6 women and variants of uncertain clinical significance (VUS) in 6 women. Of the women found to have a pathogenic mutation, 3 had no significant previous family history of cancer to their knowledge. We will present our preliminary psychosocial findings and economic analysis, and highlight the challenges and success of our model and implications for genetic testing in oncology settings. Conclusion: The initial GTEOC study recruitment rate is 55%. Pathogenic BRCA1/2 mutations have been identified in 9.2% of women and VUS in 9.2%. This method of population-based genetic testing appears to be acceptable to patients and is less resource-intensive than standard practice where all patients have a full assessment by the genetics team prior to testing.

3504M

Insecticide Exposure Induces Leukemia-Associated Gene Aberrations. *M.P. Navarrete Meneses[1], M. Betancourt[2], E. Bonilla[2], M. Altamirano[3], C. Salas[1], A. Reyes[1], M. Sanabrais[2], P. Pérez Vera[1].* 1) Instituto Nacional de Pediatría, Mexico City; 2) Universidad Autónoma Metropolitana-Iztapalapa, Mexico City; 3) FES-Zaragoza, UNAM. Mexico City.

Background: Leukemia is the most common childhood cancer. It is characterized by the presence of cells with chromosomal abnormalities, which are proposed to arise in utero. It is associated with prenatal exposure to pesticides. Epidemiological studies have demonstrated that environmental exposures to these chemicals could be implicated in leukemogenesis, however there is limited biological evidence showing that pesticides can induce leukemia-associated gene aberrations. Malathion and permethrin are two widely used insecticides; nevertheless their genotoxic and carcinogenic potentials are controversial. The aim of this study was to detect numerical and structural rearrangements in leukemia-related genes on human peripheral blood lymphocytes exposed in vitro to insecticides. Methods: Mononuclear cells from two healthy volunteers were cultured in triplicates for 72h and exposed to 200μM of permethrin or malathion for the last 24h. MLL, ETV6 and RUNX1 genes were analyzed with fluorescence in situ hybridization. Besides, numerical aberrations were assessed using centromeric probes for chromosomes 12, 18 and 14/21. Structural and numerical analysis were performed separately, 1000 nuclei were scored. Groups were compared with U-Mann Whitney test. Results: Permethrin exposure increased the frequency of cells with MLL structural aberrations and copy number deviations significantly, as well as the diversity and complexity of damage. It also induced aneuploidy significantly. An increased frequency of cells with abnormalities in ETV6 and RUNX1 was detected, however it was not significant. On the other hand, a significant increase in the frequency of cells with structural damage in MLL gene was observed with malathion exposure. This effect was not observed on ETV6 and RUNX1 genes. Neither chromosome gains nor losses were significantly induced by malathion exposure. Discussion: Permethrin exposure can affect leukemia-related genes in structure and number. The results show that this pyrethroid insecticide has clastogenic and aneuplogenic potential. Similar patterns of alterations have been reported in cells treated with leukemogenic agents such as etoposide. Malathion also increased the frequency of altered cells, however a greater effect was observed with permethrin. Conclusion: This study provides biological evidence showing that insecticide exposure is implicated in the generation of leukemia-associated gene aberrations. CONACYTCB-2012-01/183467.

3505T

A systematic approach to clinical classification of DNA sequence variants in mismatch repair genes: the InSiGHT initiative. *B.A. Thompson[1,2], A.B Spurdle[1], J. Plazzer[3], M.S. Greenblatt[4], P. Moller[5], F. Macrae[3], M. Genuardi[6,7], InSiGHT Variant Interpretation Committee.* 1) Genetics & Computational Biology, QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 2) School of Medicine, University of Queensland, Brisbane, Australia; 3) Department of Colorectal Medicine and Genetics, Royal Melbourne Hospital, Australia; 4) Vermont Cancer Center, University of Vermont College of Medicine, Burlington, VT, USA; 5) Research Group on Inherited Cancer, Department of Medical Genetics, Oslo University Hospital, The Norwegian Radium Hospital, Oslo, Norway; 6) Department of Biomedical, Experimental and Clinical Sciences, University of Florence, Italy; 7) Fiorgen Foundation for Pharmacogenomics, Sesto Fiorentino, Italy.

Clinical classification of sequence variants identified in hereditary disease genes directly affects management of patients and their relatives. The International Society for Gastrointestinal Hereditary Tumours Variant Interpretation Committee (InSiGHT VIC) undertook a collaborative effort to develop, test and apply a standardised classification scheme to germline variants in the Lynch syndrome-associated genes MLH1, MSH2, MSH6 and PMS2 (accounting for ~2% of all colorectal and endometrial cancers). Unpublished data submission was encouraged to assist in variant classification and was recognised through microattribution. The scheme was refined by multidisciplinary expert committee review of clinical and functional data available for variants, applied to 2,360 sequence alterations, and disseminated online. Assessment using validated criteria altered classifications for 66% of 12,006 database entries. Clinical recommendations based on transparent evaluation are now possible for 1,370 variants that were not obviously protein truncating from nomenclature. All data were merged into one publicly available database, which will continue to be curated according to the classification scheme. This large-scale endeavour has important implications for the clinical management of suspected Lynch syndrome families; at the same time, it provides an important model of international multidisciplinary collaboration for DNA variant interpretation.

PALB2 variant database - a joint collaboration between LOVD and ClinVar. *M.J. Landrum[1], D. Subramanian[2], G. Riley[1], D. Maglott[1], R. Villamarin-Salomon[1], S. Chitipiralla[1], J. den Dunnen[3], M. Tischkowitz[4].* 1) NCBI/NLM/NIH, Bethesda, MD; 2) Cambridge University Hospitals Trust, Cambridge, UK; 3) Human and Clinical Genetics, LUMC, Leiden, The Netherlands; 4) Department of Medical Genetics, University of Cambridge, UK.

Background Biallelic germline loss-of-function mutations in PALB2 (also known as FANCN) cause Fanconi Anemia, whereas monoallelic loss-of-function mutations are associated with an increased risk of breast cancer and pancreatic cancer. The LOVD platform, providing a flexible, freely available tool for the collection and display of DNA variants, was used to establish a PALB2 gene variant database. ClinVar was released publicly in April 2013 and provides a freely accessible, public archive of reports of the relationships among human variations and phenotypes. Here we describe a joint collaboration between ClinVar and LOVD to minimize inconsistencies in listing PALB2 variants and maximize accessibility for potential users. Methods PALB2 variants were identified through literature searches dating back to 2006 (the year PALB2 was identified), collated, classified and data uploaded to LOVD. The database was linked to Fanconi Anemia Mutation Database (Rockefeller University). Variant data was exported from LOVD and shared with ClinVar. In the ClinVar submission process, variant data were validated; the pathogenicity values were mapped to the American College of Medical Genetics (ACMG) standard terms; and variants were aggregated based on the combination of variant and disease. Much of the processing work involved synchronizing the LOVD and ClinVar data models e.g. determining whether a list of multiple phenotypes indicated individuals with all listed disorders or independent variant/disorder relationships. Results The LOVD database currently contains 242 listed variants in 671 individuals. The LOVD submission makes up 77% of the 342 PALB2 submissions to ClinVar. The other PALB2 ClinVar submissions are unpublished variants from clinical laboratories, structural variants that include PALB2 with other genes, and a handful of variants described in OMIM. 27% of the submissions in PALB2 are asserted as Pathogenic, 3% as Likely pathogenic, 32% as Uncertain significance, 41% as Likely benign, and 10% as Benign. Conclusions This provides an example of facilitated data sharing between different databases, which results in a higher-quality level of data over merely providing weblinks, because the variants have been assessed independently by different teams and data standardization is increased. Collaborations between resources such as the LOVD and ClinVar are essential for genes with important clinical consequences such as PALB2.

Combined contribution of intermediate-risk gene rare variants and modest-risk SNP genotypes to early-onset breast cancer. *E.L. Young[1], B.J. Feng[2], A.W. Stark[1], T.C. Francy[1], A.M. Paquette[1], J.S. Rosenthal[1], N. Forey[3], G. Durand[3], S. McKay-Chopin[3], M. Hashibe[4], J. Gertz[1], F. Le Calvez-Kelm[3], F. Lesueur[5], D.E. Goldgar[2], S.V. Tavtigian[1], Breast Cancer Family Registries.* 1) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, USA; 2) Department of Dermatology, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, USA; 3) Genetic Cancer Susceptibility group, International Agency for Research on Cancer, Lyon, France; 4) Department of Family and Preventive Medicine, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, USA; 5) Genetic Epidemiology of Cancer team, Inserm, U900, Institut Curie, Paris, France.

Since the introduction of genetic testing of BRCA1 and BRCA2 in women with family histories of breast cancer and/or ovarian cancer, many additional genes have been identified as breast cancer susceptibility genes, and many of these genes are included in multigene panel testing. Building from our published case-control mutation screening studies of ATM, CHEK2, MRE11A, RAD50, NBN, RAD51, RINT1, and XRCC2, we evaluated the contribution of these eight genes, plus mutation screening of BARD1 and genotyping of 18 Breast Cancer Association Consortium (BCAC) confirmed modest-risk SNPs, to early onset breast cancer among a series of 1300 cases and 1120 ethnically matched controls that did not carry pathogenic variants in BRCA1, BRCA2, or PALB2. Rare missense substitutions were graded on severity using Align-GVGD, Polyphen2, CADD, and MAPP. To avoid gene-by-gene over-fitting, we applied uniform missense substitution analysis models across all nine genes. Using attributable fraction, familial relative risk, and receiver operator characteristic (ROC) analyses, we: (1) compared the contribution of known and likely pathogenic missense substitutions to the contribution of protein truncating variants across the nine gene set, and (2) compared the contribution of the nine gene mutation screening data to the 18 BCAC SNP genotyping data. Finally, setting an odds ratio (OR) of 2.5 as a threshold for the point at which a genotype-defined risk estimate is high enough to justify early screening (early mammography or breast MRI), we estimated the fraction of cases and controls that reach the $OR \geq 2.5$ threshold on the basis of mutation screening data or SNP genotyping data. From preliminary results across several analysis models, mutation screening of the nine genes suggests that approximately 8.8% of cases and 3.7% of controls carried one or more rare variants associated with an $OR \geq 2.5$, with over half of these variants being missense substitutions. Similarly, treating 15 (of 18 now genotyped) common modest-risk SNPs as a polygene and applying a simple multiplicative model, we found that approximately 3.6% of cases and 1.2% of controls had a modest-risk SNP polygene genotype associated with an $OR \geq 2.5$. We plan on combining the intermediate-risk gene mutation screening data with the modest-risk SNP genotyping data to paint a clearer picture of clinically actionable breast cancer susceptibility explained by genes other than the established high-risk susceptibility genes.

Lynch syndrome (LS) is due to germline mutations in mismatch repair (MMR) genes and tumors of affected patients show microsatellite instability. A subset of likely hereditary cases with mismatch repair deficient (dMMR) tumors has no identified germline mutations in clinical screening of coding regions of MMR genes (*MLH1*, *MSH2*, and *MSH6*). In 98 such cases, we examined both coding and non-coding regions of key MMR genes by next generation sequencing. Germline DNA from 98 suspected LS patients (IHC loss of MLH1 [n=71], MSH2 [n=18] and isolated MSH6 [n=9]) identified in the Colon Cancer Family Registry and 90 unaffected spousal controls was sequenced using Agilent's custom capture and an Illumina HiSeq2000. We targeted the coding and non-coding regions (intronic, upstream and downstream) for *MLH1*, *MSH2* and *MSH6*. Pseudogene homology impaired adequate *PMS2* capture. Quality control filtering excluded variants based on read depth (<20), genotype quality (<30), and minor allele frequency (>5% in 1000 Genomes). Remaining variants were analyzed for potential abnormal splicing, published reports and their frequencies in suspected LS patients relative to controls. After filtering, there were 10 coding and 262 non-coding variants in suspected LS patients. Three of the coding variants (*MLH1* p.L653R; *MSH2* p.N596del; *MSH6* p.F958X) were pathogenic and the remainder predicted to be benign. There were 69 non-coding variants in *MLH1*, 144 in *MSH2* and 50 in *MSH6*. All *MLH1* variants were detected once, 4of which were novel and predicted cryptic splice sites. There was one known pathogenic *MLH1* intronic variant, c.454-13A>G. Two novel *MSH2* variants were predicted to form cryptic donor sites and 3 variants were present in >10% of cases compared to 1-3% of controls. A single private *MSH6* variant was predicted to alter splicing. IHC data correlated with variant interpretation for deleterious and suspected deleterious variants. The remaining variants in *MLH1*, *MSH2* and *MSH6* were novel and predicted to be neutral. Among 98 suspected LS cases analyzed, for which standard testing was negative, we identified 4 deleterious and 6 suspected deleterious alterations (10% rate of diagnosis). The unresolved cases may still be due to the non-coding variants discovered. Alternatively, mutations in other MMR genes, structural or epigenetic changes, or somatic alterations in these genes may explain these cases. This work was supported by grant UM1 CA167551 from the National Cancer Institute.

Background: IMPACT is a multi-national targeted prostate cancer screening study of men with a known germline mutation in *BRCA1* or *BRCA2* which is thought to predispose to the disease. The study is recruiting male *BRCA1/2* mutation carriers and a control group, who have tested negative for a mutation present in their family, to undergo annual PSA screening +/- prostate biopsy. In addition to the screening protocol 15 centres are enrolling men in a quality of life study (QoL). The aims of the QoL study are: (1) To evaluate the psychosocial impact of screening for prostate cancer in men with *BRCA1/2* mutations in terms of (a) cancer worry, (b) distress of screening and (c) health related quality of life; (2) To identify factors associated with negative psychosocial outcomes; (3) To determine levels of compliance with PSA screening over time and identify significant predictors of compliance / non-compliance. Methods: Men enrolled in the IMPACT study at collaborating sites were invited to complete a questionnaire prior to each annual screening visit. The questionnaires included sociodemographic data and the following measures: HADS, IES, SF36, PC-MAX, Cancer Worry Scale, self reported risk perception and a knowledge questionnaire (understanding of *BRCA1/2* and prostate cancer). The results of the baseline questionnaire are presented. Results: A total of 484 men enrolled in the QoL study prior to their first screening visit (prospective cohort). A further 217 men have enrolled at subsequent visits (truncated prospective cohort). Uptake of the study was 82-100% at participating sites. Mean scores for HADS and SF36 were within reported general population norms and mean IES scores were within normal range. No statistically significant differences were observed between groups (*BRCA1* mutation carrier, *BRCA2* mutation carrier, and controls). Average knowledge score was 77%, demonstrating a good understanding. Mean MAX-PC scores were low suggesting a low level of prostate-cancer specific anxiety or PSA related anxiety in the cohort. Cancer worry levels were low and *BRCA2* carriers in particular perceived their risk of prostate cancer to be higher than average. Conclusions: Uptake of the QoL study is high in participating centres. Baseline psychosocial measures for men entering the study suggest a low prevalence of distress and participants demonstrate a good level of knowledge about prostate cancer and the *BRCA1/2* genes.
